I. PREVALENCE

Childhood obesity is one of the most complex and poorly understood clinical syndromes in pediatrics. Obesity is a common nutritional disorder among children and adolescents in the United States, with an estimated prevalence of 20% as compared to 30% in the adult population. A study in Europe found that 15 and 22% of adult men and women, respectively, were obese (1). Furthermore, 60 and 75% of men and women, respectively, in urban Samoa were obese (2). It is estimated that obesity affects 7% of the world's adult population. The percentage of overweight children and adolescents has increased by almost 50% in the past two decades (3). This disturbing trend in childhood and adolescent obesity parallels a concurrent increase in prevalence of this disorder (4). It is estimated that 10–20% of obese infants will remain overweight (5). It has also been observed that about 40% of overweight children will continue to have increased weight during adolescence and 75–80% of obese adolescents become obese adults (6). Moreover, more than one-third of overweight children will eventually become obese adults (7). Obesity in children is expected to continue to increase into the 21st century.

Obesity is present in every continent. This includes the established market economies including the economies of Europe, Latin America, the Caribbean, and the Middle

East. More worrisome is the fact that the body mass index (BMI) in adults is expected to almost double in most of the major market economies of the world by the year 2030 (8). France, the Netherlands, United Kingdom, and the United States also report increasing prevalence of obesity in children and adolescents. Data from 79 developing countries and a number of industrialized nations suggests that 22 million children under 5 years of age are overweight (>+2 standard deviations above National Child Health Survey (NCHS) reference median weight for height) (9). These increases in obesity may be partly due to the greater social economic status of the market economies (10). In the future, the prevalence of childhood obesity may be as much as the current rise in adult obesity, but the consequences may be more severe as the duration of obesity will be longer. It may therefore have a greater deleterious impact on health and the rate of morbidity and mortality than obesity starting in adulthood.

Many children are at high risk of becoming overweight between the ages of 3 and 10 years. This is the time they begin school and socialization with other children. Furthermore, the risk of becoming an obese adult was 3–10 times greater if the child's weight was greater than the 95th percentile for their age. Obese parents impose even a greater risk that their children will be overweight. There is a 75% chance that children aged 3–10 will be overweight if both parents were obese. This drops

to a 25–50% chance with just one obese parent. These statistics suggest that behavior modification or treatment intervention at an early age may be important for preventing future adolescent and adulthood obesity (11).

II. MORBIDITY

Obesity in childhood is a major public health problem and is strongly linked to persistence into adulthood. This increases the obese individual's risks for hypertension (12), hyperlipidemia (13), respiratory diseases (14), diabetes (15), orthopedic conditions (16, 17), psychosocial disorders (18), and social and economic consequences (19).

The altered nutritional state in obesity results in many endocrine changes that disappear with weight loss. These include excess insulin secretion, insulin resistance, and alterations at the level of the hypothalamic pituitary gonadal and adrenal axis. Hyperinsulinemia of obesity is strongly linked with cardiovascular diseases, including type 2 diabetes mellitus, hyperlipidemia, and hypertension (20). Obesity is associated with hypertension in 10–30% of children (12) regardless of age, gender, and duration. Obese children and adolescents tend to have elevated levels of total serum cholesterol, triglycerides, and low-density lipoprotein, and decreased levels of high-density lipoproteins (12). They are also at increased risk for coronary heart disease as they grow into obese adults (21, 22). With few exceptions, the clinical features of cardiovascular heart disease are not apparent until the third or fourth decade of life. However, there is substantial evidence that the atherosclerotic process is initiated during childhood (23, 24).

In a study by Must et al., long-term morbidity and mortality of overweight adolescents were examined (25). They demonstrated that obesity in adolescent subjects were associated with an increased risk of mortality from all causes and disease-specific mortality among men, but not among women. On the other hand, the risk of morbidity from coronary heart disease and atherosclerosis was increased in both men and women who had been obese in adolescence. This suggests that body weight reduction among the young may decrease the risks for many of the obesity-related health disorders.

Increased cholesterol turnover and its concentration in the bile of obese individuals predispose them to a high incidence of steatohepatitis (26) and gallbladder disease (27). Indeed, gallstones (cholelithiasis) have been reported to be three times more common in morbidly obese people than in normal subjects. Gallstones may also result while the obese person is on a hypocaloric diet. This may be due to mobilization of adipose tissue cholesterol during weight loss (28). Furthermore, the risk of colorectal cancer and gout was increased among women who had been obese in adolescence. Finally, obesity in adolescence was a more significant predictor of these risks than being overweight in adulthood (29).

Syndrome X is a clinical quartet of hyperinsulinemia, hyperlipidemia, hypertension, and subsequent cardiovascular disease (30). It is believed that obesity is a component of this metabolic syndrome and has been described in obese children (31) and adolescents (32). In a more recent study, Chen et al. suggested that syndrome X is characterized by the linking of a metabolic entity (hyperinsulinemia/insulin resistance, hyperlipidemia, and obesity) to a hemodynamic factor (hypertension) through a shared correlation with hyperinsulinemia/insulin resistance. Clustering features of syndrome X are independent of gender and age in both black and white populations (33).

Nonautoimmune forms of youth-onset diabetes are becoming increasingly prevalent as rates of obesity in children and adolescents accelerate (15). Many health professionals have recognized an emerging epidemic of type 2 diabetes mainly affecting minorities (34–36). Epidemiological data obtained from various centers suggest an almost fourfold increase in the prevalence of type 2 diabetes among minority groups such as Native, African, and Hispanic Americans aged 10–19 years over the past 10 years (15, 37). Increasing prevalence of type 2 diabetes in the youth is not limited to North America. For instance, among Japanese junior high school students, the incidence of type 2 diabetes is almost seven times that for type 1 diabetes (38). It is believed that the increasing incidence of type I diabetes is associated with changing food patterns and rising obesity rates among Japanese school children (39). Children have hyperinsulinism as a result of obesity, as do adults, and childhood obesity is commonly associated with impaired glucose tolerance (40). The stress of obesity and the increased demand for insulin during adolescence explain the predominantly pubertal and postpubertal onset of type 2 diabetes in obese children (41).

Orthopedic complications of obesity are believed to be largely of mechanical nature. During childhood, slipped capital femoral epiphysis, Legg-Calve-Perthes disease, and genu valgum tend to be more common in obese subjects. Orthopedic disorders such as Blount's disease (tibia vara) and slipped capital femoral epiphysis are frequently seen in obese adolescents (16, 17).

Rapid weight gain or obesity during infancy and childhood tends to be a risk factor for frequent respiratory infections (14). The work of breathing is increased in obese individuals and larger body mass places increased demands for oxygen consumption and carbon dioxide elimination. Many obese subjects suffer from chronic hypoxemia secondary to ventilation–perfusion mismatch. This is characterized by increased ventilation of upper lobes and increased perfusion of the lower lobes. Insufficient elimination of carbon dioxide, in some obese subjects, leads to hypoventilation (pickwickian) syndrome (42), which is characterized by chronic hypoxemia and hypercapnia. These subjects have blunted respiratory drive to both hypoxemia and hypercapnia.

Sleep apnea is also seen in severe obesity and is characterized by cessation of air flow for 10 s or longer on 30 occasions during 7 h of sleep. Parents of obese children and adolescents usually report that their children snore loudly and sometimes appear to stop breathing. Sleep apnea is a major problem found to be associated with increased risk of traffic accidents (43). The apnea may be obstructive, central, or combined. In most patients, no anatomical abnormalities of the upper airway can contribute to the development of obstructive sleep apnea (OSA). It has been shown that the occurrence of OSA in obese subjects is related to the size of the region enclosed by the mandible (44, 45) and sites and sizes of fat deposits around the pharynx, as well as subjects' weight. In patients with OSA, alveolar hypoventilation results from increased oxygen demand during the apneic episode. Co-existent cardiopulmonary or neuromuscular disease in subjects with OSA can play a role in the development of alveolar hypoventilation. During the apneic episodes, the systemic blood pressure increases whereas the heart rate and cardiac output decrease. Apnea-associated cardiac arrhythmias have been frequently observed in patients with OSA and increases their risk for cardiovascular mortality (46). Relief of respiratory obstruction alleviates OSA. This may be accomplished by weight loss and continuous positive airway pressure (CPAP) during sleep.

Obesity is also accompanied by advanced skeletal maturity (bone age) and early menarche (29). Amenorrhea, oligomenorrhea, and/or dysfunctional uterine bleeding are common among obese adolescent females. Some of these patients will also develop polycystic ovarian syndrome (47–49).

A. Psychosocial Impact of Obesity

In addition to the medical complications associated with obesity, the juvenile-onset obese subject is also at risk for psychological morbidity (18). It has also been shown that obesity tends to confer disability greater than that associated with other forms of chronic illness (19). This disability seems to be linked to the public nature of obesity. Peer group discrimination is the factor that prompts parents to seek treatment in their obese child. Even young school-aged children have been observed to view their overweight classmates as less desirable playmates (50). Overweight children are frequently teased on the playground and usually excluded from games. Obese children are under considerable psychological stress and are generally viewed by society as clumsy, unattractive, and over-indulgent.

Overweight children as young as 5 years of age have been found to associate their obesity with lower body esteem and lower perceived cognitive ability. A parent's concern about obesity and restriction of food were associated with negative self-evaluations among girls (51). In one study a mothers' own dietary restraint and concern about their daughter's obesity predicted child feeding

practices. This suggests that a mother's control over her daughter's feeding practices and concern about the child's obesity may be an important, nonshared, environmental influence on the daughter's eating habits and relative weight (52). Moreover, obese elementary school-aged girls were more likely to be dieting and express concern about their overweight than similarly aged boys (53). All of these results suggest that childhood obesity can occur early in a child's life and has to be addressed by the whole family.

Lowered self-image, heightened self-consciousness, and impaired social functioning have been noted in some individuals who either become or remain obese during adolescence (54). Studies of obese adolescents have demonstrated obsession with being overweight, passivity, and withdrawal from social contact (18). Some investigators have found similarities between the behavior of obese subjects and racial minorities expressing prejudice (55). In fact, it has been shown that the obese persons were less likely to get admitted to a college than their lean counterparts, although there were no significant differences in their application rates, academic standing, or economic background (56). Moreover, obese individuals are 20% less likely to marry and are of lower income status than normal-weight individuals with other chronic medical conditions.

B. Economic Impact of Obesity

The increasing prevalence of obesity in adults is associated with rising health care costs. The cost of treating obesity-related illnesses to the economy of United States business sector has escalated in recent years. In one study employees of United States businesses between 25 and 64 years old were classified as nonobese (BMI < 25 kg), mildly obese (BMI 25–29), or moderately to severely obese (BMI > 29). The cost of obesity to the medical insurers of these businesses in 1994 was \$12.7 billion, including \$2.6 billion as a result of mild and \$10.1 billion due to more severe obesity. Health insurance expenditures for treating obesity-related illnesses such as hypertension, type 2 diabetes, and coronary artery disease amounted to 43% of the total amount. The rest was the result of increased sick leave, and life and disability insurance payments. Overall, obesity was responsible for 5% of all health-related expenditures in the United States in 1994 (57).

Other countries have seen similar obesity-related increases in health care costs in adults. For example, total obesity-related health care costs for Canada in 1997 was \$1.8 billion or 2.4% of total health care expenditures. The major contributors were hypertension (\$656.6 million), type 2 diabetes (\$423.2 million), and coronary artery disease (\$346.0 million). This represents a considerable amount of available health care dollars for treating obesity-related comorbidities in Canada (58).

Health care cost can be tracked according to increases or decreases in a standard measure of obesity, such as the BMI. For example, health care costs for 5689 adults more than 40 years old, who were enrolled in a Minnesota health plan, were evaluated. Data were adjusted for age, race, gender, and chronic disease status. Physical activity was associated with 4.7% lower health care charges per active day per week while BMI was associated with 1.9% higher charges per BMI unit. Never-smokers with a BMI of 25 and who participated in physical activity 3 days per week had mean annual health care charges that were approximately 49% lower than physically inactive smokers with a BMI of 27.5. These data suggest that adverse health risks translate into significantly higher health care costs (59).

The recent advent of specialized programs for treating childhood obesity limits the amount of data available to track specific costs. This is due to many of these programs either being supported by outside funding or to their operating costs being incorporated into adult obesity program budgets. However, managed care organizations are now beginning to offer benefits for the treatment of childhood obesity through better access to established community childhood obesity programs (60).

III. SOCIAL OBESITY

People want to be thin. They like to be slim and trim and they fear being even a little bit overweight. This fear is present among all individuals, even those who are not overweight, but who want to be thinner (61, 62). The likes and dislikes of the population have changed. In the past, excess body fat was a symbol of wealth, power, and status. Now people do not like this type of appearance. Even children, by the time they reach the first grade, prefer other disabilities to obesity (63). The desire to be thin constitutes a problem that must be considered as a form of social obesity. This phenomenon often translates as a fear of obesity (61).

The fear of obesity may lead people to both health-promoting and health-compromising eating behaviors. Health promoting activities include exercising; eating fruits, vegetables, and reduced-fat food; limiting the amount of food eaten; and avoiding sweets and junk food. Health-compromising activities involve the use of diet pills, laxatives, or water pills; self-induced vomiting; skipping meals; dieting and fasting (64).

A. Children

Currently, a large portion of the population, including children, is attempting to lose weight. While children should be learning to enjoy food, it appears that they are dieting without supervision. Dieting in childhood is becoming a common habit. Very young children are reporting frequent dieting. A recent national survey found that 31% of fifth grade girls have dieted (64). Abramovitz and

Birch explored 5-year-old girls' ideas, concepts, and beliefs about dieting. They found that 34–64% of the girls had ideas about dieting and weight loss and understood the link between eating and body shape. Girls' knowledge about how people diet is inappropriate. These included descriptions of modified eating behaviors, such as drinking diet shakes and sodas, eating more fruits and vegetables, and use of special diet foods and restrictive eating behaviors. Mothers seem to be modeling both health-promoting and health-compromising eating behaviors to their daughters. Girls whose mothers reported current or recent food restriction were more than twice as likely to have ideas about dieting (65). Another factor found to influence girls' ideas, concepts, and beliefs about dieting is family history of overweight. The media was also mentioned by 55% of the children as a source of dieting ideas (66).

Children not only diet, they also worry about their body appearance. More and more children are concerned about and dissatisfied with their body image. Studies have shown that 55% of girls and 35% of boys in grades 3–6 want to be thinner (66). The Children's Version of the Eating Attitudes Test showed a negative correlation with children's BMI (66). It was found that 4.8% of them had scores suggestive of anorexia nervosa. Stice et al. found that eating disturbances that emerged during childhood led to inhibited and secretive eating, overeating, and vomiting. Maternal body dissatisfaction, internalization of the thin ideal, dieting, bulimic symptoms, and maternal and paternal body mass prospectively predicted the emergence of childhood eating disturbances. Infant feeding behavior and body mass during the first month of life also predicted the emergence of eating disturbances (67).

Parents who worry about their children becoming overweight may set the stage for a vicious cycle. Johnson and Birch found those parents who control what and how much their children eat may impede energy self-regulation and put these children at higher risk for overweight (68). These findings suggest that the optimal environment for children's development of self-control of energy intake is that in which parents provide healthy food choices but allow children to assume control of how much they consume (68). The Framingham Children's Study showed that children whose parents had high degrees of dietary control had greater increases in body fatness than did children whose parents had the lowest levels of dietary restraint and disinhibition (69).

B. Adolescents

There is a high prevalence of extreme measures taken by high school students throughout the country to avoid obesity (70–72). They often diet and have inappropriate eating habits and purging behaviors. Young persons, even when they are not overweight, diet to avoid obesity at a time when they are still growing and developing (73, 74). This can adversely affect their growth, resulting in nutritional dwarfing (75).

Neumark recently published results from a national survey examining weight-related behaviors among 6728 American adolescents in grades 5–12 (64). Almost half of the female population (45%) and 20% of male adolescents reported dieting. Older adolescent girls were significantly more likely to diet than younger ones. Dieting was reported by 31% of fifth graders and increased consistently to 62% among the 12th graders. The largest increase was among adolescent girls between the eighth (40%) and ninth (53%) grades. Thirteen percent of the girls and 7% of the boys reported disordered eating behaviors (64).

In another study, Neumark studied 3832 adults and 459 adolescents from four regions of the United States for weight-control behaviors. Based on gender, weight-control behaviors were found in 56.7% of adult women, 50.3% of adult men, 44.0% of adolescent girls, and 36.8% of adolescent boys (76).

Moses et al. showed that high school adolescents in an affluent suburban location were dieting at a very high rate. Forty-one percent of the adolescents were dieting on the day of the survey. Sixty-seven percent of all the adolescents had made on their own important dietary efforts during the past 4–8 weeks. Dieting occurred in normal-weight and underweight students. About 30% of dieters were among the underweight and those of normal weight for height. However, the proportion of the overweight students who were dieting was relatively low: 50–60% (62).

A distorted perception of ideal body weight (below appropriate body weight for height) is very prevalent among high school students. Adolescents often know what their ideal weight should be, but some prefer to be 10% less than their ideal weight for their height (62). Health-compromising behaviors and the fear of obesity may have detrimental consequences in children. Inappropriate nutrient intake may lead to nutritional dwarfing, failure to thrive, and various other nutritional problems, as described in another chapter of this book and elsewhere (76).

C. Dieting/Body Image Problem

It is important to pay close attention to the new classification scheme related to behavioral and mental health concerns for children and adolescents published in 1996 by the American Academy of Pediatrics. The *Diagnostic and Statistical Manual for Primary Care* (DSM-PC) is now paying attention to dieting/body image behaviors that were, in the past, not considered to be eating disorders. Older children and younger adolescents may exhibit behaviors that do not meet full DSM-IV criteria, yet still deserve attention. The two specific complexes in the DSM-PC related to eating disorders are: dieting/body image behaviors and purging/binge-eating behaviors (77). There are two levels of pathology for both of these behavior patterns that are not healthy, but do not fulfill DSM-IV criteria for an eating disorder. In DSM-PC, *var-*

iations constitute minor deviations from normal that still might be of concern for a parent or clinician (77).

An adolescent with a dieting/body image problem will be one who exhibits voluntary food limitation in a pursuit of thinness. He or she experiences a systematic fear of gaining weight that extends beyond a simple dieting/body image variation. However, the intensity of the problem does not meet criteria for anorexia. An obese adolescent who exhibits dieting/body image behaviors and or purging/binge-eating behaviors has a more complicated problem which adds to the difficulties in treatment and long-term health.

IV. GROWTH ASSESSMENT

The measurement of body weight, the parameter commonly used to assess adiposity, is not an optimal method to differentiate between being overweight and being obese. Indeed, individuals with larger than average body frames or excess muscle mass (athletes) may be mistakenly considered obese since they have excess body weight. Since they do not have excess body fat, they are not obese but their relative weight for height may be above 120%, which is a commonly used criterion of obesity in children.

Age-specific growth charts (73) allow a more precise assessment of a child's nutritional status. These charts help the clinician to evaluate a child's weight and its relationship to height. They also provide a view of the previous growth patterns and thus establish the presence of obesity more accurately. However, weight and height nomograms also fail to take into account the frame size and body composition of the patient. The importance of growth charts in the evaluation of childhood obesity is illustrated in the example shown in Figure 1. Julie is a 5-year-old girl with a pattern of morbid obesity. Review of her growth records revealed that Julie's rate of weight gain became excessive after 3 months of age and progressed at an accelerated pace after 1 year of age. This coincided with acceleration of linear growth. The final point on Julie's growth chart (weight: 50 kg; height: 116.5 cm) represents 249% of her ideal body weight for height. In contrast, in Figure 2 the growth chart of Michael with a pattern of constitutional overweight is shown. In this patient, body weight progression was constant throughout, being two major percentiles above that of height with an excess weight for height of 38% throughout his life span. These two types of growth patterns provide clear evidence of two distinct clinical patterns necessitating different approaches. In Julie's case, all efforts need to be made to stop the disproportionate body weight accretion; in Michael's case, caution must be exercised not to interfere with the balance and adjustment already achieved by the patient in maintaining body weight. In a survey of high school children, Moses et al. showed that constitutional patterns of overweight are encountered in about 25% of

Figure 1 Growth pattern of a patient with severe obesity before and after treatment was initiated. Note that the patient was gaining excess weight for height that started after 3 months of age. Her BMI was 36.8 at the time of his first visit.

Figure 2 Growth pattern of a patient with constitutional overweight. Note that the patient's weight was in excess for height but remained proportional throughout his life. His BMI at 10 years old was 24.

the students with excess body weight for height, remaining proportional throughout their school years (62). The morbid obesity pattern of growth is rare, observed in 0.8% of students. Therefore, the clinical assessment of an obese child must include measurements of height and weight progression for the proper assessment and recommendations for treatment.

A. BMI

Body mass index (BMI) is a widely used method to define the relationship between weight and height (78). The BMI is calculated as weight (kg)/height(m²) and provides a practical clinical tool for classification of individuals with normal and those with various degrees of obesity (grades I–III): grade I, BMI 25–29; grade II, BMI 30–40; and

grade III, >40 BMI. The BMI system of classification of obesity is important because it has been found that the risk for medical complications of obese patients increases at BMI levels above 25 (79). According to the National Center for Health Statistics' Health and Nutrition Examination Survey (80), individuals with a BMI above 27 have a markedly increased risk for hypertension, hypercholesterolemia, and diabetes mellitus. In contrast, when the BMI index is less than 25, there are no apparent physical effects of obesity on the individual, although there may be social problems and psychological concerns with body appearance. However, the use of BMI has limited applications in the assessment of overweight children since its calculation is based primarily on a stable height, which is not applicable to growing children. Also, the BMI can underestimate the percentage of lean body mass

since it does not account for variations in musculature; this could lead to classification of normal children as being overweight.

Charts of BMI relative to age are used in many countries to determine childhood obesity. They are easy to use, noninvasive, and have been validated against measures of body fat. Many countries, including the United States, use the 85th percentile for BMI to define children who are overweight and then above the 95th percentile for obesity in children. Furthermore, no differences in the relationship between BMI and age exist among boys and girls up to age 20 from the United States, United Kingdom, Japan, and Singapore (81).

The stage of maturity may cause additional errors when BMI is used to determine obesity in children and adolescents from different ethnic groups (82). In spite of these ethnic differences, BMI correlates (>0.8) with body fat as determined by both skinfold thickness measurements and by densitometry (83). This suggests that BMI is a reasonable criterion for determining obesity in children and adolescents.

There are several potential errors associated with BMI as an indicator of obesity in children. The increasing height in children from birth until adulthood may cause a difference in the weight-for-height relationship assumed in current BMI-for-age charts. Gender and age also affect body weight and height. Furthermore, puberty may introduce another change in the weight-for-height relationship. Ethnic origin and social class may also affect both body weight and height. However, in adults, these relations are simpler because adult height is assumed to be fixed. Therefore, body weight is adjusted for height only. Usually this adjustment takes the form of $\text{body weight}/\text{height}^2$. However, this is not always the best adjustment depending on the age of the child. One study found that the power used to adjust height (Benn index) changed from 2.0 to 3.5 over the first 20 years of life in order to maintain the best relationship with skinfold thickness. The strongest relationships with skin-fold thickness were obtained in children between 9 and 10 years old. Using only a Benn index of 2.0 may introduce subtle errors in BMI when used in younger children. Taller children will tend to have greater BMIs than shorter children. However, trying to define which Benn index to use at certain ages will lead to more errors than if just one standard Benn index is used, such as the current Benn index of 2.0 (84).

B. Key Indicators

In the United States, percentiles are the most commonly used method for clinical monitoring of individual growth. In 2000 the National Center for Health Statistics (NCHS) growth charts were revised. The revised growth charts will include growth curves for BMI and utilize newer mathematical methods for curve smoothing. New data from the third cycle of the National Health and Nutrition Examination Survey (NHANES III) showed increased prev-

alence of overweight in children. Currently being debated is whether it is appropriate to exclude the heavier NHANES III children in the revised growth reference data. For height and weight, percentiles increase monotonically with age. This should be preserved in any curve-smoothing process while still maintaining some variability. Methodologies for smoothing curves include cubic splines, kernel regression, locally weighted regression, and running medians. Locally weighted regression is currently being applied to the NCHS chart revisions. Revised NCHS growth charts for BMI may eliminate subtle errors in some of the percentiles currently used to define childhood obesity.

C. Skinfolts

Skinfold thickness from several separate sites, including both trunk and extremities, provide a reliable estimate of obesity and regional fat distribution. The correlation of multiple skinfold measurements with total body adiposity is in the range of 0.7–0.8. One problem with skinfold measurements is that the equations used must be changed for age, gender, and ethnic background. Body fat increases with age, even through the sum of the skinfolds remains constant. This means that the fat deposition with age occurs in large part at sites other than subcutaneous ones (85). Also, triceps skinfold (TSF), which is typically the site of measurement, is often difficult to grasp and measurement reliability can be poor. It has been observed that there is a strong correlation between BMI and TSF among age- and gender-matched groups, suggesting that these measures are interchangeable for use in classification of individuals and in the evaluation of secular trends of obesity and super obesity (86).

D. Body Fat

Several methods are available for the estimation of body fat content. These include methods that measure body density derived from its specific gravity, that is, the weight of body in and out of the water. This process makes it possible to fractionate the body into its fat and lean components, assuming a density for fat of 0.91 g/cm^3 . The technique remains basically a research method; however, bioelectrical impedance analysis (BIA) has been commonly used as a noninvasive and inexpensive method for estimation of body fat and lean mass (87). Bioelectrical impedance relies on the association between conductivity and tissue fluid and electrolyte content. It has proved to be fairly reliable in assessing total body water, but is less reliable in the estimation of body fat, especially in obese children (88, 89). Other noninvasive methods, such as the use of ultrasound waves applied to the skin, can provide a measure of fat depth. In a group of children, Czinner et al. demonstrated a significant correlation ($r = 0.969$) between the body adiposity (skin fold thickness) measured with ultrasound

and calipers (90). However the data derived from ultrasound method were 15–25% lower than fat obtained by calipers. The authors concluded that the ultrasound-derived body fat estimates represented only the subcutaneous body fat and not the whole body adiposity (i.e., visceral fat). On the other hand, other studies have shown that sonography is a reliable tool in measuring small variations in quantities of intra-abdominal (visceral) fat and is superior to waist to hip ratio (WHR) in evaluating regional fat distribution and visceral adiposity (91).

Dual energy x-ray absorptiometry (DEXA) has been used as a reliable method for estimating fat-free mass and body fat. It has a unique ability to provide precise measures of regional fat mass, lean mass, and bone mineral content (92, 93). The DEXA technique can also be utilized for the evaluation of fat distribution and its role in insulin resistance syndrome and cardiovascular risk factors (94). Computerized axial tomography (CT) scan and magnetic resonance imaging (MRI) can also be used to quantitate lean and fat tissue. They provide accurate anatomical details and can reliably measure total and regional body adiposity. Numerous studies have shown the feasibility of using CT scans to measure human adiposity (95). In a recent study, Ross et al. (96) demonstrated that MRI can provide a reliable measure of subcutaneous and visceral adipose tissue in obese subjects. A principal benefit of measuring adipose tissue by MRI or CT is the development of mathematical equations from external anthropometry that can predict MRI adipose tissue.

E. Total Body Electrical Conductivity

Validation for the use of total body electrical conductivity (TOBEC) for body composition measurements in infants has allowed accurate determinations of fat-free mass and fat mass without the assumptions associated with other methods. This method is appealing due to its ease of use, lack of radiation exposure, and the fact that little subject cooperation is required. The entire procedure takes only 5 min and does not require that infants or young children be sedated. This method involves passing an individual through a large solenoidal coil driven by a 2.5 MHz oscillating radiofrequency that generates a magnetic field. Upon passage through the instrument, all electrolytes, with fat-free mass containing the majority, contribute to disruption of the magnetic field. The instrument registers the magnitude of the magnetic field disruption and provides a value referred to as the TOBEC number. The TOBEC number depends on the conductivity, the length and cross-sectional area of the conductor, as well as electrical and coil parameters. The TOBEC number equals the instrument constants multiplied by the length and volume of the conductor. The square root of the TOBEC number ($\sqrt{\text{TOBEC} \# \times \text{length}}$) has been found to be directly correlated with fat-free mass and fat mass in Hanford piglets (97).

F. Air Displacement Plethysmography

Until recently, there was no easy-to-use and accurate method to determine body composition in adults. The recent availability of the BodPod Body Composition System has allowed accurate determinations of body composition without the associated problems with hydrostatic weighting (98). The principle of the method is similar to hydrostatic weighting except that body volume is now obtained by air displacement. Subjects sit for 2 min in a 450 l chamber and a moving diaphragm determines the difference in air pressure between where the subject is sitting in the front chamber and a rear reference chamber. The pressure difference, along with the subject's body weight, are used to calculate body volume. From these results, body density is calculated and any of the standard equations for calculating fat-free mass and fat mass can be used. The procedure is entirely safe and requires no special cooperation on the part of the subject. In a validation study with 68 subjects, no differences were found in fat-free mass and percentage body fat when determined by both the BodPod Body Composition System and hydrostatic weighting (99). Furthermore, the BodPod Body Composition System can accommodate adults up to 160 kg (350 lb).

In children the BodPod Body Composition System may underestimate body fat. In one study body density was determined in 54 boys and girls from 10 to 18 years of age by both the BodPod Body Composition System and hydrostatic weighing. Body fat values calculated from both of these densities were compared to those determined by DEXA. Body fat calculated from both the Bodpod and DEXA were correlated; however, body fat estimates from the Bodpod were 2.9% lower than those derived from DEXA. This may be due to the significantly higher body density obtained from the Bodpod Body Composition System. These results suggest that body fat percentages in children derived from the Bodpod Body Composition System may not be as accurate (100).

G. Fat Distribution

In recent years, several studies have revealed major morphological and metabolic features that differentiate upper from lower body obesity (101–103). In adults, body fat distribution is more important than percentage body fat in predicting morbidity. Adults with a preponderance of abdominal fat (“android”) have a higher frequency of hypertension, hyperinsulinemia, diabetes, and hyperlipidemia than equally obese individuals with predominantly pelvic (“gynecoid”) fat distribution. The distribution of body fat is assessed using WHR. Increasing WHR in excess of 0.8 has been accompanied by abnormalities in glucose, insulin, and lipoprotein homeostasis (104, 105). Thus, the evaluation of body fat distribution is an essential element in the assessment of obesity. However, it has been observed that WHR cannot predict visceral adiposity in

obese individuals (90, 93). On the other hand, using CT scan, MRI, or visceral-to-subcutaneous fat tissue ratio (VSR) has been shown to be a better index of regional fat distribution than WHR (106, 107). Furthermore, VSR correlates more closely with metabolic variables such as levels of serum lipids, insulin, and glucose than WHR. A WHR greater than 0.8 has been associated with hyperinsulinemia, insulin resistance, and future development of noninsulin-dependent diabetes mellitus (NIDDM) in adults. In Julie's case (Fig. 1), the WHR was 0.96 with significant upper body adiposity, whereas Michael's WHR was 0.76 with modest subcutaneous adiposity. The presence of upper body obesity in markedly obese children may be associated with development of acanthosis nigricans (brownish discoloration of skin) along the skin creases of posterior cervical, axillary, and other flexural areas.

V. WHO IS AT RISK?

A. Infants and Children

It has been shown that parental fatness is related to future obesity in their children. When both parents are overweight, about 80% of their children will be obese. When one parent is obese, this incidence decreases to 40%; and when both parents are lean, obesity prevalence drops to approximately 14% (107). However, the reasons for these associations are not clear since most of the studies fail to separate the genetic and environmental influences in a critical way.

The susceptibility to obesity may begin at birth as a consequence of metabolic variations in energy expenditure. Roberts et al. (108) demonstrated that excessive weight gain among a group of infants born to obese mothers was accompanied by reduced level of physical energy expenditure (108). This was probably the result of infants mimicking the activity patterns of their moderately inactive parents or siblings. Furthermore, Ravussin et al. observed decreased levels of energy expenditure in obese compared to nonobese families (109). These findings are similar to another study in which energy intake at 6 months predicted body fatness by 1 year of age (110). In contrast, several studies have found that energy intake in infants less than 3 months old is not a determinant of body fatness by 2–3 years of age (111, 112). Later studies have verified that parental fatness is related to the incidence of their children becoming obese.

Previous metabolic studies in infants cited above (109–112), which tried to identify alterations in metabolic rate that may contribute to future obesity, were inconclusive. Recent improvements in indirect calorimetry technology have enabled more accurate measurements of infant energy expenditure. The new Enhanced Metabolic Testing Activity Chamber (EMTAC) has been validated for accurate measurements of the components of energy

expenditure, such as resting and sleeping metabolic rates, along with physical activity, in infants from birth to 6 months old (113). Furthermore, during metabolic measurements in the EMTAC, parents have unrestricted access to their infants in a comfortable environment that is as close to normal as possible. This eliminates potential errors in energy expenditure due to stress caused by forced separation between parents and infants for long periods of time. With this new technology future metabolic studies in infants will be able to determine if changes in just one or more of the components of energy expenditure contribute to future childhood obesity.

Some of the physiological components of obesity found in adults may apply to infants from the time of birth. For example, a change in the utilization of nutrients as determined by the RQ (114), a lower than average body temperature (115), and sleeping body core temperature (116) may contribute to additional positive energy balance, thus leading to body weight gain in infants. A recent study using microneurographic recordings of sympathetic nervous system activity found that lower sympathetic nervous system activity occurs in obese adults (117). However, no current studies have addressed any of these potential causes of childhood obesity.

Weight gain and adiposity in infancy and early childhood are also influenced by several environmental factors (118). For instance, birth weight, duration of feeding, male gender, and age at the introduction of solid foods seem to affect significantly the rate of weight gain during the first year of life. Maternal weight only becomes a significant determinant for adiposity during the second year of life. The latter probably reflects the maternal environmental influences that may contribute significantly to the development of obesity since they determine child's energy intake and expenditure (119).

Vigorous feeding of infants and children may set the ground for the development of obesity (120, 121). Overweight children have been observed to eat more rapidly and chew their food less than those of normal weight (121). The influence of many environmental factors on the rate of weight gain, with or without a genetic susceptibility, has been evaluated by some investigators (122). Body adiposity and growth of newborns are influenced significantly by maternal weight and rate of weight gain during the prenatal period (123). It has long been observed that infants of diabetic mothers have increased body adiposity at birth and at 1 year of age (124). It has also been shown that macrosomic infants of mothers with gestational diabetes mellitus (GDM) have evidence of increasing body size and adiposity with increasing age and that maternal GDM and maternal prepregnant adiposity are significant predictors of their unique growth patterns (125).

In a subsequent study, differences of up to 500 calories per day in energy expended as a result of spontaneous physical activity (i.e., fidgeting) were observed

among obese children compared to normal-weight children (126). Differences in basal metabolic rate (BMR) and physical activity were found in 3–5-year-old offspring of obese parents. Basal metabolic rate of children with at least one obese parent was 10% lower than that of children with lean parents (127). Children of lean parents had about twice the energy expenditure for physical activities of children with at least one obese parent, suggesting that children of obese parents are less physically active.

B. Teens

Obesity in teenagers is fast becoming a national concern. The latest results from NHANES III (1988–1994) found a high prevalence of adolescent obesity. Of 2850 children ages 12–18 years, 16% were overweight (85th percentile < BMI < 95th percentile), and 10% were obese (BMI > 95th percentile). However, a South Carolina Health Maintenance Organization (HMO) determined BMI in 30,445 children during the years 1995–1997 to determine the prevalence of childhood obesity in their members' population (128). The criteria for overweight and obesity were similar to those mentioned for NHANES III. In this subject sample 35 and 34% of the boys and girls, respectively, aged 12–17 years, were overweight. This means that 1:3 children in this HMO was above normal weight. Furthermore, 19% of the boys and 18% of the girls in this population were obese. The prevalence of obesity in this adolescent population was greater than that obtained from NHANES III (128). These surveys suggest that more programs specific for treating obesity in teenagers may be necessary.

VI. GENETICS

It has long been known that obesity runs in families. Obese parents impose even a greater risk that their children will be overweight. There is a 75% chance that children aged 3–10 will be overweight if both parents were obese. This drops to a 25–50% chance with just one obese parent. These statistics suggest that behavior modification or treatment intervention at an early age may be important for preventing future adolescent and adulthood obesity (11).

A. Twin Studies

The role of genetic factors in obesity was evaluated by Stunkard et al., who demonstrated no relationship between the body fat indices of adoptive parents and their adoptive children (129). They showed that BMI of biological parents was more closely correlated with the weight status of their offspring although they did not live together. The importance of the genetic component was also confirmed by a more recent study involving monozygotic twins (130). The BMIs of identical twins reared apart compared with those reared together were essentially the same. Also,

the use of skinfolds as genetic markers in twins has been reported (131). With the use of correlation coefficients to estimate the heritability of skinfold thickness, it has been shown that there was a significant environmental component among children less than 10 years, whereas heritability estimated in twins more than 10 years of age was very high. In a recent study involving Swedish adult twins, Heitmann et al. (132) recently suggested that although food choices seemed to play a role in the frequency of consumption of various foods, genetics also influenced the preference for several foods. However, there was no evidence that the consumption frequency of any of the foods was differentially associated with expression of genes responsible for weight gain.

B. Leptin

A major advance in understanding the pathogenesis of obesity is the discovery of the hormone leptin. It is produced by adipose tissue and has been found to modify feeding behavior in rodents by suppressing food intake and stimulating energy expenditure (133, 134). Leptin exerts its actions centrally on appetite and thermogenic control centers located in the hypothalamus. It is believed that obesity in humans is due to a desensitization of leptin reception within the hypothalamus, resulting in hyperphagia (133–135). Obese individuals have marked elevation of their plasma levels of leptin directly proportional to body fat mass (136). Sustained elevated levels of plasma leptin are proposed to uncouple leptin actions on its receptors in the hypothalamus, thereby attenuating signal transduction pathways that exert the effects of the hormone on satiety and energy expenditure (133, 137). Furthermore, leptin acts directly on receptors in pancreatic beta-cells to suppress insulin secretion in rodents (138–140). Thus, some have proposed the existence of an adipoinular axis in which insulin stimulates adipogenesis and leptin production, and leptin inhibits insulin secretion through its effect on beta-cell ATP-sensitive potassium channels (141). Seufert et al. recently proposed that in obese individuals leptin reception by beta cells is desensitized, similar to what is proposed to occur at the level of the hypothalamus (142). This desensitization of suppression of insulin secretion of beta cells contributes to the hyperinsulinemia of obesity. Hyperinsulinemia, in turn, leads to increased adipogenesis and insulin resistance, culminating in some individuals in the development of diabetes.

The recent discovery of the obese (*Lep*) gene (143) has provided new insights into the regulation of energy metabolism in the body (Fig. 3). The *Lep* gene is specifically expressed in adipocytes (143, 144) and encodes a 167 amino-acid-secreted protein called leptin. The physiological importance of quantitative changes in leptin concentration indicates that regulation of the *Lep* gene is a critical control point (145–147). Leptin receptors have been found in several hypothalamic nuclei, including the

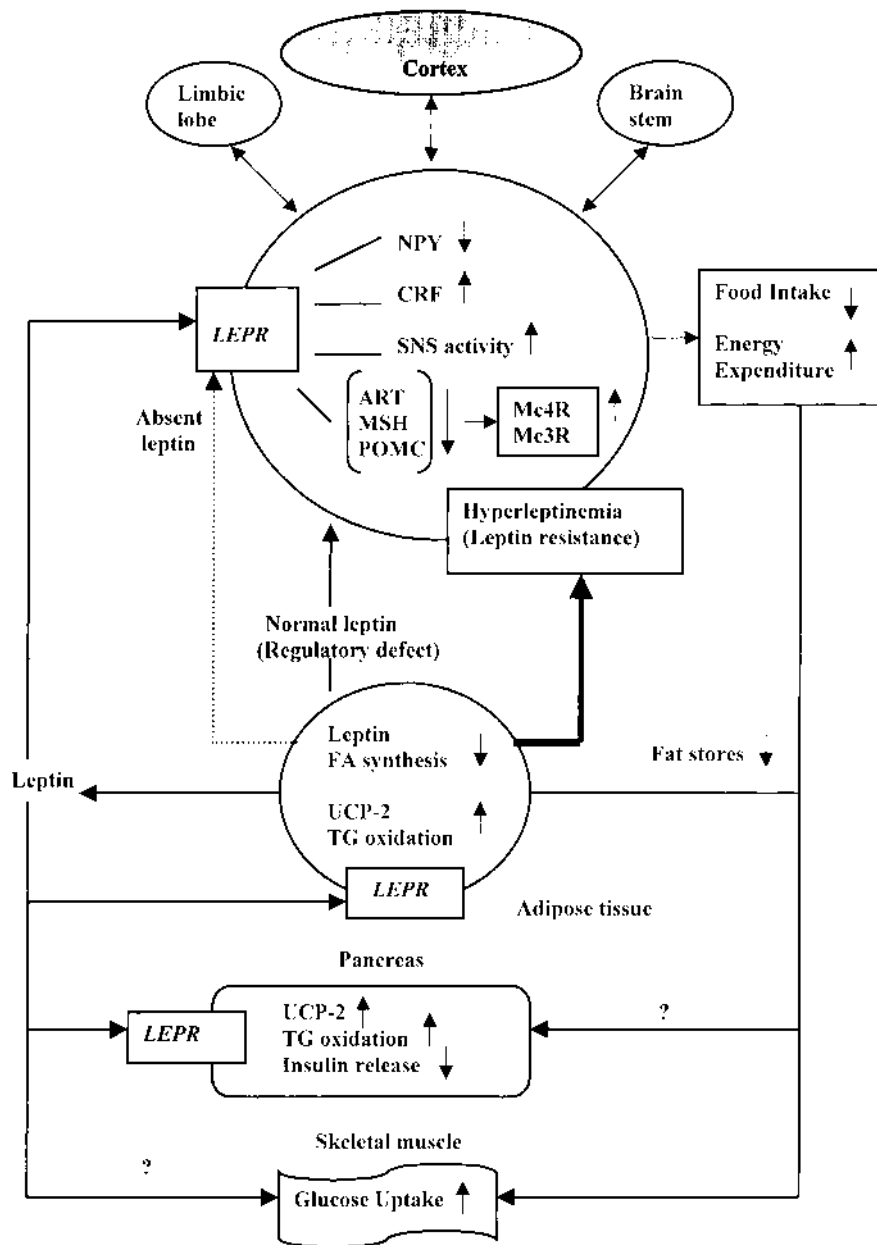

Figure 3 Schematic of the current view of the roles of leptin in energy homeostasis.

arcuate nucleus, ventromedial, lateral, dorsomedial, and paraventricular hypothalamic nuclei (148). These hypothalamic nuclei express one or more neuropeptides and neurotransmitters that regulate food intake and/or body weight. Genetic data indicate that neuropeptide Y (NPY) and one or more of its receptors act in response to absent (and possibly low) leptin, whereas melanocyte-stimulating hormone (MSH), its receptor, the melanocortin-4 receptor, and possibly the agouti-related transcript (ART) are re-

quired for the response to an increased plasma leptin concentration (149). Neuropeptide Y is the most potent orexigenic agent known when administered intrathecally. Neuropeptide Y mRNA is increased in *ob/ob* mice and decreases after leptin treatment (150). Leptin also increases corticotropin-releasing hormone (CRH) gene expression and synthesis (151), which, in turn, inhibits food intake and increases energy expenditure (152). Conversely, food intake has effects on both the plasma leptin

concentration and *Lep* gene expression. Fasting decreases and refeeding increases *Lep* gene expression (153, 154) and the plasma leptin concentration (155).

It is believed that decreased leptin expression per adipocyte could lead to obesity with normal (but inappropriately low) plasma leptin concentrations. This hypothesis is supported by the observation that *ob/ob* mice carrying a poorly expressed leptin transgene are obese, despite having relatively normal leptin levels (147). Similarly, 5–10% of obese human subjects have relatively low levels of leptin, indicative of a reduced rate of leptin production in this subgroup (156). Low leptin levels also predispose preobese Pima Indians to weight gain (157). In almost all cases, obese subjects express at least some leptin, indicating that human *Lep* gene mutations are likely to be rare. Except for a few reported cases of *Lep* mutations in massively obese subjects (158, 159), researchers have not been able to demonstrate *Lep* mutations in most obese subjects (160). Although the *Lep* gene has been linked to severe obesity in some family studies, mutations in the leptin-coding sequence were not identified (161, 162). The molecular basis for this association is unknown but could be related to differences in the amount of expression of leptin mRNA. Loci on human chromosome 2 may be linked to leptin levels and, to a lesser extent, to BMI (163). These loci are near the gene for human pro-opiomelanocortin (POMC), which is a precursor of MSH. It has been shown that abnormal melanocortin signaling in yellow agouti (A^y) or melanocortin-4-knockout mice leads to obesity and leptin resistance (164). A subset of neurons expresses both *Lep* receptor and POMC, and leptin modulates POMC gene expression (165). Krude et al. (166) recently described two red-haired subjects with severe obesity and adrenal insufficiency. It has also been shown that agonists of beta MSH and MSH decrease food intake and pretreatment of animals with a beta-MSH antagonist blunts the anorectic effect of injected leptin (167). Therefore, association of mutations in leptin and its receptor with massive obesity confirms its importance in regulating human body weight (168). However, these syndromes are rare.

Changes in *Lep* gene expression have been shown to be associated with parallel changes in plasma insulin concentration (169). Since insulin itself has a stimulatory effect on *Lep* gene expression and leptin secretion (170), it is likely that feeding-induced changes in leptin concentrations are dependent on insulin. Furthermore, insulinemia has been shown to regulate plasma leptin and to be a determinant of its plasma concentration in normal-weight and obese human subjects (171). In fact, plasma leptin level in obese children and adults correlates not only with the degree of insulinemia but also with percentage of body fat (171), suggesting that human obesity is generally associated with an insensitivity to leptin. However, investigators have recently reported that inadequate insulin-induced leptin production in obese insulin-resistant subjects may contribute to the development of obesity (172).

Lahlou et al. recently suggested that increased circulating leptin concentrations during the dynamic phase of childhood obesity are indicative of leptin resistance (173). They observed that leptin did not act as an appetite regulator in the obese children without a significant impact on basal energy expenditure. These investigators also showed that obese girls had higher leptin levels than boys. A comparable gender-related difference was found in non-obese children. This sexual dimorphism of circulating leptin levels could reflect a physiological role in the regulation of reproduction in humans. In mice, while the *ob/ob* males are normally fertile, administration of leptin to infertile female *ob/ob* mice is needed to restore fertility (174). It is therefore possible that leptin plays a role in the female gonadostat as a signaling hormone reflecting the amount of fat stores at the hypothalamic–pituitary level or directly at the ovarian level (175). It is likely that quantitative and possible functional changes in adipose tissue of girls entering puberty may physiologically increase leptin to levels that allow the hypothalamic–pituitary–gonadal axis to complete sexual maturation and prepare for pregnancy. The sexual dimorphism for circulating leptin levels observed in lean girls and boys is consistent with these metabolic considerations. Thus, the lack of premature puberty despite hyperleptinemia in massively obese girls could be taken as an additional index of central leptin resistance.

Finally, leptin increases energy expenditure by direct effects on CNS and the peripheral tissues. Leptin infusion into the CNS increases sympathetic activity to brown adipose tissue, kidney, and adrenal gland (176). However, it is not yet known whether blockage of beta-adrenergic receptors attenuates leptin-induced weight loss. Thus the role of the sympathetic nervous system in mediating the weight-reducing effect of leptin is not yet established. Leptin also prevents reduced energy expenditure normally associated with decreased food intake (145). Administration of leptin also decreases blood glucose and insulin concentrations in *ob/ob* mice (177). Leptin induces depletion of triglyceride in adipose tissue and pancreas by increasing intracellular fatty acid oxidation and gene expression of the enzymes involved in fatty acid oxidation (178, 179). Leptin also increases the expression of uncoupling protein-2 (UCP-2) in adipose tissue and pancreas (179). Uncoupling proteins disrupt the mitochondrial proton gradient in brown fat (and possibly other tissues), resulting in the generation of heat rather than ATP. However, it has been suggested that leptin treatment does not cause a net increase in 24 h energy expenditure but instead blunts the decreased energy expenditure that generally accompanies food restriction (145). It is thus uncertain whether leptin increases energy expenditure or activates uncoupling protein. In summary, a complex physiological system has evolved to regulate fuel stores and energy balance at an optimum level. Leptin and its receptors are integral components of this system. Although the entire

pathogenesis of human obesity is unknown, it is assumed to be, in part, the result of differences in leptin secretion and/or leptin sensitivity and its interaction with underlying genetic and environmental factors.

C. Ghrelin

Ghrelin is an acylated peptide hormone recently purified from rat stomach. The hormone consists of 28 amino acids in which the serine-3 residue is n-octanoylated. It is primarily synthesized in the stomach but its principal site of action is growth hormone secretagogue receptors located on hypothalamic neurons and in the brainstem. Only two amino acids are not conserved between rat and human ghrelin. The main function of ghrelin is the regulation of pituitary growth hormone secretion independent of growth-hormone-releasing hormone and somatostatin. It has been suggested that ghrelin is an endocrine link between the stomach, hypothalamus, and pituitary. This may be important for the regulation of energy balance (180–182).

There may be different effects between rodents and humans in regard to the action of ghrelin. For example, peripheral daily administration of ghrelin to both rats and mice caused body weight gain by reducing fat utilization. Furthermore, intracerebroventricular administration of ghrelin in increasing amounts generated a dose-dependent increase in food intake and body weight gain. Through the measurement of 24 h energy expenditure in a rodent calorimeter, ghrelin was found to exhibit its effect by increasing carbohydrate and reducing fat utilization without any changes in food intake. This was determined from the RQ derived from the ratio of carbon dioxide production and oxygen consumption. This change in nutrient utilization resulted in an increased amount of body fat without any corresponding changes in fat-free mass or bone mineral content. Furthermore, no changes occurred in energy expenditure or physical activity (182). It was theorized that the concentration of serum ghrelin will be increased in obese humans. Furthermore, predominantly obese ethnic groups, such as the Pima Indians of Southern Arizona, would have the greatest plasma concentrations of ghrelin. In one study, 15 lean and obese white subjects and 15 lean and obese Pima Indian adults had plasma ghrelin, insulin, and leptin determined. In contrast to the hypothesis, both obese groups had significantly lower plasma ghrelin concentrations than the respective lean groups. Furthermore, plasma insulin and leptin concentrations were increased. Moreover, plasma ghrelin concentrations were negatively correlated with body weight, percentage body fat, as well as plasma leptin and insulin. These data suggest that plasma ghrelin is downregulated in obesity. This may result from increased concentrations of both leptin and insulin. These investigators further suggest that reduced plasma ghrelin concentrations may represent adaptation to a positive energy balance associated with obesity (183).

D. Adipose Tissue Endocrine Functions

Adipose tissue is comprised of lipid-filled cells surrounded by a matrix of collagen fibers, vessels, fibroblasts, and immune cells. Its main function is the storage of triglycerides for times of energy deprivation. However, adipose tissue may be involved in other aspects of metabolism that may affect the onset of obesity. Adipose tissue metabolizes sex steroids and glucocorticoids. For example, 17 beta-hydroxysteroid oxidoreductase converts androstenedione to testosterone and estrone to estradiol. This may be important for fat distribution. Estrogens stimulate fat accumulation in the breast and subcutaneous tissue, while androgens promote central obesity. Alteration of these interconversions may predispose individuals to reproductive disorders and certain cancers (184, 185).

Adipose tissue also produces and secretes certain inflammatory cytokines, for example tumor necrosis factor alpha (TNF-alpha) and interleukin-6 (IL-6). It has been suggested that both of these cytokines prevent obesity through inhibition of lipogenesis, increased lipolysis, and promotion of adipocyte death via apoptosis. However, TNF-alpha has been found to be a mediator of insulin resistance in obesity (186, 187). C-reactive protein, stimulated by elevated IL-6, has been found to be correlated with obesity, insulin resistance, elevated TNF-alpha, and endothelial dysfunction (188).

Alteration of coagulation and complement factors may contribute to the obesity associated cardiovascular disease. Fibrinogen and plasma activator inhibitor type-1 (PAI-1) are altered in obesity and may be involved in cardiovascular disease. For example, high levels of PAI-1 have been detected after myocardial infarction. Much of the PAI-1 is synthesized by adipose tissue and is increased in proportion to visceral adiposity. This may serve as a link between abdominal/central obesity and cardiovascular disease (189).

E. Adiponectin

Plasma concentrations of adiponectin, a novel adipose-specific protein with putative antiathrogenic and anti-inflammatory effects, were recently found to be decreased in Japanese individuals with obesity, type 2 diabetes, and cardiovascular diseases conditions commonly associated with insulin resistance and hyperinsulinemia (190). It has also been shown that the degree of hypo adiponectinemia is more closely related to the degree of insulin resistance and hyperinsulinemia than the degree of adiposity and glucose intolerance.

F. Mutations

In monogenetic or dysmorphic forms of obesity, transmitted by both recessive and dominant modes of inheritance, there are also alterations in energy balance that result in obesity. Patients with Prader-Willi syndrome are

characterized by hyperphagia, hypotonia, developmental delay, hypogonadism, and short stature (191). In these children, obesity may start during the first year of life and becomes prominent by the second year, which in the presence of hyperphagia can result in morbid obesity. It was previously suggested that a low metabolic rate caused the obesity in these children (192). However, it has been demonstrated that a lower energy requirement of these children is due to less fat-free mass and not to an unusually low metabolic rate (193).

Translocation or deletion of chromosome 15 has been reported in about 50% of these patients (194). In contrast, Lawrence-Moon-Biedl syndrome is another dysmorphic form of obesity characterized by retinitis pigmentosa, hypogonadism, mental retardation, and polydactyly. It is inherited by an autosomal recessive gene (195). It is believed that excessive weight gain in these children is caused by disturbance of hypothalamic appetite center(s), which leads to increased food intake. Pseudohypoparathyroidism is also associated with obesity and short stature and is characterized by short fourth metacarpal, short thick neck, rounded facies, mental retardation, and hypocalcemia (196). It is commonly inherited as a sex-linked dominant trait and may be accompanied by hypothyroidism and gonadal failure. Other genetic syndromes that include obesity are Alstrom's, Carpenters, and Cohen's. The mechanisms of excess weight in these patients have not been elucidated as yet.

VII. ENERGY BALANCE

Obesity is a heterogeneous group of disorders that can result from an energy imbalance over an extended period of time in which energy intake exceeds expenditure. It is superficially apparent that obese subjects ingest more food relative to their needs. However, caloric intakes have been reported to be comparable among overweight and normal weight adults (197), suggesting that obese subjects have "increased metabolic efficiency."

It has been shown that low total and resting energy expenditure are risk factors for long-term weight gain in infants (198) and adults (199), respectively. However, Dwyer et al. (200) showed that obese children might not eat more than their normal-weight peers and they may expend relatively fewer calories to maintain their body weight. This phenomenon has been referred as adaptation and results after frequent dieting efforts have taken place. This results in lower energy requirements due to loss of lean body mass (201). Repeated weight reduction attempts result in alterations in body composition and decreased fat-free mass. This leads to decreased metabolic demands and thus fewer calories needed to maintain weight (202).

Reduced meal frequency, or gorging (i.e., one to two meals daily), has been associated with an increased risk of obesity (203, 204). This is also associated with high fasting serum lipid and insulin levels. Insulin stimulates

hepatic synthesis of cholesterol and tissue lipogenesis (205, 206). Increasing meal frequency, or nibbling has been shown to significantly lower serum cholesterol and insulin levels (207). This is thought to have a beneficial effect in decreasing triglyceride synthesis in adipose tissue through a reduction in postprandial glucose and insulin levels. However, this effect may be significantly minimized by a parallel reduction in the postprandial thermogenesis stimulated by insulin and glucose (208).

The main determinant of BMR is fat-free mass (FFM) and the main determinant of energy expenditure is physical activity. It is believed that minor alterations in any of these could result in positive energy balance and lead to obesity over prolonged periods of time. For example, obligatory energy expenditure, reflected by a decreased resting metabolic rate, could be the consequence of an increased metabolic efficiency in obese persons. On the other hand, a reduced level of activity could also lead to an increased energy balance and weight gain. The resting energy expenditure and the baseline activity levels are thought to be genetically determined. In fact, studies among obese Pima Indians have demonstrated low BMR values and, therefore, enhanced metabolic efficiency of energy consumption among some families with obesity (209, 210). However, other studies demonstrated that BMR values, corrected for FFM, among obese subjects were relatively higher than those in nonobese subjects (211), suggesting that attainment of energy balance and weight maintenance in obese individuals requires a larger energy intake than in nonobese individuals.

VIII. PHYSICAL ACTIVITY

It is not clear whether inactivity is a cause or consequence of obesity. However, it is believed that a sedentary lifestyle increases the risk for obesity. Furthermore, low cardiorespiratory fitness is an independent predictor of cardiovascular heart disease in obese adult men. This is comparable to diabetes mellitus, high blood pressure, and smoking (212). Physical activity in children has declined over recent decades implying an increasingly sedentary lifestyle in Western industrialized countries. Reports have indicated that physical activity declines almost 50% during adolescence, with girls becoming increasingly more sedentary than boys (213). A recent observation is that this pattern is due to a gender dimorphism in the developmental changes in energy expenditure before adolescence, independent of body composition, with a conservation of energy use in girls achieved through an appreciable reduction in physical activity (214). Social and environmental influences are also believed to have major roles in the gender and developmental variation in physical activity (215).

The role of physical energy expenditure in the development of obesity is not very clear. Obese individuals have often been described as sluggish or lazy. A study of

children and adolescents by Bullen et al. (216) indicated that obese youngsters were less active than their peers. However, an earlier study, which measured caloric expenditure by measuring oxygen consumption, found that obese individuals actually expended more calories through activity than did normal-weight individuals (217). Maffei et al. (218) recently demonstrated that walking and running are energetically more expensive for obese children than for nonobese children.

The estimates of energy requirements for children were derived in a time when more physical exertion was needed for daily living; therefore, energy requirements for children may be overestimated for today's sedentary lifestyle. Prentice et al. (219) measured energy expenditure in children aged 0–3 years by the doubly labeled water method and found that energy needs were overestimated by 15% as originally recommended by the World Health Organization (WHO) (220). Goran et al. (221) likewise showed that energy requirements were 25% overestimated for 4–6-year-old children. Fontvieille et al. (222) found that energy requirements for 5–6-year-old children were overestimated by 24% in comparison to that calculated according to the WHO. The sedentary lifestyles of today's children may easily account for consistent overestimates of childhood energy requirements. Indeed, children living a sedentary lifestyle with unlimited access to food are prone to consuming more energy than they expend, and therefore are at increased risk of obesity.

Child obesity experts have suggested that the relationship between television and obesity may be the consequence of enhanced food consumption during viewing. This may be due to the influence of food advertisements (223, 224). Experimental studies have demonstrated that a causal relationship exists between specific televised messages and children's eating behavior (225) and between television viewing and participation in sports (226). Earlier studies among children and adolescents found an association between hours of television viewing and the development of obesity (227). Indeed, this association was further supported by a recent observation that the levels of physical activity and hours of television viewing tend to have a strong relationship with body weight and degree of obesity among children (228). It is also possible that the way a child watches television and the content of the television programs may be more important than the number of viewing hours. However, it has been recently shown that television viewing has a fairly profound lowering effect on metabolic rate in both lean and obese individuals. This may be an important factor in susceptible children who are at risk for weight gain and potentially lead to obesity (224).

IX. HYPERINSULINISM

Syndrome X is a clinical quartet of hyperinsulinemia, hyperlipidemia, hypertension, and subsequent cardiovascular

disease (30). It is believed that obesity is a component of this metabolic syndrome and has been described in obese children (31) and adolescents (32). In a more recent study Chen et al. suggested that syndrome X is characterized by the linking of a metabolic entity (hyperinsulinemia/insulin resistance, hyperlipidemia, and obesity) to a hemodynamic factor (hypertension) through a shared correlation with hyperinsulinemia/insulin resistance. Clustering features of syndrome X are independent of gender and age in both black and white populations (33).

Hyperinsulinism and insulin resistance are characteristic features of obesity (229). It has been demonstrated that insulin secretion increases as the severity of obesity increases (210), and this increase in insulin secretion is accompanied by varying degrees of resistance to insulin-mediated glucose uptake (230). Indeed, the observed abnormalities in glucose tolerance in some obese adolescents are consistent with the presence of hyperinsulinemia and insulin resistance. Occasionally, young patients with a strong positive family history of type 2 diabetes develop the disease. Also, insulin resistance may result in the development of acanthosis nigricans, a hyperpigmentation of skin, which is commonly seen in the back of the neck, axillae, and other flexural areas (71). Hyperinsulinemia is usually accompanied by hyperandrogenism, which leads to hirsutism.

The presence of hyperinsulinemia favors the maintenance of the obese state by stimulating lipogenesis via activation of lipoprotein lipase and by inhibiting lipolysis. The hyperinsulinemia and insulin resistance are believed to cause preferential shunting of substrates to adipose tissue, with conversion of periadipocytes to adipocytes; this is associated with hyperplasia and hypertrophy of fat cells, inducing an unabated lipogenic state and obesity (231). It has also been shown that the lipogenic action of insulin occurs at a lower insulin concentration than its glyco-regulatory action (232). Additionally, Le Stunff et al. (233) demonstrated that hyperinsulinemic obese children oxidized more fat and less glucose than their lean counterparts. This impairment of glucose metabolism may, in part, be caused by an excessive utilization of fatty substrate (234). This finding supports the concept of decreased glucose utilization and its shunting to fatty acid and triglycerides synthesis.

The hyperinsulinemia of obesity is apparently due to a combination of increased pancreatic secretion and a reduction of hepatic extraction (235). The extent of the changes in insulin level is correlated with increasing fat cell size and degree of obesity and is more prominent in individuals with central obesity (235, 236). The mechanisms for the enhanced insulin secretion are not well understood, but one explanation is that it is an adaptive response to the diminished insulin-binding sites (237). However, dysregulation of beta-cell function has been described in obese children in the absence of insulin resistance (233). Odeleye et al. (238) found high fasting in-

ulin levels in lean prepubertal Pima Indian children are predicative of the development of adolescent obesity (238).

The observed metabolic alterations in the insulin-resistant state are predominant with regard to glucose metabolism, especially with respect to cellular glucose uptake and hepatic glucose production, whereas effects on amino acid metabolism and fat metabolism are less significant. These metabolic changes lead to blood glucose elevation (239) and enhanced fatty acid storage in adipose tissue. Kida et al. (240) demonstrated diminished insulin receptor binding in monocytes of obese children that inversely correlated with their degree of obesity. Both receptor and postreceptor binding defects appear to play a role in insulin resistance of obesity. However, it is not clear whether hyperinsulinemia-induced downregulation of insulin receptors and/or decreased receptor-induced hyperinsulinemia are the mechanisms for the observed alterations. These abnormalities correct towards normal range with weight loss.

Other investigators have evaluated the rate of body fat distribution and altered fatty acid metabolism in insulin resistance and hyperinsulinemia of obesity. For instance, obese subjects with an abdominal fat distribution have reduced hepatic insulin binding (241, 242). A possible cellular mechanism may be the result of high physiological free fatty acid (FFA) concentrations. It has been suggested that the inhibitory effect of FFA is energy dependent and does not change the total cellular number of insulin receptors or their binding characteristics, indicating that the receptor internalization or recycling is influenced (243). Svedberg et al. (244) demonstrated that obesity with high ambient FFA levels influences internalization/recycling of hepatic insulin receptors, leading to reduced cell surface binding (244). An increased supply of FFAs to muscle has been suggested to restrain glucose transport and disposal through the inhibitory action of the products of FFA oxidation (citrate, acetyl-CoA, adenosine 5-triphosphate, etc.). This is due to the FFA oxidation products' influence on key enzymes of glucose metabolism (pyruvate dehydrogenase, phosphofructokinase, and hexokinase) (234). The observed substrate competition is suggested to impede insulin action on glucose metabolism through derangement in lipid metabolism (245, 246). In children, progressive augmentation of fat stores and lipid oxidation during the first years of obesity could therefore induce a progressive reduction in glucose oxidation and decreased insulin action (233). This suggests that the increase in lipid oxidation precedes the changes in glucose oxidation and insulin levels associated with long-duration obesity.

Finally, elevated circulating levels of insulin due to insulin-producing tumor (insulinoma) or to excessive administration of insulin to an insulin-dependent diabetic patient can lead to obesity. These patients develop obesity, short stature, and hepatomegaly (Mauriac syndrome) (247).

X. HORMONAL ALTERATIONS

A. Adrenals

Adrenal glucocorticoid production is enhanced in obese children (248). Obese children tend to maintain normal serum cortisol levels due to its increased urinary clearance and in direct proportion to an increase in lean body mass. Increased clearance of cortisol has a stimulatory effect on pituitary adrenocorticotrophic hormone (ACTH) release. Adrenocorticotrophic hormone stimulates increased production of adrenal sex steroids such as dehydroepiandrosterone and testosterone. Increased production of adrenal sex steroids leads to early adrenarche (pubarche) in obese children (248).

The release of cortisol is maintained under a normal circadian rhythm. Furthermore, it is believed that elevated plasma cortisol in some obese individuals is related to the hyperinsulinemia of obesity and contributes to the characteristic body fat distribution and altered body composition (249). In obese children, serum levels of epinephrine and norepinephrine remain normal. Adrenal hypercortisolism has long been recognized in the differential diagnosis of pediatric obesity. Although some patients have a fat distribution suggestive of Cushing syndrome, the use of corticosteroid therapy for a variety of inflammatory and allergic conditions is also associated with the development of obesity. In this type of obesity the problem is transient and resolves once use of the drug is stopped. Cushing syndrome is a rare cause of obesity and these patients can be differentiated from those with exogenous obesity by the cessation of growth that accompanies excess cortisol.

B. Growth

Obese children are commonly tall for their age. This is associated with advanced skeletal maturity and early onset of puberty as well as premature pubarche (248). The lean body mass is often increased in these children (250). Reduced serum concentrations of growth hormone (GH) are characteristically seen in obese individuals and have been attributed to diminished GH secretion as well as accelerated GH clearance (251). The concentrations of insulin-like growth factor (IGF)-1 tend to vary because, unlike insulin, it circulates bound to specific proteins such as IGF-binding proteins (IGFBPs) with variable affinities (252–254). Six IGFBPs have been structurally identified, but only IGFBP-1, -2, and -3 have been well characterized in humans (251). In contrast to the lack of diurnal variation of IGFBP-2 and IGFBP-3, circulating levels of IGFBP-1 vary widely throughout the day in an inverse relationship with changes in plasma insulin (255, 256). Acute and chronic elevations in plasma insulin lower IGFBP-1 by suppressing its production by the liver, which, in turn, increases the bioavailability of free IGF-1 (257, 258). The blunted growth hormone response in

obese subjects could be secondary to negative feedback inhibition by IGF-1 (259). However, other investigators have suggested that IGF-1 levels are maintained or even enhanced by the hyperinsulinemia of obesity (260). The metabolic syndrome induced by increased adiposity appears to have profound effects on the complex interplay among GH, IGF-1, and IGF-BPs during puberty. However, the effect is an increase in the ratio of free to total IGF-1 in obese subjects, which may help to explain the lack of alteration of the pubertal growth spurt in obese adolescents even in the presence of lower GH levels. On the other hand, GH deficiency or pituitary dwarfism is reported to result in a mild degree of obesity compared to other causes of weight gain. It is believed that weight gain in a growth-deficient child is caused by diminished energy expenditure. Indeed, it has been observed that GH stimulates the growth of muscle tissue and breakdown of fat tissue, therefore affecting body composition (261).

There is a potential for reduced growth performance during obesity treatment. This may be due to the inherent reduction in nutrient intake associated with various obesity treatment programs. For example, a reduction in height velocity was found in children undergoing an energy-restrictive 6 month obesity treatment protocol. However, children undergoing a 12 month, less energy restrictive obesity treatment showed no reductions in height velocity. Furthermore, both groups had similar heights from baseline until 12 months, suggesting that the children undergoing the more restrictive 6 month protocol showed catch-up growth following treatment (262). The situation was not similar in regard to increases in fat-free mass. The more restrictive group had smaller increases in fat-free mass after 12 months than the 12 month treatment groups (263). A recent review of 10 year follow-up data in children found no significant changes in final height in regard to the amount of energy restriction during obesity treatment. Furthermore, multiple regression analysis found that childhood percentage of overweight did not contribute to predicting height change. However, a reduction in the percentile for height did occur in children from baseline to 10 years after treatment. The mean height of the children was over the 70th percentile for height prior to, and it decreased to just over the 50th percentile 10 years after, obesity treatment. These studies suggest that children participating in comprehensive obesity treatment programs, which include energy restriction, may attain an appropriate adult height and this will be similar to their parents (263). Children who diet without appropriate supervision do have growth failure (61).

C. Prolactin

Basal prolactin levels are normal or slightly elevated in obese children. However, the prolactin response to provocative stimuli is often diminished (264). Donders et al. suggested that decreased serotonin in the brain was a potential mechanism for the blunted prolactin response. Oth-

ers have hypothesized that this may be due to a hypothalamic defect that contributes to the abnormal prolactin response and aberrant appetite regulation, especially when prolactin response does not return to normal with weight loss in the same obese patients.

D. Thyroid

No evidence links thyroid dysfunction to exogenous obesity. Serum levels of thyroxine, free thyroxine, and thyroid-stimulating hormone (TSH) are normal in obese individuals. Hypothyroidism is not a common cause of obesity. Excessive weight gain, secondary to an underactive thyroid gland, is due to a combination of decreased metabolic rate and enhanced fluid retention (265). In children, hypothyroidism is associated with poor linear growth. Therefore, a normally growing but overweight child is not likely to be hypothyroid.

E. Reproductive Hormones

Puberty may begin early in tall overweight children with advanced skeletal age. Kaplowitz et al. recently demonstrated that obesity is an important contributing factor to the earlier onset of puberty in girls (266). Pubertal elevations of follicular-stimulating hormone (FSH) have been observed in the 7–9-year-old girls, without any changes in luteinizing hormone (LH) levels (266). This is usually complicated by an adiposity-related decrease in circulating concentrations of sex hormone-binding globulin (SHBG). This results in a higher fraction of free or unbound serum sex steroids that are more bioactive than the ones in lean subjects (266). In general, the SHBG abnormalities correlate with the degree of obesity, which are reversed with weight loss (266). Low serum estradiol levels and elevated progesterone levels have been observed in young prepubertal and early pubertal obese girls compared to age-matched lean girls (266).

The emergence of hyperandrogenism in pubertal girls may be associated with rapid weight gain, signs of hirsutism or virilism, and irregular menstrual periods (47). This is usually accompanied by hyperinsulinemia and insulin resistance with or without glucose intolerance. There is strong evidence that insulin exerts a regulatory effect on ovarian androgen synthesis (48). In fact, a positive correlation between the degrees of hyperinsulinemia and hyperandrogenism can be found in obese women (49).

Since insulin is believed to effect its regulatory action through LH on ovarian function, some obese patients may also present with polycystic ovaries and abnormally elevated serum LH, low follicle-stimulating hormone (FSH), and high free testosterone levels.

Obese adolescent boys appear to have an attenuated testicular response to human chorionic gonadotropin (HCG). This is probably an artifact of decreased/ro SHBG. Indeed, Glass et al. (235) demonstrated that despite a decrease in SHBG levels and increased percentage

free testosterone, the free testosterone levels were normal. Serum dihydrotestosterone levels remain normal in obese subjects. Aromatization of androgens to estrogens by adipose tissue, in males, appears to be enhanced without any evidence of clinical feminization (235). However, free and total testosterone levels may be diminished in morbidly obese males. This is commonly associated with decreased gonadotropin levels, suggesting some degree of hypogonadotropic hypogonadism (158). These alterations in pituitary and gonadal hormones return to normal range with weight loss (159).

Precocious puberty may lead to obesity. Children with precocious puberty prior to treatment show no differences in regard to lean or fat mass. However, during treatment with gonadotropin-releasing hormone (GnRH) over for several years, these children end up with a reduction of lean mass and increased fat mass. This may be due to a shortening of the prepubertal growing period and by the so-called menopausal effect of the treatment. After treatment these children end up with a greater amount of fat mass, which may lead to obesity (267, 268). In another study both boys and girls with precocious puberty had BMI scores above the 85th percentile prior to and during treatment with GnRH. After treatment the scores still remained above the 85th percentile, indicating obesity. These results suggest that children with precocious puberty are prone to obesity. Furthermore, treatment of precocious puberty with GnRH does not itself contribute to obesity.

XI. HYPOTHALAMUS

Lesions of the ventromedial area of the hypothalamus (VMH) may result from inflammatory processes such as encephalitis, arachnoiditis, tuberculosis, or trauma, or malignancy (Fröhlich syndrome) (269, 270). Children with hypothalamic obesity may present with a history of foraging and stealing foods. They have a voracious appetite and may display frequent tantrums if food is denied. In children, craniopharyngioma is the most common CNS tumor that leads to hypothalamic and pituitary dysfunction (271). Hypothalamic obesity is often coupled with other hypothalamic–pituitary disturbances, which may exacerbate the obesity (e.g., growth hormone deficiency or hypothyroidism), but the obesity resists treatment with hormonal replacement (272, 273). It is believed that hypothalamic injury leads to alterations in the appetite center, which can cause hyperphagia and obesity (274). However, there is increasing evidence that the hyperinsulinemia seen in this disorder plays a role in the development of obesity. An animal model of VMH damage results in hyperphagia, obesity, hyperinsulinemia, and insulin resistance (275, 276). It is believed that VMH damage causes a disinhibition of vagal tone (277) at the pancreatic beta cell, which leads to insulin hypersecretion and resultant obesity (278). Lustig et al. (279) recently dem-

onstrated that children with hypothalamic obesity have excessive insulin secretion during a standard oral glucose tolerance test (279). They also observed that treatment of these children with octreotide, a long-acting somatostatin receptor agonist (280), attenuated hyperinsulinemia in these children and promoted weight loss. These investigators concluded that normalization of insulin secretion may be an effective therapeutic strategy in children with this syndrome.

Alterations in dopamine systems and/or abnormalities of monoamines can cause various types of hyperphagia (281). On the other hand, serotonin is believed to act as a satiety factor and an inhibitor of feeding reward in the hypothalamus (282). The role of other humoral signals in regulation of appetite and body adiposity has been extensively studied (283, 284). For instance, it has been thought that a number of gut hormones (i.e., cholecystokinin) feed back to appetite-controlling areas of the CNS in the regulation of meal size and frequency (284, 285). A study by Stromayer et al. (285) demonstrated that administration of a cholecystokinin (CCK) antagonist L364,718 resulted in increased daily food intake in lean but not obese Zucker rats. This is consistent with other observations that CCK decreases appetite, and that satiety deficit in obese rats contributes to overeating in these animals.

The composition of food has been proposed to affect brain neurotransmitter metabolism in some individuals. For instance, individuals referred to as “carbohydrate cravers” have been described to binge on high-carbohydrate foods during the early evening and night (286). However, most individuals seem to prefer high-fat low-sugar foods because of their high palatability. Unfortunately, high-fat meals result in less intense satiety than high-carbohydrate meals of equal caloric value (287).

Finally, mild obesity may occur in adolescent patients with Klinefelter (288) and Turner syndromes (289) with primary hypogonadism. It is believed that hypogonadism results in excessive deposition of fat due to the deficiency of anabolic hormones, which are responsible for the growth of muscle. In Klinefelter syndrome, this effect is enhanced by the unopposed influence of estrogen, leading to further fat accumulation in the hips and buttocks to produce the characteristic eunuchoid appearance.

XII. TREATMENT MODALITIES

The main goal of therapy should be to achieve the objective of lifelong weight control. Therefore, it is important to know the child’s pattern of growth and weight gain. In general, any therapeutic approach for childhood obesity should be designed to induce decreased energy intake and increase energy expenditure while maintaining normal growth. Intervention to induce weight loss must consider all of the factors believed to cause obesity and the treatment modalities that have been effective. Since most of our present experience in the treatment of obesity centers

on environmental and behavioral factors, these represent the primary areas of intervention. Genetic factors also play a very significant role in obesity and can help to identify the child at risk. This allows for early intervention in a child predisposed to obesity and is indicated before obesity reaches extreme proportions. Furthermore, any form of treatment for obesity should take into account potential underlying medical conditions (i.e., hypotonia) that may frustrate or render it ineffective. Therefore, the therapeutic plan should be individualized to reach its desired goal.

There are some indications that successful treatment of pediatric obesity is possible. It has been reported by two studies that one-third of the children initially treated maintained their reduced weight after 5 and 10 years. Furthermore, preadolescent children showed better responses to initial treatment and maintenance of long-term weight loss (290). These studies are encouraging, but more research needs to be conducted to determine compliance with treatment and maintenance of weight loss into adulthood (290).

A number of treatment modalities for childhood obesity exist. However, prior to initiation of any form of therapy, a comprehensive medical evaluation is indicated. This should comprise information on the rate of growth, developmental milestones, and family history. The latter is essential to identify those with parental obesity, hypertension, diabetes mellitus, hyperlipidemia, and thyroid dysfunction. Furthermore, the assessment should include nutritional, psychological, and physical fitness evaluations as well. Obese children are not overnourished in all aspects. Indeed, the reverse may be true as excess calorie intake increases other nutrient requirements that are not necessarily provided by the diet. For example, obesity is often associated with mineral and vitamin deficits (343). It has been reported that a subgroup of obese adolescents and adults (5–43%) engages in binge eating (291). Those who do are described as rigid dieters and under tremendous psychological stress. These individuals have a higher drop out rate from weight reduction programs than those who do not binge.

XIII. DIETS

A. Dietary Intake

The role of dietary intake in obesity remains controversial, although new data have shed more light on this problem. Obese patients often claim that they do not ingest excess food (292). These patients often seek medical evaluation for failure to lose weight despite a history of severe caloric restriction. There are no differences in resting energy expenditure nor in metabolic rates between diet-sensitive and diet-resistant obese individuals. However, differences in lean body mass account for the variations in weight reduction induced by dietary intake restrictions in obese individuals. They are frequently thought to be hyporme-

tabolic and are often treated with thyroid or other hormones to facilitate weight loss. This is neither safe nor necessary; moreover, the observed minus the total predicted energy expenditure vary in relation of weight progression (293). Patients who gain weight increase their metabolic rate whereas those who are on diets and are losing weight may reduce their energy expenditure by 10–20%. Thus the results of dietary efforts can only be successful if the reduced intakes are accompanied by increased energy expenditures to overcome the metabolic adaptations that occur with dieting.

Obese individuals may reduce nutrient intake without weight loss. The possible explanations for this failure include an energy intake significantly higher than reported and a low total energy expenditure. A number of studies have demonstrated that obese individuals tend to underreport food intake compared to normal-weight subjects (294–296). Indeed, careful metabolic balance studies in some obese adults have shown a failure to lose weight despite self-reported low caloric intakes. This may be due to substantial misreporting of food intake and physical activity and not to an abnormality in thermogenesis (296). However, the problem is often confounded in the clinical setting by the difficulties in assessing food intake and food efficiency.

A high susceptibility to obesity may also be the result of unlimited availability of palatable and high-calorie-density foods. Laboratory adult rats fed a “supermarket diet” consisting of high-carbohydrate/high-fat foods (i.e., chocolate chip cookies, marshmallows, peanut butter etc.), gained 2.5 times more weight than normal controls (297). In some animals, the weight gain was not reversed after the rat was switched back to chow. It is believed that supermarket diets increase the number and size of fat cells.

Dietary composition and different rates of nutrient utilization of ingested diets can influence body weight maintenance. Using indirect calorimetric technique in nonobese males, Flatt et al. (298) demonstrated that under sedentary conditions, ingested carbohydrates are quickly metabolized while the rate of fat oxidation remains unchanged. Moreover, it has been suggested that the body tightly regulates carbohydrate balance for up to 36 h after ingestion and is not affected by alteration in the body’s fat balance (299). On the other hand, fat balance is believed to be regulated over a varying long term and it may take several days before the fat balance adjusts to new levels of fat ingestion. Thus, it is believed that excessive fat consumption over a long period of time will result in a positive fat balance and weight gain (300, 301). Therefore, a number of medical organizations including the American Heart Association (302) and the American Diabetes Association (303) currently recommend consumption of low-fat diets in the prevention and treatment of obesity. However, the relationship between the dietary fat and obesity has recently been questioned (304–306) since

both cross-sectional and longitudinal analyses have failed to show a consistent association between dietary fat and body fat (307, 308). Furthermore, recent studies indicate that weight loss on low-fat diets is usually modest and transient (304, 309). It is also noteworthy that the rate of obesity has continued to rise in the United States despite reported reduction in mean fat intake over the past 30 years, from 42% to about 34% of dietary calories (306, 307, 310, 311).

Glycemic index (GI) is another dietary factor that may influence body weight. Glycemic index is a property of carbohydrate-containing food that describes the rise of blood glucose after a meal (312). The GI of a meal is determined mainly by the amount of carbohydrate content and by other dietary factors affecting food digestibility, gastrointestinal motility, or insulin secretion (including carbohydrate type, food structure, fiber, protein, and fat) (313–316). The average American diet contains starchy foods that are primarily refined grain products, cereals, and potatoes and have a high GI. In contrast, vegetables, legumes, and fruits have generally a low GI (317). It has been suggested that a potential adverse consequence of the decrease observed in mean fat intake in recent years is a concomitant increase in dietary GI. A reduction of dietary fat tends to cause a compensatory increase in sugar and starch intake (318–320). In fact, a rise in total carbohydrate consumption and GI of American diets, over the past 2 decades, has been reported (307, 318, 320). Since fat slows gastric emptying (315), carbohydrate absorption from low-fat meals may be accelerated.

High-carbohydrate diets have been demonstrated to increase basal plasma insulin levels in animals and humans (321, 322). It has also been shown that marked obesity is associated with elevated basal plasma insulin secretory response to glucose and protein (323, 324). The hyperinsulinemia of obesity has been regarded as a compensatory adaptation to the peripheral insulin resistance characteristics of the obese state (325). Since the diets of moderately obese individuals are excessive in both total calories and in the quantity of carbohydrate ingested, the hyperinsulinemia of obesity may also be a consequence of these dietary factors rather than merely a secondary response to insulin resistance. Indeed, it has recently been shown that voluntary intake after a high-GI meal was 53% greater than after a medium-GI meal, and 81% greater than after a low-GI meal. In addition, compared with the low-GI meal, the high-GI meal resulted in higher serum insulin levels, plasma glucagon levels, postabsorptive plasma glucose, and serum fatty acids levels, along with an elevation in plasma epinephrine (326). It is, therefore, likely that the slower absorption of glucose after ingestion of high-GI meals induces a sequence of hormonal and metabolic changes that promote excessive food intake in obese adolescents. Recently, Spieth et al. suggested that a low-glycemic-index diet in the treatment of childhood obesity resulted in greater weight loss than a standard reduced-fat

diet (327). Long-term effects and safety of this diet needs to be evaluated in children.

The traffic-light diet is another approach that may be suitable for preschool and preadolescent children. This consists of a 900–1300 kcal/day diet of “tagged” foods designed to meet the age recommendations for appropriate nutrient intake using the basic four food groups outlined in the food guide pyramid. These diet groups fit food into three categories: green foods (go) can be consumed in unlimited amounts; yellow foods (caution) have average nutritional values within their group, and red foods (stop) provide less nutrient density per calorie because of high fat or simple carbohydrate content (328, 329). Combined with a comprehensive treatment protocol, this diet has been found to reduce obesity and change eating habits in preadolescent children (329–332). Furthermore, weight loss up to 10 years has been maintained when the traffic light diet was combined with behavioral, exercise, and familial components of a comprehensive treatment program (333, 334).

B. Very-Low-Calorie Diets

The national task force on the prevention and treatment of obesity published a report on the efficacy of very-low-calorie diets on weight reduction (335). Although rapid weight loss could be achieved, the long-term evolution of obese patients on these diets was disappointing. Slowly but surely they regained their weight and by 1–5 years they were of the same weight as before the treatment, regardless of the diet given.

There are few studies documenting the success of structured programs for treating childhood obesity that encompass just the use of very-low-calorie diets. Low-carbohydrate diets are usually high in protein and fat. They involve intake of large amounts of meat and restrict carbohydrate-containing foods such as fruits, vegetables, and grain products. The high intake of fat in such diets can increase the risk of coronary heart disease and other problems such as gallstones and high cholesterol. The body depends heavily on its fat stores for energy while on a low-carbohydrate diet. This can lead to ketosis. The rapid weight loss on these diets is composed of 60–70% water and the dieters often regain weight rapidly once normal eating is resumed (336, 337). Very-low-calorie restriction using a protein-sparing, modified fast (PSMF) diets (400–800 kcal/day) is designed to produce rapid weight loss of up to 5 lb (2.3 kg per week), while preserving vital lean body mass. The protein is provided as lean meat or fish, or in a milk or egg-based liquid formula. It has been suggested that these diets spare body protein by decreasing insulin levels and enhancing fat breakdown (338), while inhibiting the release of amino acids from muscle (339). However, in the past several deaths have been associated with the use of these formulas (298). Moreover, these quick-fix weight-loss schemes may be unsafe for use in

children and do not promote healthy eating behavior for long-lasting weight control.

Nutritionally balanced very-low-calorie diets, combined with exercise, may improve the outcomes in structured obesity treatment programs for children (340, 341). In one study obese adolescents entered a structured 10 week program that included exercise and behavior modification, along with a very-low-calorie diet. After 10 weeks BMI decreased from 33.8 to 29.6. Fat mass was reduced without decrements in both lean body mass or energy expenditure (342). In another study by the same investigators, 87 obese children from 7 to 17 years old participated in a year-long program similar to that described above. The results were the same and weight and body fat loss were maintained for 1 year. These results suggest that a multidisciplinary structured program to treating obese children that is maintained for long periods of time may yield positive results. However, it is important to reiterate that energy intake, not energy consumption or distribution of calories, determines weight loss (343). Therefore a balanced diet that provides a reduced intake is preferable because it achieves long-term weight control with healthier eating behaviors as described below.

C. Food Management

Many special diets and dietary regimens have been used in the management of obesity. Diets are most likely to succeed if they are individualized according to current eating patterns, degree of motivation, intellect, amount of family support, and financial considerations. Therefore, a management approach to food intake is preferable to a diet prescription. A well-balanced calorie restrictive intake that provides all the necessary nutrients is the most effective and safest treatment for obesity. The reduction in caloric intake should be based on the weight history of the child in conjunction with usual calorie intake, body size, rate of growth, degree of adiposity, desired weight, and estimated daily activity level. As a general rule moderately obese children should be placed on an energy intake and exercise level that will slow weight gain in accordance with age and growth. In specific instances, to allow for parental or patient desires, it may be appropriate to design a nutrient intake to induce a slight weight loss. To accomplish this goal, it can be assumed that 1 lb of fat represents 3500 kcal.

Initially a 10% calorie reduction in the usual nutrient intake is recommended. The food choices must be individualized to the taste and preferences of the family and the patient with the aim of meeting all the dietary goals and guidelines. This should be achieved gradually to ensure compliance while appropriate eating patterns are established. It is important to correct all potential nutritional deficits at the beginning of the treatment and to monitor any alteration that may develop throughout the follow-up period. Obese children are not overnourished in all aspects, just in energy. They often ingest inappropriate in-

takes, which may lead to essential nutritional deficits (343) or other alterations (i.e., hypertriglyceridemia).

The following is an example of an initial approach to the treatment of an obese adolescent.

A 14-year-old boy with a weight of 72 kg and a BMI 28 was examined because of obesity. The initial nutritional evaluation documented that he was ingesting the diet shown in Table 1. This diet is not unusual for an adolescent boy and is typical of this age group (344). Analysis of the diet reveals that he was ingesting 3200 kcal (44.5 kcal/kg/day), which is 128% of that recommended for his age. He was also ingesting 44% of the total calories from fat; 14.6% of the total calories from saturated fat and 723 mg cholesterol, all being very high. He also had a high sodium intake of 4739 mg, almost double than that recommended for his age.

Although his intake was very inappropriate, treatment was started with a slight modification to improve compliance. By eliminating one doughnut and switching from regular soda to diet soda, his energy intake was reduced to the level necessary to avoid weight gain and maintain his current weight (38.5 kcal/kg/day). By simply eliminating those two items from the diet, there was a drop in calorie intake of 433 kcal/day. Of course, other inappropriate dietary habits were not corrected, although cholesterol intake dropped by 19 mg/day. Once the patient adjusts to these simple changes, further work will be necessary to improve upon the excess fat intake and reduce the amount of saturated fat from the diet. Patients who do not comply with simple measures might not necessarily learn to improve their nutritional habits for life.

Table 1 Typical Intake of an Adolescent Evaluated for Obesity

	Energy (kcal)
Breakfast	
Two sausages and 2 eggs	300
Coffee (1 cup)	0
Whole milk (1 cup)	150
Fruit juice (1 cup)	110
Lunch	
McDonald's Quarter Pounder	525
French fries (10 stripes)	160
Soda (1 can)	148
Dinner	
Half chicken breast	220
Baked potato (1)	220
Salad with dressing (8 oz)	85
Daily snack	
Donuts (2)	570
Chocolate chip cookies (3)	185
Ice cream (1 cup)	270
Potato chips (10 pieces)	105
Total	3207

Another example is a 50 kg 5-year-old patient with a BMI of 37. The patient and the family were highly motivated to cease excess body weight gain and to improve upon the biochemical abnormalities detected in the work up (i.e., hyperinsulinemia). It has recently been demonstrated that hyperinsulinemia in obesity is more resistant to weight loss than normoinsulinemic obesity in children (41). Her caloric intake was reported to be 1400–1500 kcal/day. This level of caloric uptake was not excessive for maintenance of body weight (30 kcal/kg/day). However, it contained a high proportion of dietary fats. A realistic goal for her was set at 10% of body weight loss and then weight maintenance until her weight would catch up with her height and normalize the height-to-weight ratio. This was a long-term plan that would require a successful attempt at 3 years of body maintenance.

Food management was initiated without reducing the total calories, since her total daily caloric intake did not appear to be excessive for weight. Instead, her food choices were modified to reduce the fat intake. She was placed on a 1500 kcal meal plan with decreased fat content (30%) while increasing complex carbohydrates. This included increasing vegetables in her diet and substituting low-calorie snacks for high-fat foods. She was given three meals and three snacks daily. It is well recognized that frequent meals are more effective for weight control than one large meal (345). Therefore, diets that consist of one or two large meals per day were discouraged.

Day-to-day variations in caloric consumption are characteristic of normal eating patterns and thus they should be allowed as long as they are within an acceptable range. For example, it would be appropriate for Julie, on a 1500 kcal meal plan, to have a range of intakes from approximately 1200 to 1800 kcal/day. While assessment of the rate of weight loss and growth is important, periodic assessment of nutrient composition of the diet is essential. This is particularly important for such micronutrients as calcium, iron, magnesium, copper, zinc, folacin, and vitamins, since these are very likely to be deficient on a restricted dietary intake (345).

XIV. EXERCISE

Dietary management of childhood obesity should always be combined with an exercise program. However, exercise should be prescribed on an individual basis. An exercise program based upon the initial fitness level (346) with a slow progression of the intensity, frequency, and duration is required to achieve the goal of weight control. For instance, morbidly obese children may achieve maximal energy expenditure during a brisk walk, since prescriptions for more demanding physical activities like jogging are likely to be impossible at the start. Resistance training may also be a suitable component of a structured obesity treatment program. One study found that weight loss was maintained for up to 1 year in obese preadolescents after

completing a 10-week program that included resistance training combined with a low-calorie diet, behavior modification, aerobic and flexibility exercises. Furthermore, compliance with the exercise regimen was 100% (347). Physical activity has a significant influence on energy expenditure and the energy cost for most activities is generally greater for heavier people. There is also some evidence that increased activity in the obese individual may decrease appetite while increasing metabolic rate. Both obese and lean individuals experience a 19–30% decrease in resting metabolic rate within 24–48 h following caloric restriction (336). Thus caloric restriction without an increase in physical activity may not result in continued weight loss. Regular aerobic exercise combined with energy restriction will result in greater reductions in body weight than dieting alone (301).

Intermittent exercise and use of home exercise equipment are effective in inducing and maintaining weight loss (348). Individuals who used the equipment longer were those who lost more weight and sustained their weight loss for longer periods of time. The type of exercise is also important: long bouts of exercise of greater intensity were more beneficial. The benefits transcend those of body weight. The relationship between cardiorespiratory fitness and mortality in normal-weight, overweight, and obese men was clear (212). Fitness is an independent predictor of health, comparable to diabetes mellitus, cholesterol levels, hypertension, and smoking.

However, by simply engaging in leisure-time physical activity major benefits may be attained. This is often not achieved, since most persons trying to lose weight are not using a recommended combination of reducing calorie intake and engaging in leisure-time physical activity (150 minutes per week) (349). In the patients mentioned above on dietary treatment, if they added to their treatment regimen a habit of walking 20 min/day they would enhance their energy expenditure by 5.8 kcal/min. In other words, they would spend 116 kcal/day above the dietary restriction, therefore increasing weight loss and enhancing their health. The amount of energy necessary for various physical activities is shown in Table 2.

XV. FAMILY INVOLVEMENT

Supportive counseling and reinforcement can help set the goals for health professionals, patient, and parent, allowing for long-lasting results and avoidance of failure and frustration. Refusal to adhere to a weight-reduction plan may be due to lack of family support, insufficient motivation, or other psychological stresses. For instance, it has been demonstrated that children of married parents lose weight at higher rates than those of divorced parents (328). When a weight-reduction plan has been recommended, conflicts frequently arise between the patient and nondieting family members regarding the degree of dietary restriction and who is permitted to eat different foods.

Table 2 Energy Expenditure in Occupational, Recreational, and Sports Activities (kcal/min) for a 50 kg Individual

Activity	Calories expended (50 kg/110 lb)
Basketball	6.9
Cycling	
Leisure	5.9
Racing	8.5
Computer typing	1.4
Dancing	
Ballroom	2.6
Vigorous	8.4
Eating (sitting)	1.2
Football	6.6
Gymnastics	3.3
Swimming	
Backstroke	8.5
Breast stroke	8.1
Crawl, fast	7.8
Crawl, slow	6.4
Tennis	5.5
Volleyball	2.5
Fishing	3.1
Gardening: Mowing	5.6
Marching	7.1
Running: 8 min/mile	10.8
Sitting quietly	1.1
Skiing (hard snow): Moderate speed	6.0
Walking (comfortable pace)	
Fields and hillsides	4.1
Grass track	4.1
Writing (sitting)	1.5

Energy expenditure is related to the size of the individual and should therefore be related to body weight. The usual dietary energy allowance for children 4–18 years varies between 34 and 82 kcal/kg/day. For competitive and long endurance exercises in children, energy expenditure should be increased by 17.6–52.8 kcal/kg/day above usual.

Dietary restriction should never be introduced in a punitive fashion. In some cases, the obese child and the entire family may adhere to a diet similar in composition if not quantity. Participation of the entire family should help minimize the feelings of isolation of the obese child. It has been shown that family involvement is essential for the success of any obesity treatment plan. Children whose families are involved in their treatment protocol lose more weight and maintain it for more prolonged periods than those whose families are not participatory (333). Eating patterns, food choices, and other behavioral factors of importance in obesity are family characteristics.

Dietary management and physical exercise are essential components for the development of effective treatment. The area of greatest concern for psychologists is

how to get children to alter food intake and activity behaviors. Because the primary focus is on changing the child's behavior, parenting skills represent an integral component of the intervention. Stimulus-control procedures in the behavioral control of overeating have led to the development of several behavioral techniques for the treatment of obesity which include self-monitoring of body weight and/or food intake, goal setting, reward and punishment, aversion therapy, social reinforcement, and stimulus control. Several of these modifications have been found to be effective with children (328–334). These interventions are based on the assumptions that the obese child is an overeater who is hypersensitive to food stimuli and can be trained to behave like a nonobese person and subsequently lose weight. Moreover, positive family support has been shown to improve the degree of immediate and long-term weight loss in children and adolescents (330–332).

Any program designed specifically for treating obese children must include a group format with individualized counseling, parent participation, frequent sessions over a long period of time, appropriate exercise, and changes in the home environment to reinforce changes in the child's lifestyle. The behavior modification sessions should include self-monitoring, goal setting and contracting, parenting skills training, skills for managing the high-risk situation, and skills for maintenance and relapse prevention (340).

XVI. OTHER THERAPIES

A. Drugs

Long-term use of medications to suppress appetite or anti-obesity pills are not usually indicated in the treatment of pediatric obesity. Studies involving the use of anorectic drugs alone or in combination with behavior therapy have demonstrated that weight loss is no greater than when behavior therapy was used alone. When the drugs were stopped, the weight was regained more rapidly (338). Furthermore, the effectiveness of appetite-suppressant drugs (i.e., amphetamines) appears to decrease with time and there may be side effects. The addictive potential of amphetamines and the risk of depression associated with fenfluramine have resulted in the minimal use of these agents in children and adolescents. The use of serotonin agonists such as fluoxetine and fenfluramine in the short term has proven useful as an adjunct in weight-loss programs for children and adolescents (342, 350). These drugs seem to decrease appetite and carbohydrate craving. Although they are by no means the solution to weight loss, they may help individuals at the beginning of a weight loss program by suppressing appetite. They must be used with caution and for a very limited time (351). In fact, serious side effects such as pulmonary hypertension and valvular heart lesions have been associated with the use of fenfluramine

and its derivative, dexfenfluramine, in combination with another appetite suppressant (i.e., phentermine) (352). Recently, a new selective serotonin reuptake inhibitor, sibutramine (Meridia), has been shown to be effective in weight reduction trials in obese adults without significant adverse effects. However, the safety and efficacy of this agent have yet to be evaluated in obese children and adolescents.

Another potential antiobesity medication is metformin, an antihyperglycemic drug, that has been reported to enhance insulin sensitivity leading to reduced appetite and body weight in obese children and adults (353). Fremark et al. recently demonstrated that a 6 month trial of metformin treatment (500 mg twice daily) in a group of obese adolescents caused significant reductions in BMI, fasting glucose, and insulin compared to a placebo group (353). In a 2 month study, Metformin (850 mg twice daily) in a group of adolescents on a hypocaloric diet caused significant reductions in weight, fasting insulin, leptin, and lipids compared to a placebo group (354). The use of diazoxide, an inhibitor of glucose-mediated insulin secretion, in a group of hyperinsulinemic obese adults was recently shown to be effective in short-term weight reduction with few adverse effects (355). Daily subcutaneous administration of octreotide (somatostatin analogue), an inhibitor of pancreatic insulin secretion, to a group of children and adolescents with hypothalamic obesity secondary to cancer therapy likewise resulted in significant reduction in body weight over a 6 month period (279). The results of these studies imply that attenuation of hyperinsulinemia of obesity may be of therapeutic benefit in the management of this disorder. However, long-term efficacy and safety of these agents have yet to be evaluated in children.

B. Fat and Sugar Substitutes

Bulking agents and nonprescription diet aids, such as methylcellulose and other noncaloric bulk materials, have also been used in experimental and clinical attempts to inhibit food intake. The rationale for the use of such agents is that they swell in the stomach and supposedly give a feeling of satiety. Indeed, several lines of evidence suggest that dietary fiber may play a key role in the regulation of circulating insulin levels. Dietary fiber reduces insulin secretion by slowing the rate of nutrient absorption following a meal (312, 313). In the experimental setting, insulin sensitivity increases (314) and body weight decreases (315) in animals fed high-fiber diets. In addition, a recent study revealed that fiber consumption predicted insulin levels, weight gain, and other cardiovascular heart disease (CVD) risk factors more strongly than total or saturated fat consumption. Therefore, high-fiber diets (10–15 g/day) may protect against obesity and CVD by lowering insulin levels (316).

The use of inhibitors of digestive enzymes, such as intestinal lipase and disaccharidase, in obese and diabetic

adult patients has been shown to be beneficial for weight reduction and improved glycemic control (356, 357). For instance, a gastrointestinal lipase inhibitor (Orlistat) has been reported to be of potential benefit by reducing fat absorption from the intestinal tract in obese adults undergoing significant weight reduction (356). However, undesirable side effects such as diarrhea and flatulence were frequently observed in these patients. This was accompanied by reduction in the levels of fat-soluble vitamins A, D, and E, which can be prevented by multivitamin supplementation. The safety and efficacy of the latter have yet to be evaluated in pediatric patients.

There are many misconceptions about the benefit of foods containing nonnutritive sweeteners. Currently, three nonnutritive sweeteners are approved for use in the United States: saccharin, aspartame, and acesulfame K. Other sweeteners include sorbitol, mannitol, and xylitol. Many obese individuals consume foods containing these sweeteners, thinking they are reducing their caloric intake. However, many of these foods either contain the same amount of or more calories than their regular sweetened counterparts. For example, dietetic chocolate contains 168 calories per 2 oz serving. Regular sweetened chocolate only contains 150 calories for a similar-sized serving (358). Therefore, without proper advice from a dietician, many obese individuals may be overconsuming calories by including dietetic foods in their diets. These foods also tend to be more expensive.

C. Surgery

There are very few applications of surgical procedures in the management of pediatric obesity. Four types of surgical procedures have been used to change eating behavior: jejunioleal and gastric bypass, gastric plication, and jaw wiring. The jejunioleal bypass procedures are usually followed by a large weight loss. However, significant complications including diarrhea, vitamin D deficiency with osteomalacia, vitamin B₁₂ and folate deficiencies, renal (oxalate) calculi, hyperuricemia, and liver disease follow these procedures (359). A second procedure is the gastric bypass, which appears to be effective in producing weight loss without serious late complications seen with the jejunioleal procedure (360). Gastric plication (gastroplasty), involving a stapling procedure, is also widely used. Following the gastric bypass or gastroplasty procedure, patients food intake is decreased by the sensation of fullness. They also show less anxiety, depression, irritability, and preoccupation with food during weight loss compared with their weight-reduction attempts before the surgical procedure (361). In controlled studies gastric bypass appears slightly more effective than gastroplasty. Although successful initially in almost all patients, the failure rate for both procedures is high (up to 50%) (362). These procedures should be considered carefully in a select group of adolescents with significant medical com-

plications who have been frequently unsuccessful in losing weight with other conventional therapies.

D. New Therapies

The administration of exogenous leptin has been shown to result in loss of body fat in animals with elevated leptin levels (364), as well as in humans with leptin deficiency, by reducing food intake (365). Recently, Heymsfield et al. demonstrated that a 6 month administration of subcutaneous recombinant leptin in high dosages induced weight loss in some obese adults with elevated endogenous leptin concentrations who were maintained on a eucaloric diet (365). However, they suggested that additional research into the potential role for leptin and related hormones in the treatment of human obesity was needed; the medication is not the magic bullet for most obese patients.

E. Kids Weight Down Program

A program specifically designed for treating childhood obesity must be the best approach to dealing with obesity in children. A Kids Weight Down Program may include staff consisting of a registered dietician, child psychologist, physician, and exercise physiologist. The program should require that parents participate in their child's treatment. Treatment is begun after a preliminary physical exam and laboratory testing that includes a lipid profile. Treatment may consist of one or two sessions per week, for 10 weeks, for both children and parents. All medical assessments are repeated at the end of the treatment period to determine compliance and progress.

The treatment regimen consists of a moderate weight-reducing diet along with an exercise program. The recommended energy intake consists of a 10% reduction diet as the main dietary prescription, as described above. This dietary prescription should not depend on any fad diets or eliminate any ethnic or cultural foods normally consumed by the families. As part of the weekly sessions, the children must exercise twice a week under the supervision of an exercise physiologist. The child's sessions must also include lessons and games to teach the importance of an appropriate nutritionally balanced diet for weight loss. The goal should be to make the sessions enjoyable for children as well as convey knowledge about the importance of losing excess body weight. The parents' sessions consist of education about the importance of family participation in the child's treatment. Each week parents may discuss problems/solutions associated with the progress of the child's treatment. This should include some of the problems encountered in changing the family dynamics in order to foster a positive influence on the child's treatment. Having parents' sessions, separate from the children, enabled them to support one another and allow open discussion about the problems of treating an obese child. The program is usually successful for a short duration.

However, the importance of long-term follow-up and management can never be stressed enough.

The unique program suggested above is costly because of the high demand for specialized personnel. Insurance companies usually do not provide any reimbursement for participation in such a program.

XVII. YO-YO WEIGHT CYCLING

Weight cycling has a profound effect on body composition and its metabolic efficiency (366). Weight loss followed by regain results in loss from muscle, regained as fat; increased risk of heart disease; and frustration (201, 202). Chronic dieters learn to cope with dieting. They develop a very efficient metabolism and maintain their weight with fewer and fewer calories with each attempt to lose weight. There is loss of muscle mass as a result of body composition changes during weight cycling. The increased fat mass leads to elevation of basal insulin and lipoprotein lipase levels (367), resulting in more fat deposition. In addition to changes in the body composition, the patient becomes psychologically frustrated as he or she fails to achieve the desired weight loss. The outcome is a patient who ingests very few calories and yet cannot lose weight.

Chronic dieters may also be increasing their risk for heart disease more than if excess weight remained at a stable level. Dieting leads to fat mobilization and during the regaining phase, fat deposition in the arteries. The regained weight is more likely to be distributed in the upper body where it is potentially more harmful (96) and associated with a higher incidence of heart disease and glucose intolerance (104). Appropriate strategies to avoid weight cycling should be considered at the beginning of a child's weight-reduction program. When a child is ready to participate in a weight reduction program, it should represent a serious commitment of all involved.

XVIII. PREVENTION

The successful treatment of childhood and adolescent obesity is an effective approach to the prevention of severe adult disease. Long-term follow-up of children treated with diet, exercise, and behavior modification has shown significantly lower weights 5–10 years later than for children treated in other ways (332, 333, 368). However, not all obese children who were treated successfully initially were able to maintain their reduced relative body weight. Nevertheless, none of these studies has had similar design and/or control populations, making a critical comparison very difficult. In addition, the increasing prevalence of childhood and adolescent obesity suggests that even the most successful treatment may be of limited benefit if it relies on the traditional doctor/patient interaction model. Furthermore, the metabolic phenotype (i.e., hyperinsulinemia) and family history of type 2 diabetes (369), hypertension and/or hyperlipidemia, may play a major role

in a patient's response to conventional weight management strategies. Therefore, development of effective methods for weight reduction should be continued and multidisciplinary research to identify factors that prevent relapses should be encouraged.

Children should be encouraged to develop healthy eating habits and exercise patterns that prevent excessive weight gain. This is especially important for children in high-risk groups, for instance, with obese parents and those who are overweight by the time they enter school (370). Health professionals should inform parents of the potential risks and provide instructions on preventive measures at an early age. The introduction of a variety of nutritious foods to children's diets will lead to the development of healthy eating practices in children and adolescents. These foods should include an assortment of fresh or frozen vegetables and legumes; dairy products; fresh fruits; breads (preferably whole grain); and pastas, rice, cereals, and other grain products. Sweets and other nutrient-poor foods should be allowed in limited amounts that do not interfere with the child's consumption of basic foods. With relatively free access to these highly palatable choices (i.e., caloric-dense snacks), the chances of overeating are increased and may encourage the development of obesity in predisposed children. However, these changes have not been very successful in preventing the increase in obesity in children. Other lifestyle changes may be important in resolving this problem. A more appropriate approach should include reduction of sedentary activities such as television viewing and video game use. In a comprehensive study, 198 third and fourth grade students were organized into two groups. One group served as the control while the intervention group participated in a 6 month course geared toward reduction in television viewing, video tape, and game use. After completion of the course, the BMI of the intervention group was reduced from 18.8 to 18.1 kg/m². Furthermore, triceps skinfold thickness, waist circumference, and waist-to-hip ratio showed similar positive changes. Moreover, children in the intervention group self-reported fewer hours watching television while consuming meals in front of the television. However, no changes were found between the two groups in regard to high-fat food intake, physical activity, and cardiorespiratory fitness. These results suggest that just reducing television viewing and video game use contribute to positive changes in obesity indices in children (371).

Primary public health measures are critical to formulate a sound approach to the prevention of obesity in children. It is the responsibility of schools and government agencies, as well as food industries, to support measures that can improve the food habits and exercise patterns of children and adults. The schools should play an active role in providing healthy food choices in the cafeteria and provide appropriate exercise programs for normal-weight and obese children separate from competitive

athletics. Government and local authorities can insist that schools implement and promote physical fitness programs and provide easy access to exercise facilities in the community. The media should assume a responsible position with regard to idealized concepts of beauty by appropriate programming and feeding of messages to children and to society at large.

XIX. FINAL CONSIDERATIONS

Obesity and significant comorbidities are reaching epidemic proportions among children. A variety of genetic, environmental, and other factors account for the development of obesity. Understanding leptin's role in regulating food intake and energy expenditure is an important discovery. It has been identified as a component of the pathophysiological alterations in this entity, including hyperinsulinemia and its complications. Inborn alterations of leptin have also been identified in individuals with severe morbid obesity. However, most obese populations exhibit various degrees of leptin desensitization. Early recognition of excessive weight gain in relation to linear growth is important and should be closely monitored by pediatricians and health care providers. The use of BMI percentiles may also help to identify children at risk and quantify the severity of obesity. Prevention is critical, since effective treatment of this disease is limited. Food management and increased physical activity must be encouraged, promoted, and prioritized to protect children. Dietary practices must foster moderation and variety, with a goal of setting the appropriate eating habits for life. Advocacy is needed to elicit insurance coverage of the disease.

Hyperlipoproteinemias in Children and Adolescents

Kurt Widhalm

University of Vienna, Vienna, Austria

I. INTRODUCTION

A body of evidence now shows that elevated levels of plasma cholesterol, especially low-density lipoprotein (LDL) cholesterol, are associated with an increased probability of premature cardiovascular disease in the adult. This is particularly true for subjects with the most common familial hypercholesterolemia (a dominant disorder of the lipoprotein metabolism) who usually have a manifest atherosclerosis in the fourth to fifth decade. There is also no doubt that atherosclerosis starts in childhood and therefore preventive measures should be initiated as early as possible to prevent progression of the disease.

Hyperlipoproteinemias are biochemical abnormalities in which one or more lipids/lipoproteins is either elevated or has an abnormal composition. It should be the goal of any pediatrician or general physician to detect these abnormalities during childhood in order to start as early as possible with preventive therapeutic measures.

It is not well established that early reduction of atherogenic lipoproteins is associated with delayed development of atherosclerosis; however, many facts from adult studies support this theory very strongly. Nevertheless, the power of knowledge from intervention studies in adult population would not allow for randomized studies in the pediatric age group because of ethical concerns.

In this chapter the main focus will be on the clinical aspects of diagnostic and therapeutic procedures for lipoprotein disorders in children.

II. LIPOPROTEIN BACKGROUND AND BASICS

There is a strong relationship between the intake of fats, in particular saturated fats, and the development of premature cardiovascular diseases. One of the main mechanisms involved in that process is most probably the concentration and composition of plasma lipoproteins. These

particles are responsible for the transport of lipids after absorption from the gut to the liver and to the organs (Fig. 1).

Figure 1 shows clearly that cholesterol and triglycerides are ingested into the gastrointestinal tract and are converted to chylomicrons. These triglyceride-rich particles are taken up by the liver by means of a specific apo E receptor and are secreted as very-low-density lipoproteins (VLDL) into the circulation. These particles are converted to the short-lived intermediate-density lipoproteins (IDL), which are formed into low-density lipoproteins (LDL), which are smaller, denser, and contain more cholesterol. These most atherogenic vehicles are taken up by the liver by means of LDL receptors and, to a smaller extent, by a nonreceptor pathway by the so-called scavenger cells.

The smallest lipoproteins, high-density lipoproteins (HDL), are partly responsible for the transport of LDL back to the liver.

The classification and composition of the various lipoproteins are shown in Table 1.

In regard to the atherogeneity of the various plasma lipoproteins, there is enough evidence, both on a pathophysiological and on an epidemiological level, that the most pathogenic particles are LDL, and, to a lesser extent, VLDL. In contrast, HDL particles have a protective function against atherogenesis: subjects with high HDL levels are rarely affected with cardiovascular diseases. However, subjects with low levels are considered to be at higher risk, even if they have normal cholesterol concentrations.

If total and LDL cholesterol levels are elevated, fatty streaks and fibrous plaques develop in nonhuman primates, mainly due to diets high in saturated fatty acids and cholesterol. In adults, but also in adolescents, the amount of saturated fat in the diet influences the concentration of serum cholesterol strongly. However, it seems very likely that genetic factors also are involved in the regulation of cholesterol metabolism, because there are

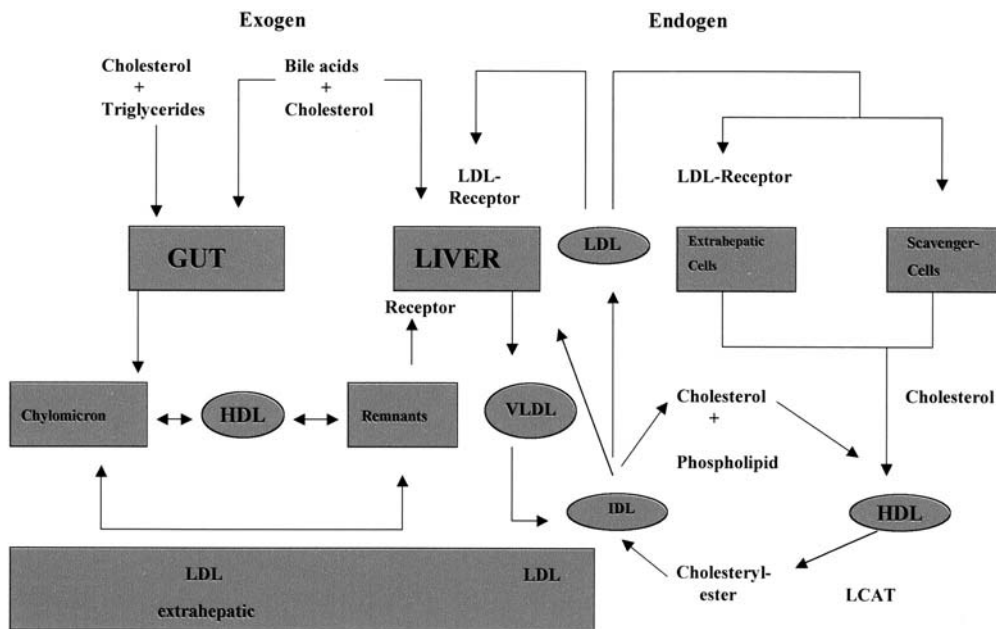

Figure 1 Schematic pathway of lipids and lipoprotein.

considerable differences in the effect of diet on the levels of plasma lipoproteins.

Intervention studies in adults have clearly shown that lowering blood cholesterol levels is associated with a reduction of coronary heart disease. This association has not yet been found in children; most probably it will be very difficult to carry out a study to establish a direct scientific evidence for this relation.

Thus, several indirect data are available to support the hypothesis, which means that lowering of elevated plasma lipoproteins, mainly LDL cholesterol, is indicated even in the pediatric age group.

First, there is clear evidence that early coronary atherosclerosis often begins in childhood and adolescence and is directly related to high serum total cholesterol, LDL cholesterol, VDL cholesterol, and low HDL levels.

Second, children and adolescents from families with a higher incidence of premature coronary heart diseases often have elevated total cholesterol and LDL cholesterol levels.

Third, there is a strong familial aggregation of total, LDL, and HDL cholesterol levels in children and their parents.

Finally, among the genetically based disorders of lipoprotein metabolism, the most common are familial hypercholesterolemia and familial combined hyperlipidemia. In affected families premature cardiovascular diseases are much more frequently diagnosed than in families with desirable cholesterol concentrations.

Lipoprotein disorders are therefore, from a preventive point of view, very important and can be diagnosed in

children. This should encourage the enforcement of therapeutic and preventive strategies for the whole family.

III. DEFINITION OF HYPERLIPOPROTEINEMIA/DYSLIPOPROTEINEMIA

The concentration mainly of total cholesterol and triglycerides in plasma or within the various lipoprotein particles is the basis of laboratory diagnosis of hyperlipidemia or hyperlipoproteinemia. Usually levels exceeding the 95th percentile or below the 5th percentile are considered abnormal. In most studies the Lipid Research Clinics Program (LRCP)-levels were used as reference guidelines for children and adults (Table 2).

According to the Expert Panel on Blood Cholesterol Level in Children and Adolescents of the National Cholesterol Education Program and the American Academy of Pediatrics, children with a parental history of elevated total cholesterol levels (>240 mg/dl) should be tested for their cholesterol levels. Children with other risk factors or with incomplete family history should be screened by the pediatrician.

Children with total cholesterol levels less than 170 mg/dl have optimal levels and do not require intervention. Children with cholesterol levels between 170 and 200 mg/dl should undergo another cholesterol measurement and the two values should be averaged. If this level is greater than 170 mg/dl, a lipid profile is recommended. On the other hand, this expert panel has recommended

that all children with a family history of premature coronary heart disease (before the age of 55 years in a parent or grandparent) should undergo a complete lipoprotein profile.

Thus, the discriminating parameter is the LDL cholesterol concentration: if this is >130 mg/dl, it is considered to be elevated. Levels <110 mg/dl are considered to be acceptable. Levels between 110 and 130 mg/dl are described as borderline.

IV. FAMILIAL HYPERCHOLESTEROLEMIA

This disorder was described as early as 1938 by the Norwegian physician Carl Müller as an inborn error of metabolism, which is characterized by increased blood cholesterol levels and by premature myocardial infarction.

From the genetic and pathophysiological point of view, two major forms can be identified; the heterozygous and the severe homozygous type.

A. Heterozygous

Heterozygous patients are carriers of one mutant of the LDL receptor gene and are found in the general population with a frequency of about 1 in 500. Therefore this disorder is among the most frequent known inborn errors of metabolism. Affected subjects often have approximately doubled LDL cholesterol levels even after birth and experience their first heart attack between the 30th and the 40th year of life. For the clinical diagnosis it is essential to know about related problems (cardiovascular diseases, sudden cardiac death, peripheral vascular disease, hypercholesterolemia).

Children and adolescents with FH commonly do not present any symptoms or signs, thus it is not easy to make an appropriate diagnosis. It is also not easy to involve those subjects in therapeutic programs because they feel completely healthy.

B. Homozygous

Homozygous subjects with FH (prevalence 1:1,000,000) carry two gene mutants from their parents, who both must have hypercholesterolemia. They exhibit a 6–10-fold elevated LDL cholesterol concentration from birth, develop cutaneous and tendinous xanthomas, and suffer fatal heart attacks due to progressive atherosclerosis.

The breakthrough work of Brown and Goldstein showed that subjects heterozygous for FH carry approximately 50% of the LDL receptors in the liver that are responsible for the catabolism of LDL particles. Homozygotes do not have any LDL receptors, or they are not functional.

During the last few years researchers have found many different mutations that are partly responsible for different steps in the uptake of LDL particles. With the use of various techniques it is possible to differentiate between defects on the LDL receptor promotor, the 18 LDL R genexons, the corresponding intron-splice sequences, or the Codon 3500 region where Apo B is located.

So far, no clinical consequences can be drawn from results based on molecular diagnosis. However, preliminary findings indicate that there could be some relation between genotype and phenotype. It could be shown by recent studies that children with total cholesterol and LDL cholesterol levels in the so-called normal range with borderline levels can be diagnosed as being affected with FH on the basis of molecular diagnostic procedures.

V. TREATMENT

The goal of treatment of young subjects with heterozygous FH is to lower elevated LDL cholesterol levels to

^aNote that different percentiles are listed for HDL cholesterol.

wards a normal range. The cornerstone of therapy is diet, which should be characterized by a low content of saturated fats and an increased content of mainly monounsaturated fats. In general, these diets contain less animal products and more fruits, vegetables, and cereals. They are also recommended for the general population in order to avoid diet-dependent health problems such as obesity, hypertension, and elevated plasma cholesterol levels, among others.

Using such a diet, many of the affected children and adolescents can achieve a lowering of total cholesterol and LDL cholesterol in the range of 10–15%.

In few studies a substitution of soy protein for animal protein has further decreased LDL cholesterol; however, up to now no food-products are available in many coun-

tries in order to enable families to introduce such diets. If the LDL cholesterol level cannot be lowered adequately by dietetic changes (into the range of 130–160 mg/dl), the use of drugs should be carefully considered. In children older than 10 years with high LDL cholesterol levels (>190 mg/dl or >160 mg/dl) and a family history of cardiovascular diseases after a 3–6 month diet period, the administration of bile-acid resins seems to be indicated. These drugs, which are not absorbed from the gastrointestinal tract, are not very palatable and therefore only a few children and adolescents adhere to this type of drug treatment. Reported results range between 15 and 25% LDL cholesterol reduction. Even in children who were placed on these drugs from years, no impairment of growth or development has been observed. However, it

would seem advantageous to add mainly fat-soluble vitamin supplements in order to ensure adequate vitamin nutrition.

The use of the widely used statins (inhibitors of the 3-hydroxy-methylglutaryl-CoA-reductase), which are the standard drugs for treatment of adults, is restricted to few trials.

These drugs are not generally licensed for subjects under the age of 18 years. However, it has been shown very clearly that even their use over years is not associated with any adverse effects on growth, development, or other variables. Furthermore, no serious side effects have been reported, whereas the LDL cholesterol-lowering effects range between 20 and 35%. These drugs might be also the agents of choice in adolescents with markedly elevated LDL cholesterol levels, because there are no other regimens currently available or on the horizon for the near future. For patients with extremely high LDL cholesterol levels and those with homozygous forms of FH, repeated LDL apheresis can be effective treatment.

In some patients liver transplantation and concomitant liver–heart transplantations have been performed to remove the organ responsible for the metabolic disorder. Gene therapy has been performed in some affected subjects; however, this type of treatment seems to be far from introduction into routine use. It has also not been possible so far to achieve longterm LDL cholesterol reductions.

VI. FAMILIAL COMBINED HYPERLIPIDEMIA

This type of lipoprotein disorder is relatively common (3–5:1,000) and is inherited as an autosomal dominant trait. In affected families different types of hyperlipidemias can be observed. One-third of the subjects present with hypercholesterolemia, one third with isolated hypertriglyceridemia, and one third have both elevated cholesterol and triglyceride levels.

Patients with this disorder usually have LDL particles that are enriched with Apo B, thus estimation of Apo B might differentiate between FCH and the familial hypertriglyceridemia. Subjects with FCH have an increased risk for cardiovascular diseases; however, the risk seems to be lower than in patients with FH.

Treatment consists of institution of a classic low-fat (saturated fats ↓, monounsaturated fats ↑, low cholesterol) diet; in some patients drugs are necessary, in which cases statins and fibrates are commonly used. There are very few reports detailing pediatric patients. Even the diagnosis is not very easy in this age group, because the lipid and lipoprotein pattern is not fully developed, as in adults.

VII. HYPERTRIGLYCERIDEMIA/CHYLOMICRONEMIA SYNDROME

Familial hypertriglyceridemia, which is characterized by an increased concentration of VLDL particles, presents

very rarely in children. If it does, the association with overnutrition and obesity is not uncommon. In such cases reduction in energy intake is important, and the intake of saturated fats should be lowered as well.

Excessive forms of hypertriglyceridemia (former type I or type V hyperlipidemia) are rare and characterized by markedly increased concentrations of triglycerides through the presence of chylomicrons. The lack of lipoprotein-lipase or the activating enzyme (Apo C-II) is responsible for this disorder.

Patients with this disorder often have triglyceride levels of 1000 mg/dl and even higher, which causes a milky plasma. The risk for atherosclerosis is relatively low; however, in some cases pancreatitis can occur as a complication. In some patients a strongly fat-restricted diet can achieve marked reduction of triglycerides, but in many of the affected subjects a sustained lowering of triglycerides cannot be attained. Diets containing MCT are not really established, whereas some attempts with fish oil (w-3-fatty acids) have been made. Drugs are not indicated for treatment of patients.

Endocrine Disorders After Cancer Therapy

Raphaël Rappaport and Elisabeth Thibaud

Hôpital Necker–Enfants Malades, Paris, France

I. INTRODUCTION

Advances in the treatment of malignant diseases have resulted in a dramatic fall in mortality rates for most of them, which means that an increasing number of survivors may have to cope with the late effects of cancer treatment. The protocols used include surgery, tumor-targeted radiotherapy, chemotherapy, and total-body irradiation and/or intensive chemotherapy followed by bone marrow transplantation. There has now been a sufficient follow-up interval for most conditions and for the current therapeutic regimens, so that most children can be followed with a prospective view of most potential complications. Appropriate therapeutic decisions can therefore be taken to avoid or minimize severe complications such as dwarfism or abnormal pubertal development. Although the primary goal is still to cure the malignant disease, knowledge of the side effects of treatment should contribute to the choice of any new therapeutic protocol.

According to the British National Registry of Childhood Tumors, acute leukemias, mostly lymphoblastic leukemias occurring in early childhood, account for one-third of all registrations. Lymphomas, most frequently non-Hodgkin's type, account for a further 10% with a higher incidence in late childhood. Brain and spinal tumors make up 25% of all tumors, and retinoblastoma, which is often bilateral and familial, is a major condition requiring cranial irradiation in infants. Most of these tumors require high dosages of radiation, which severely damage the hypothalamus and pituitary gland. The remaining childhood cancers include gonadal, bone and soft tissue sarcomas, and embryonal tumors, such as Wilms' tumors and neuroblastoma (1).

Because most children with malignant diseases are treated according to nationally or internationally driven protocols in pediatric oncology centers, it has now become clear that the most constructive evaluation and follow-up of survivors might be undertaken by a combined

endocrinology and oncology clinic. Most treatment protocols combine chemotherapy and irradiation, but chemotherapy is becoming an important and sometimes exclusive form of treatment for many conditions. It is therefore important to consider the detailed structure of a given treatment for each child, focusing on the location of the radiation fields causing direct damage to endocrine glands or to the skeleton, and on the use of cytotoxic chemotherapy that could be responsible for direct damage to the gonads (Table 1). In general, the time at which the late endocrine effects may occur is variable.

II. GROWTH

Growth depends on growth hormone secretion and the timing of puberty but also on a number of factors unrelated to pituitary deficiency, such as chemotherapy, associated acute and chronic disease effects, and exposure of cartilage plates to irradiation, as seen in children with spinal or total-body irradiation. Spontaneous growth after cranial irradiation is shown in Figure 1.

A. After High-Dosage Cranial Irradiation

Radiation doses in excess of 3000 cGy reduce final height in most children. The height loss is progressive, reaching about 1 standard deviation (SD) before puberty and 2 SD at final height. Growth retardation develops more rapidly, within 2 years, in patients given 4500 cGy or more. Bone age is delayed, and typical features of GH deficiency may appear in prepubertal patients (2).

B. After Low-Dosage Cranial Irradiation

Variable patterns of growth have been reported. Typically, there is a moderate height reduction during the acute phase of the disease and the associated induction chemotherapy. This is followed by a subnormal or normal

Table 1 Targets Critical to Growth According to Irradiation Protocols

^aHypothalamic and pituitary defect.

^bPrimary and/or secondary defects according to radiation protocols.

growth rate until puberty. An additional height loss of 1 SD may occur during puberty (2). A few patients have shown normal growth after irradiation, despite a GH deficiency (3). The overall mean loss in adult height in patients treated with cranial doses of 1800–2400 cGy varies from 0.9 to 1.4 SD (4–6). Final short stature is more likely to occur after intensive induction chemotherapy in children irradiated at a younger age, if puberty began earlier, and in patients with familial short stature. Because GH deficiency remains the prime candidate as a cause of growth retardation, all children should be tested for GH secretion before and at onset of puberty if they demonstrate a significant decrease in linear growth. This issue is even more critical in patients, most frequently girls, presenting with sexual precocity. These irradiated patients are prone to obesity in the long-term with increased circulating leptin levels independent of GH status (7).

C. After Spinal or Total-Body Irradiation

Some protocols include extensive skeletal irradiation, and these patients are exposed to more severe and early

Figure 1 Mean prepubertal height changes after cranial and craniospinal irradiation and final heights in patients treated for leukemia, head and neck tumors, or medulloblastoma. (From Ref. 61.)

growth retardation. One group of patients includes those given spinal irradiation (generally 2400 cGy) in addition to cranial irradiation for medulloblastoma. They may lose up to 2 SD of height within 2 years following irradiation and have a mean final height loss of 2–3 SD, with a short upper segment largely attributed to the lack of spinal growth (8, 9). Children irradiated before age 6 years are more severely affected. Some degree of reduced spinal growth and disproportion also occurs after whole-abdomen or, more rarely, after flank irradiation, as performed for abdominal malignancies, such as Wilms' tumors (10). Total-body irradiation as conditioning for bone marrow transplantation is another therapy that leads to growth retardation unrelated to GH deficiency. It is increasingly used as the ultimate therapy in leukemia and in some nonmalignant diseases (11, 12). The outcome of growth in these patients depends on the radiation dosage and its fractionation (13). An immediate growth retardation is observed in patients given a single 1000 cGy dose. The more recent protocols with fractionated doses of 800–1000 cGy have little impact on short-term growth. Final height has been reported to decrease by 1 SD with diminished sitting height. GH deficiency was found in 30% of these patients, with some improvement in GH production over the years (14).

Difference in treatment protocols may explain some discrepancy among reported data. Other factors such as prolonged corticosteroid therapy, renal failure, and chronic graft-vs.-host disease may also contribute to growth retardation. The frequency and severity of GH deficiency depend on the radiation protocols, and GH may not play a major role in the growth disturbance of these patients (13, 15–17). Growth retardation may be caused by several factors, the most important being direct skeletal irradiation, so that the contribution of GH deficiency to a decreased growth rate remains difficult to assess. In adult long-term survivors serum insulin-like growth factor 1 (IGF-1) values were only partly correlated with GH secretion. Normal IGF-1 levels were found in contrast with evidence of GH deficiency (18, 19) and could be explained by increased adiposity. Primary thyroid insufficiency occurs in most patients given total-body irradiation. Elevated plasma TSH appears within 2 years, but fewer than 10% of patients have overt hypothyroidism. Most boys and girls irradiated before puberty develop primary gonadal failure with elevated luteinizing hormone (LH) and follicle-stimulating hormone (FSH) levels. Delayed or absence of sex steroid secretion then contributes to growth retardation at the age of puberty and requires replacement therapy.

D. After Chemotherapy

The effect of chemotherapy on growth is difficult to assess because many factors, such as differences among protocols, infection, poor nutrition, and the disease itself, may play a role. These patients do not develop GH deficiency after treatment by chemotherapy alone, but the moderate,

early growth retardation, as reported in children also irradiated for leukemia (20) or cranial tumors (9), may be related to the induction chemotherapy and caused by a transient insensitivity to growth hormone (21). However, a recent study showed that the final height of patients treated for leukemia with chemotherapy alone was normal (6). There may even be catch-up growth in immunodeficient growth-retarded children after preparative chemotherapy for bone marrow transplantation (13). Because some data still suggest that chemotherapy has a moderately detrimental effect on growth (5), follow-up of all patients remains necessary. However, growth is unlikely to be a critical issue in nonirradiated patients.

III. PUBERTY

A surprising finding is that children who have received cranial irradiation may present with early or true precocious puberty (22, 23). This is in contrast with the delayed puberty usually accompanying idiopathic GH deficiency. Early puberty occurred in girls after cranial irradiation for leukemia, and the children who had been irradiated when very young tended to have the earliest puberty (24, 25). This is an important consideration because of the risk of excessive bone maturation and early epiphyseal closure. It also tends to narrow the window of opportunity to treat with human growth hormone (hGH) before secretion of sex steroids. Puberty not only occurs earlier but it is shortened with early menarche (26). The final height loss may even be more severe if full-blown precocious puberty is associated with untreated GH deficiency. In patients with optic glioma presenting with precocious puberty at the time of irradiation, the persistence of a normal growth rate within 1 or 2 years after cranial radiation may be misinterpreted, and excessive progression of bone age will lead to early cessation of growth. Growth hormone testing is then necessary 1 year after irradiation to unmask any associated GH deficiency and allow GH therapy to begin (27).

In contrast, gonadotropin deficiency may develop within a few years after high-dosage cranial radiation for tumors, as indicated by arrested puberty, primary amenorrhea in girls, and absence of LH and FSH response to an LH-releasing hormone (LHRH) stimulation test (28). Some girls suffer only from menstrual irregularities, and their impact on fertility has not been documented. Gonadotropin deficiency is usually associated with GH deficiency and moderate hyperprolactinemia, a combination indicating multiple hypothalamic pituitary deficiencies.

IV. GROWTH HORMONE SECRETION

The first case of induced hypopituitarism after cranial radiation for a tumor distant from the hypothalamic-pituitary region was reported in 1966 (29). Growth hormone deficiency is at present the most common pituitary defect occurring after radiation (Table 2). The hypothalamus is more radiosensitive than the pituitary gland, so that GH deficiency is probably caused by a dysfunction of GH-releasing hormone (LHRH) somatostatin control. This may explain the differences observed between spontaneous and pharmacologically stimulated GH secretion, as well as the persistence of normal GH responses to the GHRH stimulation test (31, 33). Experimental studies in monkeys (32) and the changes observed in the other anterior pituitary functions in adult patients (33) support such a hypothesis. The severity and frequency of pituitary defects vary according to the initial disease and its specific therapeutic regimens, but the radiation dosage effectively delivered to the hypothalamic-pituitary region defines the risk factor. It depends on the total dosage, the number of fractions, and the duration of treatment: a given dose delivered in a shorter time period is more likely to cause GH deficiency than one delivered over a long period (2, 34). Assessment of GH secretion requires a pharmacological GH stimulation test (35). If growth is retarded despite normal GH peak responses, it has been suggested that one

Table 2 Endocrine Abnormalities After External Cranial Irradiation in Patients Evaluated at Least 4 Years After Irradiation^a

Cause	Cases (n)	Frequency of cases with endocrine abnormality (%)				
		GH deficiency		Thyroid ^b	ACTH	LHRH ^c
		Complete	Partial			
Leukemia, 24 Gy	86	30	22	2	0	3
Face and neck tumors, 25–45 Gy	56	46	22	35	7	16
Medulloblastoma, 25–45 Gy	59	52	24	47	8	20
Optic glioma, 45–55 Gy	39	77	23	46	3	40

^aExpressed as percentage of affected cases in each patient group. GH deficiency; complete, after stimulation, GH peak <5 ng/ml; partial, 5–8 ng/ml. ACTH, adrenocorticotrophic hormone.

^bIncludes elevated plasma TSH after direct thyroid irradiation.

^cLH/FSH deficiency or precocious puberty. Evaluated in patients reaching pubertal age. Does not include primary gonadal failure.

Source: From Ref. 2.

should measure the spontaneous GH secretion during the night. If the later is subnormal, one may consider a partial GH deficiency. This condition has been described as GH neurosecretory dysfunction, and may essentially occur after low-dosage irradiation (36). Plasma IGF-1 measurement is a convenient screening method: in patients irradiated with doses higher than 3000 cGy, IGF-1 values correlated with spontaneous GH secretion (18). However, normal IGF-1 concentrations may be observed in patients with partial GH deficiency after low-dosage cranial irradiation (19). The level of IGF-1 is therefore difficult to interpret since many of these patients are moderately obese (37). Repeated GH testing may be necessary in some cases before GH deficiency is diagnosed, in patients treated with low-dosage radiation. In any case, GH responses and IGF-1 values must be interpreted according to the pubertal status of the patient (2).

GH deficiency occurs in about 75% of children treated with cranial doses between 3000 and 4500 cGy. All children irradiated with higher dosages are affected and eventually develop panhypopituitarism. The greater the radiation dosage, the earlier the GH deficiency develops, with intervals ranging from 1 year in patients irradiated with 4000 cGy for cranial tumors to more than 4 years in leukemic patients (2). The age at time of cranial irradiation is another important risk factor: younger children are more vulnerable (38). It is therefore recommended that cranial irradiation be delayed whenever possible until the child is over 3 years old. Children treated for acute leukemia with radiation doses of 2400 cGy or less do not always develop GH deficiency, and the deficiency may be restricted to the pubertal period (39). Whereas complete GH deficiency is not reversible, the long-term outcome of partial GH deficiency, as observed in patients treated with low-dosage cranial irradiation, is not firmly established. This may be partly because of difficulties in quantitatively assessing GH secretion (30). The anterior pituitary function should nevertheless be re-evaluated in these patients after adolescence to provide a reference for further follow-up during adulthood.

After total-body irradiation preparing for bone marrow transplantation, the risk of GH deficiency depends on the radiation protocol (13, 15, 17, 40). A single dose of 1000 cGy, less commonly used, generally impairs GH secretion. Doses over 700 cGy, even fractionated, induce a 50% risk of GH deficiency. Generally there seems to be no correlation between GH secretion and growth, at least during the first few years following irradiation (13). This is not surprising, because many other causative factors may play a role.

V. THYROID

The reported incidence of central hypothyroidism after cranial irradiation depends on the diagnostic criteria since most patients do not develop overt clinical hypothyroid-

ism. Even low free T4 (FT4) with normal or low thyroid-stimulating hormone (TSH) is observed in only a small percentage of patients, in the high-risk group (2). In a recent study, because of the lack of overt clinical presentation, the incidence of TSH dysregulation was assessed by combining three criteria: basal FT4, TSH response to thyrotropin-releasing hormone (TRH), and nocturnal TSH surge. Using such sensitive biological criteria it was shown that 92% of the patients with central hypothyroidism would have remained undiagnosed by evaluation of baseline thyroid function tests alone. In patients treated with 3000 cGy or more or total-body irradiation its frequency reached 39%; after lower-dosage radiation the percentage was decreased to 8%, by 10 years after tumor diagnosis (41). Mixed central and primary hypothyroidism is expected to occur if the thyroid was also irradiated. The TSH deficiency may occur even before GH deficiency, although undiagnosed by the conventional insensitive tests (41) (Table 2).

The incidence of central hypothyroidism is related to the total radiation dose. Chemotherapy with busulfan and cyclophosphamide may exacerbate the effects of irradiation. Transient hypothyroidism has also been reported during induction chemotherapy with L-asparaginase (42). The issue of latent central hypothyroidism is complex. One may consider that it should be treated with L-thyroxine to optimize spontaneous or hGH-treated growth as well as intellectual and school performance of affected children. More studies are needed to evaluate replacement therapy in these cases. Primary hypothyroidism due to direct thyroid irradiation is diagnosed by TSH elevation. It is found in patients irradiated for Hodgkin's disease or after craniospinal irradiation. Hyperfractionation of radiation therapy lowers its incidence in the long term (43).

The risk of benign nodules or thyroid cancer in later adult life is increased after radiation of the neck. Because low-dosage thyroid radiation exposure (up to 500 cGy) is a known cause of neoplasm, both head and neck therapeutic irradiation must be considered as a risk factor. Although most data are derived from patients treated for Hodgkin's disease (44), children given spinal or total-body irradiation should also be evaluated through adulthood. Ultrasonography of the thyroid is more sensitive than physical palpation. However, it is so sensitive and nodules are so prevalent in the normal population that great caution is needed in interpreting the results. Serum thyroglobulin levels correlate with the number of nodules (45). Surgery is a difficult decision. Therefore, it is important to inform all patients of the need for prolonged follow-up. It has been suggested that thyroxine therapy, at dosages that suppress TSH secretion, would help avoid recurrence after surgery of nodules (33).

VI. GONADAL AND REPRODUCTIVE FUNCTION

Risk factors for gonadal toxicity include local irradiation, type and dosage of chemotherapy, age, pubertal status,

and gender of the patient (Table 3). There are important differences between male and female gametogenesis and its relationship to gonadal endocrine function.

A. Girls

The ovocyte during postnatal life is resistant to chemotherapy. However, if ovocytes are damaged or destroyed by anticancer therapy, reduction in their number results in absence of puberty or, at a later age, in temporary or permanent cessation of ovulation with shortening of the reproductive period.

Chemotherapy-related damage to the ovary depends on the drug, its dosage, and age of the patient: gonadotoxic effects increase with age. They are minimal in prepubertal girls who have a greater reserve of germ cells and primary follicles. Alkylating agents, such as cyclophosphamide at a total dosage greater than 20 g or 500 mg/kg (46) and high-dosage busulfan permanently suppress ovarian function. Combination chemotherapy regimens have generally less effect on ovarian function in adolescent girls than in adult women. However, little is known about ovarian damage in prepubertal girls: if treated for leukemia a favorable outcome was reported (26, 47, 48). In Hodgkin's disease mechlorethamine, oncovin (vincristine), procarbazine, prednisone (MOPP) and mechlorethamine, vinblastine, procarbazine, prednisone

(MVPP) regimens, which induce a high incidence of transient or permanent amenorrhea in adults, have little effect on ovarian function in girls providing they did not undergo additional pelvic irradiation (49, 50). In contrast, a favorable outcome was reported after Adriamycin (doxorubicin), bleomycin, vinblastine, dacarbazine (ABVD) regimen (51).

Ovarian function may be severely impaired by irradiation with fractionated doses over 700 cGy, with complete destruction of the ovocytes at 2000 cGy (52) as used in patients treated for abdominal, pelvic, or genital tumors, and Hodgkin's disease. Primary ovarian dysfunction may also occur in patients who received spinal irradiation with scattered irradiation to the ovaries (53). Ovarian transposition before abdominal irradiation has been shown to protect patients from ovarian failure if performed before puberty (54).

Total body irradiation (TBI) as conditioning for bone marrow transplantation induces a high risk of ovarian failure. Permanent and total damage to the ovary occurs in girls given high dosages of busulfan, often associated with cyclophosphamide (55, 56). In contrast, chemotherapy regimens excluding busulfan have a favorable outcome. Young age at TBI and fractionated irradiation are associated with increased ovarian recovery. However, the time required for recovery may vary up to 7 (57) or 10 years (58). Transient increase in plasma gonadotropins, and ultimate recovery, were observed in 35% of the girls treated with TBI for leukemia (59). When estrogen replacement therapy is given, it should therefore be stopped periodically to detect any ovarian recovery.

Future fertility is the main issue in these patients. The prospects for normal fertility are favorable in girls treated with nonintensive chemotherapy for leukemia (60, 61) or with nitrosureas for brain and spinal tumors. There is a poor correlation between plasma gonadotropin levels and fertility: amenorrheic girls with persistently elevated plasma gonadotropins may become pregnant. Presently there is no evidence, in spite of favorable animal studies, that suppression of gonadal activity during anticancer therapy decreases the risk of gonadal toxicity.

In a recent study, a global fertility deficit of 23% was observed in women treated during childhood with alkylating agents and abdominal-pelvic irradiation with large variations according to treatment regimens (62). Radiation is the most deleterious factor. It also damages the uterus and its vascularization, which may result in a high frequency of miscarriages or premature births with a higher frequency in girls receiving TBI before puberty (56, 60, 63). These lesions are more severe when girls were treated in early childhood (64, 65). There is no increased frequency of congenital malformations. Because of uterine atrophy, as shown by reduced uterine length and endometrial thickness at ultrasound examination, some women are also unlikely to benefit from in vitro fertilization with donor ovocytes (66). Estrogen replacement therapy may be inadequate to generate normal uterine growth (67).

Table 3 Current Chemotherapy Agents Cytotoxic for the Testis and Ovary

Chemotherapy	Disease
Alkylating agents	
Cyclophosphamide	Lymphoblastic leukemia Non-Hodgkin's lymphoma Various tumors
Ifosfamide	Soft tissue tumors Ewing sarcoma Nephroblastoma
Melphalan	Bone marrow transplantation
Busulfan	Bone marrow transplantation Chronic myeloid leukemia
Dacarbazine (DTIC)	Soft tissue tumors
Carmustine (BCNU)	Hodgkin's disease Brain tumors
Lomustine (CCNU)	Hodgkin's disease
Semustine (methyl-CCNU)	Brain tumors
Other agents	
Cytarabine (cytosine arabinoside)	Lymphoblastic leukemia
Vincristine	Various tumors
Vinblastine (VLB)	Hodgkin's disease
Procarbazine	Hodgkin's disease
Cisplatin (cis-DDP)	Various tumors

Strategies to preserve fertility are available: ovarian tissue cryopreservation is being adopted by expert centers. However, there is no evidence of its ultimate efficacy in humans (68) despite favorable reports in experimental studies (69).

Clinical evaluation of ovarian activity is easy in cases with complete gonadal failure. It is less precise in patients with secondary amenorrhea with elevated FSH and LH plasma concentrations. The latter may be the only sign of ovarian dysfunction observed during posttreatment follow-up. Estrogen and progesterone replacement therapy is necessary to feminize these patients fully and allow normal pubertal growth. However, breast atrophy may result from scattered irradiation after whole abdominal or flank irradiation performed before puberty. It may require cosmetic surgery for correction (64).

B. Boys

The germinal epithelium is more sensitive to irradiation than Leydig cells. In prepubertal boys local doses between 300 and 1000 cGy, as delivered during abdominal or low spinal irradiation (craniospinal irradiation may result in a scattered dose to the gonad), induce a transient or permanent rise in serum FSH at time of puberty with later oligospermia or azospermia and reduced testicular volume (70). Germ cell dysfunction occurs after total body irradiation, single or fractionated, with a high risk of azospermia (59). Recovery of germ cell function is rare, even more so after fractionated irradiation (71). When irradiated during puberty, similar data were reported; recovery of gametogenesis is not assured and may occur years later.

Chemotherapy is essentially aggressive to germ cells. It includes alkylating agents, procarbazine, vinblastine, cytarabine, and cisplatin (Table 3). Except for the very aggressive intensive cytotoxic chemotherapy with high dosages of cyclophosphamide or busulfan, there are remarkable individual variations that may not be predictable and long-term follow-up is necessary. The elevation of serum FSH is consistent with germinal damage (72). Each regimen used in the management of a given cancer should be evaluated for its potential harm to the gonads. For instance, the effects of cyclophosphamide on sperm density are proportional to the dosage given before adulthood (73). A total dosage of 200 mg/kg or more is followed by evidence of germ cell damage, probably more extensive if treated after the onset of puberty; the prognosis of fertility is poor in most patients (74). Combination chemotherapy (such as MOPP or MVPP to treat Hodgkin's disease), regimens are generally more gonadotoxic than individual agents. Therefore, new regimens with low gonadal toxicity are being developed (75).

The Leydig cell function, in general, is preserved. Testosterone secretion and pubertal development are normal following local irradiation with doses inferior to 2000 cGy or total body irradiation although elevated serum LH

with normal testosterone values may be observed in some cases. Only males who received high-dosage testicular irradiation after one leukemia relapse experience testicular failure and require androgen replacement therapy (76).

VII. OTHER ENDOCRINE COMPLICATIONS

Deficiency in adrenocorticotrophic hormone (ACTH) and secondary adrenal insufficiency with clinical symptoms are rare complications that occur after high doses of cranial radiation for the treatment of brain tumors. In children this may cause hypoglycemia if combined with severe GH deficiency. It may occur as early as the first 2 years after radiotherapy (33). If early morning plasma cortisol levels are low and do not respond to insulin-induced hypoglycemia, hydrocortisone replacement therapy is required.

Hyperprolactinemia (usually below 100 ng/ml) after high-dosage cranial irradiation occurs during adolescence or adulthood without any clinical expression. It is an additional indicator of hypothalamic damage (33).

Cranial irradiation is never accompanied by posterior pituitary dysfunction. Calcium homeostasis remains normal although primary hyperparathyroidism had been reported to rarely occur after low-dosage neck irradiation. There is no reported evidence of primary endocrine pancreas or adrenal dysfunction after abdominal irradiation.

VIII. FOLLOW-UP AND MANAGEMENT

Long-term assessment of oncology patients is required for growth, puberty, fertility, and other late endocrine complications. Adult endocrinologists should now focus on GH-deficiency-related symptoms, obesity, bone mineral density decrease, intellectual cognitive functions, and sexual life of the survivors. Regular checkups are necessary to decide upon replacement treatment.

A. Growth Hormone Replacement Therapy

It is easy to decide after cranial irradiation for brain and facial tumors because GH therapy is generally severe. Recombinant growth hormone given at the usual dosage of 0.1 iv/kg/day (about 0.025 mg/kg/day) produces a significant improvement in growth rate. According to earlier reports, the long-term results and final heights achieved have been disappointing (77–79). One factor may have had negative effects when compared with patients with idiopathic GH deficiency: some patients had early or precocious puberty, which accelerated the skeletal maturation more quickly than the increase in growth rate. Failure to catch up with normal height may also have been related to low hGH dosage in some studies. It is therefore essential to commence hGH therapy as soon as GH deficiency and growth retardation are documented, but preferably not less than 2 years after the primary treatment, except for severe cases.

This issue is more complex in patients treated for

leukemia with low dosages of cranial irradiation. In this group GH therapy should be started before puberty only if the height loss exceeds 1 SD, because some patients maintain normal growth rates for several years until puberty despite a GH deficiency, and at time of onset of puberty if short stature and severe GH deficiency predict significant adult height loss. Again, early or precocious puberty is an additional risk factor of short stature. LHRH analog therapy should then be considered in association with the hGH treatment. In this group of patients most authors restrict the use of hGH and/or LHRH analog therapy to GH-deficient patients most at risk of final short stature because of familial short stature, cranial irradiation at a younger age, and/or early puberty. Whatever the cranial radiation dosage, those who have received additional spinal irradiation have a poor response to hGH treatment (79, 80). The same suboptimal growth response occurs after high-dosage total-body irradiation.

In patients with cranial irradiation, there is now sufficient evidence that growth can be improved by hGH therapy. Combination with LHRH analog allows these patients to reach height in the normal range, although frequently lower than calculated target height (81, 82). Reduced final height remains a critical problem in patients with craniospinal or total body irradiation.

One major concern is the potential oncogenic effect of hGH treatment. However, there is at present no evidence that hGH promotes leukemia or tumor relapse (83). A high rate of secondary malignancies has been reported in children treated before age of 3 years with alkylating agents and etoposide with or without irradiation (84). Continuation of GH therapy after final height is reached is being evaluated. These adults are often obese, with poor physical performance. However, the need for prolonged hGH therapy in adulthood may be questionable in patients who do not show profound GH deficiency. Reduced trabecular and cortical bone mineral density after cranial irradiation was observed during chemotherapy and does not seem to be correlated with the GH status. It requires follow-up in later life and appropriate intervention (85).

B. Other Issues

At present, GH replacement therapy with conventional doses is well defined and other issues should be given priority in the long term and according to the oncology therapy. Thyroid nodules occur after many years. Gonadal failure requires replacement therapy. Risk of damage to fertility can be anticipated but long-term evaluations are still necessary in patients of both genders. Skeletal dysplasia may be secondary to irradiation and appropriate replacement sex steroid therapy is necessary to minimize loss of bone mineral density. On all issues parents and patients should be warned and helped in order to face potential problems after cure of the cancer.

C. Intellectual and Neuropsychological Risks

The risk of intellectual dysfunction has been recognized for a long time and a comprehensive analysis was provided by Duffner (86) in the early 1990s. With the protocols followed at that time, precise conclusions were presented. The most important variable was age at time of diagnosis and treatment: children younger than 3 years had significantly lower IQs than patients treated at older ages. This led practitioners to postpone cranial irradiation and to treat with postoperative chemotherapy in an attempt to delay radiation until the children could better tolerate its effects. A second risk factor is large-volume irradiation, with significant changes in IQ scores documented after whole-brain irradiation. The dosage of radiation that produces neuropsychological sequelae is not precisely known.

More recent studies have shown that only-chemotherapy protocols among leukemic children had modest late effects on nonverbal cognitive skills, particularly among girls (87). However, sequelae including language and education disabilities were reported when leukemic children received cranial irradiation (24 cGy or 18 cGy) (88). Impaired academic achievement was reported as well after central nervous system (CNS) chemotherapy prophylaxis in these patients. More recent studies have shown that only-chemotherapy protocols among leukemic children had modest late effects on nonverbal cognitive skills, particularly among girls.

Children with medulloblastoma treated with irradiation at high dosages most frequently show severe neuropsychological deficit, requiring specific support (89). Over time, deficits in nonverbal and information processing skills may increase (90).

Survivors of pediatric bone marrow transplantation are being more precisely evaluated and a recent study concluded that with or without TBI, bone marrow transplantation entails minimal neurocognitive sequelae in patients who are 6 years of age or older at therapy (91). Because there is a significant incidence of learning disabilities after cranial irradiation, early and appropriate monitoring of cognitive skills may improve the neurocognitive future of these patients.

Endocrine Alterations in Human Immunodeficiency Virus Infections

Robert Rapaport and Daphne Sack-Rivers

Mount Sinai School of Medicine, New York, New York, U.S.A.

I. INTRODUCTION

On June 5, 2001, acquired immunodeficiency syndrome (AIDS) turned 20. AIDS has claimed more than 21 million lives, including more Americans than died in World War I and World War II combined (1).

The first cases of AIDS in children were reported in 1983 (2,3). Since the beginning of the epidemic, 4.3 million children have died and 1.4 million children less than 15 years of age are infected with human immunodeficiency virus (HIV) (4). Approximately 70% of all cases of AIDS occur in sub-Saharan Africa, where it is estimated that 1:4 adults is HIV-seropositive. Other regions struggling with substantial rates of new infections are the Caribbean, Southeast Asia, and Eastern Europe (1). AIDS has evolved into two distinct epidemics: a horizontal epidemic in adults, spread by sexual contact or shared needles; and a vertical epidemic in which infected mothers give birth to infected children. Since the number of HIV-infected women will continue to increase because of both intravenous drug use and heterosexual transmission, many more cases of AIDS in children are expected to occur (5).

Most cases of pediatric HIV infection worldwide are a result of perinatal transmission. During the year 2000 alone 600,000 children became infected with HIV-1 through mother-to-child transmission (4). Of pediatric HIV cases reported in children less than 13 years of age in the United States, 88% were acquired perinatally; 2% were caused by infection via blood and blood products in individuals with clotting disorders, such as hemophilia; and 10% were classified as other or not reported (6). In the United States there has been a dramatic reduction in mother-to-child HIV transmission rates, from a high of 2500 in 1992 to fewer than 400 perinatal infections in 1998. This decline reflects the Public Health Service's recommendations made in 1994 and 1995 for routine HIV counseling and voluntarily testing for all pregnant women,

and for offering zidovudine to infected women during pregnancy and delivery, and for the infant after birth (6–8). A longitudinal follow-up study of the Pediatric AIDS Clinical Trials Group Protocol 076 (PACTG 076), revealed that there were no adverse outcomes with respect to growth, cognitive/developmental function, immune function, cancers, or mortality for uninfected PACTG 076 children treated with zidovudine in utero compared to a placebo group (7,8).

The situation is less fortunate in the developing world. Mother-to-child transmission is the major mode of HIV-1 infection in children. Approximately 1600 children are infected daily with HIV (9,10). Viral burden, immunocompetence in the mother, obstetric factors, as well as other unknown inherited factors influence the risk of transmission.

In the United States, improvements in the means of detecting and treating HIV infections have led to improvements in the quality of life and survival of infected children. As these children survive longer, the effects of HIV infections on various organ systems become more apparent. It is therefore imperative to detect and treat HIV-related complications as early and effectively as possible.

The endocrine alterations observed in HIV-infected children may be caused by the direct effects of HIV infections, the severe often-debilitating chronic disease that results from infection with the HIV and/or accompanying opportunistic infections or neoplasms, or the therapeutic agents used to treat HIV-infected children.

Evidence for alterations in the endocrine system by HIV disease derives from pathological studies of autopsy material as well as from *in vitro* and *in vivo* studies and clinical trials. In this section we review existing evidence of endocrine system alterations in patients infected with HIV, with special emphasis on studies relating to HIV-infected children.

II. GROWTH

The effect of HIV infection on growth in children is expressed differently during the different stages of development.

Markson et al. (11) examined factors associated with low birth weight (LBW) in HIV-infected patients and compared them to a control group. The study population consisted of 772 HIV-infected women; 2377 women served as controls. Women who were HIV-positive had a 29% chance of delivering a LBW infant compared to a 9.3% chance for the control group. Delivery of a LBW infant was also strongly associated with illicit drug use, maternal smoking, and African-American vs. non-Hispanic white ethnicity. When they compared the odds of delivering a LBW infant among full-term deliveries, they found that HIV-infected women were three times as likely to deliver a LBW infant. After adjusting for the effects of smoking, illicit drug use, maternal risk factors, and health care delivery, HIV-infected women are at an increased risk of delivering a LBW infant.

Weng et al. (12) evaluated the effect of perinatal HIV-1 transmission and birth outcomes, such as birth weight, gestational age, head circumference, and weight/head ratio. Some 627 women and their infants were analyzed; 318 women were HIV-seropositive and 309 women were seronegative. Unadjusted mean birth weight of HIV-uninfected infants was 235 g more than HIV-infected infants. When the infants were evaluated at the end of the neonatal period, HIV-infected infants' weight was lower than the weight of HIV-negative infants born to HIV-positive mothers. The adjusted birth weight was found to be 96 g less in the infected than in the uninfected group. Maas et al. (13) studied prospectively the effects of maternal HIV infection on fetal development and neonatal morbidity in 17 neonates and 37 controls, of whom 21 were exposed to opiates. They concluded that prenatal exposure to opiates and nicotine but not HIV infection resulted in fetal growth retardation and neonatal morbidity.

Results from prospective cohort studies of pregnancy outcomes of HIV-infected mothers in the United States indicate that HIV-infected newborns weigh 0.28 kg less and are 1.64 cm shorter than HIV-exposed but uninfected controls (14). A total of 282 patients were enrolled in this study, of whom 59 were infected with HIV and 223 were not. When re-evaluated at age 18 months, the HIV-infected infants were 0.7 kg lighter and 2.2 cm shorter than the HIV-exposed uninfected children. Therefore, mother-to-child transmission of HIV is associated with a decrease in birth weight of the infant. The effect of HIV infection is on par with other determinants of birth weight, such as primiparity and gender, and somewhat lower than the effect of maternal smoking during pregnancy.

In conclusion, infants with perinatal acquired HIV tend to be shorter and have a lower birth weight. Most of these studies were done prior to the use of Zidovudine, which has been shown to cause an increase in weight (15).

Johnson et al. (16) evaluated prospectively 20 children born to HIV-infected mothers for 18 months. All infants had normal birth weights, suggesting no effect of HIV exposure on intrauterine growth. By the end of the first year of life 12 children had no evidence of infection. None of them was considered to have failure to thrive. Of the eight infected children, four (50%) exhibited growth failure, two developing a syndrome of growth failure, dermatitis, and early death. The authors' conclusion was that the growth failure accompanying HIV infection appears to be postnatal in origin.

In a group of children age 4–24 months with perinatally acquired infection, 10 who had antigen-induced lymphocyte proliferation were found to grow normally, in contrast to 8 children with absent antigen-induced lymphoproliferation, 7 of whom had failure to thrive (17).

McKinney et al. (18) compared 62 HIV-infected with 108 uninfected children <25¹/₂ months of age. The weight for length scores through the first 2 years of life were comparable in the two populations, suggesting that the HIV-infected children were not abnormally lean or wasted. However, the uninfected population was significantly longer (higher length for age scores) at 4–24 months of age than the infected children. However, the study did not take into account that 73% of the infected children had received antiretroviral treatment (Zidovudine), which has been shown to result in increased weight (Table 1).

de Martino et al. (19) studied 32 congenitally acquired HIV-infected prepubertal children, classified as Centers for Disease Control (CDC) clinical category C, who were taking two nucleoside reverse transcriptase inhibitors. The control group consisted of 248 HIV-negative children. All children were evaluated for 12 months. The height, height velocity, bone age, insulin growth factor 1, (IGF-1), and IGF-binding protein-3 (IGFBP-3) of the HIV-positive group were lower than those of controls. They also had higher spontaneous and phytohemagglutinin-stimulated interleukin-6 (IL-6) release. This was inversely correlated with height velocity, bone age, IGF-1, and IGFBP-3, suggesting that IL-6 overproduction may be a mechanism of IGF-1 and IGFBP-3 downregulation, which causes the impaired linear growth in children with perinatal HIV-infection.

In children with HIV infections, poor growth has been a consistent finding. Of the first 15 children with AIDS reported in 1983, 13 (87%) were described as having failure to thrive (FTT) (2,3). A subsequent report described FTT in 14 of 14 infants less than 7 months of age with AIDS (20). The poorly defined term FTT has been a frequently reported characteristic of infants and children with AIDS. A dysmorphic syndrome noted in HIV-infected children and named HIV embryopathy by some had, as its most commonly found feature, FTT or poor growth (21). Reviews of large numbers of HIV-infected children have consistently commented on the occurrence of poor growth in the affected children (22–25).

Table 1 Birth Weight (Wt) and Length (L) in Perinatally Acquired HIV Infection vs. HIV-Negative Infants

Reference	N	%	Diagnosis	L (cm)	Wt (kg)	Remarks
11	NA	29	HIV+	NA	LBW	9.3% born to HIV-negative mothers had LBW.
12	48	100	HIV+	NA	-0.154	206 uninfected infants born to HIV-positive mothers were 0.154 kg more at birth.
14	59	100	HIV+	-1.64	-0.28	At birth, compared to HIV-negative infants.
	59	100	HIV+	-2.2	-0.7	At age of 18 months compared to HIV-negative infants.
16	20	100	^a	normal	normal	At birth.
	8	75	HIV+	NA	NA	At 12 months, 2/8 died.

^aAt birth could not establish diagnosis.

NA, not available.

The cause of growth failure of most HIV-infected children is not known. Johann-Liang et al. (26) evaluated 23 prepubertal congenitally HIV-infected children aged 1.3–13.2 years. They observed that HIV-infected children had significantly lower IGF-1 levels compared with age- and gender-matched controls. When compared with HIV-infected children with normal growth, the group with growth impairment had lower IGF-1 levels, severe immune suppression, increased viral burden, increased IL-6 activity, and decreased total serum protein.

We evaluated 31 children with symptomatic HIV infections. We found that as a group they were not smaller than average. When individual patients were evaluated, however, we found that about 1:6 of the HIV-infected children were underweight (weight < 3%), and one-third had height and weight velocities < 3%. Those children who had more opportunistic infections and lower CD4 lymphocyte counts tended to grow most poorly. A substantial number of patients had abnormal thyroid function test results, IGF-1, and cortisol levels. Urinary growth hormone excretion was increased in the patients as a group (27).

In a retrospective analysis of 198 children enrolled in the Children's Hospital of New Jersey AIDS program, sufficient data for growth analysis were found in 122 subjects. Poor growth, defined as weight or height < 5% based on National Center for Health Statistics (NCHS) data, was noted in 10 of 22 infants less than 2 years of age, 5 of whom were girls. Of these, eight had heights and weights < 5%. Among boys older than 2 years, 15 of 49 had poor growth, 6 having low weights and heights, 7 only low heights, and 2 low weights. These data confirm our earlier finding that height was more affected than weight in HIV-infected children, suggesting that nutritional factors alone could not explain the growth failure. CD4 cell counts were lower and the incidences of opportunistic infections were higher in poorly growing children. The incidence of progressive encephalopathy was not related to the children's growth patterns (28).

Jospe and Powell reported an 8-year-old girl with growth hormone deficiency (29). Laue et al. (30) studied nine children with severe growth failure, with heights be-

tween 2 and 5 standard deviations (SD) below the mean. All children had normal levels of IGF-1, and eight of nine had normal growth hormone responses to stimulation tests with arginine and levodopa. Thyroid and adrenal function tests were by and large normal in these children and could therefore not provide an explanation for their growth failure. Schwartz et al. (31), also found normal growth hormone response to glucagon stimulation in 12 short children with average heights of 2.23 SD below the mean. Serum IGF-1 levels were low. Lepage et al. (32) compared 16 HIV-seropositive children 5–12 years of age with perinatally acquired disease in Kigali, Rwanda, with age- and gender-matched seronegative children. Of 16 patients, 12 had short stature, and 7 had low weight for age. Mean IGF-1 concentrations were lower in patients ($n = 11$) than controls, but basal (unstimulated) growth hormone levels were not different between the two groups.

Rondanelli et al. (33), looked at the circadian secretion of growth hormone (GH), IGF-1, cortisol, adrenocorticotropic (ACTH), and thyroid-stimulating hormone (TSH) in HIV-infected children. Twenty-seven prepubertal children participated in the study, of whom 14 were well-nourished HIV-seropositive and 13 were clinically healthy children chosen as controls. They demonstrated that throughout the 24 h period plasma GH, cortisol, and ACTH levels were similar and fell within normal limits in HIV-seropositive and healthy controls. Serum TSH levels were similar, except at 2400 h, when the TSH levels were significantly lower in the HIV-seropositive children than in the healthy children. Bone age and chronological age ratio were below 1.0 in 10 of the 14 children (71%), 4 of the 14 children had height < 3rd percentile, 2 of 14 children had weight < 3rd percentile, and mean basal IGF-1 levels were below normal range for 12 of 14 children. At all time points the IGF-1 circadian profile was significantly lower in HIV-seropositive children than in the control group.

Carey et al. (34) studied 1338 HIV-infected children aged 3 months to 15 years, who participated in a multicenter pediatric AIDS clinical trials to assess their somatic growth and to construct age-specific growth velocity norms. They found that there were consistent deficits in

Table 2 Growth Disturbances Observed in HIV-Infected Children

Reference	N	Height < 5%	Weight < 5%	Height velocity < 3%	Weight velocity < 3%
27	31		19% < 3%	10%	10%
28	22 < 2 yr	45%	45%	NA	NA
28	49 > 2 yr	26%	16%	NA	NA
33	14	29%	14%	NA	NA
34	1338 (3 m–15 yr)	33% < 3%	20 < 3%	NA	NA

NA, not available.

growth velocities among HIV-infected children. Approximately 33% of height and 20% of weight age- and gender-corrected velocity measurements were below the 3% percentile. These normalized growth velocities are useful means of following the growth of pediatric AIDS patients (Table 2,3).

Children with hemophilia provide a unique population for the study of the effects of HIV infection on growth. In one study, 3 of 22 boys had growth failure: 2 had low IGF-1 levels and possible neurosecretory dysregulation of growth hormone secretion (35). In another study, Jason et al. (36) noted a decline in weight percentiles in 41 children with hemophilia following the diagnosis of HIV infection. They suggested that the effect of HIV infection on weight might precede both the clinical and laboratory alterations of the immune deficiency.

Brettler et al. (37) found that growth failure, defined as decrease of more than 15 percentile points in height or weight for age for 2 consecutive years, was predictive of the development of symptoms in HIV-positive children with hemophilia. The growth failure in many cases predated the lowering in CD4 levels, generally thought to be a prognostic indicator of disease progression. In a multicenter Hemophilia Growth and Development Study, entry data revealed that, adjusted for age, HIV-positive subjects were three times as likely as HIV-negative subjects to have height for age decrement (38). Gertner et al. (39) studied a cohort of 300 boys with hemophilia. Those who were infected (62% of the total) had lower age-adjusted heights and weights than the uninfected boys. Despite decrements in growth parameters, the HIV-infected group had no evidence of wasting or malnutrition. The growth

failure was postulated to be caused by delays in pubertal maturation, reflected by delays in bone age and by differences in testosterone or sex-hormone-binding globulin secretion.

The Hemophilia Growth and Development Study (40) evaluated growth and hormone correlates in 207 HIV-positive and 126 HIV-negative males for a period of 3.5 years. Eighty-nine of 207 HIV-positive males and 31 of the 126 HIV-negative males were further evaluated according to the study protocol; subjects who demonstrated declines in height for age (measurement <5th percentile with two previous heights >10th percentile), who had not achieved Tanner stage IV level by age 15 years or who had abnormal growth velocity. IGF-1 levels were normal for age in both subgroups. In participants with abnormal growth, 47% of HIV-positive and 17% of HIV-negative had an abnormal response to growth hormone (GH) stimulation test (a value <10 ng/ml). For the entire HIV-positive population, no correlation was found between growth hormone response to stimulation test and state of immunodeficiency (CD4 count <200 vs. >200). There were no abnormalities in IGF-1 and/or thyroid function tests, and there was no correlation with CD4 count.

Another longitudinal study of the Hemophilia Growth and Development Study evaluated the association between plasma HIV RNA and CD4 T lymphocytes and height, weight, skeletal maturation, testosterone levels, and height velocity in children and adolescents with hemophilia. Two hundred and seven boys participated for a period of 7 years. They found that any increments in viral load led to decrease in both height and weight. Furthermore, participants with a baseline viral load >3125 copies/ml, had sig-

Table 3 Growth Disturbances and Hypothalamic–Pituitary Axis in HIV-Infected Children

Reference	N	Height SD below mean	IGF-I	Response to stimulation test
26	23	NA	Low	NA
30	9	2–5	100% normal	89% normal response
31	12	2.23	100% low	100% normal response
32	16	NA	69% low	NA

NA, not available.

nificant delays in achieving maximum height velocity and lower maximum velocity when compared with participants with lower viral load. A decrement of 100 cell/ml of CD4 was associated with a 2.51 cm decrement in height, 3.83 kg decrease in weight, and decreases in bone age and testosterone level. Baseline immune function was more important in predicting the outcome than were the changes from baseline (41) (Table 4).

The growth abnormalities in HIV-infected children were thought by many researchers to be due to inadequate caloric intake. Malnutrition and evidence of carbohydrate malabsorption as detected by lactose hydrogen breath tests and D-xylose absorption studies are common in HIV-infected children; these abnormalities do not seem to be predictive of or correlated with growth failure (42,43). Henderson et al. (44) studied the effect of tube feeding in 18 HIV-infected children who presented with growth failure. The study ranged from 2 to 24 months (median of 8.5 m). They observed increased weight, weight for height, and arm fat area. Tube feeding did not result in significant increase in height for age, or arm muscle area. This suggested that other variables are involved in growth. It is apparent that there are decrements both in weight and height in HIV-infected children, but malnutrition could not be directly tied to the growth abnormalities. One of the reasons is that abnormalities of growth have been observed in nourished HIV-infected children.

The results of the study by Johann-Liang et al. (26) demonstrated that total energy expenditure by HIV-infected children does not differ from energy expenditure of noninfected children. They found that a hypermetabolic state is not the basis for the growth impairment observed in HIV-infected children. Arpadi et al. (45) assessed whether elevated resting energy expenditure (REE) might contribute to the poor growth observed in HIV-infected children. In contrast to studies performed on HIV-infected adults, in which increased REE was observed, children with HIV-associated growth failure tended to have reduced levels of energy expenditure compared with children with normal growth rates.

We have measured serum and cerebrospinal fluid (CSF) levels of tumor necrosis factor (TNF) in children with HIV infections and without progressive encephalopathy (PE). We found that neither serum nor CSF levels of TNF were correlated with the degree of cachexia (wasting) in these children. Serum but not CSF TNF levels were increased in the children who had PE (46).

Miller et al. (47) studied the effect of protease inhibitors (PI) on growth and body composition in HIV-infected children. Sixty-seven HIV-infected children were evaluated for a period of 2.4 years. At baseline, the children were 1.2 SD below in weight and 1.4 SD below in height. The study results reconfirm the finding that in children treated with PIs there is a significant improvement in weight, moderate improvement in weight-for-height, and a borderline improvement in height. Furthermore, there was a significant decrease of virus load and improvement of CD4 T lymphocyte count.

The increased use of PIs and highly active antiretroviral therapy (HAART) has reduced both short-term morbidity and mortality in HIV-infected pediatric patients. The virus is not eradicated from the body and therapy is required for life. During the late 1990s there was a surge of reports (48–51) describing the toxicities that have emerged in adult patients who were treated with antiretroviral therapies, of which the most common is lipodystrophy syndrome (LDS). Lipodystrophy syndrome is characterized by body composition changes, including the development of an enlarged posterior cervical fat pad, increased truncal adiposity, breast enlargement, peripheral fat loss, and facial fat atrophy. This syndrome is also characterized by insulin resistance, hyperglycemia, and hypertriglyceridemia (52).

The cause of LDS remains controversial. Most studies, in adults, indicate that this syndrome is associated with the use of PIs (48,51). On the other hand, there have been some publications in which LDS has been described in patients not taking PIs and not treated with HAART protocols (53). Publications documenting prevalence of the syndrome have been conflicting as well. Some authors

Table 4 Growth Impairment in HIV-Infected Boys with Hemophilia

report a prevalence of 83% in patients taking PIs (54), yet others report a prevalence of only 12% (55). Lipid abnormalities are common and they constitute part of the syndrome. Papadopoulos et al. (56) demonstrated that hypertriglyceridemia is more common than hypercholesterolemia.

Hypertriglyceridemia has been described commonly in patients with AIDS, but it was found not to be related to degree of wasting as measured by total body potassium as an index of body cell mass (57). The role of cytokines as potential mediators of the wasting syndrome was also investigated. In AIDS, TNF and haptoglobin levels were not increased, but interferon-alpha (IFN-alpha) and C-reactive protein were. Levels of these cytokines, however, were not related to plasma cholesterol, high-density lipoprotein cholesterol, or free fatty acids. Plasma triglycerides were correlated with IFN-alpha levels only. The decrease in cholesterol and cholesterol-containing lipoprotein in AIDS precedes the appearance of hypertriglyceridemia and is unrelated to IFN-alpha or triglyceride levels (58).

Arpadi et al. (59) studied LDS in children. They evaluated 28 prepubertal children and found that 8 of 28 had extremity lipoatrophy with trunk fat accumulation. Lipodystrophy was associated with the use of Stavudine (a nucleoside reverse transcriptase inhibitor) or PIs. However, no information was available about whether these children had insulin resistance or increased risk of cardiovascular disease due to hypertriglyceridemia, similar to the presentation in adults. Wedekind and Pugatch (60) have observed this syndrome in three HIV-infected children. The patient they describe is an 8-year-old girl who was observed to have thinning of the extremities and an increase in abdominal girth.

Rietschel et al. (61) studied growth hormone dynamics in 21 HIV-infected subjects with lipodystrophy, 20 HIV-infected subjects without lipodystrophy, and 20 healthy controls. Subjects underwent an extensive metabolic and endocrine work-up that included lipid profiles, measurement of hemoglobin A1C (HgbA1C), free testosterone, viral load and CD4 cell counts, and urine free cortisol levels. Participants also underwent OGTT, GH sampling every 20 min from 2000 h to 0800 h to determine the IGF-1 axis. The body mass index (BMI) and age were similar between the subgroups; viral load and CD4 cell count were not significantly different between groups. No significant differences were observed in HgbA1C, fasting glucose, and urine free cortisol; free testosterone was normal in the lipodystrophy group and was found not to differ significantly from the control group. However, high-density lipoproteins (HDL) were decreased and triglycerides and cholesterol were increased in patients with lipodystrophy compared to the other two groups. Insulin area under curve was increased as well in the lipodystrophy group compared to the other two groups. Findings regarding GH parameters were as follows: mean overnight

GH concentrations, basal GH concentrations, and pulse amplitude were reduced in the lipodystrophy group, whereas GH pulse frequency did not differ among the three groups. Using a cutoff response of normal GH response to stimulation of 3 ng/ml, 33% of lipodystrophy group demonstrated GH response below cutoff, 10% of control had such a value, and the group of HIV-infected without lipodystrophy had 0 subjects. This study links reduced GH dynamics with increased visceral adiposity in lipodystrophic men infected with HIV.

Publications supporting the use of GH in adults have raised the question of whether HIV-infected adults with lipodystrophy would benefit from GH therapy. Lo et al. (62) evaluated eight men with HIV-associated visceral adiposity. The men were on a daily dosage of 3 mg GH for 6 months. At 6 months there was a significant decrease in posterior cervical fat pad, visceral adipose tissue, and an increase in lean body mass (63–65).

Helle et al. (66) evaluated the relation of immune parameters, virus load, clinical stage, and wasting to several parameters of the IGF system in 76 patients with HIV, of whom 37 had developed AIDS. IGF-binding protein-2 and IGF-binding-protein-3 protease activity were increased in subjects with AIDS compared with other HIV-infected individuals and controls. These parameters correlated positively with virus load and TNF-alpha and negatively to CD4 and CD8 cell counts. IGF-2 was decreased in AIDS patients compared to HIV-infected individuals and controls. Furthermore, AIDS patients with wasting had lower IGF-2 levels and higher IGF-binding-protein-2 levels than other AIDS patients.

In conclusion, HIV infection does affect growth either prenatally (low birth weight, length) or postnatally. Sometimes the effect of HIV infection can become apparent only later in childhood. Results of studies are sometimes conflicting because of differences in study protocols, medications, and treatment strategies, and due to variability among the manifestations of HIV infection in individuals. Pediatricians need to be aware that a child who is failing to grow normally might have a chronic condition such as HIV infection. Furthermore, with the advances in treatment, HIV is becoming a chronic disease with major endocrine effects on growth. Pinto et al. (67) report two HIV-infected prepubertal children who were treated with growth hormone for 3 years. In one child height increased from -3.6 SD to -2.0 SD below the mean and in the second child height increased from -4.7 SD to -1.9 SD.

Studies in adults are not always applicable to the special considerations that need to be addressed in the pediatric population. Future research and advances in the field may unmask the whole spectrum of HIV infection and its effect on growth and development.

III. ADRENAL FUNCTION

In patients with HIV infections, the adrenal gland has been a frequently studied endocrine organ. Earlier studies

concentrated on pathological evaluations of adrenal gland involvement in autopsy specimens. More recently, in vivo studies of adrenal function have been undertaken, but mostly in adults.

Pathological studies have demonstrated frequent involvement of the adrenal glands, most commonly by opportunistic infection, such as *Cytomegalovirus* (CMV), *Mycobacterium*, cryptococci, *Toxoplasma*, and *Pneumocystis*. Neoplasms, such as lymphoma and Kaposi's sarcoma, have also been shown to affect the adrenal glands. The frequency of adrenal gland involvement on autopsy material varies from 36 to 90% (68–76). A pattern of adrenal gland involvement with the medulla being the site of primary involvement and with areas of focal and generalized hemorrhage affecting both medulla and cortex initially described by Reichert et al. (68), has been repeatedly reported ever since. The adrenal gland is the most common extrapulmonary site of CMV infection (70).

Glasgow et al. (73) found CMV adrenalitis in 21 of 41 cases examined and widespread lipid depletion in most cases (a nonspecific finding on autopsies of critically ill patients). The adrenal cortical involvement was limited to 10% of the cortex in most, and fewer than 70% of all, cases. In an attempt to establish clinicopathological correlation, 32 cases were also analyzed for signs and symptoms of adrenal insufficiency. Common findings were hyponatremia (75%), hypotension (34%), hypokalemia (19%), hyperkalemia (16%), vomiting, diarrhea, and fever (percentage not specified). No patient had hyperpigmentation. Morning levels of serum cortisol were normal or elevated in five of five patients. One of two patients tested had a subnormal increase in cortisol after ACTH infusion. Despite significant pathological adrenal abnormalities, no clinical adrenal insufficiency was documented. The degree of adrenal cortical damage seen was considered less than that usually associated with adrenal insufficiency.

Pulakhandman and Dincsoy (77) found CMV infections in half of 74 autopsied cases of AIDS. Of those 37 cases, the adrenal gland was most commonly affected of all organs (84%) compared with the lungs being affected in 55% of cases. CMV inclusions were found in endothelial, cortical, and medullar cells. The CMV adrenalitis was diffuse in 10 cases and focal in 20. Analysis of the clinical data in 30 subjects revealed no findings related to the adrenal pathology, with the possible exception of serum sodium–potassium ratio of less than 30 in those with more severe adrenal pathology.

Adrenal function has been among the most commonly studied clinical endocrine parameters. Many of the signs and symptoms characteristic of adrenal insufficiency are seen in severely ill patients with HIV infections. However, definite adrenal insufficiency is rare in subjects with AIDS. The results of many studies of adrenal function in subjects with AIDS vary depending on the nature of the subjects studied, the severity of the disease, the concomitant intercurrent illnesses and medications to which they

are exposed, and the means of adrenal testing: baseline or stimulated levels of glucocorticoids and/or ACTH.

Most studies of adrenal function were performed in adults with HIV infections. Early reports documented both normal and diminished cortisol responses to ACTH in patients with AIDS (78–82). Membreno et al. (83) studied 74 randomly selected hospitalized patients with AIDS and 19 patients with AIDS-related complex (ARC). Based on subnormal cortisol responses to ACTH stimulation, four patients with AIDS were diagnosed as having adrenal insufficiency. Mean basal cortisol levels were higher in patients with AIDS than in healthy individuals, but ACTH-stimulated cortisol responses were not different from normal. However, stimulated levels of 17-deoxysteroid levels (corticosterone and 18-OH-deoxycorticosterone [18-OHDOC]) were lower than normal. Patients with ARC responded in similar manner to those with AIDS. Based on these findings the authors suggested that impaired 17-deoxysteroid levels, especially 18-OHDOC, might be a “harbinger of progressive adrenal disorder.” Plasma ACTH levels were normal in patients with adrenal insufficiency, suggesting a possible pituitary defect in these patients. Administration of the hypothalamic factor corticotropin-releasing hormone (CRH) resulted in subnormal 18-OHDOC responses in two patients. The authors advanced the hypothesis that HIV pituitary infection could lead to selective hypopituitarism and hypoadrenalism, with subsequent HIV adrenal infection leading to complete adrenal insufficiency.

Dobs et al. (84) reported normal cortisol responses to ACTH in 36 of 39 ambulatory patients with AIDS. Merenich et al. (85), although finding no clinical evidence of endocrine disorder, reported lower baseline cortisol and aldosterone and ACTH-stimulated cortisol levels in 40 symptomatic HIV-infected men compared with 27 HIV-infected age-matched control subjects; 1 patient had low cortisol and also low ACTH-stimulated aldosterone levels.

HIV-infected subjects have been reported to have lower responses in cortisol and/or ACTH to cold stress (86) or tetanus toxoid administration (87). Several investigators, however, have reported elevated baseline levels (88–90) or 24 h secretion (91) of cortisol and/or ACTH.

Catania et al. (92) compared proopiomelanocortin-derived peptides and cytokines in 80 patients with AIDS and in 80 normal subjects. Average plasma alpha-melanocyte-stimulating hormone levels were higher in the AIDS patients, but mean levels of cortisol, ACTH, beta-endorphins, interleukin-1 (IL-1), IL-6, and tumor necrosis factor were not different between the two groups.

In a prospective study of 98 HIV-infected patients Raffi et al. (93) found only 4 patients with low baseline and 7 with low ACTH-stimulated cortisol levels. Only two were believed to have adrenal insufficiency.

Eledrisi and Verghese (94) described three patients with AIDS who had clinical features suggestive of adrenal insufficiency, with a normal ACTH stimulation test. Fol-

lowing repeat testing, the diagnosis of adrenal insufficiency was made in one of the patients. The other two cases required the overnight metyrapone test to confirm the diagnosis. All three patients showed an improvement in their clinical condition following glucocorticoid therapy. Adrenal insufficiency can be a complication of HIV infection, and health care professionals should have a high index of suspicion of subtle adrenal dysfunction.

To explain further the effect of HIV infection on the hypothalamic–pituitary–adrenal (HPA) axis, Azar and Melby (95) administered ovine CRH (oCRH) to 25 ambulatory HIV-infected patients without AIDS and 10 normal volunteers. Six patients had diminished cortisol and ACTH responses to CRH, 6 had low cortisol and normal ACTH responses, and 13 had normal cortisol and ACTH responses. They suggested enhanced hypothalamic CRH production in HIV infections as a possible explanation for their results. Complex interaction between the immune and HPA axis, mediated by cytokines and perhaps lymphocyte-produced ACTH, has been postulated by some to explain the mechanisms by which HIV infections may affect adrenal function (96,97).

Hyponatremia has been reported in 30% to more than 50% of hospitalized patients with AIDS (98). In most patients, however, the hyponatremia has been thought to be caused by renal and/or gastrointestinal losses and the syndrome of inappropriate secretion of antidiuretic hormone (99–101). Hyporeninemic hypoaldosteronism (102) and also mineralocorticoid deficiency have been reported in patients with AIDS (103). However, the adrenal mineralocorticoid pathway is normal in both the baseline and ACTH-stimulated states in most HIV-infected patients (88,93).

Serum levels of dehydroepiandrosterone have been reported to be decreased in HIV-infected patients, to correlate with CD4 levels, and to be a reliable predictor of the progression of HIV infection to AIDS (104–107).

Norbiato et al. (108) reported nine patients with AIDS and characteristic clinical features of adrenal insufficiency with elevated cortisol levels, suggesting resistance to glucocorticoids by abnormal glucocorticoid receptors on lymphocytes.

In children with symptomatic HIV infections ($n = 28$), we measured morning serum cortisol levels and found that the lowest levels occurred in those with the lowest CD4 levels. ACTH tests performed on two children with the lowest cortisol levels were normal, suggesting normal adrenal glucocorticoid function. In several ill children with AIDS suspected of having adrenal insufficiency, we found normal baseline cortisol levels in all. In four subjects ACTH-stimulated cortisol responses were normal, excluding the diagnosis of adrenal insufficiency (27,109).

Oberfield et al. (110) found normal or slightly elevated baseline and ACTH-stimulated cortisol levels, with mildly diminished stimulated serum deoxycorticosterone and corticosterone levels in 12 HIV-infected children, 2

of whom were receiving ketoconazole, a drug known to inhibit adrenal function. Laue et al. (30) reported normal cortisol response to ACTH in eight of nine children with AIDS; the 1 patient with a subnormal response was receiving treatment with ketoconazole. Schwartz et al. (31) found normal cortisol responses to glucagon stimulation in 12 of 12 HIV infected children.

IV. THYROID

During the course of HIV infections, the thyroid gland has been reported to be affected either directly or indirectly. The mechanisms that can contribute to thyroid gland involvement include infections (111,112), neoplastic processes (113), changes in thyroid hormone secretion and binding (114–116), and drugs used to treat HIV-infected patients (117–119).

In autopsy specimens, thyroid pathology has been described in 10–14% of cases analyzed. Cytomegalovirus inclusions, Kaposi's sarcoma, and cryptococcal infections in the thyroid have been reported (70–72,111,119). Fine-needle aspiration of an area of decreased thyroid uptake in an individual with biochemical but not clinical evidence of hypothyroidism revealed *Pneumocystis carinii* infection (112). Following antibiotic therapy, the goiter decreased in size and thyroid function tests became normal.

Clinically significant evidence of hypothyroidism in individuals with HIV disease has been rare. However, many reports have attested to altered biochemical parameters of thyroid function in subjects with HIV infections, especially AIDS. The incidence of clinical or subclinical hypothyroidism in studies of large series of patients was as low as 1% (114,115). The most consistent abnormalities described have been low levels of triiodothyronine (T3), especially in the more severely ill patients, and elevated levels of thyroxine-binding globulin (TBG) (85,114–116,120–124). The lowering of serum T3 levels suggested biochemical thyroid picture noted in ill patients with nonthyroid disease. Some authors have correlated low T3 levels with severity of the critical illness and mortality among hospitalized patients with AIDS (120,122). In a minority of patients with symptomatic HIV infections, exaggerated TSH responses to thyrotropin-releasing hormone (TRH) administration have been reported, suggesting a so-called hypothyroid-like regulation of the hypothalamic–pituitary–thyroid axis in subjects with stable HIV infections (85,123).

Blethen et al. (125) studied the effect of perinatally acquired HIV infection on thyroid function (Table 5). They evaluated 53 children born to HIV-infected mothers and 17 healthy controls. T4, T3, TSH, and TBG levels were obtained from prepubertal healthy controls and the HIV-infected children. The group of HIV-infected was organized into subgroups according to the CDC criteria. Of the 53 children, 16 had maternally-derived antibodies to HIV and no evidence of HIV infection (13 of them sero-reverted), 6 were HIV antibody positive, 8 were HIV

Table 5 Thyroid Abnormalities Observed in HIV-Infected Children

Reference	N	Diagnosis	T4 (FT4)	T3 (TT3)	TSH	TBG
132	53	23/53: AIDS	Increased in 9%	Low in 9%	Increased in 22%	Increased in 44%
33	9	HIV-positive	NA	NA	NA	Increased in 100%
134	56	Perinatal HIV	FT4: decreased	TT3: decreased	Increased	Increased

NA, not available.

antibody positive with nonspecific symptoms such as fever or "failure to thrive," and 23 were classified with AIDS. In the subgroup of children with AIDS, 15 of 23 had at least one measure of thyroid function outside of the normal range for healthy children. The abnormalities observed were elevated TBG in 10, elevated TSH in 5 (none of these children had goiter or antithyroid antibodies), low T3 in 2, and elevated T4 in 2. In the subgroup of P1 and P2, only two patients had abnormal thyroid levels, and each was acutely ill at the time. The findings of this study differ from what is known in HIV-infected adults in two aspects. First, in stage P1 and P2 TBG levels remain normal, whereas in adults TBG are higher even at stage P1 (120). Second, in adults the increase in TBG is followed by an increase of T4. In children with AIDS, T4 levels were not increased compared to healthy children or to other HIV-infected children.

The presence of antithyroid autoantibodies in perinatally HIV-infected children was evaluated by Fundaro et al. (126) in 80 children: 58 born to HIV-infected mothers and 22 healthy children. Eighteen of 58 children born to HIV-infected mothers seroreverted and 40 children remained seropositive and were classified according to the CDC clinical criteria: 7 asymptomatic (stage N), and 33 symptomatic (stage A, B, C). In this study they evaluated T3, T4, TSH, free T3 (FT3), FT4, TSH, antithyroglobulin autoantibodies (TGAb), and antithyroid peroxidase autoantibodies (TPOAb). None of the children had either clinical symptoms of thyroid disease or enlargement of the gland at the time of the study. Of the symptomatic children 34% were TgAb-positive and all were TPOAb-negative. Antibodies were not found in any of the asymptomatic children, seroreverted subjects, or healthy controls. The finding of autoantibodies was not correlated with worsening immune stages and was not associated with clinical signs or symptoms of thyroiditis. Increased TSH values were observed more frequently in the symptomatic HIV-infected children. When this group was subclassified according to immune status, a positive correlation was found between immune status and TSH values. High TSH values were found more frequently in the stages with moderate or severe immunosuppression. In the healthy control group there was no increase of TBG, but an increase of TBG was observed in 68% of HIV-infected children.

Chiarelli et al. (127) studied retrospectively 109 prepubertal children (56 children with perinatal HIV infection

and 53 healthy age-matched children) for the following: total T4 (TT4), FT4, total T3 (TT3), FT3, reverse triiodothyronine (rT3), TSH, thyroglobulin (TG), TBG, CD4+ cell counts, and viral load, as well as antibodies: antithyroglobulin, antimicrosomal, thyroid peroxidase, and thyrotropin receptor. They found that TT3, TT4, FT4, and TG were significantly reduced in children with HIV infection when compared with controls, and that rT3, TBG, and TSH were increased. In all determinations autoantibodies were negative in the HIV-infected children. Their findings suggest that thyroid dysfunction precedes the worsening of the clinical course of the disease in HIV-infected children. Thyroid dysfunction correlates with disease severity and it can be observed early in the course of perinatal HIV infection.

We observed one child with AIDS and evidence of primary hypothyroidism in whom treatment with replacement doses of thyroid hormone resulted in improvement in growth velocity (128). In children with symptomatic HIV infections we noted transiently abnormal thyroid function test results in 3 of 20 patients. Serum levels of T3 and free thyroxine did correlate with an index of weight retardation: chronological age minus weight age (27). Hypothyroidism in one of nine short children with AIDS, along with elevated TBG levels in all nine, and evidence of possible central hypothyroidism (based on timed hourly TSH measurements), were reported by Laue et al. (30). Among 12 clinically and biochemical euthyroid children with AIDS, Schwartz et al. (31) reported elevated TSH responses to TRH in 5.

The results of the Hemophilia Growth and Development Study (40) revealed that in 99% of 321 subjects, including HIV-negative and HIV-positive subgroups, thyroid function tests (T4, T3, TSH) were normal for age. Subtle abnormalities of thyroid function were not investigated in this study, but even in HIV-positive boys with growth abnormalities thyroid function was normal for age. In conclusion, thyroid function can be altered in the course of HIV infection. The results from the different studies are somewhat inconsistent. The most common findings were decreased T3 and elevated TBG values.

V. GONADS

The vast majority of information regarding gonadal function in HIV-infected individuals is from studies performed

in adult men and women and from autopsy material derived from adult men. Reports have included normal (68) to atrophic testicular volume (70–72), as well as evidence of infiltration by CMV (68,70,129), Kaposi's sarcoma (68), toxoplasmosis (129,130), tuberculosis (130), retrovirus-like particles (131), and neoplasm (132). On histological examination, the testes exhibit evidence of peritubular fibrosis, arrest of spermatogenesis, germ cell degeneration and loss of seminiferous tubules and basement membranes, epididymal obstruction, prostatic inclusion, and Leydig cell atrophy (68,70–72,133–137). The presence of focal HIV-associated proteins, such as HIV P17, was documented by anti-HIV P17 monoclonal antibodies in testes and prostate (136). The possibility of immune-mediated gonadal destruction was not substantiated in one study in which immune complex deposits were found not to be increased in the testes of homosexual AIDS patients compared with those of a control group of heterosexual men without AIDS (135).

Studies of the effects of HIV infection on hypothalamic–pituitary–gonadal function have been performed mostly in adult men. Most have shown some degree of hypogonadism, especially in the most severely affected individuals. Conflicting data exist regarding the causes of the hypogonadism as primary, gonadal, or hypothalamic–pituitary in origin. Clinical evidence of hypogonadism as reflected by a history of decreased libido and impotence was reported in 28 of 42 and 14 of 42 ambulatory patients with AIDS, respectively (84). Of the HIV-infected men, 38% had low serum testosterone levels, the majority having low baseline serum gonadotropin levels. Human chorionic gonadotropin stimulation in two men resulted in normal testosterone responses, attesting to a normal testicular ability to produce testosterone. In seven of eight men, gonadotropin-releasing hormone (GnRH) stimulation resulted in normal gonadotropin responses, suggesting that the gonadal dysfunction was hypothalamic in origin. In contrast, Croxson et al. (138) described low testosterone levels accompanied by high levels of LH and follicle-stimulating hormone (FSH) in patients with AIDS, suggestive of the diagnosis of primary hypogonadism.

Rietschel et al. (139) investigated the prevalence of hypogonadism in HIV-infected men receiving HAART, or PI, nucleoside reverse transcriptase inhibitor, or nonnucleoside reverse transcriptase inhibitor compared to healthy controls. The prevalence of hypogonadism was ~20% in all medication groups. Testosterone levels and free testosterone levels were not different between the groups.

Decreased basal and also mean 24 h plasma testosterone levels have been reported by some (93,110). One study has documented elevated free testosterone levels and exaggerated LH responses to GnRH (85). Martin et al. (140) reported that HIV-positive patients had 39–51% higher levels of sex-steroid-binding proteins than HIV-negative control subjects. Isolated LH deficiency (141) and transient gynecomastia (142) have been described.

Grinspoon and others (144,146) have studied hormonal changes in patients with HIV infection and lipodystrophy. In men with lipodystrophy, with hypogonadism, it has been shown that the administration of testosterone led to improvements in lean body mass, indexes of insulin sensitivity, and the sense of wellbeing. HIV-infected women with lipodystrophy have increased androgen levels (147). Thirty-nine women were evaluated: 9 HIV-positive with lipodystrophy, 14 HIV-positive without lipodystrophy, and 16 healthy age- and BMI-matched women served as controls. Total testosterone and free testosterone levels were increased in the HIV-positive group. Sex-hormone-binding globulin levels were not significantly different between the HIV-positive group and control, but were significantly lower in the lipodystrophic group than in the HIV-positive patients without lipodystrophy.

Gonadal function has not been systematically investigated in children with HIV infections. Gertner et al. (39) documents pubertal delay accompanied by bone age delay in HIV-positive poorly growing boys with hemophilia. de Martino et al. (148) studied the onset of puberty and its progression in 212 (107 girls; 105 boys) children with perinatal HIV infection. The age of onset of puberty in girls was delayed by about 2 years and 12–15 months in boys. The progression of puberty was also prolonged in both girls and boys. More studies are needed to identify and examine gonadal function in children of all ages with HIV infections.

VI. PANCREAS

Anatomical evidence for pancreatic involvement by HIV or associated organisms has been more common than clinical evidence of either exocrine or endocrine pancreatic deficiencies (149).

Pancreatic lesions as a result of HIV, CMV, toxoplasmosis, Kaposi's sarcoma, lymphoma, and pancreatitis have been reported in autopsy material in approximately half of the patients with AIDS. The most frequent damage to the pancreas in AIDS patients is drug-induced, especially by the nucleoside analog Didanosine (DDI) and pentamidine used for prophylaxis of *Pneumocystis carinii* (71,72,150). Clinical correlation in one of these studies (150) revealed no evidence of hyperglycemia. One report described the development of insulin-dependent diabetes mellitus in two HIV-infected, drug-addicted subjects in whom neither anti-insulin nor anti-islet-cell antibodies were detected (151). In most HIV-infected patients normal glucose levels were found (84). Hommes et al. (152) used the euglycemic clamp technique to measure insulin sensitivity and clearance in 10 HIV-infected stable patients and 10 healthy control subjects. They found increased rates of insulin clearance and increased peripheral tissue sensitivity in the HIV-infected men.

Chehter et al. (153) conducted a prospective study of 109 postmortem AIDS patients and 38 controls. Pancreatic involvement was observed in 91% of the cases, but none was symptomatic. The changes, based on morphological characteristics, had no correlation with clinical or laboratory features.

Sentongo et al. (154) studied the association among steatorrhea, growth, and immunological status in children with perinatally acquired HIV infection. They postulated that the steatorrhea observed in HIV-infected children was due to exocrine pancreatic insufficiency (EPI). In their sample of 44 children with perinatally acquired HIV infection, there was a high prevalence of steatorrhea (39%) that was neither secondary to EPI nor associated with impaired growth, HIV RNA virus load, CD4 status, or the type of antiviral regimen used. The clinical significance of steatorrhea remained unclear.

Clinical presentation of acute pancreatitis in HIV-infected patients is similar to that of immunocompetent patients. Evidence of pancreatitis has not generally been reported, although Zazzo et al. (155), in a prospective study of 35 consecutive patients with AIDS admitted to an intensive care unit, found evidence of acute pancreatitis with elevated levels of amylase and lipase in 16. Of these patients, eight died and had documentation on autopsy of pancreatic infection by CMV, *Candida*, and cryptococci. Because of the lack of sufficient clinical warning signs of pancreatitis, the authors suggest laboratory measurements of amylase and lipase in critically ill HIV-infected patients. Pancreatitis has also been reported in one 3-year-old HIV-positive child (156,157).

Miller et al. (158) reported that 9 of 53 children with AIDS developed acute pancreatitis during a 6 year period. The risk of pancreatitis was greatest in patients who received pentamidine and had CD4 counts <100 cell/mm.

In conclusion, the most consistent finding in acute pancreatitis in HIV-infected patients is serum amylase and lipase values greater than three times the upper limit of normal (157).

VII. PARATHYROID

Lesions of the parathyroid glands have been reported in autopsy studies (70,72), but parathyroid dysfunction has been reported extremely infrequently. Hypercalcemia with low serum levels of parathyroid hormone and calcitriol has been described in two patients with AIDS and disseminated CMV infection (159). The hypercalcemia improved with calcitriol treatment in one patient. It was postulated by the authors that the hypercalcemia might have been caused by increased osteoclast-mediated bone resorption resulting from disseminated CMV infection with accompanying renal insufficiency. Six patients with AIDS-associated lymphoma were found to have hypercalcemia ($n = 4$) or hypercalcuria ($n = 2$), presumably because of the

deregulated synthesis of a compound such as 1,25-dihydroxyvitamin D (160).

Aukurst et al. (161) report that HIV patients with advanced clinical disease have a decreased or normal serum calcium, decreased PTH, and decreased serum 1,25-(OH)2D. They also found a decrease of osteocalcin and elevated C-telopeptide level. These findings suggest that during advanced HIV-related disease there is a disturbance of bone metabolism. This disturbance was correlated with increased activity of the TNF system. Patients with advanced HIV-related disease receiving HAART therapy had a marked rise in serum osteocalcin. This finding suggests a synchronization of the bone remodeling process during the HAART therapy. It is unclear whether the benefit is due to the HAART, the decrease of TNF, or decreased viral load.

VIII. PROLACTIN

Because of the potential immune-regulatory property of prolactin (162,163), serum prolactin levels were studied in HIV-infected individuals. Compared with HIV-negative homosexual, bisexual, or heterosexual controls, serum prolactin levels were normal in HIV-infected men, including those with AIDS (164,165).

Hutchinson et al. (166) reported four women with galactorrhea and hyperprolactinemia as an isolated endocrine abnormality following use of PIs. The mechanism underlying these findings is unclear, yet it is known that the use of PI has been linked to other endocrine abnormalities such as hyperlipidemia, diabetes mellitus, and insulin resistance.

IX. HYPOTHALAMUS AND PITUITARY

The effects of HIV infections on the central nervous system have been the subjects of numerous reports (167). Nevertheless, specific pathological documentation of lesions in the hypothalamus or pituitary of affected individuals has been rare. So-called panhypopituitarism secondary to toxoplasmosis (168) and posterior pituitary lesions in HIV-infected children with disseminated CMV (76) have been reported.

Yanovski et al. (169) postulated that the increase of abdominal adipose tissue found in HIV-infected subjects treated with PIs could be due to abnormalities in adrenal function. They designed a study to evaluate the HPA, in HIV-infected men and women receiving the PI regimen, patients with Cushing syndrome, and healthy controls. Patients on the PI regimen had normal diurnal cortisol secretion, cortisol secretory dynamics after oCRH, cortisol-binding globulin levels, and glucocorticoid number and affinity. The abnormalities noted were increased basal and CRH-stimulated plasma ACTH and 24 h urinary 17-

OHCS excretion, and decreased urinary free cortisol. The study design did not include any HIV-infected patients who were not receiving PI treatment; therefore the changes observed, although coinciding with PI treatment, could not be solely ascribed to the use of PI. They suggested that the increased intra-abdominal adiposity, dyslipidemia, and insulin resistance without total body weight gain was a distinct yet undefined form of hypercortisolism unrelated to HPA axis.

Evidence of specific hypothalamic–pituitary dysfunction in endocrine organs was reviewed in previous sections.

X. ENDOCRINE ALTERATIONS SECONDARY TO TREATMENT

In HIV-infected children and adults, the effects of the various treatment regimens employed may also cause endocrine dysfunction. These effects must be separated from endocrine defects caused by HIV and related opportunistic infections.

Hypothyroidism has been reported as a result of drugs that affect cytochrome P450 enzyme systems, such as ketoconazole (117,170) and rifampin (118), as well as interferon treatment (171,172).

Hypoadrenalism may result from ketoconazole (173–175) or rifampin (176,177) treatment. Hypogonadism and gynecomastia in men have also been noted during ketoconazole treatment (178,179). Hypoglycemia has been reported in patients with AIDS treated with pentamidine (180–183) and trimethoprim–sulfamethoxazole (184). Hyponatremia has been associated with pentamidine (185) and vidarabine (186) therapy. Hypocalcemic tetany secondary to magnesium loss has been noted during amphotericin B and aminoglycoside treatment (187). Hyperkalemia was reported in a patient with AIDS to be a result of the sodium channel inhibitory effects of trimethoprim (188).

With the increased use of PI in the treatment of HIV-infected adults, a number of studies have reported LDS and hyperinsulinemia (49,50,54,55). It is unclear whether or how PI treatment causes LDS and hyperglycemia. Hadigan et al. (189) reported hyperinsulinemia and increased truncal adiposity in HIV-infected men receiving a nucleoside reverse transcriptase protocol who were not receiving PI therapy. They found that testosterone replacement in hypogonadal men improved insulin sensitivity.

There are some reports in the literature on the development of diabetes mellitus in HIV-infected individuals (190–192). Abdel-Khalek et al. (191) reported new-onset diabetes mellitus in an 18-year-old girl with HIV. She presented with polydipsia and polyuria with nonketotic hyperglycemia. Pancreatic islet cell antibodies were negative and she had normal basal C-peptide levels, normal serum lipase and amylase, and normal BMI. She was treated initially with 1.15–1.38 U/kg/day; her HbA1c at diagnosis

was 7.6%. Later, she had hyperglycemia with serum glucose concentrations above 400 mg/dl and her HbA1c value rose to 13.6%; she required an insulin dosage of 2.22 U/kg/d.

In another publication, Lee et al. (192) reported an HIV-positive patient who presented with a random blood glucose level of 493.2 mg/dl and a 3 week history of polyuria, polydipsia, and polyphagia, with weight loss, fatigue, weakness, and blurry vision. The patient had no symptoms of infection at presentation. The patient was treated with oral hypoglycemic agents and insulin. These medications were discontinued gradually as his blood glucose level declined. Significant decrease in blood glucose values was observed when the patient discontinued all antiretroviral medications. Overall, the incidence of diabetes has not increased substantially. Some reports associate the development of diabetes with the use of PI (190–192). The likely explanation seems to be increase in insulin resistance during PI treatment only (192).

XI. FUTURE HORMONAL THERAPY IN HIV INFECTIONS

Considerable attention has focused on reversal of the weight loss and wasting accompanying AIDS. Therapeutic strategies have involved the use of appetite stimulants, such as megestrol acetate; anticytokine-directed supplements, such as dietary *N*-3 fatty acids; anabolic agents, such as steroids and growth hormone; and metabolic inhibitors, such as hydrazine sulfate (193,194).

The most extensive experience with megestrol acetate in adults has been summarized elsewhere (195–197). Clarick et al. (198) evaluated 19 HIV-infected children (11 boys and 8 girls) with a median age of 89 months (range, 28–192) who were treated with megestrol acetate for a median duration of 7 months (range, 3–11 months). Megestrol acetate treatment led to significant weight gain without linear growth acceleration.

Growth hormone and IGF-1 have been utilized in HIV-infected patients. In a prospective double-blind clinical trial, five patients each were assigned randomly to treatment with GH at either 5.0 or 2.5 mg every other day (199). Of the 10, 3 withdrew because of opportunistic infections. In the remaining patients, all of whom also received zidovudine, the higher dosages of GH reversed the pretreatment weight loss by increasing lean body mass and total body water, and decreasing total body fat and urinary nitrogen excretion. Muscle power and endurance also improved. Fasting plasma glucose, insulin, and C peptide levels increased in all. CD4 cell counts did not change. During treatment one patient became p24 antigen-positive. The short-term beneficial effects were noted only with use of the higher GH dosages.

In a short-term, carefully conducted clinical trial, Mulligan et al. (200) administered GH, 0.1 mg/kg/day for

7 days, to six HIV-positive men with an average weight loss of 19% and six healthy HIV-negative subjects. Treatment resulted in an increase in body weight, nitrogen retention, increased energy expenditure, lipid oxidation, and glucose flux, and decreased protein oxidation in both groups. These short-term effects of increases in protein anabolism and protein-sparing lipid oxidation, should they be sustained during long-term treatment, were postulated to result in increased total body cell mass.

Lieberman et al. (201) found that a single injection of GH administered to 21 patients with AIDS resulted in a smaller increase in IGF-1 than in 23 age-matched controls, suggesting partial resistance to GH in AIDS. In 10 subjects low-dosage but not high-dosage IGF-1 administration for 10 days resulted in only a transient anabolic effect, as demonstrated by a transient increase in nitrogen retention.

Waters et al. (63) studied 60 patients with AIDS wasting receiving 1.4 mg GH once a day, 5 mg IGF-1 twice a day, 5 mg IGF-1 twice a day and 1.4 mg GH once a day, and a placebo group. At 6 weeks, lean body mass increased and fat mass decreased in the groups receiving GH, IGF-1, or both. The improvements observed persisted at 12 weeks only in the group receiving GH and IGF-1 therapy. Ellis et al. (64) conducted a double-blind, placebo-controlled study in which 44 HIV-infected men received GH/IGF-1 treatment and 22 HIV-infected men received placebo treatment. The treatment group received 0.34 mg GH twice a day and 5.0 mg IGF-1 twice a day. The study duration was 12 weeks. At 6 weeks, GH/IGF-1 group had a significant increase in fat free-mass and a substantial decrease in fat. At 12 weeks, the loss of fat remained significant, whereas the increase in fat-free mass was lost in many of the subjects. The loss of body fat was not observed in the placebo group.

Lo et al. (62) studied the effect of 3 mg GH daily in eight men with HIV-associated fat accumulation. In six subjects who completed 6 months of study, GH treatment decreased total body fat and increased lean body mass. At 1 month of treatment insulin sensitivity and glucose tolerance worsened, but these improved towards baseline by 6 months.

Several studies of GH treatment are underway. Pinto et al. (67) reported two HIV-infected prepubertal children who were treated with GH for 3 years. In one child height increased from -3.6 SD to -2.0 SD below the mean and in the second child height increased from -4.7 SD to -1.9 SD.

Gonadal steroid hormone replacement has been used with increasing success in HIV-positive patients. Decreases in gonadal function have been widely reported in adults. Men with AIDS had a significant reduction in testosterone secretion despite normal gonadotropin response to testing.

Grinspoon et al. (144,146,202) report the beneficial effect of exogenous testosterone administration for hy-

po gonadal men with lipodystrophy. Patients receiving therapy had an increase in lean body mass, weight gain, and a decrease in the incidence of depression. Overall, their wellbeing, as measured by the Beck Depression Inventory, improved with testosterone replacement therapy. In women, administration of a lower dosage of testosterone (150 and 300 $\mu\text{g}/\text{day}$) led to normalization of serum testosterone levels, weight gain, and improvement in their quality of life (203).

Studies are underway to evaluate the long-term complications associated with PI therapy. As reported in other sections, the LDS might be associated with progression of atherosclerosis, cardiovascular disease, and complications that can be attributed to hyperinsulinemia. As the management of HIV-infected individuals continues to improve, we can look forward to newer, more innovative, and specifically targeted interventions to address even the hormonal dysfunction of these patients.

XII. CONCLUSION

From the initial description in the literature on June 5th, 1981, there have been many advances in the field of HIV/AIDS. There have been numerous advances in the areas of epidemiology, management, prevention, and prophylaxis of HIV disease globally. Much effort is currently being focused on prevention strategies, with vaccines playing a potentially pivotal role. Some phase III trials of vaccines have already started. Yet HIV/AIDS continues to spread. Reports indicate that rate of HIV infection from heterosexual sex is soaring among US teenaged girls. Clinicians need to promote intensive, focused, appropriate HIV prevention efforts among adolescent women.

Endocrine effects of HIV infection are not often easily recognized by clinical signs and/or symptoms, or baseline hormonal evaluation, or even stimulation tests. Therefore, health care providers need to have a high index of suspicion for possible endocrine abnormalities secondary to HIV infection and/or its treatment. Persistent and careful investigations may eventually disclose the endocrine abnormalities, the treatment of which should improve patients' quality of life.

The evaluation and treatment of endocrine alterations in subjects with HIV infections will continue to become an increasingly important clinical and investigational area of pediatric endocrinology.

Hypertension in Children: Endocrine Considerations

Julie R. Ingelfinger

Harvard Medical School, Massachusetts General Hospital for Children, Massachusetts General Hospital, and New England Journal of Medicine, Boston, Massachusetts, U.S.A.

I. INTRODUCTION

This chapter reviews pediatric hypertension caused either by endocrine abnormalities or by mutations in genes modulated by endocrine systems. Endocrine-related hypertension has been thought to account for a minority of those cases of childhood hypertension due to definable causes. However, considering an endocrine cause whenever a child presents with hypertension is mandatory, since certain identifiable conditions will otherwise be overlooked. Delineating the pathogenesis and pathophysiology of hypertension is particularly important in managing a child or adolescent with elevated blood pressure; the more specific the diagnosis, the less the likelihood of prescribing empirical and often futile regimens. The more focused treatment can be, the less the risk of assigning a child to nonspecific pharmacotherapy, with unknown long-term effects, including those on growth and development.

II. NORMAL BLOOD PRESSURE AND ITS DEFINITION

Hypertension is defined by levels above the 95th centile for age, taking into consideration height and weight centiles as well. To facilitate categorizing blood pressure as normal or elevated, the National Heart, Lung, and Blood Institute (NHLBI) Task Force in Blood Pressure Control in Childhood issued an update in 1996 that provides tables according to height centiles (Table 1) (1–3). The Task Force data, pooled from measurements in over 12,000 pediatric subjects, is helpful as a guideline. But the aware clinician must understand that these norms are based on in-office seated blood pressure determinations and do not take into account changes with posture, activity, time of day, or various stresses that occur in daily life (4–6).

If one suspects secondary hypertension, a problem in interpreting an in-office blood pressure by norms is that

epidemiologically based normal blood pressure data do not reflect what may occur in an abnormal state (5). For example, if one looks at blood pressure measurements among children and adolescents with renovascular hypertension, as was done by Hiner and Falkner (6), one sees that virtually all subjects have markedly elevated blood pressure. Furthermore, the diurnal pattern of blood pressure elevation in some forms of hypertension may be importantly distinct from a normal blood pressure pattern.

In recent years, much has been learned both about normal blood pressure in disparate ethnic groups and the circadian rhythm of blood pressure response. The reader is referred to reviews on the subject (7–12).

III. CAUSES OF HYPERTENSION

As noted in the Second Task Force report (2), most pediatric hypertension is not endocrine in nature, yet considering definable causes that are related to adrenal, thyroid, pituitary and other endocrine organs may identify a cause for hypertension. Children with specific endocrine disorders and syndromes may have a known increased risk of hypertension and will be able to benefit from specific therapy. Table 2a lists the most common causes of hypertension in each childhood age group; Table 2b lists those endocrine causes of hypertension most commonly seen in children.

IV. COMPLICATIONS OF HYPERTENSION: PATTERNS AND DIAGNOSIS

By the time a child is referred to a pediatric endocrinologist for evaluation of hypertension, it is likely that she or he has already been assessed by a primary care physician, and, possibly, by other specialists such as a pediatric cardiologist or nephrologist. Thus, some referrals

will be made for children who have findings in their history, physical examination, or laboratory data that specifically suggest an endocrine cause of hypertension. Other referrals, however, will be de novo, or will be children who have been found to have hypertension in the course of treatment or evaluation for a known endocrinopathy. Prompt and focused evaluation of elevated blood pressure is critical, given the potential complications of pediatric hypertension.

Certain findings in a hypertensive child imply a role for an endocrinologist. An endocrinologist's first approach should be to seek historical facts that suggest a familial endocrinopathy associated with hypertension, the taking of medications that would be associated with endocrine-mediated hypertension (e.g., steroids or sympathomimetic agents), or an endocrine diagnosis known to be associated with hypertension (e.g., Turner syndrome). Physical examination will, of course, focus the evaluation further, in that findings may clearly suggest a particular endocrine diagnosis (clinical hyper- or hypothyroidism, Cushing syndrome). The blood pressure should be determined in both arms and one leg, and postural changes should be noted. Blood pressure after exercise, as well as at several points in the day, may also be helpful. Ambulatory blood pressure monitoring (ABPM) may be helpful in assessing circadian rhythm and particular patterns that could be associated with endocrine hypertension.

Laboratory data help to hone in on specific forms of hypertension. Thus, the initial endocrine assessment should focus on seeking signs of catecholamine-mediated hypertension, glucocorticoid-related hypertension, or thyroid-mediated hypertension (which are discussed at length in other chapters). Next, a plasma renin level, examined

together with a measure of sodium excretion and a plasma potassium level, should provide a basis for a focused endocrine assessment (13–16). A high plasma renin level is unlikely to be associated with endocrine hypertension, although secondary aldosteronism will accompany renovascular hypertension. If plasma renin activity or concentration is low, one should then consider an underlying hormonal basis. As can be seen in Table 3, those forms of low-renin hypertension that have been fully defined are due to mutations on autosomal chromosomes and thus occur equally in males and females (16). Each will be considered in turn. It has been proposed that, in fact, many more cases of so-called primary hypertension may be associated with partial defects in steroidogenesis or factors that control steroid effects.

The diagnostic considerations include a variety of inherited disorders that have a very low plasma renin activity as a cardinal feature. These include steroid enzyme

Table 3 Low-Renin Hypertension

Signs and symptoms	Hormonal findings	Source	Genetics	Comment
<i>Steroidogenic enzyme defects</i>				
Steroid 11 β -hydroxylase deficiency	↓ PRA and aldo; high serum androgens/urine 17 ketosteroids; elevated DOC and 11-deoxycortisol	Adrenal: zona fasciculata	CYP11B1 mutation (encodes cytochrome P ₄₅₀ 11 β 18 of ZF); impairs synthesis of cortisol and 17-deoxysteroids	Hypertensive virilizing CAH; most patients identified by time they are hypertensive. Increased BP may also occur from medication side effects. CAH with male pseudohermaphroditism; female external genital phenotype in males; primary amenorrhea in females
Steroid 11 α -hydroxylase/17,20-lyase deficiency	↓ PRA and aldo; low serum/urinary 17-hydroxysteroids; decreased cortisol, ↑ corticosterone (B), and DOC in plasma; serum androgens and estrogens very low; serum gonadotrophins very high	Adrenal: zona fasciculata; Gonadal: interstitial cells (Leydig's in testis; theca in ovary)	CYP17 mutation (encodes cytochrome P ₄₅₀ C17) impairs cortisol and sex steroid production	
<i>Hyperaldosteronism</i>				
Primary aldosteronism	↓ PRA; ↑ plasma aldosterone, 18-OH- and 18 oxoF; normal 18-OH/aldo ratio	Adrenal adenoma: clear cell tumor with suppression of ipsilateral ZG	Unknown; very rare in children; female:male ratio is 2.5–3/1	Conn syndrome with aldo producing adenoma; muscle weakness and low K ⁺ in sodium-replete state As above
Adrenocortical hyperplasia	As above; source of hormone established by radiology or scans	Adrenal: focal or diffuse adrenal cortical hyperplasia	Unknown	As above
Idiopathic primary aldosteronism	High plasma aldo; elevated 18-OHF/aldo ratio	Adrenal: hyperactivity of ZG of adrenal cortex	Unknown	As above
Deoxycorticosterone-producing tumor	High plasma DOC	Adrenal: adenoma/carcinoma	Unknown	As above
<i>Dexamethasone-suppressible hypertension</i>				
Glucocorticoid-remediable aldosteronism (GRA)	Plasma and urinary aldo responsive to ACTH; dexamethasone suppressible within 48 h; ↑ urine and plasma 18OHS, 18-OHF, and 18 oxoF	Adrenal: abnormal presence of enzymatic activity in adrenal ZF; allowing completion of aldo synthesis from 17-deoxy steroids	Chimeric gene that is expressed at high level in ZF (regulated like CYP11B1) and has 18-oxidase activity (CYP11B2 functionality)	Hypokalemia in sodium-replete state
<i>Apparent mineralocorticoid excess (AME)</i>				
	↑ plasma ACTH and secretory rates of all corticosteroids; nl serum F (delayed plasma clearance)	↑ plasma F bioactive in periphery (F→B) of bi-dir. 11 β OHSD or slow clearance by 5 α / β reduction to allo dihydro-F	Type 2 11 β OHSD mutations	Cardiac conduction changes; LVH, vessel remodeling; some calcium abnormalities; nephrocalcinosis; rickets
<i>Nonsteroidal defects</i>				
Liddle syndrome	Low plasma renin, low or normal K ⁺ ; negligible urinary aldosterone	Not a disorder of steroidogenesis but of transport	Autosomal dominant abnormality in epithelial sodium transporter, ENaC, in which channel is constitutively active	Responds to triamterene
Pseudohypoaldosteronism II-Gordon syndrome	Low plasma renin, normal or elevated K ⁺	Not a disorder of steroidogenesis but of transport	Autosomal dominant abnormality in WNK1 or WNK4	Responds to thiazides

Source: Adapted from Ref. 142.

abnormalities, as well as abnormalities in transporters or in modulating genes. Yiu et al. (13) developed an algorithm for thinking about these entities, which are accompanied by low plasma renin activity (Fig. 1). The algorithm is based on the fact that a number of hypertensive syndromes share a low plasma renin as a common feature. Most are inherited either as an autosomal dominant, in which case family history is positive, or as an autosomal recessive, in which case family history is lacking.

V. STEROIDOGENIC ENZYME DEFECTS

As noted in Chapters 6 and 7, steroids are produced in the adrenal cortex, which is divided into zones: the zona glomerulosa (ZG, outer zone), zona fasciculata (ZF, middle zone), and zona reticularis (ZR, inner zone). Normally, the ZG and ZF are functionally separate. Cortisol is synthesized under the control of adrenocorticotropin (ACTH) in the ZF, while aldosterone is synthesized primarily under the influence of angiotensin II and potassium in the ZG. ACTH normally has only a secondary effect on the synthesis of aldosterone. However, when any of the enzymes that control cortisol biosynthesis is defective or acts abnormally, the feedback relationships between the hypophysis and the adrenal are interrupted, with a resultant increase in plasma ACTH. Figure 2 depicts steroidogenesis, indicating enzyme defects that can be associated with hypertension, and Figure 3 indicates regulation of aldosterone biosynthesis.

Congenital adrenal hyperplasia (CAH) is the general term used to describe enzyme defects that can occur in steroid biosynthesis, each causing a characteristic profile of plasma and urinary steroids together with a specific clinical manifestation (15,16). These defects all are autosomal recessive, have varying frequency, and have a spectrum of clinical manifestations. Any of the enzymes that are part of the pathways of steroidogenesis may have a mutation, most commonly 21-hydroxylase, not generally associated with hypertension. Enzymes with mutations that are associated with hypertension include (in order of frequency) 11- β hydroxylase >> 3 β -hydroxysteroid dehydrogenase>>>17 α -hydroxylase and cholesterol desmolase. A net salt-retaining propensity and hypertension occur in patients with the 11- β hydroxylase and 3 β -hydroxysteroid dehydrogenase defects. It is also important to remember that individuals with CAH may develop hypertension owing to overzealous replacement therapy.

A. Steroid 11- β -Hydroxylase Deficiency

Hypertension is one of the cardinal features of 11- β hydroxylase deficiency (16–21), as the abnormal adrenal steroid pattern leads to mineralocorticoid excess, the physiology of which includes decreased renal sodium excretion with consequent volume expansion and hypertension.

The virilization seen in 11- β -hydroxylase deficiency and its management are discussed at length in Chapters 6 and 7; virilization is universal in this condition. Unless the mother is treated during pregnancy, an affected female fetus will have ambiguous or masculinized external genitalia, owing to excess of adrenal androgens, while the baby's internal organs will be normal. After birth affected males and females develop progressive penile or clitoral enlargement, respectively, along with rapid somatic growth. If appropriate treatment is not initiated, early closure of epiphyses will lead to short final stature.

Hypertension is common but not universal in 11- β -hydroxylase deficiency, usually noted in later childhood or adolescence, and this hypertension often has an inconsistent relation to the biochemical profile (15,16). Hypokalemia is only variably present, although it should be remembered that potassium depletion and sodium retention may not be reflected by serum or plasma potassium values, owing to shifts from intracellular potassium to the extracellular space. Thus, total body potassium may be markedly depleted, yet serum or plasma potassium may be in the normal range. The production and release of renin are suppressed by the volume expansion. Furthermore, aldosterone production is decreased with relative decrease in circulating potassium. However, in some circumstances, the characteristic findings of low renin and elevated aldosterone have been absent (20,22–24).

Therapy of 11- β -hydroxylase deficiency should be focused on normalizing steroids. Thus, glucocorticoid administration will not only normalize cortisol function but should also reduce ACTH secretion and levels to normal, which should remove the drive for oversecretion of deoxycorticosterone (DOC). Such therapy usually cures the hypertension (17). However, if hypertension is marked, antihypertensive therapy should be used in this disorder until good control of hypertension is obtained.

Variants of 11- β -hydroxylase deficiency have been reported and likely relate to the several mutations that can cause the syndrome. For example, Zachman et al. (21) found an individual in whom 11 β -hydroxylation was inhibited for 17- α -hydroxylated steroids but in whom there was intact 17-deoxysteroid hydroxylation. Multiple mutations affecting the expression of the CYP11B1 gene have been described; these include frameshifts, point mutations, extra triplet repeats, and stop mutations (22–26). A distinct hypotensive disorder, called corticosterone methyl oxidase type II, occurs when a mutation affects CYP11B2 (aldosterone synthase). This abnormality leads to a clinical problem of terminal aldosterone synthesis and thus is accompanied by salt wasting and hypotension.

B. Steroid 17 α -Hydroxylase Deficiency

The adrenals and gonads are both affected when the enzyme 17 α -hydroxylase is abnormal, because a dysfunc-

tional 17α hydroxylase enzyme results in decreased production of both cortisol and sex steroids (the production of which requires the $17,20$ lyase function of the same enzyme) (16,17,28–30). An affected individual, irrespective of genetic sex, appears phenotypically female, and puberty does not occur. In fact, diagnosis too often occurs late: at puberty, when primary amenorrhea and lack of secondary sexual characteristics are noted (16,17,28–30). Another mode of presentation for affected children is with the presence of an inguinal hernia. Patients are usually both hypertensive and hypokalemic, owing to huge overproduction of corticosterone (compound B). The biochemical aspects of these defects are described more completely in the chapters on CAH.

This rare type of hypertension was first described in a female patient by Biglieri et al. (28), and then in a feminized male by New (29), although it has since been described in well over 100 patients (31–34). Treatment is effective if glucocorticoid replacement is initiated before puberty, but this may not always correct the hypertension. If replacement therapy fails to correct the elevated blood pressure, appropriate pharmacotherapy should be used to lower the blood pressure to maintain it within the normal ranges for age and size.

VI. PRIMARY ALDOSTERONISM: ALDOSTERONE-PRODUCING ADENOMA AND BILATERAL ADRENAL HYPERPLASIA

Aldosterone-producing adenomas (APAs) are rare in children, but they do occasionally occur, most often as solitary masses (16,35–42). Although rare (10% of total), bilateral masses may also occur. Occasionally such adenomas produce DOC rather than aldosterone. The hallmarks include hypokalemia and hypertension, and the optimal method for diagnosis can be complex and controversial, even among adults. Rather than primary aldosteronism secondary to adenomas, it is far more likely that a child will have bilateral renal hyperplasia (42).

Diagnosis should be possible when the studies for an APA fail to find a definite lesion. The number and type of tests (some invasive) are similar for APA and hyperplasia. ACTH sensitivity is assessed by suppression of the adrenal glands. Assessment of aldosterone levels, not only peripherally but also using bilateral adrenal vein sampling, may be helpful. Imaging studies including ultrasonography (41), computed tomography (CT) (43), scintigraphy

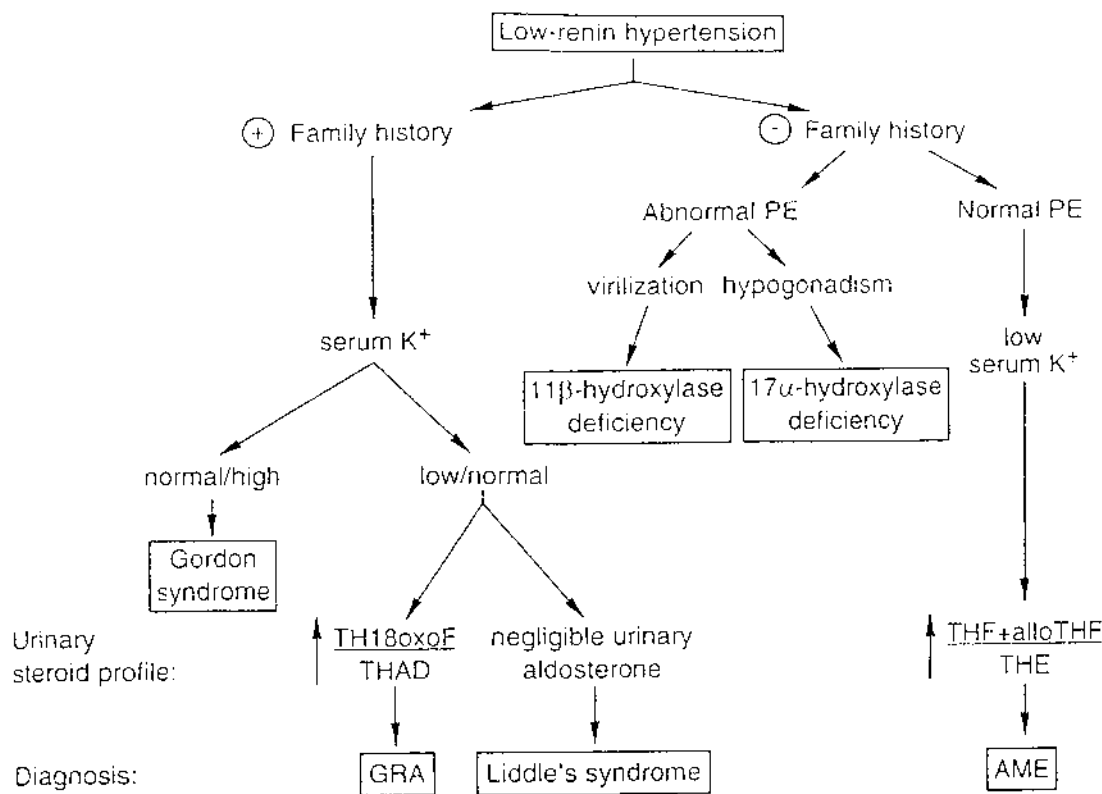

Figure 1 Low-renin hypertension algorithm. (From Ref. 13.)

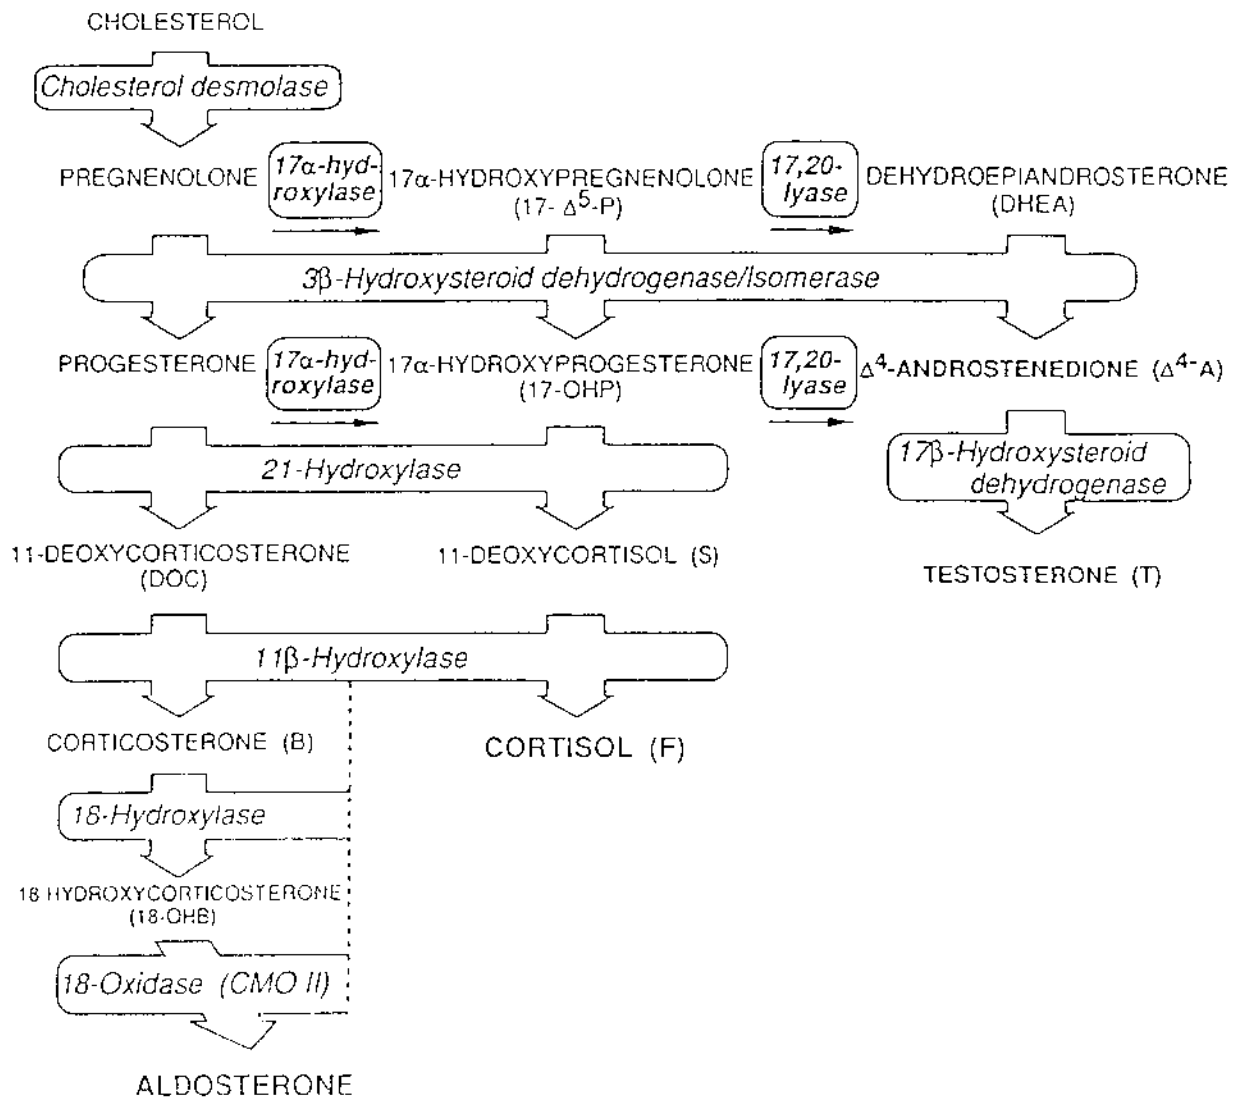

Figure 2 Steroid biosynthesis. (Reproduced from Ref. 142.)

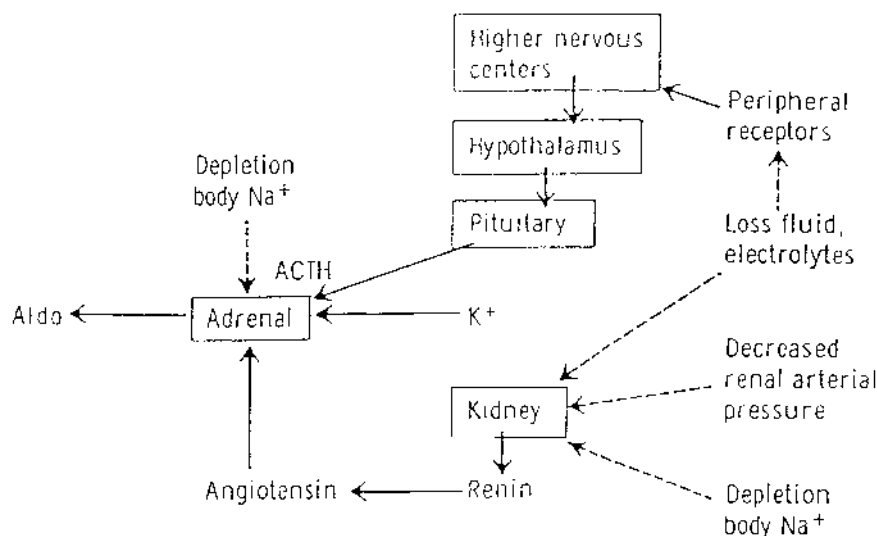

Figure 3 Aldosterone regulation. (Reproduced from Ref. 142.)

using radioiodocholesterol (44), and nuclear magnetic resonance (NMR) imaging (45) have all been used.

When APA is present, surgery is indicated (16). Surgical therapy with total or subtotal adrenalectomy for bilateral adrenal hyperplasia has been advocated, but hypertension may either continue or return. Instead, management using the nonspecific mineralocorticoid antagonist spironolactone may be more effective (16,37). Eplerenone is the first of the more specific aldosterone receptor antagonists and may prove to have a useful role (46).

VII. GLUCOCORTICOID-RESPONSIVE ALDOSTERONISM: DEXAMETHASONE-SUPPRESSIBLE HYPERALDOSTERONISM (OMIM #103900)

Glucocorticoid-responsive aldosteronism (GRA) was first reported by Sutherland et al. (47) and New et al. (48) in 1966–1967, as a novel form of increased aldosterone secretion accompanied by suppressed renin and treatable by dexamethasone. It is listed in the Online Mendelian Inheritance in Man (OMIM) as #103900. (OMIM can be accessed at <http://www.ncbi.nlm.nih.gov/Omim>.) This condition, which is inherited as autosomal dominant (49), has been reported in numerous pedigrees (50–54), and has now been identified as due to a chimeric gene duplication (the fusion of 11 β -hydroxylase and aldosterone synthase genes from an unequal crossing-over event) (55,56), leading to the regulation of aldosterone synthesis and secretion solely by corticotropin instead of by angiotensin II and potassium (54,57–59). The chimeric gene product converts cortisol to 18-hydroxy and 18-oxo metabolites (60–63).

In patients with GRA both serum and urine aldosterone levels are generally elevated, but not invariably so.

However, pathognomonic findings are generally that the urinary cortisol metabolites TH18oxoF and 18-hydroxycortisol are very high in GRA, and the ratio of TH18oxoF/tetrahydroaldosterone (THAD) is elevated. A commercially available urinary steroid profile can differentiate GRA patients from those with apparent mineralocorticoid excess (AME) or Liddle syndrome (Nichols Institute, San Juan Capistrano, CA) (63). Specific genetic testing is both sensitive and specific.

Patients have excessive aldosterone secretion, which leads to salt and water retention, plasma volume expansion, and then hypertension. When hypertension occurs, as it often does in GRA, glucocorticoid suppression can control the hypertension. GRA appears to be rare, yet it still is not often considered in the course of an evaluation of pediatric hypertension. Affected individuals often have a family history of severe so-called essential hypertension that has resisted therapy, or of family members who had early cardiovascular events including stroke and myocardial infarction.

Dluhy et al. recently reviewed the medical records of 20 children from 10 unrelated pedigrees of GRA to assess their course (64). Sixteen of the 20 developed hypertension, as early as 1 month of age. An interesting finding was that four were not hypertensive. Half of those with hypertension had conditions controllable with monotherapy [glucocorticoid suppression or aldosterone receptor/amiloride-sensitive epithelial sodium channel (ENaC) antagonists]. The rest required combination therapy, and three of those were unable to achieve blood pressure control.

Neither hypokalemia nor suppressed plasma renin activity is necessarily present at diagnosis, and thus this diagnosis might be entertained more frequently than it has been. Dexamethasone and other glucocorticoids usually control the hypertension quite easily in young individuals

with GRA, although adults with this chimeric gene may not experience resolution of their hypertension when diagnosis has been delayed.

VIII. APPARENT MINERALOCORTICOID EXCESS (OMIM #218030)

Apparent mineralocorticoid excess (AME) is marked by low-renin hypertension accompanied by hypokalemia and metabolic alkalosis (22). The syndrome was first delineated in 1977 by New et al. during their evaluation of a young Native American girl from the Zuni tribe who presented with this clinical picture (65,66). The hypertension in AME is severe, often accompanied by early end-organ damage (67). Although initial therapy with spironolactone frequently is effective, patients may well become refractory, and there is an absence of 11- β -hydroxysteroid dehydrogenase. The presence of 11- β -hydroxysteroid dehydrogenase is necessary for the prevention of mineralocorticoid activity of cortisol. When this enzyme is low or absent, cortisol-mediated hypertension can occur. In AME, cortisol acts as if it were a potent mineralocorticoid.

The microsomal enzyme 11 β -hydroxysteroid dehydrogenase (11 β -HSD) interconverts the active 11-hydroxyglucocorticoids to their inactive keto-metabolites. Both aldosterone and cortisol have an affinity for the mineralocorticoid receptor and, under usual circumstances, 11 β -HSD is protective, preventing binding of cortisol to the mineralocorticoid receptor. In AME, the slow metabolism of cortisol to the biologically inactive cortisone, with a prolonged cortisol half-life (68,69), causes cortisol to act as a potent mineralocorticoid. The metabolism of cortisone to cortisol, however, is normal.

There are two kinetically distinct forms of the 11- β -HSD enzyme. 11- β -HSD1 is widely distributed and, while its K_m for cortisol is an order of magnitude higher than 11- β -HSD2, it is NADP-preferring, and mainly acts as a reductase. In contrast, 11- β -HSD2 is present mainly in epithelia that transport sodium. It has a high affinity for cortisol and requires nicotinamide adenine dinucleotide (NAD). It is involved in sodium transport, predominantly in the kidney distal tubule. The clinical findings suggest that the 11 β -hydroxysteroid dehydrogenase enzyme is abnormal in AME (70,71). It was postulated that patients with AME had a loss of mineralocorticoid receptor specificity such that cortisol could bind to the mineralocorticoid receptor (MR) and act as a mineralocorticoid. Although defective 11 β -HSD seemed a likely explanation, the first form of this enzyme found was normal. However, it is now known that an abnormality in the type 2 isoform of 11 β -HSD is mutated in patients with AME (72–76). To date, many distinct mutations have been reported. These have been shown to impair the conversion of cortisol to cortisone.

Classic AME generally presents in early life and is associated with failure to thrive, severe hypertension, and

persistent polydipsia. The patients are volume expanded and respond to dietary sodium restriction. Plasma renin activity is impressively decreased. The diagnosis can be made biochemically by obtaining the ratio of cortisol to cortisone in the urine. There is an abnormal urinary ratio of tetrahydrocortisol/tetrahydrocortisone (THF/THE), with a predominance of THF. The generation of cortisone from cortisol after 11-tritiated cortisol is injected is only 0–6%, compared to normal: 90–95% (77).

Complications of hypertension in these children often include cardiovascular ravages of hypertension. In addition, some patients develop nephrocalcinosis and renal failure (78). Early diagnosis can do much to ameliorate the situation, if the hypertension can be controlled.

A mild form of AME has been reported in a Menonite kindred, in whom there is a P227L mutation in the HSD11B2 gene (79,80). In 2001 New et al. reported two sisters from the Iroquois Nation who appear to have resistance to multiple steroids (81). The proband was referred with mild hypertension as a possible patient with AME, yet she had resistance to glucocorticoids, mineralocorticoids, and androgens (81). Despite significantly elevated glucocorticoid levels, she had no cushingoid features and no evidence of masculinization, although her androgen levels were elevated (81). It was proposed that these two young women may have a coactivator defect (81).

Hypertension without the characteristic findings of AME has recently been described in a heterozygous father and homozygous daughter who have mutations in 11 β -HSD2 (82). Studies in patients with hypertension suggest a deficiency in 11 β -HSD2 activity, along with abnormalities that may be genetically determined (83). The 11 β -HSD2 gene appears to confer specificity for the aldosterone receptor.

Licorice-induced hypertension has a pathogenesis similar to that seen in AME (79,80,84). Glycyrrhetic acid, which is the active component of licorice, inhibits 11 β -hydroxysteroid dehydrogenase, leading to increased stimulation of the mineralocorticoid receptor (84).

IX. MUTATIONS IN RENAL TRANSPORTERS CAUSING LOW-RENIN HYPERTENSION

A. Pseudohypoaldosteronism Type II: Gordon Syndrome (OMIM #145260)

Pseudohypoaldosteronism type II (PHAII) is an autosomal dominant condition associated with hyperkalemia, acidemia, and hypertension along with increased salt reabsorption by the kidney (13,85–87). The condition is also known as Gordon syndrome or familial hyperkalemia and is listed as OMIM #145260. A hallmark of this disease is low renin hypertension and improvement with the use of thiazide diuretics or with triamterene. Aldosterone receptor antagonists do not correct the abnormalities. The pathogenesis remained elusive for a long time, although the

physiological studies and response to diuretics strongly indicated a defect in renal ion transport in the presence of normal glomerular filtration rate.

Genes for PHAII were mapped to chromosomes 17, 1 or 12 (88–90). A PHAII kindred in which linkage analysis suggested that the involved area was the most telomeric 2-centimorgan segment of chromosome 12p [lod score 5.07] was recently found to have abnormalities in the WNK1 gene. The WNK genes, a family of serine-threonine kinases, are named WNK because they have no lysine, the symbol for which is “K.” The mutations are large intronic deletions that increase WNK1 gene expression. Another family has been found with mutations in WNK4, which is on chromosome 17. These mutations are missense. WNK1 is widely expressed in the body, while WNK4 is mainly expressed in kidney, localized to tight junctions. It is thought that abnormalities in WNKs change the way potassium and hydrogen are handled in the collecting duct, thus increasing salt resorption and intravascular volume. How this occurs is not clear. It is unlikely that these kinases simply increase the activity of ENaC. More likely they either increase transcellular chloride conductance in the collecting duct, or increase paracellular chloride conductance. This may increase salt resorption and intravascular volume, and dissipate the electrical gradient and decrease K⁺ and H⁺ secretion. They might also lead to constitutive increase in activity of the Na–Cl cotransporter in the collecting duct or increase its activity in the distal convoluted tubule.

The lesson inherent in the association of WNK kinases with PHAII is that many individuals with low-renin primary hypertension respond to treatment with thiazide diuretics. Might these people have variants in WNK1 or WNK4 that predispose to hypertension? There are some data from linkage studies that suggest such an association might be important (90). Furthermore, the WNK kinases and their signaling pathways may be a fruitful target for future development of antihypertensive drugs.

B. Liddle Syndrome (OMIM #177200)

In 1963 Liddle (91) described early onset of hypertension with hypokalemia in a family who had low renin and aldosterone concentrations. Inheritance was autosomal dominant. Inhibitors of renal epithelial sodium transport, such as triamterene, worked well in controlling hypertension, but inhibitors of the mineralocorticoid receptor did not. A general abnormality in sodium transport seemed apparent, as the red blood cell transport systems were not normal (92). The concept that a major abnormality was present in renal salt handling was fostered by the fact that a patient with Liddle syndrome who needed a renal transplant experienced normalization of the blood pressure and serum potassium after the procedure (93).

The abnormality in Liddle syndrome thus looked like aldosterone excess yet had very low aldosterone levels as well as renin (94–96). Many patients have low potassium

levels, but not all do. Mineralocorticoid-dependent sodium transport within the renal epithelia needs activation of the epithelial sodium channel. The α , β , and γ subunits have been cloned and characterized. The β and γ subunits are found close to each other on chromosome 16. Mutations in these subunits have been identified in Liddle syndrome. More information can be found in OMIM, in which Liddle syndrome is listed as OMIM 177200.

X. CUSHING SYNDROME AND HYPERTENSION

Glucocorticoid excess leads to the well-described syndrome of weight gain, linear height growth attenuation, myopathy, centripetal obesity, striae, moon facies, and buffalo hump (97–100). Hypertension is part of this constellation, whether the syndrome is due to exogenous glucocorticoid therapy or to endogenous hypercortisolism from a variety of causes. The hypertension improves upon control of the underlying cause (and therapy is discussed in Chapter 6, 30). The hypertension should be controlled while the cause is being evaluated and treated.

XI. HYPERTENSION IN PHEOCHROMOCYTOMA AND NEURAL CREST TUMORS

Hypertension is nearly universal in pediatric pheochromocytoma, and management is discussed in Chapter 8, Disorders of the Adrenal Medulla: Catecholamine-Producing Tumors in Childhood. Several points concerning the hypertension in children with pheochromocytoma are worth emphasizing in this chapter as well (101–117). The hypertension seen in children and adolescents with pheochromocytoma is often constant rather than episodic; thus the diagnosis should always be ruled out in a child with marked hypertension.

Management of hypertension in a child with pheochromocytoma should be classified into the preoperative phase, intraoperative phase, and postoperative phase. Preoperatively, it is worthwhile to be certain the child's blood pressure is controlled and the child stable before surgery is attempted. The dosages of medications used are listed in Table 4. As was pointed out in Chapter 8, although alpha blockade is thought to be important, beta-adrenoceptor blockade should not be used as sole therapy, because it fails to prevent the effects of catecholamine at alpha-adrenoceptors and may cause severe hypertension.

Some sources suggest inducing volume expansion along with blood pressure control in the preoperative period, to prevent intraoperative volume instability (103,107).

Preoperatively it is wise to premedicate to avoid anxiety, which itself may precipitate catecholamine release and crisis. Perioperatively, it is important to consider the use of nonexcitatory neuromuscular medications. Fentanyl and droperidol should be avoided because they may lead

Table 4 Treatment of Catecholamine Excess: Oral Medications to Use Preoperatively

Drug	Indications/pharmacokinetics	Dose	Preparation
<i>α</i> -Adrenergic blockers			
Phenoxymethamine	Long half-life	Start at 10 mg bid → 20–40 mg bid or tid	10 mg capsules
Prazosin	Selective α_1 -antagonist; short half-life	1 mg q 8 h, up to 20 mg/ day	1, 2, 5 mg capsules
<i>β</i> -Adrenergic blockers:			
Don't use before full α -blockade			
Propranolol	Nonselective β -antagonist; may induce wheezing; biologic half-life ~4 h	1 mg/kg/dose bid to qid	10, 20, 40, 60, 80 mg tabs
Propranolol-long acting	Same as propranolol	1 mg/kg/day	60, 80 mg capsules
Atenolol	Selective β_1 -antagonist; 50% absorbed orally; peaks at 2–4 h, half-life 6–7 h; oral duration 24 h	1–2 mg/kg qd	25, 50, 100 mg tablets
<i>α/β</i> -Adrenergic blockade			
Labetalol	Combined blocker; limited pediatric information	3–4 mg/kg/day in two divided doses; increase to 40 mg/kg/day orally	100, 200, 300 mg tablets
Competitive inhibitor of tyrosine hydroxylase			
Metyrosine (Demser)	Competitive inhibitor of tyrosine hydroxylase	250 mg bid to qid	250 mg capsules

to catecholamine release. Atropine is also contraindicated, since this agent may lead to tachycardia in the presence of elevated blood catecholamines.

Monitoring arterial pressure and the cardiogram is essential during surgery, and providing muscle relaxants prior to intubation is important. Anesthesia with isoflurane or enflurane is usual and well tolerated. If a hypertensive crisis occurs during surgery, prompt therapy with intravenous phentolamine or nitroprusside is essential, as well as control of any arrhythmias that may develop. In addition to phentolamine and nitroprusside, the calcium channel blocker nicardipine has been used with success, as have labetalol, esmolol, nitroglycerine, and the dopamine 1 agonist fenoldopam.

In a recently published series from the Mayo Clinic, the majority of patients were given isoflurane for their primary volatile anesthetic, and 61% were given succinylcholine as a muscle relaxant. Most required intraoperative antihypertensive use (82%), and 45% required the use of vasopressors.

Postoperatively blood pressure normalizes in most children with resectable tumors. However, about 25% of adults do not, likely because most have concomitant primary hypertension. Those children who require continued antihypertensive therapy after resection generally have tumors that are not fully resectable, or have malignant pheo-

chromocytoma. In such situations a combination of alpha and beta blockade can control blood pressure. Metyrosine (Demser) is also useful for inhibiting catecholamine synthesis. The calcium channel blocker nifedipine is successful in decreasing clinical symptoms.

XII. HYPERTENSION IN THYROID DISEASE

Hypertension is widely stated to occur in conditions of both hyperthyroidism (118–120) and hypothyroidism (121), not surprisingly via distinctly different mechanisms. A considerable body of experimental data demonstrates that models of hyperthyroidism are accompanied by hypertension. For example, a model of hyperthyroidism in which rats are rendered thyrotoxic by injection of 0.1 mg/kg/24 h of L-thyroxine is accompanied by both hypertension and left ventricular hypertrophy. Activation of the renin–angiotensin system appears important in this form of hypertension, which is ameliorated by the angiotensin II antagonist (e.g., valsartan). Conversely, an older literature showed that spontaneously hypertensive rats had a propensity to thyroid functional abnormalities.

Clinical hypertension as part of hyperthyroidism is widely known (118–120). Treatment of the hypertension with antihypertensive agents generally proves successful.

This form of hypertension has been reported in neonates with hyperthyroidism as well as in older children. The circadian rhythm in hyperthyroidism appears to vary compared to normal, with a failure to exhibit nocturnal decrease (dipping) in blood pressure. Systolic hypertension as an isolated finding is more common than elevation of both systolic and diastolic hypertension, particularly in young patients. Increased cardiac output with decreased total peripheral resistance are observed.

Hypothyroidism has long been reported as associated with hypertension (121). However, few data truly support this claim. Rather, studies note left ventricular hypertrophy post hoc, in autopsy studies, or make this claim without providing control subjects. Therapy of the thyroid deficiency generally decreases the blood pressure for most individuals. The clinical findings include increased sympathetic nervous system tone, with an augmented alpha-adrenergic responsiveness. Cardiac output tends to be decreased, while peripheral resistance is increased. If hypertension is present, it is most often diastolic in nature. Once the hypothyroidism is corrected, patients can generally be weaned from hypotensive therapy.

XIII. HYPERPARATHYROIDISM AND HYPERTENSION

Hypertension is a frequent occurrence with hyperparathyroidism (122,123). Studies that have considered mechanisms suggest that intracellular ionized calcium is elevated and regulated abnormally in this condition. Iatrogenic hypertension may occur, since therapy may have side effects leading to hypertension. Patients with hypoparathyroidism, if treated to excess with vitamin D analogs and calcium, may likewise become hypertensive.

XIV. PREVENTION OF HYPERTENSION AND ENDOCRINE SYSTEMS

A. Expectable Hypertension in the Course of Prescribed Therapy

No discussion of hypertension in children is complete without some mention of iatrogenic forms of hypertension. A number of medications commonly used in endocrine practice may lead to hypertension: including glucocorticoids and mineralocorticoids, thyroid replacement, and estrogen-progestin combinations (124). Thus, the alert clinician prescribing such medication will monitor any individual for whom such medications are prescribed. The self-prescription or inadvertent exposure of patients to such compounds can also result in elevated blood pressure.

Glucocorticoid-related hypertension is extremely common among those taking such preparations for prolonged time periods. A recent publication noted that 88% of children receiving glucocorticoids were hypertensive

(125). The hypertension related to glucocorticoid use appears irrespective of indication and has been reported among children with neurological, renal, pulmonary, and GI disease. Given a necessary course of steroids, it is imperative that blood pressure be monitored and treated as needed until the glucocorticoid treatment can be discontinued.

B. Expectable Hypertension in the Course of a Known Diagnosis

Certain endocrine diagnoses are associated with hypertension. A child with Turner syndrome has a definitive chance of renovascular hypertension, owing to renal artery abnormalities or to renal malrotation and anatomical anomalies (126). Children with disorders of calcium regulatory hormones may develop hypercalcemia and hypercalciuria, and nephrocalcinosis with attendant renal calcification and hypertension (127). Children from families with a familial endocrinopathy should be evaluated carefully, given the frequency of neural crest tumors.

Diabetes may be associated with microalbuminuria early, and endocrinologists should, from all that is now known, monitor children with diabetes for microalbuminuria, renal function, and blood pressure. Renoprotective treatment may well be indicated (128–130).

The endocrine diagnoses for which monitoring blood pressure levels should be part of routine care are listed in Table 3.

XV. PRIMARY HYPERTENSION: HOW OFTEN ENDOCRINE?

About 25% of the adult population has hypertension, and many hypertensive individuals have salt sensitivity: blood pressure increases with a high-salt intake and decreases with a lowered salt intake. The delineation of several monogenic forms of low-renin hypertension have raised questions of whether some individuals with so-called primary hypertension might have abnormalities in genes that lead to mendelian forms of low-renin hypertension. Such mutations might not lead inevitably to hypertension but might cause a predisposition to hypertension. Recent studies of individuals with primary hypertension have detected certain polymorphisms that appear to be associated with differences in function of 11- β hydroxysteroid dehydrogenase-2. Some publications suggest that individuals with either a polymorphism in 11- β -HSD2 or who have an increased cortisol half-life seem to respond differently from others with respect to salt sensitivity. Such findings suggest that some forms of primary hypertension may be differentiated from others by their 11- β -HSD-2 activity (83,131,132,134). Since not all studies (133) support such findings, this remains an area of continuing consideration.

Table 5a Oral and Topical Hypertensives

Medication type	Drug	Route	Dosage	Adverse effects	Contraindication	Comment
Vasodilator	Minoxidil	PO	0.2 mg/kg to start	Fluid retention, reflex tachycardia	Need to get BP controlled immediately; catecholamine-mediated hypertension	May help in urgencies
	Hydralazine	PO	0.75–3.0 mg/kg/day	Vasodilation	Tachycardia; sensitivity to hydralazine	Unstable in suspension; consider periodic ANA testing
Beta blockers	Propranolol	PO	0.5–1.90 mg/kg/day divided q 6 h	Bradycardia, CHF, intensification of AV block; mental depression, visual disturbances, nightmares, hallucinations; bronchospasms; GI symptoms	Asthma, CHF, sinus bradycardia, liver disease, cardiogenic shock, diabetes (?), pheochromocytoma	May mask signs of hyperthyroidism; available in long-acting form
	Atenolol	PO	Once daily, 50 mg qd (adult)	Fewer side effects than nonselective beta blockers	Can consider using in patients with reactive airway disease	Relatively cardioselective
	Metoprolol	PO	1 mg/kg every 12 h	Fewer side effects than other beta blockers	Beta blocker of choice in asthma	Relatively cardioselective
	Nadolol	PO	1 mg/kg/24 h	Same as other beta blockers, but less severe	Beta blocker of choice in asthma	Longer duration of action permits once/day dosing
Angiotensin-converting enzyme inhibitors	Captopril	PO	0.05–0.15 mg/kg/dose (low end in infants)	Hyperkalemia, proteinuria, cough, rash, marrow suppression	Use with caution in renal artery disease (bilateral), do not use in pregnancy, or in anyone who has had angioedematous edema	More rapid onset than other ACE inhibitors
	Enalapril	PO	0.05–0.15 mg/kg/day	Similar to captopril	Similar to captopril, but longer acting. Not sulfhydryl containing, so perhaps fewer side effects	
Calcium channel blockers	Nifedipine	PO	0.25 mg/kg/dose, every 4–6 h	Vasodilation, tachycardia, nausea, vomiting, sweating, cardiac problems	Use with caution in heart failure	Absorption not affected by food
	Verapamil	PO	4–10 mg/kg/day, given 3x/day	Similar to nifedipine		Absorption delayed by food
	Isradipine	PO	0.05–0.83 mg/kg/day	Similar to nifedipine		Can be put into suspension
Alpha blockers	Prazosin	PO	1 mg to a max of 20 mg q 24 h	Orthostatic hypotension, lethargy, sedation and fatigue		First-dose hypotension may occur
	Phenoxybenzamine	PO	0.2 mg/kg/24 h	Orthostatic hypotension, nasal congestion		
Central adrenergic stimulators	Clonidine	PO or patch	0.05 mg/kg/ bid to max 2.4 mg/24 h	Lethargy, sedation, dry mouth, (?) retinal degeneration		Specific for catecholamine excess

Table 5b Parenteral and Sublingual Drugs for Use in Hypertensive Emergencies

Medication	Route	Dosage	Onset of action	Peak/duration	Adverse effects	Contraindication	Comments
Sodium nitroprusside (Nipride)	IV infusion	0.3–10 $\mu\text{g}/\text{kg}/\text{min}$	Immediate	1–2 min/2–3 min	Thiocyanate toxicity	Hepatic insufficiency	Photosensitive preparation; shield from light
Labetalol	IV bolus	0.5 mg/kg over 2 min; if no response, double dosage and repeat q 10 min to max dosage of 5 mg/kg	1–5 min	5 min/variable (generally 2–6 h)	Postural hypotension; neurological symptoms; nausea and vomiting	Bronchial asthma; CHF	
Nifedipine	Sublingual	0.25 mg/kg q 4–6 h	10–15 min	60–90 min/variable, usually 2–4 h	Vasodilatation, headache, cardiac events if preceding heart failure	Cardiomyopathy; concomitant use of beta blockers; cimetidine (relative)	Cardiac concerns less relevant in children than in adults
Esmolol	IV	500 $\mu\text{g}/\text{kg}$ over 30 s, and then infusion of 25 $\mu\text{g}/\text{kg}/\text{min}$ increasing dosage (e.g., 4 min to max 300 $\mu\text{g}/\text{kg}/\text{min}$)	1 min	mins/mins	Hypotension, CNS effects, nausea		Good drug for hypertension intraoperatively
Enalaprilat	IV, over 5 min	0.04–0.8 mg/kg/dose (child); 0.01 mg/kg starting (neonate)	15 min	1–4 h/variable	Hypotension, oliguria, hypokalemia	Renal failure, dehydration	Rx hypotension with volume
Diazoxide	IV bolus	1–3 mg/kg repeated every 5–15 min until control BP	1–5 min	1–5 min/variable (usually <12 h)	Arrhythmias, hyperglycemia, sodium and water retention	Thiazide sensitivity, diabetes, coarctation	May need diuretics to prevent fluid retention; unpredictable blood pressure drop may occur
Phentolamine	IV bolus	0.05–0.1 mg/kg	Within 30 s	2 min/5–30 min	Tachycardia, arrhythmia, marked hypotension		Specific for pheno.

Source: Adapted from Ref. 141.

Table 5c Diuretic Agents

Medication	Dosage	Onset	Peak/duration	Adverse effects	Relative contraindication
Furosemide (Lasix)	1–2 mg/kg (max, 6 mg/kg/24h)	Oral: 1–2 h IV: 5 min (child); 1 h (neonate)	1–2 h/4–6 h 30 min/2 h (child); 1–2 h/5–6 h (neonate)	Hyperuricemia, hyperglycemia, hypokalemia, hyponatremia, fluid depletion, ototoxicity	Sulfonamide sensitivity, anuria, metabolic alkalosis
Ethacrynic acid (Edecrin)	1 mg/kg (max, 25 mg total/day)	Oral: ~30 min IV: 15–30 min	2 h/6–8 h 45 min/3h	Same as for furosemide; ototoxicity more	Anuria, metabolic alkalosis
Bumetanide (Bumex)	Newborn: 0.01–0.05 mg/kg q 24 h Child: 0.015–0.1 mg/kg/dose q 6–24 h	Oral: 30–60 min IV: minutes	Oral: 4–6 h duration; IV: 30–60 min dur'n	Similar to furosemide; GI discomfort	As for furosemide
Hydrochlorothiazide (HydroDiuril)	2 mg/kg bid	Oral: 2 h	4 h/6–12 h	Electrolyte depletion; hyperuricemia; hypoglycemia	Anuria, sulfonamide sensitivity
Spironolactone (Aldactone)	1–3.3 mg/kg q 6, 8, or 12 h	Oral: gradual	3 d/2–3 d	Hyperkalemia, gynecomastia	Anuria, hyperkalemia, decreasing renal function
Metolazone (Zaroxolyn, Diulo, Mykrox)	1 mg/kg	Oral: gradual	Gradual	Similar to thiazide; also bloating, chest pain, chills	Anuria

XVI. TREATMENT

Current evidence supports the concept that blood pressure should be well within normal ranges among adults. For example, the risk of cardiovascular events among adults is higher among individuals with high normal blood pressure than in those with midrange or low-normal blood pressure (135). While no such data yet exist for children, it is more likely than not that stringent blood pressure control is important, particularly for children with health problems that can be associated with hypertension. Thus, it is reasonable to control blood pressure into the normal range in any infant, child, or adolescent with hypertension.

A primary endocrinopathy should be treated. If blood pressure is elevated, either because full therapy is not yet being administered or because therapy includes medications that can raise blood pressure, additional therapy in the form of antihypertensive treatment is indicated. Table 5 lists current oral and intravenous medications for hypertension and dosages (136–141). One should note that specific pediatric indications are presently evolving, as a result of the Food and Drug Administration's Modernization Act of 1997, which has mandated antihypertensive trials in children (137–139).

Dietary Supplements to Enhance Athletic Performance

Alan D. Rogol

University of Virginia, Charlottesville, and Medical College of Virginia, Richmond, Virginia, U.S.A.

I. INTRODUCTION

Ergogenic aids (from the Greek, *ergon*, meaning work) are ingested to enhance energy utilization by producing more, better controlling its expenditure, or increasing efficiency of use. It is apparent that true athletic success stems primarily from a combination of genetic endowment, training, technique, equipment, and proper nutrition. The ingestion of nutritional supplements may play only a small, mainly insignificant, role in the outcome of athletic endeavors. What do athletes want? They want enhanced athletic performance and many believe that one way, perhaps a shortcut, is to take nutritional supplements. Extracting and extrapolating from a wide variety of sources, it appears that the athlete truly desires increased strength, power, and endurance; as well as salutary alterations in body composition: increased lean body (muscle) mass and decreased fat mass as quickly as possible, and faster and more complete recovery from exercise (training) and competition to achieve the goal of improved performance at subsequent competitions.

These are issues for athletes of both genders and almost all ages; however, there are additional issues when the adolescent athlete is considered. Normal physiological growth should occur during the time of adolescence. This topic is covered extensively in other portions of this text. In general the linear growth rate is relatively constant at 5.5 cm/year during childhood. It continues at this rate until just before the pubertal growth spurt. This physiological event has significant variability in both *timing* and *tempo* and may be of special importance to athletes in certain sports that may select for the smaller and more delayed body type, for example, gymnastics and the light-weight wrestler. It is against the norm that one must explain variations in adolescent development in those who train for athletics and competition and in addition may take dietary supplements.

Nutritional supplements come in many varieties and forms: foods, vitamins, antioxidants, and anabolics, to mention only a few. A critical historical fact is a change in the level of scrutiny by the U.S. Food and Drug Administration (FDA). The Dietary Supplement Health and Education Act of 1994 defined a food supplement as . . . “any product that contains a vitamin, a mineral, an amino acid, an herb or other botanical; or a concentrate, metabolite, constituent, extract or combination of any of these ingredients.” Virtually overnight an exponentially growing multibillion dollar industry was spawned. In the following sections I shall review information on two herbals (ephedra and ginseng), creatine, and some anabolics including dehydroepiandrosterone (DHEA), androstenedione, and growth hormone. Growth hormone and the more potent anabolic steroids are administered parenterally and are not so readily available as the three agents noted above; however, I shall very briefly review some of the agents that act in the growth hormone–insulin-like growth factor-1 (IGF-1) system.

II. DIETARY SUPPLEMENTS: HERBAL PRODUCTS

Because of the Dietary Supplement Health Education Act in 1994 herbs and other botanicals are not subject to the stringent premarketing safety (and efficacy) evaluations that apply to other foods (and drugs). They are not subject to FDA regulation, but fall under the jurisdiction of the Federal Trade Commission. Claims are made that such products will favorably alter body composition: increase lean body mass, decrease fat mass, and perhaps alter the regional distribution of body fat. In addition, supplements are taken to decrease fatigue, permit more intensive workouts, and aid in the recovery from these intensive bursts of muscle use to allow energy expenditure for the next

training session. The message of the utility (even necessity) of these ergogenic aids is heard by the adolescent athlete who seeks athletic success, often as an avenue for social acceptance. Proper training technique includes strength training and proper nutrition; the purveyors of dietary supplements know that the message that their products can be part of the overall route to athletic success will be understood.

Although there are many herbal products for which claims are made for ergogenic properties, I shall review only two, ephedra and ginseng, for which there is some significant scientific information as ergogenic aids for humans who exercise.

III. EPHEDRA

Chinese ephedra (*Ephedra sinica*) (1) or ma huang has a long tradition (more than 5000 years) of use as treatment for respiratory ailments. Although many ingredients are found in ephedra extracts, the active pharmacological agents are ephedrine and its related alkaloids pseudoephedrine, norephedrine, and norpseudoephedrine. These and the synthetic ephedrine alkaloids are ingredients of many prescription and over-the-counter pharmaceutical products. Many of the dietary supplements today actually contain *added* synthetic ephedrine alkaloids or are combined with other stimulants, (e.g., caffeine) and thus are not really comparable to the original Chinese herbal extracts, especially with reference to the dosages of the active ephedrine alkaloid ingredients. These latter are more likely to mimic the effects of ephedrine and cause adverse events (See below), especially when combined with caffeine.

There have been several studies of the acute effects of the ephedra alkaloids on exercise performance, but the dosages often are in excess of those "recommended" for daily use. These have evaluated time to exhaustion or muscle strength. Most have shown no significant effects, except for a rise in peak systolic blood pressure (2,3). However, when combined with a high dosage of caffeine, Bell and colleagues (4) were able to determine a statistically significant increase in time to exhaustion in a cycle ergometer trial.

The ephedra alkaloids found in many dietary supplements are banned substances for some amateur and professional sporting events. After these supplements are taken, their metabolites are excreted into the urine in amounts sufficient to be detected by the usual testing procedures.

A disadvantage of the use of supplements containing ephedra, ephedra extract, or ma huang is their propensity to untoward reactions. Reports to the FDA and Poison Control Centers include many cardiovascular toxic effects including cardiac arrhythmias, myocardial infarctions, and stroke, with a number of these events being fatal. Haller performed a review of the cardiovascular and central ner-

vous system (CNS) events associated with dietary supplements containing ephedra alkaloids. Benowitz (5) found hypertension as the single most frequent adverse event followed by tachycardia and palpitations. Although these cardiovascular events and those related to the CNS did not occur with great frequency, the authors suggested that they could be devastating in *vulnerable* individuals. Central nervous system adverse events include agitation, mania, psychoses, and dependence. Although many may have followed so-called improper dosage of the supplement, the amounts taken were well within the range of those who use these dietary supplements. It is important to note that the content of ephedra alkaloids in herbal dietary supplements varied over a very wide range. In one review Gurley and co-workers (6) found lot-to-lot variations in the contents of (-)-ephedrine, (+)-pseudoephedrine, and (-)-methylephedrine of greater than 180%, 250%, and 1000%, respectively. (+)-Norpseudoephedrine, a schedule IV substance, was an ingredient of a number of the supplements tested. A majority of the products had major discrepancies (>20%) in the amounts of ephedra alkaloids actually contained and those claimed on the label. Such products *can* be very dangerous even if "used as directed," given the wide variations in ingredient content.

IV. GINSENG

Ginseng (1) usually refers to the Chinese or Korean preparation of *Panax ginseng*. It is used as a dietary and medicinal product in most of Asia, in the form of root, root extract, or root powder. The root contains multiple glycosylated steroidal saponins as *likely* active agents. Although used to improve general health (*Qi*, life energy) some more recent studies have focused on its effect on exercise performance. Some properly controlled studies have shown statistically significant improvements in physical performance (e.g., increased aerobic capacity and muscle strength) after 6 weeks of ingesting ginseng root powder (7). A number of other studies have shown small or nonsignificant changes in the cardiovascular and respiratory systems, especially in untrained, older subjects and in larger trials. It is difficult to find evidence for a salutary effect on athletic performance in the younger, training competitive athlete.

The untoward effects from the usual dosages are not prominent and it is often difficult to separate those effects (e.g., CNS stimulation) from those of the added "contaminants," such as caffeine or ephedra alkaloids (see above). No metabolites that appear on the banned list for athletes are excreted in the urine of those who take ginseng preparations.

V. CREATINE

Creatine (8-12) is a nutrient found naturally in various foods, for example, meat and fish. It is also available as

a nutritional concentrated supplement that is not on the banned list, that is, it is "legal." Its main source in the diet is fish and red meat and is found almost exclusively in skeletal muscle, where it is one of the main energy sources available to fuel the energy bursts for explosive contractions, such as those in jumping and weight training. The idea is to match ATP supply to ATP demand. Creatine exists mainly in two forms: creatine and creatine phosphate for the storage of energy in muscle. Within the muscle, 60–70% exists as creatine phosphate, which is unable to pass through biological membranes, and thus is osmotically active.

Creatine kinase

Why would an athlete supplement his or her diet with creatine? For those whose athletic endeavors include the generation of explosive power, the more phosphocreatine (PCr) stored, the more power one might generate. From the ergogenic viewpoint, the resynthesis of PCr could be the critical factor during sustained, very-high-intensity exercise. Thus the rationale for its use is based on supplementation to increase resting levels of creatine phosphate and free creatine to increase the regeneration of ATP to *delay* fatigue, and thus improve athletic performance. Depletion of phosphocreatine, especially in fast type II muscle fibers, and subsequent declines in force production are thus delayed. Investigation has focused on activities that require short or repeated bouts of energy expenditure. In fact, several laboratory studies have shown small but statistically significant increases in cycle ergometer performance (13–16); however, no studies have shown the effectiveness of creatine supplementation in subjects less than 18 years old. Others have not been able to replicate such results.

Orally ingested creatine is completely absorbed intact from the gastrointestinal tract. It is delivered to the skeletal muscle for storage, where it can quickly rephosphorylate ADP to ATP (See above) to fuel muscular contraction and stimulate myosin heavy-chain (protein) synthesis. The daily requirement is approximately 2 g/day for a 70 kg person. Approximately half comes from *in vivo* production and the other half from dietary sources. The most popular supplements are administered as a loading dose of 20–25 g for 2–5 days, followed by 2–5 g/day as maintenance. The more that is ingested, the less is synthesized.

Which teenaged athletes take creatine supplements and why do they take them? Metzler and colleagues surveyed a group of high school athletes and found that slightly fewer than 6% (but many more among 11th and 12th grade students) admitted taking creatine supplements (16). Boys were almost five times more likely than girls to supplement with creatine and the older athletes more likely than the younger athletes. Use was significantly more likely among strength-dependent athletes, for example, football players, wrestlers, ice hockey players, and

lacrosse players. The surveys indicated that those who took the supplement expected enhanced athletic performance (~75%), improved appearance (~60%: a not inconsequential reason for adolescents to take many types of supplements even among nonathletes), improved endurance (~45%), and improved speed (~40%). Ray and colleagues have also recently reported similar results (17).

Because these supplements are not necessarily made under "Good Manufacturing Practices" as our prescription drugs are, one is not assured of the potency of the product nor what other chemicals might be contained in the product. The FDA does not necessarily test these products. Most of the creatine is excreted in the urine; however, as an osmotically active substance it draws in water leading to several of its side effects: weight gain, edema, and muscle cramps. Gastrointestinal (GI) cramps are also common. In fact it is the cramping in muscle and in the GI tract that has limited its use.

VI. ANABOLIC STEROIDS

Anabolic steroids are used to increase lean tissue mass and to reduce body fat. In addition to enhanced athletic performance, athletes claim that supplementation with these compounds increases strength and weight as well as aggressiveness to permit longer and more intense workouts. Anabolic effects of androgens occur in the nonreproductive tissues and include an increase in muscle mass; acceleration of bone growth before epiphyseal closure in the adolescent; increase in bone density; stimulation of red blood cell production, as noted by increases in the circulating hemoglobin level and hematocrit; laryngeal enlargement and vocal cord thickening; and decrease in body fat (18). Androgenic effects are those that reflect the development of the primary sexual characteristics: changes in genital size and function, spermatogenesis, and sexual hair. Of some interest as well are the anticatabolic effects (19), perhaps acting by blocking the glucocorticoid receptor that might permit more rapid recovery from previous training or more intensive training sessions. There are at least two well-controlled clinical trials that show unequivocal efficacy of moderately increased levels of testosterone (20,21).

The rationale for using anabolic, androgenic steroids includes the following (22):

- The clear differential in athletic performance between men and women depends in the main on differences in body composition; on average, the lean body mass is 30% greater in men.

- The obvious anabolic effects resulting from the physiological increases in testosterone during male pubertal development.

- The production of undoubted anabolic and ergogenic effects by physiological dosages of testosterone in hypogonadal men.

The assumption that use of supraphysiological dosages of testosterone or more potent synthetic analogs would increase muscle bulk and improve athletic performance in *eugonadal* adult men.

The assumption that anabolic effects can be separated from the virilizing effect by use of *pure anabolic* agents.

The rationale may be correct, but the assumptions have in the main yet to be realized, because only one androgen receptor has been identified. I shall not consider the injectable anabolic steroids since these are really not dietary supplements. I shall consider both dehydroepiandrosterone and androstenedione below, because they are both widely available and used, as is creatine, by adolescent athletes.

VII. DEHYDROEPIANDROSTERONE

Dehydroepiandrosterone (DHEA) and its sulfate (DHEAS) are the most abundant circulating steroid hormones, with daily secretory rates of almost 30 mg/day in the adult. In addition they are precursors to both androgens and estrogens. The circulating levels change remarkably over the normal life span: in the fetus these steroids are precursors for placental estrogens. The levels then decline until midchildhood when they begin to slowly rise during a process called *adrenarche*, which may be heralded by the appearance of pubic hair, hence an often-used synonym: *pubarche*. This small rise is followed by a continued rise to a peak in the young adult. After that, the levels decline steadily to 20–25% of the maximum. This natural decline has become a target of nutritional supplementation: that is, to the suggestion that DHEA might attenuate or reverse some of the effects of aging. The aim of this supplementation is to again raise the levels of circulating DHEA to those of the young adult.

For adolescents the goal must be quite different, since it is during this period that DHEA and DHEAS levels are close to their highest. The aim must be to increase the levels of the more anabolic steroids, since the potency of DHEA is weak as an androgen (23). Despite being banned as a pharmaceutical by the FDA in 1996, DHEA has been resurrected as a nutritional supplement (so-called nutraceutical). In young men neither single doses of DHEA (50 mg) nor 150 mg/day during an 8 week resistance training protocol raised testosterone or free testosterone levels (24). Levels of DHEA and androstenedione were raised as a positive control for drug absorption. The levels of gonadotropins did not decrease as they would were a sufficiently potent anabolic steroid administered (for example, testosterone). The levels of testosterone and its free fraction also did not change. Thus, there were no discernable effects on the hypothalamic–pituitary–gonadal axis from these amounts of DHEA.

Common side effects of potent anabolic steroid administration include liver enzyme elevations and a dysli-

pidemia characterized by an increase in low-density lipoprotein (LDL)-cholesterol and a decrease, often marked, in high-density lipoprotein (HDL)-cholesterol. No alterations in the lipid profile or hepatic enzyme profile of the subjects were found. All subjects increased the amount of weight lifted, but there was no difference between those who ingested DHEA and those receiving placebo. The muscle fiber cross-sectional area of the type II fibers increased with resistance training, but there were no differences between the groups of subjects receiving DHEA and placebo. These data in young males (although not adolescents) make it unlikely that the usual amounts of DHEA supplementation will have an anabolic effect that will lead to increases in athletic performance above those gained by diligent training and a proper diet.

DHEA may have a role in patients with adrenal insufficiency, because the usual replacement therapy with glucocorticoids and mineralocorticoids does not address the issue of decreased adrenal androgens. Arlt and colleagues made a strong case for DHEA replacement therapy in women with adrenal insufficiency (25).

VIII. ANDROSTENEDIONE

Androstenedione is an anabolic steroid that is a precursor to both testosterone and estradiol. It is itself a weak androgen and poorly converted to more potent androgens; however, because of the hype engendered following its use by Mark McGwire during his spectacular season of hitting home runs for the St. Louis Cardinals, it received much undeserved press from which the manufacturers reaped an extraordinary financial benefit. Several well-done studies (See below) have been unable to find credible evidence for an anabolic effect.

Oral androstenedione administered at 100 or 300 mg/day to 20–40-year-old or 30–56-year-old men raised androstenedione concentrations in all. A total of 97 subjects were enrolled in two separate studies (26,27). The intersubject variability was remarkably high. Although there was no increase in total testosterone concentration in the older men, there were increases in free testosterone and estradiol levels. There was a 30% increase in total testosterone level in the younger men; however, this rise was accompanied by a 150% rise in circulating estradiol levels. When conjugated steroid hormone levels were assessed, the increases in excretion rates of these steroid hormone metabolites increased markedly (far out of proportion to the circulating levels of testosterone) as did circulating levels of testosterone *glucuronide* (28). Despite these changes in circulating steroid hormone levels, there were no changes in gonadotropin levels, indicating a minimal, if any, effect on the hypothalamic–pituitary–gonadal axis. Thus the ingested steroid is largely metabolized to its glucuronide conjugate and other metabolites before it is released into the general circulation. In an additional well-controlled study, the ingestion of andro-

stenedione did not stimulate muscle protein anabolism across the thigh muscles in young healthy men (29). In contrast to studies with DHEA, the levels of HDL cholesterol declined slightly in the older men.

There have been no credible studies in adolescent athletes nor do I think that one could ethically be done. The overwhelming preponderance of the evidence in younger and older adults does not indicate a salutary effect on strength or athletic performance. On the other hand, many athletes are taking androstenedione at unknown dosages and a product of unknown purity and with many other “chemical” preparations. However, some of the impurities may be on the banned list, as was found for a nandrolone metabolite contaminating an over-the-counter preparation of androstenedione (30). I suspect that no major harm is being done to the adolescent except for the cost of the product (and the resulting expensive urine), while the producers are making large profits.

IX. GROWTH HORMONE AND INSULIN-LIKE GROWTH FACTOR 1

Growth-hormone-deficient subjects are weaker and their body composition has a higher percentage of fat than normals of the same body mass index. Therapy with growth hormone (GH) increases strength and lean body mass. All of these are desired effects in athletes. Growth hormone is also likely to promote the anabolic state. Whether GH will have these effects in highly trained athletes who already have a larger lean body mass, increased strength, and little adipose tissue remains an open question. There are no comprehensive studies of highly trained athletes receiving GH supplementation. Growth hormone certainly has been used in otherwise normal individuals, including some with constitutional delay of growth and adolescence, with obvious additional benefit over and above that of puberty itself. Growth hormone is expensive (perhaps \$2,000–\$5,000 per month, depending on the dose) and many counterfeit products exist.

Another approach to increasing circulatory GH levels is to use GH secretagogues: compounds that *transiently* raise GH levels by a direct action on the pituitary or indirectly via stimulating GH-releasing hormone or inhibiting somatostatin. These include the drugs levodopa, clonidine, and perhaps glucagons and vasopressin. More to the point of supplementation would be the use of the amino acids arginine, ornithine, lysine, and tryptophan. Under controlled conditions (often very high dosages given intravenously), these amino acids have the capacity to release a large pulse of GH acutely. However, because of an absolute and then a relative refractory period for the next (spontaneous) GH pulse, it is unlikely that the overall GH secretory rate is increased for the full 24 h. The feedback loops conspire to downregulate endogenous GH release to compensate for the large additional, pharmacologically induced, GH spike.

Although insulin-like growth factor 1 (IGF-1) theoretically might deliver what the athlete desires, that is, an anabolic but nonandrogenic activity, there are two major impediments to its widespread use: hypoglycemia from large bolus injections and availability (and cost). There simply is not a large enough supply of the peptide available and what is touted to be rhIGF-1 may be counterfeit. There are no studies of IGF-1 to show an effect on athletic performance or on strength, aerobic capacity, body composition, or bone mass in athletes. Theoretically, IGF-1 ought to be anabolic in adolescents, but does it cause more than the natural changes surrounding peak height velocity?

X. CONCLUSIONS

Supplementation (doping) in an attempt to increase athletic performance has been used for centuries: potions, caffeine, adrenergics, strychnine, amphetamines, anabolic steroids, and peptides related to the growth hormone–IGF axis have been used. Irrespective of the choice of the class of the compound or specific agent, the science usually greatly trails the hype and agents’ subsequent use. Some, in fact are proven effective, for example, testosterone (20,21), but the majority of supplements have not been shown to increase anything, let alone athletic performance.

The use of drugs to enhance athletic performance is on the rise as more products become available not only to aid performance but also to avoid detection in those venues where drug testing is performed. One will note that the issues of fairness, ethics, addiction, and the roles of the enablers—coaches, trainers, and the medical community—have not been considered in this chapter. These issues as a group are critical challenges to sport in general, but are of even greater import as they apply to the adolescent athlete whose growth, body composition, and sexual development is not only incomplete but also at a critical stage. Psychosocial development is also at a vulnerable state as the adolescent is trying to become an adult with a set of moral and ethical values. What lifetime messages do we transmit by condoning these behaviors?

Using the Web to Obtain Information on Genetic and Hormone Disorders

John A. Phillips III

Vanderbilt University School of Medicine and Meharry Medical College, Nashville, Tennessee, U.S.A.

I. INTRODUCTION

New findings on the genetic basis of endocrine disorders are reported at an ever-increasing rate in a growing variety of books, journals, and other periodicals. Unfortunately, access to this and other current information on clinical and laboratory findings of familial endocrine disorders, and who performs genetic tests, cannot be found in a single journal or text. Electronic databases are now providing medical professionals rapid access to the bulk of current information and data. These electronic databases can also be searched in an interactive way for conditions that cause symptoms and signs, to permit generation of differential diagnoses that will often include rare or recently discovered disorders that many endocrinologists probably have never encountered. Access to and use of these databases can enable all endocrinologists to more frequently diagnose cases and be aware of subtleties that differentiate alternative diagnoses. These are important reasons to use electronic databases. This chapter provides information on how to use the World Wide Web for information about genetic and hormone disorders.

A. Online Mendelian Inheritance in Man

Online Mendelian Inheritance in Man (1) (OMIM) is maintained by the National Center for Biotechnology Information (NCBI). It is available without charge at <http://www.ncbi.nlm.nih.gov/Omim>. It is updated daily. In March 2001, 12,379 entries were included. A wealth of information is contained about the history, signs, symptoms, diagnosis, management, and research findings in these 12,379 genes and genetic disorders, as are detailed gene and disease focused maps. Access through hyperlinks to a variety of Web sites is another important strength. These hyperlinks include MEDLINE, GenBank retrieval system, Human Gene Nomenclature Home Page,

Online Mendelian Inheritance in Animals, The Alliance of Genetic Support Groups, The Cardiff Human Gene Mutation Database, MitoMap (the Emory University mitochondrial genome database), and databases on genes that cause retinal diseases, and a variety of other locus-specific databases. The utility of these databases and their hyperlinks in clinical applications will be illustrated in this chapter.

B. Frequently Used Terms Related to the Web

Knowing the definitions of terms that will be helpful in using the World Wide Web (WWW) is a good first step in learning how to use Web.

E-mail: Abbreviation for electronic mail. The use of a network to send and receive messages.

HTML: Abbreviation for hypertext markup language, which enables authors to insert hyperlinks. Clicking on a hyperlink displays another HTML document. Therefore, in a hypertext system one can navigate by clicking hyperlinks, which produces a display of another document that also contains selected hyperlinks.

Http: The Internet standard supporting exchange of information on the WWW. Http enables the embedding of hyperlinks in Web documents. Http also defines the process by which a Web client uses a Web browser program to generate a request for information and send it to a Web server, which is a program designed to respond to Http requests and provide the desired information.

Hypertext: A computer text form that allows readers, by clicking on the hyperlink, to display another HTML document that may also contain hyperlinks to other related documents.

Internet: The worldwide system of linked computer networks that facilitates data communication services such as remote log on, file transfer, e-mail, the WWW, and news groups. The Internet assigns every connected computer a unique Internet address so that any two connected computers can locate each other on a network and exchange data.

Log on/log off: The processes of establishing/terminating a connection with a network or computer.

Netscape Communicator: A package including a popular Web browser called Netscape Navigator that is available for Microsoft Windows, Macintosh computers, and a variety of Unix workstations.

Online information service: America Online (AOL) is an example of a for-profit firm that makes current news, stock quotes, and other information available to subscribers over standard telephone lines.

Surfing the net: Exploring the WWW by following a series of hyperlinks of interest to the surfer.

URL: Abbreviation for uniform resource locator. On the WWW, URLs are a string of characters that precisely identifies an Internet's resource types and locations. The following fictitious URL identifies a WWW document (<http://www.genetic.edu>). <http://> indicates the domain name of the computer on which it is stored; (www.genetic.edu), fully describes the document's location. In addresses, small letters ([www](http://www.genetic.edu) and [http](http://www.genetic.edu)) are used. In abbreviations not pertaining to addresses, capital letters may be used ([WWW](http://www.genetic.edu), [Http](http://www.genetic.edu), and [HTTP](http://www.genetic.edu)).

Web (World Wide Web, WWW): A global hypertext system that uses the Internet-linked computer network to facilitate data communication.

Web browser: A program that runs on an Internet-connected computer and provides access to the WWW.

Web server: A program that accepts Http-formatted requests for information. The server processes these requests and sends the requested document to the connected computer requesting the information.

Web site: A set of related documents making up a hypertext presentation on the WWW. A Web site usually has a welcome or home page that serves as the initial document. By following instructions on the home page, one can select and gain access to the information and data included in the web site.

II. USING THE WEB TO OBTAIN INFORMATION FOR DYSMORPHIC PATIENTS

A newborn baby is suspected of having some form of dwarfism. Ventriculomegaly and short limbs, as detected

by fetal ultrasound, were noted at 20 weeks gestation. Chromosome studies from amniocentesis revealed a 46, XY pattern without any abnormalities noted. The fetal head size at 30 weeks' gestation as noted on ultrasound was stated to be 35 weeks. The ventriculomegaly had resolved, and the limb lengths were those expected at 29 weeks. Physical examination detected macrocephaly, macroglossia, downward slanting palpebral fissures, cataracts, and syndactyly of the second and third fingers. Blood glucose was 28 mg/% (low).

The attending neonatologist believes that the baby "looks funny" and wants to know if you, the consulting physician, think the baby has a syndrome. He wants to know if the infant has this syndrome, how to confirm it, and what is the expected prognosis?

You, as the consulting physician, are unaware of this constellation of clinical findings and/or what syndrome might be present but must solve the problem. You decide to carry out a systematic search to obtain a list of possible syndromes that share the infant's signs and symptoms. To do this, the first step is to carry out a keyword search. Since the WWW might contain helpful information, you initiate a search beginning with the OMIM database. Using the computer in the nursery, you open Netscape Communicator, America Online, or any Web browser available on the computer, and type in the OMIM URL or address: <http://www.ncbi.nlm.nih.gov/Omim>. The OMIM homepage appears on the computer screen and you click on "Search the OMIM Database," and then enter "macrocephaly" as a search term and press the "enter" key. Ninety-nine disorders in OMIM have macrocephaly listed. This is too many items to consider, so you repeat the search using "cataract" as a finding, and 206 matching entries appear. This number of disorders is also too long, so you search using "syndactyly." Your third search produces 184 matching entries—again too many. You then decide to find out how many disorders have both macrocephaly and cataract by typing both macrocephaly and cataract, leaving a space between the two words (macrocephaly cataract) as a search string.

Only 11 entries are listed as having both of these findings (see Fig. 1). These are #109400 basal cell nevus syndrome (BCNS); *120140 collagen, type II, ALPHA-1; COL2A1, #30700 hydrocephalus due to congenital stenosis of aqueduct of Sylvius, HSAS1, HSAS, HYCX; #156550 Kniest dysplasia; #194050 Williams-Beuren syndrome, WBS; *#231675 glutaricaciduria IIC; *231680 glutaricaciduria IIA; *300005 methyl-CpG-binding protein 2, MECP2; #300279 mental retardation, X-linked, with progressive spasticity; #301050 Alport syndrome, X-linked, ATS; #312870 Simpson-Golabi-Behmel syndrome, type 1, SGBS1. Note that the entry numbers are in hypertext (color) on the screen. By clicking on any of these hypertext *numbers*, each corresponding entry is automatically opened. To narrow further the number of matches and focus your search, you add "syndactyly" and enter

[#312870](#) SIMPSON-GOLABI-BEHMEI, SYNDROME, TYPE 1; SGBS1

Figure 1 OMIM page shows results of search initiated using "macrocephaly cataract" as a search string.

"macrocephaly cataracts syndactyly" as a search string. Only one OMIM entry is listed for all three of these findings: #312870 Simpson-Golabi-Behmel syndrome, type 1; SGBS1.

You have done something remarkable. In less than 2 min, you have logged onto and searched a large electronic database of genetic and endocrine disorders to generate a successive series of progressively refined differential diagnoses. You open the single file (#312870 SGBS1) that matches your search criteria (macrocephaly cataracts syndactyly) by clicking your mouse on it, and the first of seven pages of information on SGBS1 appears on the screen for review (see Fig. 2). The clinical synopsis under Table of Contents or the complete text of this entry can then be reviewed. Note in Figure 2 that the Database Links below the Table of Contents provide immediate access to other databases, including MEDLINE. If you click on the MEDLINE database link, you will automatically see 28 publications on SGBS1. To see the abstract of any of these, you can click on the author's name in hypertext. To see all articles that, in turn, are related to each publication, you can click on "See Related Articles," which is also in hypertext. Using these hypertext links, you can obtain, select, and print the abstracts of any of the numerous articles that constitute the published knowledge about this disorder.

Since SGBS1 is a rare disorder that you may have not seen previously, you want to know if there are laboratories that can provide confirmatory tests. The GeneTests database available at <http://www.genetests.org/servlet/access> is a directory of laboratories that provide testing for genetic disorders (see list of selected Web sites below). After you register with GeneTests, you are

given a password for professional users. Using this password, you can access and search the GeneTests database for Simpson-Golabi-Behmel syndrome to find labs that provide either clinical or research testing for this disorder. In a matter of a very few minutes, you have generated a working diagnosis (SGBS1); obtained information about the pathogenesis, mode of inheritance, and findings associated with SGBS1; and gained access to a lab that can help confirm the working diagnosis. Using this information that you obtained from the Web in just a few minutes, you feel much better prepared to talk with the neonatologist and the baby's parents who are waiting for your opinions.

III. HOW TO GENERATE A DIFFERENTIAL DIAGNOSIS FOR A FAMILY HAVING UNUSUAL ENDOCRINE PROBLEMS

A 15-month-old boy is referred to you by his pediatrician who suspects he has growth hormone deficiency. The child weighed 3.2 kg at full term following an uncomplicated pregnancy, labor, and vaginal delivery. His height SDS is now -3.2 , and his length since 5 months has become progressively retarded. Your examination shows the child is proportionate and his height and weight are commensurate with each other. You note that his extremities appear normal in length, and you do not detect any kyphosis, limitation of joint motion, or dysmorphic features. His bone age is delayed greater than -2 SD. You see no skeletal abnormalities. The serum thyroxin level is abnormally low, but the levels of electrolytes, glucose, urea nitrogen, bicarbonate and anion gap, calcium, phos-

TEXT

A number sign (#) is used with this entry because of evidence that some cases of the Simpson-Golabi-Behmel overgrowth syndrome are caused by mutation in the gene for glypican-3 ([300037](#)), which maps to Xq26. A second SGBS locus (SGBS2: [300209](#)), located on Xp22, was identified by gene mapping ([Brzustowicz et al., 1999](#)). 

In 2 males, sons of sisters, [Simpson et al. \(1975\)](#) observed a 'new' dysmorphism with the following features: broad stocky appearance, distinctive facies (large protruding jaw, widened nasal bridge, upturned nasal tip), enlarged tongue, and broad, short hands and fingers. Intelligence was normal. The family referred to the appearance as 'bulldog'-like. In infancy hypothyroidism was suggested, but this was excluded by laboratory tests. Close linkage with the Xg blood group locus was excluded. [Kaariainen \(1981\)](#) told me of a tall (192 cm) 40-year-old man with operated pectus excavatum, ventricular septal defect, central cleft of the lower lip, peculiar cup-shaped ears with knobiness and nodularity, short clubbed terminal phalanges, low-pitched voice, and cataracts developing at age 35. The parents, who came from different parts of Finland, were 170 and 160 cm tall. A brother, height 180 cm, died at age 18 years of ventricular septal defect and pulmonary hypertension. He looked like the surviving brother and quite different from other members of the family. [Kaariainen \(1982\)](#) concluded that the disorder is the

Figure 2 OMIM page shows first of seven pages of information on Simpson dysmorphia syndrome. Note Database Links below Table of Contents that provide immediate access to other databases, including MEDLINE.

phorus, and urine pH are all within normal limits. A 16-year-old full sister reportedly had “panhypopituitarism” and she “didn’t go through puberty.” She was treated with “growth hormone, thyroid hormone and other shots to make her grow and go through puberty.” The results of previous endocrine blood tests on the 15-month-old show low serum levels of gonadotropins and thyroxin. Combined pituitary hormone deficiency is a logical diagnosis for the 15 month old, since there is failure of response to growth-hormone-releasing hormone (GHRH), thyroid-releasing hormone (TRH), and leuteinizing-hormone-releasing hormone (LHRH), and the magnetic resonance imaging (MRI) study reveals a hypocellular pituitary. This working diagnosis also fits with the information known about his 16-year-old sister.

You decide to perform a keyword search to produce a differential diagnosis. To utilize the WWW to obtain information on familial hormone deficiencies, you carry out this search of the OMIM database. To do this, you log onto the OMIM Home Page by entering the URL: <http://www.ncbi.nlm.nih.gov/Omim>. You then click on “Search the OMIM Database” with the mouse and enter “gh” as a search term. Using gh as the search term gives 49 hits (see Fig. 3). If you search using both gh and thyroid (gh thyroid), only 11 disorders appear on the screen (see Fig. 4). Finally, if you add gonadotropin to your keyword search (gh thyroid gonadotropin) only three OMIM entries match: *173110 POU domain, class 1, transcription factor 1; POU1F1; #262600 pituitary dwarfism III; *601538 PROPHET OF PIT1, paired-like homeodomain transcription factor; PROP1 (see Fig. 5).

The first entry (*173110 POU domain, class 1, transcription factor 1; POU1F1) contains information about the PIT1 transcription factor and includes the following interesting paragraph under Clinical Features

“Mutations of the POU1F1 gene in the human and Pit1 in the mouse are responsible for pleiotropic deficiencies of growth hormone, prolactin, and thyroid-stimulating hormone, while the production of adrenocorticotrophic hormone, luteinizing hormone (LH; 152780), and follicle-stimulating hormone (FSH; 136530) are preserved. On the other hand, patients with combined pituitary hormone deficiency due to homozygosity or compound heterozygosity for inactivating mutations of PROP1 (601538) cannot produce LH and FSH at a sufficient level and do not enter puberty spontaneously (Wu et al., 1998).”

This latter entry sounds like a very good match to the signs and symptoms of your patient.

The second entry (#262600 pituitary dwarfism III) also contains interesting information in its first paragraph

Many patients classified as exhibiting panhypopituitarism probably have combined pituitary hormone deficiency with sparing of adrenocorticotro-

pin. Mutations causing combined pituitary hormone deficiency have been described in the PIT1 (173110), PROP1 (601538), HESX1 (601802), and LHX3 (600577) genes. In addition to manifestations of the deficiency of pituitary hormones, the LHX3 mutations are associated with rigid cervical spine, and the HESX1 is associated with septo-optic dysplasia (182230).

The third entry (*601538 PROPHET OF PIT1, paired-like homeodomain transcription factor; PROP1) includes, as its first paragraph,

PROP1 has both DNA-binding and transcriptional activation ability. Its expression leads to ontogenesis of pituitary gonadotropes, as well as somatotropes, lactotropes, and caudomedial thyrotropes. Inactivating mutations of PROP1 which have an autosomal recessive mode of inheritance, cause deficiencies of luteinizing hormone (LH; 152780), follicle-stimulating hormone (FSH; 136530), growth hormone (GH; 139250), prolactin (PRL; 176760), and thyroid-stimulating hormone (TSH; 188540).

This entry sounds like the best match for the signs and symptoms of your patient.

Since this case fits the findings reported for PROP1 mutations, you decide to review the 1998 article by Wu et al. On the Web, you can obtain a copy of the abstract of this paper by clicking the mouse on either of the following: Wu et al., 1998 hypertext at the end of the paragraph cited above; or Wu et al., 1998 hypertext in either the PIT1 (173110) or PROP1 (601538) entries. Then click on the PubMed ID (9462743) that follows the reference that appears. You will then see the abstract of the reference on your screen and you can print it. Since this is a PubMed document, you can also save it as a file on your computer as shown at the bottom of the page, or you can order a complete copy through Lonesome Doc as shown at the top. You can also obtain copies of articles by clicking on MEDLINE under “Database Links” that are just below the Table of Contents of each entry (see Fig. 2). If you do a PubMed search for “gh thyroid gonadotropin familial” you will immediately find 16 related articles, of which two of the first three contain information that you may find helpful in your further evaluation and treatment of your new patient (see Fig. 6). As in the first case, you can carry out a GeneTests search to find a lab that can carry out molecular analysis of the PROP1 gene (see GeneTests in the list of selected Web sites below).

Now you have a working diagnosis (PROP1 defects), information on the pathogenesis, mode of inheritance, the findings associated with the disorder, and a way to find a lab that could be used to help confirm your working diagnosis. Obviously, with this information in hand you feel better prepared to talk with your patient’s parents and answer their questions.

IV. HOW TO OBTAIN INFORMATION ON A CASE OF ENDOCRINE NEOPLASIA

You are asked to see a 42-year-old woman who has a widely metastatic pheochromocytoma. Her history shows that her father was diagnosed with medullary carcinoma of the thyroid at 20 years of age. His thyroidectomy was complicated by severe hypertension, which led to the discovery of his also having had a pheochromocytoma. You perform a keyword search to produce a differential diagnosis. You carry out this search of the OMIM database using the terms "medullary carcinoma thyroid pheochromocytoma" and obtain nine matching entries (see Fig. 7).

The first matching entry (#171400 multiple endocrine neoplasia, type II; MEN2) contains the following information in its introduction:

A number sign (#) is used with this entry because of evidence indicating that MEN2A results from mutation in the RET oncogene (164761). Multiple endocrine neoplasia, type IIA, is an autosomal dominant syndrome of multiple endocrine neoplasms, including medullary thyroid carcinoma, pheochromocytoma, and parathyroid adenomas.

This suggests that you should consider MEN2, which is caused by mutations in the RET gene.

Figure 7 OMIM page shows results of search initiated using "medullary carcinoma thyroid pheochromocytoma" as a search string.

The second matching entry (*164761 RET protooncogene; RET) begins with the following information:

Mutations in the RET gene are associated with the disorders multiple endocrine neoplasia, type IIA (MEN2A; 171400), multiple endocrine neoplasia, type IIB (MEN2B; 162300), Hirschsprung disease (HSCR; aganglionic megacolon; 142623), and medullary thyroid carcinoma (MTC; 155240).

Since a RET gene mutation seems likely, before you see your patient you want to know if there are laboratories that can provide confirmatory tests. To get this information you access and search the GeneTests database for MEN2 and find the addresses, phone, and fax numbers of several labs that provide testing for this disorder. This testing involves sequencing of exons 10, 11, 13, 14, and 16 of the RET proto-oncogene, which include the sites of common mutations that cause MEN2. In a matter of a very few minutes, you have generated a working diagnosis (MEN2); obtained information concerning the pathogenesis, mode of inheritance, and the findings associated with MEN2; and gained access to a lab that can help confirm your working diagnosis. Having this information you feel much better prepared to talk with your new patient to address her questions about the risk of her children having a genetic predisposition to medullary thyroid carcinoma or pheochromocytoma. If she is found to have an identifiable RET mutation, testing of her children would be possible. If they test positive, prophylactic resection of their thyroids could be offered as well as frequent screening for pheochromocytomas.

V. SELECTED WEB SITES ON GROWTH AND HORMONE DISORDERS

American Diabetes Association (<http://www.diabetes.org>). For professionals as well as lay individuals. http://www.childrenwithdiabetes.com/index_cwd.htm is the online community for kids, families, and adults.

Chromosomal Variation in Man (<http://www.wiley.com/products/subject/life/borgaonkar/access.html>). A catalog of chromosomal variants and anomalies that includes citations on all common and rare chromosomal alterations, phenotypes, and abnormalities in humans. The database is organized by variations and anomalies, numerical anomalies, and chromosomal breakage syndromes.

Cytogenetic resources (<http://www.kumc.edu/gec/geneinfo.html>). Database of normal and abnormal karyotypes, empirical risks for chromosome abnormalities, and maps of genes on chromosomes.

Dysmorphic Human-Mouse Homology database (DHMHD) (<http://www.hgmp.mrc.ac.uk/DHMHD/dysmorph.html>). Searchable database of phenotypic features that generates differential diagnoses of syndromes, and genetic and cytogenetic disorders.

Endocrine Society (<http://www.endo-society.org/>). Information on the Endocrine Society, fellow societies, organizations, and patient education groups as well as resources for scientists and physicians.

- GeneMap'99 (<http://www.ncbi.nlm.nih.gov/genemap/>). Includes the locations of more than 30,000 genes and provides an early glimpse of some of the most important pieces of the genome.
- GeneTests (<http://www.genetests.org/servlet/access>). Contains a medical genetics laboratory directory, genetics clinic directory, and disease information through companion site (GeneClinics).
- Genetic Alliance (<http://www.geneticalliance.org>). Disease information as well as genetic support groups to voice the common concerns of children, adults, and families living with, and at risk for, genetic conditions.
- Genetic Conditions/Rare Conditions Support Groups and Information Page (<http://www.kumc.edu/gec/support>). For professionals, educators, and individuals seeking information on genetic disorders, birth defects, and chromosomal disorders
- Genetics Education Center (<http://www.kumc.edu/gec/geneinfo.html>). Contains information on genetic conditions; clinical genetics resources; clinical genetic centers, departments, and clinics; genetics education center; genetic courses, lectures, and educational materials; ethical, legal, and social implications of the human genome project; genetic computer resources.
- Glossary of Genetic Terms (<http://www.kumc.edu/gec/glossary.html>). Contains a variety of sites that define and illustrate genetic terms useful to clinicians, educators, and the lay public.
- Human Genome Project Information (<http://www.ornl.gov/hgmis/>). Contains information and educational materials on the Human Genome Project, including pertinence to clinical medicine and ethical, legal, and social issues.
- Human Growth Foundation (<http://www.hgfound.org/>). A lay organization established for parents and friends of children with various growth disturbances including overgrowth, growth hormone deficiency, Turner syndrome, and others.
- Information for Genetic Professionals (<http://www.kumc.edu/gec/geneinfo.html>). Contains information on cancer, cytogenetics, genetics, hyperlipidemia, neurogenetics, single-gene disorders, support groups, and genetic tests.
- International Society for Pediatric and Adolescent Diabetes (<http://www.ispad.org>). News, membership roster, meeting dates.
- Lawson Wilkins Pediatric Endocrine Society (<http://lwpes.org>). News, job listings.
- Magic Foundation (<http://www.magicfoundation.org>). A lay organization established for parents and friends of children with various growth disturbances including overgrowth, growth hormone deficiency, Turner syndrome, and others.
- March of Dimes (<http://modimes.org>). Information on birth defects for professionals and families.
- MEDLINE PubMed (<http://www.ncbi.nlm.nih.gov>). Provides access to a cornucopia of scientific and medical publications in a searchable format. It is available on the Web site of National Center for Biotechnology Information.
- National Association for Rare Disorders (NORD) (<http://www.NORD-rdb.com/~orphan>). Database of rare disorders includes symptoms, causes, diagnostic tests, and treatment for families and professionals.
- National Human Genome Research Institute (NHGRI) (<http://www.nhgri.nih.gov/>). Contains information on the Human Genome Project and ethical, legal, and social implications.
- NCBI Education (<http://www.ncbi.nlm.nih.gov/Education/index.html>). Contains PubMed and other tutorials.
- NCBI Site Map (<http://www.ncbi.nlm.nih.gov/Sitemap/index.html>). Contains over 60 links to databases including genes and diseases, gene maps, mutation databases, OMIM PubMed, and educational sites.
- Neurofibromatosis Homepage (<http://nf.org>). Contains information about neurofibromatosis and contacts for related resources.
- OMIM (<http://www.ncbi.nlm.nih.gov/Omim>). Online Mendelian Inheritance in Man contains textual information, pictures, and reference information on genes and genetic disorders containing clinical findings, references, and gene maps. OMIM has many links to NCBI's Entrez database of MEDLINE articles and sequence information, and many links to other databases.
- Policy Statements from the American Academy of Pediatrics (<http://www.aap.org/policy/pprgtoc.html>). Contains policy statements and guidelines on diagnosis and treatment of genetic disorders as well as newborn screening.
- Policy Statements from the American College of Human Genetics (<http://www.faseb.org/genetics/acmg/pol-menu.htm>). Contains a variety of policy statements about genetic diseases, genetic testing, and treatment of genetic disorders.
- Primer on Molecular Genetics (<http://www.ornl.gov/hgmis/publicat/primer/intro.html>). A Department of Energy site that contains information on molecular genetics, genetic testing, and the Human Genome Project.
- Quackwatch (<http://www.quackwatch.com/>). Information on health fraud and quackery as well as alternative treatment, such as nutritional supplements for Down syndrome.
- Rare Genetic Diseases in Children (<http://mcr2.med.nyu.edu/murphp01/lysosome/lysosome.htm>). Intends to publicize, educate, and refer those interested in or concerned about the various lysosomal storage diseases.

Simulated Genetic Counseling Session (<http://www.kumc.edu/gec/gcsim.html>). Online simulated session that illustrates the process of genetic counseling.

VI. CONCLUSIONS

The World Wide Web is here to stay. It offers access to a wealth of information on and differential diagnoses for complex genetic and endocrine problems. In addition, to information for the physician, the WWW can also provide access to specialized lab tests and educational materials for patients and their families. It behooves every physician to capitalize on the resources that computer technology can provide. As is true for most things in life, some effort must be expended to develop the expertise to accomplish these goals. We hope that the material in this chapter will help readers to succeed in using the WWW to obtain information on genetic and hormone disorders.

Hormone Measurements and Dynamic Tests in Pediatric Endocrinology

Adriana A. Carrillo

University of Miami School of Medicine, Miami, Florida, U.S.A.

Fred Chasalow

Maimonides Medical Center, Brooklyn, New York, U.S.A.

I. INTRODUCTION

Measurement of hormones has had a tremendous impact on the diagnosis of endocrine disorders. Quantification of basal hormone levels in a serial manner at different diurnal or night-sleep hours provides understanding in physiological and pathological endocrine events. However, differentiation between normal and abnormal endocrine function may require dynamic tests to determine if feedback mechanisms are intact. By providing a stimulatory agent such as medication, stimulation tests are used to document hormonal deficiency as in presence of growth hormone deficiency, adrenal insufficiency, or gonadal failure. Suppression tests are performed to determine the presence of hormonal excess by evaluating functionality of feedback mechanism, as in Cushing's syndrome and in acromegaly. The individual performing a test is referred to the pertinent chapter in this book for an extensive review of indications, precautions, and interpretations of results.

II. ROLE OF THE LABORATORY

A. General Considerations in Interpreting Test Results

Several steps are needed to interpret test results, as well as consideration of the units and reference values given by the laboratory. First, the units reported can be classified into two types: (1) mass-based units, usually used for small molecules, such as steroids and thyroid hormones; and (2) standard preparation-based units, usually used for

proteins. Both of these have specific problems. Most small molecules are generally reported in mass units (e.g., ng/dl). The pure materials are readily available and inexpensive; test solutions of known concentration can be compared from laboratory to laboratory. Some laboratories report results as ng/dl, and others use ng/ml. The System International (SI) is an effort to standardize scientific nomenclature. Small molecules are now being reported in SI units (moles per liter). When peptide hormones assays were first established, pure materials were not readily available and each laboratory generated its own standard. To solve this problem, groups with international support (National Institutes of Health and/or the World Health Organization) made large standard preparations and defined the amount of active hormone present as an International Unit (IU). As needed, a vial of the standard, with a defined concentration in IU/l would be reconstituted. Over time, the original international standards were depleted and new standards were collected, but the new standards did not have exactly the same amount of hormone as the old. Thus, depending upon when a particular laboratory established its assay, the normal values in IU will be different, but each is properly called an International Unit. Hence, knowing that a hormone is reported as IU/l does not specify the normal or expected values.

Another source of differences in laboratory results is microheterogeneity. Many peptide hormones are glycoproteins with variable amounts of carbohydrate groups, perhaps a partial cause of inactive or hyperactive molecules. Because the epitopes frequently overlap with the glycosyl groups, specific antibodies may be more (or less) immunoreactive with the active hormone or with metab-

olites or fragments, and the different standards may also be more or less contaminated with metabolites or fragments. As a consequence, the microvariation, immunoreactivity, and bioactivity correlate to a variable extent. In summary, it is not sufficient to report results as IU/l because different IUs are in use. This problem becomes more important if an endocrinologist is using several different laboratories, perhaps because of third-party payment or requirements.

The reference values are provided by the laboratory and are used for comparison with a test result rather than to identify normal from abnormal values. To have statistical validity, reference values should be established from a sample of 100–200 individuals without disease. The reference range is calculated considering 95% of all values ± 2 standard deviations (SD). It is assumed that the sample population has a normal gaussian distribution. If a test result is not between the reference parameters, different possibilities such as disease, individual variation, different populations, or use of medications may be considered to determine if further action is needed. Reference values including conventional, SI values and conversion factors are available in Addendum 1.

B. Assay Format and Design

The most commonly used format (1) for antibody-based assays is displacement analysis. With this format, a limited amount of antibody is allowed to bind to a limited amount of specific tracer for the hormone, the antibody-bound tracer is separated from the free tracer, and the antibody-bound tracer is quantitated. If the tracer is a radioactive hormone, then the assay is classified as a radioimmunoassay (RIA); if the tracer is a hormone coupled to an enzyme, then the assay is classified as an enzyme immunoassay. If the tracer is a fluorescent compound, then the assay might be classified as fluorescent immunoassay. In each format, a standard curve is generated by adding known amounts of unlabeled hormone and determining the decrease (displacement) in tracer bound to the antibody. To determine the serum concentration of a hormone, the observed displacement is compared to the standard curve. The important points to consider are that additional amounts of antibody (or binding proteins) are present in the serum or that there are closely related forms of the hormone in the serum, then the assay result is unreliable. The forms can be closely related steroids for a steroid assay; glycoproteins with differences in glycosyl groups; closely related hormones, such as the activin-inhibin or luteinizing hormone–human chorionic gonadotropin (LH-hCG) pairs; or isoforms, such as the 20 K and 22 K isoforms of growth hormone. In each of these formats, the least analytic precision occurs at the lowest concentration of analyte. Thus, alternative methodology must be used if the clinically important analyte concentration is at the lowest range of ligand concentration. In the enzyme-linked immunosorbent assay (ELISA) format, a

small amount of hormone is prebound to each well of a 96-well plate (or to a plastic or glass tube as an alternative). Then the standards and unknowns are added. The hormone-specific antibody is added and allowed to react with both the prebound and free hormone. More is bound if there is less free hormone present. The amount of antibody bound is then quantitated by a suitable technique, typically by eliminating all unbound proteins and adding a second antibody that is specific for the first antibody and to which an active enzyme is bound. Finally, the amount of active enzyme is specifically determined in each well and compared to the known amount of hormone added and to a standard curve generated for comparison with the unknowns. This format is best used for assays to detect the presence of important compounds.

In the immunoradiometric assay (IRMA) format, one hormone-specific antibody is attached to the solid support. The standards and unknowns are added, and a second hormone-specific antibody is added. Note that the second antibody used in IRMA is ligand specific rather than specific for the first antibody, as would be the case in RIA or ELISA. The second antibody is labeled with radioactive tracer, fluorescent or other nonradioactive tracer, or an enzyme. After a suitable incubation period, all unbound materials are washed away. Only when the desired analyte forms a bridge between the (first) antibody bound to the solid support and the soluble (second) antibody is the tracer or enzyme bound to the solid support and available for detection. If a pair of epitopes is very closely spaced on a ligand of interest, then the combination of antibodies cannot be used in an IRMA. As a consequence of the format, the amount of tracer bound to the bridge is approximately proportional to the amount of ligand present. At high ligand concentrations, the amount of ligand can exceed the amount of either one of the antibodies. This leads to a so-called high-dose hook effect and results in low estimations of ligand concentration. IRMA reagents are generally more expensive than reagents suitable for displacement analysis because of the requirement for two matched specific antibodies. As a compensating advantage, however, in contrast to displacement analysis, the IRMA format has its greatest analytic precision at the lowest analyte concentrations. The improved sensitivity at low concentrations and the improved specificity inherent in the method has led to widespread replacement of kits for displacement analysis (including RIA) for all analytes large enough for the generation of suitable antibodies.

C. Assay Specificity

The specificity of an assay (2,3), defined as the precision of a method to measure correctly the indicated substance, is limited by two factors: the amount and nature of sample preparation, and the specificity of the antibody. Thus, most laboratories minimize the first factor and rely on the second as much as possible. The difference between an alcohol and a ketone (such as between androstenedione

and testosterone) generally permits a 10–50-fold difference in sensitivity based on a suitable antibody (a type 2 factor). Thus, for steroids present in similar concentrations, an antibody can usually provide sufficient specificity. In patients with biosynthetic defects, however, specific intermediates may be present to 10,000-fold excess. For example, an assay kit for testosterone would not be specifically tested or approved for use in children with congenital adrenal hyperplasia. At the time of diagnosis of the non-salt-losing form (typically a boy 4–6 years of age), 17-hydroxyprogesterone levels might exceed 50,000 ng/dl. Even if the testosterone antibody had only 1% cross-reactivity with 17-hydroxyprogesterone, the contribution of 17-hydroxyprogesterone to the apparent testosterone concentration would be 500 ng/dl, a level much greater than the normal range for a 4–6-year-old boy. The large amount of 17-hydroxyprogesterone would also serve as a substrate for synthesis of testosterone. Thus, both large amounts of testosterone and a cross-reacting steroid may be contributing to the apparent hormone levels. Lack of specificity can also be compounded because of age-specific differences in secretion.

There are two different mechanisms by which binding proteins can also contribute to the lack of clinical utility of a particular assay. First, if the affinity constant of the binding protein is comparable to the affinity constant of the antibody, then it may interfere with the assay by providing additional binding sites. This would probably lead to inappropriately low hormone levels. Second, because the definition of a hormone includes passage through the blood and control of the function of a second organ, serum binding proteins (BPs) can interfere with or supplement the activity of the parent hormone. For example, some binding proteins increase the half-life of a short-lived hormone (insulin-like growth factor, IGFBP-3); others increase the amount present in the serum by increasing the solubility of a lipophilic compound (testosterone–estradiol-binding globulin); others seem to have hormonal functions of their own (corticosteroid-binding globulin). Changes in binding protein concentrations can lead to large changes in total hormone levels without corresponding changes in free levels, which are presumably the active form.

Although there is no mystery in immunoassay there are many places for error, and no single laboratory value should be considered diagnostic without confirmation.

III. PRACTICAL CONSIDERATIONS

Meticulous attention to detail, both in the selection of laboratory tests and in the test room, are the keys to a successful procedure. In particular, the most important details to evaluate are the sample size requirements, the type of tubes (e.g., serum, ethylenediamine tetraacetic acid [EDTA], or heparin) used to collect the blood, and the specific sample-processing requirements, including

whether serum samples should be separated and if they could, should, or must be frozen. In consultation with the laboratory, one should determine the amount of serum required for each analyte and prepare a table listing the exact time of sampling, the analytes for that time point, and the amount of blood required by the laboratory. The proper number and type of blood collection tubes should be collected. Recall that if a mistake is made and inappropriate or inadequate blood samples are obtained, the protocol will probably have to be repeated. Finally, arrangements must be made to transport samples to the laboratory in a manner that does not lead to degradation.

A. Mechanics

Successful testing is accomplished primarily through organization before the test. A tray should be prepared to hold completed laboratory slips, the correct number and types of tubes, labels, syringes, alcohol, arm board, and tape. This allows methodical sampling throughout the test. Normal saline lock is most often used and permits an indwelling line for both withdrawal of blood samples and delivery of medication with minimal discomfort to the patient. When using heparin lock flush (10 units/ml), a maximum of 1 ml is recommended. Withdraw and discard 1.0–1.5 ml from the line before sampling; after sampling, the line may be cleared by injection of an equal volume of the normal saline or heparin solution flush. An intravenous setup is a suitable alternative but leaves the patient somewhat less comfortable during the protocol. In a child younger than 4 years of age, it is appropriate to maintain a separate intravenous line with normal saline, in addition to the heparin lock, for emergencies during potentially hazardous testing such as insulin tolerance protocols. Although this may cause some added discomfort to the patient, loss of a line is common in young children and a patent line is essential to address any untoward events.

The size of the heparin lock needle must be selected on the basis of its intended use. A 24 gauge angiocatheter needle in a scalp vein may be adequate for infusion for an infant or young child; however, it is futile to attempt to obtain multiple blood samples from such a small needle or vein. Generally, a 22 or 23 gauge angiocatheter is adequate for both infusion and sampling.

Many of the protocols for tolerance tests include an overnight fast. Because the nothing by mouth order starts after midnight, a snack should be given just before midnight, if the child is awake at that time. Otherwise, the snack should be given at bedtime. For infants and very young children, however, an overnight fast may be too long. Therefore, the fast should conform to the child's eating patterns (i.e., an infant may be on a 3–4 h feeding schedule). In general, to avoid unnecessary fasting by young children, most tolerance tests should be started as early in the morning as possible. If the test must be postponed, the child should be fed and refasted. However, if a protocol is delayed, diurnal variation must be considered

in the interpretation of the results. In most cases, medications that might interfere with the test should be discontinued for at least 1 week. If this is not possible, the effects of the medication on the tolerance test must be considered when interpreting the results. Other factors, such as extreme agitation or exercise, can also affect the results and should be noted.

A critical factor when conducting a tolerance test is the total amount of blood that must be obtained if, as is usually the case, multiple samples are required. Within a 2 week period, the usual guideline is a maximum of 5% of the total blood volume, which is calculated by multiplying the body weight (kg) by 80 ml. Remember to include any other testing planned for the same time or within 2 weeks of the tolerance test. If the amount required is more than 5% of the patient's total blood volume, the protocol must be modified.

B. Person-to-Person Considerations

One of the greatest challenges is informing the parents and the child about the purposes and mechanics of the test. This must be done in terms understandable both to the parents and to the child. Allow sufficient time for questions and answers. While you are describing the test, judge whether the parents should stay in the room with the child during the test. In deciding whether to allow the parents to stay, exercise discretion on an individual basis.

C. Time-of-Day Considerations

Most protocols are usually performed in the morning. Almost all of these tests should be performed while the patient is fasting, although there might not be any physiological rationale for food restriction. As a consequence, normal and expected values are all based on testing in the morning. There are circadian rhythms in many hormonal secretion patterns that can be superimposed on other patterns. For example, LH and FSH are both secreted episodically with 90 min cycles, but the amplitude of the cycle is increased in the morning. As a consequence, pituitary responses to gonadotropin-releasing hormone (GnRH) may be different and basal testosterone levels are

higher in the morning and one cannot measure an acute response to hCG. Adrenocorticotrophic hormone (ACTH) is also secreted episodically with a 90 min cycle, but episodes of secretion occur more frequently in the morning and the ratio of cortisol to adrenal androgen secretion also changes with time of day. Hence, if testing is or must be performed at times other than morning, care must be used in comparing observed values to expected values. The exception to this requirement is in young infants, in whom circadian patterns have not yet been established.

IV. PRACTICAL PROTOCOLS FOR DYNAMIC TESTING IN CHILDREN

A. Dynamic Tests for Growth Hormone Deficiency

1. Screening Tests for GH Deficiency

a. Background. The most widely used screening tests (4–8) to evaluate GH deficiency are serum insulin-like growth factor-I (IGF-I) and serum IGF-binding protein-3 (IGFBP-3) levels. IGF-I (somatomedin C or sulfation factor) is secreted in the liver and cartilage in response to GH and mediates many of the anabolic and mitogenic actions of GH. The IGFs are mostly bound to specific binding proteins designated BP-3. Serum levels of IGF-I are age-, gender-, and nutrition-dependent in normal children with a sharp increase at the time of puberty. IGF-I levels are not highly specific for GH deficiency. Low serum IGF-I levels also occur in children with GH receptor and/or postreceptor defects, thyroid disorders, delayed puberty, diabetes, and malnutrition. Serum IGFBP-3 has less age, gender, and nutrition dependence than IGF-I levels.

b. Indications. The diagnosis of GH deficiency in childhood must be based on auxiological criteria. Candidates for evaluation of the GH–IGF–IGFBP axis include children in the lowest fifth height–growth or bone age percentiles, when proper consideration is made for family history; children with syndromes associated with short stature; children who have acute changes in their growth charts; and children who have sustained possible insults to the pituitary, such as chemotherapy, radiotherapy, or physical injury to the head.

c. Preparation and Medication. None is needed.

d. Sampling. A single sample is obtained at the time of a routine patient visit. There is no time of day or dietary restrictions. Some laboratories require plasma, rather than serum, for IGF-I assays. Check with the laboratory before collecting a sample. IGFBP-3 levels are determined on serum. Thus, both serum and plasma may be needed.

e. Normal and Expected Values (IGF-I Levels). Normal levels (see Table 1) were determined by collecting samples from children of normal height. However, the de-

Table 1 Insulin-Like Growth Factor I (IGF-I)

Age	Males (ng/ml)	Females (ng/ml)
2 mo–6 yr	17–248	17–248
6–9 yr	88–474	88–474
9–12 yr	110–565	117–771
12–16 yr	202–957	261–1096
16–26 yr	182–780	182–780
<26 yr	123–463	123–463

From Ref. 6.

sired ideal test comparison is between children with short stature without GH deficiency and children with short stature with GH deficiency.

f. Normal and Expected Values (BP-3 Levels). The normal range is from 2.5 to 10 mg/dl, with a small dependence, compared with the normal variation in RIA or IRMA assays, on differences in age and gender. Serum levels less than 2.4 mg/dl are associated with GH deficiency. Slightly higher values occur at the time of puberty.

g. General Considerations. Although a major screening tool for diagnosing GH deficiency, IGF-I has limited sensitivity due to significant overlap with normal values. Low levels of IGF-I may be found in normal children, mainly under 5 years of age. About 50% of low levels of IGF-I are not associated with GH deficiency but with receptor and postreceptor defects. Furthermore low serum IGF-I levels with normal GH secretory dynamics may be indicative of other disorders associated with growth failure, such as nutritional inadequacies, inadequate spontaneous GH secretion, and psychosocial growth failure. Low serum IGFBP-3 levels are suggestive of GH deficiency; however, up to 43% of normal short children were reported to have low IGFBP-3 levels. In summary, IGF-I and IGFBP-3 are helpful tests in the diagnosis of severe GH deficiency, but their sensitivity and specificity are still suboptimal.

h. Basic Physiology of Growth Hormone Secretion. GH is secreted episodically with most episodes occurring during rapid eye movement sleep (Chap. 3). Serum concentrations are typically below the sensitivity of most conventional assays (<1–2 ng/ml) (9–13). Random serum samples (at least 90%) cannot be used to evaluate GH deficiency. A variety of pharmacological agents have been identified to induce GH secretion, and suitable dynamic test procedures have been developed. There are two factors necessary for the evaluation of the response to pharmacological stimuli for GH secretion: knowledge of normal and inadequate responses to the particular protocol, and laboratory selection of methods and reagents for the evaluation of serum GH levels. The pharmacodynamics of GH secretion and metabolism determine the design of the serum-sampling protocol. Episodes of active GH secretion by the pituitary last about 5–10 min, and the half-life of GH is 20–30 min. Thus, the specific protocol for a tolerance test must collect serum every 20–30 min to detect an episode of secretion.

i. Normal Values. Serum GH concentration over 10 ng/ml usually indicates adequate GH response to pharmacological stimulation. A single value over 10 ng/ml is sufficient to evaluate the response; there is not usually a second serum sample with a concentration over 10 ng/ml because GH concentration will decrease by half before the next sample is obtained. At the present time, the generally recognized criteria for GH deficiency are responses of less than 10 ng/ml (or 10 μ g/l) to two different pharmacolog-

ical stimuli for GH secretion. However the interpretation of these values must be made in accordance with the child's data (see Chaps. 1–3). The stimuli can have their effects at the level of the hypothalamus, pituitary, or both. High serum glucose levels inhibit GH secretion. Thus, each protocol must also include a significant period of fasting before the test.

j. Expected Frequency of Inadequate GH Secretion in Response to a Tolerance Test. Children with Prader-Willi syndrome, Russell-Silver syndrome, Down syndrome, other syndromes associated with short stature, Turner syndrome, or a history of cranial irradiation or of treatments for leukemia have a very high frequency (perhaps up to 100%) of inadequate GH secretion. Thus, there should be a high index of suspicion for a diagnosis of GH deficiency if a child also has one of these syndromes. Children with GH deficiency frequently continue to cross growth lines on growth charts and show significant bone age delay.

k. General Considerations. The following sections describe protocols for dynamic tests to evaluate the GH secretory capacity of the pituitary gland. These tests are expensive, not free of side effects, and require special conditions. There are two major groups of GH tests: screening tests that include exercise, levodopa, and clonidine; and definite tests that comprise arginine, insulin, and glucagon tests. Two different dynamic tests, sequentially or simultaneously, are required to confirm the diagnosis of GH deficiency.

During the immediate period of prepuberty, differentiating between growth hormone deficiency and constitutional growth delay is difficult. Sex steroid priming with testosterone or estrogen administered for Tanner stage I or II is recommended before growth hormone testing. One protocol for androgen priming is the administration of 100 mg depot testosterone 7–10 days before the actual GH tolerance test. For girls and boys, some endocrinologists prime with ethynil-estradiol. The protocol we use is 0.02 mg for children less than 50 pounds (23 kg) and 0.05 mg for those over 50 pounds (23 kg) given 18 h, 12 h, and 1 h prior to start the test.

Pharmacological tests involving the use of potent medications may mask the diagnosis of partial GH deficiency. Caution must be taken in interpreting results in obese children who undergo provocative testing for GH secretion, due to a negative impact of adipose tissue on GH secretion. Table 2 shows the protocols most commonly used in the assessment of GH secretion.

2. Arginine and Combined Arginine-L-Dopa Test for GH Secretion

a. Indications. The arginine stimulant apparently works by inducing insulin secretion and dopamine acts by blocking somatostatin secretion. The combined test (14–16) thus stimulates GH secretion by two separate mech-

Table 2 Growth Hormone Stimulation Tests

Test	Dosage	Timing peak of GH	Side effect
Arginine L-dopa	Arginine hydrochloride 0.5 g/kg/IV to a maximum of 30 g over 30 min	30–60 min	Late hypoglycemia
	L-dopa 125 mg if body weight <13.5 kg 250 mg >13.5 <31.5 kg 500 mg >31.5 kg		Nauseas, emesis, headache
GHRH	1 or 2 μ g/kg, IV bolus	15 or 30 min	Flushes
Glucagon	0.03 mg/kg to a maximum of 0.1 mg IM/SQ	2–3 h	Late hypoglycemia
Insulin-induced hypoglycemia	0.05–0.1 IU/kg IV bolus	30–60 min	Severe hypoglycemia requires IV glucose Not recommended in newborn or small children
Clonidine	5 μ g/kg to a maximum of 250 μ g	60 min	Drowsiness, hypotension
Exercise	20 min exercise	20–40 min postexercise	Exhaustion-induced asthma

anisms. Perhaps as a consequence, the combined protocol has fewer false-positive results than when either agent is administered alone. The test is used primarily when a second pharmacological test for GH secretion is required.

b. Preparation. Nothing should be given by mouth after midnight or following bedtime snack. Have arginine prepared for administration. Plan ahead: not all pharmacies have stocks of arginine, and it may have to be specially ordered in advance.

c. Medications. After the baseline serum sample is obtained, arginine HCL (0.5 g/kg to a maximum of 30 g) is administered intravenously over a 30 min period. If the combined arginine-L-dopa protocol is used, L-dopa is administered orally (PO) immediately after the baseline blood sample is obtained. Then arginine is administered. The dose of L-dopa should be as follows: 125 mg for children less than 13.5 kg; 250 mg for children between 13.5 and 31.5 kg; and 500 mg for children over 31.5 kg.

d. Sampling. Blood for GH assay should be sampled at 0, 30, 60, 90, and 120 min.

e. Special Considerations. As with the L-dopa protocol, nausea and vomiting frequently occur in toddlers. Be prepared. Do not stop taking blood samples. Children should be recumbent and may be given water throughout the test.

3. Clonidine Stimulation Test for GH Secretion

a. Specific Indications. Clonidine is an alpha 2-adrenergic agonist (17–20) that increases the growth-hormone-releasing hormone secretion, and inhibits somatostatin-releasing inhibiting factor (SRIF). This agent is probably the best choice for avoiding false-positive results. Children who fail to secrete GH in response to phar-

macological dosages of clonidine seldom secrete GH in response to any other test.

b. Preparation. The patient should receive nothing by mouth for at least 4–6 h before the test and is generally not receiving other medications.

c. Medications. Administer clonidine, 5 μ g/kg, after baseline sample is drawn, to a maximum of 250 μ g.

d. Sampling. Blood for GH assay should be drawn at 0, 60, and 90 min and blood for cortisol assay at 0 and 90 min. Usually the 60 min sample has the highest amount of GH, the 90 min sample being about 30% lower.

e. Special Considerations. Clonidine is an agent that lowers blood pressure. Blood pressure should be monitored at 0, 30, 60, and 90 min. In young children, clonidine frequently causes drowsiness, which lasts for several hours. Parents should be aware of this possible, transient side effect. Patients should have a place to lie down and may sleep or lie quietly throughout the procedure. Drowsiness may prolong the fasting period and may cause hypoglycemia. The patient must be encouraged to eat or drink after the test is finished. Water may be given freely throughout the test period.

4. Dexamethasone Response Test

a. Indications. Dexamethasone (21–23) can be used to induce growth hormone secretion with the same time course as glucagon. When used in this way, dexamethasone administration has no reported side effects. This test is not widely used for clinical purposes.

b. Preparation. Patients should fast after midnight.

c. Medications. After collection of the baseline serum sample, dexamethasone (2 mg/m^2) is administered intravenously as a bolus.

d. Sampling. After bolus administration of dexamethasone, serum samples should be obtained every 30 min for 2 h, every 15 min for 2 h, and then every 30 min for the fifth hour. The serum samples may be withdrawn from a heparin lock.

e. Normal Values. A peak of GH secretion should occur between 2 and 4 h after dexamethasone administration. The peak GH concentration should exceed 5 ng/ml in normal individuals. In patients with GH deficiency, the peak response does not exceed 5 ng/ml . Patients with obesity may also respond poorly.

f. General Considerations. Patients can drink water as desired throughout the test. At the conclusion of the protocol, patients should be fed. Like the galanin test, this protocol has not been widely utilized. Additional study is necessary to improve the response pattern.

5. Exercise-Induced GH Secretion

a. Indications. This test is frequently used as a screening test (24,25) to evaluate the need for more formal testing for GH secretion. This is a suggested protocol to take advantage of an active (hyperactive) child. Use caution with exercise-challenged children.

b. Preparation. The patient should have fasted for 3–4 h before the test.

c. Medications. None are needed.

d. Sampling. The stimulus is 20 min mild exercise: going up and down stairs, running up and down the corridor, and 20 min on an exercise cycle or bicycle. Final heart beat should exceed 120 beats/min. Obtain blood samples at the end of the exercise and at 20 and 40 min after completion of exercise or severe crying episode.

e. General Considerations. Water should be provided freely, as requested. As soon as the first serum sample is obtained at the conclusion of the exercise period, the child may eat and drink as desired. Most offices do not have the equipment for an exercise test. The usual occasion to use this protocol is a chance recognition of exercise, inadvertently performed by an active young child. Although the test is simple, safe, and inexpensive, up to one-third of normal children have an absent GH response.

6. Galanin Response Test

a. Indications. Galanin is a neuropeptide (26,27) that participates in the regulation of GH secretion, apparently in the hypothalamus. Thus, the response to galanin tests the hypothalamus–pituitary secretory pathway. This test is not widely used for clinical purposes.

b. Preparation. As with most of the pharmacological tests to evaluate GH secretion, the test should be performed in the morning after an overnight fast.

c. Medication. Galanin (p-galanin 1-29; Clinalfa AG, Switzerland) is administered over 1 h as an intravenous infusion at a total dosage of $15 \mu\text{g/kg}$ body weight.

d. Sampling. After a baseline sample is obtained, the galanin infusion is started and additional serum samples are obtained every 15 min for 2 h.

e. Normal Values. The peak response occurs between 1 and 2 h after the start of the infusion. The expected peak response is a peak level greater than 5 ng/ml . Note that the expected response is lower than with many other pharmacological tests for GH secretion. Obese children respond poorly or do not respond at all.

f. General Considerations. Patients may drink water, if desired, during the test. At the conclusion of the serum-sampling protocol, patients should be allowed to eat. The only reported side effect is a temporary bad taste when the galanin infusion is started. Galanin has fewer side effects than either clonidine or insulin administration. This may be due to the fact that galanin is a natural part of the GH secretion mechanism. However, galanin is not currently approved by the Food and Drug Administration (FDA) as a pharmaceutical agent in the United States and must be obtained as part of a research protocol at this time. The protocol described here has not been standardized for using galanin as an inducer for GH secretion. Additional studies are needed to establish the validity of this test.

7. GH-Releasing Hormone Test for Pituitary Reserve for GH Secretion

a. Indications. Administration of GH-releasing hormone (GHRH) evaluates the ability of the pituitary to secrete GH directly (28–33). Due to fluctuations in somatostatin secretion, there is great variability in the GH response. Thus, inhibitors of endogenous somatostatin such as piridostigmin and arginine have been used to enhance the GH response and to reduce the intra- and interindividuality variability. If a patient secretes GH in response to GHRH but not to pharmacological stimuli that function in the hypothalamus, then a defect in the hypothalamus is indicated.

b. Preparation. The test should be performed in the morning after an overnight fast.

c. Medication. Intravenously inject human pituitary GHRH at a dosage of $1 \mu\text{g/kg}$ over a period of 1 min. The patient may experience some flushing immediately after the infusion.

d. Sampling. Serum samples for evaluation of GH should be obtained at 0, 15, 30, 45, and 60 min. Earlier protocols also collected a late sample at 90 min, but this

does not seem to be needed because the peak generally occurs within the first hour after administration of GHRH.

e. Normal Values. Children with pituitary defects fail to secrete GH to a peak of 10 ng/ml. The peak serum level usually occurs in the 15 or 30 min sample.

f. General Considerations. Most individuals with idiopathic GH secretion have a defect in hypothalamic regulation of pituitary secretion of GH. Hence, most patients secrete GH in response to GHRH but do not secrete GH in response to normal physiological processes. High endogenous (or exogenous) levels of somatostatin block the effect of GHRH.

8. Glucagon Test for GH Secretion

a. Indications. This test is the best choice in young children and infants (34,35). Glucagon induces GH secretion by stimulating endogenous insulin secretion to compensate for elevated serum glucose levels. It is a good substitute for the insulin tolerance test that could be risky in newborn and small children.

b. Preparation. Give nothing by mouth after midnight. Patients must have normal glucose reserves at the start of the test.

c. Medications. After baseline sample is drawn, glucagon is administered intramuscularly (IM) or subcutaneous (SQ) at a dosage of 0.03 mg/kg to a maximum of 1 mg.

d. Sampling. For evaluation of GH secretion, serum samples should be obtained at 0, 1, 2, 2-1/2, and 3 h after administration of glucagon. For other indications for the glucagon tolerance test, different sampling protocols are required. Be sure to collect the last samples.

e. Normal Values. At least one sample with a GH concentration over 10 ng/ml of GH secretion usually occurs between 2 and 3 h after glucagon administration.

f. Specific Considerations. The administration of glucagon causes a temporary increase in serum glucose levels. As part of the rebound process, insulin is oversecreted and serum glucose levels decrease. Hence, a glucagon tolerance test cannot be used as a stimulus for GH secretion in individuals with a limited ability to secrete insulin. Young children frequently experience nausea and vomit during the course of this test. Be prepared.

9. IGF-I Generation Test

a. Indications. This procedure examines GH receptor function by evaluating its ability to increase serum IGF-I levels (36–39). This test is useful for identifying patients with GH resistance. There are major variabilities in administration of GH, timing of samples, and cutoff levels of the normal IGF-I response.

b. Preparation. No specific preparation is necessary, but an adequate diet must be maintained.

c. Medications. Daily doses (4 or 7 day protocol) of GH (0.025–0.05 mg/kg/day \times 7 days or 0.1 mg/kg/day \times 4 days) are given SQ. Parents or guardians may administer the additional GH injections.

d. Sampling. A baseline sample should be obtained on days 1, 5, and 8 when using dosages of 0.025 or 0.05 mg/kg/day. If the 0.1 mg/kg/day GH dosage is used, blood should be obtained before the first GH injection and 8–16 h after the fourth injection. Samples taken on intermediate days are often helpful, but are not required.

e. Normal Values. In response to GH administration, serum levels of IGF-I should triple or increase to a high normal level for age and gender. IGFBP-3 and the acid-labile subunit are measured as well.

f. General Considerations. The GH should be administered at the same time each day, either in the morning or in the evening. The dose administered is equivalent to the normal daily secretion. There are no reported side effects. Children who do not respond to GH administration with an increase in IGF-I levels are not good candidates for GH therapy.

10. Insulin Stimulation Test for GH Secretion

a. Specific Indications. This test is generally considered the gold standard (40–42), but is risky and must be done under appropriate surveillance. The mechanism of stimulation is the counterregulatory response to insulin-induced hypoglycemia. Although there are few children with responses classified as false-negative, many children have responses classified as false-positive. A false-positive response is defined as occurring in a patient who fails to secrete GH in response to insulin but secretes GH in response to other pharmacological stimuli. In contrast, a false-negative response occurs if a patient secretes GH in response to insulin but does not secrete GH in response to other pharmacological or physiological stimuli. False-positive responses may be caused by insulin insensitivity, which leads to an inadequate induced hypoglycemia. The reserve of the adrenal cortex for cortisol secretion can also be confirmed during this protocol. If cortisol reserve is adequate, then at least one sample will have a cortisol level over 20 μ g/dl. This test is not recommended for newborn or small children as they are more sensitive to insulin, nor for those with suspected hypopituitarism with risk of adrenal insufficiency.

b. Preparation. Give nothing by mouth after midnight. Calibrate and prepare for use a bedside device for rapid serum glucose measurement. Prepare a 50% glucose solution, and fill a 25 ml syringe. (Fill two syringes if the patient is larger than 25 kg.) An intravenous line with saline solution should be established in small children.

c. Medications. To start the protocol in children over 4 years of age, 0.1 unit/kg regular insulin should be administered. For younger children, a dosage of 0.05 unit/

kg is usually sufficient. However, if used for infants, the dosage must be one tenth (0.01unit/kg) and must be administered under careful observation. It is preferable to use glucagon or a different provocative test.

d. Sampling. Serum samples should be obtained before insulin administration and then at 15, 30, 45, and 60 min. Serum glucose levels must be evaluated at the bedside at each time point during the protocol. Glucose levels must decrease by 50% of the initial value or to less than 40 mg/dl. However, more severe hypoglycemia must be avoided because it can lead to seizures, coma, or death.

e. Monitoring and Dangers of Hypoglycemia. At the bedside, each blood sample must be immediately evaluated for serum glucose levels. It is not sufficient to send the sample to the hospital laboratory. If a child shows symptoms of hypoglycemia (blood glucose level less than 40 mg/dl, rapid pulse, diaphoresis, hot, and lethargic) and the signs do not improve by the next scheduled blood sampling, the 50% glucose solution should be administered (1 g/kg) from the previously prepared syringes. If this occurs, do not stop collecting serum samples according to the protocol. After the test protocol is complete, either administer the glucose solution (0.5–1.0 g/kg) or require the patient to eat and ensure that a good meal is ingested and not vomited. The patient must be monitored until serum glucose levels return to normal. Water should be provided as requested.

f. Normal and Expected Values. About 20 min after the glucose nadir there should be an episode of GH secretion. The peak level should be above 10 ng/ml. In some patients the response is delayed. Children with GH deficiency have a response of less than 10 ng/ml. About 20% of children with short stature and severe bone age delay can have a false-positive response.

g. Special Considerations. For the test to be valid, serum glucose levels must decrease more than 50% from the baseline or to less than 40 mg/dl. If signs of severe hypoglycemia occur, administer glucose but continue to collect serum for GH assay. Children with GH deficiency frequently have enhanced response to insulin, thus making them more likely to have an episode of severe hypoglycemia. Hence, this test requires the presence of either an experienced nurse or a physician.

Shah et al. (37) recently reported three cases of iatrogenic illness as a result of tolerance tests for GH deficiency (two with insulin and one with glucagon). Two of the three children died as a result of hyperglycemic hyperosmolar coma, perhaps as a result of inappropriate management after the test. Both children who died were shown to have GH deficiency when the serum obtained during the test was analyzed. Examination of the case reports suggests that the coma may have been avoided had immediate, appropriate action (not overreaction) been taken by an attending physician. In each case, analysis of serum samples showed severe hyperglycemia as a con-

sequence of excessive administration of glucose to treat hypoglycemia or rebound hypoglycemia induced by the tolerance test.

11. L-dopa Stimulation Test for GH Secretion

a. Indications. This test is frequently used (43) as the second test necessary to confirm the diagnosis of GH deficiency.

b. Preparation. Give nothing by mouth after midnight on the night before the test.

c. Medications. L-dopa is given orally immediately after the baseline blood sample is obtained. The dosage is as follows: 125 mg for children less than 13.5 kg; 250 mg for children between 13.5 and 31.5 kg; and 500 mg for children over 31.5 kg.

d. Sampling. Draw blood for GH assay at 0, 30, 60, 90, and 120 min.

e. Normal Values. At least one serum value should be above 10 ng/ml. Usually, the samples with high levels of GH are the last samples collected during the protocol.

f. Expected Values. If there is no sample with a concentration of GH greater than 10 ng/ml, then the test is diagnostic for GH deficiency.

g. Special Concerns. Nausea and vomiting frequently occur in toddlers. Be prepared. Do not stop taking blood samples. Children should be recumbent and may be given water throughout the test.

12. Overnight Test for Spontaneous GH Secretion

a. Indications. This procedure is used to evaluate spontaneous GH secretion rather than secretion in response to pharmacological stimulation (44,45). This is the diagnostic test necessary to document inadequate spontaneous GH secretion or a neurosecretory defect in GH secretion. This test is not used as often as it was used in the past due to the cost, including admitting the patient to the hospital overnight.

b. Preparation. Patients can be tested in the hospital or at home with the aid of an experienced home care service. In either case, patients should go to bed at the usual time but not later than 11 p.m. A heparin lock can be used to cause the least disturbance in sleep pattern.

c. Medication. No medication is needed as part of the tolerance test.

d. Sampling. Serum samples should be obtained every 20 min from 8 p.m. to 8 a.m., a total of 37 samples over 12 h.

e. Normal Values. There are two criteria for evaluating the adequacy of overnight GH secretion: mean levels, and number and height of episodes of secretion. The mean level is the simple average of the 37 samples col-

lected. This is a representation of the total amount of GH secreted during the 12 h period. The evaluation of normal values is confounded by practical and ethical considerations: Institutional Review Boards (IRBs) do not permit testing truly normal individuals. With this caveat, most reports suggest a normal lower limit of the mean about 3 ng/ml. Means below this limit probably indicate inadequate physiological secretion.

The second method of evaluating results is after deconvolution analysis using the Veldhuis and Johnson cluster analysis program. The program permits the evaluation of the number of episodes of secretion and the half-life of serum GH. There should be 6–10 episodes of secretion, with at least four peaks over 10 ng/ml. Fewer peaks of lower peak height are consistent with the diagnosis of inadequate spontaneous secretion or neurosecretory defect.

f. Special Concerns. In view of the large number of samples collected and the general limitation of using no more than 5% of total blood volume for laboratory testing in any 2 week period, it is frequently necessary to limit the amount of serum obtained in each sample. Hence, it is necessary to discuss with the laboratory the absolute minimum amounts of blood necessary for each sample. For example, if the laboratory requests 1 ml serum for a GH assay, then each sample collected must have 2 ml whole blood and the total volume collected is about 75 ml. If the patient weighs 10 kg, then total blood volume is only approximately 800 ml and the amount necessary would represent almost 10% of the total, which is an unacceptable proportion. This test is difficult to perform, expensive, and unspecific. No normative data for comparison purposes are available yet.

13. Combined Hormonal Stimulation Test

a. Indication. The combined hormonal stimulation test (CHST) is used for evaluation of the pituitary function by combined sequential hormonal administration in children with pathological short stature (46). As many as 30% of patients with growth hormone deficiency may have associated pituitary deficiencies. The CHST includes simultaneous assessment of the following axes: growth, thyroid, gonadal, and adrenal. In prepubertal children, the assessment of the gonadal axis can be eliminated unless LH and FSH deficiencies are suspected.

b. Preparation. Indicate nothing by mouth after midnight on the night before the test.

c. Medications. Sequential administration of insulin, thyrotropin-releasing hormone, gonadotropin-releasing hormone, and levodopa is required. First 0.1 unit/kg body weight of regular insulin is infused intravenously (IV) over 90 s. This is followed by 100 µg of gonadorelin IV (10 µg/kg, max 100 µg), and protirelin (7 µg/kg to a maximum of 400 µg IV) over 90 s. Afterward L-dopa is given orally at the dosage of 125 mg for children < 13.5

kg, 250 mg for children between 13.5 and 31.5 kg, and 500 mg for children > 31.5 kg.

d. Sampling. The following table illustrates timing for measurements of glucose, growth hormone, TSH, LH, FSH and prolactin.

Time (min)	Glucose	GH	Cortisol	FSH	LH	TSH	Prolactin
0	X	X	X	X	X	X	X
20	X	X					
45	X	X		X	X		
60	X	X	X				
90	X			X	X		
120	X					X	

e. Special Concerns. For detailed information about specific monitoring of each test, see the pertinent section in this chapter. Special attention must be given to hypoglycemia induced by insulin. There should also be an assessment of the amount of blood required for all these tests and the cost of performing them.

f. Normal Results. Normal values for each test are described in each specific section elsewhere in this chapter.

g. Special Considerations. There are potential modifications to this test. The first is to perform the full CHST as described but store the samples for measurement of TSH, LH, FSH, and prolactin until GH deficiency is confirmed, thereby reducing the expenses if the diagnosis is not growth hormone deficiency. The second modification is to select who will undergo the thyrotropin-releasing hormone and/or gonadotropin releasing hormone test. These tests provide an effective means of evaluating multiple pituitary functions in 2 h.

B. Tests for Thyroid Function

1. Calcium-Pentagastrin Test

a. Indications. This test is generally used for the detection of thyroid medullary carcinoma (47,48) as part of the work-up for multiple endocrine neoplasia (MEN) syndrome. In patients with MEN who are at high risk for the disorder, this test should be repeated on a yearly basis to confirm that thyroid medullary carcinoma has not recurred.

b. Preparation. Patients should fast after midnight or bedtime snack; water is permitted as desired. The test should be performed with the patient in a supine position.

c. Medications. Elemental calcium (2 mg/kg) is infused intravenously over 1 min; pentagastrin (0.5 µg/kg) is administered as a bolus immediately thereafter.

The elemental calcium content of some common calcium salts is calcium gluconate, 10%; calcium lactate, 13%; and calcium chloride, 27%.

d. Sampling. Serum samples for calcitonin are obtained at 0, 1, 2, 3, 5, and 10 min after administration of both stimulants.

e. Normal Values. Normal values should be established in conjunction with the laboratory.

f. Expected Values. An increase of five times over the baseline level during the test is diagnostic of medullary thyroid carcinoma.

g. General Considerations. The test protocol leads to some minor discomfort. Infusion of calcium may be accompanied by a mild generalized flush or feeling of warmth, the urge to urinate, and a sensation of gastric fullness. These symptoms are self-limited and usually do not last longer than 5 min. Pentagastrin may cause some discomfort in the pharynx and substernal and retrosternal areas, a sense of gastric fullness, abdominal cramping and nausea, and dyspepsia. These symptoms also last less than 2 min. It is extremely important to maintain patent intravenous access during the calcium infusion; infiltration of calcium into subcutaneous tissue can cause tissue necrosis.

Screening for DNA mutations of the RET proto-oncogene is more sensitive in detecting medullary carcinoma (Chapter 8). Measurement of plasma calcitonin after calcium and pentagastrin provocative testing is still used for detecting persistent or recurrent medullary thyroid carcinoma (MTC) postoperatively.

2. Thyroid Suppression Test

a. Indications. This test is used in the diagnosis of thyrotoxicosis (49,50). Radioiodine uptake by the thyroid gland should be decreased by exogenous thyroid hormone administration in a properly functioning gland. If uptake continues after treatment with thyroid hormone, then the gland is autonomous and the patient is at risk for thyrotoxicosis.

b. Preparation. Medications that affect thyroid function should be discontinued at least 1 week before the test.

c. Medications. Triiodothyronine (75 μg ; Cytomel) is given orally daily (25 μg PO three times per day) for 7–10 days.

d. Sample. Radioactive iodine uptake studies should be performed before and after treatment.

e. Normal Values. Radioactive iodine uptake in the thyroid should decrease by 50% of the initial value. Failure to suppress is indicative of an autonomous gland.

f. General Considerations. No side effects of this test have been reported. However, the test is contraindicated during pregnancy.

3. TRH Test

a. Indications. The first generation of assays could only quantitate TSH levels greater than 1 mIU/l. In many cases, however, a TSH test does not differentiate between hyperthyroidism and euthyroidism. In response to thyrotropin-releasing hormone (TRH) TSH is secreted, reaching a maximal level 5–10 times the basal TSH level. Thus, during a TRH tolerance test in euthyroid individuals (51,52), serum TSH increases into the range that could be detected by the assay methodology even though the basal level could not be detected. In contrast, the TSH levels in individuals with hyperthyroidism remained undetectable or very nearly so. With the new third- and fourth-generation TSH tests, it is possible to evaluate very low levels of TSH, and TRH is no longer used to evaluate hyperthyroidism. At the present time, TRH tolerance tests are used primarily for evaluation of prolactin secretion or secondary hypothyroidism.

b. Preparation. The patient should discontinue all thyroid medication and chronic aspirin therapy for at least 1 week before the test.

c. Medication. TRH (7 $\mu\text{g}/\text{kg}$ up to a maximum of 400 μg) should be administered intravenously over 90 s.

d. Sampling. Samples should be collected before the administration of TRH and at 15 min intervals for 1 h after treatment. Baseline samples should be assayed for triiodothyronine and thyroxine. All the samples should be assayed for TSH and prolactin.

e. Normal Results. TSH should increase to 5–10 times higher than the basal level. Prolactin levels should increase to three to five times over basal levels, with the peak secretion 15–30 min after TRH administration.

f. Expected Values. Individuals with hyperthyroidism or secondary hypothyroidism do not raise their TSH levels into the normal range. High basal prolactin levels without increase during the tolerance test are suggestive, but not diagnostic, of prolactinoma.

g. General Considerations. TRH may cause an increase in blood pressure and is contraindicated in patients with hypertension or cardiovascular disease. During the infusion of TRH subjects may feel a strong urge to urinate. Thus it is useful to suggest that patients urinate before the start of the protocol. Other side effects of TRH infusion are nausea, vomiting, and facial flushing. These effects only last for 30–90 s. Because of the nausea, an overnight fast or omission of the last meal should be considered, although this is not specifically required for the test.

C. Tests for Parathyroid Function

The following protocols were used to evaluate parathyroid function before the availability of RIA tests for parathyroid hormone (PTH). At present, these protocols are occasionally used to detect and evaluate minimal degrees of

dysfunction, perhaps associated with partial resistance to PTH or partial protein S deficiency.

1. Ethylenediaminetetraacetic Acid Infusion Test (53,54)

a. Indications. This test is a direct method for detecting disorders of the parathyroid gland, including both hypoparathyroidism and pseudohypoparathyroidism in its different forms. Ethylenediamine tetraacetic acid (EDTA) is a calcium-specific chelating agent. It is metabolized by excretion in urine with its chelated cations, mostly calcium. Thus, the infusion of EDTA leads to a decrease in serum calcium levels; the response to this stimulus forms the test. Under the regulation of hormones secreted by the parathyroid gland, normal individuals respond to its stimulus by mobilization of calcium stores and restoration of serum calcium levels within 12 h.

b. Preparation. Patients should fast overnight before the test and should be recumbent for the duration of the test.

c. Medication. Intravenous infusion of 50 mg/kg trisodium EDTA in 300 ml 5% dextrose over 1 h period is used. To reduce discomfort at the site of infusion, procaine hydrochloride (1 or 2%) or lidocaine should be added to the infusion. Care should be taken to ensure that the tubing is primed with the anesthetic before the administration of EDTA.

d. Sampling. Draw blood for calcium immediately before EDTA infusion, immediately after infusion, and at 4, 8, and 12 h after the start of the infusion. Serum samples may also be assayed directly for parathyroid hormone and calcitonin to differentiate the basis for the disorder.

e. Normal Values. Preinfusion calcium values should be within the normal range for the laboratory. Post-infusion levels should fall immediately by 2–3 mg/dl. The failure of calcium levels to return to preinfusion levels within 12 h after EDTA infusion is indicative of the lack of proper function of the parathyroid hormone. Further tests may be necessary to identify the exact nature of the disorder.

f. General Considerations. Patients in whom calcium stores may be challenged should be monitored carefully until normal serum calcium levels are restored. Paresthesias of the face and extremities may occur, and patients should be forewarned. Positive Chvostek's and/or Trousseau's signs may be seen at any time in the 24 h period. Patients should be observed carefully for signs of tetany; appropriate measures must be taken should tetany or seizures ensue.

2. Ellsworth-Howard Test

a. Indications. The test is used to differentiate between hypoparathyroidism and pseudohypoparathyroidism (55,57).

b. Preparation. All supplemental medications used to treat hypoparathyroidism and pseudohypoparathyroidism, such as calcium or vitamin D, should be withheld for 8–12 h before the testing period. Patients should be fasted over the same period.

c. Medications. Over a 15 min period, PTH 200–300 IU is administered intravenously in 50 ml normal saline with 0.5% human serum albumin.

d. Sampling. Collect urine 1 h before PTH infusion and for 5 h afterward. Assay for cyclic AMP.

e. Expected Values. Expected values are listed in Table 3.

D. Tests for Prolactin Secretion

1. Dopamine Inhibition of Prolactin Secretion

a. Indications. Dopamine normally inhibits prolactin secretion (58). Thus, this test is used when hypersecretion of prolactin is suspected.

b. Preparation. Give nothing by mouth from midnight or after the bedtime snack.

c. Medication. L-dopa is given PO immediately after the baseline blood sample is obtained. The dosage is as follows: 125 mg for children less than 13.5 kg; 250 mg for children between 13.5 and 31.5 kg; and 500 mg for children over 31.5 kg.

d. Sampling. Draw blood for prolactin assay at 0, 40, 60, 90, 120, and 180 min after administration of L-dopa. In view of the method of evaluation of the result, two baseline samples should be obtained: one 15 min before and the second just before the administration of L-dopa.

e. Normal Values. Prolactin levels should decrease to less than 50% of the baseline value within 1–3 h. Lack of suppression suggests autonomous or hypersecretion of prolactin.

f. General Considerations. Nausea and vomiting frequently occur in toddlers. Be prepared. Do not stop taking blood samples. Children should be recumbent and may be given water throughout the test.

Table 3 Expected cAMP Values After PTH

Diagnosis	Cyclic AMP after PTH infusion (μmol)
Normal adults	3.90 ± 0.35
Pseudohypoparathyroidism	0.63 ± 0.12
Idopathic hypoparathyroidism	4.43 ± 0.54
Pseudopseudohypoparathyroidism	2.98 ± 0.49

2. TRH-Induced Prolactin Secretion

a. Indications. This test is often used to confirm abnormalities of prolactin secretion (59). Although the mechanism is unknown, TRH stimulates prolactin secretion.

b. Preparation. The patient should be off all thyroid medication and chronic aspirin therapy for at least 1 week before the test. For their own comfort, patients should be requested to urinate before the start of the test.

c. Medication. After collection of a baseline sample, TRH (7 $\mu\text{g}/\text{kg}$ up to a maximum of 400 μg) should be administered intravenously over 90 s.

d. Sampling. Serum should be collected every 15 min for 1 h after administration of TRH. The samples should be assayed for prolactin.

e. Normal Values. In children, prolactin levels should increase three- to fivefold during the test. The peak usually occurs at 15 or 30 min. Men have a similar response. In women, the increase can be somewhat larger.

f. General Considerations. TRH may cause an increase in blood pressure and is contraindicated in patients with hypertension or cardiovascular disease. Because during the infusion of TRH subjects may feel a strong urge to urinate, it is useful to suggest urination before the start of the protocol. Other side effects of TRH infusion are nausea, vomiting, and facial flushing. These effects only last for 30–90 s. Because of the nausea, an overnight fast or omission of the last meal should be considered, although it is not directly required for the test.

E. Tolerance Tests for Adrenal Cortex Function

1. Basic Physiology of Adrenal Cortex Function

ACTH has two major effects on the adrenal cortex: it serves as a growth factor, and it stimulates the secretion of steroids. Within 15 min of an endogenous or exogenous episode of ACTH secretion, the adrenal cortex secretes cortisol in large amounts and smaller amounts of androgens and intermediates. At the time of biochemical adrenarche, the reticularis increases the production of DHEA, but the serum level of DHEA-S is not increased during an ACTH-stimulatory episode. Tolerance testing for the adrenal cortex primarily involves testing for the adequacy of cortisol production and for excessive production of either intermediates of cortisol production or adrenal androgens other than DHEA-S. Evaluating the adequacy of cortisol production is one of the main purposes of ACTH tolerance testing. Following are specific protocols to evaluate different aspects of adrenal function.

2. Dexamethasone Suppression Test (Overnight)

a. Indications. This test is a screening test for Cushing's syndrome or excessive cortisol and/or androgen

production (60,61). In women or girls with hirsutism, it can also be used to differentiate between the ovary and the adrenal as the source of excess androgen production. If the source of excess androgen production is the ovary or autonomous adrenal function, then androgen levels are not suppressed by overnight dexamethasone suppression. (Chap. 6).

b. Preparation. No specific preparation is needed. The test need not be performed in the hospital. Dexamethasone can be provided to the parent, administered at the proper time at home, and the child brought for serum collection the following morning.

c. Medication. For children over 25 kg, prescribe 1 mg dexamethasone at bedtime. For children smaller than 25 kg, administer 0.5 mg dexamethasone at bedtime.

d. Samples. A single serum sample is obtained between 8 and 9 a.m.

e. Normal Values. The morning serum cortisol level should be less than 2 $\mu\text{g}/\text{dl}$.

f. Expected Values. In the absence of extenuating circumstances, serum cortisol levels in excess of 2 $\mu\text{g}/\text{dl}$ are abnormal and a physiological basis should be explored. Children with Cushing's syndrome may have cortisol levels after dexamethasone suppression as low as 4 $\mu\text{g}/\text{dl}$ in the early course. This level should slowly increase under the continuing ACTH-induced hyperplasia.

g. General Considerations. Most texts and review articles suggest cutoff values of 5–10 $\mu\text{g}/\text{dl}$. However, these values were obtained with chemical tests for cortisol that were less specific than the RIAs now used. The use of 2 $\mu\text{g}/\text{dl}$ (more than 2.5 standard deviations above the mean) might result in a few more false-positive results, but it leads to fewer false-negative ones, which is the real purpose of a screening test.

Dexamethasone suppresses ACTH secretion and therefore prevents its function as a growth factor for the adrenal cortex. Repeated administration leads to inadequate adrenal reserves.

3. Dexamethasone Suppression Test (High-Dosage)

a. Indications. This test is used to define further the control of cortisol secretion for individuals who do not have adequate suppression with the overnight dexamethasone test (62,63).

b. Preparation for Part 1. No specific preparation is needed.

c. Medication for Part 1. Dexamethasone, 20 $\mu\text{g}/\text{kg}$ per day, to a maximum of 0.5 mg/dose, is given PO every 6 h for 2 days beginning on day 3 of the test. Older children and adults may be given 0.5 mg every 6 h for eight doses.

d. Sampling for Part 1. The 24 h urine collections are started on day 1. Each urine sample should be assayed

for 17-ketogenic steroids, urinary free cortisol, and creatinine. Serum should be collected each morning and assayed for DHEA-S and cortisol.

e. Normal Values for Part 1. The 17-ketogenic steroids should fall to ≤ 7 mg/day (≤ 3 mg/g creatinine) by the day of the test. Urinary free cortisol should be suppressed by more than 50% in normal subjects.

f. General Considerations for Part 1. Food and water should be available as desired throughout the test period. The test can be done on an outpatient basis. Patients who do not suppress the urinary free cortisol levels should be tested with high dosages of dexamethasone (part 2 of the protocol). In general, if the results are not available or are ambiguous, part 2 of the protocol should be performed immediately.

g. Preparation for Part 2. Part 2 should be performed immediately after completion of part 1 as days 5 and 6 of the combined protocol.

h. Medication for Part 2. Dexamethasone, 2 mg/dose, is given PO every 6 h for 2 days beginning on day 5 of test.

i. Sampling for Part 2. The 24 h urine samples are collected on days 5 and 6. Each urine sample should be assayed for 17-ketogenic steroids, urinary free cortisol, and creatinine. Serum should be collected each morning and assayed for DHEA-S and cortisol.

j. Normal Values for Part 2. The 17-ketogenic steroids and urinary free cortisol should be suppressed by more than 50% even in subjects with adrenal hyperplasia or Cushing's syndrome. In patients in whom they are not suppressed during part 2 of the protocol, the presence of an independent, steroid-producing tumor must be explored.

4. Low-Dosage ACTH Stimulation Test

a. Indications. This test is used to evaluate the integrity of the hypothalamic-pituitary-adrenal axis adrenal reserve (64,65). Evidence supporting the use of a low-dose (1 μ g) ACTH test rather than the standard ACTH test (250 μ g) has increased over the past years. A low-dose ACTH test has more sensitivity in detecting subtle states of adrenal insufficiency and provides more physiological concentration of ACTH.

b. Preparation. The patient should be off medications that interfere with ACTH secretion (glucocorticosteroids) for at least 1 week before the test. If the patient has been receiving chronic steroid treatment, the withdrawal process may take a few months.

c. Medications. In the morning, after collecting baseline serum samples, a single intravenous bolus of 1 μ g Cortrosyn is administered. Although a 1 μ g ampule would be desirable, this presentation is not available. We advise dilution by the pharmacist following an established protocol. Dilute the 250 μ g vial with 10 ml NaCl (25

μ g/ml) and take an aliquot of 0.2 ml. Diluted to 1 ml, this will yield a final concentration of 1 μ g/ml. Glass or plastic tubes can be used.

d. Sampling. Baseline sample and additional sample at 30 min will be sent for cortisol measurement. Some authors recommend a single sample at 30 min.

e. Normal Values. Various cutoff set points of serum cortisol levels have been proposed to indicate normal adrenal function. However, a cutoff of 600 nmol/l (22 μ g/dl) is an optimal level with 100% sensitivity and 83% specificity. High sensitivity of a test is preferred in life-threatening conditions such as adrenal insufficiency.

5. Standard-Dose ACTH Stimulation Test

a. Indications. This protocol is used to evaluate the adequacy of cortisol secretion and adrenal reserve, primarily to eliminate a diagnosis of Addison's disease or congenital ACTH unresponsiveness (66-69).

b. Preparation. The patient should be off medications that interfere with ACTH secretion, especially high-dose glucocorticoids or other steroids. High-dose steroids must be discontinued for at least 1 week to permit restoration of the normal biosynthetic reserve.

c. Medications. In the morning, after collection of baseline serum samples, a single intravenous bolus of 0.25 mg Cortrosyn is administered.

d. Sampling. Before the administration of Cortrosyn, a baseline sample is obtained. An additional sample is collected 30 min after administration of Cortrosyn. Each sample is assayed for cortisol, 17-hydroxyprogesterone, progesterone, and 17-hydroxypregnenolone. The exact interval between the administration of ACTH and the second sample must be noted.

e. Normal and Expected Values. Cortisol levels should exceed 16 μ g/dl in either the baseline or post-ACTH sample. Cortisol levels may not be decreased in individuals with 21-hydroxylase deficiency. For evaluation of 21-hydroxylase deficiency, the sum of the increase in progesterone and 17-hydroxyprogesterone concentrations is divided by the time between the samples. Individuals who are heterozygous for the congenital adrenal hyperplasia (CAH) trait have responses between 9 to 30 ng/dl/min. Increases below 7 ng/ml/h are typical of normal homozygous individuals. For evaluation of 3, β -hydroxysteroid dehydrogenase deficiency, the ratio of 17-hydroxypregnenolone to 17-hydroxyprogesterone levels is considered. Normal individuals have a ratio of less than 10, and higher ratios are considered diagnostic.

f. General Considerations. However, because of the variable timing of the morning endogenous ACTH secretory episodes and the secretion of ACTH when a child is frightened, the baseline values are often already stimulated. Therefore a dexamethasone suppression test should be continued as described below.

6. Dexamethasone-Suppressed ACTH Stimulation Test

a. Indications. This protocol differs from the simple ACTH stimulation test by the administration of a single dose of dexamethasone at bedtime before the test (70,71). This step serves to block the normal morning episodes of ACTH secretion and eliminates the continuing secretion of cortisol and its intermediates. As a consequence, before the administration of ACTH, the adrenal cortex synthesizes and secretes only small amounts of steroids. Without the dexamethasone treatment, the so-called white coat syndrome (fear of doctors) experienced by many children leads to immediate ACTH secretion and thus to high levels of steroids in the baseline samples. In fact, on many occasions, the baseline samples have higher levels of steroids than the samples obtained after ACTH administration. In contrast, after dexamethasone pretreatment, the presence of steroids in the baseline samples can be attributed either to gonadal secretion or to ACTH-independent pathways. The protocol is used to confirm a suspected diagnosis of complete or partial steroid biosynthetic defects. The phenotype characteristic of heterozygote carriers for 21-hydroxylase deficiency can also be identified. The dexamethasone pretreated protocol was specifically developed to overcome the variation in baseline steroid intermediate levels caused by uncontrolled endogenous episodes of ACTH secretion.

b. Preparation. A single dose of dexamethasone ($0.5 \mu\text{g}/\text{m}^2$) is administered just before the subject goes to bed, usually between 10 and 11 p.m. Patients should fast from the time of dexamethasone treatment until the completion of the test. Water may be consumed as desired. Menstruating women should be tested in the follicular phase of the cycle.

c. Medications. In the morning, after collection of baseline serum samples, a single intravenous bolus of 0.25 mg Cortrosyn is administered.

d. Sampling. Two baseline samples are obtained 15 min and right before the administration of Cortrosyn. Additional samples are collected 30, 45, and 60 min after the administration of Cortrosyn.

e. Normal and Expected Values. The test is evaluated by considering the difference between the baseline and stimulated samples of steroid levels. The baseline level is obtained by averaging the two baseline samples; the stimulated level is the average of the two highest samples obtained after Cortrosyn administration. As a consequence of the continued function of the long-acting synthetic glucocorticoid, the morning episodes of ACTH secretion do not occur. Thus, baseline levels of steroid intermediates are not elevated. Expected values are listed in Table 4.

f. General Considerations. Girls (but not boys) with idiopathic, premature adrenarche frequently have re-

sponse phenotypes similar to those of carriers for 21-hydroxylase deficiency. It is not clear whether the genotype is also similar to that of carriers for 21-hydroxylase deficiencies. About 15% of girls with features of hyperandrogenism have steroid secretory patterns typical of nonclassic 21-hydroxylase or 3, β -hydroxysteroid dehydrogenase deficiency. When older populations are tested, the frequency of deficiency syndromes decreases, perhaps because of prior identification of severely affected individuals.

After dexamethasone suppression, there are four common causes of elevated baseline levels of cortisol, androgens, or steroid intermediates: the subject did not take the dexamethasone; breakthrough ACTH secretion; gonadal secretion of steroids; and lack of regulatory control, perhaps caused by Cushing's syndrome. If the subject does not take the dexamethasone, the baseline samples are frequently similar to stimulated values. Ovarian secretion of 17-hydroxyprogesterone, DHEA, and androstenedione is most common in patients with polycystic ovarian disorder or during the luteal phase of the menstrual cycle. The source of excess steroids in the baseline samples can be attributed to the ovary if the cortisol level is less than $2 \mu\text{g}/\text{dl}$ or less than $5 \mu\text{g}/\text{dl}$ in a woman taking birth control pills. Finally, with the exceptions noted, baseline cortisol levels in excess of $2 \mu\text{g}/\text{dl}$ are suggestive of Cushing's syndrome. Thus, the addition of dexamethasone pretreat-

Table 4 Expected Steroid Values

Steroid	Baseline levels	Stimulated levels
Normal individuals		
Cortisol ($\mu\text{g}/\text{dl}$)	≤ 2	12–24
17-Hydroxyprogesterone (ng/dl)	≤ 50	50–150
Androstenedione (ng/dl)	≤ 50	50–200
Dehydroepiandrosterone (ng/dl)	≤ 200	400–800
Heterozygote for 21-hydroxylase deficiency		
Cortisol ($\mu\text{g}/\text{dl}$)	≤ 2	12–24
17-Hydroxyprogesterone (ng/dl)	≤ 50	150–500
Androstenedione (ng/dl)	≤ 50	50–200
Dehydroepiandrosterone (ng/dl)	≤ 200	900–1300
Individuals with 21-hydroxylase deficiency		
Cortisol ($\mu\text{g}/\text{dl}$)	≤ 2	12–24
17-Hydroxyprogesterone (ng/dl)		≥ 2000
Androstenedione (ng/dl)	≤ 50	50–200
Dehydroepiandrosterone (ng/dl)	≤ 200	900–1300
Individuals with 3 β -hydroxysteroid dehydrogenase deficiency		
Cortisol ($\mu\text{g}/\text{dl}$)	≤ 2	12–24
17-Hydroxyprogesterone (ng/dl)	≤ 50	150–500
Androstenedione (ng/dl)	≤ 50	50–200
Dehydroepiandrosterone (ng/dl)	≤ 400	1600–8000

ment the night before the administration of ACTH increases the validity of the entire Cortrosyn tolerance test procedure.

7. Metyrapone Test

a. Indications. Metyrapone blocks the conversion of 11-deoxycortisol (compound S or cortexolone) to cortisol (72–74). The test is used to assess pituitary ACTH reserve, adrenal insufficiency, and the extent of adrenal suppression for patients receiving prolonged glucocorticoid therapy for any reason.

b. Warning. For patients in whom adrenal insufficiency (Addison's disease) is suspected, an appropriate steroid medication should be kept at bedside in case of an adverse reaction.

c. Preparation. The patient should be off all medications that interfere with ACTH production, including glucocorticoids, drugs that accelerate the action of metyrapone (such as diphenylhydantoin), and drugs that alter the concentration of 17-ketogenic steroids, such as penicillin and its variants.

d. Medication and Sampling: 24 h Test. Metyrapone, 300 mg/m² in children or 750 mg in adults, is orally administered every 4 h for six doses. Basal 24 h urine should be collected before the administration of metyrapone and for the next 3 days. The urine is assayed for creatinine and for 17-hydroxycorticosteroids. Serum should be obtained 4 h after the last dose of metyrapone and assayed for ACTH, cortisol, and 11-deoxycortisol.

e. Normal Values: 24 h Test. In normal individuals, 17-hydroxycorticosteroids levels should be greater than 9 mg/m²/24 h during the metyrapone treatment. Plasma cortisol levels should be less than 8 µg/dl, and 11-deoxycortisol levels should exceed 10 µg/dl.

f. Medication and Sampling. Single-dose test. Metyrapone, 30 mg/kg to a maximum of 1 g, is administered as a single oral dose at midnight. Serum should be obtained at 8 a.m. and assayed for ACTH, cortisol, and 11-deoxycortisol.

g. Normal Values: Single-Dose Test. The results of the test should be considered in the following order: First, ACTH levels should be elevated. Inadequate ACTH secretion suggests inadequate pituitary reserve for secretion of ACTH. Second, cortisol levels should be less than 8 µg/dl; higher levels suggest inadequate therapy (rapid metabolism) or excessive production of cortisol, perhaps caused by Cushing's syndrome. Third, 11-deoxycortisol levels should exceed 10 µg/dl; lower levels suggest adrenal insufficiency, caused by either lack of recovery from high-dosage therapy or Addison's disease.

h. General Considerations. Hypotension and vomiting may occur during the administration of metyrapone. Transient vertigo may be avoided by administering the

drug with milk or a meal. Patient's activity should be mild throughout the day of drug treatment.

F. Tests for Pheochromocytoma

This diagnosis is frequently suspected but is actually very rare in children. In this disorder, catecholamine secretion from the adrenal medulla no longer responds to proper hormonal regulation (Chap. 8).

1. Clonidine Suppression Test

a. Indications. Clonidine suppresses catecholamines arising from the sympathetic neuroendocrine system but not from a pheochromocytoma (75,76).

b. Preparation. Nothing should be given by mouth after midnight or for 10–12 h before the test. B-adrenergic-blocking drugs should be discontinued 48 h before the test; concomitant administration of these drugs can lead to severe bradycardia and decreased cardiac output. Adequate hydration must be maintained (or restored) before the test because of the possibility of potentiating hypovolemia.

c. Medication. Clonidine, 0.005 mg/kg to a maximum of 0.25 mg, is administered as a single oral dose.

d. Sampling. Draw blood for measurement of free catecholamines (epinephrine and norepinephrine) at 0, 1, 2, and 3 h after clonidine administration.

e. Normal Values. By 3 h after clonidine treatment, circulating catecholamine levels should decrease to less than 500 pg/ml. Failure to suppress the circulating levels is usually diagnostic of pheochromocytoma.

f. General Considerations. Because of the hypotensive effects of clonidine, blood pressure should be monitored during the protocol and the patient should be in a supine position. Patients may become very drowsy 30–45 min after clonidine administration. Various clinical laboratories have different instructions for the handling of blood plasma for catecholamine assay. Refer to the specific laboratory you intend to use and their protocol.

2. Glucagon Test

a. Preparation. The patient should rest quietly in a supine position without environmental stress or distraction (77). A heparin lock should be established at least 30 min before the start of the test.

b. Medication. After collection of baseline blood pressure data and serum, the test is started by the intravenous administration of 0.5 mg glucagon.

c. Sampling. Blood pressure should be determined 10 and 5 min before glucagon administration and after 5, 10, 20, 25, and 30 min of glucagon. Plasma should be collected for catecholamine levels at 0, 5, and 10 min after glucagon administration.

d. Normal Values. In normal patients, there should not be a rise in blood pressure. If a 0.5 mg dose of glucagon does not produce a rise in blood pressure, the test can be repeated with 1 mg glucagon administered as an intravenous bolus. A significant elevation in blood pressure and catecholamines for 5–15 min after glucagon administration is indicative of pheochromocytoma.

e. General Considerations. Patients must be supine throughout the test period. Performing the test in a darkened room without disturbance is often helpful. Various clinical laboratories have different instructions for the handling of blood plasma for catecholamine assay. Refer to the specific laboratory you intend to use and their protocol.

G. Test for Acromegaly: Glucose Test for Suppression of GH Secretion

a. Indications. Individuals with autonomous GH secretion do not blunt GH response to hyperglycemia as occurs physiologically (78). This response is indicative of GH excess, including acromegaly. It should be noted that young infants and diabetics in poor control often have paradoxical GH secretion. Elevated levels of IGF-I (>2 SD) are considered a good initial screening test suggestive of GH excess. It is important to use age-referenced comparative values, especially when evaluating adolescents who have highest levels among all age groups (Chap. 5).

b. Preparation. Overnight fast is prescribed before the test.

c. Medication. After collection of a baseline serum sample, glucose, 1.75 g/kg body weight to a maximum of 75 g, is given by mouth (Glucola, Trutol, or Dextol Cola is commonly used).

d. Sampling. Serum should be obtained for glucose and GH at the time of glucose administration and every 30 min for 2 h.

e. Normal Values. GH levels should decrease to less than 5 ng/ml. GH levels above 10 ng/ml confirm a diagnosis of GH excess. Values between 5 and 10 ng/ml are inconclusive.

f. General Considerations. As desired, patients can drink water and walk during the protocol.

H. Tests for Regulation of Serum Glucose Levels

1. Glucose Tolerance Tests

a. Indications. This test is useful for the evaluation of impaired glucose tolerance and insulin resistance or hypersensitivity (79,80). The test must include insulin levels to make an accurate diagnosis. A new cutoff point of less than 109 mg/dl is considered the upper limit of normal fasting plasma glucose level (FPG). Impaired fasting glucose (IFG) corresponds to a range of 110–126

mg/dl. FPG greater than 126 mg/dl indicates a provisional diagnosis of diabetes mellitus, and must be confirmed on a separate day. If the FPG is <126 mg/dl and there is a high suspicion for diabetes, an oral glucose tolerance test (OGTT) is indicated. The intravenous protocol should be reserved for patients with gastrointestinal disturbances or intolerance to oral glucose load. The intravenous protocol may also be preferred when assessing insulin secretion reserve or residual function of β -pancreatic cell in patients at high risk of developing diabetes or in patients with diabetes if indicated.

b. Preparation. For 3 days before the test, patients should be on a high-carbohydrate diet (at least 60% of calories from carbohydrates). Patients should fast after midnight or after a bedtime snack the night before the test. Medications that may act as hyper- or hypoglycemic agents should be discontinued.

c. Medication: Oral Protocol. After the baseline serum sample is obtained, glucose solution, 1.75 g/kg body weight to a maximum of 75 g, is administered as an oral solution. Trutol, Glucola, and Dextol Cola are commonly used commercial solutions.

d. Sampling: Oral Protocol. Draw blood for glucose and insulin at 0, 30, 60, 90 min, and at 2, 3, and 4 h after glucose administration. Urine is measured for sugar and acetone at each void throughout the protocol.

e. Expected Values: Oral Protocol. The criteria established by the National Diabetes Data Group in 1979 have been revised by an International Expert Committee sponsored by the American Diabetes Association.

2 h postload plasma glucose levels less than 140 mg/dl are normal.

2 h postload plasma glucose levels greater than 140 but less than 200 mg/dl indicate an impaired glucose tolerance test.

2 h postload glucose levels higher than 200 mg/dl indicate a provisional diagnosis of diabetes mellitus.

Impaired fasting glucose and impaired glucose tolerance tests are associated with insulin resistance, obesity, dyslipidemia of the high-triglyceride and/or low-HDL type, and hypertension.

f. Medication: Intravenous Protocol. After the baseline serum sample is obtained, glucose, 0.5 g/kg body weight, is given as an intravenous bolus over a 3–4 min period. It is preferable to have two separate intravenous lines, one for infusion of glucose and one for obtaining blood samples. The first line may be discontinued after the infusion is complete.

g. Sampling: Intravenous Protocol. Draw blood for glucose and insulin at 0, 1, 3, 5, 10, 20, 30, 45, and 60 min after the start of the glucose infusion.

h. Normal Values: Intravenous Protocol. For quantitative evaluation of the first-phase insulin response

(FPIR), the parameter used is the sum of plasma insulin values for 1 and 3 minutes (designated insulin [$1' + 3'$]). Normal values for individuals over 8 years of age are insulin ($1' + 3'$) $> 100 \mu\text{U/mL}$. Normal values for individuals between 3 and 8 years of age are insulin $\Sigma (1' + 3') > 60 \mu\text{U/ml}$. Individuals at high risk for developing diabetes mellitus have a low FPIR ($< 48 \mu\text{U/ml}$).

The disappearance curve of glucose is plotted as a function of time on semilogarithmic paper and the K value (glucose disappearance rate) determined. $K = 0.693 \times 100/T_{1/2}$ where $T_{1/2}$ is time in minutes for the glucose to fall to half of its initial value. A K value less than 1.4 indicates impaired glucose tolerance in persons less than 50 years of age. Insulin levels should reach their peak within 10 min of the start of the infusion.

i. General Considerations. Patients may drink water and move about freely during the test. The test should be postponed until 2 weeks after any acute illness. There is a risk of hyperosmolality in patients with elevated baseline blood glucose levels.

2. Hypoglycemia Workup

a. Indications. The following plan is valuable when evaluating hypoglycemia in children (81–83). Hyperinsulinemia, glycogen storage disease, factitious hypoglycemia, carnitine deficiency, fatty acid oxidation disturbance, and inborn errors of metabolism are indications for the use of this workup. The protocol evaluates metabolic changes that occur during a fast.

b. Preparation. The test should be conducted under close supervision. For younger children, maintain a separate intravenous line with 0.25 normal saline, in addition to the heparin lock, both for hydration and to ensure a patent venous line other than the heparin lock. The patient should be on a high-carbohydrate diet (60% of calories from carbohydrates) for 3 days. The diet should include frequent feedings. No high-fat foods should be allowed on the evening before the start of the test, and the patient should fast after midnight or bedtime snack. Test and prepare a bedside device to measure glucose (Dextrostix, Chemstrip bG, or equivalent). In anticipation of hypoglycemia, have at hand syringes prepared with glucagon, $30 \mu\text{g/kg}$, and 50% glucose, 1 ml/kg body weight.

c. Medications. Glucagon, $30 \mu\text{g/kg}$ to a maximum of 1 mg, is administered by slow intravenous push.

d. Sampling.

Part 1. Approximately 4 h after fast is begun collect baseline blood sample and administer the first glucagon challenge. The baseline serum should be assayed for glucose at bedside and the hypoglycemia panel (insulin, GH, cortisol, venous blood gases, phosphorus, uric acid, lactate, alanine, ketones, β -hydroxybutyrate, free fatty acids, carnitine, and glucagon) at 5, 15, 30, and 60 min after

glucagon administration, draw and test blood for glucose and insulin.

Part 2. All urine is collected and evaluated for ketones and specific gravity. Every 2 h blood should be collected and assayed for glucose at bedside. Every 4 h blood should be collected and assayed for glucose and hypoglycemia panel at bedside.

Part 3. If at any time blood glucose is less than 40 mg/dl in whole blood (or less than 45 mg/dl in serum or plasma) with or without symptoms, then confirm with laboratory glucose measurement and assay for the hypoglycemia panel. Terminate the test with a 50% glucose solution, 1 ml/kg as an intravenous push over a couple of minutes. If severe symptomatic hypoglycemia and/or convulsions occur at any point, collect the serum sample and terminate the fast at once by administering the 50% glucose solution, 1 ml/kg intravenously. The serum should be assayed for the hypoglycemia panel and electrolytes.

If no hypoglycemia occurs within 24 h of the first glucagon test, perform a second glucagon tolerance test and terminate the protocol. If no hypoglycemia occurs but the patient develops metabolic acidosis (HCO_3^- less than 15 mEq/l, with or without normal pH), repeat the glucagon tolerance test and terminate the test.

Part 4. After the fast, you may consider the following additional tolerance tests needed for further evaluation of defective gluconeogenesis: 0.5 g/kg alanine, 1.0 g/kg glycerol, and 1.0 g/kg fructose. In each case blood should be collected at 0, 15, 30, 45, 60, and 120 min after administration and assayed for glucose, serum ketones, lactic acid, and β -hydroxybutyrate.

e. Normal Values. Glucose levels should remain above 40 mg/dl throughout the 24 h fast. Episodes of hypoglycemia are considered abnormal at any time throughout the test, whether or not there are symptoms. Episodes of GH secretion greater than 10 ng/ml should follow about 20 min after any hypoglycemic episodes. Cortisol levels of 8–20 $\mu\text{g/dl}$ are normal under nonstressful conditions. Under the conditions of this fast, levels should increase by 10 $\mu\text{g/dl}$ or exceed 20 $\mu\text{g/dl}$. In samples obtained during hypoglycemic episodes, low glucose-insulin ratios (ratio of 3 vs. ratio of 6 as observed in normal individuals) are indicative of hyperinsulinism. The concentration of metabolites must be considered to evaluate the pathophysiology of hypoglycemia in other patients.

f. General Consideration. Only children over 4 years of age should be submitted to the full 24 h fast protocol. Patients must remain quiet but can sit in a chair or lie down, as they desire. They can drink water and use the bathroom freely. The intravenous infusion rate should be adjusted according to water intake. Parents should be encouraged to remain with the child, if this will lower the child's stress. If the patient fails to develop ketonuria during the test, the possibility of surreptitious food intake should be considered. Glucagon may cause some mild ab-

dominal discomfort and/or nausea. Hence, it should be administered by slow intravenous push. The patient should be checked frequently for vital signs and symptoms of hypoglycemia, including convulsions, stupor, tremors, coma, or decreased blood pressure. A flow sheet should be maintained and all data recorded as rapidly as possible.

I. Tests for Gonadal Function

1. Acute Response to hCG Administration

a. Indications. This protocol is useful to confirm the diagnosis of nonclassic 17-ketosteroid reductase deficiency, typically in a teenage boy with severe gynecomastia (84,85).

b. Preparation. The test should be performed in the morning. Patients should eat a normal breakfast and can continue to eat and drink as desired and as appropriate.

c. Medications. At bedtime at home, the patient should take 1 mg dexamethasone. In the morning (about 9 a.m.), the patient should receive 4000 IU hCG as an intramuscular injection.

d. Samples. Serum samples should be obtained before the administration of hCG and 2, 4, 6, 24, and 48 h later.

e. Normal Values. In normal males, the testosterone-androstenedione ratio increases in response to hCG. The final testosterone levels should exceed 300 ng/dl, which are adult normal levels. In patients with partial 17-ketosteroid reductase deficiency, the sum of testosterone and androstenedione concentrations equals the adult normal levels, but the ratio is about equal rather than in excess of 4:1.

f. General Considerations. The two major sources of androstenedione are the adrenal gland and the testis. Administration of dexamethasone serves to eliminate secretion from the adrenal and thus permits monitoring of testicular synthesis.

Compared with testosterone, androstenedione is the preferred substrate for aromatization. Thus, the excess production of androstenedione leads to excess production of estrogens and the development of gynecomastia. Many boys at puberty develop mild gynecomastia that disappears as testosterone production increases. In normal individuals, the 17-ketosteroid dehydrogenase is substrate-(androstenedione) and product- (testosterone) activated, thus leading to complete conversion of androstenedione to testosterone. However, the enzyme of some individuals does not have the proper kinetic properties and does not fully convert all androstenedione to testosterone. The incomplete deficiency disorder is inherited as an autosomal recessive trait. This test helps to identify these patients.

2. Tonic Response to hCG Administration

a. Indications. This test is used to aid in the diagnosis of vanishing testis syndrome, disorders of steroidogenesis, micropenis, ambiguous genitalia, or other circumstances in which there is a question about normal testicular function (86,87).

b. Preparation. No specific preparation is needed.

c. Medication. Four daily doses of hCG (5000 IU/m² per dose) are administered as intramuscular injections. Alternative protocols use only 3000 IU/m² every day or every other day.

d. Samples. A baseline serum sample and a stimulated sample obtained 24 h after the last dose of hCG should be assayed for testosterone and androstenedione.

e. Normal Values. Testosterone should increase to normal adult levels or greater than 300 ng/dl. Androstenedione should not exceed one-quarter of the observed testosterone level.

f. General Considerations. Prolonged administration of hCG can lead to bone age advancement. Progesterone or other intermediates can be assayed if the testosterone response is inadequate.

3. Gonadotropin Sleep Study

a. Indications. This test is useful in patients with suspected polycystic ovarian disease and in suspected cases of precocious puberty (88,89).

b. Preparation and Medication. None is needed.

c. Sampling. Sample serum for LH and FSH from the heparin lock every 20 min, overnight for up to 12 h. In small children for whom the amount of blood drawn may be a critical factor, the test may be modified by limiting the period of sample collection and increasing the interval to 30 min.

d. Normal Values. Normal, prepubertal children have no nocturnal episodes of gonadotropin secretion.

e. General Considerations. There are no side effects of this protocol.

4. GNRH (Factrel) Response Test

a. Indications. The response to the administration of gonadotropin-releasing hormone is useful for evaluating the role of pituitary dysfunction in children with premature or delayed puberty (90–93). Tolerance test responses can be used to differentiate central nervous system dysfunction from peripheral dysfunction in patients with both premature and delayed puberty. In children with premature puberty, peripheral dysfunction (testotoxicosis, McCune-Albright syndrome, and ovarian follicular cysts) is frequently associated with hypogonadotropism, whereas hypergonadotropism can be caused by central nervous system dysfunction (hamartoma or

craniopharyngioma). In contrast, in children with delayed puberty, peripheral dysfunction is associated with hypergonadotropinism (Turner syndrome) and hypogonadotropism suggests dysfunction in the central nervous system (Kallman syndrome, Prader-Willi syndrome, and constitutional delay). The test is also useful in evaluating the extent of damage caused by radiation or chemotherapy in children with leukemia or brain tumors. In this group, the results can indicate the need for endocrine replacement therapy.

b. Preparation. Although not required, many physicians request that the patient fast overnight before the test and the test be performed in the morning. Certainly, there is time-of-day variation in the secretory pattern for LH and FSH, and most of the normal data have been collected in this manner. Thus, using a consistent protocol makes easier the comparison of results to previous studies.

c. Medications. Administer an intravenous bolus dose of 10 $\mu\text{g}/\text{kg}$ to a maximum of 100 μg GnRH (Factrel, Ayerst Laboratories, New York, NY).

d. Sampling. Baseline samples ($n = 2$) should be obtained 15 min apart before the administration of the GnRH. Stimulated samples should be obtained 15, 30, 45, 60, and 90 min after treatment. For comparison with published values, the baseline samples and the three highest stimulated samples should be averaged. This protocol minimizes slight variations in secretory pattern and in laboratory values.

e. Normal Values. The response pattern changes with age, gender, and development. After 6 months of age and before puberty, basal levels for both LH and FSH are frequently less than 2 IU/l. Stimulated levels less than 5 IU/l are indicative of hypogonadotropism, and levels in excess of 50 IU/l are indicative of hypergonadotropinism. With a few exceptions, the increase in both gonadotropins should be similar in magnitude. Girls within a year of menarche often have FSH levels about twice those of LH. Individuals with mild or partial steroid biosynthetic defects often have higher LH than FSH levels.

f. General Considerations. Patients need not remain seated but can walk about during the test. There are many units for LH and FSH. Be sure to check that the

units reported by the laboratory are the same units used for reporting normal values.

J. Test for Diabetes Insipidus: Water Deprivation Test

a. Indications. This protocol is most useful in the diagnosis of diabetes insipidus and in differentiating among neurogenic (hypothalamic central) diabetes insipidus, nephrogenic (renal) diabetes insipidus, and primary polydipsia (inappropriate thirst mechanism or psychogenic diabetes insipidus).

b. Preparation. No special preparation is necessary. Treatment for diabetes insipidus with vasopressin, desmopressin (DDAVP), or analogs should be discontinued 48–72 h before the protocol. Careful attention to the possibility of dehydration should be given after the medications are stopped.

c. Medication. After obtaining the first pair of urine and plasma samples, water and food are restricted for 3 h. At the end of the period of restriction, a second pair of urine and plasma samples is obtained. No food or drink may be consumed during the protocol.

d. Sampling. Paired samples are evaluated for urine osmolality (Uosm) and plasma osmolality (Posm).

e. Normal Values. At any time during the protocol, baseline Uosm in excess of 400 mOsm/kg with normal Posm (between 275 and 300 mOsm/kg) eliminates a diagnosis of diabetes insipidus. Baseline Uosm less than 300 mOsm/kg with normal Posm is consistent either with overhydration or with diabetes insipidus. After the 3 h water-deprivation period, individuals with overhydration or with diabetes insipidus may still have Uosm less than 30 mOsm/kg. However, individuals with overhydration have Posm between 275 and 290 mOsm/kg while Posm remains above 290 mOsm/kg in individuals with diabetes insipidus.

f. General Considerations. Some physicians have extended the period of water deprivation to 7 h or even longer. However, care must be taken to ensure that the patient does not ingest water surreptitiously and/or does not become dehydrated.

Addendum 1 Reference Table for the Conversion of Current Units to SI Units

Substance	Conventional unit (CU)	Conversion factor (CF)	SI unit (Cu × CF)
Aldosterone	ng/dl	0.027	nmol/l

Reimbursement Issues in Endocrinology: A Coding Supplement

Bridget F. Recker

Staten Island University Hospital, Staten Island, New York, U.S.A.

I. REIMBURSEMENT

There are many so many issues related to reimbursement that simply thinking about reimbursement could fill you with dread. The complexities of practicing medicine, coding your services, and being reimbursed for your services has led to the creation of many separate businesses. How then can any practitioner not become overwhelmed with the task?

There are over 7000 current procedural terminology (CPT) codes and the International Classification of Diseases 10 (ICD-10) is already in use. As soon as you learn to assimilate all you need to know about documentation, billing, and reimbursement, new, improved coding is implemented. The basis for all coding and reimbursement is reflected in the patients' medical record documentation. If it is not written down as being assessed, discussed, or performed, it was not done. With audits being done routinely by third-party payers, the failure to recognize this important factor and respond to it can be costly.

A sure sign that this problem is greater than us is the number of companies that have sprung up to address your practice nightmares. Companies that teach, assess, implement, and provide the actual services included in medical practice management increase annually. Medicine has led to the creation of an entire industry. I think the industries supporting medical practices are doing better than the medical practices, for they will not provide the service

without definite reimbursement dollars from the practice. Unfortunately, medical practices are having greater fiscal management problems than ever. When did you lose control over your fate?

II. CPT CODING

The CPT codes for medical and healthcare services change annually. Many books define these codes and give some examples. Since the codes are updated annually, you need a new guidebook annually. If there is a new book with updated codes and new rules, you have to learn how to use them to your benefit. As you can see, without a lot of work and learning, you can never know all about coding.

CPT Codes are standardized five-digit codes describing the services provided during health care/medical encounters. Each encounter needs to be clearly documented in the patient's medical record. Documentation that reflects the stated billed codes must be written. The fact that a code is published does not ensure that all insurers you deal with will accept that code. Also, some patients' policies may specifically exclude certain codes.

Making matters more mystifying is that some insurance companies have created their own internal codes that relate to published CPT codes. However, you are not given the road map with which to decipher their system. When a submitted code is queried or denied, it becomes more difficult to understand what has been denied and what has been approved for payment. With the CPT codes being updated annually, little lag time is given for correct coding. These updates attempt to stay current with trends in clinical practice by adding, updating, and revising codes to reflect changing technology and practice. Once a code has been changed, you have a specific period of time in which to update your billing system. When staff

The information in this publication is taken from publicly available sources.

CPT codes, descriptions, and material only are Copyright 2001 American Medical Association. All Rights Reserved. No fee schedules, basic units, relative values, or related listings are included in CPT. The AMA assumes no liability for the data contained herein. Applicable FARS/DFARS restrictions apply to government use.

or billing services do not make the appropriate changes, financial difficulties ensue. For instance, Medicare gives you a definite date after which a code that has been changed will no longer be recognized for reimbursement. After that time, you are not able to appeal or recoup your losses. Why would Medicare standards be important to you? Because most third-party payers follow Medicare rules within a short period of time.

The reimbursement schedule for services (CPT codes) is driven by the Resource-Based Relative Value System (RBRVS). These values are also updated annually and published in the *Federal Register*. The Health Care Financing Administration (HCFA) introduced RBRVS in 1992 to quantify health care and equalize reimbursement. Under this system a national standardized fee schedule for payments to physicians was enacted. In 2001 HCFA's name changed and is now known as the Centers for Medicare and Medicaid Services (CMS).

The RBRVS incorporates the cost of resources required including time, mental effort, practice overhead, stress, technical skill, and malpractice costs. All of Medicare fees as well as the greater portion of private insurer fees are now based on this system. Many third-party payers including Medicaid programs and managed care organizations are using variations of the Medicare RBRVS to determine physician reimbursement and capitation rates. Since the RBRVS fee schedule was developed for Medicare originally, particular pediatric CPT codes and practice expense issues were not addressed. Work on this issue continues by the American Academy of Pediatrics. CPT codes are the property of the American Medical Association.

There are also modifiers involved in CPT coding and these are added like a suffix to a word. Success with CPT modifier reporting requires a thorough review of CPT guidelines and some detective work to identify health plan requirements for specific modifier codes. The modifier that should be used most frequently is -25. It identifies an evaluation and management service separately provided on the same day as a procedure. You should be using this modifier more than you think. You should use a separate ICD9 code for the office visit and the procedure. There are also HCPCS codes, which represent non-physician services such as medications, intravenous (IV) solutions of varying volumes, sterile trays, supplies, and durable medical equipment.

Handheld personal digital assistants (PDAs) can be used with CPT software to customize practice coding, improve record keeping (particularly in-patient data), and improve billing. You can have at your fingertips the fields necessary to capture important patient data and the coding necessary to define your encounter. The downloading capabilities will forever free you from those little note pads you try to keep track of and submit to the practice billing office in a timely manner.

III. ICD-9 (ICD-10 COMING)

The International Classification of Diseases (ICD-9) (1) documents specific diagnoses, signs, and symptoms. Codes for special screening states, accidents, injuries, or adverse events are included. ICD was developed by the World Health Organization to accumulate and analyze international morbidity and mortality data. In 1989, the government mandated the use of ICD-9 coding. It describes the clinical situation the patient is in, thus giving third-party payers a clinical picture of the individual. The ICD code establishes the link with the CPT code. For instance, a CPT code for a thyroid biopsy would never be reimbursed for an individual seen with an ICD code for a foot infection. The link between these two entities does not exist and the medical necessity of the procedure is not established. ICD-9 is also updated annually with changes, and now the new version of this the ICD-10 is on our doorstep. ICD-9 and HCPCS codes are maintained and regulated by CMS.

As an example, you see a patient every few months or so for evaluation and management of hypothyroidism. The simple ICD-9 code for this encounter and the one most frequently used by most practitioners is 245.2 or Hashimoto's disease. But did the patient raise any other issues you considered or evaluated such as brittle nails (703.8), dry skin (701.1), puffy eyes (374.82), hair loss (704.00), tiredness (780.79), abnormal weight gain (783.1), or throat pain (784.1)? Perhaps one of the later issues required the greatest amount of thought and discussion but you did not address the issue in the medical documentation for the patient. Maybe one of the later issues should have been the diagnostic code for the encounter, followed by the hypothyroid code. Such inclusions could support the need for a higher use of evaluation and management codes, requested follow-up appointments, and laboratory evaluations.

The ICD for mortality has been modified approximately every 10 years. The ICD-10 is the first revision since 1979. Revisions are necessary for the same reason that CPT codes are revised: to reflect changing medical science and technology. ICD-10 varies from the previous version (2) in detail: double the number of categories listed, a change to alphanumeric coding, rearrangement of chapters, addition of chapters, titles for cause of death have been changed, and conditions reordered. Some of the coding rules have also changed. Further information on the states' implementation of ICD-10 can be found at the NCHS website.

IV. LINKING CPT AND ICD CODING

Creating the link between CPT codes and ICD codes is essential for practice survival. If you provide prolonged attendance to a patient, it must be linked to a specific event. For instance, if a patient experiences hypotension

during an arginine test, the ICD code for this occurrence would be related to E944.5: an adverse effect of arginine in therapeutic use. If a child experienced nausea or vomiting following levodopa administration, it would be a toxic effect of levodopa: E936.4.

Evaluations of medical practices are challenging, time-consuming, and costly. Clinicians do not always attend to economic evaluations and this may lead to overlooked clinical benefits and needless costs. Practitioners need to be well informed and remain current in their knowledge of CPT and ICD coding. The individual who signs the bill is ultimately responsible for any bill submitted in their name. This responsibility lasts beyond the signature and encompasses the entire billing process. Practitioners need to audit their billing processes and react to discovered inconsistencies. This in itself will improve reimbursement.

V. COLLECTIONS

The collection process begins at the front desk. The importance of this step in providing care and expecting to be reimbursed for your skill is frequently undervalued. Practices such as mailing a new patient packet prior to an individual's first office contact or requesting that an individual arrive early to complete necessary paperwork can save time and prevent errors. Patients need to be clearly informed in a professional manner as to exactly what the office policy is regarding payment and reimbursement. The patient information sheet should be reviewed and any areas that have been omitted or are unclear should be clarified. The front desk staff sets the tone for your office. A calm, professional, relaxed manner will aid in collecting needed payments from patients. The practice expectations should be clearly stated, with all options for payment given at the time of service.

Patient intake is the most important time frame for timely reimbursement. Having correct information at the start of every encounter will hasten reimbursement. Forms, which maximize patient responsibility, must be completed annually. Employees must be trained in the correct policies and procedures of the office billing system. They must be held responsible for knowing them and for adhering to them. Control of patients at the front desk is of paramount importance. Communication skills are essential for discussing billing issues with patients and gaining an understanding of and cooperation with even the most unreasonable and difficult individuals encountered in the process. Linking the salaries of individuals specifically involved with the billing process to reimbursement (accounts receivable) seems a win-win arrangement.

Talking money is extremely difficult and uncomfortable for most practitioners. Yet this is an extremely essential skill. Presenting programs that may not be covered by insurers should not determine their fate. Learning how to talk to customers about these programs and get them

to commit to them can be as easy as selling vitamins. When you know that an insurer does not cover a particular service, let the patient know this up front and resolve the payment problem prior to delivering the service rather than after the service is given. There is a high price to pay for insurance snags and the duplicate work effort required of your staff handling these issues.

Requesting payment in the right manner with the right approach is essential and should be the only behavior you accept from the front desk staff. It is difficult to understate the importance of this step. If reimbursement for provided services is denied due to improper patient information, the only one to blame for the delay in payment is you. A copy of your practice's general billing policies should be given to patients both new and established. Policies should include the law regarding waiving copayments and deductibles and any other insurer-specific payments. Exemptions to these policies due to financial hardship would need to be clearly written and documentation provided to analyze the situation fully.

VI. DENIAL AND APPEAL

Claims are denied at an almost predictable rate. Claims are denied with the knowledge that most denials are accepted by practices without queries or action. It is assumed that medical providers do not have the time, knowledge, or experience to investigate the reason for or purpose of the claims denial. Delayed insurance payments weaken your practice financially. A thoughtful, established plan to avoid this occurrence should be in place.

Explanations of benefits (EOBs) often state only "claim denied" and you have to guess at the reason for the denial. Not accepting the statement that a claim is denied is worth the time and effort to reply aggressively. EOBs must be reviewed on a regular basis in order to keep current with your practice reimbursement expectations. A thorough review of EOBs will help to identify the particular insurer or code that is leading to decreased revenues. Tackling the major problem and resolving it can only spur you on to taking greater control of your practice's future.

Numerous denials are overturned following the first appeal letter. However, if not overturned you must continue to file appeals until you receive an acceptable answer. It is important to keep the appeal active until it is resolved. Once a practitioner or practice is noted to be persistent regarding appeals, the carrier begins to recognize them as someone who will follow through on the appeal process. In this case, if cloudy issues arise on your claims, they will most likely be paid so that the insurer does not hear from you.

If your appeal was reviewed and remains denied, you should request other individuals to review it, such as the company president or legal counsel. Your letters to them should be concise and state your case clearly. The person

reviewing your claim may not have enough knowledge of your specialty to have made an informed decision. You may have other cases in which the same insurer approved such treatment. You should try to speak on equal terms to those in control of the appeal. Once an appeal moves up to the next level, you must be diligent in addressing issues on a like plane: physician to physician, or physician to president or legal counsel, not physician to administrative assistant or clerk. Recognizing that you are extremely busy and time pressured, the importance of this task cannot fall to anyone other than you. If it is not important enough for you to get on the telephone, it will probably not be important enough for them to reverse their decision on the denial. You can also petition for a face-to-face meeting, with support personnel invited, to further address the issue under consideration. It is always prudent to request a written response to all issues and to keep all communication filed.

As an example, arginine 10% intravenous solution used in growth hormone evocative testing is an unlisted drug in the CPT codes. If filed electronically, this charge will automatically be denied as all unlisted codes are. This claim must go to paper to be considered. Along with the drug, the package label's administration instructions clearly state that the patient must be placed at bed rest for at least 30 min prior to the infusion. This additional 30 min of professional time should therefore be included in the fees for the test.

Another line of financial fallout is underpayment of claims. Medical reimbursement rates are readily accessible to the public. Many companies can provide average reimbursement rates (fee analyzers) broken down by CPT code, medical specialty, and geographic location. Software programs are also available to assist in this effort. This is a robust tool to evaluate underpayment on claims. This information can be used to appeal poorly paid claims by attaching a letter with the usual and customary rate and the reimbursed fee received. Knowledge of this method of practice fee-setting is a concise way to negotiate with third-party payers. It allows for an actual cost of your services for each CPT code; this is then used in contract negotiation. As your malpractice or overhead increases, these increases can be factored into the CPT codes equally. The recovered amounts can be amazing. Looking for denied claims is not enough; you must look for paid but lowered rates.

Timely filing is of the utmost importance. Filing deadlines are becoming shorter and shorter.

VII. CONTRACTING

Conduct a managed care contract review. Providers should understand the contract requirements and not participate in those plans that result in additional costs. Review, and get clarification if needed on, questionable terminology and the dispute resolution procedures. When you sign

your name on the annual contract with third-party payers, have you reviewed those fees for the services you provide most along with evaluation and management codes? Often when you are in larger practice groups, the decision-makers for the group are only interested in the higher reimbursed codes (such as surgical ones). Yet when your specialty is reviewed, your receivables vs. cost are questioned. Maybe your evocative/suppressive testing codes have been repeatedly denied or rates decreased without you being aware of it. The fees for the codes you use most are the ones you must review before signing any annual contract. The information you receive may eventually lead your practice toward participating in plans that will support your practice's future as well as your patients' care.

VIII. CHART REVIEWS

Third-party payers and managed care organizations are conducting chart reviews and grading physicians on their findings. They are only interested in what was actually written down—documented—in the medical chart. They rate their reviews on the quality of the care you provide. They look for continuity of care including follow up and review of all received reports and records. Audits can lead to fines equal to or greater than the overpayment the reviewers believe you received. The process takes time and creates an enormous amount of stress for you and your staff. Preprinted flow sheets and checklists, which correspond to evaluation and management code components, will help avoid undercoding and overcoding errors. Remember: if it is not documented, it was not done.

IX. STIMULATION TESTING

Receiving reimbursement for stimulation/evocative testing is a function of staffing, setting, time, and the payer. It is a constant struggle in most offices to test patients in a safe environment and receive reimbursement for your time, knowledge, blocking of the test room, and monitoring. Although the American Association of Clinical Endocrinologists (AACE) has the creation of an evocative/suppressive testing code (CPT) on their agenda of tasks to accomplish, it is not at the forefront of current discussions.

A standardized protocol for the evocative/suppressive testing should be in place. Space and time for performing the test should be available. There are many facets to an evocative/suppressive test, including:

- Intravenous access
- Administration of agents of stimulation/suppression and flush solutions for multiple draws (intravenous, subcutaneous, oral)
- Repeated line access
- Timed specimen collection
- Patient monitoring

Example: Evocative/Suppressive Test Coding

Arginine/Growth Hormone Evocative Test

CPT code	Description
99211–99215	Office/outpatient evaluation and management; established patient
–25 modifier	Separate E&M same day as procedure
90780	IV infusion; up to 1 h
±90781	IV infusion; each additional hour to 8 h (i.e., normal saline drip infusion during test)
J3490	Unlisted drug—Arginine
90784	IV injection—× how many times
J1642	Heparin lock drug—× how many times/units
99000	Handling/transport of specimens

When a physician, nurse practitioner or physician's assistant performs the testing, the prolonged services codes can also be used based on the amount of total face-to-face time delivered.

Know the rules for coding evocative/suppressive testing. Supplies and drugs should be coded, physician attendance if required should be documented and coded, prolonged physician attendance codes are not reported separately if prolong infusion codes are used, and J codes are used to report injectables. It is better to give the patient a prescription for the medications to be used to cut down on practice expenses and the reimbursement follow up.

If reimbursement for testing in your practice area is insufficient, you may need to consider other options. One option is to meet with and negotiate with the insurer to evaluate the issue further. Provide information concerning the medical necessity of the procedure, the testing protocols, and any supporting information relating to specific patient cases. You may need to write a letter to the medical director of the health care plan clearly stating the need and the amount of financial remuneration requested. If the reimbursement dilemma cannot be resolved, a practice policy will have to be decided upon defining under which circumstances testing for members of those insurers are performed.

X. DIABETIC EDUCATION

Many health plans have limited or no coverage for diabetes training and supplies. Some providers have agreements with insurers to provide for these services. Companies are reviewing outcome measures of diabetes programs such as hemoglobin A1C, eye evaluations, lipid management, and timely monitoring of diabetes complications. They are making reimbursement based on chart audits of these elements. The problems are great and the possible solutions worrisome.

As Medicare sets guidelines for reimbursement linked

with American Diabetes Association recognition programs, there are other movements afoot. Pharmacists, in many instances, are being given the pivotal role in diabetes education. Mississippi pharmacists are receiving payments from Medicaid for providing diabetes care to patients. A major insurer in New Jersey that covers near 1 million lives has contracted with a network of pharmacists for diabetes self-management education. The Department of Veterans Affairs is already using its pharmacists to manage diabetes as well as other chronic diseases. The move is on to improve patient outcomes while providing services, especially in the chronic disease management arena. Codes and reimbursement rates are being established for pharmacists. They will not need years of study or extensive knowledge of diabetes to reach a level of skill necessary to provide and be recognized for reimbursement dollars. Pharmacists' time will be valued and compensated. This recognition for pharmacy reimbursement has become known as medication therapy management services (MTMS). The American Society of Consultant Pharmacists has developed a new payment formula for Medicare/Medicaid pharmacy services (3). The fee would be derived by recognizing the product cost, administrative overhead, dispensing fee, and professional services. Does this sound familiar? HCFA appears willing to accept pharmacists as providers of disease management services. The American Medical Association administers the CPT codes and will therefore work with the pharmacy organizations to develop billing codes.

An article in *Drug Topics* (4) reported some interesting findings. Pharmacists responding to a questionnaire (17% response rate) reported that 52% had stopped doing business with a third-party payer. The reason cited by 89% of these pharmacists was low reimbursement rates. Additional issues noted included slow or no payment along with restrictive formularies. Does any of this sound familiar? Eight out of 10 pharmacists reported that their business did not suffer due to this decision. It would probably not be a surprise to find out the payers pharmacists had the most problems with.

What the pharmacies are experiencing with reimbursement issues mimics the experiences of medical practitioners. They are hiring more technicians and less experienced pharmacists as they face a greater volume of work. In many instances, they cannot even afford to hire more technicians. The pharmacists are looking into other areas, including providing immunizations and vaccinations to customers. As physicians struggle with time and effort involved in providing diabetes education, you must wonder if they are aware of the silently evolving change in the future of diabetes education. Do we want to turn this important responsibility as well as others over to local pharmacists?

XI. CLINICAL TRIALS

Whether or not to participate in clinical trials becomes a resource vs. cost and balanced budget decision. Although

Table 1

Code	Diagnosis	4th digit code	5th digit
240	Goiter, simple—4th digit required	240.0	
	Goiter, unspecified—4th digit required	240.9	
241	Nontoxic nodular goiter—4th digit required		
	Nontoxic uninodular goiter	241.0	
	Nontoxic multinodular goiter	241.1	
	Unspecified nontoxic nodular goiter	241.9	
242	Thyrotoxicosis with or without goiter—4th and 5th digit required		
	Without mention of thyrotoxic crisis or storm		0
	With mention of thyrotoxic crisis or storm		1
	Neonatal thyrotoxicosis	775.3	
	Toxic diffuse goiter	242.0	0 or 1
	Toxic uninodular goiter	242.1	0 or 1
	Toxic multinodular goiter	242.2	0 or 1
243	Congenital hypothyroidism		
	Congenital dysmorphogenetic goiter	246.1	
244	Acquired hypothyroidism—4th digit required		
245	Thyroiditis—4th digit required		
	Acute thyroiditis	245.0	
	Subacute thyroiditis	245.1	
	Chronic lymphocytic thyroiditis	245.2	
250	Diabetes mellitus—4th and 5th digit required		
	Hypoglycemia in infant of diabetic mother	775.0	
	Neonatal diabetes mellitus	775.1	
	Nonclinical diabetes	790.2	
	Type II—not stated as uncontrolled		0
	Type I—not stated as uncontrolled		1
	Type II—uncontrolled		2
	Type I—uncontrolled		3
	Diabetes mellitus without mention of complication	250.0	
	Diabetes with ketoacidosis; without mention of coma	250.1	
	Diabetes with hyperosmolarity	250.2	
	Diabetes with other coma	250.3	
	Diabetes with renal manifestations; use additional codes to specify manifestation	250.4	
	Diabetes with ophthalmic manifestations; use additional codes to specify manifestation	250.5	
	Diabetes with neurological manifestations; use additional codes to specify manifestation	250.6	
	Diabetes with peripheral circulatory disorders; use additional codes to specify manifestation	250.7	
	Diabetes with other specified manifestations; such as diabetic hypoglycemia, hypoglycemic shock—use additional codes to specify manifestation	250.8	
	Diabetes with unspecified complications	250.9	
251	Other disorders of pancreatic internal secretion—4th digit required		
252	Disorders of parathyroid gland—4th digit required		
	Hyperparathyroidism	252.0	
	Hypoparathyroidism	252.1	
	Other specified disorders of parathyroid gland	252.8	
	Unspecified disorder of parathyroid gland	252.9	
253	Disorders of the pituitary gland and its hypothalamic control—4th digit required		
	Acromegaly and gigantism	253.0	
	Other and unspecified anterior pituitary hyper function	253.1	
	Panhypopituitarism/hypopituitarism	253.2	
	Pituitary dwarfism; isolated deficiency of GH, Lorain-Levi dwarfism	253.3	
	Other anterior pituitary disorders; isolated or partial deficiency of an anterior pituitary hormone other than growth hormone	253.4	
	Diabetes insipidus	253.5	

Table 1 Continued

Code	Diagnosis	4th digit code	5th digit
	Nephrogenic diabetes insipidus	588.1	
	Other disorders of neurohypophysis	253.6	
	Iatrogenic pituitary disorders	253.7	
	Other disorders of the pituitary and other syndromes of diencephalohypophyseal origin	253.8	
	Unspecified; dyspituitarism	253.9	
255	Disorders of adrenal glands—4th digit required		
	Cushing's syndrome; adrenal hyperplasia due to excess ACTH, ectopic ACTH syndrome, iatrogenic syndrome of excess cortisol, overproduction of cortisol	255.0	
	Hyperaldosteronism	255.1	
	Adrenogenital disorders; Adrenogenital syndromes, CAH	255.2	
	Other corticoadrenal over activity	255.3	
	Corticoadrenal insufficiency; Addisonian crisis, Addison's disease NOS	255.4	
256	Ovarian dysfunction—4th digit required		
	Hyperestrogenism	256.0	
	Other ovarian hyperfunction	256.1	
	Postablative ovarian failure	256.2	
	Other ovarian failure; delayed menarche, ovarian hypofunction, primary ovarian failure NOS	256.39	
	Polycystic ovaries	256.4	
	Hirsutism	704.1

	Malnutrition of mild degree	263.1	

Table 1 Continued

Code	Diagnosis	4th digit code	5th digit
	Arrested development following protein-calorie malnutrition; nutritional dwarfism, physical retardation due to malnutrition	263.2	
268	Vitamin D deficiency—4th digit required		
	Vitamin D-resistant: osteomalacia, rickets	275.3	
	Rickets, active	268.0	
	Rickets, late effect	268.1	
	Osteomalacia, unspecified	268.2	
270	Disorders of amino acid transport and metabolism—4th digit required		
271	Disorders of carbohydrate transport and metabolism—4th digit required		
272	Disorders of lipid metabolism—4th digit required		
783	Symptoms—4th and 5th digit required for some		
	Anorexia; loss of appetite	783.0	
	Anorexia nervosa	307.1	
	Abnormal weight gain	783.1	
	Obesity—5th digit required	278.0	0
	Morbid obesity	278.0	1
	Localized adiposity/fat pad	278.1	
	Acanthosis nigricans	701.2	
	Striae	701.3	
	Fatigue/lethargy	780.7	9
	Pallor	782.6	1
	Flushing	782.6	2
	Abnormal loss of weight	783.2	1
	Underweight	783.2	2
	Feeding problem, infant	783.3	
783	Lack of normal physiological development in childhood		
	Abnormal posture	781.9	2
	Unspecified, inadequate development, lack of development	783.4	0
	Failure to thrive; failure to gain weight	783.4	1
	Delayed milestones; late walker, late talker	783.4	2
	Short stature; growth failure, growth retardation, lack of growth, physical retardation—includes constitutional short stature, stature inconsistent with chronological age	783.4	3

many practitioners would like to participate, the task becomes too great for the time involved. Bennett et al. (5) reported findings suggesting that phase II and III clinical trials resulted in a modest increase in cost over standard treatment. Policy makers have also decided to support clinical trial reimbursement initiatives. You have to think and decide which resources you can assign to a clinical trial protocol. There is a lot of responsibility and work involved in these protocols; entering into an agreement should be thoughtfully considered before starting protocols in your practice. The principal investigator's history of participation in clinical trials is extremely important. Your first attempts should be carefully done with few queries or problems in completing the study. It is also essential that you meet your agreed-upon quota of study subjects. Sponsors are very interested in this factor when reviewing your application to be an investigator in their trial. Sponsors are looking for investigators with good

clinical practice and a certificate in Human Subjects Protection. A good history of successful completion of clinical trials greatly increases your chances by reputation in being awarded further clinical trials from sponsors. You have to start slowly with careful planning and this part of your practice will grow over time into a rewarding part of your practice.

XII. WHAT IS NEEDED?

A sign stating "Wanted: trained coders only" is needed. You and your billing staff need to attend courses, including the Medicare courses, to keep updated on coding and reimbursement issues. The practice should have a code fee profile based on its RBRVS incorporating the cost of resources for your practice in your geographic area. Any investment that increases receivables for your practice is a sound investment. There are many links on the Internet

where you can find easily accessible information and companies that address this issue.

XIII. FREQUENTLY USED DIAGNOSED CODES FOR THE PEDIATRIC ENDOCRINE PRACTICE

This list is a quick list of common codes used in a pediatric endocrine practice (see Table 1). It does not adequately represent the many different presentations a child or young adult might bring to your attention nor are all possible diagnoses mentioned. Please refer to official sources for further definitions and instructions on use of these codes.

I. STANDARDS OF GROWTH AND DEVELOPMENT

A. Neonates

- Figure 1** Curve of birth weight against gestational age.
Figure 2 Curve of length and head circumference against gestational age.
Figure 3 Growth curves of infants with low birth weight.
Figure 4 Growth curves of infants with low birth weight (not corrected for gestational age).
Figure 5 Phallic lengths of premature and full-term infants.
Figure 6 Phallic diameters of premature and full-term infants.
Figure 7 Ratio of clitoral diameter to infant's weight plotted against menstrual age.

B. Infants

- Figure 8** Weight of infants breastfed at least 12 months: boys and girls.
Figure 9 Length of infants breastfed at least 12 months: boys and girls.
Figure 10 Head circumference of infants breastfed at least 12 months: boys and girls.

C. Females

- Figure 11** Length and weight for age: birth to 36 months.
Figure 12 Head circumference for age and weight for length: birth to 36 months.
Figure 13 Height and weight for age: 2–20 years.
Figure 14 Height/weight percentiles.
Figure 15 Height velocity.
Figure 16 Height and pubertal development.

- Figure 17** Body mass index for age.
Figure 18 Progression of puberty: staging of breast and pubic hair.
Figure 19 Mean height and standard deviation, 2–18 years.
Figure 20 Prediction of adult height from the height and the age at menarche.

D. Males

- Figure 21** Length and weight for age: birth to 36 months.
Figure 22 Head circumference for age and weight for length: birth to 36 months.
Figure 23 Height and weight for age: 2–20 years.
Figure 24 Height/weight percentiles.
Figure 25 Height velocity.
Figure 26 Height and pubertal development.
Figure 27 Body mass index for age.
Figure 28 Progression of puberty: staging of genitalia and pubic hair.
Figure 29 Mean height and standard deviation: 2–18 years.
Figure 30 Penile growth: birth to adolescence.
Figure 31 Testicular growth: 4–18 years.
Figure 32 Testicular volume: birth to 16 years.

II. MISCELLANEOUS STANDARDS

- Figure 33** Arm span in relation to age and standing height: birth to 20 years.
Figure 34 Upper to lower segment ratio, both sexes: birth to 16 years.
Figure 35 Sitting height in relation to age and standing height: birth to 20 years.
Figure 36 Average anthropometric measurements.

- Figure 37** Measurement of the shoulder-to-elbow length and elbow-to-end-of-third-metacarpal length.
Figure 38 Upper arm length, girls: 4–16 years.
Figure 39 Upper arm length, boys: 4–16 years.
Figure 40 Total upper limb length at birth.
Figure 41 Total upper limb length, both sexes: 4–16 years.
Figure 42 Hair-grading system.
Figure 43 Development of dentition.
Figure 44 Appearance of osseous centers: birth to 5 years.
Figure 45 Appearance of osseous centers: 6–13 years.
Figure 46 Chronological order of union of epiphysis with diaphysis.
Figure 47 Triceps and subscapular skinfolds, males and females: 4–16 years.
Figure 48 Body surface area.
Figure 49 Clinical observation of brachymetacarpia.

III. STANDARD GROWTH CHARTS FOR CHILDREN WITH GENETIC OR PATHOLOGICAL CONDITIONS

- Figure 50** Height and weight for Turner syndrome, girls: 2–19 years.
Figure 51 Height and weight for Down syndrome, male: birth to 36 months.
Figure 52 Height and weight for Down syndrome, male: 2–18 years.
Figure 53 Height and weight for Down syndrome, female: birth–36 months.
Figure 54 Height and weight for Down syndrome, female: 2–18 years.
Figure 55 Height curve for achondroplasia, male: birth to 18 years.
Figure 56 Height velocity for achondroplasia, male: birth to 18 years.
Figure 57 Upper and lower segments for achondroplasia, males: birth to 18 years.
Figure 58 Head circumference for achondroplasia, male.
Figure 59 Height curve for achondroplasia, female: birth to 18 years.
Figure 60 Height velocity for achondroplasia, female: birth to 18 years.
Figure 61 Upper and lower segments for achondroplasia, females: birth to 18 years.
Figure 62 Head circumference for achondroplasia, female.
Figure 63 Height curves for males and females with Prader-Willi syndrome.
Figure 64 Height and weight for Marfan syndrome, male: 2–24 years.
Figure 65 Height and weight for Marfan syndrome, female: 2–24 years.
Figure 66 Height curve for Noonan syndrome, male: birth to 18 years.
Figure 67 Height curve for Noonan syndrome, female: birth to 18 years.
Figure 68 Growth curve for diastrophic dysplasia, birth to 18 years (no gender specified).
Figure 69 Growth curve for spondyloepiphyseal dysplasia congenital: birth to 18 years (no gender specified).
Figure 70 Growth curve for pseudoachondroplasia: birth to 18 years (no gender specified).
Figure 71 Curve for ear length of males with fragile X syndrome: birth to 28 years.
Figure 72 Curves for testis volume of males with fragile X syndrome: birth to 28 years.
Figure 73 Height curve for cri du chat syndrome (CDCS), female: birth to 24 months.
Figure 74 Height curve for cri du chat syndrome, female: 2–18 years.
Figure 75 Weight curve for cri du chat syndrome, female: birth to 24 months.
Figure 76 Weight curve for cri du chat syndrome, female: 2–18 years.
Figure 77 Head circumference for cri du chat syndrome, female birth to 15 years.
Figure 78 Height curve for cri du chat syndrome, male: birth to 24 months.
Figure 79 Height curve for cri du chat syndrome, male: 2–18 years.
Figure 80 Weight curve for cri du chat syndrome, male: birth to 24 months.
Figure 81 Weight curve for cri du chat syndrome, male: 2–18 years.
Figure 82 Head circumference for cri du chat syndrome, male: birth to 15 years.
Figure 83 Height curve for Williams syndrome, female and male: 0–20 years.
Figure 84 Weight curve for Williams syndrome, female: 0–20 years.
Figure 85 Head circumference for Williams syndrome, female: 0–20 years.
Figure 86 Height curve for Williams syndrome, male: 0–20 years.
Figure 87 Weight curve for Williams syndrome, male: 0–20 years.
Figure 88 Head circumference for Williams syndrome, male: 0–20 years.
Figure 89 Length, weight, and head circumference for neurofibromatosis type 1, females: 3–36 months.
Figure 90 Length, weight, and head circumference for neurofibromatosis type 1, males: 3–36 months.

I. STANDARDS OF GROWTH AND DEVELOPMENT

A. Neonates: Figures 1-7

Figure 1 Smoothed curve values for the mean \pm 2 SD of birth weight against gestational age. (From Usher R, McLean F. Intrauterine growth of live-born Caucasian infants at sea level: standards obtained from measurements in 7 dimensions of infants born between 25 and 44 weeks of gestation. *J Pediatr* 1969; 74(6):901-910.)

Figure 2 Smoothed curve values for the mean \pm 2 SD of crown-heel length and head circumference against gestational age. (From Usher R, McLean F. Intrauterine growth of live-born Caucasian infants at sea level: standards obtained from measurements in 7 dimensions of infants born between 25 and 44 weeks of gestation. *J. Pediatr* 1969; 74(6):901-910.)

Figure 3 Mean growth curves of three groups of low-birth-weight infants. (A) Very premature and appropriate in size. (B) Moderately premature and appropriate in size. (C) Full-term but severely undergrown. These curves are plotted against the gestation age for that group. (From Babson SG. Growth of low birth weight infants. J Pediatr 1970; 77(1):11-18.)

Figure 4 Growth curves of three groups of low-birth-weight infants plotted without correction for gestational age. (From Babson SG. Growth of low-birth-weight infants. J Pediatr 1970; 77(1):11-18.)

Figure 5 Phallic length of premature and full-term infants. Stretched phallic length of 63 normal premature and full-term male infants (●), showing lines of mean \pm 2 SD. Correlation coefficient is 0.80. Superimposed are data for two small-for-gestational-age infants (Δ), seven large-for-gestational-age infants (\blacktriangle), and four twins (\blacksquare), all of which are in the normal range. (From Feldman KW, Smith DW. Fetal phallic growth and penile standards for newborn male infants. *J Pediatr* 1975; 86(3):395-398.)

Figure 7 Ratio of clitoral diameter to infant's weight plotted against menstrual age. Measurements were made with calipers on 69 premature and 90 term infants in the first 3 days of life. There was no difference in measurements between black infants and white infants. Clitoral diameter had reached term size by 27 weeks' menstrual age. Clitoral diameter varied from 2 to 6 mm, but did not change with menstrual age. The ratio of clitoral diameter to body showed a significant negative correlation to menstrual age. (From Riley WS, et al. *J Pediatr* 1980; 96:918.)

Figure 6 Phallic diameter of premature and full-term infants. Phallic diameter of 63 normal premature and full-term male infants (●), showing lines of mean \pm 2 SD. Correlation coefficient is 0.82. Superimposed are data for two small-for-gestational-age infants (Δ), seven large-for-gestational-age infants (\blacktriangle), and four twins (\blacksquare), all of which are in the normal range. (From Feldman KW, Smith DW. Fetal phallic growth and penile standards for newborn male infants. *J Pediatr* 1975; 86(3):395-398.)

B. Infants: Figures 8–10

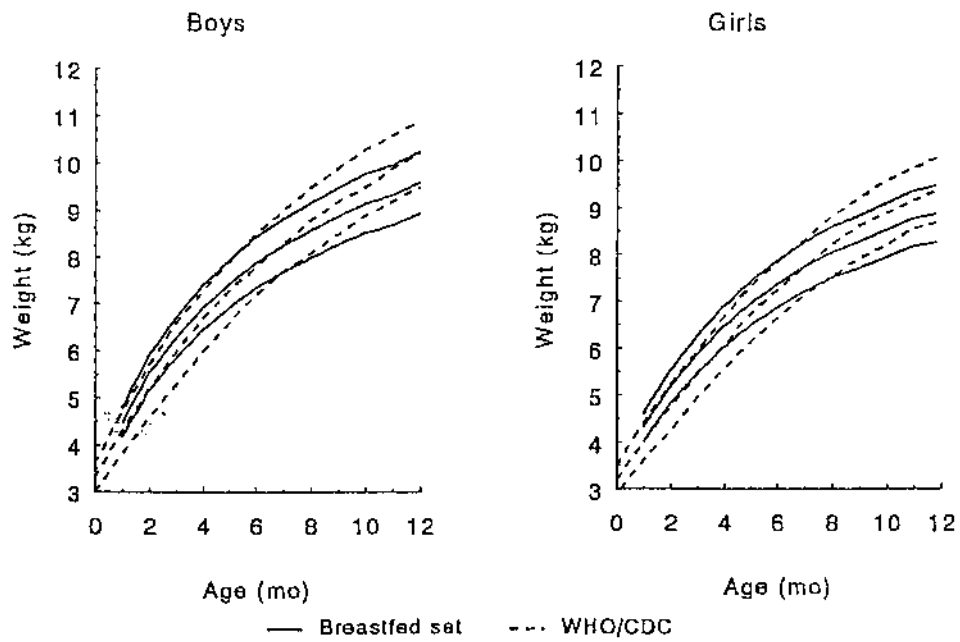

Figure 8 Weight quartiles of infants breastfed at least 12 months (n = 226) in comparison with the WHO/CDC reference (1986). (From Dewey KG, Peerson LA, Brown KH, et al. *Pediatrics* 1995; 96:495.)

Figure 9 Length quartiles of infants breastfed at least 12 months (n = 226) in comparison with the WHO/CDC reference (1986). (From Dewey KG, Peerson LA, Brown KH, et al. *Pediatrics* 1995; 96:495.)

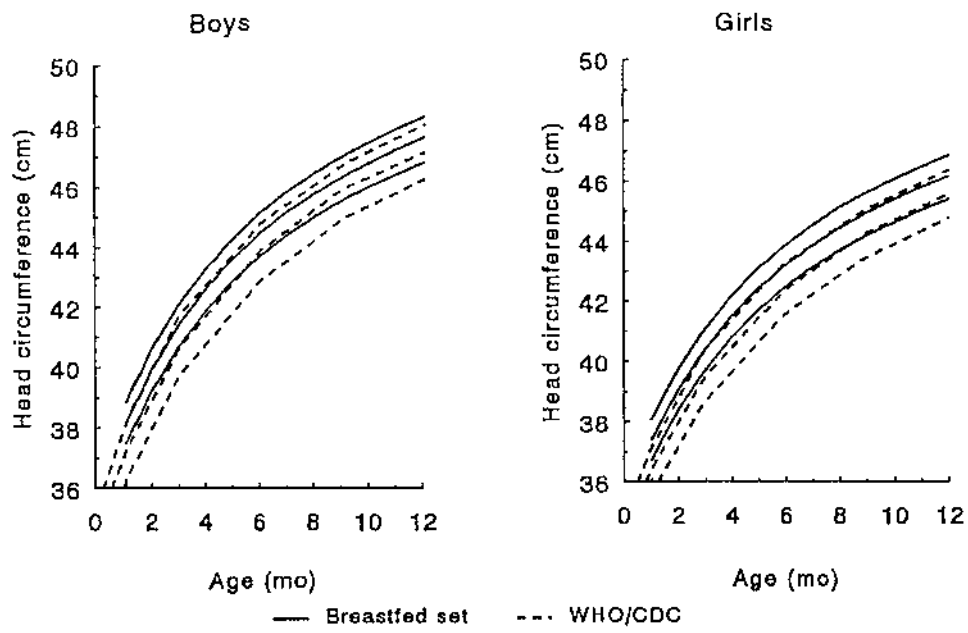

Figure 10 Head circumference quartiles of infants breastfed at least 12 months (n = 226) in comparison with the WHO/CDC reference (1986). (From Dewey KG, Peerson LA, Brown KH, et al. *Pediatrics* 1995; 96:495.)

Figure 11 Length and weight for age, girls: birth to 36 months. (Developed by the National Center for Health Statistics in collaboration with the National Center for Chronic Disease Prevention and Health Promotion (2000); <http://www.cdc.gov/growthcharts>.)

Figure 12 Head circumference for age and weight for length, girls: birth to 36 months. (Developed by the National Center for Health Statistics in collaboration with the National Center for Chronic Disease Prevention and Health Promotion (2000); <http://www.cdc.gov/growthcharts>.)

Figure 13 Stature for age and weight, girls: 2–20 years. (Developed by the National Center for Health Statistics in collaboration with the National Center for Chronic Disease Prevention and Health Promotion (2000); <http://www.cdc.gov/growthcharts>.)

Figure 16 Height and pubertal development, girls. (From Tanner JM, Davis PSW. J Pediatr 1985; 107.)

Typical Progression of Female Pubertal Development

Pubertal development in size of female breasts.

Stage 1. The breasts are preadolescent. There is elevation of the papilla only.

Stage 3. There is further enlargement of breasts and areola with no separation of their contours.

Stage 2. Breast bud stage. A small mound is formed by the elevation of the breast and papilla. The areolar diameter enlarges.

Stage 5. The breasts resemble those of a mature female as the areola has recessed to the general contour of the breast.

Stage 4. There is a projection of the areola and papilla to form a secondary mound above the level of the breast.

Stage 5. The breasts resemble those of a mature female as the areola has recessed to the general contour of the breast.

Pubertal development of female pubic hair.

Stage 1. There is no pubic hair.

Stage 2. There is sparse growth of long, slightly pigmented, downy hair, straight or only slightly curled, primarily along the labia.

Stage 3. The hair is considerably darker, coarser, and more curled. The hair spreads sparsely over the junction of the pubes.

Stage 4. The hair, now adult in type, covers a smaller area than in the adult and does not extend onto the thighs.

Stage 5. The hair is adult in quantity and type, with extension onto the thighs.

Figure 26 Height and pubertal development, boys. (Tanner JM, Davis PSW. J Pediatr 1985; 107.)

Typical Progression of Male Pubertal Development

Pubertal development in size of male genitalia.

Stage 1. The penis, testes, and scrotum are of childhood size.

Stage 2. There is enlargement of the scrotum and testes, but the penis usually does not enlarge. The scrotal skin reddens.

Stage 3. There is further growth of the testes and scrotum and enlargement of the penis, mainly in length.

Stage 4. There is still further growth of the testes and scrotum and increased size of the penis, especially in breadth.

Stage 5. The genitalia are adult in size and shape.

Pubertal development of male pubic hair.

Stage 1. There is no pubic hair.

Stage 2. There is sparse growth of long, slightly pigmented, downy hair, straight or only slightly curled, primarily at the base of the penis.

Stage 3. The hair is considerably darker, coarser, and more curled. The hair spreads sparsely over the junction of the pubes.

Stage 4. The hair, now adult in type, covers a smaller area than in the adult and does not extend onto the thighs.

Stage 5. The hair is adult in quantity and type, with extension onto the thighs.

^aMales only.

Figure 36 Average anthropometric measurements. (From Wilkins, Lawson. *The Diagnosis and Treatment of Endocrine Disorders in Childhood and Adolescence*. Courtesy of Charles C. Thomas, Publisher, Springfield, Illinois, 1966.)

Figure 37 Measurement of shoulder-to-elbow length (SE) and elbow-to-end-of-third metacarpal length (EMC) is shown using an anthropometer. SE is the distance between the shoulder and the tip of the elbow; EMC is the distance between the tip of the elbow and the distal end of the third metacarpal on a closed fist. (From Tanner JM, Davies PSW. *J Pediatr* 1985; 107:317-327.)

Figure 38 Upper arm length, girls: 4–16 years. (From Manila RM, Hamill PVV, and Lemeshow S. Manual of physical status and performance in childhood. 1973; 1B:1048; New York: Plenum Press.)

Figure 39 Upper arm length, girls: 4–16 years. (From Manila RM, Hamill PVV, and Lemeshow S. Manual of physical status and performance in childhood. 1973; 1B:1048; New York: Plenum Press.)

Figure 40 Total upper limb length at birth. (From Sivan Y, Merlob P, and Reisner SH. Am J Dis Child 1983; 137:829.)

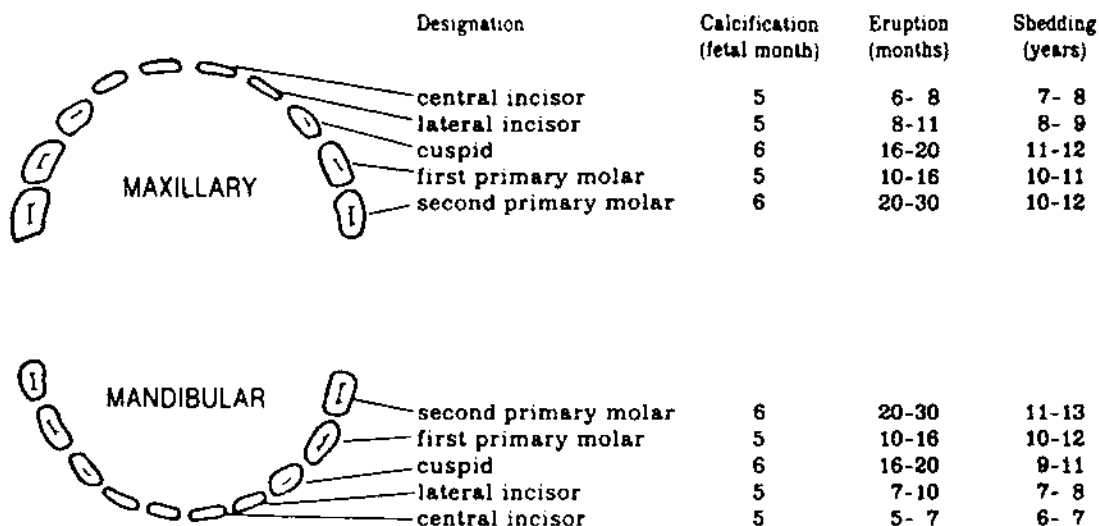

Figure 41 Total upper limb length, both sexes, 4–16 years. (From Martin and Saller. Lehrbuch der Anthropologie, Stuttgart: Gustave Fische.)

Site	Grade	Definition
1. Upper lip	1	A few hairs at outer margin.
	2	A small moustache at outer margin.
	3	A moustache extending halfway from outer margin.
	4	A moustache extending to midline.
2. Chin	1	A few scattered hairs.
	2	Scattered hairs with small concentrations.
	3 & 4	Complete cover, light and heavy.
3. Chest	1	Circumareolar hairs.
	2	With midline hair in addition.
	3	Fusion of these areas, with three-quarter cover.
	4	Complete cover.
4. Upper back	1	A few scattered hairs.
	2	Rather more, still scattered.
	3 & 4	Complete cover, light and heavy.
5. Lower back	1	A sacral tuft of hair.
	2	With some lateral extension.
	3	Three-quarter cover.
	4	Complete cover.
6. Upper abdomen	1	A few midline hairs.
	2	Rather more, still midline.
	3 & 4	Half and full cover.
7. Lower abdomen	1	A few midline hairs.
	2	A midline streak of hair.
	3	A midline band of hair.
	4	An inverted V-shaped growth.
8. Arm	1	Sparse growth affecting not more than a quarter of the limb surface.
	2	More than this: cover still incomplete.
	3 & 4	Complete cover, light and heavy.
9. Forearm	1, 2, 3, 4	Complete cover of dorsal surface; 2 grades of light and 2 of heavy growth.
10. Thigh	1, 2, 3, 4	As for arm.
11. Leg	1, 2, 3, 4	As for arm.

Figure 42 Hair-grading system. (From Rerriman D, Gallwey JD. *J Clin Endocrinol Metab* 1961; 21:1440–1447.)

PRIMARY (DECIDUOUS) TEETH

DESIGNATION OF TEETH

211111|101112
 211110|11111

Deciduous teeth designated by 1; permanent teeth by 2, missing teeth by 0. Upper row indicates maxillary teeth, lower row of numbers indicates mandibular teeth. Vertical line locates the midline.

SECONDARY (PERMANENT) TEETH

Figure 43 Development of dentition. (From Simon FA, Stevenson RE. Pediatric Patient Care. University of Texas Press, 1975.)

Figure 44 Chronological order of appearance of osseous centers, birth to 5 years. (From Wilkins, Lawson. *Diagnosis and Treatment of Endocrine Disorders in Childhood and Adolescence*. Courtesy of Charles C Thomas, Publisher, Springfield, Illinois, 1966.)

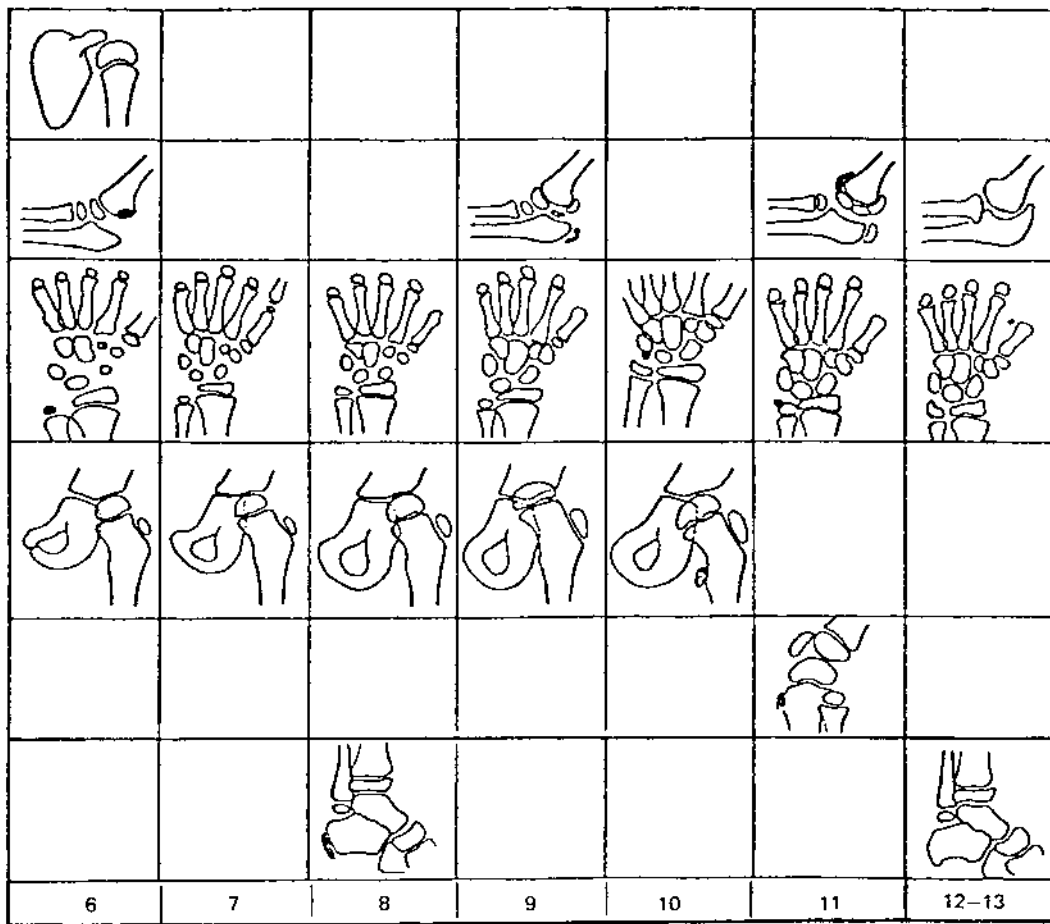

Figure 45 Chronological order of appearance of osseous centers, 6–13 years. (From Wilkins, Lawson. *The Diagnosis and Treatment of Endocrine Disorders in Childhood and Adolescence*. Courtesy of Charles C Thomas, Publisher, Springfield, Illinois, 1966.)

	12 Yrs.	13 Yrs.	14 Yrs.	15 Yrs.	16 Yrs.	17 Yrs.	18 Yrs.
Shoulder							Head of humerus Great tuberosity
Elbow	Trochlen & capitulum	Olecranon	Ext. epicondyle Head of radius				
Hand		Styloid of ulna			Ep. metacarpals & phalanges		Ep. radius & ulna
Hip					Head of femur Trochanters		
Knee							Ep. femur, tibia & fibula
Foot	Ep. os raleis				Ep. metatarsals & phalanges	Ep. tibia & fibula	

Figure 46 Chronological order of union of epiphysis with diaphysis. (From Wilkins, Lawson. The Diagnosis and Treatment of Endocrine Disorders in Childhood and Adolescence. Courtesy of Charles C Thomas, Publisher, Springfield, Illinois, 1966.)

Figure 47 Triceps and subscapular skinfolds, males and females: 4–16 years. (From Schlueter K, Funck W, Pachalay J, and Weber B. Eur J Pediatr 1976; 123:255.)

Alternative (Mosteller's formula)

$$\text{Surface area (m}^2\text{)} = \sqrt{\frac{\text{Height (cm)} \times \text{Weight (kg)}}{3600}}$$

Figure 48 Body surface area nomogram and equation. (Arch Dis Child 70:246, 1994.)

Figure 49 A straight ruler is applied against the distal ends of the third, fourth, and fifth metacarpals of a tightly closed fist. The clinical observation of brachymetacarpia V was confirmed radiologically when the fifth metacarpal bone failed to intercept a straight line connecting the distal ends of the third and fourth metacarpal bones by more than 2 mm. (Tanner JM, Davies PSW. *J Pediatr* 1985; 107:317–327.)
