The outcome of treatment of papillary and follicular thyroid carcinoma in children is generally favorable. Mortality tends to be in the range of 1% at 10 years (6, 106). With more prolonged follow-up, 5–7% of patients may die from thyroid cancer and another group of similar size may die from conditions resulting from treatment of their cancer (106). The patients most likely to die from thyroid cancer seem to be those younger than 10 years of age at the time of diagnosis (5, 107).

Management of medullary thyroid carcinoma in children focuses on detection of inherited disease before appearance of symptoms or signs. In the past, affected family members were detected by provocative tests stimulating calcitonin secretions. Pentagastrin (currently unavailable) and calcium infusion have been used in this

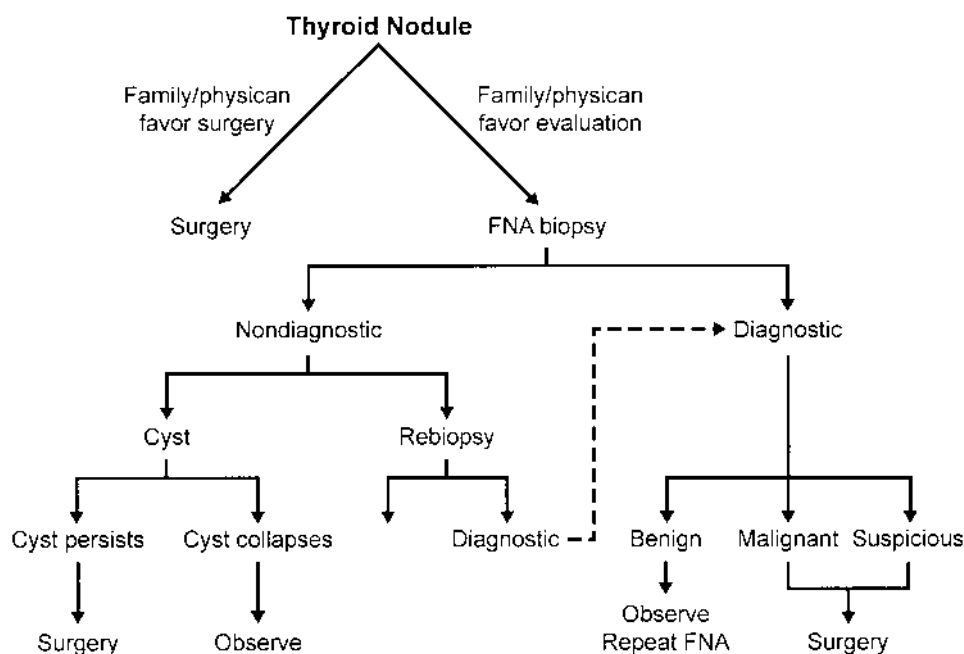

Figure 15 Thyroid nodules in children may be removed surgically if this approach is favored by the family or the physician. Otherwise, fine-needle aspiration (FNA) is the most cost-effective test to guide further evaluation and treatment.

setting (15, 108). Formed medullary thyroid carcinoma may be detected in children with MEN 2 as early as 2 to 3 years of age (15, 109). The need to perform surgery early in these patients is highlighted by the finding of lymph node metastases of medullary thyroid cancer in children as young as 5 years of age (110, 111). These reports suggest that thyroid surgery should be performed in RET-positive children by 5 years of age and perhaps as early as 2 years of age.

Because of the possibility of pheochromocytoma in MEN 2 patients, all should undergo appropriate measurement of serum and urine catecholamines and catecholamine metabolite studies. Additionally, patients who may have MEN 2A should have studies of calcium since hyperparathyroidism can be treated at the same time that thyroidectomy is being performed. Preoperative calcitonin levels should be measured.

There is general agreement that patients with medullary thyroid carcinoma should undergo total thyroidectomy. Patients with familial disease have bilateral multifocal tumors. Similar multifocal disease may be found in 5–30% of patients with apparently sporadic medullary thyroid cancer (110, 112).

If serum calcitonin levels remain elevated postoperatively, physical examination and neck ultrasonography may reveal persistent cervical lymph node metastases that should be surgically excised. Aggressive surgical therapy of patients without obvious disease in the neck, mediastinum, liver, or lungs may render approximately 30% of postoperation hypercalcemic patients normocalcitic

nemic with a follow-up of approximately 6 years (113). A more conservative approach to such patients has been advocated by others in view of their 10-year survival rate of 86% (114).

Hypoparathyroidism and Mineral Homeostasis

Jaakko Perheentupa

University of Helsinki, Helsinki, Finland

I. INTRODUCTION

Starting with an outline of the basic physiology of mineral homeostasis, this chapter discusses the disease states involving deficient parathyroid hormone (PTH) effect, hypoparathyroidism in the wide sense of the word. Commonly, the name hypoparathyroidism (HP) is limited to meaning deficient secretion of PTH, while defects in the effector mechanism of PTH are collectively called pseudo-HP (PHP). Causes are many, both inborn and acquired, and several of them are not well understood. Delay in the recognition of these disorders may lead to permanent brain damage or even death. Effective therapy is available. It is not, however, a real substitution therapy but employs calciferol sterols, which lack the renal effects of PTH and are potentially toxic. Hence, the therapy needs to be carefully monitored.

II. PHYSIOLOGICAL BACKGROUND: THE PARATHYROID GLANDS AND HORMONES

The homeostasis of calcium (Ca^{2+}) and inorganic phosphate (Pi) ion concentrations in the extracellular fluid (1) is maintained by an integrated regulation of their absorption from the intestine, reabsorption from the glomerular filtrate, and movement into and out of the skeleton. The parathyroid glands (PTG) are the regulatory center that controls tightly the concentration of Ca^{2+} in the extracellular fluid (Fig. 1); its function is adjusted by the Ca^{2+} -sensing receptors present on the surface of its cells. The action of PTG is directly mediated by PTH and indirectly via the steroid hormone calcitriol. Also, extracellular concentrations of the minerals exert direct short-loop feedback effects on the rate of their reabsorption in the kidney tubules and the production of calcitriol.

Most people have four PTGs, with an average total weight of 120 mg in the adult. The lower pair arise in

association with thymus from the third branchial pouch and migrate caudally to separate from the thymus at the 18 mm embryo stage. They assume a variable final location, commonly at the lower pole of the thyroid gland but sometimes mediastinally even at the level of the pericardium. The upper pair derive from the more caudal fourth branchial pouch and remain stationary with final location at the upper pole of the thyroid. Chief cells, the major cells of the glands, are arranged in cords and sheets. These cells regulate plasma Ca^{2+} concentration on a minute-to-minute basis by rapidly adjusting their secretion of stored PTH in response to changes in that concentration; synthesize, process, and store large amounts of PTH in a regulated manner; and replicate in response to a chronic hypocalcemia.

The actions of the PTH are stimulation of renal production of calcitriol, which increases intestinal absorption of Ca and Pi; stimulation of Ca reabsorption and inhibition of Pi reabsorption from renal tubules; and stimulation of osteoclastic bone resorption and release of Ca and Pi ions from the skeleton (Fig. 1).

The gene for PTH, located in chromosome 11p15, consists of three exons and two introns encoding pre-pro-PTH of 115 amino acids including a 25-residue signal so-called pre sequence, and a 6-residue pro sequence (2–3). These sequences direct the protein into the secretory pathway. The prehormone is cleaved during posttranslational processing to a 90 amino acid pro-PTH and then to the 84 amino acid mature PTH (1). This PTH is stored in secretory granules. It is secreted with chromogranin A, which may behave as autocrine or paracrine regulator of PTH release (1). As a regulatory mechanism, a portion of the PTH is inactivated by proteases within the secretory granules and secreted as carboxy-terminal fragments (4). Several polymorphisms of the PTH gene have been reported, which allow linkage studies (5–7).

PTH_{1-34} possesses the full adenyl cyclase stimulating activity of the hormone, residues 1 and 2 being nec-

Figure 1 Calcium homeostasis. The parathyroid glands control the extracellular fluid Ca^{2+} concentration by regulating the flux of Ca from the kidneys and skeleton and, through adjusting the production of calcitriol by the kidneys, from the intestine. This control is mediated by PTH; its secretion is regulated through feedback by ECF Ca^{2+} concentration.

essary for this potency, and residues 10–34 for binding to a specific cell membrane receptor (8). A PTH molecule lacking residues 1 and 2 is a competitive inhibitor of the hormone in vitro, lacking the biological potency but retaining the full receptor-binding activity.

PTH-related peptide (PTHrP), a polyhormone produced by PTG, is similar to PTH in its amino terminus, which in both peptides comprises the receptor-activating domain, accounting for the binding of both peptides to the receptor shared by them, the PTH/PTHrP receptor. PTHrP is the precursor of multiple biologically active peptides, which are of vital importance during the organogenesis. An amino-terminal peptide PTHrP₁₋₃₆ with its PTH-like domain can activate the PTH/PTHrP receptor fully and produce all the classic actions of PTH. Midregion PTHrP peptides stimulate placental Ca transport, presumably through a specific receptor. Carboxy-terminal fragments inhibit bone resorption and stimulate osteoblast growth. PTHrP acts as a calciotropic hormone during fetal life and lactation. PTHrP secreted by fetal PTG stimulates placental transport of Ca in the sheep (9), whereas PTH has no such effect. PTHrP may be the signal responsible for the adaptation of maternal Ca metabolism to the stress of lactation (10). Hypoparathyroid mothers can maintain normocalcemia during lactation. Large amounts of PTHrP are secreted in milk, but its role is unknown. Also, PTHrP may delay the differentiation of growth plate chondrocytes and allow them to proliferate and form orderly columns of cells (11). Various PTHrP peptides are responsible for many different local functions in diverse tissues and through several receptors, while PTH uses the shared receptor to regulate the systemic homeostasis of

Ca^{2+} . Otherwise, only in hypercalcemia of malignancy enough of PTHrP reaches circulation to produce systemic effects (12).

A. The Ca^{2+} -Sensing Receptor

At normal extracellular Ca^{2+} levels PTH is synthesized at a nearly maximal rate, and changing Ca^{2+} concentration has no rapid effects on PTH mRNA expression. The primary control of availability of PTH probably works via the effect of Ca^{2+} on PTH secretion and degradation. At high Ca^{2+} levels a smaller proportion of the secretion of PTH is intact PTH and a larger proportion PTH fragments.

Both positive and negative regulatory elements exist in the 5' flanking region of the PTH gene (3). Cytoplasmic levels of prepro-PTH mRNA may be directly regulated by Ca^{2+} ; probably Ca^{2+} modifies the PTH gene transcription. Calcitriol is also a potent downregulator of the expression of the gene. Normal extracellular concentration of Mg^{2+} (8) is a prerequisite of normal PTH secretion: both hypermagnesemia and hypomagnesemia inhibit it. Persons with low borderline plasma Mg^{2+} concentration recover slower from induced reduction of plasma Ca^{2+} than persons with high normal plasma Mg^{2+} (13).

The extracellular Ca^{2+} concentration is monitored by Ca^{2+} -sensing receptors (CaRs) that are plentiful on the surface of the chief cells of the parathyroid glands, and are also present in the kidneys in the juxtaglomerular apparatus, along the luminal surface of the proximal convoluted tubule, the basolateral surface of the cortical thick ascending limb of the loop of Henle, and the apical and luminal membrane of the inner medullary collecting duct (14), in the intestine (15), parts of the brain (16), the thyroid C cells, breast, and the adrenal glands (17). The human 1078 amino acid protein, encoded by CaR gene in chromosome 3q13, consists of three structural regions: a large amino terminal extracellular domain that contains clusters of acidic amino acids thought to be involved in binding of Ca^{2+} , seven transmembrane helices characteristic of the G protein-coupled receptors, and a cytoplasmic carboxy terminal domain. Once activated by Ca^{2+} , the CaR activates phospholipase C through a G protein. Through intracellular accumulation of inositol triphosphate and, secondarily, Ca^{2+} , this activation leads to inhibition of the secretion and synthesis of PTH, and activation of its proteolysis. The receptor lacks specificity: it is also stimulated by other divalent cations, most importantly Mg^{2+} .

B. Regulation of PTH Synthesis and Secretion

There is an inverse sigmoidal relationship between extracellular Ca^{2+} concentration and the release of intact PTH, with the normal set point (the 50% response) at approximately 1.25 mmol/l (Fig. 2). The chief cells of the PTG are exquisitely sensitive to small fluctuations in extracel-

Figure 2 ECF Ca^{2+} concentration determines the secretory rate of PTH following a sigmoidal dose–response curve. The normal level of the ECF Ca^{2+} concentration corresponds approximately to the midpoint of the slope. The minimum secretory rate is not zero. (From Ref. 19.)

lular Ca^{2+} concentration (18, 19) signaled by their CaRs (17). When extracellular Ca^{2+} concentration decreases below the system set point, the secretion of preformed PTH is stimulated in seconds to minutes. In addition to decreases in the intracellular concentrations of inositol triphosphate and Ca^{2+} , increased production of cAMP is also involved. PTG adenyl cyclase has an absolute requirement for Mg^{2+} , is stimulated by low Ca^{2+} concentration, and has a sensitivity to inhibition by high Ca^{2+} concentrations some 100–200-fold higher than this enzyme in other cell types. If the extracellular Ca^{2+} concentration is not corrected, the PTH gene expression increases in hours. Chronic hypocalcemia leads to an increase in the number of the chief cells and the size of PTG. Conversely, increased extracellular Ca^{2+} concentration inhibits the secretion and synthesis of PTH, and activates the proteolysis of PTH. These cause a rapid decrease in the release of intact PTH. A Ca^{2+} independent, nonsuppressible baseline component of PTH secretion is also present.

Newborn infants under 3 days of postnatal age have poorer PTH secretory responses to hypocalcemia than older infants. Postnatal age here has a dominant effect over gestational age (20).

C. Parathyroid Hormone in the Circulation

After being released from the PTG, PTH has a half-life in the circulation of 2 min. This means that the plasma level is determined by the rate of secretion, and responds rapidly to changes in it. PTH is cleared by the hepatic Kupffer's cells and the kidneys. Its carboxy-terminal fragments released circulate longer, mainly because they are cleared exclusively by glomerular filtration. Hence, most of the immunoreactive PTH in the plasma is a mixture of

carboxyterminal fragments. In normocalcemia, the proportions of the intact PTH, its active aminoterminal fragment, and its inactive carboxyterminal fragments in plasma are approximately 10%, 10%, and 80% (1). At low extracellular Ca^{2+} levels large quantities of the intact hormone are secreted, and at high levels more of the carboxyterminal fragments are secreted.

D. Cellular Mechanism of Parathyroid Hormone Action

The regulation of mineral ion homeostasis by PTH is mediated mainly through the PTH/PTHrP receptor present in the kidney, intestine, skeleton and cartilage, aorta, adrenal gland, urinary bladder, brain, and the skeletal muscles. It acts through three distinct second messenger pathways (Fig. 3).

The PTH/PTHrP receptor gene is located in chromosome 3p22–p21.1. The receptor is a 585-amino acid membrane-bound protein with seven transmembrane domains (27, 28). It has a striking homology with the receptors of calcitonin and secretin, and lacks homology with the other G protein-linked receptors. A PTH-sensitive adenyl cyclase has been identified in skin fibroblasts, cardiac cells, and vascular smooth muscle. PTH may regulate cytosolic Ca^{2+} in those cells (26).

The $G_s\alpha$ subunit is coded for by the *GNAS1* gene located in chromosome 20q13.2. It is a complex gene, comprising at least 17 exons, including three alternative first exons. The $G_s\alpha$ is produced by one of the four major splice variants derived from this gene (21). Two of the splice variants are expressed only from the paternal allele, and one only from the maternal allele (cf. Sec. XV.C.).

A second PTH receptor has been identified (29, 30). It is not expressed in the skeleton and the kidney, and its role remains unclear. PTH_{1-84} binds to a cell surface receptor distinct from the PTH/PTHrP receptor. Such carboxy-terminal fragments stimulate osteoclast formation and activity (31).

III. CALCITRIOL (1,25-DIHYDROXYCALCIFEROL)

Calcitriol increases the intestinal absorption of Ca and Pi and thereby their concentrations in the extracellular fluid; increases bone reabsorption; enhances the capacity of PTH to promote Ca reabsorption in the renal tubuli; is a powerful differentiation factor for committed osteoclast precursors, causing their maturation to form multinucleated cells capable of resorbing bone; suppresses the expression of the PTH gene; and has profound effects unrelated to mineral homeostasis, on the hematopoietic tissues, immune system, skin, and muscles (32).

The inactive prohormone vitamin D_3 or cholecalciferol is formed in sun-exposed skin. A byproduct in the synthesis of cholesterol, 7-dehydrocholesterol, undergoes

Figure 3 Binding of PTH to the PTH/PTHrP receptor activates three distinct second-messenger pathways (cAMP, inositol 1,4,5-trisphosphate, diacyl glycerol), varying in different target cells. Different heterotrimeric (α , β , γ) guanine nucleotide-binding proteins (G proteins) couple the receptor to the effectors. Binding of PTH to the receptor facilitates activation of the G protein, a process in which the α subunit exchanges bound GDP for GTP and dissociates from the $\beta\gamma$ dimer and the receptor. The free, GTP-bound α subunit is the primary modulator of the effector molecules. An intrinsic GTPase activity of the α subunit acts as a molecular timing mechanism: after a predetermined interval, GTP is hydrolyzed to GDP (21). G_s activates adenylyl cyclase leading to production of cAMP, which activates protein kinase A. G_q activates phospholipase C, which hydrolyzes phosphatidyl-inositol 1,4,5-trisphosphate to diacyl glycerol (DAG) and inositol 1,4,5-trisphosphate (IP_3). The DAG activates protein kinase C, and the IP_3 activates a receptor on microsomal vesicles that directs the movement of Ca^{2+} from microsomal vesicles into the cytosol. Also, an inhibitory G protein (G_i) complex, mediating inhibitory signals to the adenylyl cyclase, is present in the epithelial cells of proximal renal tubules (22). The phospholipase C/protein kinase C cascade may be predominant (23) in the actions of PTH on bone remodeling and the Ca reabsorption in the distal renal tubuli (24–26).

photochemical cleavage of the bond between carbons 9 and 10 of the sterol B ring. The resulting previtamin D undergoes a temperature-dependent rearrangement producing the vitamin. In prolonged sunlight alternative inert products are formed, and excessive production of the vitamin is avoided. Both vitamins D_2 , from plant sources, and D_3 are also components of food. They are hydroxylated in the liver to 25-(OH)D, a partially active compound, and in the mitochondria of the proximal tubules of the kidney and placenta further to the hormone calcitriol (1,25-(OH) $_2$ D) or, alternatively, to 24,25-(OH) $_2$ D, which is a less active compound of unclear significance. These hydroxylations in the kidney are the key points in the regulation of the synthesis of calcitriol. Vitamins D_2 and D_3 , and their corresponding metabolites, are potent in

humans. Calcitriol acts on the kidneys, skeleton, intestine, and PTG. Also, it regulates the activity of T lymphocytes, and is a growth factor for many types of cells, both normal and tumoral (33).

A. The Production of Calcitriol and Its Regulation

Vitamins D_2 and D_3 are absorbed from the duodenum and jejunum into the lymphatic channels. In states of fat malabsorption this absorption may fail (34–36). Both prohormones are stored in adipose tissue and muscle in amounts depending simply on their intake. Their hydroxylated metabolites are less fat-soluble and less likely to be stored in amounts that may be harmful. Conversion to 25-(OH)D depends directly on the quantity of circulating vitamin D.

The synthesis of the 1- and 24-hydroxylases is regulated reciprocally so that conditions favoring the synthesis of one inhibit the synthesis of the other (37, 38). High PTH concentration, low concentration of calcitriol, and low extracellular concentrations of Pi and/or Ca^{2+} increase the synthesis of 1-hydroxylase, and vice versa. Manipulation of Ca intake within the normal range has a pronounced effect on circulating calcitriol levels by modifying the secretion of PTH (39). Low extracellular concentrations of Pi promote the synthesis of calcitriol, and high concentrations inhibit it. These effects are independent of PTH. In turn, calcitriol stimulates mobilization of Pi from bone and its absorption from the intestine. Thus a plasma phosphate–calcitriol feedback loop exists regulating plasma Pi concentration independently of the Ca^{2+} –PTH–calcitriol loop.

B. Calciferols in Plasma

Normally, the total concentration of D_2 and D_3 in plasma is 2.6–26 nmol/l (1–10 ng/ml), and their half-lives in the circulation are about 24 h. The major circulating form is the 25-(OH)D, with an average plasma concentration of 75 nmol/l and a circulating half-life of about 15 days. Its concentration reflects accurately the vitamin D reserve of the body. Calcitriol circulates at almost 1000-fold lower concentrations (Table 1) with a half-life of 6–8 h (40); 15% is excreted as urinary metabolites and 50% as fecal metabolites. However, the ratio of the active free concentrations of calcitriol and 25-(OH)D is only 1 to 100.

These sterols are bound to albumin and a specific α -globulin, vitamin-D-binding protein (DBP), of which only about 5% is saturated at physiological levels of the sterols. The protein appears also to have a storage function. When bound to this carrier, calcitriol is the most freely dissociable of the group. However, less than 1% of it is unbound, freely diffusible, constituting the active fraction. In general, its concentration remains constant when the DBP levels change.

Table 1 Reference Values for Parameters of Mineral Metabolism

Parameter	mmol/l	mg/dl	Conversion factor
Ca, serum, ionized	1.18–1.30	4.7–5.2	0.25
total	2.20–2.65	8.8–10.6	
Calcitriol, plasma	50–150 pmol/l	20–60 pg/ml	2.40
25(OH)-D, plasma	25–125	10–50 ng/ml	2.50
Mg, serum, newborn	0.75–1.15	1.82–2.80	0.41
child and adult	0.70–1.00	1.70–2.40	
PTH intact, serum (IRMA)	1.1–5.8 pmol/l	10–55 pg/ml	
Pi (as P) serum, newborn	1.40–3.05	4.3–9.4	0.32
1 to 5 months	1.55–2.60	4.8–8.1	
6 to 24 months	1.30–2.20	4.0–6.8	
2 to 3 years	1.16–2.10	3.6–6.5	
prepubertal child	1.16–1.80	3.6–5.6	
puberty	1.07–1.95	3.3–6.0	
after puberty	0.80–1.40	2.5–4.3	
TmP/GFR, newborn	1.30–3.46	4.0–10.7	0.32
3 months	1.30–3.07	4.0–9.5	
6 months	1.30–2.62	4.0–8.2	
child	1.30–2.58	4.0–8.0	
puberty: gradual decrease to adult values			
adult	0.71–1.45	2.2–4.5	

Source: Values for TmP/GFR are from Refs. 52 and 53.

C. Cellular Mechanism of Calcitriol Action

Like other steroid hormones, calcitriol binds in its target cells to a specific cytoplasmic receptor, vitamin D receptor (VDR) (41). It has a high affinity for calcitriol, and lesser affinities for the other homologs such as 25-(OH)D and vitamin D₃. The sterol–receptor complex is translocated to the nucleus where it binds to response elements on specific DNA and activates or suppresses gene transcription. Heterodimerization of the VDR with the retinoid X receptor is essential for its transactivating function (42). The synthesis of several proteins is increased: calbindins, the 25-(OH)D 24-hydroxylase, the VDR itself, the plasma membrane Ca pump, osteocalcin, osteopontin, and others. The synthesis of some other proteins such as PTH, PTHrP, collagen type I and IL-2 is reduced. In addition to genomic actions, calcitriol has rapid nongenomic activities. It increases cytosolic Ca in a number of cell types, including osteoblasts, parathyroid cells, enterocytes and myocytes within seconds to minutes. These are probably carried out by a distinct receptor (32).

The VDR gene, located in chromosome 12q13–14 (43), is a member of the steroid receptor supergene family. The human VDR is a 50 kD protein consisting of 427 aminoacids; its amino terminal 110 residues constitute the DNA-binding domain with two Zn-fingers, and amino acids 150–410 the steroid-binding domain. The receptor is present in a great variety of cells (32).

D. Synthetic Analogs

Two synthetic vitamin D analogs are therapeutically important, 1 α -(OH)D₃ and dihydrotachysterol (DHT). These do not need the 1-hydroxylation for activation and are therefore potent in states of reduced 1-hydroxylation activity such as HP. DHT is rapidly hydroxylated to 25-(OH)DHT. 1 α -(OH)D₃ is similar in potency to the hormone, presumably after 25-hydroxylation in the liver.

IV. THE KIDNEYS

Regulation of urinary excretion plays an important role in the homeostasis of minerals, especially Pi (1). This regulation is mediated by PTH. Also, plasma concentrations of the divalent cations influence their own excretion. The PTG–kidney axis regulates the intestinal absorption of Ca²⁺ and Pi, by determining the rate of synthesis of calcitriol.

A. Mineral Reabsorption and Effects of the Parathyroid Hormone

The mRNA encoding the PTH/PTHrP receptor is expressed in the convoluted and straight proximal tubules, the cortical portion of the thick ascending limb, and the distal convoluted tubules (44, 45). All these segments show cAMP accumulation in response to PTH (46). The

responses of other second messengers in the cells of the proximal and distal tubules seem to differ strikingly. The increase in intracellular free Ca^{2+} depends entirely on its release from intracellular stores in the proximal cells, but largely on extracellular Ca^{2+} in the distal cells (47). PTH-dependent renal actions that require the second messengers cAMP, and increases in intracellular free Ca^{2+} and inositol 1,4,5-triphosphate, include the inhibition of the reabsorption of Pi, the stimulation of the 25-(OH)D-1 α -hydroxylase, and the reabsorption of Ca^{2+} from the distal convoluted tubules (47, 48) (Fig. 4).

The total rate of Pi excretion is always less than its filtered load, normally 5–20%. Pi is reabsorbed in the proximal tubules by a pH- and Na^+ -dependent, active, saturable mechanism involving types I and II Na^+ /Pi cotransporter (49, 50). Hence this reabsorption has a maximum rate (TmP). If other factors remain unaltered, increased plasma PTH concentration reduces TmP and decreased concentration enhances it. TmP in turn determines the fasting plasma Pi concentration, which is maintained close to the value of the quotient of TmP and the glomerular filtration rate (TmP/GFR, Fig. 5, Table 1). This quotient is also called the Pi threshold. TmP/GFR is the best laboratory indicator of renal PTH action (51–53). In response to an injection of PTH, an abrupt increase in Pi

Figure 4 Effects of PTH in the kidney. The three effects are marked + (stimulation) and – (inhibition): inhibition of the reabsorption of phosphate and Na^+ in the proximal tubule; stimulation of the synthesis of 1-hydroxylase in the proximal tubule, and, thereby production of calcitriol (1,25(OH) $_2$ D); and stimulation of reabsorption of Ca^{2+} in the distal tubule. The proximal tubule has a different mechanism for reabsorption of Ca^{2+} ; this is associated with the absorption of Na^+ and is not affected by PTH.

excretion occurs within minutes. PTH induces a rapid endocytosis of the type II Na^+ /Pi cotransporters, resulting in a reduction of their number at the apical membrane of the proximal tubules, and their degradation (54). Calcitriol may have a permissive role for this effect (55). Lack of PTH results in an increased TmP/GFR and thus an elevated plasma Pi level. PTH likewise reduces the reabsorption of bicarbonate, and in HP plasma bicarbonate levels are often elevated.

The tubular reabsorption of Ca^{2+} and Mg^{2+} is in normal circumstances extremely efficient: only 1–3% of the filtered load is excreted. Reabsorption takes place at multiple sites. Of Ca^{2+} approximately 60–70% is reabsorbed in the proximal tubule, 20% within the thick ascending limb of Henle, 5% in the distal tubule, and 10–15% in the collecting duct. Of Mg^{2+} , only some 20% appears to be reabsorbed in the proximal tubule and 70% within the thick ascending limb of Henle (56). The reabsorption mechanisms are different in the various sections (Fig. 4) (57).

The proximal process is mostly passive, unsaturable, and strongly linked to Na^+ reabsorption. The majority is absorbed through the paracellular pathway by diffusion and solvent drag. A smaller part presumably enters the cells via Ca^{2+} channels of the apical membrane. Most of it is extruded into the extracellular fluid (ECF) through the basolateral membrane by an Na^+ / Ca^{2+} exchanger, a carrier protein, that derives its energy from the inwardly directed Na^+ gradient generated by the continuous activity of the Na^+ , K^+ -ATPase. A small part may be extruded by plasma membrane Ca^{2+} -ATPase pump (58). Factors that enhance the delivery of Na^+ to the distal tubule (high Na^+ intake, furosemide) lead to a decrease in the fractional reabsorption of Ca^{2+} in the proximal tubule. For Mg^{2+} , the proximal reabsorption mechanism is unknown (56).

In the thick ascending limbs of Henle's loop, reabsorption of Ca^{2+} and Mg^{2+} proceeds through both an active, transcellular pathway, and by passive mechanisms through the paracellular pathway. The high transtubular voltage gradient generated by the luminal Na^+ / K^+ / 2Cl^- transporter is important for the reabsorption of Ca^{2+} and Mg^{2+} . Their resting absorption is passive and is driven by the ambient electrochemical gradient for the divalent cations. PTH stimulates their active transcellular absorption in the cortical thick ascending limbs. Vasopressin, through stimulating Na^+ absorption by the Na^+ / K^+ / 2Cl^- cotransporter, causes parallel increases in the absorption of Ca^{2+} and Mg^{2+} by elevating the transepithelial voltage and the driving force for passive absorption. Loop diuretics bumetanide and furosemide, by inhibiting the Na^+ / K^+ / 2Cl^- cotransport, decrease the transepithelial voltage and diminish the absorption of Ca^{2+} and Mg^{2+} with a consequent increase in their excretion (58).

In the distal convoluted tubules Ca^{2+} enters the cells through the Ca^{2+} channels of the apical membrane. Its efflux is presumably mediated by the plasma membrane

Figure 5 Nomogram for determination of renal threshold Pi concentration, TmP/GFR . TmP/GFR is obtained by drawing a straight line from the serum Pi concentration on the left vertical scale through the value on the lower diagonal scale of the quotient of Pi and creatinine clearances (C_{PO_4}/C_{creat}) [calculated as $(U-P \times S-Cr)/(S-P \times U-Cr)$, where U stands for urine, P for Pi, S for serum, and Cr for creatinine]. The point of intersection of that line and the right vertical scale indicates the value of TmP/GFR . On the vertical scales the outer scales are in mg/100 ml and the inner scales in mmol/l. For reference values see Table 1. (From Ref. 51.)

Ca^{2+} -ATPase pump and an $Na^+ - Ca^{2+}$ exchanger. There is no paracellular absorption. This is the major site of the Ca^{2+} -retaining action of PTH. It stimulates the apical entry of Ca^{2+} through the Ca^{2+} channels. This action hyperpolarizes the membrane voltage. These effects of PTH require the activation of both protein kinases A and C. The thiazide diuretics and amiloride stimulate the Ca^{2+} transport and membrane voltage in the distal convoluted tubules similarly to the effects PTH (58).

The distal Ca^{2+} reabsorption mechanism is saturable, independent of Na^+ transport, but dependent on the Ca^{2+} -sensing receptors that are abundant there (59). Saline diuresis (except when induced by thiazide diuretics) is accompanied by an increase in Ca^{2+} excretion, because the distal reabsorptive capacity is overwhelmed by the increased distal delivery of Ca^{2+} . Only the distal reabsorp-

tion is adjusted by PTH (23, 25). Patients with HP, when normocalcemic while taking calciferol medication, excrete about threefold more Ca^{2+} than normal subjects (25, 64).

B. Effects of Extracellular Ca^{2+} and Mg^{2+}

Extracellular homeostasis of Ca^{2+} is also maintained by a short-loop feedback mechanism involving a direct effect of Ca^{2+} on the nephrons. Ca^{2+} -sensing receptors are present in the basolateral membrane of the tubular cells in the thick ascending limb of the loop of Henle. Activation of these receptors by elevated concentrations of Ca^{2+} (or Mg^{2+}) in the peritubular compartment inhibit the reabsorption of Ca^{2+} and Mg^{2+} , thus increasing the urinary excretion of Ca^{2+} , Mg^{2+} , Na^+ , and Cl^- (59). The high transtubular voltage gradient generated by the luminal

$\text{Na}^+/\text{K}^+/\text{2Cl}^-$ transporter is important for the reabsorption of Ca^{2+} and Mg^{2+} . Activation of the apical CaR stimulates phospholipase C, leading to release of arachidonic acid, metabolites of which inhibit the apical K^+ channel and may also inhibit the $\text{Na}^+/\text{K}^+/\text{2Cl}^-$ transporter. This results in a marked reduction of the transluminal voltage, leading to a decrease in the paracellular transport of Ca^{2+} and Mg^{2+} . Activation of the CaRs also inhibits the PTH-stimulated adenylyl cyclase, reducing the cAMP-mediated transport of Ca^{2+} and Mg^{2+} . These actions explain the steep relationship between extracellular Ca^{2+} and urinary Ca excretion. Increased extracellular Ca^{2+} thus leads directly to increased urinary excretion of Ca^{2+} , and vice versa (60). Because CaR is activated by Mg^{2+} , hypermagnesemia leads to a renal loss of Ca^{2+} even during hypocalcemia (61).

The CaRs are also present on the apical and luminal membranes of the inner medullary collecting ducts, where their activation inhibits the vasopressin-mediated increase in water permeability (62). The inhibition of the $\text{Na}^+\text{K}^+\text{2Cl}^-$ cotransporter in the thick ascending limb reduces the medullary hypertonicity and hence the effectiveness of the countercurrent mechanism, thus further reducing the urine concentrating ability (60). This results in dilution of urine, which helps to prevent nephrolithiasis.

The CaRs are also activated by polycationic compounds such as neomycin and gentamicin. This may account for the effects of these drugs on the kidney, including nonoliguric renal failure, perhaps due to impairment of the vasopressin-sensitive renal concentrating mechanism via activation of the CaR of the collecting ducts.

Also, extracellular Ca^{2+} participates in the control of the production of calcitriol by the proximal tubule, independent of PTH. Hypercalcemia reduces this production. This effect is probably mediated by the CaRs.

C. Effects of Calcitriol

Calcitriol suppresses the synthesis of the 1-hydroxylase and induces the synthesis of 24-hydroxylase in the cells of the proximal tubules.

Both PTH and calcitriol are needed for the normal control of the fractional Ca^{2+} excretion (63). Calcitriol seems to have no role in the proximal mechanism of Ca^{2+} absorption. In contrast, all the components of the transport of Ca^{2+} that are genomically regulated by calcitriol are located within the distal segments of the nephron. Their roles appear to be identical here and in the intestine (Sec. VI).

Calcitriol does not appear to exert a direct influence on TmP, but it has a permissive role in the phosphaturic effect of PTH. When used in the treatment of HP, vitamin D sterols reduce Pi reabsorption from elevated to normal levels. This results largely from an increase in plasma Ca^{2+} , which directly reduces proximal tubular Pi reabsorption. Calcitriol may be involved in the inherent ability

of the nephrons to adapt to altered plasma Pi levels. This adaptability is independent of PTH, but appears to be more efficient in the presence of calcitriol than in its absence (49).

V. THE SKELETON

The skeleton serves as a store of the Ca and Pi ions through two metabolic systems: the homeostatic and the remodeling system. The main regulators of both systems are PTH and calcitriol. Both PTH and calcitriol exert dual actions, which provide a basis for coupling of the bone formation and the bone resorption processes. In the homeostatic system the surface osteocytes alter on a minute-to-minute basis the flux of mineral between the skeletal surface compartment and the extracellular fluid. The remodeling system consists of osteoclasts resorbing old bone and osteoblasts laying down new bone.

PTH activates the adenylyl cyclase and stimulates proliferation in the chondrocytes and chondroprogenitor cells. It stimulates bone formation and increases bone mass. This effect is mediated by the insulin-like growth factors IGF-I and IGF-II, and by TGF β , which are released during osteoclastic bone resorption. PTH binds to osteoblasts that are actively laying down bone matrix, and inhibits synthesis of collagen type I. Also, it inhibits maturation of osteoblast precursors. On the other hand, PTH stimulates bone resorption by increasing the activity and number of osteoclasts. These cells lack receptors of both PTH and calcitriol, and their response to these hormones depends on contact with osteoblasts. In vitro, PTH_{53-84} stimulates glucocorticoid-primed osteoblast alkaline phosphatase activity, and inhibits the mitogenic effect of PTH_{1-34} on mouse cartilage explants. PTH regulates both these systems with calcitriol in a permissive role, especially in the homeostatic system (64). During sustained hypocalcemia these hormones inhibit the osteoblastic bone formation while activating the osteoclasts and increasing their number.

Calcitriol is essential for the development and maintenance of mineralized skeleton. Its major targets are osteoblasts and their precursors: stromal cells and preosteoblasts. It regulates the genes associated with osteoblast proliferation and differentiation, and enhances the expression of the genes that are specific markers of mature osteoblasts. Induction of interleukin-11 by calcitriol appears to mediate its effect on the osteoblastogenesis (65). On the other hand, calcitriol mobilizes Ca stores by inducing the dissolution of bone mineral and matrix (66). It induces bone resorption by enhancing osteoclastogenesis and osteoclast activity. It recruits undifferentiated stem cells in the bone marrow to become osteoclasts. Calcitriol appears to induce release of osteoblast-derived resorption factors that stimulate osteoclast activity (67). For that, osteoclast-osteoblast cell contact is required. Calcitriol appar-

ently induces mineralization simply by maintaining the circulating concentrations of Ca^{2+} and Pi.

The role of 24,25-(OH) $_2$ D $_3$ in bone metabolism is controversial.

Modest elevations of plasma concentrations of calcitriol (e.g., to 70 pg/ml) are not associated with hypercalcemia, which only develops with elevations to the range of 125 pg/ml (1).

VI. THE INTESTINE

One of the main functions of calcitriol is to enhance the efficiency of the small intestinal Ca and Pi ion absorption (32, 68). These are absorbed along the entire small intestine, but calcitriol primarily stimulates the Ca^{2+} transport in the duodenum, and the Pi absorption in the jejunum and ileum. The absorption of Ca^{2+} is precisely regulated according to the needs of the body, and calcitriol is the only hormone known to stimulate it directly. PTH is involved only as the regulator of the synthesis of calcitriol. Calcitriol enhances the entry of Ca^{2+} through the plasma membrane into the absorptive cell, its movement through the cytoplasm, and its transfer across the basolateral membrane into the circulation.

Calcitriol regulates the absorption at the brush-border membrane by rapid nongenomic mechanisms. It is presumed to increase the fluidity of the microvillus membrane, which allows Ca^{2+} channels to move to the cell surface and enhance the Ca^{2+} uptake at the membrane. A VDR-mediated induction of various brush-border proteins follows. These include the Ca^{2+} -binding calmodulin, calbindin $\text{D}_{9\text{K}}$, brush-border bound calbindin $\text{D}_{28\text{K}}$, an integral brush-border protein, and alkaline phosphatase. The calbindins bind Ca^{2+} , because they possess a much greater affinity than the brush-border membrane to the Ca^{2+} . They facilitate the entry of Ca^{2+} by decreasing its concentration adjacent to the brush-border. The calbindins also function as intracellular Ca^{2+} translocators and Ca^{2+} -buffering agents, thus facilitating the intracellular diffusional transfer of Ca^{2+} to the basolateral membrane. When the Ca^{2+} -bound calbindin reaches the basolateral membrane, it releases the Ca^{2+} to the plasma membrane Ca^{2+} pump, which has an even greater affinity to the Ca^{2+} . The Ca^{2+} must be pumped into the extracellular fluid against an electrochemical gradient by an energy-requiring, Na^+ -dependent process. Calcitriol stimulates the expression of the plasma membrane Ca^{2+} pump and the $\text{Na}^+/\text{Ca}^{2+}$ exchanger. Calmodulin and calbindin stimulate the activity of the Ca^{2+} pump. Also, activation of the Ca^{2+} -channels appears to be important for the extrusion of the Ca^{2+} from the basolateral membrane into the general circulation.

Calcitriol also increases active Pi transport. This is independent of the Ca^{2+} transport and less dependent on calcitriol. In the absence of calcitriol, Pi is absorbed at half-normal rate. Na^+ is required at the brush-border surface, and an Na^+/Pi cotransporter moves luminal Pi uphill

into the cell, using the energy from the downhill Na^+ gradient. Calcitriol appears to stimulate Pi transport by inducing the synthesis of additional cotransporter units and by decreasing the permeability of the brush-border membrane to Na^+ , thus helping to maintain the gradient required for the uphill Pi transport.

Net Ca^{2+} absorption normally averages about 20% of the Ca^{2+} intake, but can vary over the range of 15–75%, depending on the calcitriol status. The absorption of Pi and Mg^{2+} is a linear function of their dietary intake (69). Both are absorbed predominantly by (separate) active carrier-mediated transport mechanisms, and by passive diffusion. The proportion absorbed is about 3fold larger for Pi than for Ca^{2+} .

VII. CALCIUM, PHOSPHATE, AND MAGNESIUM IN PLASMA

A. Calcium

The total content of Ca in normal human plasma (Table 1) consists of three fractions: approximately 47% is free Ca^{2+} , another 47% is protein-bound (70% of it being bound to albumin), and 6% is complexed to phosphate, citrate, and bicarbonate, and freely diffusible through membranes. The free Ca^{2+} is the regulated, physiologically important fraction.

The regulation of the plasma Ca^{2+} concentration is so precise that it normally fluctuates by less than 0.025 mmol/l (0.1 mg/dl) in either direction from its so-called set value. The skeletal and renal effects of PTH make up a fast-acting short-loop feedback system. The renal–intestinal effect provides a slower (12–24 h) long-loop feedback system (1).

The binding to albumin is pH-dependent: the concentration of Ca^{2+} decreases in acute alkalosis and increases in acute acidosis. If plasma albumin concentration decreases by 50%, the total Ca concentration is reduced by about 20%. Also, for every 10 g/l (g/dl) reduction in plasma albumin, the total Ca decreases by approximately 0.25 mmol/l (1.0 mg/dl). These changes as such do not alter the Ca^{2+} concentration. Total Ca varies little with age, the actual extent depending on the protein concentration.

A decrease in the concentration of Ca^{2+} increases Na^+ permeability and enhances the excitability of all excitable cells. An increased concentration has the reverse effect.

Hypocalcemic challenges are of varying severity. A 12–15 h fast is a mild challenge. Because of continued loss of Ca^{2+} loss via the urine, its plasma concentration decreases slightly and is rapidly corrected by increased entry from the kidneys and skeleton, induced by a minor increase in PTH secretion (Fig. 6). A stronger challenge, such as an extra urinary loss of Ca^{2+} after administration of a high dosage of furosemide, calls for a moderate increase in PTH secretion; part of the response is an in-

Figure 6 Sequence of adjustments (long arrows) in response to hypocalcemia. The short arrows indicate directions of changes in concentrations in the extracellular fluid (middle), in release from the skeleton (left), in retrieval in the kidneys, and in absorption from the intestine (right).

crease in the synthesis of calcitriol. The increased PTH activity also decreases the renal reabsorption of Pi and this rids the extracellular fluid of the extra Pi. The plasma levels of Ca^{2+} and Pi are thus normalized, but a mild secondary hyperparathyroidism persists, with the improved intestinal absorption of minerals replacing what was initially mobilized from the skeleton.

Hypercalcemia, even a slight rise in plasma Ca^{2+} , is combatted by suppression of the PTH secretion. This leads to an increased urinary loss of Ca^{2+} , and a reduced entry of minerals from the skeleton and, with prolonged hypercalcemia, through suppression of the synthesis of calcitriol, from the intestine. The hypercalcemia raises the concentration of calcitonin in plasma. Calcitonin directly, in minutes, inhibits osteoclastic bone resorption. However, it does not appear to contribute in an important way to the protection against hypercalcemia. A limit to the protection against hypercalcemia is set by the excretory capacity of the kidneys. This may be impaired by a vicious cycle based on the fact that hypercalcemia leads to excessive urinary loss of water and hence tends to cause dehydration.

B. Phosphate

Plasma Pi concentration is more variable than the Ca concentration. It is influenced by age (Table 1), diet, and some hormones. No known endocrine factor protects it as a primary function. An adequate ion-product of Ca^{2+} and Pi is required for normal mineralization of the skeleton. Of the total plasma Pi about 52% is ionized; 35% is complexed to Na^+ , Ca^{2+} , and Mg^{2+} ; and 13% is protein-bound. The role of the kidneys is paramount in the main-

tenance of a normal plasma Pi level, which tends to be close to TmP/GFR (Sec. IV.A.; Fig. 5).

A decrease in plasma Pi leads to an activation of the renal synthesis of calcitriol and thereby to an increased intestinal absorption of Ca and a slight rise in its plasma level. Suppression of PTH secretion follows, leading to a reduction of the renal Pi clearance and an enhancement of Ca clearance. Within 3–4 days of phosphate withdrawal, its excretion may be virtually abolished and even the phosphaturic response to exogenous PTH becomes blunted. An excess of plasma Pi is cleared rapidly by normal kidneys, because the filtered Pi load exceeds the renal threshold.

C. Magnesium

The plasma concentration is less narrowly regulated for Mg^{2+} than Ca^{2+} . It is determined principally by the renal threshold for Mg excretion. Roughly one-third is protein bound, 15% is loosely complexed with Pi and other anions, and 55% is free Mg^{++} . Extracellular Mg is critical for normal neuromuscular excitability and nerve conduction. The mechanisms of Mg homeostasis are poorly understood. PTG responds similarly to changes in plasma Mg^{++} than to changes in plasma Ca^{2+} , but less sensitively.

VIII. MANIFESTATIONS OF DEFICIENT PARATHYROID HORMONE ACTION

A. Chemical Effects

Deficiency of PTH action leads to a decrease in the production of calcitriol, resulting in a bihormonal deficiency. Hypocalcemia and hyperphosphatemia are pathognomonic to frankly deficient PTH action. The hypocalcemia results from reduced osteocytic Ca transfer due to both deficiencies, a decrease in PTH-dependent osteoclastic bone resorption and distal tubular Ca reabsorption, and impaired intestinal Ca absorption due to calcitriol deficiency. The hyperphosphatemia is caused by increased renal tubular Pi reabsorption due to the absence of its adequate inhibition by PTH. The hyperphosphatemia further lowers calcemia by physicochemical means and by further reducing calcitriol synthesis.

1. Hypocalcemia

Severity of deficiency of PTH action varies. Consequently, plasma Ca concentration in different patients ranges from 1.25 mmol/l (5 mg/dl) to normal (70). In all cases the stability of the plasma Ca level is impaired. It fluctuates with changes in Ca intake and reciprocally with changes in plasma Pi concentration (71). Even in the mildest cases the reserve capacity of the calcemia homeostatic system is limited, but normocalcemia is maintained by its maximal activity. In the next degree of severity normocalcemia is maintained in normal situations, but periodic

hypocalcemia ensues with fasting or an otherwise unusually low Ca intake, and with excessive phosphate influx from the intestine, or breakdown of intracellular organic phosphate compounds during febrile illness. With more severe failure, hypocalcemia is continuous and minor hypocalcemic factors evoke symptoms.

Hypocalcemic patients are hypocalciuric, although their Ca excretion is high relative to their plasma Ca level.

2. Hyperphosphatemia

This is a much less constant feature than hypocalcemia, because less PTH effect is needed to maintain a normal renal Pi threshold (Sec. IV.A.) than to maintain normocalcemia (70), and because Pi flow from the skeleton and intestine is subnormal owing to the deficiency of PTH effect.

3. Other

Because deficiency of PTH effect also causes increased renal reabsorption of bicarbonate, plasma bicarbonate levels and blood pH may be elevated (72). Bone remodeling is reduced and this is reflected by decreased urinary excretion of hydroxyproline in a majority of patients (73). Subnormal levels are usual for plasma osteocalcin but uncommon for alkaline phosphatase (73–75).

B. Clinical Manifestations

The main cause of clinical manifestations (76) of deficient PTH effect is hypocalcemia, largely as a result of increased irritability of the central and peripheral nervous systems. Manifestations are more likely to appear when plasma Ca level is falling rapidly than during steady hypocalcemia. Low concentrations of Mg^{2+} and H^+ (alkalosis), and high concentrations of Pi and K^+ predispose to tetany. Moderately longstanding hypocalcemia may be symptomless.

1. Tetany

Tetany refers to a spectrum of manifestations of increased neural excitability. It ranges from signs evocable by testing (latent tetany), and minor tingling sensations and numbness of the hands to abdominal pain and major convulsive seizures with loss of consciousness. A typical attack of tetany (2) begins with increasing tingling starting in the fingertips, around the mouth and sometimes in the feet, and spreading proximally and over the face. Numbness may follow. The muscles then feel tense and go into spasm in the same pattern as the sensory symptoms. The hands and forearms are the parts of the body most commonly involved. First, the thumbs become adducted, followed in order by flexion of the metacarpophalangeal joints, extension of the interphalangeal joints, and flexion of the wrist and elbow: the classic “obstetrician’s hand” posture. The muscle spasm causes pain, which may be severe. A similar spasm in the feet is less common, with

plantar flexion of the toes, arching of the feet, and contraction of the calf muscles. With a severe attack the face may become involved, with wrinkling of the forehead, a staring gaze, and pursed lips. Hypocapnia and increased epinephrine secretion (due to panicking) worsen the tetany. Hyperventilation is a common feature of hypocalcemic tetany, and hysteria is often incorrectly diagnosed.

a. Atypical Tetany. Patients may experience cramps, stiffness, or clumsiness. With longstanding hypocalcemia they may have frequent mild paresthesias and cramps instead of clearly defined attacks of tetany, or may have carpal spasm only during prolonged use of the hand and forearm. Symptoms may be provoked by hyperventilation due to emotional stress or exercise. The symptoms may be exclusively sensory. Limping and falling may occur as a result of leg spasms. The symptoms may be unilateral. Laryngeal spasm may occur, causing stridor, crowing respiration, and cyanosis. Minor difficulties in vocalization are not uncommon. Smooth muscle spasms may cause dysphagia, abdominal pain, biliary colic, and wheezing with shortness of breath. Persistent diarrhea may occur (77). Infants are unlikely to develop carpopedal spasms, but are prone to tremors and twitches.

b. Signs of Latent Tetany. Signs of latent tetany remain useful in diagnosis and in adjusting therapy. Chvostek’s sign is elicited by tapping the facial nerve with a fingertip as a hammer, 1–2 cm anterior to the earlobe just below the zygomatic process. The response consists of twitching of the muscles innervated by the facial nerve, and is graded as level 1 with twitching of upper lip at the corner of mouth only, level 2 as twitching of the alae nasi also, level 3 as contraction of the orbicularis oculi also, and level 4 as contraction of all the muscles of that side. The relative sensitivity with which these signs are elicited varies individually. A grade 1 sign is said to be found in >25% of normal children (76). Trousseau’s sign is evoked by a sphygmomanometer cuff on the upper arm when inflated to above the systolic pressure for up to 3 min. The sensory and motor manifestations of tetany develop to a typical carpal spasm within 2 min. In the mildest cases the patient can overcome the spasm. In the severest, not even the examiner can overcome it. Only the severe grade of the sign is abnormal with certainty, since the milder grade occurs in a small percentage of normal subjects. The sign depends on induction of ischemia of the ulnar nerve.

c. Seizures. Seizures resembling epilepsy occur. These are of two distinct types. First, as hypocalcemia lowers the threshold for pre-existing subclinical epilepsy, epileptic seizures of any type may occur (78). The other type consists of generalized tetany followed by prolonged tonic spasms. It may be preceded by the sensory symptoms of tetany. During the seizure there may be tongue biting, loss of consciousness, incontinence, and postictal confusion. Hypocalcemia is frequently associated with characteristic changes in the EEG (79); in severe hypocalcemia irregular, sharp spike-and-wave patterns may

appear. These changes may not disappear for some days after restoration of normocalcemia, and abnormal background activity may continue for several weeks.

2. Other

a. Basal Ganglion Calcification and Extrapyramidal Signs. In patients with HP or, especially, PHP untreated for many years, small irregular calcifications may be seen in the basal ganglia in skull radiographs, and particularly on computed tomographic scans (80). These lesions may cause various extrapyramidal signs, including choreoathetosis, dystonic spasms, and classic parkinsonism.

b. Papilledema and Raised Intracranial Pressure. In longstanding untreated HP there may be swelling of the optic discs. This may occur within as little as 2 weeks after the onset of HP as seen following thyroid surgery. It is moderate in degree (<4 diopters) and unaccompanied by hemorrhage or impaired vision. It may lead to suspicion of an intracranial tumor. The papilledema usually begins to subside within a few days of normocalcemia, but may take several weeks to disappear.

c. Psychic Disorders. Impaired mental functioning occurs in patients with longstanding HP or PHP. Psychiatric disorders of many kinds have also been described.

d. Dermal and Dental Changes. The skin may be dry and scaling, the nails brittle and fissured, and the hair coarse, dry, fractured, and easily shed. Eruption of teeth may be delayed and their roots may be blunted. These nail and tooth changes are distinct from the ectodermal dystrophy of autoimmune polyendocrinopathy–candidiasis–ectodermal dystrophy (APECED; Sec. XI.A.).

e. Cataracts. Lenticular cataracts are a common complication of chronic hypocalcemia. They first appear as discrete punctate or lamellar opacities in the cortex, separated by a clear zone from the capsule (81). They may occur in distinct layers, more in the posterior pole than the anterior, and within 5–10 years they become confluent, with total opacification of the lens. Control of hypocalcemia arrests their progression.

f. Cardiovascular and Muscle Disorders. Hypocalcemia delays ventricular depolarization and prolongs the Q-T_c and ST intervals on the electrocardiogram. A 2:1 heart block may occur. Ca²⁺ exerts a positive inotropic effect on the myocardium, but hypocalcemia rarely causes clinical cardiac problems. However, congestive heart failure does occur in children with HP (82) and sudden death due to ventricular arrhythmia is possible.

Myopathy, in the mildest cases reflected by markedly supranormal plasma creatine kinase levels, has been reported in several hypocalcemic patients (83, 84).

IX. CAUSES OF HYPOPARATHYROIDISM

Congenital HP may be due to hyperfunction of the CaR, a specific defect in the synthesis or processing of PTH,

and aplasia or hypoplasia of PTG. PTG aplasia and hypoplasia occur as isolated defects and as part of malformation syndromes. Depending on its severity, congenital HP may manifest neonatally or only (even several years) later. Late manifestation may be due to failure of growth of hypoplastic PTG. Hence it may be difficult to differentiate between inborn and acquired forms of HP, and the inborn defects should be considered in cases of HP manifesting at any age (77). Acquired HP may be due to autoimmune destruction or other kinds of damage to PTG, and transient disturbances of the function of PTG (Table 2).

X. FAMILIAL ISOLATED HYPOPARATHYROIDISM

The criteria of this heterogeneous group include no demonstrable anatomical cause, no evidence of APECED, no developmental defects that might indicate an embryological disorder such as familial branchial pouch dysgenesis, and undetectable or subnormal plasma levels of immunoreactive PTH. Age at manifestation varies even

Table 2 Causes of Postneonatal Hypoparathyroidism

Type II

within pedigrees, often from newborn to adult (85, 86), or there may be no manifestation at all (87).

A. Autosomal Dominant Isolated Hypoparathyroidism

1. Hypercalciuric Hypocalcemia (MIM 146200)

This, apparently the commonest entity of autosomal dominant isolated HP, is caused by mutations leading to constitutionally activated CaR (Sec. II.A.) (88–90). Severity of the phenotype varies depending on the mutation, and even within families. Several patients have had seizures already in the first week of life, others show symptoms only in adulthood or no symptoms at all. At least 12 activating mutations have been observed, most of them in the extracellular domain of the CaR (89–91), and at least five in the transmembrane domains or the intervening extracellular loops (92). These mutant CaRs show a leftward shift and higher maximum in the dose–response curve for extracellular Ca^{2+} -activated accumulation of IP_3 , indicating that these mutant receptors have increased activity and probably increased activity per receptor than the wild-type receptor (93). The setpoint for maintenance of plasma Ca^{2+} levels is subnormal and plasma PTH levels are maintained subnormal for the level of Ca^{2+} . Besides familial occurrence, at least five sporadic cases have been reported, with de novo mutations (91, 94, 95).

In a series of six kindreds, 11 of a total of 20 affected members had carpopedal spasms or childhood seizures (90). Two of them had calcifications of the basal ganglia, and in one of those the seizures continued to adult life. The other nine affected subjects had asymptomatic hypocalcemia; 16 subjects also had hypomagnesemia. Most of them (84%) were hyperphosphatemic. Serum PTH concentration was within normal range, but low for the hypocalcemia. Urinary Ca excretion was either inappropriately within the normal range or supranormal at the time of the initial diagnosis. In all the patients it was supranormal for the level of calcemia, and higher than in untreated subjects with idiopathic or postoperative HP and similar levels of hypocalcemia. Conventional treatment with vitamin D preparations frequently led to overt hypercalcemia, with renal calcification and impairment. This was probably due to presence of the abnormally active CaRs in their distal tubules, with reduced reabsorption of Ca^{2+} . Some of the patients even developed polyuria and polydipsia during normocalcemia, probably due to the presence of the abnormal CaRs in the collecting ducts leading to subnormal water permeability. Some of the patients experience hypercalcemic symptoms, polydipsia, polyuria, and weakness at serum Ca^{2+} levels approaching the lower limit of normal (92).

2. HP Due to Mutant PreproPTH Gene (MIM 2212001)

A point mutation in the preproPTH gene has been observed in a father and two of his (six) children with au-

tosomal dominant HP, resulting in disruption of the hydrophobic signal sequence. It is presumed to impair translocation of the preproPTH molecule across the endoplasmic reticulum (86, 96). The children had hypocalcemic seizures in infancy. The father had no history of hypocalcemic symptoms, and his failing Ca^{2+} homeostasis appeared only as a subnormal plasma PTH response to hypocalcemia induced by an EDTA infusion test.

B. Autosomal Recessive Isolated Hypoparathyroidism (MIM 241400)

Two kindreds with autosomal recessive isolated HP have been published, each with a mutation in the PTH gene. In one kindred, each of the three affected members experienced hypocalcemic seizures in the neonatal period and had undetectable circulating PTH concentrations with normal renal response to PTH_{1-38} . A donor splice mutation was detected at the exon 2–intron 2 boundary, resulting in loss of exon 2 in the PTH mRNA. As exon 2 encodes the initiation codon and the signal peptide, loss of this exon presumably prevents translation of the PTH mRNA and translocation of the peptide. Affected members of the kindred were homozygous for this mutation (97).

In another large pedigree, HP manifested with seizures in the neonatal period or infancy. It was associated with a homozygous point mutation in exon 2 of the PTH gene, located at the first nucleotide of position 23 in the 25-amino acid signal peptide. Since this is the –3 position in the signal peptide, the resulting prepro-PTH mutant is presumably not cleaved by signal peptidase at the normal position, and it might be degraded in the rough endoplasmic reticulum (98).

C. X-Linked Isolated Hypoparathyroidism (MIM 307700)

Two large kindreds with X-linked recessive isolated HP have been reported from eastern Missouri (99, 100). Only male subjects were affected; they had hypocalcemic seizures starting in the neonatal or early infantile period. Circulating immunoreactive concentrations of PTH were undetectable, and renal response to bovine PTH was normal. In a careful search at autopsy of one of the patients who died accidentally as a teenager, no PTH tissue could be identified (101). The mutant gene, which thus appears to cause defective development of PTG, was localized to Xq26–27 (102).

XI. AUTOIMMUNE POLYENDOCRINOPATHY–CANDIDIASIS–ECTODERMAL DYSTROPHY (APECED) (MIM 240300)

This condition has been given many names, most commonly type I autoimmune polyglandular disease/syn-

drome (103). I prefer the term APECED (73), because it includes the two identifying features and does not include specific endocrinopathies (none is constant) (104). This autosomal recessive disease (105, 106) manifests as a widely variable combination of three groups of components (104, 107): autoimmune destruction of tissues, predominantly endocrine glands; consequences of a partial defect of cell-mediated immunity, most commonly chronic superficial candidiasis; and ectodermal dystrophy.

A. Clinical Picture

The commonest components are mucocutaneous candidiasis, HP, and adrenocortical insufficiency, but more than 10 other components may occur. The following description is mainly based on my experience with 89 Finnish patients (104, 120, 120a).

1. Endocrinopathies

HP appeared at an age varying from the 1st year to the 5th decade of life, with peak incidence at 2–11 years. Its prevalence gradually reaches 86% (Table 3). It remained the only endocrinopathy in 20% of our patients at the age 20 years and in 18% at 30. Several patients had experienced vague tetany for a few years before the diagnosis. In some patients we observed progression of HP from latent to severe over a few months. Addison's disease appeared from the 4th year to the 5th decade, with peak incidence at 4–12 years. Its prevalence reaches 79% (Table 3). It remained the only endocrinopathy in 8% of our patients at the age of 20.0 years and 11% at 30.0. Deficiencies of cortisol and aldosterone appeared even 5 years apart. Type I diabetes mellitus appeared at the age of 4–58 years, with highest incidences in the second, fourth, and fifth decades. Hypogonadism develops eventually in more than two-thirds of female patients and in one-quarter of males. It was due to autoimmune gonadal atrophy in all except one male patient, who had gonadotropin deficiency. Male infertility due to antisperm antibodies does also occur. Hypothyroidism rises eventually in prevalence to 18%. Parietal cell atrophy appears to reach one-third prevalence by the age of 40 years, with peak incidence at around 15 years. Pituitary hormone deficiencies occur, mostly singly. Growth hormone deficiency occurred in 4% of our patients (in one with adrenocorticotrophic hormone [ACTH] deficiency), and several others are on record. Three patients have been reported with central diabetes insipidus (108–109), and two patients with ACTH deficiency (110).

2. Other Autoimmune/Possibly Autoimmune Components

Alopecia was present in 33% of our patients, by the age of 2.5–30 years, being the first or part of the initial manifestation in 2%. Vitiligo of highly variable extent appeared in 21% of our patients at the age of 1.7–47 years.

In a few patients the spots faded, but in most patients they grew larger with time.

Gastrointestinal disorders are common. Autoimmune hepatitis is the most dangerous of all the common components of APECED. It was evident at the ages of 0.7–16 years in 17% of our 89 patients. Of them three died of fulminant hepatitis within 2 months, despite intensive therapy. Six other patients had clearly elevated serum levels of alanine aminotransferase, which subsided without immunosuppressive medication. Cholelithiasis may occur (112).

Sjögren syndrome was reported in 12% of a series of 41 patients and scleroderma in one patient (108). One of our patients died of complications of rapidly advancing rheumatoid arthritis. Eight (9%) of our pediatric patients experienced over several months a flashing rash, often associated with peaks of fever. Several cases of autoimmune hemolytic anemia are on the record (108), including one of our patients. Several patients with acquired splenic atrophy have been reported (108, 112, 113, 120a). Interstitial nephritis occurred in 7% of our patients; two of them needed a donor kidney.

Of our patients 16% had prolonged periods of watery or fatty diarrhea. Specific diagnosis was reached only in a few of them. Most of the patients with watery diarrhea had HP and they experienced periods of a vicious cycle of diarrhea and hypocalcemia. Of note, a patient's intractable diarrhea and therapy-resistant hypocalcemia responded to high dosage intravenous methylprednisolone and maintenance oral methotrexate (114). Atrophy of the exocrine pancreas with insulin deficiency occurred in one patient. Two other such cases are on record (115, 116); in one fat excretion responded to immunosuppressive medication (116). The chronic diarrhea of a 12-year-old patient of ours was caused by defective bile acid reabsorption and controlled with cholestyramin therapy. Intestinal lymphangiectasia was reported as a cause of diarrhea in one patient (117).

3. Ocular Disease

Keratopathy may be a serious problem and calls for intensive local medication with glucocorticoid and often antimicrobials. Of our patients 22% showed keratopathy at the ages of 1.0–16 years. Five of them became blind. The early symptoms are intense photophobia, blepharospasm, and lacrimation (Fig. 7). In 10% of our patients keratopathy was the first or part of the initial manifestation of APECED, or the second only to oral candidiasis. Less common eye manifestations include recurring iridocyclitis, optic atrophy, retinal detachment, and severe dry eye (111).

4. Nonautoimmune Components

Candidiasis involves the mouth first, appearing in the mildest cases as intermittent soreness of mouth corners

Table 3 Prevalences (%) of the Common Components^a of APECED, Estimated^b from Finnish Series of 89 Patients (45 males)

Component	Age (years)								Age range at appearance	
	1	2	5	10	15	20	30	40		
Hypoparathyroidism	0	6	33	64	78	84	85	86	1st year to 5th decade	
Hypoadrenocorticism	0	0	8	39	63	71	77	79	3 years to 5th decade	
Diabetes mellitus	0	0	2	3	6	10	14	23	4 years to 6th decade

^aPrevalences of the components of ectodermal dystrophy are only known for a subgroup of 68 patients of various ages: enamel hypoplasia of permanent teeth 77%, pitted nail dystrophy 52%, and calcium salt deposits of the tympanic membranes 33% with no history of middle ear disease (Ahonen et al., 1990).

^bEstimated from the observed incidence rates over the age intervals, assuming that all the patients live until the age of 40 years.

^cPrimary amenorrhea in 52%, secondary in 48%, prevalence known from age 15 only.

^dPrevalence known only from age 20.

^eIncludes (2 of 21) patients without clinical disease but with circulating antibodies against parietal cells and/or intrinsic factor.

^fIncludes three patients who died of fulminant hepatitis.

^gThe early oral candidiasis may easily be unnoticed, the earliest figures are hence probably too low.

^hOne third of these patients developed blindness or severely impaired vision.

ⁱChronic or periodic diarrhea/obstipation. Three of 89 patients had alternating periods of both.

Source: Perheentupa, unpublished.

(angular cheilosis) (Fig. 7). Its peak incidence is over the first year of life. In some patients it appears late, and in our series the prevalence of 100%, intermittent cases included, was not reached until the fifth decade of life (Table 3). Mild oral candidiasis may remain unnoticed, hence its prevalence figures at early ages, as reported in the literature, are probably erroneously low. More severe forms include an acute inflammation of most of the oral mucosa, hyperplastic chronic candidiasis with thick white coating of the tongue, and atrophic disease with scant coatings and a scarred thin mucosa with leukoplakia-like areas (118). This chronic condition is carcinogenic; four of our patients had evidence of epithelial carcinoma of the oral mucosa at the age of 27–45 years, and three of them died of it. Hence, candidiasis should be carefully evaluated and suppressed by good dental care and oral hygiene, and local and systemic antimycotics. Candidal esophagitis is painful and may cause strictures. Intestinal mucosal candidiasis may manifest as abdominal pain, meteorism and diarrhea. The infection may spread to the skin of the face and hands, and to the nails. Postpubertal female patients often experience candidal vulvovaginitis.

5. Ectodermal Dystrophy

The most frequent component of ectodermal dystrophy (Fig. 7) is enamel hypoplasia of permanent teeth (118, 119), which affects three-quarters of our patients (104). Pitted nail dystrophy is present in one-half and tympanic membrane calcium salt deposits in one-third of our patients.

6. Individual Variation

The clinical picture varies also very widely in aspects other than age at appearance of the individual disease components. In our series the total number of component diseases varies from 2 to 10 (median 4), and the number of endocrine components from 1 to 5 (median 2). The so-called classic triad of candidiasis, HP, and adrenal insufficiency was present in 50% of the patients at the age of 20.0 years, in 55% at 30.0, and 40% at 40.0 years.

The first components to appear as part of the initial clinical picture were candidiasis in 54%, HP in 31%, adrenal insufficiency in 6%, keratopathy in 7%, chronic diarrhea in 7%, alopecia in 2%, flashing rash with fever in

Figure 7 Ectodermal manifestations of APECED. a. Keratopathy and angular cheilosis. b. Hyperplastic chronic candidiasis of the tongue with angular cheilosis. c. Enamel hypoplasia in permanent teeth. d. Pitted nail dystrophy of second, fourth, and fifth fingers with eroding nail candidiasis of the thumb.

2%, hepatitis in 1%, and vitiligo in 1%. Of the endocrinopathies the first one was HP alone in 64% and adrenal insufficiency alone in 27%, HP and adrenal insufficiency together in 6%, GH deficiency in 1%, and hypothyroidism in 1%.

B. Follow-Up

For a review of the follow-up for HP, see Sec. XVII.B.7. Patients with the diagnosis of APECED should receive written information about the possibility and symptoms of further disease components with instructions on where to turn in case they appear. Later, it is necessary to check repeatedly that the patient has adopted this information. The patient should be examined at least once or twice annually for the possibility of new disease components: thorough anamnestic details and physical examination including search for oral candidiasis, search for antibodies, and determination of serum levels of Ca, Pi, Na, K, alanine aminotransferase, ACTH, TSH and the GnHs, plasma renin activity, and blood glycohemoglobin, as appropriate in the patient's situation.

C. Immunology

A limited T-cell defect appears to be part of APECED (120). It is reflected by cutaneous anergy or weak delayed-type hypersensitivity reactions to PPD and *Candida* antigens, and the high prevalence of mucocutaneous *Candida* infections. No consistent abnormality of T cells has been demonstrated in laboratory studies. The destructive autoimmune attack of endocrine glands appears initially as infiltration by lymphocytes and macrophages. The process is presumed to be T-cell-mediated. Antibodies to certain antigens of the gland commonly appear in blood, most frequently antibodies against intracellular enzymes. The role of such autoantibodies in the destructive process remains unclear, but they are important as diagnostic messengers from the process and appear commonly before clinical hormone deficiency is evident. No antiparathyroid autoantibodies are recognized. Association with HP of autoantibodies against the Ca^{2+} -sensing receptor has been reported (121), but this finding has not been confirmed. Such antibodies were not found in any patient of a large series of our Finnish patients with HP of APECED (Spiegel AM, Perheentupa J, unpublished).

The most frequently found antiadrenocortical antibodies are directed against 21-hydroxylase (P450c21). Although positive results do not always predict Addison's disease, this disease is almost always preceded by their appearance in blood. Anti-P450c21 antibodies are equivalent to antiadrenal antibodies demonstrated by indirect immunofluorescence (122, 123). Of the other enzymes of adrenal steroid hormone synthesis, cholesterol side chain cleavage enzyme (P450scc), 3 β OH-steroid dehydrogenase (3 β HSD), and 17 α -hydroxylase (P450c17) are also present in the ovarian granulosa and theca cells, and the testicular Leydig cells (124–129). Circulating antibodies against them predict development of premature ovarian failure (130). Sera positive by immunofluorescence against those steroid-producing cells contain antibodies specific to P450scc, P450c17, and/or (rarely) 3 β HSD (128).

Patients with autoimmune vitamin B₁₂ malabsorption or so-called pernicious anemia have autoantibodies against the intrinsic factor or the gastric H⁺/K⁺-ATPase. The latter is the specific antigen to the parietal cell antibody detected by indirect immunofluorescence (131, 132). In the chronic autoimmune hepatitis of APS-1, P450 1A2 may be the specific hepatic autoantigen (133–135).

In alopecia, immunoreactivity has been observed against differentiating keratinocytes in hair follicle (136). Antibodies against tyrosine hydroxylase correlated with presence of alopecia in patients with APS-1 (137, 138), and antibodies against transcription factors SOX9 and SOX10 with presence of vitiligo in various patients (137). Antibodies against tryptophan hydroxylase of intestinal mucosa correlate with intestinal dysfunction in patients with APS-1 (139).

D. Genetics

APECED is caused by loss-of-function mutations in both copies of the *AIRE* (for AutoImmune REgulator) gene on chromosome 21q22.3 (140, 141). *AIRE* contains 14 exons. It is mainly expressed in subsets of epithelial and monocyte lineage cells in thymus medulla; in rare cells in lymph node paracortex and medulla, spleen, and fetal liver; and in very few blood leukocytes. These all are antigen-presenting cells. Wider expression is disputed, but it has been also reported in the respiratory system, central nervous system, endocrine glands, urinary system, and genitals (142). Human and mouse *AIRE* promoters include conserved sites for several transcription factors, which are thymus-specific or important in hematopoiesis (143).

The *AIRE* protein consists of 545 amino acids. At its amino terminal is a highly conserved ASS domain necessary for subnuclear targeting and dimerization, which appears to be essential for its transcription activating action (144). The SAND domain is needed for DNA binding, two plant homeodomain type Zn fingers presumably serve protein–protein interaction, and two nuclear localization signals and four LXXLL motifs act in nuclear re-

ceptor binding. Human and mouse *AIRE* proteins are 71% identical (143, 145). They exist in nucleoplasmic granules, and occasionally along the cytoplasmic microtubular cytoskeleton (146, 147). The protein is an activator of gene transcription (144, 148), but its exact physiological role is unknown. It may be involved in determination of thymic stromal organization and thus in the induction of self-tolerance (149, 150).

To date, some 35 mutations of *AIRE* have been described in patients with APECED, most of them in four mutational hotspots (116, 141, 144, 151–153). Many are either missense mutations in the ASS region (presumably preventing the dimerization of the protein) or nonsense mutations leading to its truncation. The internationally most common mutation, C889T, covers almost 90% of the Finnish APECED genes (140, 144). It leads to a deletion of both Zn fingers and most of the SAND domain. The second most common mutation (140, 144), predominant in the United States (152) and United Kingdom (153), is a 13 nucleotide deletion, which leads to a protein lacking the C-terminal third. The predominant Sardinian mutant protein (154) consists only of the N-terminal fourth. All the reported Iranian Jewish patients are homozygous for a missense mutation in a single nucleotide, which disrupts the dimerization domain (144). In some 10% of the *AIRE* genes of clinically ascertained patients, identification of a mutation has failed (144). These may be mutations of the promoter region or the introns.

Determinants of the wide variability of the APECED phenotype are unknown. The Iranian Jewish patients have been reported to have much less candidiasis and adrenocortical insufficiency than other patients (155), which could depend on their unique mutation. Otherwise the phenotype variation seems not to depend on nature of the mutation. The HLA appears not to be a determinant of the variation, and there are no gender-specific differences.

XII. HYPOPARATHYROIDISM OF DYSMORPHIC SYNDROMES

A. DiGeorge Malformation Complex (MIM 188400; DiGeorge Syndrome, Dysbranchiogenesis, Shprintzen Velocardiofacial Syndrome, Conotruncal Anomaly Face Syndrome)

According to the traditional definition, DiGeorge malformation complex (DMC) is a causally heterogeneous developmental field defect of the third and fourth pharyngeal pouches (99). Its main components are hypoplasia of the PTG, which may present as neonatal tetany or seizures; a deficit of T cells with susceptibility to infection, due to hypoplasia or aplasia of the thymus; congenital defect of the heart or the great arteries, particularly affecting the outflow tract; and a characteristic facial dysmorphism. At least three of these four components are required for the

clinical diagnosis of DMC (156). However, the prevalence of these components has probably been overestimated, because DMC has been delineated by studying series of thus clinically diagnosed patients. Cases are often labeled as complete (with thymus aplasia) or partial DMC (thymus hypoplasia). This division does not correlate with presence or absence of other anomalies, save the fact that PTG aplasia is commonly associated with thymus aplasia (157). Patients with complete DMC die early (158). Reliable diagnosis of thymic aplasia can only be made at autopsy.

There is disagreement about the names and definitions of this malformation complex. Because approximately 90% of the patients with the clinical diagnosis of DMC have monosomy of the DiGeorge chromosome region (DGCR) of chromosome 22q11.2, some authors consider that this majority should be termed monosomy 22q11.2 syndrome and separated from other causative groups, particularly that caused by hemizygosity of DGS2 of chromosome 10p (see below). Because most large series of patients published were selected according to the clinical diagnosis of DiGeorge syndrome, that is discussed next. Then the available information specific to the chromosomal deletion syndromes will be presented.

1. Incidence and Age at Manifestation

Hundreds of patients have been reported. A neonatal manifestation occurred in 83% of cases, mostly cardiac problems, and in one-third of cases convulsions (157, 159). Sometimes the first symptoms only appeared at school age, and in several cases DMC was diagnosed in an asymptomatic adult patient because of symptomatic disease of his or her offspring (160). In the 1960s and 1970s some 80% of recognized patients died within a year of birth, a majority from cardiac causes and one-fifth from infection (157).

2. Endocrine Disorders

Hypocalcemic convulsions occurred in 61% and hypocalcemia in 85% of the reported cases (157, 159). The hypocalcemia resolved in early childhood in a majority of patients (26 of 40) (159). However, deficient function of the parathyroids may still manifest in adulthood during a hypocalcemic stress, such as an infusion of disodium edetate (161–163). It may even evolve again to frank symptomatic HP (162). PTGs were searched for at autopsy in 85 patients; a hypoplastic PTG was observed in 30, and none could be found in 41 even by careful serial sectioning (157). A malformation of the thyroid gland is also common (157) and at least two of 44 patients were hypothyroid (159). Calcitonin-producing C cells of the thyroid gland, belonging to the derivatives of the third and fourth branchial pouches (cephalic neural crest cells) are deficient in numbers (164, 165).

3. Cardiac Defects

Approximately 90% of recorded patients have had a cardiac defect, half of them an anomaly of the aortic arch,

most commonly type B interrupted arch or right aortic arch. One fifth have truncus arteriosus communis (157–159). Hypoplastic left heart and coarctation of the aorta also occur. The right outflow tract is affected in some 12% of the patients, predominantly by obstructive anomalies, and a similar proportion has Fallot's tetralogy. An associated ventricular septal defect is present in a majority of the patients, and associated valve anomalies are common. In contrast, isolated septum defects and valve anomalies are infrequent, but ventricular septal defect alone may be present in late manifesting cases. One fourth of the patients have an aberrant right subclavian artery that may cause dysphagia. The spectrum of circulatory anomalies ranges from left heart hypoplasia to an harmless abnormality of the subclavian artery.

4. Immune Defect

Although infections are relatively rare causes of early death of patients with DMC, susceptibility to infections becomes more prominent with increasing age. Half of the 20 patients who died at the ages of 3–12 months succumbed in pneumonia or sepsis (157). Bacteria and *Candida albicans* were the common agents. However, patients have a predominantly mild cell-mediated immunodeficiency, usually associated with infections characteristic of humoral immunodeficiencies (166). Comparison between 19 newborns with chromosome 22q11.2 deletion detected because of a cardiac defect and comparable newborn cardiac patients without deletion showed that the deletion group had significantly lower peripheral blood T-cell numbers, although the function of their T cells was largely preserved. A subgroup with markedly diminished T-cell numbers showed an increase in these cells over the first year of life (167). Only two cases of malignant neoplasm seem to be on record (157). Failure of the descent of thymus is very common, but immunodeficiency requiring correction occurs only in approximately 25% of the cases. Such patients can be identified by CD4+ T cell enumeration, and by in vitro proliferation response to phytohemagglutinin (159, 168, 169). Approximately three-quarters of patients have frankly subnormal T-cell counts or evidence of thymus hypoplasia. Of 85 patients tested only five had a completely normal immune function. In the others findings varied greatly. The total blood lymphocyte count was normal in 71%. B lymphocyte counts were supranormal in half the patients, but antibody production capacity was subnormal in one-third. IgG responses to immunization with bacterial polysaccharides may be particularly impaired (170). Diversification of the immunoglobulin VH gene repertoire is restricted (171). Many patients have hypergammaglobulinemia (171). Transplantation with fetal thymus tissue or bone marrow has given promising results (157, 172). There may be a specific predisposition to autoimmune diseases: several cases of Graves' disease and idiopathic thrombocytopenia have

been reported, as well as two patients with juvenile rheumatoid arthritis (173).

5. Dysmorphic Features

All patients have some facial dysmorphism, but the features that are most helpful for the diagnosis are ear shape, prominence of nasal root, and, in the younger child, small mouth (159). The ears are low set and posteriorly rotated with deficient upper helices and an increase in anteroposterior diameter, giving a relatively circular shape (Fig. 8). At least one-fourth of the patients have a hearing deficit. The root and bridge of the nose are wide and prominent (Fig. 8), and there is a marked indentation on either side of the nasal tip above the midpoint of each nostril. Most patients have micrognathia, and about one-fourth have palatal clefts. The lips are often prominent and U-shaped, and the philtrum is short and poorly modeled. Lateral displacement of the inner canthi is frequent. Telecanthus with short palpebral fissures is common. The eyes may slant upward or downward (Fig. 8).

A great number of variable other malformations have been reported. Among these, different renal and urinary tract anomalies are most common. Other frequent sites are the pharynx, gastrointestinal tract, lungs, spleen, skeleton, brain, and genitals (157, 159).

In the older child the features overlap with Shprintzen velocardiofacial syndrome (MIM 192430) with a bulbous nose, square nasal tip, and hypernasal speech associated with submucous or overt palatal clefting (174).

6. Development and Growth

Of surviving patients, at least one-half have had moderate to severe developmental delay, in some series all have (158). Hypoxic episodes may have contributed to this (159), and management of hypocalcemia and avoidance of hypoxia are important in prevention of developmental problems. Growth is said to be retarded, with stature often below the third percentile (157). Mild to moderate learning difficulties are frequent.

7. Causes

Approximately 90% of the patients have a deletion within chromosome 22q11.2 (segmental monosomy) identifiable with fluorescent in situ hybridization (175–181). A minority have a microscopic deletion, and some patients have monosomy of the whole chromosome 22. The DGCR contains several genes (see MIM 188400). Most of the cases are sporadic with a de novo deletion. In many families multiple members carry the deletion with the variable phenotype behaving as an autosomal dominant trait (182). In approximately 25% of the cases one of the parents has the deletion (159), and for such couples the risk of any child being affected is 50%.

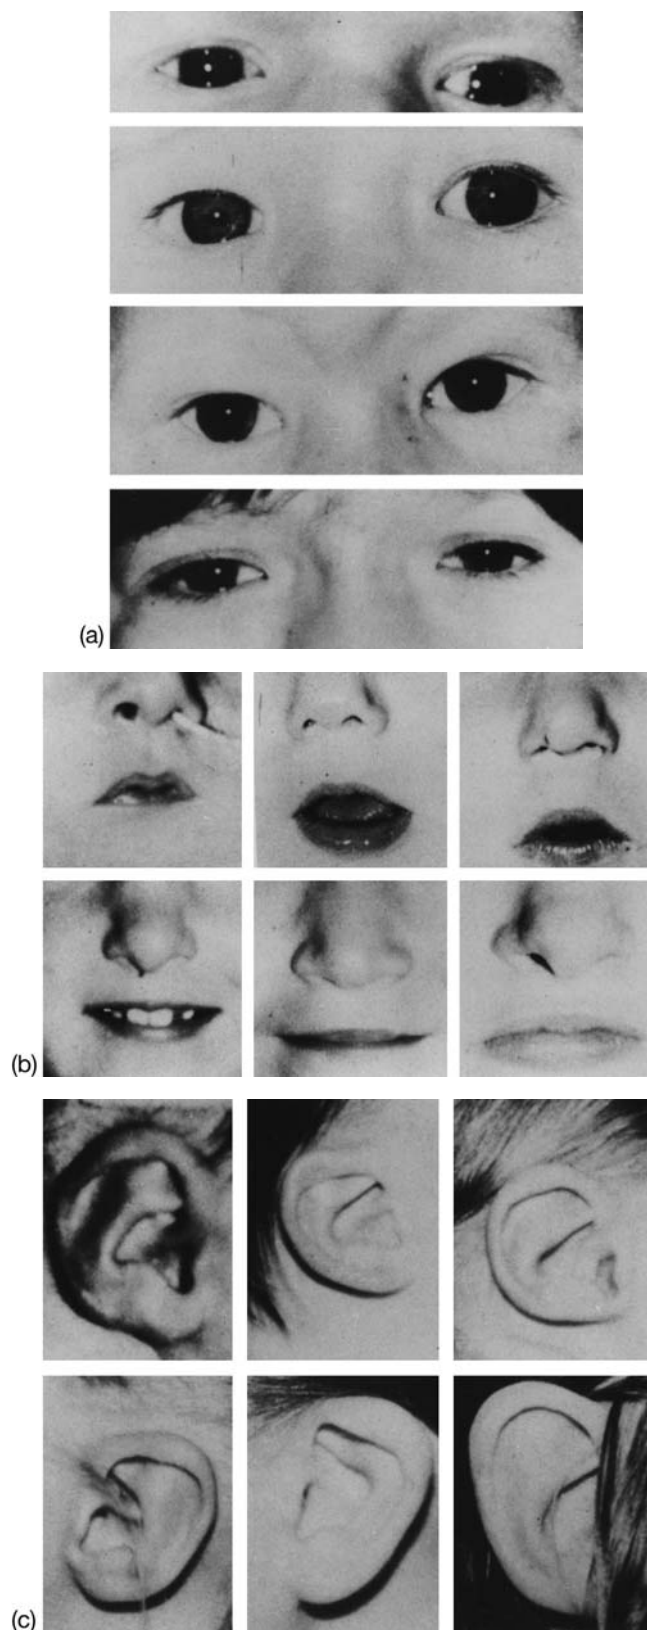

Other established causes of DMC include monosomy of a section (DMC2) of chromosome 10 p, or fetal exposure to alcohol, retinoic acid, or maternal diabetes mel-

litus. There is evidence for a common denominator of these conditions, namely existence of a dysmorphogenetically reactive unit; a population of cephalic neural crest cells (183).

8. Monosomy 22q11.2 (22q11.2 Deletion Syndrome)

A spectrum of phenotypes, often collectively called CATCH22 (for cardiac defect, anomaly of face, thymic hypoplasia, cleft palate, HP), is associated with heterozygous deletions of chromosome 22q11.2 (monosomy 22q11.2, the DiGeorge critical region I [DGCR-I]). This spectrum includes the overlapping entities DMC, the Shprintzen velocardiofacial syndrome (174, 184), so-called conotruncal anomaly face, and isolated outflow tract defects of the heart (conotruncal heart defects: tetralogy of Fallot, truncus arteriosus, and interrupted aortic arch) (159, 185, 186). Most of the cases are sporadic, but many families show autosomal dominant transmission. The same deletion may cause phenotypes that vary within families from normal to syndromic (187–189) and differ even between identical twins (190). In fact, over 90% of patients have the same deletion breakpoints (191).

In a European collaborative study of 558 patients with deletions of 22q11 (192), in 204 cases of the 285 patients with known parental deletion status neither parent had the deletion. Of the 79 cases with known gender of the parent with the deletion, it was maternal in 61 and paternal in 18. Growth data were available for 131 of the 158 patients whose heights and/or weights were below the median; 57 of 158 were below the third percentile for either height or weight. Forty-four patients had died, and of the 29 for whom age at death was available, 16 had died within the first month of life and 25 within the first 6 months consequent to congenital heart disease. There was only one death from severe immune deficiency. Of 338 patients 107 were developmentally normal; 37 of the 107 had speech delay. Of the 231 patients with abnormal development, 102 had a mild delay and 60 had either moderate or severe learning difficulties. Of 252 children in the study 22 had behavioral or psychiatric problems, including two with episodes of psychosis; 11 of 61 adults had a psychiatric disorder, and four of the 11 had had at least one episode of psychosis. Of the 545 patients who underwent cardiac studies, 409 had significant cardiac pathology, most commonly tetralogy of Fallot, ventricular septal defect, interrupted aortic arch, pulmonary atresia/ventricular septal defect, or truncus arteriosus. Of the 496 patients examined, 242 had otolaryngeal abnormalities, 72 either an overt cleft palate or submucous cleft; 161 patients had velopharyngeal insufficiency without clefting. Of 159 patients with hearing data available, 52 had abnormal hearing, which was of conductive type in all the 17 patients appropriately examined. A total of 49 of 136 patients had renal abnormalities, with absent, dysplastic, or multicystic kidneys in 23; obstructive abnormalities in

14; and vesicoureteric reflux in six. A total of 203 of 340 had recorded hypocalcemia, 108 of them with a history of seizures, and 42 of these seizures secondary to hypocalcemia. Most cases of hypocalcemia were reported in the neonatal period, but one patient presented at 18 years of age. Of 218 patients with laboratory and clinical evaluation of immune function and thymus status, only four were classified as having a major immune function abnormality. Two of these had died, one of them consequent to severe immunodeficiency. Of 548 patients 94 had minor abnormalities of the skeletal system, and 39 had ocular anomalies. Of the patients' offspring, 27 of 35 had more severe congenital heart disease than the parent and eight the same degree of severity. Developmental status was worse in nine of 17 and the same in seven of 17. Palatal abnormalities were better in 10 of 22 children and similar to the parent's in 12 of 22 children. Of the families 12 had a total of 26 affected siblings; they showed considerable variation in heart abnormalities between the siblings; developmental status was similar in most cases.

The phenotype varies widely. What has been discussed above with regard to the DMC is probably valid for monosomy 22q11.2. Several patients have been described with HP, facial abnormality, and intellectual impairment (173). The deletion appears to predispose to schizophrenia (193).

In northern England the minimum birth prevalence of the 22q.11.2 deletions was 13:100,000 live births, making it the second most common cause of congenital heart disease after Down's syndrome (194).

9. Partial Monosomy 10p

Monosomy of the tip of the short arm of chromosome 10 (p13-pter) is a rare anomaly (1:27,500 consecutive births in Tokyo; 195), and another cause of a spectrum of phenotypes that includes among others DMC (196), velocardiofacial syndrome, and the syndrome of HP, deafness, and renal dysplasia (HDR syndrome; MIM 146255). It is a contiguous gene spectrum. More than 50 patients have been reported (197). Two nonoverlapping regions have been defined that contribute to this complex phenotype. The proximal one is DiGeorge critical region II (DGCR-

Figure 8 Characteristic facial features in patients with the DiGeorge malformation complex. a. Nasal root and eyes (from the top) of a baby, an infant, a young child, and a teenager. b. The tip of the nose, philtrum, and mouth. Age increases from neonate to young child on the top row and on into teenage years on the bottom row. The length of the philtrum, the size of the mouth, and the thickness of the lips are variable. c. Abnormalities of the ear, from neonate (top left) to adult (bottom right). (From Ref. 159.)

II) on 10p13–14. Hemizygosity for it may cause cardiac defects and T-cell deficiency. Hemizygosity for the distal one on 10p14–10pter may cause the HDR syndrome: HP, sensorineural deafness, renal dysplasia and, perhaps, T-cell deficiency (197–199). Patients with cardiac defect and HP have haploinsufficiency of both these chromosome regions (197). The HDR syndrome appears to be caused by haploinsufficiency of the *GATA3* gene (MIM 131320; 200), which belongs to a family of zinc-finger transcription factors involved in vertebrate embryonic development. It is abundantly expressed in T-lymphocyte lineage and is thought to participate in T-cell receptor gene activation through binding to enhancers (201). Investigation for *GATA3* mutations in three HDR probands identified one nonsense mutation and two intragenic deletions that predicted a loss of function, as confirmed by absence of DNA binding by the mutant *GATA3* protein (200). *GATA3* is thus essential in the embryonic development of the parathyroids, the auditory system and the kidneys.

Phenotypic external characteristics include an abnormally shaped, usually microcephalic skull, prominent forehead, epicanthic folds, downward slanting palpebral fissures, hypertelorism, ptosis, flat nasal bridge, everted nostrils, micrognathia, prominent upper lip, low-set dysplastic ears, high-arched or cleft palate, short neck, and hand and foot abnormalities. Most patients have been retarded in intellectual and motor functions. The deafness is of the sensorineural type, bilateral, nonprogressive, and more severe at the higher frequencies. At least one patient had conductive hearing loss. Prenatal- or postnatal-onset growth deficiency is common. Eye abnormalities are frequent: fundus anomalies, arteria hyaloidea persistens, microphthalmus, strabismus, exudative maculopathy, astigmatism, cataract, and amblyopia. Half the patients have genital and/or urinary tract abnormalities, which may include kidney aplasia, hypoplasia or dysplasia, hydronephrosis, ureter duplex, ureteral stenosis, cystic kidneys with normal filtration rate (202), steroid-resistant nephrotic syndrome due to fetal glomeruli (203), hypoplastic penis and scrotum with cryptorchidism, and hypospadias. Limb anomalies include syndactyly, clinodactyly, clubbed hands and feet, short terminal phalanges, short upper limbs, proximally implanted or broad thumbs, and pre-axial polydactyly. Half the patients have heart defects: septum defects, patent ductus arteriosus, pulmonary stenosis, coarctation of aorta, or truncus arteriosus. Many patients died neonatally of cardiac failure. Postmortem observations included hypoplasia or aplasia of the olfactory bulbs and tracts, and hypoplasia of the cerebellum and brainstem (204). Two patients had hypothyroidism. Probably several patients previously thought to present different entities should be classified as belonging to this group (202, 203, 205). A boy with the hypoparathyroidism/sensorineural deafness/renal dysplasia (HDR) syndrome had recurrent cerebral infarctions of the basal ganglia with hemiplegia, the first one at the age of 7 months (206).

Approximately 80% of cases have been due to a de novo mutation. In the others a parent carries a balanced translocation (207).

B. Autosomal Recessive Syndromes of Kenny-Caffey and Sanjad-Sakati

The autosomal recessive syndromes of Kenny-Caffey (*KCS1*, MIM 244460) and Sanjad-Sakati (HP/retardation/dysmorphism [HRD], MIM 241410) are very rare. They have the same mutant gene locus in chromosome 1q42–q43 and appear to be allelic or perhaps even caused by the same mutation (208–209). The *KCS1* is characterized by extreme growth failure, congenital HP, abnormal physiognomy, and mental retardation, which is mostly severe but sometimes mild (210–211). The physical findings have included microcephaly, prominent forehead, deep-set eyes often with microphthalmos, and esotropia, depressed nasal bridge with beaked nose, long philtrum, thin upper lip, micrognathia, large and low-set and/or posteriorly rotated ears, often with floppy ear lobes, small hands and feet, cryptorchidism, and micropenis. All patients in the first series had cortical thickening of long bones with medullary stenosis. In the original series of patients with HRD (210) all had tetany or convulsions, nine of 12 neonatally. Immune system abnormalities were not observed. What appeared to differentiate HRD from *KCS1* was that none of the patients had medullary stenosis. With the next series of patients with the HRD (212) this difference disappeared; seven of eight patients had medullary stenosis. Also, all the patients presented with hypocalcemia neonatally, three patients had neonatal septicemia, and there were three probable additional cases in the families who had died of neonatal sepsis; all four patients tested had subnormal T-lymphocyte counts. All the reported patients with HRD were of Middle Eastern origin (210, 212–214), and so is a large series of patients diagnosed the *KCS1* (215).

C. Autosomal Dominant Syndrome of Kenny-Caffey

Characteristics of the autosomal dominant type 2 syndrome of Kenny and Caffey (*KCS2*, MIM 127000) were originally (216) described as markedly stunted stature with slender dense tubular bones and narrow marrow cavities. Congenital HP is a frequent (>70%) component. In 23 of 24 patients serum PTH levels were inappropriately low or undetectable, but in one levels were high as measured by N-terminal assay but undetectable by carboxy-terminal assay (217). No PTG was found at the one autopsy that has been reported (217). Other frequent features are macrocephaly, absent diploid space in calvarium, delayed closure of the anterior fontanelle, dysmorphic face, and eye abnormalities (microphthalmia, hyperopia, papillary pseudoedema) (217–220). Micro-orchidism is com-

mon, with suspected subfertility. The short stature was short-limbed in three families and proportional in the others.

D. Other Syndromes

Among 212 cases collected from literature of the Kearns-Sayre syndrome associated with a distinct defect of the mitochondrial genome, 14 had HP. Four of these patients were hypomagnesemic, five had hypogonadism, four had diabetes mellitus, and two had hypothyroidism. These associated endocrinopathies were not more prevalent than in the non-HP patients (221).

Two brothers have been described with a probable X-linked recessive syndrome with congenital lymphedema of all limbs and pulmonary lymphangiectasia, HP, nephropathy, dysmorphism (medial flare of eyebrows, broad nasal bridge with lateral displacement of the inner canthi, hypertrichosis of the face and forehead, short nail beds, brachydactyly, and an increased carrying angle), prolapsing mitral valve, and brachytelephalangy. One of them had cataracts and the other dry itchy skin (222).

In one family six members in three generations had autosomal dominant HP associated with short stature and premature osteoarthritis; in at least two of them HP appeared in childhood (223).

Single cases with HP have been observed in association with the Dubowitz syndrome (MIM 223370; 224, 225), Hallermann-Streif syndrome (226, 227), Mulibrey nanism (MIM 253250; 228), and Silver-Russel syndrome (MIM 180860; 229).

E. Other Congenital Isolated PTH Deficiency

Isolated PTG hypoplasia (also termed transient congenital HP or transient congenital PTG dysplasia; 230, 231) may become manifest as late neonatal tetany, or may not appear until the age of several weeks. Calcemia is then usually normalized within weeks or months. However, these patients may have permanent latent HP. Tetany may recur during a hypocalcemic stress, and permanent HP may occur after several years (161, 224, 232, 233).

XIII. TRANSIENT HYPOPARATHYROIDISM

HP limited to the neonatal period is discussed in Chapter 21.

A. Critical Illness

Hypocalcemia is frequently associated with critical illness in children (153–155), and some of these children have PTH deficiency (234, 235). Of 145 patients admitted to a pediatric intensive care unit (53 after major surgery, 92 for acute medical problems) 71 had subnormal total serum Ca. Subnormal serum Ca^{2+} was observed in 26 of them; but many others presumably had it because Ca^{2+} could

not be predicted from total Ca. As a group, these 26 patients were more critically ill than the rest; 17 had inappropriately low plasma PTH level (234). No information was given on magnesemia, although hypomagnesemia is very common in critically ill patients (236).

According to others, hypocalcemia in critically ill children was often associated with hypercalcitoninemia (237) or hypermagnesemia (238). These dysmineralemias seem to predict high mortality (234, 238) and their correction may improve the outcome.

Children with severe burns may develop hypocalcemia, Mg depletion, HP, and renal resistance to PTH infusion. Fourteen sequentially recruited children with a burn of at least 40% of total body surface area were given a urinary Mg retention test a median of 20 days after the burn. Seven of them remained Mg depleted, which was not attributable to the burn size or to time from burn to study, or combined enteral and parenteral Mg intake. Both the Mg-depleted and the nondepleted group had low intact serum PTH levels in relation to serum Ca^{2+} concentration, indicating persistent HP. Thus, not the Mg depletion but rather a reduced set point for Ca suppression of PTH secretion was concluded to be the chief cause of the persistent HP (239).

In an experiment, sheep were subjected to a 40% total body surface area burn or sham burn receiving anesthesia and fluid resuscitation only. The burned sheep were hypocalcemic and hypomagnesemic compared with the sham-burned controls. In their PTGs and kidneys the CaR mRNA was increased by 50% with a corresponding increase in the intensity of CaR immunoreactivity associated with the cell surface in the PTGs. These findings are consistent with upregulation of the parathyroid CaR and a related decrease in the set point for Ca suppression of PTH secretion that may contribute to the reported post-burn HP and hypocalcemia (240).

B. Maternal Hyperparathyroidism

HP is common in infants born to hyperparathyroid mothers; the maternal disease is often undiagnosed. Symptoms usually appear within the first 2 weeks, but may be delayed (241). Complete recovery is the rule, but the condition may be prolonged, and even permanent (242). It is presumed that this HP develops because of suppression of the fetal PTG by fetal hypercalcemia maintained by excessive placental transfer of Ca from the hypercalcemic mother.

C. Magnesium Depletion

HP is a frequent manifestation of Mg depletion. The mechanism involves impaired secretion of PTH (243, 244), target cell resistance to PTH, and independent disturbance of the blood–bone equilibrium. Mg depletion may be due to an inborn error of metabolism, a specific defect in the intestinal absorption of Mg, called primary

congenital hypomagnesemia (MIM 248250; 245, 246). It usually manifests as tetany at the age of 1–4 months. Serum Mg levels are <0.4 mmol/l (<1.0 mg/dl), distinct from the less severe hypomagnesemia frequently encountered in late neonatal hypocalcemia (247). The hypocalcemia can only be controlled by continuous Mg substitution. Mg deficiency may also occur as an acquired condition caused by nonspecific intestinal malabsorption (chronic diarrhea, Crohn's disease, large resection of small bowel) (248) and renal wasting of Mg^{2+} due to loop di-

uretics, aminoglycosides, pentamidine, cyclosporine, and diabetic ketoacidosis, transplanted kidney, urinary tract obstruction, or the diuretic phase of acute renal failure. This type of HP is resistant to the calciferols, and can only be corrected by Mg repletion (Fig. 9).

D. Toxic Influence

Transient HP may occur during cytotoxic therapy with asparaginase (249), adriamycin, cisplatin, cytarabine,

Figure 9 Plasma concentrations of immunoreactive PTH (IPTH), total Ca, Ca^{2+} , Mg, and renal phosphate clearance (P_c) in a patient with HP caused by severe hypomagnesemia. First, hypocalcemia was made more severe by an oral phosphate challenge; this did not result in increased secretion of PTH. Then Mg was replenished by intramuscular injections of Mg sulfate. The shaded areas indicate the normal ranges. (From Ref. 243.)

or amphotericin B (250). The condition may be complicated by acute renal failure and hypomagnesemia. The role of drugs and various metabolic derangements in the causation of the HP is unclear. L-asparaginase leads to necrosis of chief cells in rabbit PTG, with ensuing HP (251). (See also Sec. XII.A.)

XIV. OTHER ACQUIRED HYPOPARATHYROIDISM

A. Surgical Removal or Lesion of PTG

This condition, which is the most common variety of HP in adults (76, 251), is rare in children. After thyroid surgery hypocalcemia is relatively frequent and must not be equated with HP. A sudden transition from the hyperthyroid to the euthyroid state, with reversal of negative bone Ca balance, is often associated with so-called hungry bone phenomenon. Such hypocalcemia disappears spontaneously within 24–48 h and is unlikely to cause tetany.

Postoperative HP may be caused by PTG injury due to ischemia, depending on the extent of dissection and hemostasis (76). Patients recovering from postoperative HP usually do so within a few weeks to 6 months, but occasionally only after years. Latent HP may persist with intermittent relapses during hypocalcemic stress. This is inevitable after delayed recovery (76).

B. Irradiation Damage

Permanent combined HP and hypothyroidism has occurred in the infant after ^{131}I treatment of the hyperthyroid pregnant mother (252). Otherwise, irradiation HP is rare because the PTGs are relatively resistant to radiation.

C. Infiltration

Iron storage in the PTG is a rare cause of HP; it is usually associated with similar destruction induced by hemosiderosis of the thyroid gland, gonads, pancreatic islets, liver, myocardium, and, occasionally, pituitary gland. This condition may complicate any disease in which blood transfusions are frequently required, such as thalassemia

major and hypoplastic anemia. In β -thalassemia major, HP commonly manifests in the second decade of life, but latent HP may occur much earlier (253, 254).

HP may also develop in Wilson's disease (MIM 277900), presumably due to deposition of copper in the PTG (255).

Destructive infiltration by a metastasizing neoplasm or by amyloid is rare in children.

XV. PSEUDOHYPOPARATHYROIDISM

Pseudohypoparathyroidism (PHP; 21, 256) is a group of diseases with supranormal plasma levels but deficient action of PTH, indicating end-organ resistance. The resistance can be further proven by giving a test intravenous injection of PTH: phosphaturic, calcemic, and calcitriolemic responses are absent or markedly blunted.

A. Types of Pseudohypoparathyroidism

Because of the complexity of the signal transduction cascade of PTH (Sec. II.D.; Fig. 3), there are many possible sites for failure. Several kinds of basic defects have been identified in PHP, and others will certainly follow (Table 4; 256). The primary basis for classification is location of the defect proximal or distal to the generation of cAMP. Proximal defects are identified by absence or markedly blunted response of plasma and urinary cAMP to exogenous PTH stimulation; this is the criterion for PHP type I. In this type the renal mechanism of response to cAMP is intact as evidenced by responsiveness to injected (di-butyl) cAMP (257). In patients with distal defects, plasma and urinary cAMP responses to exogenous PTH are normal and basal urinary cAMP excretion may even be supranormal; such patients have type II PHP.

The second basis for classification is the extent of the consequences of the defect. Although PTH shares the G_s protein complex and the adenylyl cyclase of the cellular signal transduction cascade with other hormones (258), a part of the cascade is specific to PTH (and PTHrP) by structure (PTH receptor) or cell type (effector phosphoproteins of the cascade). Defects of the shared components may cause resistance to several hormones. Most of the

Table 4 Clinical and Laboratory Findings in Patients with Different Types of PHP

	Serum Ca	Serum Pi	Serum PTH	Urinary cAMP	Pi-uric response	Serum TSH	AHO	Gs α activity	Gs α mutation
PHP-Ia	↓	↑	↑	↓	↓	(↑)	+	↓	+
pPHP	→	→	→	→	→	→	+	↓	+
PHP-Ib	↓	↑	↑	↓	↓	→	–	→	–(?)
PHP-Ic	↓	↑	↑	↓	↓	(↑)	+	–	–
PHP-II	↓	↑	↑	→	↓	→	–	→	–(?)

PHP, pseudohypoparathyroidism; pPHP, pseudo-PHP; Pi, inorganic phosphate; AHO, Albright's hereditary osteodystrophy; Gs α , α subunit of guanyl-nucleotide binding protein.

known cases are due to inactivating mutations in the gene *GNAS1* encoding the α subunit of the stimulatory G protein ($G_{s\alpha}$, Sec. II.D.). Such mutations are the cause of PHP-Ia and pseudo-PHP (pPHP). All patients are heterozygous and have one normal *GNAS1* allele and one defective allele. Mutations of *GNAS1* may also be involved in PHP-Ib. In kindreds with PHP-Ia and pPHP, at least 25 heterozygous nucleotide exchanges in *GNAS1* gene have been identified causing variable mutations of $G_{s\alpha}$ (21, 256). $G_{s\alpha}$ is ubiquitously expressed, but appears to have tissue-specific roles, and its heterozygous mutations may cause autosomal dominant diseases with resistance only to a few hormones. In some type I patients normal quantity of $G_{s\alpha}$ has been observed; in one such patient a mutation of the adenylyl cyclase was identified (259).

In addition to the entities mentioned, there are at least two others: PHP-Ic and PHP-II. Patients with PHP-Ic have no detectable defect in the $G_{s\alpha}$ protein, despite clinical and laboratory features similar to patients with PHP-Ia.

Patients with PHP-Ia, PHP-Ic, and pPHP share an abnormal habitus called Albright's hereditary osteodystrophy (AHO, Fig. 10). Patients with PHP-II are similar to those with PHP-Ib in having no skeletal and developmental defects, but differ by having normal urinary cAMP excretion but blunted phosphaturic response to exogenous PTH. PHP-Ic and PHP-II are poorly characterized compared with the other types.

B. Albright's Hereditary Osteodystrophy

Albright's hereditary osteodystrophy (AHO) is the collective name of the abnormal features of habitus that patients with PHP-Ia, PHP-Ic and pPHP have (Fig. 10; 260): short stature, round or moon-shaped face, depressed nasal bridge, thick-set stocky or obese body, and bone anomalies. The latter include selective shortness and stubbiness of metacarpals (brachymetacarpia of, in decreasing order of prevalence, metacarpals IV, V, I, III, and, rarely and

Figure 10 Abnormal features of habitus in the Albright hereditary osteodystrophy (AHO) in an 11-year old girl. a. Short stocky habitus with round face. b,c. Plump hands. d. Feet with short metatarsals. A bone was excised from this girl's upper eyelid.

never alone, II), metatarsals (brachymetatarsia IV, V, III, I), and phalanges (brachyphalangia, most often of distal phalanx I leading to a thumb nail width to length ratio of >2.0), radius curvus, cubitus valgus, coxa vara, and genu valgum (261). Short digits arise from early closure of the epiphyses, preceded by decrease in longitudinal growth. Cone-shaped epiphyses may be formed, and phalangeal rudimentary or pseudo epiphyses occur (251). Hand and foot abnormalities generally are not apparent before the age of 4 years, and AHO habitus may only appear slowly to be clear by school age. It may become more pronounced in successive generations (262). Selective brachymetacarpia or brachymetatarsia and/or heterotopic soft tissue ossifications, and absence of tall stature, have often been used as the minimum criteria of AHO (263).

Dental abnormalities are common: enamel hypoplasia, small crowns, enlarged pulp chambers, root canals with open apices, pulp stones, blunted roots, delayed eruption of deciduous and permanent teeth, hypodontia, thickening of the lamina dura, and early tooth loss due to caries (264).

Height SD score correlates with the activity of the G_s protein (265). Bone age is often advanced rather than retarded, unless hypothyroidism is present.

A mild to moderate mental retardation occurs in 50–75% of patients; it is also associated with the deficiency of the G_s activity (266). Subnormal senses of smell (elevated detection and recognition thresholds for all vapors) and taste (detection and recognition thresholds supranormal for sour and bitter, normal for salt and sweet) are part of the picture (251, 267). Olfaction is known to be mediated by $G_{olf}\alpha$ protein, which shows 88% amino acid identity to $G_s\alpha$ (268, 269).

Hypothenar dermatoglyphic patterns and distally located triradii are frequent (270). Degenerative changes occur in the hip joints, even necrosis of the femoral head (271). Spinal cord compression has occurred as a result of combination of abnormal vertebral fusion, shortened vertebral lamina, and soft tissue calcifications within the spinal canal (272). Hypertension is common in adult patients (273).

C. Genetics: Important Role of Imprinting

Both PHP-Ia and pPHP are caused by the same $G_s\alpha$ -affecting mutations of the *GNAS1* gene in chromosome 20q13.2, as evidenced by common occurrence of both diseases in the same kindreds. In such kindreds, all patients with pPHP are offspring of healthy women with men affected with either PHP-Ia or pPHP, whereas all patients with PHP-Ia are offspring of healthy men with women affected with either of the two disorders (274). This results from paternal imprinting of the hormonal resistance: PHP-Ia occurs only if the defective gene is inherited from a mother affected by either PHP-Ia or pPHP (275).

The pattern of imprinting is complex. Although $G_s\alpha$ expression may derive in only the maternal allele in some

tissues, it may derive from both alleles in other tissues (276). Hence, there may be no $G_s\alpha$ in some tissues but 50% of the normal level in other tissues. This may explain why there is resistance to some of the hormones using $G_s\alpha$ -coupled receptors, while the resistance is partial or absent to some others (21). In contrast, the mode of inheritance of AHO is dominant; this remains to be explained. AHO is presumed to be caused by the same heterozygous *GNAS1* mutations responsible for the decrease in the activity of the $G_s\alpha$ protein. The PTH/PTHrP receptor also has an important role in chondrocyte proliferation and differentiation and thus in skeletal growth (277). Reduced concentrations of $G_s\alpha$ in the proliferative layer of the growth plate chondrocytes might result in an insufficient PTHrP-dependent inhibition of chondrocyte maturation, and hence to the abnormally short bones of AHO (256).

PHP-Ib, in all four kindreds studied, was also invariably inherited from an obligate female carrier, indicating paternal imprinting. DNA study of these kindreds showed that the genetic defect of PHP-Ib maps to an approximately 8 cM region on chromosome 20q13.3, the region that includes the *GNAS1* gene (278). In the equivalent region of the mouse, *gnas* is the only known imprinted gene. Several different splice variants of it are known that are specific to parent-of-origin in expression, and the same is true for the human *GNAS1*. Hence the current data indicate that mutations of *GNAS1* (other than those affecting the $G_s\alpha$ protein) are also responsible for at least some forms of PHP-Ib (256).

D. Pseudohypoparathyroidism Type-Ia (MIM 139320)

In addition to resistance to the actions of PTH, PHP type Ia (PHP-Ia) includes AHO and partial resistance to other hormones.

1. Renal Resistance

The PTH resistance in patients with PHP-Ia (and particularly those with PHP-Ib) is clearest in the proximal tubules. All responses to PTH are impaired: production of cAMP and calcitriol, and excretion of Pi and bicarbonate. The lack of phosphaturic response to PTH causes hyperphosphatemia, which probably further inhibits the production of calcitriol, aggravating its deficiency. The calcitriol response to an acute lowering of plasma Pi level is also subnormal, in clear contrast to patients with PTH deficiency. There is no such difference in calcitriol response to dibutyryl cAMP injection. This suggests that there may be an abnormality in the 1α -hydroxylase system. Indeed, many features of the disease appear to be secondary to the calcitriol deficiency. One such secondary defect is in the distal tubular Ca reabsorption response to PTH; it is normalized by correction of the hypocalcemia and the calcitriol deficiency (25; Fig. 11). The primary

Figure 11 Comparison of urinary Ca excretion (vertical scale) at three different concentration ranges of calcemia (horizontal scale; the width of each column represents the mean \pm SD of the individual concentrations) between patients with PHP (shaded columns) and HP (nonshaded columns) during therapy with different dosages of $1\alpha(\text{OH})\text{D}_3$. Normal controls had the same mean values as the normocalcemic patients with PHP. The patients with HP (in contrast to the patients with PHP) have marked hypercalciuria at all levels of plasma Ca. (From Ref. 25.)

renal resistance thus seems to be confined to the proximal tubular actions of PTH.

Significantly stronger calciuria and lower plasma PTH levels have been observed in type I PHP patients without AHO than in those with AHO, despite similar calcemia levels (279). This observation is consistent with normal PTH responsiveness of the distal tubules.

2. Skeletal Resistance

Whether skeletal resistance to PTH is an innate part of PHP has been a matter of dispute. The remodeling system appears active; there is even evidence for its acceleration due to the supranormal levels of PTH. In contrast to patients with HP and similar degrees of hypocalcemia and hypocalcitriolemia, patients with PHP as a group have subnormal bone density (280), and more than doubled urinary excretion of hydroxyproline (an index of osteoclastic bone degradation) (73, 280). They respond to exogenous

PTH by an increase in hydroxyproline excretion similarly to patients with HP (280). During substitution therapy, an inverse correlation appears between plasma Ca level and hydroxyproline excretion, and this excretion is normalized in most patients during normocalcemia (73). However, plasma alkaline phosphatase activity and osteocalcin concentration (markers of osteoblastic bone formation) are normal in patients with PHP in contrast to supranormal levels in patients with primary hyperparathyroidism, although plasma PTH levels are more elevated in patients with PHP (73). In patients with HP, osteocalcin levels are subnormal. Despite the higher plasma PTH levels in patients with PHP than patients with hyperparathyroidism, none of the three markers of bone turnover was different between these patient groups, suggesting that the remodeling system does have some degree of resistance to PTH in PHP (73). Radiological evidence of hyperparathyroidism, subperiosteal resorption, and/or cysts have been reported in PHP, but are rare (251, 260, 280–283). Seven of 18 patients with such changes had slipped capital femoral epiphysis (283). Histological hyperparathyroid changes (osteitis fibrosa) are much more common; they disappear during adequate therapy (283).

The increased bone turnover in response to high PTH levels may contribute to the maintenance of calcemia. Estrogen, which blocks PTH-mediated bone resorption, has induced hypocalcemia in women with normocalcemic PHP (284). The other skeletal metabolic system, the mineral homeostatic system, is unresponsive to PTH, but this may be secondary to the calcitriol deficiency (285, 286). Prolonged treatment with pharmacological dosages of vitamin D has restored the calcemic responsiveness to PTH in some patients to normal (285, 286), and physiological amounts of calcitriol normalize calcemia (287, 288). In fact, PTH resistance of this system is part of the pathophysiology in vitamin D-deficiency rickets (289). It is assumed that this osteocytic system is more calcitriol-dependent than the osteoclastic–osteoblastic remodeling system (280).

In conclusion, if there is skeletal resistance to PTH in PHP, it is only partial in contrast to the complete resistance of the proximal renal tubules.

3. Clinical and Metabolic Picture and Their Variability

Most patients maintain normocalcemia for the first several years of life: hypocalcemia and hyperphosphatemia occur at an average age of 8 years, and rarely before the age of 3 years (260). Plasma PTH levels may be elevated much earlier, and sometimes this is associated with mild hypercalcemia. Clinical manifestation may occur only at an adult age. Often, the hypocalcemia or the hyperphosphatemia has been noted incidentally. The hypocalcemia may alternate with normocalcemia. Hence, the resistance may be acquired and depend on factors other than the primary defect (260). Deficiency of calcitriol is a possibility, as

described above for the skeletal homeostatic system and the distal tubular Ca reabsorption. The response of cAMP to exogenous PTH is defective from early infancy (271); it is further impaired with the development of hypocalcemia and improves during spontaneous remissions (290). However, the spontaneous normocalcemia recovery periods seem not to be associated with an increase in calcitriolemia (290). Pregnancy, despite its high estrogen levels, has temporarily improved PHP patients' Ca homeostasis. This may be due to production of calcitriol by the fetally derived trophoblastic portion of placenta.

The regulation of PTH secretion is qualitatively normal, and persistent hypocalcemia maintains supranormal secretion of HPT. Plasma levels of PTH and Ca show an inverse correlation (73). Spontaneously normocalcemic patients may also have supranormal plasma PTH (73, 271). During therapy with an active vitamin D analog, plasma PTH is normalized only when plasma Ca^{2+} levels are brought to the upper normal range; this indicates an elevated set point for suppression of the PTH secretion (74), presumably due to an involvement of the G_s protein-cAMP system in PTG. In some patients the secretion of PTH may be suppressed secondary to calcitriol deficiency (271).

In addition to the hypocalcemia, often associated with grand mal seizures, the first manifestation may be either primary nongoitrous hypothyroidism, which may be congenital (291–293), or features of ovarian hypofunction, subcutaneous ossifications, bone pain (294), or slipped capital femoral epiphysis (283) caused by cystic bone disease. Convulsions seem to be more prevalent in PHP than HP, occurring in as many as 60% of the patients, and mostly resembling grand mal seizures.

Ossified plaques and nodules, also called osteomas, occur frequently in subcutaneous tissues, brain, and heart; they may be present at birth and years before hypocalcemia develops (262, 295). Calcifications of the basal ganglia have been observed in up to 100% of adult patients (80), and have often given the first clue to the diagnosis of PHP (80).

Hypertension may be common in adult patients (273).

4. Other Endocrine Abnormalities

Resistance to other hormones is frequent, but variable even between affected siblings (260, 264, 271, 296–298). Clinical hypothyroidism due to thyroidal resistance to TSH is quite common, and it frequently precedes the clinical HP. It was observed in 15 of 26 patients (299), and TSH response to TRH was exaggerated in nearly all the patients. Hypothyroidism may even be the first and congenital manifestation; it is often detected by neonatal screening (291, 292).

Clinical hypogonadism is common in female patients, due to ovarian gonadotropin resistance. It may result in incomplete development of secondary sexual characteristics, primary amenorrhea or delayed menarche, and infer-

tility. Menstrual function ranges from amenorrheic to normal (298). Plasma levels of the gonadotropins are generally not elevated. Fertility may be subnormal in male patients, because few of them seem to have reproduced (260).

As a group, the patients have a significantly subnormal plasma cAMP response to glucagon test, indicating subnormal hepatic cAMP (although normal glucose) response to glucagon (298). Prolactin deficiency is less common (300, 301). GH secretion has usually been reported as normal, but there are exceptions (293, 302). Single cases of resistance to ADH (303) and ACTH (304) have been reported.

Two unrelated males have been observed with both precocious puberty and PHP Ia. They had identical mutations of *GNAS1*, which resulted in a temperature-sensitive $G_s\alpha$ that is rapidly degraded at the normal body temperature but constitutively activated in the cooler environment of the testis, resulting in so-called testotoxicosis (MIM 176410) (305).

E. Pseudopseudohypoparathyroidism (MIM 300800)

Patients with pseudopseudohypoparathyroidism (pPHP) have the AHO habitus and the approximately 50% subnormal level of $G_s\alpha$ activity similarly to patients with PHP-Ia, but no endocrine abnormality and a normal cAMP response to PTH. The latter feature differentiates pPHP from the normocalcemic phase of or incompletely expressed PHP-Ia. Pedigrees with G_s protein deficiency commonly include both members with P-PHP and those with PHP, and the level of G_s is similarly deficient in the cell membranes of both kinds of patients (306, 307).

F. Pseudohypoparathyroidism Type Ib (MIM 603233)

Patients with PHP type Ib (PHP-Ib) have normal appearance and intelligence with hormone resistance limited to PTH. Symptomatic hypocalcemia appears, as in PHP-Ia, usually within the first decade of life but in some patients only much later (308). The disturbance appears to be produced predominantly by renal resistance to PTH, which results in impaired excretion of Pi and production of calcitriol. The skeleton appears to respond normally to PTH, releasing continuously Ca^{2+} and Pi (308a). The inevitable secondary hyperparathyroidism may lead to hyperparathyroid skeletal disease, sometimes called pseudohypohyperparathyroidism. Short stature is common (298). Although this bone resorption helps to maintain relatively normal calcemia, it also maintains a flux of Pi into blood. Because of renal PTH resistance, the excretion of Pi is inefficient and results in hyperphosphatemia. The activity of $G_s\alpha$ is normal. Mutations in the genes coding for PTH and the PTH/PTHrP receptor seem to be excluded (309).

PHP-Ib may vary considerably in severity, even within kindreds, from seizure-causing disease to absence of even the laboratory abnormalities at adult age (278). Seasonal variation can also be significant. Although most cases have been considered to be sporadic, it may just be that other cases in the family have been asymptomatic.

One patient had severe osteitis fibrosa cystica with bone pain, which only resolved after parathyroidectomy. Osteoblastlike cells cultured from her trabecular bone responded normally to PTH and calcitriol (294).

G. Pseudohypoparathyroidism Type II (PHP-II; MIM 203330)

At least 20 patients of PHP type II (PHP-II) have been reported (260). It appears heterogeneous and, in at least some cases, acquired. Hence, all reported features may not be universally true. In contrast to patients with type I, patients with type II have normal Na^+ and bicarbonate excretory responses to PTH. After prolonged normocalcemia has been maintained by Ca infusion or vitamin D administration, some of these patients have shown a normal phosphaturic response to PTH (263, 310). This suggests that the primary defect may be absence of a response to PTH in the renal cell membrane permeability to Ca^{2+} . Age at onset of this disease varied from 1.8 to 70 years (260). In one patient clinical manifestation occurred only during the hypocalcemic stress of the second half of her pregnancies (311). This is in contrast to the improvement of Ca homeostasis experienced during pregnancy by patients with PHP-I. Hyperparathyroid bone disease has been reported in some patients (260).

PHP-II may occur with vitamin D deficiency (312, 313). Sjögren syndrome may include PHP-II, presumably by an autoimmune mechanism (314).

XVI. DIAGNOSIS

A. Diagnosis of Hypocalcemia

The Chvostek test (Sec. VIII.B.1.b.) is very useful for obtaining immediate evidence pointing to or ruling out hypocalcemia. A grade 2 sign suggests, and higher grades indicate, hypocalcemia; the more severe, the stronger the sign. Absence of the sign argues against hypocalcemia, but does not exclude it.

In a convulsing patient with some evidence of hypocalcemia, it may be advisable to give a Ca-gluconate injection (Sec. XVII.A.) after inserting a venous catheter and taking adequate samples of blood to allow definite studies in case of hypocalcemia or hypoglycemia. Cessation of the convulsion during or immediately after the injection provides strong evidence for hypocalcemia, but continuation of the convulsion may not exclude it. In case of hypocalcemia, determinations must also be obtained of serum Mg, Pi, total protein, urea, or creatinine, and, preferably, Ca^{2+} .

B. Diagnosis of Deficient Parathyroid Hormone Effect and Latent Hypoparathyroidism

Manifestly deficient PTH effect is recognizable from the coexistence of hypocalcemia and hyperphosphatemia, provided that primary renal failure is excluded by determination of serum creatinine or urea (Fig. 12). In mild cases of HP the serum Pi concentration may be normal.

To identify persons at risk of hypocalcemia during periods of hypocalcemic stress due to fasting, exceptionally low Ca intake or high Pi intake, or therapy with loop diuretics, reserve capacity of PTG should be evaluated with the EDTA infusion test (Table 5) in normocalcemic patients with components of the syndromes that often include HP, especially the DiGeorge malformation complex (Sec. XII.A.), or with a history of so-called transient HP in the neonatal period of later (161, 162, 225, 232, 233).

C. Differentiation of Hypoparathyroidism and Pseudohypoparathyroidism

Features of AHO in the habitus and radiographic evidence of hyperparathyroidism strongly suggest PHP. Characteristics of a specific form of HP (APECED, the DiGeorge malformation complex, the Kenny–Caffey syndromes, hypomagnesemia, surgical HP) may suggest or even give a definite diagnosis. HP and PHP are differentiated by simultaneous measurements of serum Ca and intact PTH (315) or PTH_{1-32} . In unclear cases, those measurements should be obtained during hypocalcemia (before therapy, or induced by cessation of therapy, or by an EDTA infusion; Table 5), because that increases plasma PTH in PHP, accentuating the contrast between subnormal levels in HP and supranormal levels in PHP. Subnormal levels include levels within the so-called normal range during hypocalcemia.

A determination of serum 25-hydroxyvitamin D may be needed to exclude vitamin D deficiency, which may cause PTH resistance (313) and suppress the supranormal levels of PTH in PHP. Some patients with PHP may show the characteristic supranormal plasma PTH levels only after repletion of calcitriol (271). Hypomagnesemia may likewise have to be corrected to reveal the supranormal PTH levels of PHP (316).

The PTH test (Fig. 13) may help to confirm or exclude PHP, in addition to being the key to the diagnosis of the specific type of PHP. This test may not differentiate between HP and PHP-II, however, because the cAMP response is normal in both. The phosphaturic response should differentiate between these two conditions but is not quite reliable but may give both false-positive and false-negative results even when the ideal response index, the relative decrement in TmP/GFR (Sec. IV.A.), is used (317, 318).

An alternative approach is to test whether the kidneys respond to a PTH test dose by an increase in plasma cal-

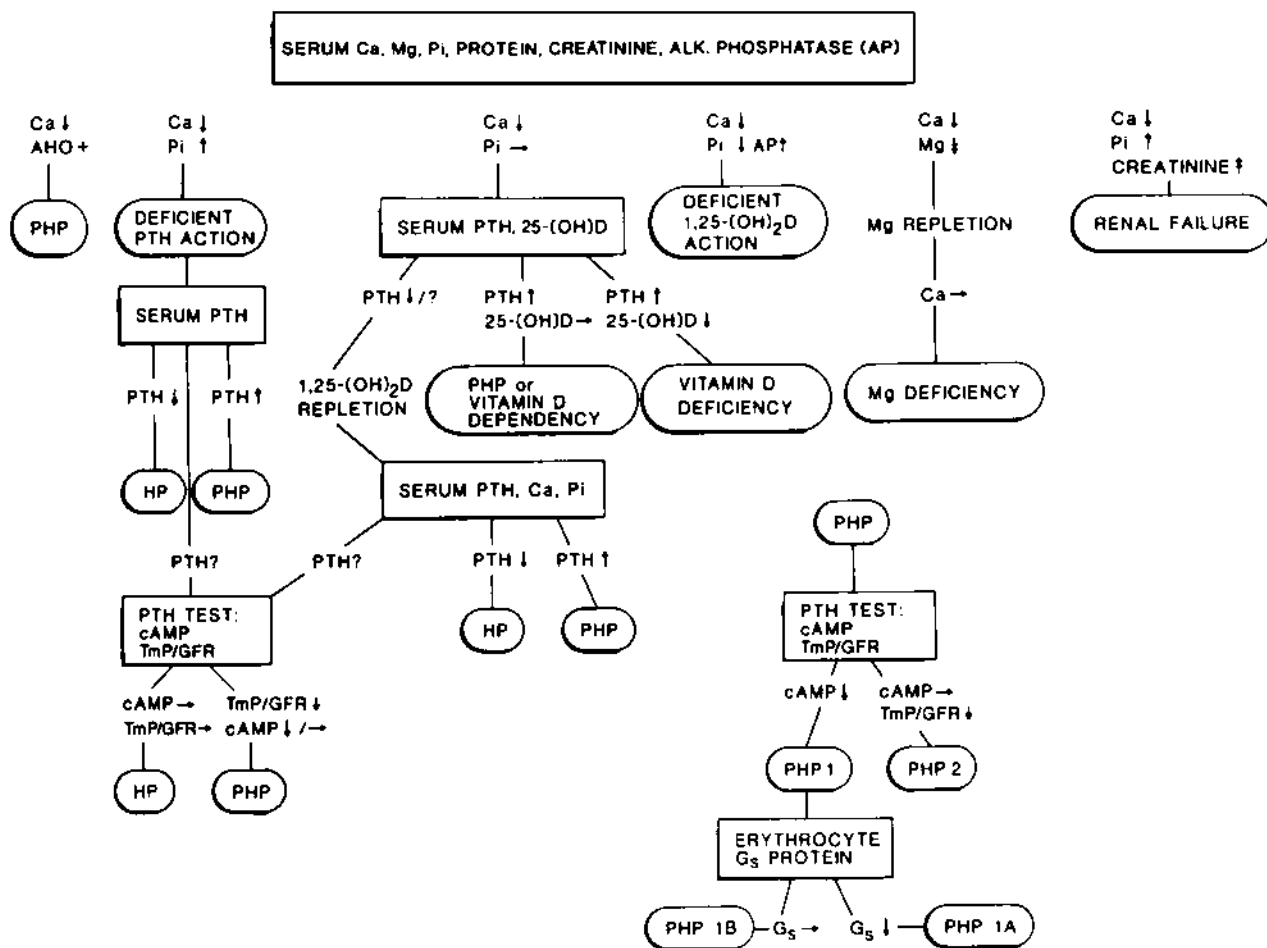

Figure 12 Flow diagram of diagnostic procedure for suspected hypocalcemia. Pi, inorganic phosphate; ↓, subnormal; ↑, supranormal; →, normal; AHO, the Albright hereditary osteodystrophy; TmP/GFR, quotient of maximum rate of tubular phosphate reabsorption and glomerular filtration rate (relative decrement of this quotient is the best index of PTH effect on tubular reabsorption of phosphate [Sec. IV.A.; Fig. 5]). Plasma cAMP measurement may be preferable to urine cAMP in the PTH test (Fig. 13). In a normocalcemic patient with suspicion of latent HP, perform EDTA test (Table 5).

citriol. In a small series of mostly adult patients, all 14 patients with HP showed a 24 h increment in plasma calcitriol of at least 24 pmol/l (10 pg/ml), whereas the responses all four patients with PHP were below this limit (319). Another method is to observe whether the skeleton responds to a trial treatment with PTH over some days by an increase in calcemia.

D. Diagnosis of Specific Forms of Hypoparathyroidism

Patients with APECED should be identified, because of their risk of developing new, possibly dangerous, components of the disease. A firm clinical diagnosis of APECED requires the presence of at least two of the following: chronic or recurring mucocutaneous candidiasis, HP, and adrenocortical failure (or antiadrenal or 21-hy-

doxylase autoantibodies). If a sibling fulfills this criterion, one of any of the autoimmune or clear ectodermal components of APECED (Sec. XI) suffices for the diagnosis. The two-out-of-three-criterion became fulfilled within the first 5 years of life in only 22% of our patients, in the next 5 year period in another 45%, in the second decade of life in a further 22%, in the third decade in 4.5%, and only later in 2%. It was not fulfilled in a male patient by the time of his death at the age of 45 years from oral cancer, a consequence of APECED; his *postmortem* diagnosis depended on his sister's diagnosis. Thus the criterion gives no false-positive diagnoses, but false-negative results are common, especially at a young age.

Hence, for appropriate clinical diagnosis, knowledge of the disease components other than the above-named three most common ones should be utilized. When a person under the age of 50 years has a disease that belongs

Table 5 EDTA Infusion Test of PTG Reserve**Procedure**

After an overnight fast infuse over 2 h disodium EDTA intravenously 75 mg/kg (not exceeding 3 g) in 200–500 ml (depending on the size of the patient) 5% glucose solution containing 0.1 mg/kg lidocaine.

Obtain blood samples for determinations of serum Ca^{2+} and PTH just before the infusion and at 30, 60, 120, 180, and 240 min.

Assessment

Normal PTG reserve is indicated by a clear rise in serum PTH already at 30 min, and full recovery of serum Ca^{2+} by 240 min. Defective reserve is reflected by absent or subnormal rise of serum PTH and delayed recovery of serum Ca^{2+} levels.

Source: Refs. 163, 251.

to the components of APECED, he or she should be evaluated for the ectodermal, oral, and ophthalmic components. If two components of APECED are present without any other definite explanation, the patient should be evaluated for development of further components, or a search for *AIRE* mutations should be considered. Mutation diagnosis (Sec. XI.D.) is available from several specialized laboratories internationally. The relatively large number of mutations, and the fact that many others remain unrecognized, causes problems in the mutation approach to the diagnosis. Hence, APECED cannot be thus excluded.

It is also important to identify patients with hypocalcemic hypercalciuria among subjects with HP, to avoid renal complications. A finding of hypocalcemia not associated with an undetectable or very low serum PTH concentration (but not supranormal as in PHP) and normal or supranormal calciuria should suggest that diagnosis. However, it is not possible to detect all cases by those measurements. Family screening for hypocalcemia, especially of the patient's parents, is advisable and may indicate dominant inheritance. The single-strand conformational polymorphism (SSCP) technique may be helpful for rapid molecular genetic screening for mutations of the *Ca-R* (90), but the same limitations are valid for the DNA diagnosis of hypocalcemic hypercalciuria as for APECED.

DiGeorge malformation complex-type dysmorphic facial appearance in an individual with a major outflow tract defect of the heart or a history of susceptibility to infections should raise suspicion of this condition. In infancy, hypocalcemia is a characteristic feature, although it may be intermittent and has a tendency to resolve during the first year. Immunological assessment relies on chest radiography to detect a thymic shadow (a notoriously unreliable investigation, particularly in a stressed infant) and measurement of the CD4-positive subset of lymphocytes. The investigations of choice are a standard karyotype to

exclude major rearrangements, and search for the 22q11.2 and 10p monosomies by the fluorescence *in situ* hybridization techniques (178, 181). Parents should be screened for carrier status (320). The possibility of HP and an immune defect should be kept in mind in apparently isolated cases of conotruncal defects, particularly truncus arteriosus communis, D-transposition of the great vessels, Fallot's tetralogy (321), and supracristal ventricular septal defect.

Phenotypic differences between DiGeorge malformation complex as associated with monosomy of 22q11 and monosomy 10p, involve a higher frequency of renal abnormality and deafness, and more heterogeneous cardiac defects in the latter. The type of deafness differs: about one-third of the patients with monosomy of 22q11 have a conductive hearing loss owing to recurrent otitis media or palatal abnormality or both, while the deafness in patients with monosomy 10p is sensorineural.

To diagnose the transient nature of neonatal and surgical HP, substitution therapy should be interrupted in the young infant with HP (the first time at 6 weeks after its introduction) and in surgical HP (the first time 3 weeks after its introduction), with close observation of the patient for recurrence of hypocalcemia. Absence of recurrence proves the transient nature of the disorder. However, PTH reserves should be tested for permanent subnormal levels (Sec. XVI.B.).

HP secondary to maternal hyperparathyroidism is confirmed by definite diagnosis of the mother's disease and the transient nature of the infant's HP. HP secondary to Mg depletion (XIII.C) is confirmed if hypomagnesemia is severe and Mg repletion corrects the HP. Mg deficiency appears to be a more frequent secondary feature of HP than commonly recognized. It may be particularly prevalent in patients with hypocalcemic hypercalciuria (322).

Isolated idiopathic HP can be positively differentiated from APECED only if the patient belongs to a kindred with definite case(s) of isolated idiopathic HP.

E. Type Diagnosis of Pseudohypoparathyroidism; Diagnosis of Pseudopseudohypoparathyroidism

The type of PHP should be determined for assessing the risk of hypothyroidism and hypogonadism and for purposes of genetic counseling. Presence of AHO points to types Ia and Ic, and its absence to Ib and II. Firm diagnosis requires that the PTH test be performed with bio-synthetic fragments of human PTH, such as PTH_{1-34} or PTH_{1-38} , with determination of plasma and/or urinary cAMP response (Fig. 13) (317, 318). The patient should have a steady water diuresis during the test (323). Deficient cAMP response identifies type I and normal response identifies type II. PHP-Ia is recognized from evidence of other hormone resistance, most readily by a supranormal TSH response to TRH test. Deficient activity

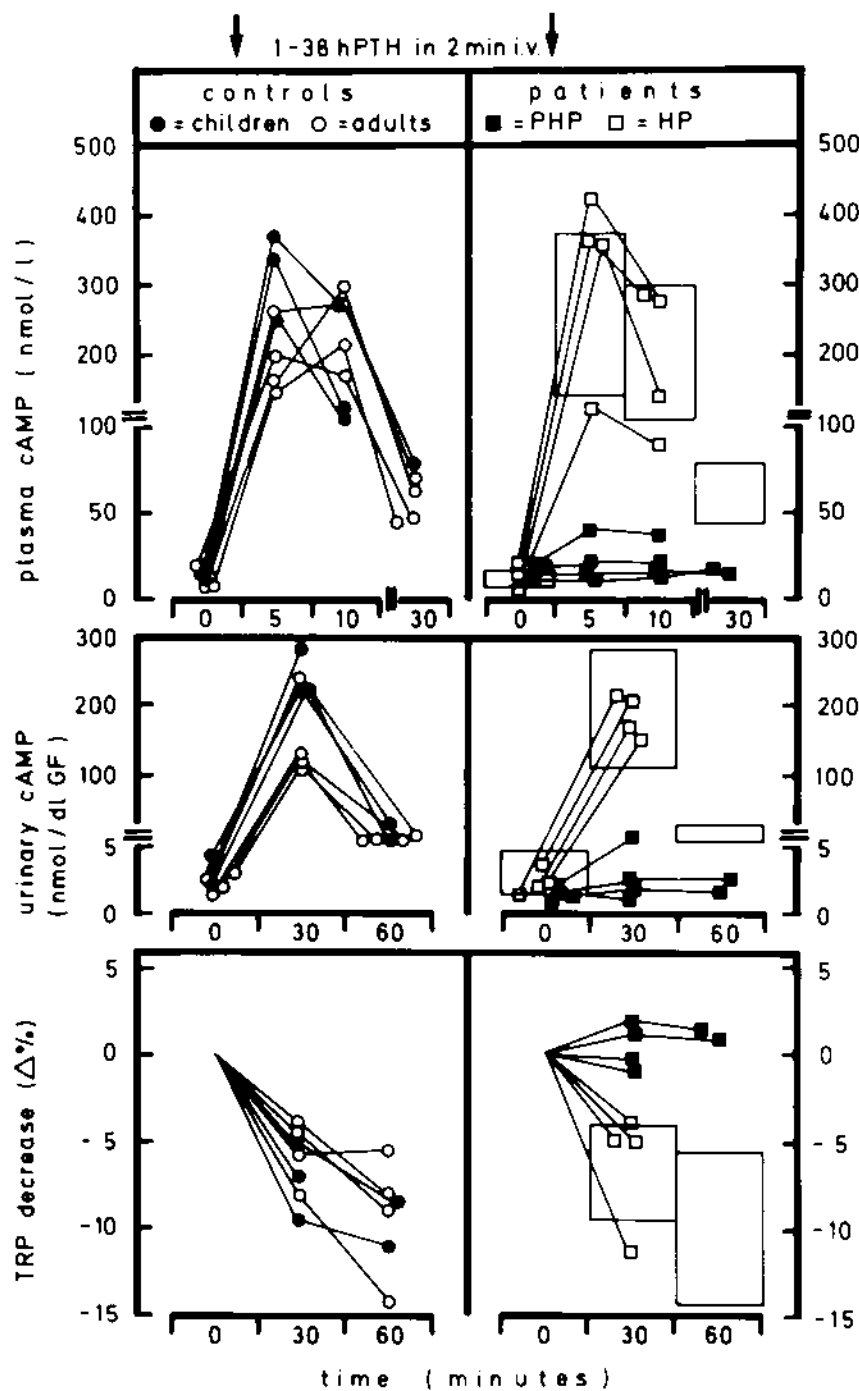

Figure 13 PTH test: effect of an intravenous injection of human PTH ($0.5 \mu\text{g/kg}$ of PTH_{1-38} over 2 min) on cAMP concentration in plasma (upper panels, nmol/l) and urine (middle panels, nmol/dL glomerular filtrate), and on tubular reabsorption of phosphate (TRP, lower panels, decrease in %) in controls (left) and in patients with PHP and HP (right). The rectangles in the right panels indicate the ranges of controls. (From Ref. 318.)

of the Gs protein may be demonstrated or excluded by studying erythrocyte membranes (324), and specialized laboratories can search for G_{α} -affecting mutations of the *GNAS1* gene (324a).

The definition of P-PHP is the presence of AHO with a normal cAMP response to the PTH test (Fig. 13).

XVII. THERAPY

A. Therapy of Tetany

A patient who is convulsing or has laryngeal stridor or severe tetany should promptly be given an intravenous injection of 10% Ca-gluconate solution. This solution contains 0.22 mmol/ml (8.8 mg/ml) Ca. The most rapid effect can be attained by injection of 0.25 ml/kg (0.055 mmol or 2.2 mg/kg) over not less than 2 min. This may ameliorate the tetany for 15 min to several hours; if not, the injection may be repeated in case of confirmed hypocalcemia. A continuous infusion should then follow: 1.8 ml/kg (0.4 mmol; 16 mg Ca/kg) of the 10% solution over 6–12 h (325). Extravasation of the solution should be strictly avoided, because of the risk of tissue necrosis. It should preferably be given diluted (e.g., 1:10 in 5% glucose solution). Oral administration of Ca salts is efficient for the control of hypocalcemia and is preferable to prolonged infusion. Liberal amounts should be given orally; for example, 50 mg Ca/kg/24 h in four or five divided doses. To sequester Pi in the intestine, dosages may be 4fold higher. The Ca content of oral preparations varies: carbonate 40%, chloride 36%, lactate 13%, gluconate 8.8%, and glucobionate 6.5%. Thus, 2.5 g, 2.8 g, 7.7 g, and 11.0 g are required, respectively, to provide 1.0 g Ca. Chloride can only be given in dilute (2%) solution (preferably in fruit juice) because it irritates the gastric mucosa. During fat malabsorption, the effect of oral administration may be poor.

B. Long-Term Therapy

1. General Aspects

The aim of therapy for patients with HP is to maintain plasma Ca at around the lower limit of the normal concentration range (2.0–2.2 mmol/l [8.0–8.8 mg/dl], Ca^{2+} 0.98–1.08 mmol/l) so that hypocalcemic manifestations are limited to the mildest symptoms and harmful hypercalciuria is avoided. Plasma Pi levels should also be normal. If therapy is successful, HP does not disturb the patient's life, and long-term complications will be avoided. The most serious risk to be most carefully avoided is hypercalcemia. It easily remains unnoticed, yet may cause irreparable kidney damage in a few weeks. In addition to drugs, therapy includes regular intake of relatively large amounts of fluid (to avoid low urine flow) and normal nutrition, with particular avoidance of fasting and high phosphate intake.

Treatment of patients with hypercalciuric hypocalcemia (Sec. X.A.) must be undertaken particularly carefully because of their higher level of hypercalciuria. Asymptomatic patients should not be given any medication for their hypocalcemia, and even symptomatic patients should be given only enough to alleviate their symptoms, not to make them normocalcemic.

In patients with PHP, in contrast to those with HP, therapy should aim at maintaining plasma Ca at a high-normal level (73). The basic differences between these two conditions dictating this difference in therapy are that normocalcemia causes hypercalciuria in HP but not in PHP, and that in PHP even low normal calcemia is associated with secondary hyperparathyroidism, which may harm the skeleton.

Two principles of long-term drug therapy apply: (a) PTH replacement with a calciferol sterol is a necessity; and (b) oral Ca supplementation is a recommendable adjunct therapy, and oral Mg should be added to avoid Mg depletion. The dosage of the sterol has to be carefully adjusted and frequently readjusted, because the need may fluctuate even after long periods of steady normocalcemia. Serum Ca and Pi levels, and urinary Ca excretion, must be regularly monitored. Responsibility for control of calcemia lies with the family. The patients should carry a physician-alert sign identifying that he or she has the disease.

The patient and family should be well informed about the patient's lack of normal tolerance of varying Ca intake. Once the substitution therapy has been adjusted to a level of Ca intake, this should be maintained. An extra intake of Ca, such as an unusually large amount of milk or a tablet containing 1 g Ca, which would be well tolerated by a normal person by means of a prompt reduction of PTH secretion, may produce a period of hypercalcemia in the patient. A reduction of Ca intake due to fast or a change in diet may likewise lead to hypocalcemia, because of the absence of a normal ability to increase promptly the secretion of PTH.

PTH1-34, should it become available affordably, would offer the benefits of physiological replacement therapy. Two daily subcutaneous injections seem to provide for normocalcemia without the risk of hypercalciuria (322).

2. Sterol Therapy

Calciferol sterols (Table 6) are the only drugs generally available for long-term replacement therapy. Hypocalcemia can be effectively controlled with them and the desired level of calcemia can be maintained, because they increase the flow of Ca^{2+} from the intestine and skeleton (Fig. 14). Normocalcemia will, in itself, restore the inherent ability of the kidneys to adjust the excretion of Pi to phosphatemia. Reaching a sustained decrease in plasma Pi levels requires, on average, 2 months (326). However, the sterols lack one important renal action of PTH: stimulation of the distal tubular reabsorption of Ca^{2+} . Hence,

Table 6 Calciferol Sterols Used in the Therapy of Patients with HP and PHP

Sterol	Average dosage ^a ($\mu\text{kg/day}$)	Average half-life (days)	Comments
Calcitriol	0.03	1	Good, limited experience
1 α (OH)D	0.06	2	Good, limited experience
DHT	20	7	Highly recommended
25(OH)D	4	15	Questionable value
D ₂ and D ₃	50	30	Risk of cumulative action

^aIndividual variation in requirement is great, and may fluctuate. Therapy should be initiated with about half this dosage, and the dosage carefully adjusted according to response. Frequent monitoring of serum Ca and Pi levels and 24 h urinary Ca is mandatory, even in patients with stable response (see text). Clear onset of action is usually evident approximately at half-life, a plateau in 2–4 half-lives, and after discontinuation of the drug, its action continues for 2–3 half-lives, but this may be much longer for the D vitamins.

normocalcemic patients with HP excrete on average three-fold more Ca in urine than normal persons (Fig. 11). This poses a risk of Ca sedimentation in the kidneys. To avoid this danger plasma Ca levels should be maintained no higher than the lower border of the normal range, and measurements of urinary Ca excretion are a part of the routine monitoring of therapy. In contrast, patients with

PHP normalize calciuria with therapy (Fig. 11). It is assumed that their endogenous PTH stimulates the distal tubular absorption of Ca^{2+} as soon as their calcitriol levels are normalized. Even optimized sterol therapy does not substitute for normal PTH secretion, which varies greatly according to mineral balance.

The D vitamins (D₂ and D₃ are identically efficient) have a slow, prolonged, and cumulative action. They involve a risk of severe prolonged hypercalcemia, even after years of stable maintenance of normocalcemia, because they are stored in the adipose tissue. The stores may become large enough to maintain replacement therapy for as much as 6 months (77). Therefore, vitamin D is not recommended for routine replacement therapy, especially not for labile patients, and when regular laboratory monitoring cannot be guaranteed. The effect of vitamin D is probably based on the generation of large amounts of 25-(OH)D, which has a low affinity for the VDR. 25-(OH)D₃ is available in the United States and some other countries. It has little to recommend it, particularly if its cost is high.

Calcitriol and 1 α -(OH)D are the fastest- and shortest-acting derivatives, and probably good alternatives for therapy. Two very favorable reports have appeared on the long-term use of calcitriol in children with HP. None of them had APECED (in which HP may be very labile and the longer-acting DHT may therefore be the drug of choice). In a report on 10 children (326) the dosage, initially 0.25 $\mu\text{g/day}$, was raised in increments of 0.25 μg until normocalcemia was achieved, over a minimum of 3 days. The final dosage was 0.50–1.25 $\mu\text{g/day}$, given in two or three divided doses. It was neither weight- nor age-related. Hypercalcemia was observed eight times during a total of 35 patient years; it was controlled by an interruption of therapy for 3 days. Hypocalcemia was registered 10 times, half of them transient and related to intercurrent febrile illness. In a report on four children (327), the dosage required to maintain plasma Ca at levels above 2.0 mmol/l (8.0 mg/dl) was 0.75–1.00 $\mu\text{g/day}$. Only two hypercalcemic and two hypocalcemic periods were observed during a total of 21 patient years.

In a comparative study of therapy in adults with HP or PHP (328), the mean daily doses required were similar with calcitriol (1.5 μg) and DHT (450 μg). In contrast, consistently in several studies (25, 328, 329) of 1 α (OH)D, more was required in patients with HP (4 μg) than with PHP (2 μg). This may reflect a pathophysiological difference between these two diseases. Long-term safety of 1 α (OH)D has been established (330).

Crystalline DHT is an intermediate-acting derivative, and an excellent drug for long-term therapy. This vitamin D derivative has multiple advantages for use in patients requiring pharmacological dosages, as in HP (331). The crystalline form of this drug has an ideal duration of action.

It is important to become well acquainted with the use of one drug, and establish clear rules for it, which must also be given to the patient and parents. The author's

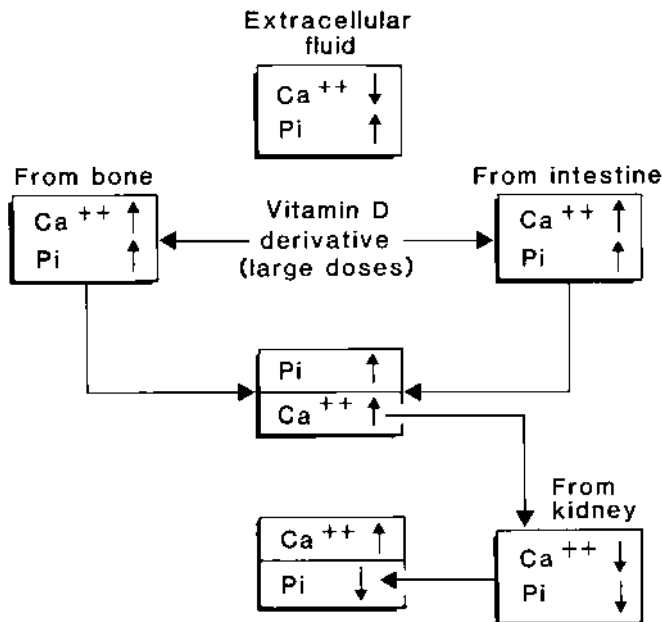

Figure 14 Effect of therapy with calciferol sterols in HP. For explanations and comparison, see Figure 6; this therapy is not complete replacement of PTH because the calciferols lack the renal effects of PTH.

rules for DHT therapy are provided as an example. The full effect of a dose of DHT is reached in 10–20 days. In regular therapy, one daily dose is given or, in the case of a very small dose (<0.05 mg), one dose every second day. Therapy is started with a dose likely to be too small rather than too large. The dose is increased at intervals of 10–14 days as necessary to maintain the ideal serum Ca level. For fine adjustment, the increments/decrements of the dose should be around 10%. At the start of therapy and whenever the dose is increased, an extra dose is given that is sevenfold the increment. Whenever the dose needs to be adjusted slightly downward, a similar omission (sevenfold the decrement) is made at once. In moderate hypercalcemia (at or above 2.6 mmol/l, 10.4 mg/dl; Ca^{2+} 1.27 mmol/l) the DHT intake is discontinued for a few days and restarted only when a repeat serum Ca determination shows a decrease to close the ideal level.

3. Refractoriness to Sterol Therapy

Some patients become refractory to oral sterol therapy. This is not uncommon in patients with APECED, and another kind of case is on record (331, 332). In APECED one frequent contributing factor is fat malabsorption. Patients with this condition need to be monitored very carefully. Usually, however, maintenance of the recommended level of calcemia will keep the malabsorption under control. Fat malabsorption leads to a vicious cycle: like other lipids the sterol is poorly absorbed and this causes impairment of the hypocalcemia, which makes the fat malabsorption more severe. The cycle might be broken by increasing the oral doses of the sterol and Ca, and by decreasing fat intake or replacing ordinary fat by medium-chain triglycerides, which are more completely absorbed in this situation than are ordinary fats (77).

It is important to use the shorter-acting derivatives in the oral therapy of these patients, because very high doses (even 20-fold the regular dose) may be needed. In these situations serum Ca needs to be monitored several times weekly so that the dose may be immediately reduced when the calcemia starts to improve. Parenteral administration of calcitriol or 1α -(OH)D may help to break the cycle, if daily injections can be arranged. An attempt to decrease the malabsorption by intravenous Ca infusion failed, since the large amount of Ca passed rapidly into the urine.

Mg deficiency may sometimes be a factor in the resistance (77), and magnesemia reflects the Mg nutrition poorly. MgCl_2 , in dosages up to 2 mmol/kg day orally, has reduced the sterol requirements of some refractory patients (77, 331).

Other factors may be involved. One patient of ours, who has had no clear steatorrhea, has been resistant to oral therapy with both DHT and 9α -fluorocortisol.

4. Calcium and Magnesium Supplementation

The ideal long-term therapy of HP probably includes a supplement of approximately 20 mg elementary Ca/kg

daily (up to the total dose of 1.0 g) given as one of the oral preparations (Sec. XVII.A.), the most palatable of which may be the effervescent tablets. It must be divided in three to four doses to avoid single doses in excess of 7 mg/kg, and undue fluctuation of plasma Ca level (Sec. XVII.B.1.). This supplementation may help to control the hyperphosphatemia, and it offers the possibility of rapid correction of intervening hypercalcemia by stopping the substitution. However, if taking the supplement regularly would be uncertain, or if the supplementation is thought to be too stressful, it should not be prescribed at all. A good balance can usually be achieved without it.

The supplementation should be used at the beginning of therapy at least as long as the patient is expected to be hypocalcemic. In intervening situations of hypocalcemic stress (Sec. VII.A.) or hypocalcemia, a temporary substitution may be restarted, or the dosage of continuing substitution may be increased. However, single dosages should not exceed 7 mg/kg.

A daily oral supplement of 50 to 200 mg Mg is also recommended.

5. Therapy of Hyperphosphatemia

In the beginning of therapy for HP or PHP, it is advisable to restrict ingestion of milk and cheese for 2 months to reduce phosphate intake. The corresponding amount of Ca should be replaced with one of the oral Ca preparations. The described therapy commonly leads (within approximately 2 months) to normalization of phosphatemia, because the correction of hypocalcemia directly reduces the supranormal tubular Pi reabsorption. Furthermore, normalization of calcitriol activity may partially restore the inherent tubular ability to adapt to phosphatemia (Sec. IV.C.).

In some patients, however, the normalization of phosphatemia fails. In such patients, the dietary phosphate restriction should be continued. Aluminum hydroxide and carbonate, a dose with each meal, have been used for intestinal binding of Pi in patients with chronic uremia. These chemicals carry a risk of aluminum toxicity. Furthermore, my personal experiences with this therapy in HP have not been successful.

6. Therapy of Magnesium Deficiency

Secondary Mg deficit should be eliminated with oral administration of Mg chloride, citrate or lactate, which may need to be continuous. Often, 2 mmol/kg Mg daily divided in three or four doses is adequate (77).

In HP secondary to Mg depletion, the initial therapy consists of an intravenous infusion of a solution of Mg chloride or gluconate; 1–2 mmol/1.7 m²/h is generally required to reach and maintain normal plasma level of Mg^{2+} . In a convulsing patient, the replacement may be started by giving slowly a bolus of 5–10 mmol/1.7 m², and continued at a rate of 5–7.5 mmol/1.7 m²/h for the

first 1–2 h. The use of intramuscular MgSO_4 is not recommended, because the injections are painful.

Deficits of Ca, K, and Pi should simultaneously be corrected. Oral calciferol should be given for vitamin D efficiency; calcitriol should not be used because it may worsen the hypomagnesemia (333). The intracellular deficit of Mg is only slowly corrected and most of the infused Mg^{2+} may be excreted, hence the infusion may have to be continued for 3–5 days. The therapy can then be continued with oral Mg salts, 2 mmol/kg daily (up to a total daily dose of 1.0 g Mg or 40 mmol) divided in four doses (77).

7. Laboratory Follow-Up

Serum Ca and Pi determinations should routinely be done together. The accuracy and precision of Ca determinations are often less than excellent, and an unexpected value should be promptly confirmed before being taken as a basis for adjustment of therapy. Measurements of plasma Ca^{2+} are preferable to measurements of total Ca (326). Plasma total Ca may change postprandially, depending on the nature of the meal. Therefore, measurements after an overnight fast are preferable to random measurements. Also, prolonged application of a tourniquet leads to spurious elevation of plasma Ca. Normal plasma Pi levels depend on age (Table 1). Increments and decrements of 0.4 mmol/l (1.0 mg/dl) may occur after phosphate- or carbohydrate-rich meals, respectively. Therefore samples for routine determinations should be taken after an appropriate fast (overnight for all but infants).

It is our rule to have these determinations done at the maximum intervals of 6 weeks even in patients with stable levels. During labile periods, repeats may be needed even twice weekly. Frequent determinations of 24 h urinary Ca are recommended to check that the kidneys are not at risk for hypercalciuria, which is not reliably reflected by calcemia (77). Shorter collection periods are not recommended, because of the inconsistent diurnal variation of calciuria. The 24 h excretion should remain below 0.1 mmol/kg (4 mg/kg). If this rate is exceeded, calcemia should be maintained at a lower level. We do most of the laboratory checking by having the laboratory closest to the patient's home take the blood samples and mail the serum and a sample of urine to our laboratory. The 24 h urine specimens are likewise collected at home and, with a few milliliters of glacial acetic acid added, a sample from the measured total mixed volume is mailed to the laboratory. This is clearly more reliable than the use of unknown laboratories.

Serum Mg levels should also be checked at least twice annually for the development of secondary Mg deficiency. Serum creatinine levels should likewise be checked even in patients with no known hypercalcemic periods.

8. Control by the Patient or the Parents

Parents and cooperative patients must be familiar with the symptoms of hypocalcemia and, especially, hypercalcemia

(headache, increased nocturnal urine flow, thirst, anorexia, nausea, vomiting, constipation, lethargy, weakness, alterations of mental status) to be able to react to these without delay. They need detailed written information about the disease and these symptoms, including the immediate steps to be taken if they should appear. These steps include having a blood sample taken without delay to check serum Ca and Pi levels, contacting the physician, and, should this fail, first-aid adjustment of the drug therapy according to rules that are provided.

The parents and cooperative patients should be taught to perform the Chvostek test (Sect. VIII.B.1.b.). The value of this test needs to be established individually: in some cases, even the grade I sign may be significant. Some patients have discovered personal methods for recognizing hypocalcemia.

9. Patients with Associated Addison's Disease

In patients with HP who also have Addison's disease, it is important to anticipate a decrease in Ca absorption and, consequently, hypocalcemia whenever the cortisol substitution dosage is increased even slightly, and the opposite may occur after a decrease in dosage.

Unexpected hypercalcemia may be the first signal of Addison's disease.

10. Special Aspects of Pseudohypoparathyroidism

In patients with PHP, maintenance of normocalcemia is likely to improve endogenous Ca mobilization, and bring about a decrease in the sterol requirement. In contrast to patients with HP, patients with PHP during adequate sterol therapy have normal calciuria (Fig. 11). Hence, they should not need continuous Ca supplementation.

It is essential that hypothyroidism, which is frequently associated with PHP-Ia, be diagnosed and treated.

11. Therapy of Complicating Hypercalcemia

Intervening hypercalcemia should be prevented through adequate monitoring, even during prolonged periods of stable normocalcemia, through an anticipatory decrease in replacement therapy in hypercalcemic risk situations (reduced mobility during illness, unusually high intake of milk products), and familiarity of the patients and parents with symptoms of hypercalcemia.

In hypercalcemia it is particularly important to maintain a relatively large fluid intake. Ca supplementation must be interrupted and foods with a high Ca content must be eliminated: milk, cheese, fish with bones (canned salmon, sardines etc.), leafy greens, and almonds. Mild hypercalcemia in a patient receiving a short- or intermediate-acting sterol may be controlled by a break of one-half to a complete half-life of the sterol in taking the sterol therapy followed by a decreased dose. In moderate hypercalcemia (serum Ca at or above 2.6 mmol/l, 10.4 mg/dl, Ca^{2+} 1.27 mmol/l) it is advisable to delay rein-

roduction of the sterol until serum Ca has returned to the target level. This is mandatory during therapy with vitamin D. During this therapy, and even during therapy with DHT, the patient may be unusually sensitive to reintroduction of the drug after a hypercalcemic period.

Some patients enter a vicious cycle in which hypercalcemia causes increased urine flow and a hyponatremic dehydration, which in turn aggravates the hypercalcemia. In these situations, rapid rehydration with a physiological Na^+ solution is mandatory. The rehydration with the ensuing natriuresis will usually rapidly alleviate the hypercalcemia.

In severe hypercalcemia (at or above 3.0 mmol/l, 12.0 mg/dl, Ca^{2+} 1.47 mmol/l) stronger measures are needed. Available alternatives are therapies with calcitonin and glucocorticoids (20–40 mg/m²/24 h prednisolone in four daily doses, to inhibit the intestinal absorption of Ca), maintaining natriuresis with an intravenous infusion of physiological Na^+ solution, and furosemide (which increases calciuria in contrast to thiazide diuretics).

12. Risk Situations

Febrile illness and fasting predispose to hypocalcemia. The stress of a febrile illness may cause breakdown of intracellular organic phosphate compounds, with an increase in extracellular Pi leading to a decrease in Ca^{2+} level (77). Fasting reduces the inflow of Ca. Immobility, because of bed rest for illness, predisposes the patients to hypercalcemia. If motility is markedly reduced, as in transition from a normally moving to a motionless state, a preventive reduction of the sterol dosage should be considered, and plasma Ca and Pi levels should be evaluated closely.

Introduction of therapy with thiazide diuretics or anticonvulsants is another hypercalcemogenic intervention; these drugs reduce calciuria. The opposite is true of furosemide. A decrease in the glucocorticoid dosage also elevates calcemia, and an increase does the reverse.

I. INTRODUCTION

Although it makes up less than 1% of total-body calcium stores, extracellular calcium plays a critical role in mammalian physiology. This circulating divalent cation regulates cell membrane electrical potential, neurotransmitter release, renal function, and cardiovascular tone. Thus, maintenance of serum calcium levels in the normal range is a fundamental homeostatic mechanism. The task of maintaining circulating calcium levels in the normal range is the domain of the parathyroid glands. Elevation in calcium levels, as in hyperparathyroidism, impairs renal function and can affect other organ systems. Thus, proper recognition and treatment of hyperparathyroidism are essential.

II. THE PARATHYROID GLANDS

The parathyroid glands are paired structures located behind or within the superior and inferior aspects of the thyroid (1). In 84% of individuals, four parathyroid glands are present (1). The superior pair of glands is generally found 1 cm above the recurrent laryngeal nerve and inferior thyroidal arteries, behind the upper thyroid. The inferior glands are located behind the inferior poles of the thyroid. In 13% of individuals, a fifth gland is present in the region of the thymus (1). Each gland is small, measuring less than $6 \times 5 \times 2$ mm in adulthood (1).

The parathyroid glands are encapsulated by fibrous connective tissue (1). Within the glands, fibrovascular bundles divide the stroma into cordlike structures. Chief cells, of epithelial origin, are typically the only cell type recognized within the glands before puberty. After puberty, fat deposition occurs within the glands, and fat con-

tent may reach 10–50% of parathyroid cell mass in adults (2). Oxyphilic cells are rare in children and make up less than 5% of parathyroid tissue in adults (3).

Parathyroid gland embryogenesis occurs during early gestation (4). During gestational week (GW) 6, the dorsum of the third pharyngeal pouch differentiates into the inferior parathyroid glands. The ventral region of this pouch differentiates into the thymus. The thymic and parathyroid primordia are contiguous until GW 10, when the parathyroids separate from the thymus. The fourth pharyngeal pouch gives rise to the superior parathyroid glands. At GW 10, both pairs of glands come to lie on the dorsal surface of the thyroid gland, which completes its migration from the foramen cecum to the pretracheal region by GW 8 (4).

There may be excessive migration of both the superior and inferior parathyroid glands (1). Thus, the final resting location of each gland pair may be inferior to the normal position. The superior glands may migrate to the region of the lower thyroid, and the inferior glands may migrate below the suprasternal notch to within the thymus (1). Parathyroid tissue may also migrate to within thyroid tissue (5).

The factors involved in parathyroid gland formation and migration are unknown. Transgenic animal studies suggest that the homeobox gene *Hox-1.5* may be involved in parathyroid gland development. The selective deletion of *Hox-1.5* in mice results in abnormal differentiation of the third and fourth branchial arches and a phenotype similar to DiGeorge syndrome (parathyroid hypoplasia, cardiac abnormalities, and thymic hypoplasia) (6). In humans, sequences on 22 p11 appear to be essential for parathyroid gland development, since a deletion on this region classically results in the DiGeorge disease phenotype (7).

In X-linked recessive idiopathic hypoparathyroidism, genetic mapping has localized the gene defect region to

Xq 26–Xq 27 (8, 9). However, the specific genes involved have not been identified. Impaired parathyroid gland formation has also been associated with deletions of mitochondrial DNA (10).

Chief cells differentiate during the embryonic period and are functional during fetal life (4). Oxyphil cells do not differentiate until 6 years after birth (3). After birth, parathyroid hormone (PTH)-related peptide levels fall and PTH levels increase (11).

III. PARATHYROID HORMONE AND REGULATION OF ITS SECRETION

A gene on the short arm of chromosome 11 in humans encodes PTH (12, 13). A preprohormone of 115 amino acids is encoded, which is cleaved to an 84 amino acid peptide for secretion (14–16). The hormone is secreted by exocytosis of secretory vesicles. Intravesicular degradation of PTH may occur, and is reduced in the setting of chronic hypocalcemia as to maximize the bioactive intact PTH. PTH secretion is regulated largely by external calcium levels. At low calcium levels PTH secretion is stimulated, whereas PTH release is suppressed at high levels. In vivo and in vitro studies suggest that the ionized calcium concentration required to achieve half-maximal suppression of PTH secretion is 0.99 mmol/l (17, 18). In normal circumstances, circulating levels of intact PTH range between 10 and 65 pg/ml (19). During hypocalcemia, levels may rise fivefold (19). During hypercalcemia, levels are undetectable, or less than 10 pg/ml (19).

The mechanism by which extracellular calcium regulates PTH secretion involves a novel protein found on the parathyroid cell surface that senses ionized extracellular calcium levels. This calcium-sensing receptor (CaSR) has a long extracellular N-terminal moiety where calcium binds in a molecular pocket (17). The receptor is related to the metabotropic glutamate receptors found in the central nervous system (CNS), has seven transmembrane-spanning regions, and an intracellular C-terminal tail that is important for signal transduction via G-proteins. The CaSR is found in the parathyroid glands, kidney, brain, bone, and other sites (20). When activated by binding calcium atoms, the CaSR signals the parathyroid glands to inhibit PTH secretion. As the concentration of ionized calcium declines, CaSR occupancy is reduced, and PTH secretion is restored. Activating mutations in the CaSR result in autosomal dominant hypocalcemia (21, 22). In contrast, inactivating mutations of the CaSR result in familial hypocalciuric hypercalcemia (FHH) in the heterozygous form and severe neonatal hyperparathyroidism in the homozygous state (see below) (21, 22).

Hypomagnesemia may also stimulate PTH secretion, presumably related to the affinity of the CaSR for magnesium (23). However, when magnesium levels drop below 1.5 mg/dl, PTH secretion may be impaired (23). Hyperphosphatemia may also increase PTH secretion. In many clinical situations this is secondary to phosphate-

induced suppression of calcium levels (24). However, ambient phosphate levels have been shown to regulate parathyroid secretion when calcium levels are fixed (25). This effect may play a role in the development of secondary hyperparathyroidism in chronic renal failure, when serum calcium levels may not be decreased (25).

The vitamin D metabolite, 1,25-dihydroxy vitamin D, can also directly inhibit PTH secretion, and decrease the abundance of PTH message (26). 24,25 dihydroxy vitamin D has also been shown to inhibit PTH secretion and reduce parathyroid gland mass (27). Thus, these compounds are useful in preventing and treating secondary hyperparathyroidism.

IV. ASSAYS FOR PARATHYROID HORMONE

A variety of assays for PTH are available. Two-site assays detect intact PTH (1–84) utilizing a distinct antibody to the C-terminus to capture the molecule to a solid phase, and then a specific amino-terminus directed antibody coupled to a radioisotope or chemiluminescent moiety, which serves as the detection signal (28, 29). These assays are useful in settings in which clearance of PTH fragments is impaired, such as in renal failure.

In comparison with two-site assays, assays directed to the midmolecule fragment may detect hyperparathyroidism before PTH elevations are evident using the two-site assay (30). We have also used specific radioimmunoassays with antibodies directed toward the N-terminus of the molecule, but have found that the available N-terminal assay is less discriminatory than late midmolecule assays. Thus, measurement of PTH levels using two-site and midmolecule assays may be needed if PTH levels obtained using one assay do not fit with the clinical picture.

Another useful tool for assessing PTH activity is the measurement of nephrogenous cAMP (31). This assay involves measurement of cAMP and creatinine levels in a 2 h urine collection and measurement of plasma cAMP and creatinine levels at the midpoint of the urine collection (31). The calculated urinary cAMP excretion, corrected for the filtered plasma component, represents the cAMP generated by the kidney and is an excellent index of PTH bioactivity at the kidney.

Evidence of excess PTH activity may also be associated with radiographic evidence of bone resorption, particularly at the tips of phalanges, and at the clavicle (32, 33). However, such changes are apparent after long-standing hyperparathyroidism and provide only a gross estimate of PTH action.

V. PTH/PTHrP RECEPTORS

Parathyroid hormone exerts its many of its biological effects via specific cell surface receptors. The identification of a family of parathyroid hormone receptor has enhanced the understanding of PTH action (34, 35). The first-iden-

tified PTH/PTHrP receptor is a monomeric protein of 585 amino acids, with seven transmembrane spanning domains, and has affinity for both PTH and PTHrP. The receptor couples with guanine nucleotide-binding proteins (G proteins). Receptor occupation activates adenylate cyclase, leading to intracellular cAMP accumulation and subsequent activation of protein kinase A. Receptor activation stimulates the protein kinase C pathway as well, activating the membrane phospholipase C, which leads to intracellular accumulation of inositol phosphates and diacylglycerol and increases in intracellular calcium (34, 35).

At least two other members of this family have been subsequently identified, including the PTH-2 receptor, which has much greater affinity for PTH, does not significantly bind PTHrP, and may serve as a receptor for a novel ligand in the hypothalamus (34, 35). A third receptor appears to be a specific receptor for PTHrP, with little affinity for PTH (35).

Activating mutations of the PTH/PTHrP receptor results in Jansen's metaphyseal chondrodysplasia demonstrating a critical role for PTH in metaphyseal development (36). In contrast, the absence of functional PTH/PTHrP receptors is seen in Blomstrand chondrodysplasia (37).

VI. MECHANISM OF PARATHYROID HORMONE ACTION

PTH is a major regulator of calcium metabolism and acts on kidney, bone, and the intestine to increase the net flow of calcium into the extracellular fluid space. In the adult, approximately 15 mg/kg calcium is ingested and 12 mg/kg is excreted in the feces, yielding net calcium absorption of 3 mg/kg/day (38). The absorbed calcium is either deposited in the skeleton or excreted in the urine. At calcium intakes above 10 mg/kg/day, net calcium absorption increases only slightly (38).

PTH acts on the kidneys to effect renal tubular reabsorption of calcium (39). The kidneys filter about 8000 mg calcium/m² each day (38, 40). The vast amount of filtered calcium is reabsorbed, with only about 5% eliminated in the urine (150–250 mg/m²/day) (41, 42). During hypercalcemia, urinary calcium excretion may increase more than fourfold, whereas excretion falls during hypocalcemia (41). About 60% of filtered calcium is reabsorbed in the proximal tubule. The remaining calcium is reabsorbed by the loop of Henle or distal tubules, where PTH-stimulated calcium reabsorption acts to maintain serum calcium levels in the normal range.

While promoting calcium reabsorption, PTH induces renal phosphate wasting. Thus, following PTH-induced bone dissolution, calcium returns to the circulation and phosphate is excreted in the urine. The effects of PTH on renal phosphate handling occur primarily at the proximal tubule (43). PTH also influences the tubular reabsorption of bicarbonate, glucose, and amino acids. Bicarbonate,

glucose, and amino acid wasting may attend hyperparathyroidism, resulting in a clinical picture similar to renal tubular acidosis or Fanconi's syndrome (43–45). During hypoparathyroidism, there can be excessive bicarbonate reabsorption, which may result in metabolic alkalosis (43, 45). PTH also stimulates activity of the renal enzyme 25-hydroxyvitamin D-1-alpha-hydroxylase, promoting formation of 1,25-dihydroxyvitamin D (calcitriol) (46) (47). Calcitriol is the most potent vitamin D metabolite with respect to the effect of intestinal transport of calcium (48).

Mechanisms of PTH action on bone are complex (49). Following peripheral injection of PTH, osteoclast proliferation and activity are induced leading to bone dissolution and calcium and phosphate release (50). These effects occur more than 12 h after PTH administration and do not acutely influence calcium levels. These effects are thought to be mediated by a direct effect on osteoblasts, which trigger release of cytokines and other factors that influence bone-resorbing osteoclasts. One recently identified factor that mediates PTH-induced osteoblast stimulation of osteoclast differentiation and action is RANKL, or the osteoprotegerin ligand (50). A pool of rapidly exchangeable bone calcium is thought to mediate the acute effects of PTH on endosteal bone cells. Activation of these cells induces calcium release from bone within a few hours (51).

In contrast to the well-known PTH stimulation of bone resorption, recent data demonstrate an anabolic effect of PTH on bone when administered intermittently (52, 53). These data further indicate that the osteoblast is a primary target of PTH, and emphasized a potential role for PTH as a therapy for osteoporosis.

VII. PATHOGENESIS OF HYPERPARATHYROIDISM

Hyperparathyroidism occurs when PTH is released independently of calcium levels or the so-called set point for calcium-induced suppression of PTH secretion is elevated (18, 54). Hyperparathyroidism is typically a disease of adulthood, presenting between 40 and 60 years of age (55). It is more common in women than in men, and the incidence in the population is between 0.05 and 0.5%. Of individuals with hyperparathyroidism, 85% have parathyroid adenomas (56). The remaining 15% have diffuse parathyroid hyperplasia.

Over the past several years, there have been important advances in our understanding of hyperparathyroidism. Recent data suggest that parathyroid adenomas result from the clonal expansion of individual parathyroid cell lines (57). In some individuals a candidate oncogene (PRDAI: Cylin D1) is abnormally rearranged within the PTH locus (11q13) (58). This gene encodes a 295 amino acid cyclin protein, which may be important in cell cycle regulation (58). It has been postulated that the overexpression of PRAD I plays a role in the development of parathyroid adenomas (58). Abnormalities of the retinoblastoma gene

were also recently found in parathyroid adenomas (59). In contrast to PPAD1, mutations in the tumor-suppressor genes RAD51 and RAD54 have not been detected in parathyroid adenomas. Likewise, mutations in the CaSR gene have not been identified in sporadic adenomas. On the other hand, loss of heterozygosity in the MEN1 region on chromosome 11q13 has been found in 30% of sporadic parathyroid tumors (60).

In contrast to adenomas, the pathogenesis of parathyroid hyperplasia may involve different mechanisms. Diffuse hyperplasia of the parathyroid glands may occur following longstanding stimulation of parathyroid activity in response to hypocalcemia. Individuals with chronic hyperphosphatemia from renal failure or exogenous phosphate administration may develop secondary hyperparathyroidism. Over time the calcium concentration needed to suppress PTH secretion gradually increases, leading to a new steady state in which the serum calcium is maintained at a higher level (18, 61). Ionized calcium concentrations of 1.1–1.4 mmol/l may be needed to achieve half-maximal suppression of PTH secretion (normal = 0.99 mmol/l). Eventually, PTH secretion may not be suppressible even by high circulating levels of calcium. Supporting this hypothesis, individuals with tertiary hyperparathyroidism may show a spectrum of evolving parathyroid dysfunction. For example, in one of our patients with multiglandular hyperplasia, the set points for PTH suppression of three distinct glands were 1.1, 1.4, and 1.6 mmol/l, respectively. In the fourth gland, PTH secretion was not suppressible even by high calcium levels (61).

VIII. DIFFERENTIAL DIAGNOSIS

Hyperparathyroidism is rare in children. Thus, other causes should be sought in the hypercalcemic child. The differential diagnosis is extensive, and several specific causes of hypercalcemia are listed here.

In the newborn period, William's syndrome, must be considered (62, 63). These individuals may have hypercalcemia but do not usually have hypophosphatemia. The hypercalcemia usually resolves by the time the child is 1 year of age and is very rarely evident after the fourth year. Affected children may be small for gestational age and have a characteristic facial appearance and supravalvular aortic stenosis. William's syndrome is due to a deletion of the elastin gene locus on chromosome 7 (64). Parathyroid hormone levels are usually suppressed in this disorder, although we have encountered two infants with William's syndrome, proven by FISH analysis of the elastin locus, who have elevated circulating levels of PTH.

It is also important to differentiate FHH from hyperparathyroidism. FHH is characterized by the combination of hypercalcemia and relative hypocalciuria (65, 66). Individuals with FHH do not require parathyroidectomy and almost always have a benign course. FHH is caused by an inactivating mutation of CaSR (21, 67). Thus, PTH

levels are usually in the upper range of normal, or are modestly elevated. Serum calcium levels usually range between 10 and 12 mg/dl. Because the CaSR is expressed in the kidney, renal calcium reabsorption is also increased. The generous PTH levels augment renal calcium reabsorption, contributing to hypocalciuria. By examining renal calcium excretion, it may be possible to differentiate FHH from hyperparathyroidism, since more than 99% of filtered calcium is reabsorbed in FHH, whereas renal calcium reabsorption is generally less than that in hyperparathyroidism. However the differentiation between FHH and hyperparathyroidism may not be straightforward. A family history also aids in the diagnosis of FHH. A parent is often found to have the biochemical features of FHH, reflecting the characteristic autosomal dominant mode of inheritance.

Vitamin D intoxication may induce hypercalcemia at dosages more than 100 times the physiological requirement (68). Excessive vitamin D fortification of dairy milk (up to 10,000 u/l; normal 400 u/l) has led to epidemic hypercalcemia (68). Excessive vitamin D supplementation of infant formulas has been described (69). During vitamin D intoxication PTH levels are suppressed and serum phosphate values are normal or modestly elevated.

We have also cared for low-birth-weight infants with hypercalcemia due to unregulated intestinal calcium absorption when placed on breast milk fortifiers. The high calcium load of the supplements plays a large role in this condition. With advancing age intestinal calcium absorption declines, and the tendency for hypercalcemia falls.

Other causes of hypercalcemia include subcutaneous fat necrosis, in which elevated circulating levels of 1,25 dihydroxyvitamin D have been described. Immobilization, vitamin A intoxication, malignancy, granulomatous disease (including cat-scratch fever), and thiazide diuretic therapy should be considered in the differential diagnosis of hypercalcemia in a child.

IX. RECOGNITION AND DIAGNOSIS

Recognition of hyperparathyroidism in its early stages is important because longstanding hypercalcemia may adversely affect several organ systems. The combination of hypercalcemia, hypophosphatemia, and phosphaturia suggests hyperparathyroidism. However, in some individuals calcium elevations may be episodic (70). In individuals with hyperphosphatemia, or those receiving phosphate therapy, hypercalcemia may also be masked (61).

The tubular reabsorption of phosphate (TRP; $[1 - \text{Up} \times \text{SCr} / \text{UCr} \times \text{SP}] \times 100\%$) is normally greater than 85%. During parathyroid hormone excess, the TRP may fall to as low as 50%. However, in up to 40% of individuals with hyperparathyroidism, hypophosphatemia may not be present and the TRP is normal (56).

The urinary excretion of calcium is a function of the filtered calcium (which is proportional to the serum

calcium level) and the reabsorbed calcium (enhanced by PTH at the distal tubule). Thus, the fractional excretion of calcium is reduced when hyperparathyroidism is present. To assess renal calcium handling, so-called spot urine samples that calcium/creatinine concentration ratios are convenient, eliminating the need for 24 h urine collections, which are often difficult to obtain in young children.

In normal children over 4 years of age, urinary calcium excretion is approximately 2 mg/kg/day, and hypercalciuria is defined as excretion of levels >4 mg/kg/day (38, 40). Over the 24 h day, 10–20 mg/kg creatinine is excreted in the urine. Thus, in children over 4 years of age, the urinary calcium–creatinine ratio is normally less than 0.1 (mg/mg), with a ratio >0.2 defined as hypercalciuria. Urinary calcium excretion is relatively high in infancy. Thus, urinary calcium/creatinine ratios are higher than in older children and range between 0.2 and 0.7 (71, 72).

If suspected, hyperparathyroidism should be confirmed by measurement of circulating PTH levels. If PTH levels are normal when measured using two-site intact PTH assays, measurement of PTH levels by midmolecule should also be performed when the diagnosis remains a possibility.

X. PRIMARY HYPERPARATHYROIDISM

Fewer than 100 cases of isolated primary hyperparathyroidism have been reported in children (73–78). Both parathyroid adenomas and multiglandular hyperplasia have been described. It is postulated that primary hyperparathyroidism in children represents early presentation of the sporadic form of hyperparathyroidism that typically affects adults. No clear pattern of inheritance is generally found; although several kindreds have been reported in whom primary hyperparathyroidism affects several generations (79).

Hypercalcemia is usually not an indication for a parathyroidectomy in FHH, when one mutant copy of the CaSR is present. However, severe neonatal hyperparathyroidism occurs within FHH kindreds in individuals homozygous for mutations of the CaSR (22, 80, 81). In affected individuals, severe hyperparathyroidism presents within the first few days of life, with serum calcium levels as high as 15–30 mg/dl. The serum phosphate level is usually low, and the serum PTH level is elevated. Nephrocalcinosis may be present, reflecting intrauterine hypercalcemia. This is a life-threatening condition that requires emergency extirpation of the parathyroid glands.

Hyperparathyroidism may also be a feature of the inherited multiple endocrine neoplasia syndromes, MEN I and MEN II, which are autosomal dominant disorders (82, 83). Hyperparathyroidism is the most common presenting feature of MEN I (97% of cases), which is also associated with tumors of the pancreas (40%) and pituitary (20%). Hyperparathyroidism may occur in 20% of cases of MEN

IIa (84, 85), which is associated with medullary carcinoma of the thyroid and pheochromocytoma. Hyperparathyroidism typically presents during adulthood, although cases have been reported in children. MEN IIb (MEN III) is not associated with primary hyperparathyroidism, although both MEN IIa and MEN IIb are caused by mutations in different domains of the rearranged during transfection (RET) proto-oncogene (86, 87).

Radiation exposure may be associated with the development of hyperparathyroidism. An increased incidence of hyperparathyroidism has been reported in adult survivors of the Hiroshima atomic blast (88). It has been suggested that the incidence of hyperparathyroidism is greater three decades after head and neck radiotherapy (89, 90). Hyperparathyroidism has also been reported in a few patients treated with radioiodine for Graves' disease (91, 92), however, with no greater frequency than that observed in the normal population (93). Primary hyperparathyroidism has been described in one infant with congenital hypothyroidism (76).

Carcinoma of the parathyroid glands can present with biochemical features similar to those of primary hyperparathyroidism. Although there are very few reports of parathyroid carcinoma in children (94), parathyroid carcinoma has been reported in adolescents with familial hyperparathyroidism (95, 96).

XI. SECONDARY AND TERTIARY HYPERPARATHYROIDISM

Secondary and tertiary hyperparathyroidism are often seen in hypocalcemic and/or hyperphosphatemic states, such as vitamin D deficiency. An appropriate response to hypocalcemia (secondary hyperparathyroidism) may evolve into autonomous PTH secretion (tertiary hyperparathyroidism) following prolonged hypocalcemic stimulation of parathyroid gland activity.

In the newborn period secondary hyperparathyroidism may be seen in children born to hypocalcemic mothers. This typically resolves within several months of birth (97, 98). We have cared for infants with transient hyperparathyroidism whose mothers did not have hypocalcemia; hypercalcemia resolved by 3 months of age.

Secondary hyperparathyroidism is a classic feature of moderate to severe vitamin D-deficient rickets. Diffuse parathyroid hyperplasia has been described in these patients (99) and progression to tertiary hyperparathyroidism may occur in the setting of chronic disease. Efforts should be taken place to prevent this progression since severe parathyroid hyperplasia may not be reversible and surgical extirpation of the parathyroid glands required (61).

Chronic elevation of serum phosphate levels may be the most common cause of secondary hyperparathyroidism in children. The inability of the kidneys to excrete phosphate accounts for this phenomena (100, 101). This scenario is especially troublesome for a skeletal system

already at risk for metabolic bone disease. Thus, parathyroid function should be routinely monitored during chronic renal failure, and parathyroidectomy is needed in the setting of irreversible hyperparathyroidism (101–103).

The regulation of parathyroid hormone secretion in X-linked hypophosphatemic rickets (XLH) is complex. Although earlier descriptions of the disorder suggest that circulating levels of PTH are normal prior to the initiation of therapy (104), we have found that many patients with XLH have elevated PTH levels prior to treatment. The recent demonstration that PHEX (the mutated gene in XLH) is expressed in parathyroid glands (105) raises the possibility that disordered regulation of PTH secretion may be part of the XLH phenotype. Phosphate therapy exacerbates the propensity of the parathyroid glands to secrete PTH in patients with XLH, even in the absence of hyperphosphatemia or hypocalcemia. Furthermore, this secondary hyperparathyroidism is a very frequent feature of phosphate-treated patients and may evolve into tertiary hyperparathyroidism. Hyperparathyroidism in XLH is seen more commonly when dosages of phosphate exceed 4 g/day elemental phosphorus (there are about 0.25 g of elemental phosphorus per g of phosphate). Secondary hyperparathyroidism also occurs when lower dosages of phosphorous are used without sufficient calcitriol (61, 106). Thus, phosphate should not be used as solitary treatment of XLH.

Routine measurement of PTH levels in individuals with XLH is an important aspect of disease management, and is critical for making appropriate dosage adjustments in a timely manner. Adjunctive therapy with 24,25 dihydroxyvitamin D also mitigates secondary hyperparathyroidism in XLH and improves skeletal mineralization (27). Thus, improvement in parathyroid status may improve the long-term skeletal outcome of the disease.

XII. COMPLICATIONS OF HYPERPARATHYROIDISM AND HYPERCALCEMIA

The adverse effects of hyperparathyroidism are related to excessive bone resorption and hypercalcemia. Excessive PTH activity leads to loss of skeletal mineral content, microarchitectural defects, and osteopenia (107). In adults with hyperparathyroidism, demineralization may be recognized on standard radiographs (56). Dual-energy x-ray absorptiometry is a much more sensitive means of detecting these changes (108).

Hyperparathyroidism affects the kidneys in several ways. Hypercalcemia can directly reduce the glomerular filtration rate. Longstanding hypercalcemia may lead to deposition of calcium in the tubules, especially during hyperphosphatemia, resulting in nephrocalcinosis (109, 110). Nephrocalcinosis can be detected by ultrasound, which should be performed in individuals with hyperparathyroidism (111). Nephrolithiasis is well described in adults

with hyperparathyroidism (56), yet is unusual in children with hyperparathyroidism. Calcium levels in excess of 15 mg/dl also may result in polyuria secondary to nephrogenic diabetes insipidus.

Hypercalcemia also affects other systems. Hypercalcemia may induce increased cardiovascular tone and hypertension (112). High calcium levels may lead to heart block and shortening of the ST segment (112). The central nervous system is also sensitive to the effects of calcium at high levels (113). Impaired mentation and convulsions may occur at levels above 15 mg/dl (113). Muscle weakness and hyporeflexia may occur (114). Gastric ulcers and constipation may reflect hypercalcemia (115). Anorexia may attend hypercalcemia.

Patients are at increased risk for pancreatitis (116, 117). We have recently cared for a child who presented with recurrent pancreatitis associated with hypercalcemia (11–12 mg/dl) secondary to a parathyroid adenoma.

XIII. TREATMENT OF HYPERPARATHYROIDISM AND HYPERCALCEMIA

Acute therapy of hypercalcemia is indicated for symptomatic individuals or when the total calcium exceeds 13 mg/dl (56, 118, 119). Treatment with intravenous saline (3000 ml/m²/day; 200–400 ml/kg/day) and furosemide (1 mg/kg every 4–6 h) lowers calcium levels within hours (120). After correction of acute hypercalcemia, a high-sodium diet promotes continued renal calcium excretion. Oral furosemide therapy (1–2 mg/kg/day divided in two or three divided doses) may be of benefit.

Adjunctive therapy with prednisone is usually not effective management of hypercalcemia due to hyperparathyroidism (44). Calcitonin may initially lower serum calcium levels, but patients often become refractory to the medication after several dosages. Bisphosphonates, which inhibit bone resorption, can be used to manage severe hypercalcemia over the short term, but are not recommended as a definitive treatment. Oral or intravenous phosphate therapy can lower circulating calcium levels (56), but leads to precipitation of calcium and phosphate salts in the vascular system and kidneys and is no longer recommended.

Calcimimetic agents that act to inhibit PTH secretion by activating CaSR hold promise as a therapy for parathyroid hyperplasia (121). They are not yet available for widespread clinical use to treat hypercalcemia of any cause. Selective ablation of parathyroid glands by embolization has been shown to be effective only for some ectopic parathyroid glands (122).

Surgery is the definitive cure for hyperparathyroidism. If isolated adenomas are detected, these should be removed. In the setting of multigland parathyroid hyperplasia, our usual approach is to remove three and one-half or four glands. In adults, treatment of the asymptomatic

patient with hyperparathyroidism has been the subject of debate (123, 124). Surgery is recommended for asymptomatic individuals with evidence of demineralization, nephrolithiasis, or nephrocalcinosis (118, 119, 123, 124). However, observation may be recommended for individuals without evidence of complications, as long as renal function, bone density, and gastrointestinal status is assessed regularly (118, 119, 123, 125, 126).

Prolonged observation is generally not recommended for children with hyperparathyroidism. Given the longevity of the course in children, progressive skeletal mineral loss, and potential consequences of exposure of the kidneys to long-term hypercalcemia, we choose prompt surgery for patients in this age group.

Preoperative localization of hyperactive parathyroid tissue is a challenging undertaking (118, 119). High-resolution ultrasonography, computed axial tomography, magnetic resonance imaging, and radionuclide scanning have been used to localize parathyroid tissue (127–130). Increasingly we are impressed with the ability of high-resolution Doppler ultrasound to localize parathyroid adenomas. Arteriography and selective venous sampling have been used to localize abnormal parathyroid tissue (131), but successes with this technique are highly variable.

Rapid PTH assays in the intraoperative setting are a new and important means for localizing hyperfunctioning parathyroid tissue (132, 133). The surgeon is able to monitor acutely the effects of gland removal and can be reassured regarding the removal of the abnormal tissue. After removal of the pathological parathyroid gland(s), PTH levels will promptly fall. If PTH levels do not fall after a gland is removed, additional parathyroid tissue must be identified and resected.

XIV. MANAGEMENT AFTER PARATHYROIDECTOMY

After successful resection of hyperactive parathyroid tissue, serum calcium levels may rapidly fall. Intraoperatively, a Chevostek's sign may be elicited by tapping over the facial nerve in the temporal–mandibular region in hypocalcemic patients. Laryngospasm may occur.

Management of postoperative hypocalcemia may require intravenous infusions of calcium if symptoms are present or hypocalcemia is severe. Our usual goal is to maintain serum calcium in the lower range of normal using 30–50 mg/kg/day elemental calcium. When a subtotal parathyroidectomy is performed, the remaining parathyroid tissue that was previously suppressed by hypercalcemia will become functional within 30 h after surgery (134). Thus, calcium levels usually stabilize within 48 h after surgery. If hypocalcemia persists beyond the second postoperative day, oral calcitriol therapy should be started (0.025–0.5 μ g twice per day). This potent vitamin D metabolite has a rapid onset of action and increases intestinal

calcium absorption. The dosage may be advanced until serum calcium levels stabilize. When serum calcium levels are stable and intravenous therapy is no longer needed, the calcitriol dosage can be gradually reduced.

Adequate dietary calcium must also be provided for calcitriol to increase calcium levels. Thus, oral calcium supplementation is useful in this setting, since few children and adolescents have adequate dietary calcium intake. We provide up to 1g elemental calcium per day, divided in three doses. Care should also be taken to avoid hypercalcemia during vitamin D therapy, because single episodes of hypercalcemia can induce permanent renal damage in children.

If the serum magnesium concentration is low (<1.5 mg/dl), the function of any residual parathyroid tissue may be compromised. In this event, supplemental magnesium should be given.

Hyperphosphatemia may also occur after parathyroidectomy. This is usually transient and spontaneously corrects with normalization of the serum calcium. If hypocalcemia and hyperphosphatemia persist, lowering serum phosphate levels will allow the serum calcium to rise. This can be accomplished by administering oral calcium or aluminum-based antacids.

If intravenous calcium infusions are needed, they can usually be discontinued shortly after surgery (134). However, individuals with significant skeletal demineralization are at risk for so-called hungry bone syndrome and may require prolonged intravenous infusion of calcium (135). The growing child with hyperparathyroidism and metabolic bone disease is at increased risk for development of hungry bone syndrome.

We have cared for two adolescent girls with XLH who required intravenous calcium infusion for 3 months after total parathyroidectomy to prevent symptomatic hypocalcemia (61). Preoperatively, gross demineralization was noted in radiographs of the hands. To facilitate discharge from the hospital, indwelling central venous catheters were placed, allowing infusions at home. After 45 days, it was possible to administer calcium during the night, allowing schooling during the day. Following the appearance of urinary calcium (calcium/creatinine ratio >0.02), it was possible to stop intravenous therapy within a few weeks.

XV. SUMMARY

Childhood primary hyperparathyroidism is a rare disorder that may present in an extremely severe form in neonates, sporadically in children, or as part of MEN syndromes. Secondary and tertiary hyperparathyroidism may occur in children with chronic hypocalcemia such as in vitamin D deficiency, or in renal disease, accompanied by hyperphosphatemia. Another condition that results in secondary hyperparathyroidism is X-linked hypophosphatemic rickets. The constellation of hypercalcemia, hypophosphatemia,

temia, and renal phosphate wasting suggests PTH excess. By measuring PTH levels, hyperparathyroidism can be diagnosed, but requires careful differentiation from FHH. Long-term hyperparathyroidism is likely to lead to skeletal demineralization and renal damage. Thus, surgery is usually indicated for pediatric patients with hyperparathyroidism rather than observation. Children with demineralization and bone disease may be at risk for hungry bone syndrome postoperatively. The child with significant chronic hypocalcemia following parathyroidectomy is best managed with calcitriol and provision of adequate oral calcium.

Neonatal Calcium and Phosphorus Disorders

Winston W. K. Koo

Wayne State University, Detroit, Michigan, U.S.A.

I. INTRODUCTION

The maintenance of calcium (Ca) and phosphorus (P) homeostasis requires a complex interaction of hormonal and nonhormonal factors; adequate functioning of various body systems, in particular, the renal, gastrointestinal, and skeletal systems; and adequate dietary intake. From a clinical perspective, this is reflected in the maintenance of circulating concentrations of Ca and P in the normal range and integrity of the skeleton. In the circulation, the amount of Ca and P constitutes less than 1% of the total body content; however, disturbances in serum concentrations of Ca and P are associated with disturbances of physiological function manifested by numerous clinical symptoms and signs. The skeleton, in contrast, is the major reservoir for Ca (the most abundant mineral in the body) and for P, which together with Ca forms the major inorganic constituent of bone. At all ages, 99% of total body Ca is in the skeleton as is about 89% of the total body P. Thus, the skeleton has the dual function of providing both structural and mechanical support and being a reservoir for mineral homeostasis. Disturbances in Ca and P homeostasis result in osteopenia and rickets in infants and children, and osteomalacia and osteoporosis in adults.

Mechanisms to maintain Ca and P homeostasis in the neonate are the same as for children and adults. However, the newborn infant has a number of unique challenges to maintain Ca and P homeostasis during adaptation to extrauterine life and to continue the rapid rate of growth. These include an abrupt discontinuation of high rate of intrauterine accretion of Ca (>120 mg/kg/day) and P (>70 mg/kg/day) during the third trimester, a smaller skeletal reservoir available for mineral homeostasis, high requirement for Ca and P for the most rapid period of postnatal growth with an average gain in length of >25 cm during the first year, and delay in establishment of adequate nutrient intake for at least a few days after birth. There also

may be diminished end-organ responsiveness to hormonal regulation of Ca and P homeostasis at least during the first days after birth, although the functional capacity of the gut and kidney for Ca and P absorption and retention improves rapidly within days after birth. These issues are exaggerated in infants with heritable disorders of mineral metabolism such as extracellular calcium-sensing receptor mutations, and in infants experiencing adverse prenatal event such as maternal diabetes, intrapartum problems such as perinatal asphyxia, or postpartum complications such as multiple immature organ function with premature birth. In any case, it is important to review the physiology and molecular basis of mineral metabolism to allow a better understanding of the pathophysiology of clinical disorder. This in turn allows a more rational approach in the management of the neonate to minimize iatrogenic causes and the adverse impact of disorders of mineral homeostasis.

II. MAINTENANCE OF CALCIUM AND PHOSPHORUS HOMEOSTASIS

A. Circulating Calcium Concentrations

Serum Ca is found in three forms: approximately 40% is bound predominantly to albumin, approximately 10% is chelated and complexed to small molecules, and approximately 50% is ionized; complexed and ionized Ca are ultrafiltrable. Fetal circulating calcium concentrations as reflected in cord sera are higher than maternal concentrations and are indicative of active placental transfer. Cord serum total calcium concentrations (tCa) increase with increasing gestational age. Serum tCa may be as high as 3 mmol/l (conversion 1 mmol/l = 4 mg/dl) in cord blood from infants born at term, and they are significantly higher than paired maternal values at delivery (1–4). Serum tCa reaches a nadir during the first 2 days after birth (5–8); thereafter, it increases and stabilizes generally above 2.0

mmol/l (8 mg/dl). In infants exclusively fed human milk, the mean serum tCa increases from 2.3 to 2.7 mmol/l (9.2 to 10.8 mg/dl) over the first 6 months postnatally (9). Serum tCa in infants and children generally remains slightly higher than adult values (9–11). Normally, serum tCa in children and adults remains stable, with a diurnal range of <0.13 mmol/l (0.5 mg/dl) (12). During the third trimester of pregnancy a modest reduction in maternal serum tCa concentration (average 0.1 mmol/l, 0.4 mg/dl) occurs concomitant with a decrease in serum albumin concentration (13).

Serum ionized calcium concentration (iCa) is the best indicator of physiological blood Ca activity (14). Measurement of serum iCa is firmly established in clinical medicine, and the availability of highly reliable iCa analyzers allows simple, rapid, and direct determination of iCa in whole blood, plasma, and serum by ion-selective electrodes. Some differences exist in the reported values for circulating iCa as a result of differences in the design of the reference electrode, formulation of calibrating solutions, and the lack of a reference system for iCa (15,16). Serum iCa also decreases in the presence of high serum albumin (17), magnesium (Mg) (18), phosphorus (P) (19), and bicarbonate levels (20). Clinical situations may affect iCa measurement. For example, the use of heparin may decrease iCa, and iCa is inversely related to blood pH (21). The effect of the latter may be minimized by the immediate analysis of the serum samples for iCa. Freezing serum samples in 5% CO₂-containing tubes may minimize the impact of pH variations if measurement of iCa is delayed for 1 week.

Normal serum iCa range from 1.0 to 1.5 mmol/l (conversion, 1 mmol/l = 4 mg/dl) in the neonate and from 1.18 to 1.32 mmol/l in adults (1,22,23). Cord serum iCa levels increase with gestational age and, similarly serum tCa are higher than paired maternal values (1,2,4,13). In term infants, serum iCa levels average 1.25 mmol/l with 95% confidence limits of 1.1–1.4 mmol/l (4.4–5.6 mg/dl) and there is a decline in serum iCa in the first 48 h of life with a nadir at 24 h (24). Serum tCa and iCa levels are correlated in infants (7,24) and adults (23) but is inadequate to predict one from the other with sufficient accuracy. Serum iCa levels remain generally slightly higher in infants and children than in adults (11). In adults, a circadian rhythm for serum iCa has been reported, with a peak occurring at 10:00 a.m.; the maximal change between peak and trough values is small, averaging 0.08 mmol/l (0.32 mg/dl) (12). Serum iCa levels are stable and normal during pregnancy (2,4,13).

The concentration of iCa is critical to many important biological functions, and there is a finely tuned regulation of extracellular iCa and maintenance of an extremely large iCa concentration gradient across the plasma membrane. In the cell, distribution of Ca is not uniform. The cytosolic compartment contains 50–150 nmol Ca/liter water; a larger intramitochondrial Ca pool contains 500–10,000

nmol Ca/liter cell water. In contrast, extracellular fluid iCa levels are 1 million nM (1 mmol/l). At least two adenosine triphosphate (ATP)-dependent mechanisms are involved in the maintenance of the Ca concentration gradient across the plasma membrane. The Ca messenger system is a nearly universal means by which extracellular messengers regulate cell function (25). Cellular enzyme cascades are activated with a transient increase in intracellular iCa (26,27). The measurement of intracellular Ca is not freely available.

Ca concentration in the extracellular fluid is maintained relatively constant by the effects of interdependent hormonal mechanisms consisting of parathyroid hormone (PTH), 1,25-dihydroxyvitamin D [1,25(OH)₂D], and calcitonin (CT) that regulate the influx and efflux of Ca among extracellular fluid, bone, kidney, and gut. Other systemic and local factors also are important in influencing Ca flux, particularly under pathological conditions such as humoral hypercalcemia of malignancy (HHM), and their role in Ca homeostasis under physiological conditions is being studied.

The daily flux of Ca between bone fluid and extracellular fluid across the bone lining cells has been estimated to be as much as 12 mmol (500 mg). It is strongly related to systemic and local factors controlling bone formation and resorption (28–30). In growing infants, there is an extensive exchange of bone Ca with extracellular fluid (31).

The kidney is a major regulator of extracellular fluid Ca concentration, primarily by modulation of Ca excretion. Normally, 98% of the daily renal ultrafiltrate of Ca of about 125 mmol (5000 mg) is reabsorbed. Altered renal regulation of Ca excretion is primarily responsible for the development of some hypercalcemic states, including familial hypocalciuric hypercalcemia; it may also occur during chronic thiazide diuretic therapy. The renal capacity for acute regulation of extracellular fluid Ca concentration, however, may be overwhelmed when net Ca input into the extracellular fluid from the gut or bone exceeds the kidney's capacity for Ca excretion (32,33). The latter situation is exemplified best by hypercalcemia of malignancy. Conversely, in hypocalcemic states, the kidney cannot reduce Ca excretion sufficiently to prevent the occurrence of hypocalcemia.

The gut is important in chronic control of extracellular fluid Ca, primarily through regulation of dietary Ca absorption and the presence of hormonal stimulatory factors, including 1,25(OH)₂D (34,35). Gut hyperabsorption of Ca may be associated with hypercalciuria and nephrocalcinosis, but there is no major effect on the development of hypercalcemia (36,37). In the growing skeleton, appropriate dietary Ca intake is of great importance in Ca homeostasis and skeletal mineralization (38).

B. Circulating Phosphorus Concentrations

The total P in serum can be classified into an acid-insoluble fraction, comprising mainly phospholipids, and an acid-soluble fraction, comprising a small amount of or-

ganic ester phosphate and all of inorganic phosphate. Normally, more than 90% of the inorganic phosphate is diffusible.

There is also active placental transfer of P. Cord serum P concentrations at term ranges from 1.8 to 2.3 mmol/l (conversion, 1 mmol/l = 3.1 mg/dl). There are large variations in postnatal serum P concentrations. In most newborn infants there is a rise in serum P over the first 48 h after birth (2,4–6), probably unrelated to intestinal absorption of P because dietary P intake is limited at this age. Renal excretion of P is low and contributes to the maintenance of high serum P. Serum P concentrations are high during infancy (1.25–2.60 mmol/l, 3.9–8.0 mg/dl) compared with those in adults (0.9–1.5 mmol/l, 2.8–4.6 mg/dl) (39), and there is a rough correlation between the rate of skeletal growth and serum P concentration. In adults, serum P has a biphasic diurnal rhythm, with peaks in the afternoon and at 3:00 am; maximal change between peak and trough values is <0.4 mmol/l (1.2 mg/dl) (12). Serum P concentrations also fall by about 0.1 mmol/l (0.3 mg/dl) after a meal (40). During pregnancy, maternal serum P concentration remains stable (13).

In the cell, phosphate is the principal intracellular anion and is mostly in the form of organic phosphate. The intracellular inorganic phosphate is normally in equilibrium with both extracellular phosphate and intracellular glyceraldehyde-3-phosphate, an intermediate compound in the regeneration of ATP. The cellular phosphorus/nitrogen ratio is relatively constant. For example, it is 0.07 (by weight) in muscle, and gains or losses of nitrogen by the body are usually accompanied by corresponding gains or losses of extraosseous P (41). The relationship between potassium, the major intracellular cation, and P is more variable.

Maintenance of P concentration in the extracellular fluid requires the effects of interdependent hormonal mechanisms that regulate the influx and efflux of P among extracellular fluid, kidney, gut, and bone. In the growing infant, serum P often varies with the status of calcium homeostasis, in particular, from PTH activity; and to the amount of dietary P intake. The net effect of increased PTH activity is to decrease serum P since its phosphaturic effect is greater than its ability to increase the mobilization of bone P, and to increase gut absorption of P.

Renal function in the neonate is well known to affect serum P concentrations. Renal excretion of P is low in the immediate newborn period and probably contributes to the high serum P. Renal capacity for P excretion can be overwhelmed by dietary P ingestion even in otherwise healthy neonates; for example, hyperphosphatemia in those fed cow-milk-based formulas (42). In contrast, hypophosphatemia can occur despite almost total reabsorption of P from the renal ultrafiltrate in infants, especially preterm infants receiving low P intake from human milk (43,44) or parenteral nutrition (45,46). In the growing infant, the gut absorbs dietary P with great efficiency and skeletal

turnover involves the release and deposit of P just as it does for Ca. There is a net influx of P from extracellular fluid to bone for mineralization and skeletal growth. Thus dietary P intake has a major role in P homeostasis and maintenance of appropriate skeletal mineralization (47).

III. HORMONAL CONTROL OF CALCIUM AND P HOMEOSTASIS VIA PTH, CT, AND 1,25(OH)₂D

PTH and 1,25(OH)₂D, and possibly CT, appear to maintain Ca and P homeostasis by intermodulation of their physiological effects on each other and on the classic target organs: kidney, intestine, and bone. PTH serves as the major component of rapid response to hypocalcemia, whereas 1,25(OH)₂D, with its major effect on elevating intestinal absorption of Ca, is responsible for a slower but more sustained contribution to the maintenance of normocalcemia. CT, on the other hand, appears to function in the opposite role to PTH but with the capacity to stimulate the production of 1,25(OH)₂D, which in theory may serve an additional regulatory role in the maintenance of Ca homeostasis. The direct action of PTH and CT results in a net decrease in serum P, whereas 1,25(OH)₂D increases serum P. Maintenance of serum Ca and P in turn are critical to the growing skeleton.

A. Parathyroid Hormone

Parathyroid hormone is synthesized in the chief cells of parathyroid gland. It is stored and secreted mainly as an 84-amino-acid polypeptide. In humans, the PTH gene, along with the genes for insulin, β -globulin, and CT, is located on chromosome 11p15, and restriction site polymorphisms near the PTH gene have been detected (48,49). The initial translational product of the mRNA is a 115-amino-acid prepro-PTH. Prepro-PTH then undergoes proteolytic cleavage in endoplasmic reticulum to remove the amino-terminal signal sequence to form pro-PTH. The prohormone-specific region is cleaved further during subsequent intracellular processing to generate the 84-amino-acid secreted form of the intact hormone. The PTH is stored in secretory granules and colocalized and secreted with chromogranin A, a protein that may act in autocrine or paracrine-regulated release of PTH.

About 50% of the newly generated PTH is also proteolytically degraded intracellularly and some of the inactive fragments also secreted (50). After release into the circulation, the intact PTH molecule has a serum half-life of 5–8 min and undergoes a series of cleavages by endopeptidases in the liver and kidney. The amino-terminal fragments contain the biologically active fractions, with the 1–34 fragment having the most calcemic activity; modifications at the amino terminal, particularly at the first two residuals, can abolish its biological activity. The mid-region and carboxyl-terminal fragments are biologically

inert, although the latter may have some *in vitro* biological activity.

Circulating immunoreactive PTH is a complex mixture of intact 1-84 PTH, N-terminal fragments and several inactive C-terminal peptides. The fragments are cleared principally by glomerular filtration and are present in greater concentration than the whole molecule because of their slower clearance rates. PTH molecules reactive in the widely used commercial immunoradiometric assays (IRMA) designed to detect both amino- and carboxy-terminal epitopes of the peptide have been considered as so-called intact IPTH assays. However, there have been reports that large 7-84 fragment of PTH is also detected by these assays. This large fragment is biologically inactive and present in greater concentrations in uremic state or hyperparathyroidism. It increases the PTH concentration by 30-50% using the conventional IPTH technique compared to the latest chemiluminescence or IRMA techniques that measures the so-called whole or bio-intact PTH (51,52). Therefore, the treatment of secondary hyperparathyroidism based on the data from conventional IPTH assays theoretically may lead to oversuppression of biologically active PTH, although the clinical significance of this possibility remains to be defined. In any case, consistency of the PTH assay methodology and serial measurements are critical to the interpretation and management of pathological states.

PTH concentrations in cord blood frequently are low and do not correlate with PTH concentrations in maternal sera (2,4,53). Earlier studies of higher levels of bioactive PTH in cord sera from cytochemical assay (54) may be related to elevated concentrations of parathyroid hormone-related protein (PTHrP) (3,4), since PTH-like bioactivity was tightly correlated with levels of PTHrP in the pig (55) and sheep (56). Small amounts (about 5%) of perfused fragments (34-84, 44-68, and 65-84 amino acids), but probably not the whole PTH molecule, have been reported to cross the human placenta (57). Serum IPTH concentrations increase postnatally coincident with the fall in serum Ca in both term and preterm infants (2,53,58-60). The rise in serum IPTH is greater for preterm infants with hypocalcemia than in term infants (2), reflecting appropriate PTH response. Serum PTH concentrations are similar for children and adults but increased in the elderly (61,62). Serum IPTH showed no change during normal pregnancy (2,4,63). In adults, serum IPTH is present in picomolar concentrations. It has a significant circadian periodicity (64-66), spontaneous episodic pulsatility with distinct peak property (64), and a significant temporal coupling with serum iCa and P (64,66,67) and prolactin secretion (65).

In physiological terms, PTH is the most important regulator of extracellular Ca concentration. PTH acts directly on bone and kidney, and indirectly on intestine. Immediate control of blood Ca is probably due to PTH influence on the mobilization of Ca from bone, probably

synergistically with 1,25(OH)₂D; and to increase renal distal tubular reabsorption of Ca. PTH increases acutely within minutes the rate of Ca release from bone into blood. Chronic effects of PTH are to increase the numbers of osteoblasts and osteoclasts and to increase the remodeling of bone. Continuous exposure to elevated levels of PTH leads to increased osteoclastic resorption of bone. Other PTH effects on bone include enhanced collagen synthesis, activities of alkaline phosphatase, ornithine and citrate decarboxylases, and glucose-6-phosphate dehydrogenase; DNA, protein, and phospholipid synthesis; and calcium and phosphate transport. Renal actions of PTH include the stimulation of sodium/calcium exchange and calcium transport channel, decrease reabsorption of sodium, phosphate (decrease in sodium dependent phosphate cotransporter, NPT-2) and bicarbonate, and stimulation of renal 25 OHD-1 α -hydroxylase (32,33,67-70). However, in severe phosphate deficiency or hypophosphatemia, there may be paradoxical resistance to PTH action at the renal tubule and clinically manifested as continued calciuria and without phosphaturia (43). Maintenance of steady-state calcium balance is probably from increased intestinal Ca absorption secondary to increased 1,25(OH)₂D production. There also may be a direct PTH effect on intestinal Ca absorption (71). In contrast to its classic action on Ca mobilization from bone, the amino terminal fragments of PTH and PTHrP, and small pulses of PTH, have an anabolic effect on bone independent of its resorptive action (72-74). Other tissues such as skin fibroblasts, cardiac cells, and vascular smooth muscle also have PTH-sensitive adenylate cyclase, but the physiological importance of PTH in these nonclassic target tissues is not well defined.

PTH's effects on end-organ systems appear to be mediated through its binding to specific receptors. The type 1 PTH receptor has been identified in bone and kidney. It binds equally to PTH and PTHrP, and belongs to a superfamily of guanine-nucleotide-binding (G) protein-coupled cell membrane receptors (GPCR) including those for CT, growth hormone-releasing hormone, corticotrophin-releasing hormone, glucagon, secretin, vasoactive intestinal polypeptide, and others (75). Another PTH receptor (type 2) responds only to PTH, although its main endogenous ligand appears to be a 39 amino acid peptide, hypothalamic tubular infundibular peptide (TIP-39) (76). It has been found in the brain, pancreas, and intestines but the physiological significance of this receptor remains ill defined. The gene for the PTH/PTHrP receptor is located on chromosome 3p21.1-P24.2. It contains 17 exons and encodes a mature glycoprotein of 593 amino acids (77). The type 1 PTH receptor consists of extended extracellular, ligand-binding amino-terminal, and intracellular G protein-associated carboxyl-terminal domains and seven transmembrane domains. Signal transduction mediated by G proteins results in multiple second messenger pathways to effect both stimulatory and inhibitory end-organ re-

sponses. The strongest and best-characterized second messenger signaling pathway is the PTH-stimulated coupling of the type 1 PTH receptor to G_s class protein (composed of three subunits; α , β and γ , and is encoded by *GNAS1* gene localized to 20q13.3), which activates adenylyl cyclase, an enzyme that generates cyclic AMP. Coupling of type 1 PTH receptor to the G_q class protein activates phospholipase C that generates inositol phosphate (IP₃) and diacylglycerol (DAG). These second messengers in turn lead to stimulation of protein kinases A and C and Ca transport channels and result in a variety of hormone-specific tissue responses.

PTH gene show separate sites for interaction and regulation by Ca and vitamin D. Extracellular Ca is the most potent regulator of PTH secretion and is mediated by the cell-surface Ca-sensing receptor (CaR), which detects minute perturbations in the extracellular iCa concentration and responds with alterations in cellular function that normalize iCa (78). The human CaR gene is located on chromosome 3q13.3-q21 and encodes a cell-surface protein of 1078 amino acids. The CaR gene is developmentally up-regulated (79), and CaR transcripts are present in numerous tissues including chief cells of the parathyroid glands, kidneys (in particular the thick ascending limb), brain, and nerve terminals, and also the intestine, lung, and skin (78,80). It is a member of GPCR superfamily and contains at least seven exons of which six encode the large (–600 amino acid) amino-terminal extracellular domain and/or its upstream untranslated regions, while a single exon codes for the remainder of the receptor consisting of a seven-member membrane-spanning domain and a cytoplasmic carboxy-terminal intracellular domain (78).

Low or falling serum Ca levels act within seconds to result in secretion of preformed PTH. There is a sigmoidal type of PTH secretion in response to decreased serum Ca and is most pronounced when serum Ca is in the mildly hypocalcemic range. PTH secretion is 50% of maximal at a serum iCa of 1 mmol/l (4 mg/dl); this is considered as the calcium set point for PTH secretion. Sustained hypocalcemia increases PTH mRNA within hours. Protracted challenge leads within days to cellular replication and increased gland mass. High serum Ca levels suppress PTH secretion via activation of CaR (80,81). It in turn activates phospholipase C and generation of IP₃ and DAG, and probably increases the proteolytic destruction of preformed PTH. Hyperphosphatemia stimulates PTH secretion, probably by lowering the serum Ca concentration (67,81). A decrease in serum Mg concentration also can stimulate PTH secretion (82,83), although chronic hypomagnesemia inhibits secretion of PTH possibly from increased target tissue resistance to PTH (84). The latter may be related to inactivity of adenylyl cyclase, a Mg-requiring enzyme. Other systemic factors (catecholamines, prostaglandins, growth hormone, CT, estrogen, progesterone, cortisol, and somatostatin) and local factors (interleukin-1) modulate PTH secretion and function (85,86).

However, their role in the regulation of calcium metabolism under physiological conditions is not clear. In chronic renal failure, downregulation in the expression of renal CaR may account for the development of secondary hyperparathyroidism (87) and downregulation of PTH receptors may account for the skeletal resistance to calcemic effect of PTH (88). In the kidney, CaR decreases the basal and PTH-stimulated paracellular reabsorption of Ca, Mg, and sodium via multiple mechanisms. These include inhibition of cAMP accumulation; and stimulation of phospholipase A₂ activity, thereby promoting the release of free arachidonic acid that is metabolized via the lipoxygenase pathway to P450 metabolites that inhibit the activities of NaK₂Cl cotransporter and the K⁺ channel. This may affect renal water regulation by inhibition of vasopressin-abated water flow (32,33,68,69,80). Extracellular Ca exerts numerous other actions on parathyroid function, including modulation of the intracellular degradation of PTH, cellular respiration, membrane voltage, the hexose monophosphate shunt, and others (25,26,80). Maintenance of Ca homeostasis through other organs also may be possible with the presence of CaR in the intestinal cells and probable modulation of CT secretion from changes in intracellular calcium (26,89). Vitamin D and its metabolites 25 hydroxyvitamin D (25 OHD) and 1,25(OH)₂D, acting through vitamin D receptors decrease the level of PTH mRNA (90).

B. Calcitonin

Calcitonin monomer is a 32-amino-acid peptide secreted primarily from the thyroid C cells and also from many extrathyroidal tissues including brain, pituitary, mammary gland, and other tissues (91–95). CT-containing cells and parathyroid gland cells are thought to derive developmentally from the same tissue source as the neural crest. In the rat, the number of thyroid C cells and secretion of CT increase from fetal life to suckling (93), which are periods of rapid growth. There is probably no placental crossover of CT; the human placental tissue is able to produce CT in response to the presence of Ca in the culture medium (94). In human neonates, the CT content in crude tissue preparations of thyroid is larger than that of the adult thyroid (95).

There are two calcitonin genes, α and β , located on chromosome 11p15.2 near the genes for β -globulin and PTH. Two different RNA molecules are transcribed from the α gene: one is translated into the precursor for CT and the other message is translated into the precursor for CT gene-related peptide (CGRP) (91–97). The initial translational product of the mRNA is prepro-CT, which undergoes proteolytic cleavage to form pro-CT. The larger prohormones include peptides linked to the amino and carboxy terminals of the CT sequence (i.e., flanking peptides). Calcitonin and equimolar amounts of non-CT secretory peptides, corresponding to these flanking peptides, are generated during precursor processing. CGRP is found

predominantly in nerve fibers in the central and peripheral nervous system, blood vessels, thyroid and parathyroid glands, liver, spleen, heart, lung, and possibly bone marrow. CGRP, a 37-amino-acid peptide, is also generated from the larger precursor molecule. It is synthesized wherever the CT mRNA is expressed (e.g., in medullary carcinoma of thyroid). The β or CGRP-2 gene is transcribed into the mRNA for CGRP in the central nervous system and does not produce CT. Seventy-five amino-terminal residues of each prohormone for CT and CGRP are predicted to be identical. Pro-CT is a 116 amino-acid peptide, whereas the pro-CGRP is a 103 amino-acid peptide.

Circulating immunoreactive CT and CGRP are a heterogeneous mixture of different molecular forms and are recognized as long as the antigenic epitopes recognized by the antiserum are expressed. Immunoreactive CT or CGRP concentration is expressed in gravimetric or molar equivalents of synthetic CT or CGRP. Sample preparation with initial extraction, gel chromatography and high-performance liquid chromatography separation, and the use of two-site immunoassay can improve the sensitivity and specificity of CT measurements. Serum CT concentrations during pregnancy are variable (2,98). They are high at birth compared to paired maternal CT concentrations (98). Serum CT further increases during the first few days after birth and may reach levels five- to 10-fold higher than adult CT concentrations (58,59,99,100). Serum CT concentrations decrease progressively during infancy (61,99); however, in preterm infants up to 3 months after birth, the mean serum CT concentrations may remain twice the adult value (99). There is also a small peak of serum CT concentration during late childhood. In human adults, the basal serum CT concentration may be lower in women than in men, but it is not affected by old age. The CT secretory response to Ca infusion is lower in women and with old age (101). In human adults, serum CT and CGRP concentrations are found in the picomolar range. Diurnal variability has been reported for serum CGRP but not for serum CT (102–104). In normal individuals, larger precursor molecules of CT such as procalcitonin is not detected (105).

Classic bioactivity of human calcitonin (hCT) is present in the full 32 amino-acid structure or its smaller fragments, such as hCT 8–32 and hCT 9–32; the ring structure of CT enhances, but is not essential for, hormone action. Basic amino acid substitutions confer a helical structure in this region as found in salmon and other non-mammalian CT, and result in greater potency in lowering serum Ca and probably longer circulating half-life ($t_{1/2}$) (97). The kidney appears to be the dominant organ in the metabolism of human CT. A small percentage of the metabolic clearance rate of CT in humans may be accounted for by enzymatic degradation in blood. Injected hCT monomer disappears from the blood *in vivo* with a $t_{1/2}$ of approximately 10 min; in contrast, the $t_{1/2}$ of hCT in

plasma incubated *in vitro* at 37°C may be longer than 20 h (106). Depending on the animal species, other sites such as liver, intestine, and bone may be involved in the metabolism of CT.

In humans, changes in Ca and P metabolism are not seen despite extreme variations in CT production. In the neonate, there is neither an identifiable hypocalcemic response to the postnatal surge in serum CT nor a blunting of CT secretion in the presence of hypocalcemia. In adults, there is no definite effect attributable to CT deficiency, for example, totally thyroidectomized patients receiving only replacement thyroxine; or CT excess, for example, patients with medullary carcinoma of thyroid, except for the chronic suppression of bone remodeling. The clinical significance of CT is related to its use as a tumor marker in the management of medullary carcinoma of the thyroid, and its pharmacological effect to inhibit osteoclast-mediated bone resorption and to increase renal Ca clearance. The pharmacological activities of CT are useful for the suppression of bone resorption in patients with Paget's disease, for limited use in the treatment of osteoporosis, and for early-phase treatment of severe hypercalcemia (92). In addition, CT also increases renal clearance of Mg, P, and sodium and free water clearance (32,33). The net effect of CT is a lowering of serum Ca and P concentrations. Thus, the bioactivity of CT on calcium metabolism frequently is opposite that of PTH; CT probably modulates the effect of PTH on organs.

The clinical role of CT and associated molecules, particularly its non-calcium-related actions, are increasingly being expanded (92,97,105). For example, CT and CT receptors may play an important role in a variety of processes as wide-ranging as embryonic development and sperm function/physiology; and the possible use of serum procalcitonin as a marker of inflammation/sepsis. Its production in neuroendocrine cells in the lung and intestine is increased after exposure to bacterial endotoxin and inflammatory cytokines TNF and IL-6, thus increasing serum procalcitonin.

There are distinct but overlapping effects of CT and CGRP. CGRP primarily affects catecholamine release, vascular tone and blood pressure, and cardiac contractility. Its clinical role probably also lies in its potential pharmacological effect (97,105,107–109). The influence of CGRP on Ca and P homeostasis is minor compared to that of CT. However, amylin, a pancreatic islet-derived or synthetic 37 amino acid peptide, is a member of the CGRP family with a potent hypocalcemic effect despite sharing only 15% of its amino acid sequence with human CT. The hypocalcemic effect of amylin is probably mediated by the CT receptors on osteoclasts, and it is 100-fold more potent than CGRP (110). Both CT and CGRP inhibit gastric acid secretion and food intake.

Calcitonin function is mediated by binding to receptors linked to G proteins, a member of the GPCR superfamily, and activation of adenylate cyclase and phospho-

lipase C. The calcitonin receptor (CTR) gene is located on chromosome 7q21.2-q21.3 and encodes a 490 amino acid, seven-transmembrane G protein-linked receptor. Two isoforms of human calcitonin receptor arise by alternative splicing of an exon of 48 nucleotides that encodes a 16 amino acid insertion within the first intracellular loop. The isoform with the insertion (hCTR-1) activates only adenylate cyclase, whereas the other isoform (hCTR-2) activates both adenylate cyclase and phospholipase C (92,97,111). The role of receptor activity modifying proteins to modify the calcitonin receptor-like receptor (CRLR) posttranslationally is being defined. CGRP functions are also mediated by receptors (109).

Secretion of CT is stimulated by an increase in serum Ca and Mg concentrations and by gastrin, glucagon, and cholecystokinin, along with several other structural analogs of these hormones (e.g., pentagastrin, prostaglandin E₂), and by norepinephrine. Secretion of CT is inhibited by hypocalcemia, propranolol, and other adrenergic antagonists, somatostatin, and chromogranin A (92,97). Calcitonin gene transcription is positively regulated by glucocorticoid (112) and negatively regulated by protein kinase C (113), Ca, and vitamin D (114). Calcitonin may activate the 1-hydroxylase system independent of PTH and increase 1,25(OH)₂D production (115), whereas 1,25(OH)₂D decreases CT gene expression in adult rats but is ineffective in 13-day-old suckling rats (116). The latter observation may be related to fewer 1,25(OH)₂D receptors in C cells of immature rats. Calcitonin-induced refractoriness to its own actions is a well known phenomenon *in vitro* and *in vivo*, and clinically is manifested as the so-called escape phenomenon during therapy with calcitonin. This probably results from downregulation in the number and functional reduction of receptor mRNA (117).

C. Vitamin D

Vitamin D (Mr 384) can be obtained from diet or synthesized endogenously. It must undergo several metabolic transformations primarily in the liver and kidney to form the physiologically most important metabolite, 1,25(OH)₂D, which functions as a hormone in the maintenance of mineral homeostasis. Under *in vivo* conditions, there are over 30 other vitamin D metabolites, with and without putative functions.

Dietary vitamin D (1 μg = 40 IU) is derived from plants as ergocalciferol (vitamin D₂) and from animals as cholecalciferol (vitamin D₃). Dietary vitamin D is absorbed into the intestinal lymphatics (118), and about 50% of the vitamin D in chylomicron is transferred to DBP in blood before uptake by the liver (119). In animals, vitamin D₃ can be synthesized endogenously in the skin. During exposure to sunlight, the high-energy ultraviolet (UV) photons (290–315 nm) penetrate the epidermis and photolyze 7-dehydrocholesterol (provitamin D₃) to previtamin D₃. It then undergoes a thermally induced isomerization to vitamin D₃ that takes 2–3 days to reach

completion. Thus, cutaneous synthesis of vitamin D₃ continues for many hours after a single sun exposure. Vitamin D₃ is carried in the circulation by DBP to other sites for further metabolism. Vitamin D₃ synthesis in the skin is directly dependent on the amount of sunlight exposure and affected by time of day, season and latitude (peak sunlight at midday, in summer and lower latitudes); amount of skin area exposed, and duration of sunlight exposure. Melanin in the skin competes with 7 DHC for ultraviolet photons but the production of vitamin D₃ can be compensated for by increasing the duration of sunlight exposure; use of topical sunscreen blocks the ultraviolet photons; and aging, which decreases the capacity for cutaneous synthesis of vitamin D₃. Previtamin D₃ is photolabile. Continued exposure to sunlight causes the isomerization of previtamin D₃ to biologically inert products, principally to lumisterol. No more than 10–20% of the initial provitamin D₃ concentrations ultimately end up as previtamin D₃, thus preventing the excessive production of previtamin D₃ and vitamin D₃ (120).

In mammals, vitamins D₂ and D₃ appear to metabolize along the same pathway, and there is little functional difference between their metabolites. The term vitamin D is frequently used generically to describe vitamins D₂ and D₃ and, correspondingly, their metabolites.

In the circulation, vitamin D and its metabolites are protein bound, mainly to DBP (about 85%) and to albumin (about 15%) (121). The DBP gene is located on chromosome 4q11-13. It is a member of a gene family that includes serum albumin and α -fetoprotein (122). DBP is a 52 kD globulin in the rat and approximately 58 kD in the human; it is normally <5% saturated with vitamin D metabolite. Its affinity to vitamin D metabolites depends inversely on the distance between the 3 β -hydroxy group and other hydroxyl groups on each vitamin D metabolite. Thus, its affinities for 25 OHD, 24,25(OH)₂D and 25,26(OH)₂D are greater than for vitamin D and 1,25(OH)₂D (123). The amount of DBP may influence the concentration of “free” 1,25(OH)₂D in plasma, which is important in determining the bioactivity of the hormone.

In the liver, vitamin D is hydroxylated at carbon 25 to 25-hydroxyvitamin D (25-OHD). The vitamin D-25 hydroxylase activity is found predominantly in the cytochrome P450-containing enzyme, CYP-27 protein, on the inner surface of the mitochondrial membrane. This protein also catalyzes 27-hydroxylation of cholesterol derivatives. The CYP-27 gene is located on chromosome 2q33 and encodes a polypeptide of 531 amino acids processed to a mature 56.9 kD protein of 498 amino acids (124). Quantitatively, 25 OHD (1 nmol/L = 0.4 ng/ml) is the most abundant vitamin D metabolite in the circulation and is a useful index of vitamin D reserve.

In the kidney, 25 OHD is hydroxylated further to 1,25(OH)₂D with 25-OHD-1 α -hydroxylase (CYP 1 α), and to 24R,25-dihydroxyvitamin D (24,25(OH)₂D) with 25-OHD-24R-hydroxylase (CYP 24). This occurs primar-

ily in the mitochondria of proximal tubules. The genes for these enzymes have been localized to chromosome 12q13-14 and 20q13.3, respectively (125–127). The human gene encoding the CYP 1 α is 5 kb in length, located on chromosome 12, and comprises nine exons and eight introns; its exon/intron organization is very similar to other mitochondrial P450 enzymes cloned to date (127). Recent reports that 25 OHD can be metabolized to 1,25(OH)2D in the colon, prostate, and skin have raised the possibility that 1,25(OH)2D may be needed for cellular health of extrarenal tissues in addition to its classic action on mineral metabolism (128).

Regulation of 25-hydroxylase activity is limited and there are few limitations to the production of 25 OHD. At high concentrations of vitamin D, the mitochondrial enzyme will form significant quantities of 25 OHD. This in part explains the serum 25 OHD variations with season and vitamin D intake. The latter can increase serum 25 OHD to more than fivefold of upper normal range. The *in vivo* administration of 1,25(OH)2D decreases serum 25 OHD (129). Ca deficiency increases the metabolic clearance of 25-OHD (130).

The activity of 1 α -hydroxylase, and therefore production of 1,25(OH)2D, are tightly regulated. It is the rate-limiting hormonally regulated step in the bioactivation of vitamin D. PTH increases transcriptional activity of the CYP 1 α gene promoter and increases mRNA for 1,25(OH)2D. Decrease in serum or diet Ca or P increase mRNA for (127,130) and serum concentration of 1,25(OH)2D (131). In contrast, hypophosphatemia associated with tumor-induced osteomalacia, autosomal dominant hypophosphatemic rickets (ADHR), and X-linked hypophosphatemia (XLH) do not elicit appropriate phosphate conservation or an increase in 1,25(OH)2D production. They have similar phenotypic manifestations characterized by hypophosphatemia, decreased renal phosphate reabsorption, normal (inappropriately low) or low serum calcitriol concentrations, normal serum Ca and PTH, and defective skeletal mineralization. XLH results from mutations in the PHEX gene, encoding a membrane-bound endopeptidase, whereas ADHR is associated with mutations of the gene encoding FGF-23. The latter is a small heat-sensitive molecule of <25 kD that inhibits sodium-dependent phosphate wasting and probably inhibits CYP 1 α . The endopeptidase PHEX degrades native FGF-23, which presumably provides the biochemical link among these clinical syndromes (132).

Other factors that enhance 1,25(OH)2D production include estrogen, prolactin, growth hormone, insulin-like growth factor-I, and PTHrP (133–135). 1,25(OH)2D production is feedback regulated and is inhibited by chronic deficiency or low circulating Mg (82,131,134,136). Mg deficiency also lowers serum 1,25(OH)2D response to low-Ca diet (137) but does not appear to limit 1,25(OH)2D production in animals (138). The effect of Mg on 1,25(OH)2D metabolism is presumably related in

part to its role as a cofactor of the 1 α -hydroxylase enzyme (136). In contrast to the rapid increase in PTH secretion and serum PTH concentrations, measurable alteration in serum 1,25(OH)2D concentrations usually occurs only hours after exposure to an appropriate stimulus. Extrarenal production of 1,25(OH)2D in macrophages, particularly in granulomatous disease states, may not be tightly regulated; is stimulated by γ -interferon, but is not responsive to changes in dietary calcium intake (134).

1,25(OH)2D function, like other steroid hormones, is mediated primarily through modulation of the cellular genome by binding to specific nuclear receptors (vitamin D receptor, VDR), a 424-amino-acid phosphoprotein. The VDR gene contains nine exons and is located on chromosome 12q13-14 near the site of the gene for 25 OHD-1 α -hydroxylase (125,139). VDR is a member of the nuclear receptor superfamily of steroid–retinoid–thyroid hormone–vitamin D transcription regulatory factors. It has several functional domains including a zinc finger-mediated N-terminal DNA-binding domain, a C-terminal hormone-binding domain, and a hinge region important for nuclear localization. The VDR interacts with the retinoic acid X receptor (RXR) to form a heterodimeric RXR–VDR complex that binds to specific DNA sequences, termed vitamin-D-responsive elements (VDREs) (139). After 1,25(OH)2D binds to the receptor, it induces conformational changes (140) that result in the recruitment of a multitude of transcriptional coactivators that stimulate the transcription of target genes. Vitamin D receptors are upregulated by 1,25(OH)2D at both the mRNA and protein levels. They also are increased during growth, gestation, and lactation but show an age-dependent decrease in mature animals and humans, supporting the notion that vitamin D receptors may be up- or downregulated, depending on Ca needs (126,139,141). All vitamin D target cells that possess VDR can metabolize vitamin D via the 24-hydroxylation pathway (126).

Two basic clinical functions define the major classic action of vitamin D. The first is that vitamin D is required to prevent rickets in children and osteomalacia in adults. The second is the prevention of hypocalcemic tetany. These functions are maintained by 1,25(OH)2D through its effect on a number of target tissues, primarily intestine, kidney, and bone, and modulating effects from other hormones including PTH and CT. However, VDR is present in numerous cell types, and 1,25(OH)2D-VDR action clearly transcends bone and calcium/phosphate homeostasis. Its actions extend into cell growth and differentiation and immune, neural, and endocrine function (126,139).

Intestinal absorption of Ca and P consists of a passive (concentration-dependent) and active component. Classic vitamin D-dependent active Ca absorption in the intestine involves multiple components. At the brush-border membrane, non-genome-mediated action of 1,25(OH)2D occurs within seconds to minutes to transport Ca into the cell, probably mediated through a 1,25(OH)2D-binding

membrane receptor that opens voltage-gated Ca ion channels (71,142). Ca transport through the cytosol is facilitated by binding to Ca-binding proteins (CaBP, or calbindin D). There are at least two CaBPs and their expression depends on the animal species and the organ studied. In mammals, the 7.5–10 kD CaBP (calbindin D 9K) is found mainly in the duodenum, whereas the 28 kD CaBP (calbindin D 28K) is found mainly in the kidney and cerebellum. In avian species, such as the chicken, calbindin D 28K is found in the intestine. 1,25(OH)₂D stimulates transcription of the CaBP gene, with resulting accumulation of CaBP mRNA and protein in 1 or more hours after 1,25(OH)₂D treatment (143). In the rat, there is an age-dependent increase in intestinal calbindin D 9K extending from the fetal period and reaching adult levels soon after weaning. The level decreases in older rats (144). At the basolateral membrane (BLM), 1,25(OH)₂D causes an increase in the concentration of ATP-dependent plasma membrane iCa pump (PMCA) (145) and stimulates the extrusion of Ca (146). Administration of 1,25(OH)₂D also induces brush border enzyme activities, such as alkaline phosphatase that facilitates the movement of Ca across cell membranes. The progressive increase in affinity for Ca among the successive components as the Ca is transported from the brush border to the BLM also facilitates Ca transport (143). There are conflicting reports on 1,25(OH)₂D-induced changes in membrane fluidity from altered lipid composition of intestinal cell membranes.

Vitamin D metabolites are also needed for the maintenance of P homeostasis by increasing intestinal absorption. Active transport processes of P across the intestine include a saturable, sodium-dependent Na-K-ATPase that involves the endoplasmic reticulum, an unsaturable and sodium-independent component for brush border uptake and basolateral membrane exit processes, and a Ca- and vitamin D-dependent component (147,148). Intestinal P absorption is well established in infants of human and animal species and may be as high as 90% of P intake. In preterm infants, P absorption appears not to be significantly affected by vitamin D intake (149).

The effect of vitamin D and its various metabolites on ion transport is much less marked on the kidney than on the intestine. In humans, conflicting data have been reported on the effect of vitamin D and its metabolites on renal excretion of Ca and P, probably because of the difficulty in controlling the many variables that may influence renal handling of these minerals. The mechanisms of absorption vary significantly from one segment to another, as the extent of hormonal regulation. The active, transcellular component regulated by PTH, 1,25(OH)₂D, CT, and Ca-sparing drugs such as thiazide type diuretics, acts primarily at the distal tubule. Both the active (regulated by PTH and CT) and the passive paracellular transport of Ca (32,33,68,142,150) and P (69,151,152) occur at the thick ascending limb. The model for vitamin D-dependent Ca transport across the intestinal epithelial cells also may

be applicable to the active renal Ca transport since VDR, CaBP, and PMCA are found in both cell types and respond similarly to changes in vitamin D, Ca, or P status (143). In the rat kidney, developmental changes in the calbindin D 28K also show an age-dependent change similar to that for the intestinal calbindin D 9K (144). In the human, calbindin D 28K gene is located on chromosome 8. Analogous to rat and chicken, the human calbindin D 28K also contains six EF-hand-like domains, and there are at least four functional binding sites for Ca. Vitamin D depletion is associated with decreased renal P reabsorption that is corrected rapidly by physiological amounts of 1,25(OH)₂D, probably from stimulation of sodium-dependent phosphate cotransporter (NPT2) in the brush border membrane of proximal tubules and possibly from changes in the lipid composition of tubular membrane (69,70,143,151). In any case, renal P retention is extremely effective at low dietary intake in infants (43,45,46) and adults (151,152) with tubular reabsorption of P *approach* 100% in infants with increased P need while receiving low dietary P.

Bone mineralization of skeleton is thought to be predominantly secondary to the action of 1,25(OH)₂D in increasing the intestinal absorption of Ca and independently of P; these two actions, thereby, elevate plasma Ca and P concentrations. This is supported by the finding that the skeletal abnormalities present in homozygous VDR knockout mice are completely ablated by normalizing serum Ca and P (153), and that Ca therapy improves bone abnormalities in hereditary hypocalcemic vitamin D-resistant rickets patients (154). Additionally, 1,25(OH)₂D acts on receptors of osteoblasts (enhances differentiation and inhibits proliferation) and osteocytes to promote bone formation and the production of osteocalcin, osteopontin, and alkaline phosphatase. Both PTH and 1,25(OH)₂D interact with their specific osteoblast surface receptors to induce the production of RANK ligand that interacts with RANK receptors on the immature osteoclast precursor to differentiate into mature osteoclasts (155). This leads to mobilization of bone minerals and contributes to maintenance of Ca and P homeostasis.

Quantification of vitamin D and its metabolites has been achieved by several different methods. The more routine approaches include high-performance liquid chromatography with detection by ultraviolet absorbance or binding assays. Immunoassays based on antibodies raised to vitamin D metabolite conjugates also are available. Values from different laboratories cannot be compared without making direct comparison of their assay procedures. Interlaboratory coefficients of variation for the measurement of 25-OHD, 24,25(OH)₂D, and 1,25(OH)₂D may range between 35% and 52% (156). Furthermore, differences between vitamins D₂ and D₃ in their affinity to the vitamin D binding protein and receptors and different chromatographic behavior on various preparative chromatographic systems (157) demand that great care be

taken with assay techniques when dealing with patients who have significant vitamin D₂ intake. To ensure reliable results, appropriate vitamin D standards must be used for standard curve generation in performing competitive protein binding assays of these compounds.

Maternofetal transfer of vitamin D and its metabolites varies, depending on the species. In humans, the cord serum vitamin D concentration is very low and may be undetectable, probably because of poor maternofetal crossover. The 25 OHD concentration is directly correlated with, but lower than, maternal values, consistent with placental crossover of this metabolite; 1,25(OH)₂D concentrations also are lower than maternal values, but there is no agreement on the maternofetal relationship of this and other dihydroxylated vitamin D metabolites (1,158–160). In vitro experiments demonstrate that 25(OH)D and 1,25(OH)₂D may cross the perfused human placenta (161). In vivo, some placental crossover may occur after maternal exposure to pharmacological doses of vitamin D (162) or 1,25(OH)₂D at 17–36 μg/day (163). In the latter case, consistently elevated (10 times normal) maternal plasma 1,25(OH)₂D concentrations (170–500 + pg/ml) resulted in similarly elevated cord serum 1,25(OH)₂D concentrations (470 pg/mL) at delivery. However, the placenta, like the kidney, produces 1,25(OH)₂D, making it difficult to ascertain just how much fetal 1,25(OH)₂D results from placental crossover versus placental synthesis.

Seasonal and racial variations in serum 25 OHD concentrations occur, presumably from variations in endogenous production. Serum 25-OHD is lower in winter and in African-Americans; serum 1,25(OH)₂D is higher in African-American mothers. These differences may be reflected in cord serum values (158–160). The vitamin D metabolite 24,25(OH)₂D also crosses the placenta and varies with the seasons, being highest in autumn (160). The significance of this finding is unclear as 24,25(OH)₂D may be a metabolic product of 25 OHD to prevent vitamin D toxicity. It appears that the human fetus receives the bulk of its vitamin D already metabolized to 25 OHD.

Serum 1,25(OH)₂D in the newborn become elevated within 24 h after delivery (1) and appears to vary according to Ca and P intake (45,46). African-Americans have higher 1,25(OH)₂D concentrations than whites in infancy and early childhood (164), but not in the older pediatric or adult population. In normal adults, serum 1,25(OH)₂D concentrations are relatively constant and maintained within approximately 20% of the overall 24 h mean (165), and show no seasonal variation (166). The latter is consistent with the tightly regulated 1α-hydroxylase activity. Serum 1,25(OH)₂D is lowered in the elderly, possibly in part related to a decrease in the responsiveness of 25(OH)D-1α-hydroxylase enzyme activity (167) and, probably low vitamin D production in northern latitudes (168). The circulating t_{1/2} of 25(OH)D is 2–3 weeks, depending on the vitamin D status of the individual; it is decreased in vitamin D-deficient individuals. 1,25(OH)₂D

has a much shorter t_{1/2} of 3–6 h (169). Metabolites of 25 OHD and 1,25(OH)₂D may undergo enterohepatic circulation after exposure to intestinal β-glucuronidase. The physiological role of enterohepatic circulation of vitamin D metabolites has not been precisely quantitated (170, 171).

Human milk vitamin D, but not 25 OHD concentration, correlates with maternal vitamin D intake (169). Infant serum 25 OHD concentration does not correlate with either human milk vitamin D or 25(OH)D concentrations. The major sources of vitamin D for human-milk-fed infants are from endogenous synthesis after sunlight exposure (172–174) or from vitamin D supplementation (172,175,176). It appears that for an infant living in temperate regions, approximately 2 h/week of sunshine exposure while fully clothed but without a hat, or 400 IU vitamin D supplement, is sufficient to maintain normal vitamin D status (173). Neonates, even very-low-birth-weight infants, appear to have adequate capacity to absorb and metabolize vitamin D. In infants receiving standard supplementary vitamin D intake, circulating 25 OHD and 1,25(OH)₂D concentrations may be increased to levels comparable to, and sometimes exceeding, adult values (176–178). Circulating 25 OHD and 1,25(OH)₂D concentrations in infants also appear to be dependent on Ca and P intake (43,45,46).

The enzyme 25 hydroxyvitamin D-24 hydroxylase (CYP 24) is present in all vitamin D target cells and is strongly induced by 1,25(OH)₂D. In kidney and intestine in particular, upregulation of the 24-hydroxylase enzyme in response to 1,25(OH)₂D treatment is rapid and occurs within 4 h (179). The 24 hydroxylase catalyzes several steps of 1,25(OH)₂D degradation, collectively known as the C24 oxidation pathway, which starts with 24-hydroxylation and culminates in the formation of the biliary excretory form, calcitric acid. Physiological production of 24R,25(OH)₂D is therefore an important means to regulate the circulating concentration of 1,25(OH)₂D and catabolism of vitamin D, although it may have a role in bone integrity and fracture healing in the chick model (180). Thus both the synthesis and degradation of 1,25(OH)₂D are tightly regulated events, and that the target cells for vitamin D contains the means to regulate its activity at the cellular level. Most of the other vitamin D metabolites are derived primarily from further metabolic alterations to 25 OHD and 1,25(OH)₂D through oxidation or side chain cleavage and have poorly defined physiological function. However, many analogs of vitamin D metabolites are being studied for the numerous potential pharmacological actions that involve less calcemic-inducing and greater maturation and differentiation effects (126).

IV. NONCLASSIC CONTROL OF CALCIUM AND P HOMEOSTASIS

Maintenance of mineral homeostasis is intimately related to skeletal health since the skeleton is the major reservoir

for Ca and P, and any disturbance in skeletal health can affect Ca and P homeostasis. Skeletal health, particularly in the growing skeleton, requires the integrated actions of classic calciotropic hormones, endocrine modulators of growth, numerous cytokines and growth factors and their receptors, as well as their endogenous modulators. Many factors such as growth hormone, insulin-like growth factor-I, estrogen, progesterone, cortisol, and tumor necrosis factor can affect the secretion or function of one or more of the calciotropic hormones (86,112,133,135,179,181). Many factors such as insulin-like growth factor-I, transforming growth factor- β 1, interleukin 1 and 6, and tumor necrosis factor- α in turn can be modulated by calciotropic hormones (85,182,183). The ultimate effect on mineral homeostasis involved bone formation and/or bone resorption and flux of Ca and P between extracellular fluid and bone, with or without direct involvement by calciotropic hormones. Many factors such as cytokines can function in a paracrine (i.e., cell-to-cell) or autocrine (i.e., cell-to-own cell) fashion, particularly under pathological conditions (155,183–188), whereas, some factors such as parathyroid hormone-related protein (PTHrP) may act both systemically and locally (189).

PTHrP and PTH genes appear to be members of the same gene family. PTHrP cDNA encodes a 177 amino acid protein consisting of a 36-amino-acid precursor segment and a 141-amino-acid mature peptide. The mature PTHrP contains several structural or functional domains. The N-terminal 1–13 region has eight of 13 residues similar to PTH. The amino acids 34–111 segment is highly conserved among species while amino acid 118 to the C-terminus is poorly conserved. PTHrP gene expression is found in an extensive variety of normal endocrine and nonendocrine tissues. PTHrP biological activity and immunoreactivity for PTHrP mRNA have been found in many tissues by as early as 7 weeks of gestation, including the fetus, placenta, lactating breasts, and milk in human (190–192) and in various tissues in the pig (55) and sheep (56).

Both PTH and PTHrP appear to bind to the same G-protein-linked receptor. Synthetic and recombinant PTHrPs can mimic the effects of PTH on the classic PTH target organs, involving activation of adenylate cyclase and other second messenger systems (75,77).

Several PTHrP assays with varying sensitivities and specificities have been developed (193) that account for the variability reported between assays. The stability of PTHrP in plasma samples may be enhanced if sample collection is done in the presence of protease inhibitors. Circulating immunoreactive PTHrP concentrations are low or undetectable in normal subjects. Serum PTHrP is increased during pregnancy (3,4) and is similar to (4) or lower than (3) the umbilical cord concentrations. In cord serum, PTHrP concentrations are 10–15-fold higher than that of PTH. Amniotic fluid PTHrP concentrations at mid-gestation and at term are 13–16-fold greater than the cord

or maternal levels (194), and the concentration of PTHrP in milk is 100-fold higher (192).

PTHrP concentrations in the circulation of individuals with humoral hypercalcemia of malignancy (HHM) are elevated (193). The amino-terminal fragment PTHrP 1–74 appears to be specific for HHM, whereas the carboxy-terminal fragment PTHrP 109–138 is elevated in the serum of patients with HHM or renal failure. The levels of PTHrP in these patients are similar to the concentration of PTH (10^{-12} – 10^{-11} mol/l).

In clinical terms, PTHrP, also known as PTH-like peptide, PTH-like protein, or human humoral hypercalcemic factor, is the humoral mediator secreted by tumors that results in the syndrome of HHM. Currently, the measurement of PTHrP is of clinical utility primarily as a tumor marker in HHM. Physiologically, PTHrP is an important paracrine regulator of several tissue-specific functions that may directly or indirectly affect fetal and neonatal mineral homeostasis, probably through its effect on smooth muscle relaxation, placental calcium transport, lactation, fetal bone development, and in the control of cellular growth and differentiation (189,190).

V. HYPOCALCEMIA

Neonatal hypocalcemia may be defined as a serum tCa concentration below 2 mmol/l (1 mmol/l = 4 mg/dl) in term infants and 1.75 mmol/l (7 mg/dl) in preterm infants with iCa below 1.0–1.1 mmol/L (4.0–4.4 mg/dl), depending on the particular ion-selective electrode used. These definitions are made from a clinical viewpoint because serum Ca concentrations are maintained within narrow ranges under normal circumstances and the potential risk for disturbances of physiological function increases as the serum Ca concentration further decreases. Furthermore, improvements in physiological function (e.g., changes in cardiac contractility, blood pressure, and heart rate) are reported in hypocalcemic infants undergoing Ca therapy (195–197), and a higher mortality rate has been reported for children with hypocalcemia in pediatric intensive care setting (198).

Clinically, there are two peaks in the occurrence of neonatal hypocalcemia. An early form typically occurs during the first few days after birth, with the lowest concentrations of serum Ca being reached at 24–48 h of age; late neonatal hypocalcemia occurs toward the end of the first week and generally presents as neonatal tetany. These findings reflect the traditional clinical practice of screening for biochemical abnormalities in small or sick hospitalized infants during the first few days, and in symptomatic infants after hospital discharge. The nadir of the serum Ca concentration may occur at less than 12 h (7,199–201) or not until some weeks after birth (202, 203), and that many neonates, particularly those with genetic defects in Ca metabolism, may be hypocalcemic but remain asymptomatic and undetected during the early ne-

onatal period. This also may contribute to the less frequent diagnosis of late neonatal hypocalcemia compared to early neonatal hypocalcemia. It seems preferable to classify neonatal hypocalcemia based on risk factors (Table 1) rather than the traditional early or late onset.

A. Pathophysiology

The pathophysiological mechanisms of hypocalcemia are varied and frequently interrelated but not fully defined (Table 2). In most cases of neonatal hypocalcemia, there is a decrease in both tCa and iCa. There exists a common basis for its occurrence particularly so-called in early onset hypocalcemia. These include the abrupt discontinuation of placental Ca supply after birth, limited or no dietary calcium, transient limited increase in the serum PTH concentration, possibly end-organ resistance to 1,25(OH)₂D, and elevated serum CT concentration. These problems are exaggerated in the preterm infant and accounts for the inverse relationship between the frequency of hypocalcemia with birth weight and gestational age; over 50% of preterm very-low-birth-weight neonates may have hypocalcemia (7,199–201). Small preterm infants often have associated illnesses that preclude early enteral feeding but many clinicians do not use calcium-containing parenteral nutrition for 1 or more days after birth, thus increasing the risk for hypocalcemia. Resistance to pharmacological dosages of 1,25(OH)₂D demonstrated in vitro (204) and in vivo (7,200) might contribute to hypocalcemia in small preterm infants. The amount of calcium

retention from milk feeds even in healthy term infants probably is less than 20 mg/kg body weight on the first day, rising to about 45–60 mg or more/kg on the third day; these amounts are significantly lower than the daily in utero Ca accretion of over 100 mg/kg during the third trimester (47). Excessive P load from diet including increased dietary P can be from cow-milk ingestion (6) and even with humanized cow-milk-derived formulas with lower P content (42) or from cereals (205); from accidental overdose of oral phosphate supplement (206) or phosphate-containing enema (207,208) can result in hypocalcemia.

Other clinical situations include any chronic diarrheal condition, especially if associated with steatorrhea, is generally associated with intestinal malabsorption of Ca and possibly impaired enterohepatic circulation of vitamin D and vitamin D metabolites. Specific intestinal malabsorption of Mg (209) may lead to Mg depletion and, secondarily, to hypocalcemia, which can be corrected only when the Mg disturbance is corrected. The most common cause of intestinal malabsorption of Mg is surgical resection of large segments of small bowel, with or without fistula losses of various minerals. The use of high P (106–120 mg/100 kcal) and a fixed Ca (180 mg/100 kcal) content formula can lower the fecal loss of Mg (210) in preterm infants, whereas P depletion may be associated with increased urinary Ca and Mg (32,33,136,211).

Pathophysiology of some situations with hypocalcemia remain ill defined: for example, despite the hypocalcemic effects of CT, the serum CT concentrations continued to increase in neonates of normal and diabetic pregnancies irrespective of the variation in serum calcium (59,201); in neonates with birth asphyxia (201); and in preterm infants (58). The stimulus for the postnatal rise in serum CT, despite falling serum Ca, is unknown. There are conflicting reports on the effect of Ca supplementation to suppress the postnatal surge in CT secretion (58,212). However, serum CT is increased after an intravenous bolus of Ca during exchange blood transfusion (213). Infants with intrauterine growth retardation may have hypocalcemia if they are also preterm (58) or have birth asphyxia (58,201,214); otherwise, there is apparently no increased incidence of hypocalcemia related to growth retardation per se (8,215).

Maternal use of the anticonvulsants phenytoin and phenobarbital may be associated with neonatal hypocalcemia, presumably from increased clearance of vitamin D secondary to the induction of hepatic cytochrome P450 enzyme system (216). However, other maternal factors including seasonal variation in sunlight exposure, increased maternal age and parity, and poor socioeconomic status (217), may contribute to development of neonatal hypocalcemia, presumably in part from varied and probably deficient maternal vitamin D. However, there is no seasonal variation in the rate of early neonatal hypocalcemia (218) despite seasonal variation in maternal and fetal vi-

Table 1 Risk Factors for Neonatal Hypocalcemia

Maternal
Insulin-dependent diabetes
Hyperparathyroidism
Vitamin D or magnesium deficiency
Anticonvulsant use (?)
Narcotic use (?)
Peripartum: Birth asphyxia
Infant
Intrinsic
Prematurity
Malabsorption
Malignant infantile osteopetrosis
Parathyroid hormone: impaired synthesis, secretion, regulation or responsiveness
Extrinsic
Diet
Inadequate calcium
Excess phosphorus
Enema: phosphate
Exchange transfusion with citrated blood
High rate of intravenous lipid infusion
Phototherapy (?)
Alkali therapy (?)

Table 2 Pathophysiology of Neonatal Hypocalcemia

Physiological basis	Mechanism	Clinical association
Calcium total and ionized Calcium ionized	Decreased intake or absorption Increased Ca complex	Prematurity; malabsorption syndrome Chelating agent (e.g., citrated blood for exchange transfusion, long-chain free fatty acid)
Magnesium	Decreased tissue store or absorption	Infant of insulin-dependent diabetic mother; maternal hypomagnesemia; specific Mg malabsorption (rare)
Phosphorus	Increased	Endogenous and exogenous (e.g., dietary, enema) phosphate loading
pH	Increased	Respiratory or metabolic alkalosis (e.g., shifts Ca from ionized to protein-bound fraction)
Parathyroid hormone	Impair or defective synthesis or secretion Impair regulation Impair responsiveness	Maternal hypercalcemia; DiGeorge association, hypoparathyroidism, hypomagnesemia; PTH gene mutations Activating mutations of calcium-sensing receptor: autosomal dominant or sporadic hypocalcemia with hypercalciuria Chronic hypomagnesemia; inactivating mutation of type 1 PTH receptor (?); pseudohypoparathyroidism
Calcitonin	Increased	Infant of insulin-dependent diabetic mother, birth asphyxia, prematurity
1,25-Dihydroxyvitamin D Osteoclast activity	Decreased responsiveness Absent	Prematurity Malignant infantile osteopetrosis

tamin D status as indicated by maternal and cord 25 OHD concentrations (158,160). Hypomagnesemia may be contributory to hypocalcemia in infants of mothers with insulin-dependent diabetes (219), although it is conceivable that both hypocalcemia and hypomagnesemia may be the result of a common insult from the diabetic pregnancy. Maternal vitamin D or Mg deficiency probably predisposes to but is not the primary cause of hypocalcemia in the neonate. Malignant infantile osteopetrosis may present with neonatal hypocalcemia (220), presumably reflecting continue Ca uptake from unopposed bone formation.

Neonatal hypocalcemia from impaired synthesis or secretion of PTH in the newborn can occur secondary to developmental defects of parathyroid gland, specific mutations of PTH gene, or maternal hypercalcemia. Neonatal hypocalcemia is often the first manifestation that leads to the diagnosis of maternal hyperparathyroidism (202, 203).

Hypocalcemia (in varying degree of severity) from so-called transient congenital hypoparathyroidism (TCHP) may occur in association with DiGeorge and velocardiofacial/Shprintzen syndromes. Both syndromes may represent different degrees of the same disorder with partial or complete absence of derivatives of the third and fourth pharyngeal pouches, and possibly the fifth pouch, and are often associated with defective development of the third, fourth, and sixth aortic arches. Other clinical manifestations may include some combination of congenital heart disease, primarily involving the aortic arch, decreased T-cell number or function, and possibly thyroid C-cell deficiency (221,222). Deletion of 22q.11 has been reported in these patients (223), and DiGeorge association may be

inherited in an autosomal dominant fashion (224). Neonates with TCHP may have prolonged hypocalcemia that requires treatment until late infancy or early childhood, and hypoparathyroidism may recur in later childhood (225–227).

Hypoparathyroidism in the infant is a heterogeneous group of disorders and may occur sporadically or with differing mendelian modes of inheritance (228–232). Synthesis of defective PTH can occur in the autosomal dominant form with a point mutation in the signal peptide-encoding region for the prepro-PTH. The autosomal recessive form is associated with a mutation in the donor splice site leading to transcriptional loss of the second exon and prevention of translation. The X-linked recessive form is associated with embryonic dysgenesis of parathyroid glands. Hypoparathyroidism from fetal parathyroid hypoplasia or dysgenesis usually requires life long treatment to prevent hypocalcemia.

Defects in the regulation of PTH can result in hypocalcemia. A variety of missense, nonsense, deletion, and insertion mutations of CaR gene, some with mendelian modes of inheritance, can result in altered receptor activity and clinical disease. Activating CaR mutations with reduction in EC50 (concentration of extracellular Ca required to elicit half of the maximal increase in intracellular inositol phosphate) manifested as autosomal dominant or sporadic cases of hypocalcemia with hypercalciuria have been reported (233–235). Hypocalcemia is usually mild and asymptomatic, and diagnosis is often delayed beyond the neonatal period, although hypocalcemia was likely to be present during the immediate newborn period.

Neonatal hypocalcemia may result from relative defective or inadequate response to PTH. Inactivating mutation of the type 1 PTH receptor gene as documented in Blomstrand's chondrodystrophy is manifested as the prenatally lethal form of short limb dwarfism (236). Theoretically this defect may result in hypocalcemia but the regulation of serum Ca has not been evaluated *in vivo*.

Newborn infants increase serum PTH coincident with a fall in serum Ca (53,58–60), presumably reflecting abrupt withdrawal of the placental transfer of Ca, and the increase in PTH may be insufficient to maintain normal serum Ca. This may reflect the relative inadequacy or transient nature of the PTH response. For example, in situations of induced hypocalcemia, such as during an exchange transfusion using citrated blood (213,237) or feeding of the relatively high P content of cow-milk formula (42). The ability of the neonatal parathyroids to respond to hypocalcemic stress increases with age (237). Impaired end-organ response to PTH also occurs with chronic hypomagnesemia and may involve simultaneous impairment in both PTH and 1,25(OH)₂D pathways (83,136,137).

End-organ unresponsiveness to PTH associated with genetic defect is classically manifested as pseudohypoparathyroidism type 1a (PHP-1a) or Albright's hereditary osteodystrophy. The biochemical basis of the defect is proximal to cyclic AMP production. It is inherited in an autosomal dominant fashion with heterozygous inactivating mutations in the maternal *GNAS1* exons that encode the α -subunit of the stimulating G protein ($G_{s\alpha}$). The gene *GNAS1* is located on chromosome 20q13.3 and encodes 13 exons that are alternatively spliced to yield four $G_{s\alpha}$ proteins. Multiple mutations include abnormalities in splice junctions associated with deficient mRNA production and point mutations that result in diminished amount and activity of the G proteins have been reported. The inactivating mutation of the gene impaired the production of adenylate cyclase second messenger system, leading to resistance to multiple hormones (including PTH, vasopressin, and thyrotropin) that activate $G_{s\alpha}$. Clinical manifestations include short stature, round face, brachymetacarpals and brachymetatarsals, dental dysplasia, subcutaneous calcifications, abnormalities in taste, smell, hearing, and vision, and developmental delay. Biochemical abnormalities include hypocalcemia, hyperphosphatemia, increased circulating PTH, and insensitivity to the administration of exogenous PTH (unaltered urinary calcium, P, and cAMP) in the absence of compromised renal function. The extent of resistance to other hormones is variable and the complete biochemical picture is usually not evident until 2–3 years after birth (231,238,239).

Parent-specific methylation with parental imprinting of the *GNAS1* gene involving selective inactivation of either the maternal or paternal allele is possible and led to different phenotypic expression. In the case of the $G_{s\alpha}$

gene, it is paternally imprinted (silenced) so that the disease PHP-1a is never inherited from the father carrying the defective allele but only from the mother. However, the defective allele is not imprinted or silenced in all tissues and reflects haplotype insufficiency. For example, PHP type 1b is characterized by isolated resistance to PTH without the accompanied skeletal manifestations. Paternal isodisomy of chromosome 20q in patients that lack the maternal-specific methylation pattern within *GNAS1* results in normal $G_{s\alpha}$ protein and activity in the fibroblast but not in the renal proximal tubules (240). There is a third type, PHP-1c, reported in a few patients that differs from PHP-1a only in having normal erythrocyte levels of $G_{s\alpha}$, presumably there is a post- $G_{s\alpha}$ defect in adenyl cyclase stimulation. All type 1 PHP individuals show a deficient urinary cAMP response to the administration of exogenous PTH. Whereas, individuals with pseudopseudohypoparathyroidism (PPHP) have typical clinical manifestation of PHP-1a but have normal serum Ca and normal response of urinary cAMP to exogenous PTH. The mutated *GNAS1* gene is inherited from the father (i.e., paternal imprinting) with suppression of the mutant copy in selected tissues (241) and there is a 50% reduction but not absent $G_{s\alpha}$ subunit.

Neonatal hypocalcemia with seizure and so-called transient features of pseudohypoparathyroidism has been reported (242). These infants have elevated serum PTH and P with hypocalcemia at diagnosis. Response to exogenous human PTH (1–34) show little phosphaturic effect although there was brisk response in plasma and urine cAMP and alkaline phosphatase. After initial treatment for hypocalcemia, the serum Ca and PTH spontaneously normalized before 6 months of age.

Decreases in serum iCa can occur without decreases in serum tCa. Agents that complex Ca in the blood would be expected to decrease ionized Ca. Such agents include citrate, which is used as an anticoagulant for blood storage. During exchange blood transfusion, iCa can be decreased to 0.5 mmol/l in spite of administration of conventional amounts of Ca (i.e., 0.5–1 ml of 10% Ca gluconate for each 100 ml blood exchanged) during the transfusion (213,237). Increased levels of long-chain free fatty acids from intravenous lipid emulsion can complex Ca and reduce iCa *in vitro* (243), thus hypocalcemia potentially can occur with excessive rate of intravenous lipid infusion. Alkalosis can result in shifts of Ca from the ionized state to the protein-bound fraction (14,20,21). Because alkalosis per se increases neuromuscular hyperirritability, the combination of decreased serum iCa and alkalosis may precipitate clinical tetany in an infant with borderline serum Ca status. In clinical practice, administration of sodium bicarbonate in the therapy of metabolic acidosis often occurs in situations with high risk of hypocalcemia such as prematurity or perinatal asphyxia, whether it has an independent role in the development of hypocalcemia is not known. Hypocalcemia in neonates

receiving phototherapy is thought to result from the stimulation of a complex system of extraretinal photoreception, which results in neuroendocrine sequelae and hypocalcemia (244). For reasons that are unclear, infants born to narcotic-using mothers have been reported to have a lower serum iCa if they manifest withdrawal symptoms (245).

B. Diagnosis

Suspicion of hypocalcemia must be confirmed by measurement of serum tCa and iCa since clinical manifestations are many and varied and may be indistinguishable from other common neonatal diseases. Diagnostic work-ups are listed in Table 3. The less mature the infant, the more subtle and varied are the clinical manifestations and they are frequently asymptomatic. Clinical manifestations may include, irritability, jitteriness, or lethargy; feeding poorly with and without feeding intolerance; abdominal distention; apnea; cyanosis; and seizures and may be confused with manifestations of hypoglycemia, sepsis, meningitis, anoxia, intracranial bleeding, and narcotic withdrawal. Frank convulsions are seen more commonly with so-called late neonatal hypocalcemia. The classic signs of peripheral hyperexcitability of motor nerves: carpopedal spasm (spasm of the wrists and ankles, Trousseau's sign), facial spasm (Chvostek's sign), and laryngospasm (spasm of the vocal cords) are uncommon in newborn infants.

The level of iCa that determines which feature of tetany will be manifested varies among individuals and by other components of the extracellular fluid (e.g., hypo-

magnesemia and alkalosis) lower whereas hypokalemia and acidosis raise the threshold for tetany. At physiological concentrations of hydrogen and potassium ion, tetany may develop in older infants at an iCa less than 0.8 mmol/l (3.2 mg/dl) and will almost always be manifested, with the possible exception of preterm infants, at an iCa less than 0.6 mmol/l (2.4 mg/dl). If serum albumin concentrations are normal, the corresponding serum tCa concentrations usually are less than 1.8 mmol/l (7.2 mg/dl). In the preterm infant, serum iCa may not decrease to the same extent as tCa (7,201,246), presumably in part because of the sparing effect of lower serum albumin and acidosis found frequently in these infants, which tend to increase iCa. This also may partially explain the frequent lack of signs of hypocalcemia in preterm infants. The measurement of electrocardiographic QT intervals, corrected for heart rate (247), and standard nomogram relating serum tCa and total protein to ionized Ca (248), have little value for the prediction of neonatal serum iCa. Serum tCa is correlated with iCa (7,23,24,246) but is also inadequate for the prediction of one from the other. Confirmation of hypocalcemia as the cause of clinical symptoms is its reversibility when serum tCa or iCa has been normalized.

C. Management

Any neonate with seizures should have blood drawn for diagnostic tests before therapy (Table 4). Intravenous administration of Ca salts is the most effective and most rapid means of elevating serum Ca concentrations. Gradual or abrupt decrease in heart rate during the infusion is

Table 3 Diagnostic Work-Up for Neonatal Hypocalcemia

History: Screen for risk factors (see Table 1).

Physical Examination

General examination with focus on peripheral and central nervous and cardiovascular systems.

Associated features (e.g., infant of a diabetic mother, prematurity, birth asphyxia, congenital heart disease, pseudohypoparathyroidism etc.).

Investigations^{a,b}

Serum total and ionized calcium (tCa and iCa), magnesium and phosphorus, total protein and albumin, and simultaneous intact or whole parathyroid hormone.

Acid–base status.

Complete blood count (lymphocyte count).

Electrocardiogram (Q-Tc > 0.4 s or Q_o-Tc > 0.2 s).

Chest x-ray (thymic shadow, aortic arch).

Urine calcium, phosphorus, magnesium, and creatinine.

Meconium and urine screen for narcotics.

Maternal serum total and ionized calcium, magnesium and phosphorus, urine calcium and phosphorus, if suspect maternal or heritable Ca disorder, particularly in persistent neonatal hypocalcemia.

Additional work-up as indicated: vitamin D metabolites, T-cell number and function, malabsorption studies, response to exogenous PTH, molecular genetic studies (deletion of 22q11, PTH receptor and end-organ responsiveness abnormalities, and calcium-sensing receptor defects, etc.) and family screening.

^aIf serum tCa and iCa levels are normal, diagnostic work-up should focus on non-calcium-related causes of clinical symptoms: serum glucose, sepsis workup, screen for excretion of illicit drugs, neuroimaging studies, and others.

^bResolution of clinical symptoms when serum tCa or iCa has been normalized confirms the role of hypocalcemia.

Table 4 Management of Neonatal Hypocalcemia**Acute-phase therapy**

Correction of hypomagnesemia, acid–base problem, or others, if possible.

Intravenous 10–20 mg elemental Ca/kg as 10% Ca gluconate or 10% Ca chloride (provides 9 mg elemental Ca/ml or 27.2 mg/ml, respectively) with dextrose water or normal saline infused over 5–10 min under constant electrocardiographic (ECG) monitoring; repeat as necessary until resolution of severe symptoms such as seizures.

In infants that are not fed enterally, this is followed by intravenous continuous infusion at 50–75 mg elemental Ca/kg/day. Sometimes parenteral nutrition containing 50 mg elemental Ca/100 ml is preferred and continued until feeding.

In asymptomatic infants, oral 50–75 mg elemental Ca/kg/day in 4–6 divided doses. Elemental Ca/ml of calcium carbonate (40 mg), glubionate (23 mg), gluceptate (18 mg), gluconate (9 mg), lactate (13 mg), or chloride (27 mg). One ml of each compound contains 40, 23, 18, 9, 13, and 27 mg elemental Ca, respectively. Should be given appropriate low-phosphate milk feeding.

Once serum tCa normalized, halve the Ca supplement for 2 days, then discontinue.

Serial serum tCa (+/– iCa) every 12–14 h until clinically stable, every 24 h until normalized, and at 24 h after discontinued Ca supplement.

Maintenance therapy: treat underlying disorder if possible

For diet-induced hyperphosphatemia: use very-low-phosphorus formula (PM 60/40, Abbott Laboratories, Columbus, OH) until serum Ca and P normalized.

Higher Ca doses and prolonged therapy, may be needed (e.g., hypoparathyroidism).

Follow-up

Resolution of acute and residual effects from hypocalcemia and underlying disorder.

Frequency of clinical and laboratory monitoring depends on underlying disorder.

Family screening and genetic counseling as appropriate.

Complications

Treatment-related: minimal with continuous ECG monitoring during Ca infusion, avoid infusion into arterial lines (causes arterial spasm and tissue necrosis), check patency of venous lines prior to infusion (extravasation causes tissue necrosis). Risk for nephrocalcinosis and nephrolithiasis in patients with absent or nonfunctional parathyroid hormone, since protective hypocalciuric effect is absent.

Short-term: depends on the symptomatic manifestations: seizure, apnea, cyanosis and hypoxia, bradycardia and hypotension, and others. Risk of metastatic calcification from aggressive Ca treatment in the presence of hyperphosphatemia.

Long-term: primarily dependent on underlying cause.

Prevention

Minimize the predisposing risk factors for hypocalcemia, if possible.

Early milk feeding and use of calcium-containing parenteral nutrition.

an indication to slow or stop the infusion. There is little information on the comparative efficacy of Ca preparations in the treatment of neonatal hypocalcemia. In neonates, 10% Ca gluconate (0.45 mmol [18 mg] elemental Ca/kg) can effectively increase serum iCa, heart rate, cardiac contractility, and blood pressure (195–197). In children, small equimolar doses (0.07 mmol [2.8 mg] elemental Ca/kg) of 10% Ca chloride compared to 10% Ca gluconate may result in higher mean arterial blood pressure with a slightly greater mean increase (0.06 mmol/l, 0.2 mg/dl) in the measured serum iCa (249). Prolonged use of Ca chloride in high dosages may be associated with acidosis and probably should be avoided. With intravenous Ca therapy, bolus infusion may be associated with a transient slight decrease in blood pH and serum P (250) and with hypercalcemia (237). Continuous infusion probably is more efficacious than intermittent therapy (251) to maintain serum Ca in the normal range.

Arterial infusion of Ca in high concentrations potentially is fraught with many dangers and should be avoided.

Massive sloughing of soft tissue may occur in the distribution of the arterial supply, for example, inadvertent administration into a mesenteric artery theoretically can lead to necrosis of intestinal tissues. If umbilical venous catheter is used, the tip should not be intracardiac as administration of Ca directly into the heart may result in arrhythmia. However, parenteral nutrition solutions containing standard mineral (including calcium) content can be safely infused through appropriately positioned umbilical venous or umbilical arterial catheters. Direct admixture of Ca preparation with bicarbonate or phosphate solution will result in precipitation and must be avoided.

All oral Ca preparations are hypertonic, and there is a theoretical potential for precipitating necrotizing enterocolitis in infants at risk for this condition. Oral Ca preparations generally contains higher Ca concentration than intravenous preparations, and is useful for infants, particularly those requiring fluid restriction. However, syrup-based oral Ca preparations have a high sucrose content that may constitute a significant carbohydrate and osmolar

load for small preterm infants and may be associated with an increase in frequency of bowel movements. As an alternative an intravenous preparation can be used orally if the fluid volume is tolerated. Concurrent Mg deficiency, if present, must be treated to obtain maximal response to Ca therapy.

The duration of supplemental Ca therapy is usually 2–3 days for early neonatal hypocalcemia. Vitamin D metabolites, 1,25(OH)₂D at 0.05–0.2 $\mu\text{g}/\text{kg}/\text{day}$, intravenously or orally (252) and 1 α -hydroxyvitamin D at 0.33 μg twice daily orally (253); and exogenous PTH (214) have been used in the treatment of neonatal hypocalcemia. However, there is no practical advantage to the use of these agents in place of Ca for the treatment of acute hypocalcemia.

Vitamin D or one of its analogs is often used in addition to adequate Ca intake for the treatment of severe persistent hypocalcemia. The use of 1,25(OH)₂D is preferred because it can raise serum Ca within 1–2 days after initiation of therapy and leaves no residual effects within several days of its discontinuation. Vitamin D has slower onset of action of 2–4 weeks and the residual effect also lasts several weeks after its discontinuation, thus making dosage adjustment more difficult. In situations in which PTH is absent or nonfunctional, its hypocalcemic action cannot occur; therefore raising the serum Ca concentration may cause hypercalciuria, renal stones, nephrocalcinosis, and possible renal damage. These complications have been reported during therapy in patients with activating CaR mutation even while the patients are normocalcemic (234).

Successful management of neonatal hypocalcemia also depends on the resolution, if possible, of the primary cause of hypocalcemia. For example, in phosphate-induced hypocalcemia, high-phosphate formulas and solids should be discontinued, and human milk or a low-phosphate formula should be substituted. Use of aluminum hydroxide gel to bind intestinal phosphate should be avoided because of potential risk for aluminum toxicity (254).

Neonatal hypocalcemia may resolve spontaneously. However, hypocalcemia probably should be corrected, because Ca potentially can alter important cellular functions in which calcium serves either as a first or second messenger in cellular activity. Early milk feeding and the use of calcium-containing parenteral nutrition within hours after birth are the best means to minimize the development and recurrence of hypocalcemia, and may negate the need for use of Ca supplementation. Delaying premature delivery and minimizing perinatal asphyxia, judicious use of bicarbonate therapy and mechanical ventilation, for example, during intentional induction of alkalosis in the treatment of persistent pulmonary hypertension (255) are also useful measures to minimize neonatal hypocalcemia. Maintenance of normal maternal vitamin D status with exogenous vitamin D supplement, if needed, may in theory be helpful in maintaining normal fetal vitamin D

status and may secondarily prevent hypocalcemia in some neonates. Early feeding and provision of Ca to the gut may be important in enhancing the ability of vitamin D metabolites to prevent neonatal hypocalcemia.

Pharmacological prevention of neonatal hypocalcemia has focused primarily on the prophylactic use of Ca salts or vitamin D metabolites. In newborn infants, Ca supplementation results in sustained lowering of serum IPTH concentrations compared to unsupplemented controls (60). Ca supplementation may theoretically decrease the metabolic stress from hypocalcemia and minimize the potential for depletion of tissue Ca stores. Early studies used up to 1.8–2.0 mmol (72–80 mg)/kg/day of oral Ca supplement (256,257) and about half this amount intravenously (258) to prevent hypocalcemia. However, it should be noted that a similar amount of Ca can be provided from an intake of 150–200 ml/kg/day of standard term infant formula or human milk. Standard preterm infant formula can provide almost 5 mmol (200 mg) Ca/kg/day and parenteral nutrition with 1.25–1.5 mmol (50–60 mg) Ca/100 ml can easily provide 1.5 mmol (60 mg) Ca/kg/day. These amounts of Ca are well tolerated as they have been the standard practice in most neonatal nurseries for over a decade. Early feeding or parenteral nutrition must be considered as the best means to prevent neonatal hypocalcemia particularly for the preterm infant. Vitamin D₃ at 30 μg (conversion, 1 μg = 40 IU)/day orally (259), 25(OH)₂D at 10 $\mu\text{g}/\text{kg}/\text{day}$ orally (260), 1 α -hydroxyvitamin D₃ at 0.05–0.1 $\mu\text{g}/\text{kg}/\text{day}$ intravenously (261), and 1,25(OH)₂D at 0.5–1 $\mu\text{g}/\text{day}$ orally (262) or 0.1–4 $\mu\text{g}/\text{kg}/\text{day}$ intramuscularly or intravenously (7,200) have been used in attempts to prevent neonatal hypocalcemia with variable degrees of success. In small preterm infants, serum Ca was normalized only at pharmacological dosages of 1,25(OH)₂D (7). Regular follow-up clinical and laboratory monitoring such as evaluation of serum Ca and IPTH, are necessary in some situations, because there are no definitive measures to determine whether the infant with so-called transient hypoparathyroidism that may last for several years or is at risk for recurrence of hypoparathyroidism and hypocalcemia as late as adolescence (225–227).

VI. HYPERCALCEMIA

Hypercalcemia in infants is rare. However, it is increasingly being diagnosed because serum Ca is usually part of a panel of chemistry tests, and because of increasing knowledge of its pathogenesis. Hypercalcemia is present when serum tCa levels are more than 2.75 mmol/l (11 mg/dl) or when iCa is more than 1.4 mmol/l (5.6 mg/dl). In pathological hypercalcemia, elevation of serum iCa usually occurs simultaneously with elevation of tCa; however, elevated tCa may occur without elevation of iCa. Elevation of protein available to bind Ca (e.g., prolonged application of tourniquet before venipuncture, transuda-

tion of plasma water into tissues, in adult patients with multiple myeloma, and possibly adrenal insufficiency) may result in elevation of serum tCa. A change in serum albumin of 1 g/dl generally results in a parallel change in tCa of about 0.2 mmol/l. Conversely, reduced albumin binding of Ca may result in normal serum tCa in the presence of elevated ionized Ca (263).

A. Pathophysiology

Hypercalcemia in infants, particularly in the neonatal intensive care setting, is often iatrogenic from inadequate provision of dietary phosphate during and after hospitalization (43,44; Table 5). Phosphate deficiency or hypophosphatemia stimulates 1α -hydroxylase and synthesis of 1,25(OH)₂D, which enhances intestinal absorption and renal reabsorption of Ca and P. Increased Ca absorbed in the presence of increased 1,25(OH)₂D cannot be deposited in bone in the absence of phosphate and contributes to hypercalcemia. Details for the hormonal response to hypophosphatemia are discussed in the previous section. The use of Ca supplementation can result in hypercalcemia if there are periods of absent or inadequate phosphate intake (264) and this is augmented by decreased

renal Ca excretion in the neonate or from underlying illness.

Neonatal hyperparathyroidism frequently results in marked hypercalcemia. It may be a sporadic congenital occurrence or show a mendelian inheritance, or it may be secondary to maternal hypocalcemia. Hereditary primary hyperparathyroidism manifested in neonates is associated with inactivating mutations of CaR. The severity of hypercalcemia is related to the extent of CaR mutation. Mild hypercalcemia (serum tCa <3.0 mmol/l, 12 mg/dl) associated with heterozygous mutated CaR is manifested clinically in most patients with familial hypocalciuric hypercalcemia (FHH). The normal urinary Ca excretion despite hypercalcemia is an effect of the mutated CaR in the kidneys. Serum PTH is usually within the normal range but is higher than expected for the degree of hypercalcemia. FHH has been reported in patients from 2 h to 82 years of age and is usually diagnosed in infants as part of a screening procedure after diagnosis of a family member with hypercalcemia or familial multiple endocrine neoplasia. It is inherited as an autosomal dominant trait with a high degree of penetrance (265,266). There usually is significant hypophosphatemia and a modest increase in serum Mg concentration, and functional parathyroid glands are needed for full expression (265–268). Neonatal hyperparathyroidism associated with FHH that resolves spontaneously over several months has been reported (269). More severe hypercalcemia with serum tCa of 3 to 3.3 mmol/l (12–13 mg/dl) has been attributed to coexpression of the normal and mutated CaR, with the latter having a functional equivalent of a so-called dominant negative effect (233,270). The most marked hypercalcemia (serum Ca >4 mmol/l, 16 mg/dl) occurs in neonatal severe hyperparathyroidism with homozygous inactivating germ-line mutations of the Ca-sensing receptor gene; the disorder can be lethal within the first few weeks of life (271,272).

Activating mutations of the PTH/PTHrP receptor gene in Jansen metaphyseal dysplasia presumably have the receptor defects in the kidney, bone, and chondrocytes at the growth plate. The clinical manifestation include postnatal-onset short-limb dwarfism with radiographic rachitic changes, and mild hypercalcemia occurs in about 50% of affected patients (273,274).

Maternal hypocalcemia results in neonatal hyperparathyroidism (275). Neonatal hyperparathyroidism also may occur in the presence of maternal (276) or neonatal (277,278) renal tubular acidosis. In these situations, metabolic acidosis independently increases bone resorption (279), enhances the renal effects of hyperparathyroidism (280), and the hypercalcemic effect is augmented by decreased renal excretory capacity of the neonate.

Elevated serum PTHrP and hypercalcemia are found in an increasing number of infants with a variety of tumors (281–283). There is also associated mortality in some cases although the relative contribution of hypercalcemia and the underlying disease to death is not clear.

Table 5 Pathophysiology of Neonatal Hypercalcemia

Phosphate deficiency
Low or no phosphate but calcium-containing parenteral nutrition
Very-low-birth-weight infants fed human milk or, less commonly, standard formula
Parathyroid-related
Hereditary primary hyperparathyroidism
Calcium-sensing receptor inactivating mutations: familial hypocalciuric hypercalcemia, neonatal severe hyperparathyroidism
PTH receptor activating mutation
Secondary hyperparathyroidism
Maternal: hypocalcemia, renal tubular acidosis
Neonatal: renal tubular acidosis
Parathyroid hormone-related protein-secreting tumors
Vitamin D
Excessive intake in
Mother: increase milk vitamin D
Neonate: high-dosage vitamin D prophylaxis, overfortification of milk
Subcutaneous fat necrosis (increase 1,25 dihydroxyvitamin D)
Calcitonin response impairment (?) in congenital hypothyroidism
Vitamin A excess
Uncertain pathophysiological mechanism
Idiopathic infantile hypercalcemia/Williams syndrome
Extracorporeal membrane oxygenation therapy
Severe infantile hypophosphatasia
Blue diaper syndrome

Other pathological conditions associated with increased bone turnover or increased intestinal or renal Ca absorption may result in hypercalcemia. Hypercalcemia was reported in 34% of neonates and infants from intermittent high-dosage vitamin D (600,000 IU each 3–5 months) prophylaxis (284). Hypercalcemia also has been reported in infants given human milk with very high vitamin D content (7000 IU/L) from high-dosage vitamin D therapy for maternal hypoparathyroidism (285), milks with excessive vitamin D fortification from errors during processing (286,287), and in preterm infants given chronic vitamin D supplementation in addition to high-Ca and high-P milk formula (288). Neonates with extensive subcutaneous fat necrosis may develop hypercalcemia after a period of low or normal serum Ca concentrations. There is often a history of perinatal asphyxia (289–291) and anecdotal report that body cooling (291) for the treatment of birth asphyxia could augment the development of subcutaneous fat necrosis. Hypercalcemia is reported to occur between 2 and 16 weeks, most commonly at 6–7 weeks. Increased prostaglandin E activity, increased release of Ca from fat and other tissues, and unregulated production of 1,25(OH)₂D from macrophages infiltrating fat necrotic lesions have been postulated to be responsible for the hypercalcemia in these conditions (292). Vitamin A toxicity is associated with hypercalcemia presumably secondary to increased bone turnover (293).

Hypercalcemia may develop before and during thyroxine therapy of infants with congenital agoutrous hypothyroidism (294). In theory, deficient CT response to Ca loading or an increased degradation of CT may be responsible for the hypercalcemia.

Neonatal hypercalcemia is reported in other situations in which the pathophysiology remains uncertain. Idiopathic infantile hypercalcemia, often considered as part of Williams syndrome, is associated with varying manifestations including hypercalcemia, mental retardation, elfin facies, and supraaortic stenosis. There also may be prenatal and postnatal growth failure. The presence of hypercalcemia in infants with Williams syndrome is variable, and serum Ca may be normal, but the presence of nephrocalcinosis and soft tissue calcifications in some of these infants suggests that hypercalcemia may have occurred previously. An exaggerated response to pharmacological dosages of vitamin D₂ (18,000–100,000 IU) (295) and a blunted CT response to Ca loading and PTH infusion (296) may contribute to the pathogenesis of hypercalcemia of idiopathic infantile hypercalcemia. Several genetic defects in idiopathic infantile hypercalcemia, including hemizyosity at the elastin gene on the long arm of chromosome 7, have been reported (297,298). No mutation of the CT/CGRP gene has been detected (299). However, the cellular mechanism that led to the phenotypic expression remains unknown. Transient hypercalcemia occurs in infants during extracorporeal membrane oxygenation therapy varies from <5% (300,301) to about 30% (302) depending on whether the cutoff point used

was >2.5 or >2.25 mmol (12 mg or 11 mg/dl) respectively. Severe infantile hypophosphatasia is associated with hypercalcemia. It is a rare autosomal recessive disorder associated with decreased synthesis of tissue nonspecific alkaline phosphatase from a deletion or point mutation in its gene located on chromosome 1. These patients have severe bone demineralization, low serum alkaline phosphatase, and elevated urinary pyrophosphate and phosphoethanolamine. The condition may be lethal in utero or shortly after birth because of inadequate bony support of the thorax and skull, although milder phenotypes are compatible with survival to adulthood (303,304). Blue diaper syndrome is a rare familial disorder with defect in intestinal transport of tryptophan. The blue discoloration of the urine results from the hydrolysis and oxidation of urinary indican, an end-product of intestinal degradation of unabsorbed tryptophan and hepatic metabolism of its intermediate metabolites. Hypercalcemia and nephrocalcinosis usually do not manifest until some months after birth (305).

B. Diagnosis

Neonates with hypercalcemia may be asymptomatic despite the onset of hypercalcemia at birth (Table 6). In these cases, there is often delayed for weeks or months before diagnosis is made coincidental to a chemistry panel screening during the course of other illness or because of hypercalcemia in another family member.

Severe hypercalcemia can be fatal (272,281,289,293) although some of the infants have other potentially lethal underlying conditions such as hepatic sarcoma. Symptoms and signs frequently are nonspecific and include lethargy, irritability, poor feeding with or without feeding intolerance, constipation, polyuria, dehydration, and failure to thrive. Hypertension associated with hypercalcemia in adults also may occur in infants, although it may be in part related to relative fluid overload in infants who require extracorporeal membrane oxygen (ECMO) therapy. Ectopic deposition of a solid phase of calcium and phosphate in walls of blood vessels, and in connective tissue about the joints, gastric mucosa, renal parenchyma, and cornea may occur with persistent hypercalcemia, especially when accompanied by normal or elevated levels of serum P. Anatomical anomalies (e.g., elfin facies, evidence of congenital heart disease, subcutaneous fat necrosis) may be present on physical examination.

C. Treatment

Therapy depends on the extent of elevation of serum Ca and whether the infant is symptomatic (Table 7). For mildly elevated serum tCa (<12 mg/dl) in the presence of iatrogenic cause (e.g., phosphate free parenteral nutrition or the use of Ca supplement without any dietary phosphate intake), resolution of the underlying cause should resolve the problem. Dietary P deficiency induced hypercalcemia is becoming less common with the increasing

Family screening depends on the primary diagnosis	

use of commercial fortifier for human-milk-fed preterm infants, and the use of high Ca- and high P-containing infant formula and parenteral nutrition for the preterm infant. In patients with low serum P concentrations, large amounts of phosphate supplement may result in diarrhea and hypocalcemia and the possibility of metastatic calcification (306).

With moderate to severe hypercalcemia, the initial treatment is nonspecific with expansion of extracellular fluid compartment and furosemide-induced diuresis (307). Minimal information is available on the use of hormonal and other drug therapy for neonatal hypercalcemia. Non-mammalian sources of CT (e.g., salmon CT) has a greater hypocalcemic effect and longer duration of action compared with recombinant human CT. However, salmon CT has greater potential for allergic reaction and induction of antibody formation. The hypocalcemic effect decreases after a few days of any CT treatment. Steroid-induced hypertension, hyperglycemia, and gastrointestinal hemor-

rhage are significant problems (308), and thus are not recommended for long-term therapy. Bisphosphonates, oral etidronate (25 mg twice daily), and intravenous pamidronate (0.5 mg/kg) have been used for treatment of hypercalcemia in the mother and neonate (291,309). However, long-term effects on growth plate, bone production, and mineralization remain unknown (310), and its use should be restricted to acute short-term therapy. Dialysis in the neonate is not without technical or metabolic complications. In rare cases, parathyroidectomy may be necessary, although it is not always effective.

Treatment for chronic conditions also includes restriction of dietary intake of vitamin D and Ca and minimizing exposure to sunlight to decrease endogenous vitamin D production. A low-Ca, low-vitamin D₃, low-iron infant formula is available for the management of hypercalcemia in infants (Calcilo XD, Abbott Laboratories, Columbus, OH). This formula contains only trace amounts of Ca <10 mg/100 kcal and no vitamin D. Long-term use of this formula alone will lead to calcium depletion; iatrogenic vitamin D deficiency is also a concern in this situation, and both can result in deleterious consequences.

Neonatal hypercalcemia may not develop until some weeks after the onset of the insult and may resolve spontaneously as in subcutaneous necrosis. Therefore, serum Ca should be monitored at regular intervals in certain situations to determine the onset of hypercalcemia and to determine the need to continue treatment. Family screening for hypercalcemia should be done unless a specific nonfamilial cause for hypercalcemia is established in the index case.

VII. HYPOPHOSPHATEMIA

An infant can be considered to be hypophosphatemic when serum P concentration is <1.3 mmol/l (conversion, 1 mmol/l = 3.1 mg/dl).

A. Pathophysiology

Hypophosphatemia usually has a nutritional basis and occurs most frequently in infants receiving low P intake from parenteral nutrition (45,46) and in preterm infants fed unfortified human milk (43,44,311; Table 8). Hypophosphatemia occurs with administration of glucose, and it may be accentuated during starvation (312,313). The so-called refeeding syndrome from overzealous increase in the delivery of nutrients, particularly calories, can be associated with multiple electrolyte abnormalities, including hypophosphatemia, hypokalemia, hypomagnesemia, and hypocalcemia, and life-threatening complications (313–316). Glucose and P moved from extracellular to intracellular compartments to meet the metabolic needs leads to lowering of serum P. This decreases renal phosphate load and secondarily decreases urinary phosphate excretion. Insulin facilitates these processes (317). Respiratory alkalosis, liver disease, and hypokalemia also

Table 7 Management of Neonatal Hypercalcemia**Acute**

Remove causative factor, if possible (e.g., discontinue vitamin D and Ca supplement).

Intravenous normal saline (20 ml/kg) and loop diuretic (furosemide 2 mg/kg). Reassess and repeat every 4–6 h as necessary. Monitor fluid balance and serum calcium, magnesium, sodium, potassium, phosphorus, and osmolality every 6–12 h. Prolonged diuresis may require Mg and potassium replacement.

Use lower Ca content milk or parenteral nutrition if possible to maintain nutrition.

In neonates with low serum P (<1.3 mmol/l; 4 mg/dl), oral phosphate supplement at 0.5–1 mmol (15–30 mg) elemental P/kg/day in four divided doses may normalize serum P and Ca. In infants not being fed, can use parenteral nutrition containing usual amount of phosphate (1–1.5 mmol (31–46 mg)/100 ml).

Minimal data on the use of hormone (e.g., subcutaneous or intramuscular recombinant human calcitonin [4–8 IU/kg every 6 h], +/- oral glucocorticoid [prednisone 0.5–1 mg/kg/d]. Other drugs (e.g., bisphosphonates [pamidronate 0.5 mg/kg intravenously]) are experimental.

Peritoneal or hemodialysis with a low-calcium dialysate may be considered in severely symptomatic patient refractory to medical therapy.

Parathyroidectomy may be needed when clinically stabilized.

Maintenance

Depends on underlying cause.

Additional general therapy may be needed: low-Ca, no-vitamin-D infant formula (Calcilo XD, Abbott Laboratories, Columbus, OH); minimal sunlight exposure to lower endogenous synthesis of vitamin D.

Follow-up

Resolution of acute and residual effects from hypercalcemia and underlying disorder.

Frequency of clinical and laboratory monitoring depends on underlying disorder (e.g., in extensive subcutaneous fat necrosis, regular serum calcium is needed to monitor for the later onset and the need to continue treatment).

Family screening and genetic counseling as appropriate.

Complications

Acute: fluid electrolyte imbalance.

Chronic: failure to thrive, nephrocalcinosis, hypocalcemia and bone demineralization from excessive limitation of Ca and vitamin D intake, and those associated with underlying disorders.

may contribute to so-called shift hypophosphatemia. In infants receiving parenteral nutrition, hypophosphatemia is exaggerated if there is an associated rapid increase in delivery of carbohydrates (glucose), probably the result of transcellular shift of P in addition to a relative or absolute deficiency in P intake.

Hypophosphatemia from decreased intestinal P absorption can be an early manifestation of vitamin D deficiency (318,319). In theory, any severe and prolonged malabsorption syndrome may be associated with hypophosphatemia. Excessive nutrient intake, including sodium, glucose, amino acids, particularly if they are delivered intravenously, may exceed the renal reabsorptive capacity or lead to extracellular fluid compartment expansion. Both can result in increased renal loss of water and the infused nutrients including P, since renal excretory mechanisms for most nutrients (including P and water) are interdependent and are generally affected by sodium-dependent cotransport systems. Thus, increase in renal excretion of any of these nutrients potentially can increase the renal P excretion (69).

Nonnutritional causes of neonatal hypophosphatemia are much less frequent than nutritional causes. In the latter situations, the primary mechanism for hypophosphatemia

is probably decreased renal P reabsorption, which may or may not be secondary to elevated PTH.

B. Diagnosis

Serum P is usually normal at birth (Table 9). Hypophosphatemia may occur within days of birth or from the onset of the causative factor such as the use of phosphate-free parenteral nutrition. Acute hypophosphatemia in neonates is usually asymptomatic and may be diagnosed from routine screening because of a family history of disturbances in mineral metabolism. Hypophosphatemia may be an early manifestation of P deficiency. Chronic hypophosphatemia is indicative of P deficiency and may have multiple clinical consequences affecting hematological, immunological, cardiorespiratory, neuromuscular, skeletal, and peripheral and central nervous systems (320). These include impairment of oxygen release from hemoglobin, neutrophil dysfunction, muscle weakness and respiratory failure, and skeletal demineralization and deformity. Clinical signs such as muscle weakness attributed to hypophosphatemia are usually noted when the serum P concentration is <0.7 mmol/l (2.2 mg/dl). However, many of the clinical signs of P deficiency are masked by the un-

gen delivery associated with hypophosphatemia. More dramatic skeletal manifestations of prolonged and severe hypophosphatemia, such as rickets and osteomalacia, usually are not present until after the neonatal period (38, 47,231,319,321–325). Infants with X-linked hypophosphatemic vitamin-D-resistant rickets (HDDR), a dominantly inherited disorder of renal P wasting, usually do not have hypophosphatemia at birth. However, serial monitoring of infants in these families show hypophosphatemia, decreased percentage renal tubular reabsorption of P ($100\% \times \text{P clearance/creatinine clearance}$), increased bone turnover as indicated by increased serum alkaline phosphatase and increased urinary hydroxyproline, occur in affected infants as early as 3 weeks after birth (325) and in most affected infants by 3 months (324,325). Onset of growth delay and radiographic rachitic changes depend on the success of therapy and may occur during infancy. In other situations, such as neonatal primary hyperparathyroidism and Fanconi's syndrome, the presenting symptoms and signs may be unrelated to hypophosphatemia.

In most cases of neonatal hypophosphatemia, the diagnosis can be made with a careful review of the history and results of a few laboratory investigations. Severe hypophosphatemia (serum P < 0.7 mmol/l) can result from nutritional causes and is typically associated with hypercalcemia, almost total absence of P in the urine and urine Ca may be elevated (i.e., renal tubules that are resistant to the PTH effects) (43).

C. Treatment

Nutritional hypophosphatemia may be treated with P supplementation at 0.5–1.5 mmol/kg elemental P per day. Calcium supplementation (see Sec. V.C) is useful because it may minimize the fall in serum Ca concentration during P treatment, and it would alleviate Ca deficiency, which also occurs frequently in these infants (47). However, the best means to deliver the appropriate amount of P and Ca is by providing a balanced intake of all nutrients with high-P and high-Ca milk or parenteral nutrition (47). Standard vitamin D supplementation of 400 IU/day is adequate therapy for vitamin-D-deficient rickets in infancy (319). Therapy of nonnutritional hypophosphatemia varies with underlying disorder. For example, early administration of 1,25(OH)₂D at 30–40 ng/kg/day and phosphate at 40–50 mg/kg/day in addition to adequate general nutritional intake can improve mineral metabolism and may be useful to obviate severe growth delay and leg deformities (324, 325).

VIII. HYPERPHOSPHATEMIA

An infant can be considered to be hyperphosphatemic when the serum P concentration is >2.6 mmol/l (conversion, 1 mmol/l = 3.1 mg/dl).

A. Pathophysiology

Nutritional causes usually occur with the infusion of excessive P content (45) or alternating delivery of Ca and P in parenteral nutrition solution (264). Ingestion of cows' milk-type formulas (42; Table 10) and early introduction of high-P-containing cereals (205) may lead to neonatal hyperphosphatemia. Accidental overdose of oral phosphate supplement can be fatal (208). Vitamin D (291) and vitamin A (298) toxicity may result in hyperphosphatemia, in addition to hypercalcemia, from increased bone turnover. Nonnutritional causes include an excess phosphate load from the use of P-containing enemas (206,207). Other causes are usually associated with diminished P excretion. Neonates with asphyxia may have increased release of intracellular P to the extracellular compartment in addition to a low renal glomerular filtration. Decreased P excretion and hyperphosphatemia in the neonate can result from intrinsic renal failure, such as congenitally dysplastic kidneys, and from absent or nonfunctional PTH, such as hypoparathyroid and pseudohypoparathyroid states.

B. Diagnosis

History and physical examination consistent with clinical situations (Table 10) are useful for the diagnosis. Clinical features associated with underlying disorder such as Albright's hereditary osteodystrophy may be present. Serum P is usually normal at birth even in neonates with intrinsic renal failure or PTH disorders and increases during the first few days. There is usually concurrent hypocalcemia. Hyperphosphatemia, and hypocalcemia, may occur within hours after a phosphate load (208). Hyperphosphatemia may be asymptomatic, or it may be manifested because of its associated hypocalcemia effects (see Sec. V).

C. Treatment

Removal of excessive P load if possible, for example eliminating or minimizing the P load with the use of so-

called humanized formulas with low P content and a high Ca/P ratio of about 2:1, and temporarily discontinuing the use of cereals. A brief period of Ca supplementation is necessary if there is associated hypocalcemia.

Nonspecific lowering of serum P for the acute management of hyperphosphatemia may be achieved with normal saline infusion and forced natriuresis as for hypercalcemia (see Sec. VI). The use of Ca or aluminum salts as chelating agent for intestinal phosphate in the presence of hyperphosphatemia may predispose to metastatic calcification with the former (306) and potential for aluminum toxicity (254) and are not recommended.

For conditions that cause long term hyperphosphatemia, the treatment is aimed at the underlying cause.

IX. SKELETAL MANIFESTATIONS OF DISTURBED MINERAL HOMEOSTASIS

A. Pathophysiology

True fetal or congenital rickets is rare (Table 11). It may result from severe maternal nutritional osteomalacia associated with Ca and vitamin D deficiency (326–328), maternal hypoparathyroidism (203) or hyperparathyroidism (202), or prolonged maternal treatment with Mg sulfate (329) or phosphate-containing enemas (330).

The most frequent cause of skeletal abnormalities in infancy is nutritional deficiency. In the Western world, rickets and osteopenia presenting during infancy occur most frequently in small preterm infants and may occur in more than 30% of extremely low-birth-weight (<1 kg) infants. The rate of occurrence depends on the nutrient intake and is associated most frequently with prolonged

intake of soy formula, unfortified human milk, and/or low-Ca and low-P parenteral nutrition (47). In infants born at term, prolonged exclusive human milk feeding with limited exposure to sunshine, macrobiotic diet, and prolonged total parenteral nutrition are factors that contribute to the development of osteopenia and rickets (38, 319,321–323). The common underlying causes in preterm infants appear to be mineral deficiency, particularly Ca and P, whereas in term infants Ca deficiency is also important. Preterm infants fed unfortified human milk or term infants fed standard milk formula often have low serum 25OHD concentrations. The major reason for the low serum 25OHD in these situations is the increased metabolism of 25OHD with mineral deficiency, in particular, Ca deficiency (see Sec. III.C). Ca and P deficiency was demonstrated as the major cause of osteopenia and rickets in preterm infants over 2 decades ago (331). This has been confirmed by many investigators (47) and the use of high-Ca and high-P milk and parenteral intake with a daily supplementation of 400–800 IU vitamin D is sufficient to maintain serum 25OHD in the normal range (177, 331,332). Unfortunately, vitamin D deficiency secondary to inadequate mineral deficiency is still frequently misdiagnosed as the primary cause of osteopenia, fracture, and rickets in preterm infants and treated with more vitamin D supplement without improving the mineral and general nutritional support. Calcium deficiency also is an important cause of rickets in young children living in subtropical regions with adequate vitamin D status (38). Isolated nutritional deficiency of copper and ascorbic acid has been reported in preterm infants with clinical and radiographic manifestations similar to rickets (47). Chronic diuretic therapy, commonly used in infants with bronchopulmonary dysplasia, and contamination of nutrients with toxins such as aluminum are added risk factors (246,323). The extent, however, to which each specific risk factor is responsible for the development of osteopenia, fractures, and rickets is difficult to define in critically ill infants receiving multiple therapies and suboptimal nutritional support.

Acquired and heritable forms of rickets that occur despite adequate availability of vitamin D usually are associated with renal tubular disorders and metabolic defects in vitamin D and PTH metabolism (202,203,231,324, 325). These causes of rickets are rare, and their skeletal manifestations may present during infancy.

B. Diagnosis

History of significant nutritional defect in the mother either from self-selected dietary restriction or cultural habits (e.g., extensive covering of the body with lack of sunlight exposure), or family history of metabolic disorders and disturbed bone mineral metabolism should raise the awareness of the potential for nutritional and skeletal problems in both the mother and infant.

Infants with congenital rickets may be asymptomatic at birth leading to a delay in diagnosis unless investiga-

tions are performed as part of the work-up for disturbances in maternal mineral metabolism. Most postnatal cases of rickets and osteopenia are diagnosed incidentally during the radiographic investigation of skeletal complications such as fractures or nonskeletal problems such as respiratory illness. Radiographic features such as generalized bone demineralization and widening, cupping, and fraying of the distal metaphyses confirm presence of osteopenia and rickets (332–334).

Classic clinical features of rickets such as severe skeletal deformities, including kyphoscoliosis and bowing of the legs, may not be present if the diagnosis is made early in infancy, before significant growth and weight-bearing have occurred. This is particularly true for the preterm infant whose skeletal problem typically is diagnosed between 2 and 6 months postnatally. With the current practice of early discharge of preterm infants from neonatal units, it is possible that some nutritional rickets could be diagnosed after hospital discharge. If there are associated fractures, it may be misdiagnosed as child abuse. Clinical hypotonia is probably due to a decrease in intracellular phosphate pool of skeletal muscle (335).

Serial biochemical changes commonly include persistently low serum inorganic phosphate, elevated serum alkaline phosphatase activity more than five times the normal adult upper limit, and other bone turnover markers in serum and urine also can be elevated. Serum Ca is usually normal except in late severe nutritional rickets. Vitamin D deficiency as indicated by low or undetectable serum 25 OHD is possible; and is usually secondary to mineral deficiency in a small preterm infant. There may be elevated serum 1,25(OH)₂D and IPTH with Ca, P, and vitamin D deficiency. The elevated PTH and 1,25(OH)₂D still may be relatively insufficient to maintain Ca and P homeostasis if the Ca and P intake remain low. Urine changes may reflect increased serum IPTH with increased urine P excretion and Ca conservation. However, in chronic mineral deficiency, particular of P, urine findings may reflect changes of PTH resistance, in which case urine P would be minimal while there is calcuria. Measurement of specific trace mineral status may be useful if deficiency is suspected (177,336–339). The use of dual energy X-ray absorptiometry (DXA) allows a more accurate quantification of the degree of bone mineralization (340). Additional investigations are needed if inherited renal tubular disorders and for disorders of vitamin D and PTH metabolism are suspected.

C. Prevention and Treatment

Rickets and fractures from nutritional deficiencies respond well to adequate nutrient intake. The best treatment for nutritional osteopenia, fractures and rickets is prevention. For preterm infants, these skeletal problems appear to have become less frequent with increased Ca and P intake through the widespread use of high-Ca and high-P parenteral nutrition until establishment of enteral feeding with human milk containing commercial fortifier or for-

mulas designed specifically for preterm infants (47). Human milk is likely to be low in a number of nutrients including protein, sodium, calcium, P, and possibly other nutrients for the needs of the very small preterm infant (43,47,311,341,342). All very small preterm infants, particularly those with birth weights less than 1500 g should receive commercial fortifier containing multiple nutrients during their hospital stay and probably after hospital discharge.

With established osteopenia with or without fractures or rickets, the use of Ca and P supplementation alone is inappropriate since bone growth requires protein and multiple other nutrients for matrix formation and mineralization. In addition, further large increases in Ca and P intake beyond the current recommended intake is probably not advisable because of the risks of bezoar and even intestinal obstruction with excessive oral intake (47), and hyperphosphatemia with intravenous intake (45). In preterm infants, most fractures show significant callus formation at diagnosis and only require splinting support (343). Short-term analgesia is needed if the fracture is recent and without callus formation. The ingestion of the recommended daily amount of Ca and P should be adequate for otherwise healthy term infants (344,345).

Normal vitamin D status can be maintained in enterally fed healthy term infants without vitamin D supplementation provided adequate sunlight exposure is assured (173–175). In any case, a daily supplementation of 400 IU vitamin D should be adequate (175,176). Enterally fed preterm infants given high Ca- high P- and vitamin-D-fortified preterm infant formula or human milk with similar fortification from commercial human milk fortifiers probably do not require vitamin D supplementation. In any case, a daily supplementation of 400–800 IU vitamin D should be adequate (177,331,332). For infants who require parenteral nutrition as the major source of nutritional support, a maximum total daily intake of 400 IU vitamin D is sufficient to maintain vitamin D status regardless of the gestational age of the infant (45,46). For infants with established nutritional vitamin D deficiency, a daily supplementation of 400 IU vitamin D in addition to adequate overall nutritional support is also adequate (319).

Specific therapies are required for inherited renal tubular disorders and for disorders of vitamin D and PTH metabolism and usually include one or more of the following: calcium, phosphate, and 1,25(OH)₂D.

D. Monitoring and Follow-Up

The goal is for affected infants to grow normally without residual defect. Regular clinical assessment and growth measurements are essential. Short-term follow-up of infants with nutritional rickets including preterm infants show no major residual physical deformity (319,343). Skeletal maturation as assessed by ossification centers of the wrists for preterm infants is similar to term infants at 1 year of age (343). However, long-term linear growth in the extremely low-birth-weight infants may remain de-

layed (346), indicating that bone mineral status in the smallest preterm infants still may be suboptimal despite the relatively uncommon occurrence of radiographic rickets and fractures on follow-up. Screening for other affected family members and molecular studies may be warranted in heritable conditions.

Biochemical monitoring of nutritional rickets includes maintaining normal serum Ca, P, and alkaline phosphatase levels, while avoiding hypercalciuria (<0.15 mmol, 6 mg Ca/kg/day) every 1–2 weeks until normalized. Measurement of bone turnover markers, IPTH, vitamin D metabolites such as 25OHD and 1,25(OH)₂D, and any other abnormal biochemical parameter, every 1–2 months until normalized. Standard skeletal radiographs every 2–4 months to check for healing and remodeling. Serial measurements of bone mineral content by DXA every 2–4 months also may be useful to monitor the progress of bone mineralization during long-term follow-up. Other specific monitoring would depend on the underlying cause.

Metabolic Bone Disease

Joseph M. Gertner

Serono Inc., Rockland, and Children's Hospital, Boston, Massachusetts, U.S.A.

I. INTRODUCTION

Metabolic bone diseases in childhood can be broadly classified into diseases that result from metabolic defects intrinsic to the skeletal system and those that result from an abnormal milieu in which the skeleton is developing. Recent years have seen an explosion of knowledge regarding both types of metabolic bone disease. In the first section I review rickets and rickets-like conditions, which are generally disorders in which bone is affected by an abnormal extraskelatal milieu.

II. RICKETS

The recognition of rickets as a deforming bone disease of childhood is centuries old. Early in the 20th century, Huldshinsky (1) in Vienna made the critical observation that artificial sunlight could cure and prevent rickets, and Mellanby, working in England, showed that a lipid-soluble substance made in the skin or ingested in the diet was necessary to prevent rickets (2). This substance was classified among the essential food factors and called vitamin D, although it differs from true vitamins in that mammals, including humans, can synthesize it *in vivo*. The last 30 years have seen the recognition that vitamin D needs to be activated, via hepatic and renal hydroxylations, to 1,25 dihydroxyvitamin D (calcitriol) and that the latter is a hormone the production of which is sensitive to hormonal, metabolic, and nutritional regulation. Calcitriol is a sterol derived from cholesterol with considerable structural homology to the adrenal and gonadal steroids. Its principal actions are mediated by the binding of calcitriol to a specific intracellular receptor of the steroid/thyroid/retinoic acid class, followed by interaction of the hormone-receptor complex with the nucleus, where it acts to regulate the transcription of certain specific genes.

In the mid-20th century, Winters in North Carolina and Prader in Zurich described forms of rickets that did

not respond to standard replacement therapy with vitamin D. Winter's discovery eventually led to an appreciation of the role of non-vitamin-D-dependent mineral (particularly phosphate) metabolism in skeletal development. The observation by Prader opened a field of inquiry that would eventually link the pathophysiology of vitamin D metabolism and calcitriol-receptor interactions to skeletal disorders in childhood. This section reviews the morphological manifestations of rickets and the associated skeletal histopathology. The specific clinical and biochemical features of rickets as a result of disorders of nutrition, vitamin D metabolism, and calcitriol-receptor interaction are then reviewed. Next, I review the skeletal effects of phosphate depletion, particularly renal phosphate wasting. Finally, rickets and rickets-like conditions caused by renal failure and less common nutritional, metabolic, and genetic disorders are reviewed.

A. Nomenclature

Rickets can be caused by a number of distinct abnormalities of vitamin D intake and metabolism and of mineral homeostasis. As the underlying causes of the varieties of rickets are discovered, more rational names can be applied to individual rachitic syndromes. The terms vitamin-D-resistant rickets and renal rickets are no longer used because they may be applied to a number of conditions that do not resolve with administration of nutritionally adequate dosages of vitamin D or that are attributable to a variety of defects in renal function, respectively. The names of the various kinds of rickets given in this chapter have been selected as the most unambiguous and informative with regard to cause.

B. Definition

Rickets is a bone disease of childhood resulting from the undermineralization of the cartilaginous epiphyseal

growth plate. Rickets is confined to children because the growth plate exists only when the skeleton is growing. Widening and flaring of the epiphysis are seen with all forms.

C. Structural and Clinical Pathology

Softening of the skull (craniotabes) leading to permanent frontal bossing occurs when the onset is in infancy. The ribs (costochondral junctions), ankles, wrists, and knees are other sites commonly affected in growing children. Softening of the long bones is common in severe cases. The nature of the deformity is age dependent. The arms may be affected when used for weight-bearing in babies. The typical lower limb deformity is genu varum when the age of onset is under 3 or 4 years and genu valgum when rickets starts in school-age children. These differences may be caused by the changing relative rates of growth at various epiphyses. (See Fig. 1.)

D. Extraskelatal Clinical Features

The structural and orthopedic features of the various types of rickets are similar, but this is not true of the extraskelatal manifestations of the conditions that lead to rickets. Hypocalcemia leading to tetany and seizures occurs in vitamin D deficiency and related disorders but not in rickets because of phosphate depletion. Many types of rickets are associated with weakness and myopathy; others are not. Other nonskeletal tissues are also involved in selected forms of rickets, including the hair in calcitriol resistance and the teeth in familial hypophosphatemia. Because of this heterogeneity, nonskeletal manifestations are de-

scribed under the heading of each individual type of rickets.

E. Nutritional Rickets

Nutritional rickets, once the scourge of poorer children in industrial northern countries, is now largely a disease of developing nations. However, cases occur in the United States and other advanced industrial countries, posing a significant challenge to preventive health services in these countries. Although the term nutritional rickets has generally been reserved for the disease that results from a deficiency of vitamin D, it has been recognized in recent years that calcium deficiency, alone or in combination with vitamin D deficiency (3), can affect large numbers of children in at-risk populations.

F. Symptoms

Vitamin D deficiency rickets can present at any age during childhood. In severely endemic areas, the deformities and hypocalcemia of rickets may exist at birth (neonatal rickets). When it presents at birth, the softening of the skull (craniotabes) and the neuromuscular consequences of hypocalcemia dominate the clinical picture. More typically, it appears in toddlers aged between 1 and 2 years with a triad of deformity, weakness, and bone pain (Fig. 2). Most frequently, there is enlargement of the epiphyseal growth plates at the ankles and wrists and expansion of the growth plates at the costochondral junctions (rachitic rosary). The lower limbs may be bowed (genu varum), especially if the child is walking. Because of the proximal muscle weakness of vitamin D deficiency and possibly

Figure 1 Widening of the epiphyses indicates rickets, and the bending of the lower femoral shafts demonstrates the accompanying osteomalacia in a 5-year-old boy with Fanconi syndrome as a result of cystinosis.

Figure 2 Longstanding nutritional rickets. Note the frontal bossing, rachitic rosary of the costochondral junctions, and deformities of the lower limbs.

because of bone pain, a child who had been walking may become reluctant to walk and revert to crawling or shuffling. There may be tenderness on pressure over the long bones. Growth and weight gain may be impaired either because of a specific deficit in long-bone growth because of vitamin D deficiency or generalized undernutrition of which the vitamin D deficiency is only a part. Associated hypocalcemia may lead to tetany or seizures. In populations in which calcium deficiency appears to be a common cause of rickets the symptoms are quite similar to that seen in vitamin D deficiency (4).

In older children the presentation of nutritional rickets tends to be more subtle, with the gradual appearance of genu varum up to the middle of the first decade and with a knock-kneed or genu valgum deformity occurring in preadolescents. In this age group, as in infants, vitamin D deficiency may also present with hypocalcemia with little or no physical or radiological evidence of skeletal disease. Such children may have a hypocalcemic seizure, or they may complain of distressing paresthesiae or tetany.

G. Radiology

The characteristic radiological changes of rickets are widening, cupping, and fraying of the epiphyses (Fig. 3), together with metaphyseal distortion from osteomalacia with malalignment of the long bones resulting from both the epiphyseal and metaphyseal changes. The sites at which these changes are seen vary with the age of the patient and with the cause of the rickets. In infants the wrists and ankles are most likely to show abnormalities, along with the costochondral junctions. In metabolic bone disease of prematurity rickets is often detected at chest x-ray, not only from the costochondral junctions but also because of abnormalities of the proximal humeral and medial clavicular epiphyses. In older children the major epiphyseal changes are more often seen at the knees and hips. The last epiphysis to fuse at adolescence is the iliac crest, which may therefore show rachitic changes in mature teenagers when all other epiphyses are closed. When rickets is treated the widened epiphyses calcify, often to a density higher than seen in the x-rays of healthy children.

Figure 3 Cupping, fraying, and widening of the epiphyses at the wrist in a young child with nutritional rickets.

In familial hypophosphatemic rickets the upper limbs and costochondral junctions tend to be spared and the major impact is on the lower limbs. The fraying of the upper tibial epiphysis is often much more marked medially than laterally. The osteomalacic bending of long bones (Fig. 1) is not often seen today except in longstanding disease or in those varieties of rickets (such as calcitriol resistance) for which there is no effective treatment.

Malalignment of the lower limbs, on the other hand, is common. Young children tend to show a bow-legged deformity (*genu varum*), but rickets of onset in an older age group often gives rise to the opposite, knock-kneed (*genu valgum*) deformity. In contrast to the epiphyseal changes, the changes in alignment do not resolve rapidly with treatment. They may resolve slowly, however, as remodeling and growth proceed over the years following successful treatment of the rickets.

H. Biochemical Changes

Table 1 summarizes the biochemical abnormalities in various types of rickets.

The biochemical abnormalities in nutritional rickets are a subset of those seen in rickets generally. In almost all cases of rickets, bone turnover rates are increased and the attempt to synthesize new osteoid is accompanied by an elevation in serum alkaline phosphatase levels. In nutritional rickets serum calcium levels are usually low, although cases of significant vitamin D deficiency rickets may have normal serum calcium, presumably as a result of parathyroid compensation. The hyperparathyroidism leads to phosphaturia and hypophosphatemia. Eventually parathyroid compensation becomes inadequate and serum calcium falls. Finally, the renal tubule may lose its sensitivity to parathyroid hormone (5), with the result that the renal tubular threshold for phosphate rises with a corresponding increase in serum phosphorus (6).

Vitamin D metabolite levels reflect the nutritional deprivation. The most abundant metabolite in the plasma, the level of which most closely reflects vitamin D nutritional status, is calcidiol (25-hydroxyvitamin D).

I. Epidemiology

In vitamin D deficiency, dietary history may reveal prolonged breastfeeding, a failure to take prescribed vitamin supplements, or, in countries where milk is fortified with vitamin D, an aversion to or intolerance for milk. Disorders of the alimentary tract may also contribute to nutritional rickets, most notably gluten sensitive enteropathy (7), biliary atresia (8), and surgical short gut syndromes (9). Darkly pigmented skin may play a part in reducing the proportion of incident ultraviolet radiation capable of catalyzing the first step in vitamin D formation. However, the nutritional and socioeconomic deprivation conducive to the development of rickets occurs in all human groups.

In contrast to vitamin D deficiency, often associated with prolonged nursing, calcium-deficiency rickets is associated with early discontinuation of breastfeeding and the consumption of diets low in calcium and that may contain inhibitors of calcium absorption (10).

Anticonvulsant rickets is a special case of vitamin-D-deficiency rickets. Patients taking phenobarbital and phenytoin were noted over 30 years ago to have an increased incidence of raised alkaline phosphatase and an increased risk of rickets (11). Subsequent work has shown that phenytoin may be responsible for a variety of relatively mild disturbances of calcium and bone mineral metabolism. These are not necessarily related to vitamin D. Phenobarbital, however, by inducing enzymes that catalyze the hepatic conjugation of vitamin D metabolites, can increase the rate of loss of vitamin D from the body, giving rise to vitamin D deficiency in subjects with marginal states of vitamin D nutrition.

III. DISORDERS OF VITAMIN D METABOLISM

As noted, vitamin D is activated by two hydroxylation steps catalyzed by the hepatic microsomal cytochrome P450 enzyme, vitamin D 25-hydroxylase, and the renal mitochondrial cytochrome P450, 25-hydroxyvitamin D 1 α -hydroxylase, respectively. Defective activation can oc-

Table 1 Biochemical Abnormalities in Various Types of Rickets

Fanconi syndrome	↓ to N	↓	↑	↓	N	↓	N or ↑	N or ↑
Renal failure	↓ to ↑	↑	↑	↓	N or ↓	↓	↑	↓ to ↑

cur if sufficient enzyme-bearing tissue is not available, if enzyme activity is inhibited by the hormonal and ionic milieu, and when genetic disease has reduced or destroyed enzyme activity. In practice, much redundancy exists in the availability of enzyme for the 25-hydroxylation of vitamin D, so that hepatic cirrhosis is not accompanied by a deficiency of calcidiol unless associated biliary obstruction leads to fat malabsorption causing substrate (vitamin D) deficiency. Despite suggestive cases in one family (12), no genetic syndrome caused by a deficiency of vitamin D 25-hydroxylase has been well characterized to date.

The formation of calcitriol in the kidney is tightly regulated and can be pathologically inhibited by a lack of renal tissue or by an excessive extracellular fluid concentration of inorganic phosphate. These conditions prevail in renal failure, which is discussed later. In rare cases, however, the 1 α -hydroxylation of calcidiol may be defective in the absence of any other renal dysfunction.

A. Calciferol Deficiency Rickets (Vitamin D Dependency Type 1, or Pseudodeficiency Rickets)

In 1961, Prader and colleagues (13) described an autosomal recessively inherited form of persistent infantile rickets they named pseudodeficiency rickets. The name arises from the close resemblance of the disease to vitamin D deficiency, the major clinical differences lying in the early onset and severity of the rickets and the failure to respond to replacement dosages of vitamin D. A few years later, Fraser, Scriver, and colleagues noted that pseudodeficiency rickets, also called vitamin D dependency rickets, could be treated with low dosages of calcitriol. The condition thus became the first inborn error of vitamin D deficiency to be recognized as such (14). The concept of an abnormality of 1- α hydroxylation was supported when radioreceptor assays for vitamin D metabolites showed patients with pseudodeficiency rickets to have normal levels of calcidiol and very low levels of calcitriol. The assumption that the disease was caused by a mutation of the gene for the 1- α hydroxylase was confirmed after chromosomal mapping of the trait to 12q 1314, cloning of the 1- α hydroxylase gene and sequencing of that gene in affected individuals (15).

Undiagnosed or untreated vitamin D dependency type I can lead to severe deformity, accompanied by hypocalcemia and weakness. However, the disease is readily amenable to treatment with physiological replacement dosages of calcitriol (0.5–2.0 $\mu\text{g}/\text{day}$).

B. Vitamin D Dependency Type II: Calcitriol Resistance (Vitamin-D-Dependent Rickets Type II)

In 1978, two groups independently described patients who appeared to have vitamin D dependency type I but in whom circulating levels of calcitriol were very high. The

patients of Marx et al. (16) were siblings with severe hypocalcemic rickets who responded to treatment with high dosages of vitamin D₂ or of calcitriol. Three families were described independently 2 years later (from Israel, the United States, and Japan) in which this type of rickets was associated with severe alopecia. The inheritance pattern of the disease and the high frequency of consanguinity in affected kindreds strongly suggest recessive inheritance. The biochemical features resemble those of calcitriol deficiency except that calcitriol levels are high. The patient's condition resists the administration of calcitriol, although some patients respond to dosages as high as 12.5–20 $\mu\text{g}/\text{day}$. The successful use of parenteral and oral calcium to treat this condition (17) is of practical importance because resistance to vitamin D metabolites may be nearly complete in affected patients, offering no other chance for normal bone development. The finding is also of theoretical importance because it implies that the major contribution of calcitriol to skeletal mineralization is the provision of ionized calcium to the extracellular milieu rather than a direct action of calcitriol on bone cells.

The pathogenetic mechanism underlying vitamin D dependency type II is resistance to calcitriol, which has been demonstrated at the subcellular level. The calcitriol receptor may fail to bind hormone because of a mutation at the hormone-binding site (18). Receptor binding may also be normal but hormone action is prevented by impaired interaction of the hormone–receptor complex with the nucleus because of mutations of the DNA-binding so-called zinc fingers (19). In other cases of clear calcitriol resistance, mutations are apparently absent from both the hormone and the DNA-binding regions (20). It is of interest that alopecia accompanies cases of calcitriol resistance of various genetic causes, indicating that normal hair growth may have a direct requirement for functional calcitriol receptors.

IV. DISORDERS OF PHOSPHATE HOMEOSTASIS

Table 2 shows the classification of hypophosphatemic rickets.

A. Physiology

Phosphorus exists in the body largely as phosphate ion bound to organic molecules to form organophosphates. In the serum, about two-thirds of circulating phosphate forms part of such organic molecules bound to protein, but one-third is unbound and is measured after separation from the bound form as so-called inorganic phosphate (Pi). Concentrations of phosphate in the serum are given in molar units or in mass units, which refer to the quantity of elemental phosphorus within molecules of inorganic phosphate.

Table 2 Classification of Hypophosphatemic Rickets

Class of rickets	MIM no.	Inheritance	Comments
Isolated phosphaturia, low urine calcium			
Familial hypophosphatemic rickets	307800	X-linked dominant	Relatively common
Autosomal hypophosphatemic rickets	241520	Autosomal recessive	Very rare, phenotypically identical to 307800
Tumor rickets	—	Not familial	
McCune-Albright syndrome	174800	Not familial	Activation of receptor G proteins
High urine calcium: HHRH	241530	Autosomal recessive	Mild cases may have nephrolithiasis only
Fanconi syndrome: proximal tubular failure			
Cystinosis	219800	Autosomal recessive	Lysosomal cystine storage; progressive uremia
Dent's disease	310468	X-linked	May be a variant of "X-linked nephropathy"

The systems that control phosphate homeostasis tend to regulate total body phosphate content rather than, as in the case of calcium, absolute ionic concentration in the extracellular fluid. This difference accords with the different extracellular roles of calcium and phosphate. Tight control of extracellular Ca^{2+} is essential for the correct function of calcium-dependent cellular activation processes. In contrast, the function of extracellular phosphate is mostly as intracellular organophosphates providing intermediaries in energy metabolism, signaling systems, and the genetic code. In accord with these observations is that no well-characterized hormonal system operates primarily to regulate serum phosphate concentration. Instead it is total body phosphate that is sensed and regulated.

The intestinal absorption of dietary phosphate is largely unregulated, about two-thirds of the phosphate content of digested foodstuffs being absorbed. The regulation of phosphate balance lies almost entirely at the level of the proximal renal tubule, which can vary the rate at which filtered Pi is reabsorbed from the tubular fluid. This reabsorption, which normally accounts for 85–95% of filtered Pi, is facilitated by one or more saturable, sodium dependent transporters located on the brush-border membrane. Two genes coding for such transporters in the human have been cloned. Theoretically, the causes of disorders of phosphate homeostasis could be attributable to intrinsic disorders of one or more of these transporter systems or to dysregulation of their function.

1. Dietary Regulation

The renal tubular reabsorption of Pi is extraordinarily sensitive to the dietary intake of phosphorus, specifically to the relationship of the intake of phosphate to that of total calories. In classic studies defining the phosphate-deprived state, Lotz et al. found a sharp reduction in urinary phosphate excretion, increased calciuria, and such symptoms as muscle weakness (21). The reduction in urinary phosphate excretion is rapid, occurring before there is time for serum phosphate to fall significantly, thus leading

to the view that there exists a diet-sensitive hormonal system regulating urinary phosphate excretion. The mechanism whereby such a system might influence renal tubular phosphate transport is still unknown but is much closer to elucidation with the recent elaboration of the concept of so-called phosphatonin and the demonstration of the role played by fibroblast growth factor 23 (FGF23) in disorders of phosphate homeostasis (see below).

2. Parathyroid Hormone and PTH-Related Protein

Although primarily functioning as a regulator of Ca^{2+} , parathyroid hormone (PTH) also affects renal phosphate control by inducing phosphaturia. Patients with hyperparathyroidism are hypophosphatemic and, conversely, hypoparathyroidism is associated with hyperphosphatemia. PTH-related protein (PTHrP), circulating in excess in patients with humoral hypercalcemia of malignancy, leads to hypophosphatemia, presumably because of the interaction of PTHrP with renal PTH receptors.

3. Vitamin D Endocrine System

The adequacy of phosphate nutrition and the level of Pi in the serum are major regulators of the renal $1-\alpha$ hydroxylation of calcidiol to calcitriol. Calcitriol levels are generally high during phosphate deprivation and in the face of hypophosphatemia and are depressed by phosphate excess. Although phosphate regulates the activation of vitamin D, the converse, a vitamin D effect on phosphate homeostasis, appears to play only a minor part in normal physiology.

B. Disordered Control of Serum Phosphate

The control of serum phosphate resides primarily in the proximal renal tubules. Primary disorders of renal tubular phosphate reabsorption, or secondary failure of this process due to lesions outside the tubule, can lead to excessive renal phosphate loss and consequent metabolic bone

disease. Phosphate-wasting states are listed in Table 2. Because they lead to hypophosphatemia, their chief manifestations, when chronic, are rickets and osteomalacia, the general features of which have been discussed.

C. X-Linked Hypophosphatemic Rickets

X-linked hypophosphatemic rickets (XLH), a condition dominated by proximal renal tubular phosphate wasting, is by far the most common cause of this type of phosphaturic rickets. Rickets appears in the first year of life. The skeletal changes resemble those of vitamin D deficiency, but the lower limbs are much more severely affected than the upper and the rachitic rosary is not seen. Frontal cranial bossing is common, and rarely there may be a degree of craniosynostosis. There is a striking absence of muscular weakness. Dental deterioration and dental abscess formation are common and may constitute presenting symptoms of the disease. On radiological studies the bones often appear more dense than normal, in contrast to the appearance in nutritional rickets. The lower limbs are more severely affected than the upper, and, characteristically, the lateral portion of the lower femoral epiphysis appears more severely affected than the medial.

Physical growth is impaired. Untreated, the disease results in severe growth retardation and deformity in males, who are hemizygotes. The course is more variable in heterozygous females, some being seriously affected; in others, short stature or the biochemical finding of a reduced renal tubular resorptive capacity for phosphorus may be the only manifestation.

The biochemical findings (Table 1) are dominated by hypophosphatemia with normocalcemia. The renal tubular phosphate threshold (22) is always subnormal in hypophosphatemic rickets. The normal calcitriol concentration is the face of hypophosphatemia (which generally stimulates calcitriol formation) suggests that the underlying defect involves vitamin D metabolism as well as renal tubular phosphate transport. This concept is supported by observation that calcitriol formation stimulated by PTH infusion (23) or by phosphate deprivation (24) is impaired in subjects with FHR relative to normal individuals.

The gene responsible for XLH, originally designated *PEX* and later *PHEX*, has been mapped to the Xp.21 region of the X chromosome and cloned (25). Numerous mutations have been discovered in patients with XLH (26) but there is little evidence of genotype/phenotype associations in this phenotypically rather variable disorder. By homology with genes of known function *PHEX* most probably codes for a membrane metalloprotease and appears to be most strongly expressed in osteoblasts (27). Its precise substrate, and the way in which impaired function lead to phosphate wasting, is still not known but may relate to the role of FGF-23 in the cause of autosomal dominant hypophosphatemia, as discussed in the next section.

D. Autosomal Dominant Hypophosphatemic Rickets

This condition is phenotypically similar to XLH (28). However, its inheritance follows an autosomal dominant pattern. Recent information on the gene responsible for autosomal dominant hypophosphatemic rickets (ADHR) has shown that it codes for FGF-23 (29). This factor appears to be released by the skeleton and to act on the renal tubule as a phosphaturic factor. Work is now (2001) proceeding to determine whether FGF-23 could be a controlling hormone for phosphorus homeostasis (30). This work could radically enhance our understanding of the phosphate homeostatic system.

E. Hereditary Hypophosphatemic Rickets with Hypercalciuria

Low urinary calcium excretion is a biochemical feature common to most types of rickets, including vitamin D deficiency, vitamin D dependency and resistance, and X-linked hypophosphatemia. However, two apparently separate syndromes are known in which hypophosphatemic rickets is accompanied by hypercalciuria.

In 1985, Tieder et al. (31) described an inbred Bedouin family, many members of which had short stature with rickets of infantile onset. Affected subjects had profound hypophosphatemia, parathyroid suppression, elevated calcitriol levels, and marked hypercalciuria, in contrast to FHR patients who suffer from severe muscular weakness. In other described cases, the rickets may be relatively mild, without significant growth impairment.

This form of hypercalciuric rickets, hereditary hypophosphatemic rickets with hypercalciuria (HHRH), is a rare, autosomal recessive inherited condition in which renal phosphate wasting leads to the expected elevation in calcitriol concentrations. Thus, the condition stands in contrast to XLH, in which calcitriol levels are low despite phosphate wasting and hypophosphatemia. As a consequence of elevated calcitriol levels affected subjects may hyperabsorb calcium, which leads to the excessive urinary calcium excretion with resulting nephrolithiasis. Most cases have been described in Middle Eastern and North African populations, but apparently sporadic cases have been seen in North Americans of English and Irish ancestry.

Unlike X-linked familial hypophosphatemic rickets, HHRH has proved relatively easy to control with oral phosphate. Because calcitriol levels are high in the disease and PTH is suppressed, there is no need to supplement with a vitamin D metabolite and no danger of secondary or autonomous hyperparathyroidism. In the author's limited experience and in published reports, the response to therapy has been excellent in terms of increased strength, prevention of deformity, and statural growth.

F. Dent's Disease

Another type of hypercalciuric rickets, now named Dent's disease, was first described by Dent and Friedman (32). Hypophosphatemic hypercalciuric rickets is associated with generalized tubulopathy and eventual renal failure. The disease is inherited as an X-linked recessive trait. Its cause has been identified as a mutation in the gene, *CLCN5*, coding for a chloride channel and expressed in the proximal renal tubule (33).

G. Tumor (or Oncogenous) Rickets

Hypophosphatemic rickets is occasionally found in children and adults bearing a small mesenchymal tumor, usually benign (34). The tumor is often classified as a hemangiopericytoma, but benign fibromas, some malignant tumors, and nontumorous conditions such as the linear nevus sebaceus syndrome have been linked to this type of hypophosphatemia. The hypophosphatemia is accompanied by inappropriately low levels of calcitriol, and the degree of osteomalacia or rickets may be severe. Resection of the tumor from affected individuals has resulted in complete and rapid resolution of the hypophosphatemia, leading to the inescapable conclusion that the tumor, often very small, must be secreting an intensely phosphaturic substance that has been called phosphatonin. Since the identification of FGF-23 as the phosphaturic factor in ADHR (see above), this substance has been looked for and found, in tumors associated with hypophosphatemia (30), leading to the strong suspicion that FGF-23 is indeed phosphatonin.

H. McCune-Albright Syndrome

Also called polyostotic fibrous dysplasia, this is a pervasive multisystemic disease of childhood onset that appears to be nonfamilial. Patients show a progressive fibrosis and deformity of bone affecting noncontiguous parts of the skeleton, although completely normal bony architecture is preserved elsewhere. The fibrous dysplasia may lead to pain, weakness, and fractures, with associated disturbances of gait. Children with fibrous dysplasia often manifest hyperactivity of one or more endocrine systems, particularly precocious puberty, thyrotoxicosis, and acromegaly. They also show large, irregularly shaped pigmented skin nevi characteristic of the disease. Many of these children have a phosphaturic state that can lead to rickets and osteomalacia, with worsening of the bone pain and deformity. Following the recognition that most of the manifestations of the disease could be explained by hyperresponsiveness of cyclic AMP-dependent hormone receptors, Weinstein et al. (35) demonstrated that McCune-Albright syndrome is caused by somatic mutations in the gene coding for the α subunit of the G protein gene (*GNAS*) that controls the regulation of such receptors. The receptors are thus constitutively activated even though the

target organs are not exposed to high levels of the hormonal or other stimulus that would normally be required for activation. In this model the hypophosphatemia would presumably be a result of activation of renal tubular PTH receptors in the absence of excessive PTH concentrations. However, the possibility remains that cells in the abnormal bone are secreting a phosphaturic factor directly reducing tubular phosphate reabsorption.

I. Generalized Tubulopathies (Fanconi Syndrome)

This group of disorders is characterized by excessive urinary losses of all the factors primarily reabsorbed from the proximal tubular fluid. These include glucose, phosphate, bicarbonate, and amino acids. Genetic causes are generally responsible for proximal tubular failure in children.

J. Cystinosis

Severe Fanconi syndrome is seen in cystinosis, an autosomal recessive lysosomal storage disease in which cystine accumulates intracellularly. The onset is in infancy, with failure to thrive and rickets. Affected children are hypophosphatemic and acidotic and go on to develop progressive renal glomerular failure. Treatment with phosphate supplements, calcitriol, and alkalinizing agents, such as the citrates of sodium, potassium, or magnesium, can ameliorate the bone disease. However, until recently only renal transplantation could prevent early death from uremia. The introduction of cysteamine and related sulfur-containing compounds to reverse lysosomal cystine overload and preserve renal cell function has greatly improved the prognosis in this formerly fatal disease (36).

K. Other Causes of Fanconi Syndrome

Genetic conditions in which the impact of the associated Fanconi syndrome is relatively minor include Lowe syndrome (cause of tubular failure unknown), Wilson's disease, and type I glycogen storage disease, which are recessive conditions of copper and carbohydrate metabolism. Another form of Fanconi syndrome that has attracted interest recently is Dent's disease (see above).

L. Nonrenal Disorders: Dietary Phosphate Insufficiency

Dietary phosphate deficiency is very uncommon in adults and older children and is usually seen in association with the abuse of aluminum-containing antacid gels, which bind phosphorus in the gastrointestinal tract. In the premature infant, however, a bone disease that encompasses a spectrum of disturbances resulting in rickets, osteomalacia, and osteoporosis may occur as a result of an oral or parenteral intake insufficient to meet the phosphorus needs of the rapidly growing infant.

V. RICKETSLIKE CONDITIONS

A. Hypophosphatasia

This term is used to describe a group of inherited diseases characterized by variable defects in bone mineralization, absent or subnormal serum alkaline phosphatase (ALP) activity, and an excess of natural ALP substrates in the blood or urine. The condition has been classified into five categories according to the age of onset of symptoms and signs: perinatal lethal, infantile, childhood, adult, and odontohypophosphatemia (37). In the last of these dental disease (particularly early shedding of teeth) is the only manifestation. The severity is inversely related to the age of onset. In addition to ricketslike bone deformity, affected individuals may show hypomineralization, fractures, hypercalcemia, and early loss of teeth. Serum ALP levels are low, but vary widely. There appears to be broad correlation of serum tissue-nonspecific alkaline phosphatase (TNSALP) levels with clinical severity (Fig. 4). Increased urinary excretion of phosphoethanolamine and in-

organic pyrophosphate is pathognomonic for the disease. Although the severity, age of onset, and mode of inheritance vary, clinical cases of hypophosphatasia are all attributable to mutations in the same gene, TNSALP mapped to 1p36.1–34. This gene codes for liver and bone alkaline phosphatase but not for placental or intestinal alkaline phosphatase. As shown by Whyte et al. (38), plasma levels of pyridoxal phosphate (a form of vitamin B6) are considerably elevated in patients with hypophosphatasia. This has been attributed to a failure of hydrolysis of pyridoxal phosphate outside the cells and led to the characterization of TNSALP as an ectoenzyme bound to the outside of cell membranes.

B. Skeletal Manifestations of Trace Metal Disorders

A variety of metallic elements are essential for bone health. Disease can occur both as a result of deficiency and from excess. Table 3 lists the more important ele-

Figure 4 Serum alkaline phosphatase levels in child and adult controls and three categories of hypophosphatasia. (Adapted from Ref. 37.)

Table 3 Effects of Trace Element Nutritional Status on the Skeleton in Childhood

Element	Excess		Deficiency	
	Cause	Manifestation	Cause	Manifestation
Aluminum	Parenteral nutrition, chronic renal dialysis	Rickets, hyperparathyroid bone disease, uremic osteodystrophy		
Copper	Wilson's disease	Osteoporosis	Prematurity, elemental diets	Osteoporosis
Manganese				Osteoporosis (54)
Zinc			Prematurity, elemental diets, absorption defects (e.g., acrodermatitis enteropathica)	Stunting of bone growth

ments concerned, together with the principal causes of imbalance of each element in children, the major skeletal manifestations of excess and deficiency, and references to more detailed information.

VI. METABOLIC AND GENETIC DISORDERS INTRINSIC TO THE SKELETON

A. Introduction

This section reviews the osteoporotic syndromes in childhood followed by some of the skeletal dysplasias. Many of these heritable disorders of the skeleton, with stereotypic deformities, malformations, and growth failure in children can now be explained in terms of genetic disorders of several of the proteinaceous components forming the matrix of bone.

B. Osteoporotic Syndromes in Childhood

1. Definition and Overview

Osteoporosis is the state in which the quantity of material within the bones, both matrix and mineral, is pathologically diminished. It is to be differentiated from osteomalacia in which there is a failure of mineralization on a background of adequate matrix. The term osteopenia is often used to describe an abnormally low density of skeletal material not sufficiently severe to cause symptoms or loss of function. Since osteopenia, thus defined, differs from osteoporosis only in degree the terms are often used interchangeably.

Since osteopenia and osteoporosis are essentially disorders of the proteinaceous matrix of bone they often occur in situations in which protein balance is disturbed by reduced anabolism and/or increased protein catabolism. Another consideration, emphasized by Frost and Schönau (39) comes from the crucial interactivity of bone and muscle at all stages of life and particularly during childhood growth. Given the major trophic role of muscle force on bone development, it is easy to understand why osteo-

porosis should develop alongside neuromuscular diseases such as Duchenne's muscular dystrophy.

Online Inheritance in Man (OMIM) (40) lists 65 inherited disorders involving osteoporosis. Most of these cause symptoms in childhood and most involve disorders of connective tissue matrix. Some of the more important categories of childhood osteoporosis, genetic and acquired, are listed in Table 4.

We generally think of osteoporosis as a disease of later life, particularly common in women and associated in its pathogenesis with the hormonal changes of menopause. This section will touch on developmental topics linking child health to postmenopausal osteoporosis, but its main emphasis will be on osteoporosis occurring in children. Osteopenia and consequent fractures in premature infants are important topics in their own right. The causes, presentation, and treatment of metabolic bone disease of the newborn (41) will, therefore, not be covered here.

2. Clinical Manifestations

Osteoporosis has been called the silent epidemic. Although this alludes to a number of medical and sociologic factors in the elderly population, the description also fits the unobtrusive way in which osteoporosis and its consequences develop. In general, osteoporosis is painless until fractures occur. The prime exception is osteopenia due to malignant infiltration of bone. Osteoporosis in childhood is usually discovered fortuitously by radiological examination or screening in at-risk children, following x-rays done for other purposes, or after a fracture has occurred. Fractures of the peripheral skeleton are more common in the lower limbs and their circumstances may not immediately point to the existence of osteopenia. On the other hand, in the absence of severe trauma, vertebral fractures in children are almost invariably due to osteoporosis, local or generalized. Such fractures cause pain, deformity (kyphosis), and loss of height. The latter may not be as easily appreciated in a growing child as in an adult whose height has been unchanged previously.

Table 4 A Classification of Osteoporosis in Childhood

Category	Diagnosis	Comments
Genetic disorders of connective tissue matrix	Osteogenesis imperfecta Ehlers-Danlos syndrome Osteoporosis-pseudoglioma syndrome	
Locally mediated bone resorption	Malignancies including leukemia Thalassemia and other causes of myeloid expansion or proliferation	Skeletal pain may be severe May be exacerbated by chelating agents used to treat iron overload
Cytokine-mediated catabolic states affecting connective tissue matrix	Inflammatory bowel disease Inflammatory arthritis	May be worsened by corticosteroid use May be worsened by corticosteroid use
Endocrine and metabolic	Hypercortisolism, iatrogenic or due to pituitary or adrenal disease Thyrotoxicosis Hypogonadism	Includes failure to convert androgens to estrogens and estrogen receptor defects
Disuse and underuse	Anorexia nervosa Congenital and acquired paraplegia Muscular dystrophy	
Unclassified	Idiopathic juvenile osteoporosis	Usually remits at puberty; heritable disorders of collagen identified in some cases (82)

3. Skeletal Turnover and the Development of Osteoporosis

Once formed, both cortical and trabecular bone are in a state of constant dynamic activity with osteoblasts forming new matrix, calcification of that matrix, and osteoclastic removal of existing bone. Bone cells are able to regulate each others' activity in a paracrine fashion, giving rise to the concept that the processes of bone formation and resorption are coupled (42). During childhood this process leads to a net gain of skeletal material, reaching a plateau in the early 20s and thereafter declining, as

shown in Figure 5. Much of this mineral gain is a consequence of somatic and skeletal growth, but the bones also appear to increase in density (i.e., mass of calcified tissue per unit volume of bone) until early adult life. Adult osteoporosis is due to a preponderance of bone resorption over formation in a skeleton of more or less static proportions. A similar imbalance between formation and resorption may also give rise to osteoporosis in childhood, but a failure to add new bone material as the skeleton grows may lead to a reduction in bone density by a mechanism unique to childhood.

Figure 5 The rapid accumulation and slow loss of bone mineral in males and females.

4. Measurement of Bone Density and Normal Ranges

Because the presence or absence of fractures is a crude measure of skeletal integrity, densitometric methods have been devised to diagnose less extreme degrees of osteopenia. In recent years bone densitometric techniques have become sophisticated. The low radiation dosages administered have permitted study of normal children with the publication of normative data from a number of surveys (43). The two methods that can currently provide usable data on bone density in children are dual-energy absorptiometry (DXA) and quantitative computed tomography (qCT). Relatively inexpensive, delivering a low radiation dosage, and with an increasing body of normative data for children, DXA is the most widely used method. The major drawback of DXA bone densitometry in children is that it actually measures the attenuation of an x-ray beam across a projected cross-section of bone. This attenuation

depends not only on the actual density of skeletal mineral but also on the dimensions of the bone along the axis of the x-ray beam and in the plane perpendicular to that beam. These dimensions and their relation to one another change through childhood, so that corrections based on the child's height and weight have to be applied to the machine's output (44).

Quantitative computed tomography gives a true bone density (mass/unit volume). However, both its cost and radiation dosage preclude the study of large number of child subjects using techniques devised for detailed imaging, so far fewer normative data are available. Low-radiation methods for qCT in children do exist and this method still has potential importance (45).

5. Classification

Following the classification in Table 4, detailed discussion of some of the individual causes follows. The bone matrix consists of collagen and a large number of noncollagenous proteins. Genetic or acquired defects in the structure and/or assembly of matrix proteins can lead to osteopenia, as exemplified by the defects in collagen synthesis that cause osteogenesis imperfecta.

C. Osteogenesis Imperfecta

The term osteogenesis imperfecta (OI) describes several inherited conditions characterized by an increased incidence of bone fractures on minimal trauma.

1. Causes and Taxonomy

The various types of OI are caused by mutations that affect the nature or synthetic rate of the peptide chains that constitute type I collagen, which is the major collagen of the skeleton. The gene coding for the affected collagen chain is designated by a symbol of the type COLnAm where *n* is an Arabic numeral denoting type of collagen while the numeral *m* differentiates between the gene for the A1 chain and A2 chain of the collagen type in question (46). Although some of these affect nonosseous connective tissue, the impact of most falls particularly heavily on the skeleton.

OI is classified into subtypes that are genetically, pathologically, and clinically distinct from one another.

Their taxonomy was clarified by Sillence (Table 5) just as molecular techniques for the analysis of collagen structure and the associated genes were becoming available. The Sillence classification is still useful for clinical purposes and has superseded the formerly used terms OI congenita and OI tarda as well as other descriptive and eponymous terms.

2. Pathophysiology

For a more fundamental understanding of the pathophysiology of the OI syndromes, as well as for genetic counseling and potential prenatal diagnosis, we need a molecular view that is not offered by the Sillence classification. This area remains complicated because of the large size of the collagen molecule and the large number of distinct mutations observed in OI. Although mutations affecting the α -1 chain of collagen are more commonly reported, mutations in both α -1 and α -2 collagen can cause any of the clinical varieties of OI.

3. Inheritance

Both Sillence types II and III were generally considered to be inherited as autosomal recessives. However, some occurrences of multiple cases in siblings born to unaffected parents are now considered to be due to germ-line mutations in which multiple germ cells are heterozygous for a dominant mutation expressed in the offspring.

4. Clinical Features

The clinical features of OI depend on the genetic type of the disorder, the age of onset, and the severity of the skeletal effects. Babies affected at birth have a poor prognosis. Those in Sillence type II are born with multiple fractures that have arisen in utero, some healing with shortening and broadening of the long bones. Stillbirth or early death usually results from respiratory failure or brain damage. In type III the fractures are less widespread, and shortening and deformity of the limbs can be absent at birth. These children often survive for several years with progressive severe deformities of the long bones (Fig. 6). Once again, respiratory failure is often the terminal event. Types I and IV of Sillence are milder conditions in which the mode of inheritance is dominant. The skeletal ten-

Table 5 Sillence Classification of Osteogenesis Imperfecta

Type	Fragility	Sclerae	Teeth	Inheritance	Comments
IA	Present	Blue	Abnormal	Autosomal dominant	Relatively common
IB	Present	Blue	Normal	Autosomal dominant	Variable severity
II	Extreme	Blue ^a	—	? dominant (germ cell)	Perinatal presentation
III	Severe	Normal	Normal	? dominant (germ cell)	Skeletal deformity
IVA	Present	Normal	Abnormal	Autosomal dominant	Uncommon
IVB	Present	Normal	Normal	Autosomal dominant	Variable severity

^aSclerae are often blue in normal infants

Figure 6 Severe deformity in a young boy with type II osteogenesis imperfecta.

dency to excess fracturing is accompanied by lax-joint-ness, easy bruisability, and conductive deafness. The teeth can be affected by dentinogenesis imperfecta (so-called subtypes Ia and IVa), whereas patients with subtypes Ib and IVb have normal teeth. The identifying characteristic of type I is a persistent blueness of the sclerae (blue sclerae are normal in infancy). Type IV patients present a very similar clinical picture, but the sclerae are a normal white.

D. Homocystinuria

Screening studies of urine from mentally retarded persons revealed some patients with a distinctive appearance, who excreted excess amounts of the sulfur amino acid homocystine. Homocystinuria (MIM #236200) is a recessively inherited disorder caused by the absence or inadequate function of the enzyme cystathionine synthetase. This rare condition has provoked considerable research interest di-

rected toward the high incidence of two very common associated disorders: arterial thromboses and osteoporosis. Tall stature through childhood, and persisting into adult life, is a frequent finding in homocystinuria. The limbs tend to be thin and spindly, with a decreased upper/lower segment ratio. Other skeletal manifestations are severe osteoporosis, beginning in adolescence, and kyphoscoliosis. There is downward dislocation of the lenses, leading to secondary glaucoma, myopia, and retinal detachment. Vascular changes are a frequent source of morbidity in homocystinuria.

E. Hormonal Osteoporosis

1. Hypogonadism

Both androgenic and estrogenic hormones have been considered anabolic for bone and osteoblasts bear receptors for both classes of hormones. In both genders there is a sharp increase in bone mineral content during puberty. Osteopenia is seen in adolescents and young adults of either gender in a variety of settings of gonadal hormone deficiency.

2. Turner Syndrome (XO Gonadal Dysgenesis)

Symptomatic osteoporosis used to be common in young women with Turner syndrome before estrogen replacement became routine. There is discussion as to whether osteoporosis is part of the phenotype or entirely secondary to estrogen deficiency manifesting in the early teens. Recent data show that, even with adequate estrogen replacement, osteopenia may persist in patients with Turner syndrome. It is possible that growth hormone, used to promote growth in these short girls, may lead to an increase in bone density acting synergistically with administered estrogens (47).

3. The Exercise–Anorexia–Amenorrhea Triad

Reduced gonadal hormone output is a hallmark of anorexia nervosa and is also present in many highly trained athletes. Anorexia and athleticism represent different life situations but there are areas of physiological overlap in the anorectic's urge to exercise and the athlete's concern for a trim, muscular, and efficient body. Both in anorexia and in athletic training there are reports that boys as well as girls may suffer from diminished gonadal function, but the diagnosis is made far more commonly in young women and girls and more is known about the skeletal consequences in female subjects. Bone mineral content is reduced in anorexia leading to measurable osteopenia (48) and to concern that these patients will be likely to develop clinically significant osteoporosis in middle age. However, it is rare for osteoporotic fractures of the vertebrae or appendicular skeleton to present in young anorexics. It is hard to tell how much of the osteopenia of anorexia is due to hypoestrogenemia and how much to nutritional deficiency, but analogy with more clearly defined varieties

of hypogonadism indicates that hormonal deficiency plays a major causative role.

Exercise, by periodically varying the load imposed on various parts of the skeleton, is anabolic to bone. Nevertheless female athletes (and other trained young women such as ballerinas) lose bone and may become osteoporotic. Undoubtedly the bone loss stems mainly from acquired hypogonadism, the negative effect of which exceeds the benefit from exercise. The major differences from the anorectic state are that these women are, by and large, well-nourished. In contrast to the situation in anorexia, fractures, particularly cortical microfractures of the lower limbs, are not uncommon. This is related to the great strain imposed upon the limbs by these girls' activities. Bone loss may not be fully reversed with estrogen treatment.

F. Male Hypogonadism

Young men with Kallman syndrome and other causes of hypogonadism are recognized to be osteopenic. Their reduced bone mass is reversible upon administration of androgens. Despite the presence of androgen receptors in bone, doubt has been cast on the role of androgens on bone by the fascinating cases of males who cannot make estrogens (aromatase deficiency) or in whom mutated receptors (49) cause estrogen resistance. In both of these unusual disorders, men developed significant osteopenia despite normal testosterone levels.

G. Glucocorticoid Excess

Cushing's syndrome, endogenous or due to administered glucocorticoids, is a major cause of pathological bone loss in children. It is usually accompanied by severe failure of linear growth. The bone loss can be severe with frequent fractures of the appendicular skeleton as well as vertebral crush fractures. The cellular causes of steroid osteoporosis probably relate more to the catabolic effects of glucocorticoids on matrix protein than to any effect on calcium handling at gut or renal level. No reliable treatment exists for glucocorticoid osteoporosis. Attempts to prevent it have been made by altering the schedule of steroid administration (e.g., alternate-day doses), and by the use of analogs such as deflazacort, designed to have an improved therapeutic ratio. Established disease has been treated with vitamin D, calcium supplements, antiresorptive agents, and anabolic agents such as androgens and growth hormone, all to little avail.

Endogenous and factitious thyrotoxicosis in childhood may cause osteoporosis if untreated for a long period.

Hyperparathyroidism may be associated with bone loss but the sites of skeletal damage are quite specific and different from those seen in patients with true osteoporosis.

H. Nutritional and Metabolic Osteoporosis

1. Liver Disease

The liver is involved in calcium metabolism as the site of the first (25-hydroxylation) step in the activation of vitamin D. In addition, bile production is essential for the normal absorption of both vitamin D and calcium. As a result, severe bone disease, often a combination of rickets and osteoporosis, can affect young children with biliary obstruction (8).

2. Immune and Inflammatory Disease

Cytokines such as those that serve as chemical links between cells of the immune system exert major actions on the relative activities of bone-forming and bone-resorbing cells (42, 50). Conditions as diverse as systemic mastocytosis, inflammatory bowel disease, rheumatoid arthritis, and the hyper IgE syndrome, in which cytokine production is deranged, may be associated with osteoporosis. Juvenile rheumatoid arthritis, in which disuse osteoporosis is combined with steroid effects and, probably, a catabolic effect of immune cytokines, causes a particularly troublesome osteoporosis.

3. Neoplastic Disease

Crush fractures of the vertebrae and pathological fractures through malignant deposits in appendicular bone are not uncommon in patients with childhood malignancy, particularly leukemia and, less commonly, neuroblastoma. The radiological appearances are often patchy, with some areas of the skeleton appearing normal (51). However, diffuse osteopenia is not uncommon. Malignant osteoporosis of childhood is often painful, providing a strong clue to the underlying diagnosis. The rate of bone resorption may be high enough to cause hypercalciuria or even hypercalcemia, but the absence of biochemical abnormalities does not exclude malignancy as a cause for childhood osteoporosis. The evaluation and treatment of the child with leukemias and other malignancies will not be considered further here.

I. Miscellaneous and Unknown

1. Disuse Osteoporosis

Repetitive mechanical stresses are major stimuli to the formation of new bone and the gain of skeletal mass. Conversely, weightlessness, bed rest, and paralysis lead to bone loss. Lower limb fractures are common in nonambulatory children with spina bifida and cerebral palsy. Often nutritional factors contribute to the development of bone disease in these multiply handicapped individuals. A variety of orthopedic approaches may be necessary to handle the fractures but correction of the underlying cause is generally not an option.

Acute paraplegia may cause rapid bone loss, particularly in healthy growing children who have higher bone

turnover rates than adults. Although osteoporosis of the paralyzed limbs is the rule in such cases, the major clinical problem is the rapid rise in serum and urinary calcium that may occur in the first few days after injury.

2. Burns

Bone loss after burn injury has been attributed to immobilization. However later work (52) suggested that biochemical markers of bone formation can remain depressed for years after burn injury. The cause of such long-lasting depression of skeletal function after burns remain to be discovered.

3. Idiopathic Juvenile Osteoporosis

Idiopathic juvenile osteoporosis (IJO) describes a severe and rapidly progressive form of osteoporosis seen in the years before puberty (53). The disease affects children of either gender and its cause is unknown. There is now increasing evidence that some cases are due to genetic abnormalities in collagen structure (54).

The most striking feature of IJO is that the bone loss remits with the onset of puberty. At that stage, while residual deformity persists, new growth takes place in the absence of further fractures. IJO is not known to be a familial condition, but the possibility that it is due to an underlying disorder of collagen formation, much like an osteogenesis imperfecta, cannot be ruled out.

The remission of IJO with puberty is a feature shared by many other types of osteoporosis in adolescents, even those whose causes have nothing to do with gonadal hormone status, such as steroid osteoporosis and osteogenesis imperfecta. The natural history of these conditions bears witness to the powerful effect of gonadal hormones on bone.

J. Pediatric Aspects of Adult Osteoporosis

This critically important topic has received much attention. If bone mass increases steadily throughout childhood and the early 20s and is then subject to an inevitable decline, it follows that measures to promote skeletal accretion in youth may prevent the ravages of bone loss later in life. The factors contributing to the gain in bone mass in childhood are complex. They may include calcium nutrition (55), the timing of puberty and other hormonal influences, as well as innate genetic traits. A start in unraveling these genetic factors may have been made by the observation that polymorphisms in the noncoding region of the vitamin D receptor gene are predictors of adult bone mass (56). Doubtless other genetic influences will be discovered since there is certainly a familial component to postmenopausal osteoporosis.

VII. SKELETAL DYSPLASIA

The nomenclature of these conditions seems at first sight to be quite complex. However, in many cases, the con-

nection to the principal clinical and radiological findings is logical and depends on whether the bony dysplasia defects occur in the epiphyses, the metaphyses, or the vertebral bodies (57). An overall classification of the bony dysplasias (Table 6) is provided on the website of the International Nomenclature of Constitutional Disorders of Bone located at Cedars-Sinai Hospital in Los Angeles (58). Names of selected skeletal components together with the names and descriptions of the diseases caused by mutations of these proteins are given in Table 7.

As can be seen from Table 7, the skeletal dysplasias may result not only from abnormalities in structural proteins but also from abnormalities in components of cell-signaling systems active in the skeleton.

Most of these conditions do not disturb the homeostasis of the extracellular biochemical milieu and do not, therefore, show any characteristic biochemical changes in serum. However, there are occasional exceptions to this rule (e.g., Jansen's dysplasia and Albright's hereditary os-

teodystrophy). Although some specific therapies are being explored, the explosion of genetic knowledge about these syndromes has only just begun to generate hypotheses concerning innovative ways to treat some of these distressing disorders.

A selection of these disorders is discussed below. The various syndromes are grouped primarily by cause rather than by morphology.

A. Disorders of Skeletal Structural Protein

1. Type I Collagen

Mutations in the genes coding for this collagen give rise to osteogenesis imperfecta, considered above under the section on osteoporosis.

2. Other Collagenopathies

Mutations in type II collagen (COL 2A1) are responsible for a number of dominantly inherited bony dysplasias including achondrogenesis and hypochondrogenesis and some of the spondyloepiphyseal and the spondyloepimetaphyseal dysplasias.

Some of the defects seen in collagen type II collagenopathies, particularly Stickler-type dysplasia, are mimicked by the effects of mutations in type XI collagen, while other types of multiple epiphyseal dysplasias have been traced to mutations in type IX collagen.

Collagen type X is found principally in epiphyseal growth plate cartilage. Mutations can be responsible for Schmid-type epiphyseal dysplasia, which is a dominantly

inherited condition that often mimics rickets in its somatic effects and radiological appearances. A major area of differentiation from rickets is that children with Schmid-type epiphyseal dysplasia do not have increased plasma markers of bone turnover, such as alkaline phosphatase, nor any of the other abnormalities of plasma biochemistry that characterize the various forms of rickets.

Cartilage oligomeric matrix protein (COMP) is a matrix protein secreted by chondrocytes that has been found to be mutated in pseudoachondroplasia (PSACH) (59). COMP appears to play a role in the trafficking and organization of other matrix proteins. PSACH is a relatively common disorder usually inherited in an autosomal dominant manner. Patients may not show any abnormality until the second year of life, after which they manifest progressive evidence of limb shortening and disproportion. The face and cranium are not affected in the same way as achondroplasia.

3. Hormone and Growth Factor Receptors

a. Fibroblast Growth Factor Receptor 3: Achondroplasia. A conceptual breakthrough regarding the ways in which the cellular biology of developing bone could affect shape and structure was reached with the discovery that achondroplasia was due to mutations in the gene for the FGFR3. Achondroplasia is a familial autosomal dominant inherited condition characterized by short-limbed growth failure and abnormalities of the cranial and facial bones. The appearances of a large head with frontal bossing and hypoplasia of the midface are easily recognized.

In addition to the morphological abnormalities described, affected individuals may also manifest certain central nervous system disorders including megencephaly, hydrocephalus, and craniocervical instability. In rare cases, the last of these may lead to drastic neurological impairment or to sudden death.

The gene for achondroplasia was mapped to 4 p 16.3 in 1994. Shortly afterwards two groups independently discovered the cause to lie in a specific mutation of FGFR3 (380 gly_arg) (60). This mutation leads to a gain-of-function for the receptor, which, among other things, leads to premature epiphyseal fusion. Subjects in whom the entire FGFR3 gene is deleted do not have achondroplasia. Hypochondroplasia, a milder form of the disorder, may be caused by the same or other mutations in FGFR3.

Homozygosity for the 380 gly_arg mutation leads to a fatal neonatal skeletal dysplasia called thanatophoric dysplasia.

b. PTH Receptor (Jansen's Metaphyseal Dysplasia). Jansen's metaphyseal dysplasia is much less common than achondroplasia. Its interest lies in the fact that it too is due to an activating mutation of a receptor. However, in this case the receptor is for a systemic hormone system, namely the PTH system. PTH and the PTH-related peptide PTHrP share the same receptor, sometimes referred to as the PTH/PTHrP receptor. Since PTHR

signals the presence of a systemically distributed ligand, it might be expected that constitutive activation of the receptor has systemic consequences, in this case hypercalcemia. It was, in fact this hypercalcemia that provided the first clue as to the molecular cause of the syndrome (61).

c. Alpha Subunit of G-Protein.

Albright's hereditary osteodystrophy. Bony dysplasias may also be related to two separate groups of mutations in the gene coding for the widely distributed alpha subunit of the stimulatory G-protein (GNAS), integrated into a number of membrane bound receptors. AHO is due to loss-of-function mutations in GNAS. When these mutations are inherited from the mother, they lead to reduced function of the PTH receptor with the biochemical features of pseudohypoparathyroidism. However, biochemical abnormality is not the cause of the associated skeletal malformations, which may coexist with a mutant GNAS gene and normal biochemical values.

AHO is characterized by short stature and brachydactyly. Subcutaneous ossifications, which may be extensive, are frequently found and the syndrome is frequently accompanied by cognitive impairment, obesity and hypothyroidism. Where the function of the PTH receptors is affected hypocalcemia, elevated serum PTH level and parathyroid hyperplasia occur.

McCune-Albright syndrome. McCune-Albright syndrome (MAS) is a nonfamilial syndrome due to somatic cell mosaicism conferring constitutive activation of GNAS in various parts of the skeleton and in other organs. Because of the occurrence of hypophosphatemic rickets and osteomalacia in the syndrome, it is discussed above in the section on rickets.

d. Other Abnormalities in the Control of Structural Development: Peroxisomal Enzymes (Peroxisins 1, 2, 5, 6, or 7). These enzymes contribute to the turnover of intracellular matrix by controlling the transport of matrix proteins into peroxisomes where they are prepared for catabolism. Dysfunction or absence of the peroxisomes, due to mutations in the peroxisins, can lead to a variety of inherited nonskeletal diseases including adrenoleukodystrophy and Zellweger syndrome (62). Skeletal effects include rhizomelic chondrodysplasia punctata (MIM number 215100), an autosomal recessive disorder, and craniofacial dysmorphism and stippled patellas, found in a variant of Zellweger syndrome.

e. SHOX. The short stature homeobox (SHOX) gene, located on the pseudoautosomal region of both the X and Y chromosomes, codes for a protein believed to act as a transcription factor. The gene is expressed in osteogenic cells and monosomy of the SHOX gene appears to account for the short stature, and, possibly other skeletal abnormalities (63) seen in Turner syndrome.

Leri-Weil disease is an apparently dominantly inherited form of skeletal dysplasia with disproportionate

short stature and a deformity of the wrist known as Madelung's deformity. The syndrome has been attributed to mutations in SHOX (64). The disorder may be noted at birth and is classified as a dyschondrosteosis because the malformations affect bone derived from cartilaginous growth plates, while growth plate histological examination shows severe disturbance of the arrangement of chondrocytes (65). The reason for the unusual genetics (4:1 female preponderance of cases) was explained when it was understood that the gene involved was located on the X chromosome and the pseudoautosomal region of the Y.

Diastrophic dysplasia is a recessively inherited skeletal dysplasia affecting disparate regions of the skeleton including the vertebrae (scoliosis) and the feet to cause club foot. There is also a characteristic deformity of the position of the thumb designated hitchhiker thumb. The gene responsible has been mapped to 5q32–q33.1 and identified as a sulfate transporter essential for the normal formation of proteoglycans that form the cartilaginous matrix (66).

B. Storage Diseases

1. Glycosidases and Sulfatases

A large number of storage diseases affect the skeleton, many of them producing specific skeletal and nonskeletal manifestations. Because of the extensive effects on the skeleton these disorders are grouped by the International Nomenclature of Constitutional Disorders of Bone as dysostosis multiplex.

The mucopolysaccharidoses are lysosomal storage disorders in which mucopolysaccharides accumulate due to dysfunction in one of a number of degradative enzymes. Skeletal abnormalities include widening and deformity of the diaphyses of tubular bones and in the spine, kyphosis, vertebral beaking, and other abnormalities in vertebral morphology. Affected patients may also have cognitive impairment, visceromegaly, and involvement of the joints, eyes, and ears.

Other lysosomal storage diseases that can affect the skeleton include the glycoside deficiencies, fucosidosis and the mannosidoses, the GM1 gangliosidoses, the sialidoses, and the mucopolipidoses. The reader is referred to the relevant articles in *Online Mendelian Inheritance in Man* for a discussion of the definition, causes, and inheritance patterns of the individual syndromes as well as a tabulation of the relevant original literature (40).

2. Osteoclast Dysfunction (Osteopetrosis)

Osteopetrosis describes a group of disorders of bone resorption. In its severe form, manifestations are present at birth and prove fatal during infancy or early childhood. The inability to resorb and remodel bone prevents the formation of the intramedullary spaces needed for hematopoiesis and inhibits the development of the cranial nerve foramina in the skull. As a result affected babies are ane-

mic with massive hepatosplenomegaly due to the need for extramedullary hematopoiesis in those organs. Those affected are also often blind and deaf due to maldevelopment of the foramina for the 2nd and 8th cranial nerves.

Children with severe, recessive osteopetrosis are vulnerable to a variety of pyogenic infections including abscesses and osteomyelitis. Neutrophils, monocytes, and lymphocytes from affected children lack the ability to generate superoxide radicals, which are an important component of the process of destruction of phagocytosed micro-organisms (67). Affected infants may show biochemical defects, particularly hypocalcemia due to a failure to mobilize bone from the skeleton and hypophosphatemia due to associated secondary hyperparathyroidism.

One autosomal recessive form that has been well characterized is the form associated with renal tubular acidosis. Acid generation catalyzed by the enzyme carbonic anhydrase is an essential part of successful osteoclastic bone resorption. Absence of enzymic activity results in osteopetrosis and, in the renal tubule, in systemic acidosis. In this form of osteopetrosis the age of onset is higher and severity of the osteopetrosis less than in the so-called malignant infantile form described above. Recently mutations in the CA2 carbonic anhydrase gene have been identified in affected individuals. Other forms of osteopetrosis are much milder and may be noted during adult life following fractures through abnormally sclerotic bone or as an incidental finding on inspection of skeletal x-rays (68).

Infantile osteopetrosis is inherited as an autosomal recessive trait and is, therefore, commonly seen in consanguineous families and within strongly inbred population groups. Within recent years mutations in the osteoclast-specific subunit of the vacuolar proton pump (TCIRG1) have been identified in most, but not all, cases of severe infantile osteopetrosis. A defect in the chloride channel gene, CLCN7, has also been detected in some affected children in whom linkage studies appeared to exclude involvement of TCIRG1.

VIII. TREATMENT OF SKELETAL DISORDERS

A. Nutritional Rickets

The treatment of vitamin D deficiency rickets is to provide adequate but not excessive replacement doses of vitamin D. With the recommended daily allowance of vitamin D in childhood at 400 IU (10 μg) we have found that four to five times this dose (i.e., 1600–2000 IU/day) almost always reverses the biochemical and structural changes of vitamin D deficiency. Alkaline phosphatase may rise initially (the so-called flare effect) but after 24 weeks begins to fall toward normal. This approach to treatment constitutes a so-called diagnosis by therapy because unusual and unexpected forms of resistance to standard doses of vitamin D do not respond to replacement doses and then

become the focus of more extensive investigations. Treatment may be discontinued when all physical, radiological, and biochemical fractures of rickets have been reversed and the family counseled on dietary and lifestyle changes that can provide the child with the recommended daily allowance (RDA) of vitamin D.

One group of patients who do not respond to vitamin D in doses of four to five times the RDA is that with severe malabsorption syndrome. In such patients, vitamin D should be given intramuscularly, using 100,000–600,000 units. If the malabsorption cannot be reversed by specific therapy, the dose can be repeated after some weeks or months as biochemical indices of osteomalacia begin to worsen again. Intramuscular vitamin D therapy is less often used for children with straightforward nutritional vitamin D deficiency. However, the technique still has its advocates for cases where continued medical supervision and patient adherence to the prescribed regimen are uncertain (69). There is no need to use the hydroxylated metabolites of vitamin D (calcidiol and calcitriol) in the treatment of rickets caused by vitamin D deficiency.

Rickets due to calcium deficiency is being diagnosed increasingly in developing countries in which many children's diets are deficient in this element. In a trial conducted by Thacher et al. (4), 1000 mg/day elemental calcium as an oral supplement, alone or in combination with two intramuscular injections of vitamin D, was clearly superior, over a 3 month interval, to treatment with vitamin D alone.

B. Prevention of Nutritional Rickets

Vitamin D deficiency rickets can be prevented in healthy children by permitting adequate exposure to sunlight and/or by ensuring an adequate dietary intake of the vitamin. Although the majority of the US population is believed to receive most of its vitamin D from solar irradiation (70), this may not apply to impoverished persons living in crowded surroundings or to those immobilized by disability. To target these children and others who may be at risk, the US government has ordered the fortification of milk with vitamin D since the 1930s. In many other advanced countries this policy is not followed, and this difference in public policy may well account for the higher incidence of vitamin D deficiency in the United Kingdom and other European countries than in the United States. Children who do not receive dairy milk may be at increased risk for vitamin D deficiency unless they receive adequate sunshine exposure. This includes infants and lactose-intolerant, vegan, or other milk-averse individuals. Formula-fed infants can be assumed to be receiving adequate nutritional vitamin D. Breastfed babies, however, can receive dietary vitamin D only insofar as the mother is herself adequately nourished. Most of the infantile rickets seen in the United States comes from this breastfed group. Breastfed babies and milk-avoiding growing chil-

dren should receive vitamin D supplementation according to the RDA, which is 400 IU.

Although US Food and Drug Administration guidelines specify that milk should be fortified with 400 IU per quart (900 ml), reports from Holick and colleagues have shown that many milk samples are inadequately or far too heavily fortified (71). In some cases this has led to vitamin D intoxication and consequent hypercalcemia in heavy drinkers of milk.

The use of calcium fortification to prevent calcium deficiency rickets in children at risk from this deficiency has received considerable recent attention.

C. Pseudodeficiency Rickets

Pseudodeficiency rickets is caused by the inability to hydroxylate calcidiol (25-hydroxivitamin D) at the 1- α position. Since the product of this reaction, the active metabolite of vitamin D, calcitriol, is readily available as a therapeutic agent, simple substitution therapy is possible and has been reported to be fully effective in replacement dosages of 0.5–2.0 μ g/day (72).

D. Calcitriol Receptor Defects

Carefully conducted therapeutic trials have shown that the osteopathy of vitamin D dependency type II can be sharply improved by the intravenous infusion and/or oral administration of calcium (17). The dosages used by Hochberg et al. were high (3.5–9 g elemental calcium/m²/day) but the treatment was effective in restoring serum calcium levels, reducing deformities, and accelerating linear growth.

E. Familial Hypophosphatemic Rickets

The aims of treatment in familial hypophosphatemic rickets (FHR) are to reduce deformity and optimize statural growth while minimizing the side effects of therapy. The recognition that FHR is primarily a disease of phosphate wasting led Glorieux et al. (73) to propose a regimen of high-dosage phosphate replacement. Such regimens form the mainstay of modern treatment and are always supplemented with a vitamin D preparation, usually calcitriol.

Phosphate is given as a soluble buffered sodium and/or potassium salt. The dosage is calculated in terms of elemental phosphorus and ranges from 0.5 to 1.5 g/day depending on the size of the patient. Emphasis was placed on the need to space doses as widely as possible over 24 h to maximize the period over which phosphate concentrations are enhanced. One of the major untoward effects of this treatment is hyperparathyroidism, which is unusual in untreated XLH (although the author has observed asymptomatic cases) but common during treatment. Rarely this has necessitated parathyroidectomy (74). Evidence that hyperparathyroidism may be exacerbated at night has led to the suggestion that a nocturnal dose of

phosphate not be given. Calcitriol is given for two reasons. First, even though calcitriol levels are generally normal in untreated FHR, additional supplementation may promote skeletal mineralization. Second, hyperparathyroidism is minimized by the additional intestinal calcium absorption that follows calcitriol supplementation. There is some evidence that another vitamin D metabolite, 25,25 dihydroxyvitamin D, might be effective in suppressing parathyroid hyperfunction (75) but, this treatment is still experimental.

Treatment is monitored biochemically by measuring serum alkaline phosphatase levels (the most readily accessible marker of bone turnover), urinary calcium excretion, and PTH levels. In affected children, alkaline phosphatase levels should be below the pediatric upper limit, with high levels generally indicating active osteomalacia and requiring higher doses of phosphate. Urinary calcium and PTH measure opposite ends of the spectrum of desirable calcitriol supplementation. This should be increased (and/or the phosphate decreased) if PTH is elevated and decreased if urinary calcium excretion is excessive (above 4 mg/kg/day). Occasionally it is impossible to find a therapeutic combination that achieves all these goals.

Nephrocalcinosis and occasionally nephrolithiasis occur frequently in affected children. These renal changes are probably consequences of excessive urinary calcium excretion during therapy (76); they rarely lead to significant renal glomerular impairment. Thiazide diuretics, which reduce urinary calcium excretion, have been used to reduce the chance of renal damage from hypercalciuria, but they are not widely used in treatment.

The results of treatment of FHR have been surprisingly controversial. Most modern authors are convinced that deformity is reduced and, perhaps less confidently, that treatment leads to improved adult stature. A trial of human growth hormone showed improvement in growth velocity but a worsening in alkaline phosphatase levels, reflecting activity of the rickets. The characterization of the genes and their products responsible for XLH and ADHR may eventually lead to the design of more rational therapy directly targeted at the cellular cause of the phosphaturia.

F. Hypophosphatasia

Despite the tremendous progress in understanding the molecular and enzymological pathogenesis of this disease, there are as yet no specific therapies for hypophosphatasia.

G. Childhood Osteoporosis

Childhood osteoporoses are rare and their causes are multifactorial; therefore, a variety of treatment modalities needs to be adopted. As in many rare conditions, it has often proved impractical to prove the efficacy of specific

treatments in clinical trials. General approaches include reversal of the cause if known, for example, reducing steroid dosage in steroid osteoporosis and replacing gonadal hormones in osteoporosis due to hypogonadism. As in adult osteoporosis, the administration of calcium supplements is generally held to be helpful.

In recent years there has been strong interest in the use of bisphosphonates such as pamidronate (77), given intravenously, and alendronate (78) and residronate, given orally. The reader should note that little published literature on the topic relates to controlled clinical trials and that much remains to be learned about the safety, efficacy, and optimal dosing regimens involved in the use of these agents.

H. Osteogenesis Imperfecta

Treatments including fluoride, vitamin D, calcitonin, and zinc have been proposed for OI, but there is no evidence that any are able to lessen the skeletal fragility. Recently it has been shown that bisphosphonates, particularly pamidronate (mean dosage of 6.8 mg/kg intravenously every 4–6 months) can alleviate bone pain and reduce the incidence of fractures in children with osteogenesis imperfecta (79). Conservative treatment and orthopedic correction continue as the mainstays of therapy in OI.

I. Osteopetrosis

The close relationship between the osteoclast line and cellular components of the immune system have led to attempts to treat affected children with compatible bone marrow grafts, where available (80). This method of treatment is still regarded as optimal, but treatment may not be available if a suitable donor cannot be found and still carries a high risk of failure when performed (81). Other forms of treatment include the use of interferon gamma, which can normalize superoxide production in affected osteoclasts, and high dosages of calcitriol.

I. INTRODUCTION

Relative to glucose homeostasis, the neonate is considered to be in a transition between the complete dependence of the fetus and the complete independence of the adult. The neonate must become independent after birth, balancing between glucose deficiency and excess to maintain euglycemia. The dependence of the conceptus on the mother for continuous substrate delivery in utero contrasts with the variable and intermittent exogenous intake orally that is the hallmark of the neonatal period and beyond. The maintenance of euglycemia especially in the sick/or low-birth-weight neonate is difficult. This is especially true in so-called micropremies (birth weight ≤ 1000 g), who represent a majority of the patient days in the neonatal intensive care nursery (1). Maturation of neonatal homeostasis is influenced by the integrity of the specific pathways of intermediary metabolism important in glucose metabolism. The heterogeneity that is the hallmark of neonatal glucose metabolism is illustrated by the multiplicity of conditions producing or associated with neonatal hypo- and hyperglycemia. This reinforces the concept that the neonate is vulnerable to carbohydrate disequilibrium. This topic has been the subject of a number of recent evaluations (2–7).

II. NEONATAL EUGLYCEMIA AND HYPOGLYCEMIA

A prime example of the heterogeneity that exists in neonatal glucose metabolism is that there are no uniform standards accepted for specific limits for euglycemia. It is well accepted that glucose is the major substrate for carbohy-

drate metabolism. At birth the maternal supply of glucose to the neonate ceases abruptly. Although the neonatal plasma glucose concentration is usually in the normoglycemic range at delivery, its actual concentration depends on factors such as the last maternal meal, the duration of labor, the route of delivery, and the type of intravenous fluid administered to the mother.

As an example, Figure 1 depicts the mean plasma glucose and insulin concentrations of mothers and their neonates who received either no glucose (Ringer's lactate) ($n = 14$) or glucose (Ringer's lactate + 5% dextrose) ($n = 15$) as a bolus infusion during anesthesia for elective cesarean section (8). Blood samples for plasma glucose and insulin concentrations were taken prior to intravenous fluid administration and at the time of delivery. Corresponding samples were taken from the neonate's umbilical vein and artery at 30 min and hourly after birth for 4 h. As noted in Figure 1, all mothers and infants receiving glucose had hyperglycemia and hyperinsulinemia at delivery. The neonatal plasma glucose concentration declined rapidly during the first 4 h of life. With one exception all neonates evidenced normal plasma glucose concentrations repeatedly and all were clinically asymptomatic. The changes in the neonate following glucose infusion to the mother reflect the differences that can occur in the neonate depending on the type of intravenous infusion administered at delivery.

After normal delivery, the plasma glucose concentration declines to approximately 50 mg/dl by 2 h of age, but equilibrates at approximately 70 mg/dl at 72 h after birth. Cornblath and Reisner have evaluated the blood glucose concentration over time in an old but classic analysis of both term and relatively low birth weight neonates (9).

Figure 1 Plasma glucose and insulin concentration for mothers and the neonates. Maternal I and II, samples obtained prior to fluid infusion and at delivery of infants, respectively. V, umbilical venous; A, umbilical arterial samples; (n), number of determinations. (From Ref. 8.)

Their data suggested that concentrations below 40 mg/dl or greater than 125 mg/dl are abnormal after 3 days after birth. Critical adjustments are required by the neonate in the first 72 h after birth to maintain glucose homeostasis.

Srinivasan et al. evaluated plasma glucose concentrations in normal full-term neonates who weighed between 2500 and 4000 g and were appropriate for age between 37 and 42 completed weeks of gestation (10). The predicted glucose concentrations during the first week of life are noted in Figure 2. All neonates were fed after 3 h. The data indicated that the nadir in plasma glucose concentration is between 1 and 2 h and that a significant rise occurs during the third hour. The mean glucose concentration in this study ranged from 50 to 80 mg/dl during the first week of life.

No similar evaluation of the limits of euglycemia has been reported for the preterm neonate. This difficult study is clearly necessary because of the general lack of consensus that exists relative to definition of euglycemia. What should be apparent from this discussion is the variation not only in the definition of euglycemia but also in the so-called normal concentration of glucose at any particular time. An obvious example of this latter situation is

noted in Figure 3. In the four types of neonates commonly cared for in a neonatal unit, term appropriate for gestational age (AGA), term small for gestational age (SGA), preterm AGA, and preterm SGA, plasma glucose concentration changed constantly and in an apparent random fashion (11). This chapter will catalog the various causes of hypoglycemia as well as the mechanisms controlling neonatal glucose homeostasis.

A. Definition of Hypoglycemia in the Human Neonate

Although hundreds of papers in the literature focus on the subject of neonatal hypoglycemia, this topic remains controversial. Areas of disagreement involve definition, method/site of sampling, symptoms, significance of asymptomatic status, management, and its effect on neurodevelopmental outcome (12, 13). Koh et al., who surveyed the definition of hypoglycemia in pediatrics textbooks as well as the opinion of over 200 consultant pediatricians in the United Kingdom, considered the controversy relative to the definition (14). They documented substantial variation in the definition of hypoglycemia not

Figure 2 Plasma glucose concentrations in term neonates weighing 2.5–4.0 kg. (From Ref. 10.)

only among the pediatricians surveyed but also among caregivers within the same nursery.

One can postulate four possible approaches to the definition of hypoglycemia in the neonate: statistical, clinical, neurophysiological, and neurodevelopmental.

First, from a statistical standpoint, if a normally distributed curve of glucose concentration exists for the healthy term and preterm neonate, a glucose concentration less than 2 standard deviations of the mean would represent hypoglycemia. In 1965 Cornblath and Reisner reported the data that prevailed in this regard for many years (9). Ninety-five percent of the term neonates in that report had blood glucose concentration >30 mg/dl while 98% of the preterm infants had values >20 mg/dl. Hypoglycemia in the preterm neonate (birth weight [BW] <2.5 kg, in

1965) was defined as blood glucose concentration <20 mg/dl.

Other studies have tried to establish norms for euglycemia in the neonate. Many studies reported concentrations higher than those reported by Cornblath et al. (10, 15). These reports suggested that an average lower limit of 95% CI for neonatal blood glucose concentration is probably ≈ 45 mg/dl. However, generalization of this knowledge is an inaccurate approach to the problem for multiple reasons. The population studied in these reports varied relative to the following: the source of the blood samples; the methods of assay; whether blood or plasma glucose concentration was measured (i.e., plasma glucose concentration is up to 18% higher than that of the blood) (13); feeding schedules (i.e., early vs. late feeding);

Figure 3 Plasma glucose concentration for the four groups of neonates studied during the first 9 h of life. (From Ref. 11.)

whether the neonate was fed formula or breast milk (i.e., formula induced a higher insulin response than breast milk and may cause lower glucose concentration in formula-fed neonates) (16); cross-sectional vs. longitudinal design; and other metabolic fuels provided at the time of the study, among other issues.

Marconi et al. reported fetal glucose concentration obtained during cordocentesis using venous blood samples (17). We can extrapolate from the data obtained at different gestational ages that venous blood glucose concentrations ranged from 54–108 mg/dl (Fig. 4). That study is probably of greater importance and relevance to the healthy neonate both term and preterm. It is clear that blood glucose concentration was rarely less than 54 mg/dl. This is in agreement with venous cord blood concentrations reported from the neonate by Hawdon et al. that were greater than 47 mg/dl (18).

Second, a clinical approach considers a glycemic concentration to be safe, if clinical symptoms associated with hypoglycemia (Table 1) are not observed, or if these

symptoms have disappeared at that concentration. A classic report, published in 1959 and based on this definition, continues to be influential in clinical practice currently. In that report clinical manifestation of hypoglycemia (i.e., including tremors, irritability, limpness, apnea, seizures, and coma) were observed at a glucose concentration <25 mg/dl and resolved by increasing the blood glucose concentration to >40 mg/dl (19).

There are many concerns with this approach including the observation of extremely low blood concentrations in asymptomatic neonates, especially after glucose screening became a routine clinical practice. If we accept the argument presented in that analysis, we should then consider these extremely low blood glucose concentrations, as observed in the asymptomatic neonates, to be acceptable. The nonspecificity of the symptoms associated with hypoglycemia is another concern, especially when these symptoms are also associated with many other neonatal illnesses. Most of these studies did not evaluate the availability of other energy substrates to the neonate that may

Figure 4 Umbilical venous glucose concentrations (UMB VENOUS CONC) and gestational age for AGA pregnancies ($n = 77$). Dashed lines, mean \pm 2 SDs of fetal glucose concentration during pregnancy. Glucose concentrations are noted in mmol/L. Each mmol/L of glucose = 18 mg/dl. (From Ref. 17.)

compensate for the lower glucose concentration. The availability of other substrates may have a protective effect on the brain.

Third, a neurophysiological definition of hypoglycemia has been introduced, based on alteration of neurophysiological functions relative to different glycaemic concentrations. Koh et al. evaluated the latency of the auditory evoked response waveform, based on the fact that the inferior colliculus has one of the highest obligatory rates of glucose utilization in the brain (20). They reported that as blood glucose concentration declines (i.e., below 47 mg/dl), the latency between waves 1 and 5 gradually increased until wave 5 disappeared. Restoration of wave 5 was documented when hypoglycemia was corrected; however, it took a few hours in some instances before this restoration was achieved. Among the 17 children they studied, there were only 5 neonates.

Other studies have failed to demonstrate similar effect of hypoglycemia not only on auditory evoked response but also on electroencephalographic (EEG) signals as well as visual evoked potential (21, 22). Future research in the neurophysiological field evaluating electrical signals of different areas of the brain and utilizing other available methodology (e.g., near-infrared spectroscopy or positron emission technology) should be of great value and interest in the future.

Fourth, an approach can be based on neurodevelopmental outcome of the neonate relative to symptomatic or asymptomatic hypoglycemia. The study reported by Lucas et al. provides the most helpful information in this area (23). In their study 661 neonates, all preterm, were evaluated at 18 months of age for neurodevelopmental outcome. Bayley motor and mental developmental scores were blindly assigned to the infants and then these scores

were correlated with their neonatal glycaemic concentrations. Data were adjusted for gender, gestational age, birth weight, days of mechanical ventilation, and other social risks. The observed low glucose concentration ranged from 9 to 72 mg/dl.

These investigators demonstrated that two-thirds of the neonates had a blood glucose concentration <47 mg/dl for a period of time ranging from 3 to 30 days. They found the highest regression coefficient at plasma glucose concentration <47 mg/dl. A more important finding was that if hypoglycemia (level <47 mg/dl) existed for 5 or more consecutive or separate days, the risk of neurodevelopmental deficit (scores <70) significantly increased, regardless of the severity of hypoglycemia during that time. They also suggested that even at lower blood glucose concentration, transient hypoglycemia was tolerated

better than prolonged and milder forms of this disequilibrium.

These data reflect the relative inability of the clinician to diagnose hypoglycemia in the neonate. However, there are enough data to support a definition based on the above approaches to the understanding of hypoglycemia in the neonate. A blood glucose concentration of 54–108 mg/dl may represent a more desirable euglycemic range for the term and preterm neonate including the micropremie.

B. Measurement of Neonatal Glucose Concentration

Problems in the definition of euglycemia are accentuated by the lack of attention given to details of measurement of neonatal glucose concentration. Failure to measure the glucose concentration rapidly enough would allow red blood cell oxidation of glucose, resulting in falsely low values. A number of centers previously use the Dextrostix technique, which was thought to be reliable if directions were followed carefully. However, the company cautioned that the reagent strips were not intended for use with neonatal blood. This point is moot since Dextrostix is no longer on the market. However, we suggest that abnormal values, obtained by any strip or meter method either in the hypoglycemic or hyperglycemic range, need to be corroborated with laboratory determination of glucose concentration prior to correction of the suspected disequilibrium, unless the patient is symptomatic (3).

Furthermore, more recent investigations allow one to question if glucose strips should be used at all. Several studies have evaluated various means of assessing blood glucose concentration. Frantz et al. (24) reported that the Dextrostix test strip was able accurately to identify blood glucose concentrations of <50 mg/dl. However, they used fresh heparinized blood from adults to evaluate reliability, which may not be applicable to the neonate. Perelman et al. (25) evaluated rapid glucose determination in the neonate, comparing the Dextrostix Ames Meter, Chemstrip bG test strip, and Stat Tek Meter methods with a glucose analyzer. The investigators concluded that there was modest accuracy in estimating whole blood glucose concentration. They suggested that confirmation by conventional laboratory techniques was necessary before therapeutic intervention. Wilkins and Kaira (26) compared blood glucose test strips for the detection of neonatal hypoglycemia. In 101 blood samples, results of three glucose test strip methods were compared with a laboratory determination of glucose concentration. Two test strips (BM test glycemic 20-800 test strips and the Reflecto-Test hypoglycemia test strips) gave rapid and reliable estimates, but Dextrostix test strips tended to overestimate all blood glucose concentrations.

Conrad et al. (27) suggested that the Glucostix, the Dextrostix, and the Chemstrip bG test strips were relatively unreliable, with *r* values of 0.73, 0.74, 0.83, respectively, compared with the YSI analyzer in tests of 104

neonatal blood samples obtained by heelstick. They tested one glucose reflectance meter (the Glucometer M), which had an *r* value of 0.73 when correlated with the YSI analyzer. The investigators suggested that the YSI analyzer should be used preferentially in the determination of blood glucose concentration in the neonatal intensive care unit.

Lin et al. evaluated four glucose reflectance meters in use at the time of their study (28). The manufacturers claimed that these meters could reliably measure whole blood glucose concentrations as low as 20 mg/dl. To determine whether the accuracy of the determination would be affected by the technique of obtaining capillary blood by heelstick, the investigators used cord arterial blood from a separate group of neonates for comparison. All blood was sequentially analyzed five different times on each meter and the YSI analyzer. Evaluation of the data showed that accuracy was limited in heelstick blood whether one evaluated the percentage of difference between the means or the least-squares regression for all the meters tested. The use of cord blood appeared to be associated with greater accuracy than the use of capillary blood obtained by heelstick in the analyses. The reason for the poor correlations with capillary samples and the high variability in the values of blood glucose concentrations remains unclear. There was no relationship between accuracy and reliability of the various glucose reflectance meters. The Diascan S meter, which seemed to have accuracy closest to that of the YSI analyzer, was clearly not the most reliable in comparison with the YSI analyzer. However, the One Touch meter, which had the best reliability among the four glucose reflectance meters tested, was the least accurate. The investigators concluded that, contrary to the manufacturers' claims, glucose reflectance meters should probably not be used for evaluation of capillary blood glucose concentrations in the high-risk neonate.

Holtrop et al. evaluated the sensitivity and specificity of glucose oxidase peroxidase chromogen test strips by comparing values of 272 samples of serum glucose concentration with values obtained by Chemstrip bG (29). The diagnostic sensitivity of a test strip ≤ 40 mg/dl to predict a serum glucose concentration ≤ 34 mg/dl was 86% with 78% specificity. The positive predictive value with a 21% prevalence of serum glucose ≤ 34 mg/dl was 52% with a negative predictive value of 95%. Fifty-eight of the serum glucose concentrations were ≤ 34 mg/dl and the strips reported values greater than 40 mg/dl in eight. The investigators concluded that more sensitive and specific methods are required for the neonate.

As noted above, it is important to remember that the blood glucose concentration is usually 10–15% lower than the corresponding plasma glucose value. Finally, care must be taken when the test is performed because erroneously high values can be caused by isopropyl alcohol mixing with the blood on the strip that is read by reflectance colorimetry (30).

III. GLUCOSE METABOLISM

A. Methods of Evaluation

Metabolic research in the human neonate is generally limited by several basic ethical constraints, as discussed in a recent review (31). First, the studies must be noninvasive or minimally so. Second, blood samples should be invariably small, particularly those obtained from the very-low-birth-weight neonate. Third, given the limited direct access to most organ systems, the approaches used must allow extrapolation from the sampled data to events occurring in otherwise inaccessible areas. Fourth, the maximal information possible must be obtained from any given study owing to the difficulty of recruiting and the need to study the smallest number of subjects necessary to evaluate the proposed hypotheses adequately.

Many of the above constraints on perinatal metabolic research have been reduced or eliminated by methodological advances in the field. Kinetic studies utilizing stable isotopic tracers in conjunction with mass spectrometric quantification have been the most popular technique in investigating glucose metabolism in the human neonate. This technique is advantageous because both the substrate and the tracer are measured simultaneously with high precision and that minimizes measurement errors. The sample size required for the measurement is small, compared to other analytical methods, which is a major advantage in studies performed in the neonate.

Kinetic studies have been used to evaluate glucose production and utilization (32–34), gluconeogenesis (35), oxidative and nonoxidative disposal of glucose (36–39), insulin sensitivity via the euglycemic hyperinsulinemic clamp (40), as well as other aspects of glucose energy metabolism especially during total parenteral nutrition in the human neonate (41).

B. Evaluation of Hepatic Glucose Production

During kinetic studies utilizing stable isotopic methodology, glucose infusion, glucose absorbed from the gastrointestinal tract, glycogenolysis, and gluconeogenesis may collectively contribute to the rate of glucose appearance in the metabolic pool (i.e., plasma). Only the latter two variables reflect the endogenous rate of glucose production, primarily from the liver.

Measurement of the true rate of glucose production usually gives a good estimate of glucose requirement of the body and the rate of its utilization under basal conditions (42). To measure the true rate of endogenous glucose production, the neonate has to be fasted for at least 3 h prior to the study, resulting in minimal glucose being absorbed from the gastrointestinal tract during the study. No exogenous glucose should be infused during the basal period of the study, except for the tracer isotope that is usually infused at very slow rate. In investigations involving the micropremie (birth weight = 1000 g) the endogenous

glucose production rate under basal conditions cannot be measured for obvious ethical considerations. The rate of glucose infusion, glycemic concentration achieved and the pancreatic β -cell response to the infused glucose during any given study would individually or collectively affect the measured rate of glucose production. The dichotomy that exists in the neonatal literature relative to the endogenous glucose production rate response to plasma-insulin concentration, glycemic concentration and, correspondingly, to the rate of glucose infused, is probably secondary to many of these issues (43).

Our laboratory as well as others has previously demonstrated, in the preterm neonate, that persistent glucose production (glucose production ≥ 1 mg/kg/min) exists during glucose infusion at rates similar to or slightly greater than the basal glucose production rate of the human neonate (i.e., 4 to 7 mg/kg/min) (32, 33, 44). Developmentally this is in marked contrast with the adult, in whom glucose production can be suppressed when glucose is infused at a rate equal to or slightly greater than the basal endogenous glucose production rate (i.e., 2–3 mg/kg/min; Fig. 5) (45–48). Other investigators have suggested that plasma glucose concentration of the human neonate, rather than the rate of glucose infusion to the neonate, has an important regulatory effect on the rate of endogenous glucose production (49, 50).

When the results of glucose kinetics studies in three groups of neonates (i.e., the AGA term, the SGA term and the low-birth-weight [LBW] preterm neonate) were combined, Kalhan et al. reported a linear and negative correlation between plasma glucose concentration and endogenous glucose production (33). Complete suppression of glucose production was not achieved in their study.

Zarlengo et al. used the hyperglycemic clamp technique in a group of LBW neonates to evaluate the effect of glycemic concentration on the rate of glucose production (50). They reported complete suppression of glucose production at a plasma glucose concentration of ≥ 75 mg/dl. An average glucose infusion of 8.7 mg/kg/min was used in that study.

We have previously studied, in a comparable group of neonates, the glucose production response to three different glycemic concentrations (150, 200, and 250 mg/dl) utilizing the hyperglycemic clamp technique (51). A significant reduction in the rate of endogenous glucose production was observed in all groups. Complete suppression of glucose production was not consistent within or among the groups, except in the 250 mg/dl group. To achieve this glycemic level, glucose was infused at an average rate of 16 mg/kg/min.

The dichotomy in results also exists in studies that involve the micropremie. Hertz et al. showed a correlation between glucose production and glycemic concentration in the very LBW (VLBW) neonate (49). They reported a reduction in endogenous glucose production at moderate glucose infusion rate. Complete suppression of glucose

Figure 5 Glucose production rate for each neonate and adult during saline or glucose infusion. (From Ref. 32.)

production was achieved at a relatively high glucose infusion rate and plasma glucose concentration.

Other investigations that evaluated relatively similar groups of VLBW neonates have reported a higher glucose production rate and persistent glucose production during glucose infusion. Sunehag et al. studied 10 neonates born at ≤ 30 weeks gestation (44). They reported a persistent glucose production during glucose infusion at two consecutive rates of 1.7 and then 6.5 mg/kg/min. Although there was incomplete suppression of glucose production, it is evident that the neonate can partly reduce endogenous glucose production in response to higher rates of glucose infusion. A significant correlation was found between glucose production and plasma insulin concentration but not with glucose concentration. The investigators suggested that insulin plays more important role in the control of endogenous glucose production.

In two groups of smaller AGA neonates (gestational age [GA] 25–27 weeks), Farrag et al. demonstrated persistent glucose production when glucose was infused at both 4 and 8 mg/kg/min (work in progress). There was no significant correlation between endogenous glucose production and either glycemic concentration or plasma

insulin concentration. At the higher glucose infusion rate (8 mg/kg/min) the rate of endogenous glucose production was almost double that reported by Sunehag et al. This is in agreement with the data reported by Keshen et al. and demonstrated a negative correlation between glucose production rate and body weight in the VLBW neonate (35). Table 2 summarizes the results of these three studies.

Although there are differences among the data sets (in weight, gestational age, glycemic concentration, and rate of glucose infused) there is a general agreement that the neonate is able, at least partly, to decrease his or her rate of endogenous glucose production when receiving glucose infusion. However, there is no agreement as to whether glycemic concentration plays a more important role, in the control of hepatic glucose production, than plasma insulin concentration or vice versa.

Relative to the effect of insulin on glucose production, Farrag et al. also reported in the preterm neonate that endogenous glucose production persisted during a wide range of insulin infusion rates (Fig. 6) (40). In that study the investigators applied the euglycemic hyperinsulinemic clamp technique, for the first time, to evaluate insulin sensitivity in the human neonate. When insulin was infused

Table 2 Comparison of Three Studies Evaluating Glucose Production Rate in the Micropremie During Two Different Glucose Infusion Rates for Each Study

Reference	Study weight (g)	Glucose infusion rates (GIR ₁ and GIR ₂) (mg/kg/min)	Plasma glucose concentration (mg/dl)	Glucose production rate after infusion (mg/kg/min)
49	854 ± 51	GIR ₁ = 6.2 ± 0.4 GIR ₂ = 9.5 ± 0.5	113 ± 12 136 ± 15	1.67 ± 0.45 0.32 ± 0.07
44	976 ± 262	GIR ₁ = 1.7 ± 0.2 GIR ₂ = 6.5 ± 0.3	65 ± 20 110 ± 23	4.3 ± 1.3 1.4 ± 1.1
Farrag et al., in progress	708 ± 39 677 ± 39	GIR ₁ = 4.0 ± 0 GIR ₂ = 8.0 ± 0	58 ± 9 83 ± 13	3.0 ± 0.8 2.5 ± 1.0

at rates that ranged from 0.5 to 4.0 mU/kg/min, that resulted in physiological and pharmacological plasma insulin concentrations (i.e., ranged from 10 to 89 μ U/ml), only a reduction of 41–58% of preinsulin glucose production rate was achieved. In a subsequent study this concept was noted to be true for the term, as well as the smaller preterm neonate (28–31 weeks gestation) immediately after birth and in the same preterm neonate when restudied after the conclusion of the neonatal period (\geq 28 days of age) (52). In that study endogenous glucose production was comparably reduced by 36–60% during insulin infusion at a rate of 2 mU/kg/min. This is again in marked contrast with what is known to be the adult glucose production response to insulin infusion. Our lab-

oratory as well as others has demonstrated complete suppression of glucose production, in the adult, at low plasma insulin concentration and/or minimal insulin infusion rate (32, 45).

Many factors are known to play an important role in glucose homeostasis: glucose infusion rate, glycemic concentration, insulin, and contrainsulin-regulatory hormones. There is no evidence that any of these factors plays a dominant role in the control of hepatic glucose production in the human neonate. Most of the differences between the neonate and the adult in glucose homeostasis are believed to be related to the stress of labor (53, 54). This concept is clearly important in the transition, in the regulation of glucose homeostasis, from the complete de-

**Figure 6** Endogenous glucose production over time subdivided by the various insulin infusion rates (i.e., 0.2, 0.5, 1.0, 2.0, and 4.0 mU/kg/min) administered to the neonate as well as the 2 mU/kg/min rate administered to the adult. (From Ref. 40.)

pendence of the fetus to the complete independence of the neonate in the immediate neonatal period (43). However, there is evidence that these distinctive physiological and metabolic differences between the neonate and the adult continue through the neonatal period and for months afterwards (13, 55). There is also evidence that this pattern of neonatal glucose homeostasis is consistent with the ontogeny of the glucose transporters (i.e., Glut 2) that occurs both at the hepatocyte and at the pancreatic β -cell (56).

Thus the control of glucose production in the neonate is a complex process that is only partially controlled by insulin and glycemic concentrations. This unique response of the liver to insulin and glucose may be of physiological relevance in the human neonate. It is clearly important to ensure adequate glucose delivery to the brain under different metabolic circumstances. This may be of particular importance for the neonate who lacks the autonomy to do so during this critical stage of his or her development. The ontogeny of this process requires further evaluation at both the physiological and molecular levels. The developmental switch to an adultlike response, as has been demonstrated in some of its aspects, most probably requires maturation past the neonatal period (52, 55, 57).

C. Evaluation of Glucose Utilization

It is important to recognize that glucose is utilized by a variety of tissues with different metabolic characteristics (45, 47). First, there are tissues that utilize glucose independent of insulin (e.g., brain). Second are tissues that increase their glucose utilization with increments in plasma glucose concentration independent of increments in insulin concentration (e.g., liver, gut and the red blood cell). Third are tissues dependent on insulin for glucose utilization (e.g., adipose tissues, skeletal and cardiac muscles). It is also important to recognize that these tissues

host different glucose transporters (GLUTs) that are expressed in a tissue-specific pattern (Table 3).

The factors that control the gene expression and function of these transporters probably dictate the metabolic characteristics of the corresponding host tissue (58, 59). The ontogeny of these transporters within any given tissue can explain some of the developmental differences between the neonate and the adult. GLUT-1 is the predominant isoform of the fetus; it is found in virtually all tissues (60–62). It has a very high affinity for glucose and can effectively transport glucose to organs across the blood–tissue barrier. This may be crucial to meet the energy requirement of the fetal tissues during this stage of rapid growth and differentiation. After birth GLUT-1 decreases and other isoforms such as GLUT-2 in the liver, GLUT-3 in the brain, and GLUT-4 in the muscle increase (63–67).

There are two facilitative glucose transporters involved in the brain uptake of glucose. GLUT-1 is primarily responsible for transport of glucose across the blood–brain barrier and GLUT-3 is responsible for the uptake of glucose into the neuron. Evidence from animal studies suggests that GLUT-1 is downregulated by high glucose concentrations while GLUT-3 is not (65, 68). There is otherwise little information available relative to the regulation of GLUT-3. Insulin regulates the expression of GLUT-4 in insulin-sensitive tissues such as adipose tissue and skeletal and cardiac muscle (58). The effect of insulin is rapid and reversible because it primarily translocates intracellular vesicles of glucose transporters to the plasma membrane (69). This step can be rate-limiting for insulin induced glucose uptake under most conditions (70, 71). Except for GLUT-1, which is abundant in fetal life and decreases after birth, some of the other transporters appear to be developmentally regulated. They are found in fetal tissues in smaller amounts that increase after birth and reach adult levels later in life (62, 63, 67, 72).

Table 3 Distribution of Glucose Transporters

Glucose transporter isoform	Primary site of expression	Affinity to glucose
GLUT-1	All fetal tissues, erythrocytes and blood-tissue barriers	High affinity (+++)
GLUT-2	Hepatocyte, pancreatic beta cell and small intestine	Low affinity (+)
GLUT-3	Neurones and testis	Highest affinity (++++)
GLUT-4	Adipose tissue, skeletal muscle and cardiac muscle	Moderate affinity (++)
GLUT-5	Small intestine and sperm	Fructose uptake (+)
GLUT-6	Pseudogene	None
GLUT-7	Liver (endoplasmic reticulum)	Unknown

On the physiological level there is an agreement that neonatal glucose utilization positively correlates to increase of glucose infusion, glycemic concentration, as well as plasma insulin concentration (40, 49, 50). However, it is not clear when this positive correlation would reach plateau in response to each of these factors. In the larger preterm neonate we have demonstrated that endogenous glucose production is sensitive to low insulin concentration, reaches plateau quickly, and then becomes nonresponsive to higher insulin concentrations (Fig. 7) (40). Relative to glucose utilization, although we established a strong positive correlation between insulin concentration and glucose utilization, a plateau was not reached with insulin infusion up to 4.0 mU/kg/min that resulted in a plasma insulin concentration of 89 μ U/ml (Fig. 8) (40).

In a comparable group of neonates, we have recently demonstrated that glucose utilization was not significantly different among three groups of neonates evaluated at three glycemic concentrations: 150, 200, and 250 mg/dl

(51). We utilized the hyperglycemic clamp technique in that study. To achieve these glycemic concentrations, glucose was infused at an average rate of 12.8, 14.4, and 16.0 mg/kg/min, respectively. At least in this group of preterm neonates there was no added benefit, in term of glucose utilization (i.e., glucose utilization reached plateau), in increasing glucose infusion from 12.8 to 16.0 mg/kg/min or glycemic concentration from 150 to 250 mg/dl. Similar studies will be important to duplicate in the micropremie to determine the optimal rates of glucose infusion and the appropriate glycemic concentration for these neonates.

D. Oxidative and Nonoxidative Disposal of Glucose

It is important not only to evaluate the overall ability of the neonate to utilize glucose but also to understand how the utilized glucose contributes to his or her energy metabolism. Glucose is generally utilized by either a non-

Figure 7 Percentage decrease in endogenous glucose production (A) and percentage increase in glucose utilization (B) subdivided by the various insulin infusion rates (i.e., 0.2, 0.5, 1.0, 2.0, and 4.0 mU/kg/min) administered to the neonate as well as the 2 mU/kg/min insulin rate administered to the adult. (From Ref. 40.)

Figure 8 Regression plot correlating the percentage increase in glucose utilization relative to plasma insulin concentration in the neonate. (From Ref. 40.)

oxidative or an oxidative disposal (43, 73). Nonoxidative disposal represents glucose utilized for structural or energy-storage purposes. Only glucose utilized by oxidative disposal will contribute to the energy expenditure of the neonate (73, 74). In the preterm neonate, van Goudoever et al. evaluated the contribution of glucose oxidation to total energy expenditure at glucose infusion rate of 4 mg/kg/min (75). They found that glucose was oxidized at a rate of 2.9 mg/kg/min, which represents 50% of the total glucose utilized by the neonate. They concluded, based on arithmetic calculations, that the contribution of glucose oxidation to total energy expenditure was limited. Other studies evaluating glucose oxidation in the preterm neonate while receiving total parenteral nutrition reported oxidation of up to 65% of total glucose utilized (38, 76). Since glucose represents the main source of energy for the preterm neonate during most of the neonatal period, it is important to determine the extent of glucose oxidation and its contribution to total glucose utilization. It is also important to understand if he or she can adapt to progressive increases in the amount of glucose infused with corresponding increases in the rate of glucose oxidation (77). This knowledge will assist clinically in determination of the optimal rate of glucose infusion, which is the rate appropriate to the neonate's capacity to oxidize glucose.

To answer some of the above questions, we evaluated glucose utilization, both oxidative and nonoxidative, in the preterm neonate (57). We also wanted to determine if hyperglycemia is partly related to diminished glucose oxidation capacity in the preterm neonate. We used stable isotopic infusion of $\text{NaH}^{13}\text{CO}_3$, followed by $[\text{U}-^{13}\text{C}]$ -glucose, and then analyzed breath and plasma samples to

determine glucose oxidation and total glucose utilization, respectively. This was done over the range of glucose infusion commonly provided clinically in neonatal intensive care units (i.e., 4–8 mg/kg/min). We compared the data obtained within the first 4 days after birth to those obtained from the same neonate at a postnatal age of at least 1 month at the same glucose infusion rates. Thus, we could evaluate the developmental contribution of glucose utilization, both oxidative and nonoxidative, to glucose metabolism in the micropremie.

In that study, we established a significant linear and negative correlation between glycemic concentration and the percentage of glucose utilized by oxidation. We also found that the percentage of glucose oxidized was significantly higher in the immediate neonatal period ($\approx 68\%$) than that oxidized at about 5 weeks of life ($\approx 47\%$) by the same neonate. This was true at both glucose infusion rates with each micropremie serving as his or her own control at the same glucose infusion (4.0 or 8.0 mg/kg/min). We also found that soon after birth the micropremie was able to oxidize significantly higher rates of glucose when glucose was infused at a rate of 8.0 vs. 4.0 mg/kg/min. We found that the preterm neonate was able, soon after birth, to oxidize glucose at rates up to 7.5 mg/kg/min (95% CI 5.5–9.4 mg/kg/min) when they received glucose infusion at a rate of 8 mg/kg/min. The glucose oxidation rate may exceed the rate of glucose infusion, reflecting the contribution of endogenous glucose production to the total pool of glucose available for oxidation. None of these neonates developed hyperglycemia during glucose infusion at 8.0 mg/kg/min and at that rate blood glucose concentration averaged 83 ± 14 mg/dl (mean $[\text{M}] \pm$ standard error of the mean $[\text{SEM}]$) (57).

These results should encourage the use of glucose infusion at a rate of 8 mg/kg/min in the preterm neonate after the first day of life: the study age ranged from 27 to 96 h. The clinical practice of using as low a glucose infusion rate as possible in the preterm neonate to avoid hyperglycemia limits energy intake not only from glucose but also from fat and protein, since the composition of parenteral alimentation is usually administered proportionally (54). Hyperglycemia did not result from the rates of glucose infusion employed in these studies. However, the addition of fat and/or amino acids can increase the risk of this complication (41, 78). The risk of hyperglycemia should be weighed against the benefit of providing adequate energy, especially when insulin infusion has been shown to improve peripheral glucose utilization and enhance glucose tolerance significantly in the preterm neonate (40, 79).

We found nonoxidative disposal to be significantly higher in the older neonates when they were studied after the conclusion of the neonatal period (the late study) compared to themselves when they were studied in the immediate neonatal period (the early study). It is important to recognize that the metabolic state of the neonate is different during these two periods. Early after birth the caloric intake of the micropremie is insufficient to satisfy his or her energy expenditure, since he or she is in a catabolic state. If the neonate is medically stable after the conclusion of the neonatal period (i.e., similar to our study population) and receiving adequate caloric intake, he or she will be in an anabolic state.

The nonoxidative disposal of glucose represents its utilization by different metabolic pathways (43, 73, 80). In an anabolic state lipogenesis is a major route for nonoxidative disposal (38). Other nonoxidative pathways for glucose may include glycogenesis, cycling in the pentose phosphate pathway, and/or formation of a carbon skeleton for amino acids (73, 74, 76). The extrauterine developmental switch from a catabolic state (the early study) to an anabolic one (the late study) during the course of the current investigation can, at least in part, explain the significant increase in the contribution of the nonoxidative disposal of glucose to total energy metabolism in the late studies. Other factors, such as the change in the substrate available for energy metabolism from primarily glucose to a mixture of fat and carbohydrates, may play an equally important role in that phenomenon.

IV. CLINICAL ASSESSMENT

A. Incidence

It is not surprising that variations in the estimated incidence of hypoglycemia exist in the neonatal literature. Different reports vary relative to populations, definitions, screening methods, clinical status, as well as strategies for nutrition and fluid management. The incidence ranges from 7 to 57% based on these variations (13).

B. General Pathophysiological and Metabolic Considerations

The close relationship between maternal and fetal glucose, the repetitive occurrence of wide swings of neonatal glucose concentration, and the retarded disappearance of an acute glucose load in both term and preterm neonates indicate that the regulation of neonatal carbohydrate metabolism is poorly developed 72 h after birth (81). The birth process brings the necessity of a period of readjustment to allow subsequent control. In the low-birth-weight neonate especially, this adjustment is delicate and may result in abnormal consequences. We have already discussed the difficulties in the definition of hypoglycemia. One of the main clinical difficulties with the definition is the nonspecific symptoms, which include the signs and symptoms listed in Table 1. These difficulties are compounded by the occurrence of symptoms at different concentrations of blood glucose in different neonates and the lack of a universal threshold below or above which symptoms may occur (2, 7).

During steady-state glucose metabolism, glucose production equals glucose utilization and glycemic concentration is maintained within a narrow range. A simplistic approach will attribute hypoglycemia to decreased glucose production and/or increased glucose utilization. As discussed earlier, the neonate, on a per kilogram body weight basis, is able to produce glucose at adequate rates. There is evidence that the enzymatic pathways for glucose production via glycogenolysis as well as gluconeogenesis are intact in the term and preterm neonate (43). It is also recognized that the glycogen stores are limited in the preterm neonate as glycogen accumulation primarily takes place in the third trimester (13, 43, 54). Based on that, gluconeogenesis is the major route of glucose production in these neonates.

The change in metabolic milieu that occurs at birth, including the reduction of plasma insulin concentration as well as the elevation of cortisol concentration, catecholamines, and glucagon, favors the induction of gluconeogenesis. Of course the clamping of the cord and the termination of maternal glucose supplementation initiate and enhance these changes. The time necessary to induce and transcribe the involved enzyme's protein of gluconeogenesis, in metabolically functioning amounts (about 2 h), coincides with the clinical observation that the lowest blood glucose concentrations in the neonate were measured between 1–2 h after birth. The absence of stored glycogen in the low-birth-weight neonate makes hypoglycemia almost inevitable in the first few hours after birth if exogenous glucose is not provided.

The brain is the major site of glucose utilization in the neonate and the major site of concern as well. The neonate has the greatest brain to body weight ratio during human development. Some investigations have concluded that up to 90% of the glucose produced is utilized by the brain, via oxidation (82). Other investigations conclude

that the entire amount of glucose oxidized, in the term neonate, is insufficient to satisfy brain glucose requirements (83). There is evidence that the neonatal brain utilizes other metabolic substrates soon after birth, including lactate and ketones (73, 84–86). There is evidence from animal and human studies that during hypoglycemia the brain reduces its glucose consumption by more than 50% and increases its utilization of other substrates (e.g., ketones and lactate) by 15-fold or greater (73, 85, 86). There is also evidence that the term neonate can efficiently mobilize similar substrates during fasting (87). Furthermore, free fatty acids, glycerol, and ketone concentrations were negatively correlated with blood glucose concentration in these term neonates (18, 88). This ability to mobilize other energy substrates to adapt to hypoglycemia has a protective effect on the brain.

There is evidence that the preterm neonate lacks this protective ability (89). The lack of energy stores in form of glycogen, as discussed earlier, and adipose tissue is prominent in these neonates. Although fat cannot substitute glucose for brain energy metabolism, its mobilization and oxidation reduce glucose uptake by other tissues and make more glucose available for the brain (13). Levistky et al. demonstrated that nonesterified fatty acids and ketone body concentrations of the preterm infant are significantly lower than those of the term infant (86). Moreover, preterm infants with low blood glucose concentrations did not show increased ketone body concentrations, as did their term counterparts. This discussion emphasizes that, in the micropremie, cerebral defenses against hypoglycemia are limited, and prolonged episodes, even of milder nature, of hypoglycemia may have a more significant effect on the brain of the preterm than that of the term neonate.

There is evidence, as recently reviewed by Simmons, that the immaturity of GLUT-2 function in the hepatocyte as well as in the pancreatic β -cell may play a role in the pathophysiology of neonatal hypoglycemia (58). GLUT-2 is a low-affinity glucose transporter that occurs only in the hepatocyte and pancreatic β -cell. In the mature hepatocyte the low affinity of this transporter allows glucose release into the plasma in response to small reduction in plasma glucose concentration. This process is sensitive even within the normal glucose concentration range, resulting in maintenance of euglycemia.

In the newborn period, studies in multiple species demonstrate that the hepatocyte expresses a relatively high amount of GLUT-1 but relatively low levels of GLUT-2 (56). Decreased GLUT-2 expression may limit the hepatocyte sensitivity and responsiveness to changes in glucose and insulin concentration during hypoglycemia (40). This is in agreement with data from our laboratory demonstrating that the preterm neonatal liver was nonresponsive to progressive increment in insulin rates of infusion and plasma concentrations. We attributed this nonresponsiveness to insulin to intracellular mechanism(s) that probably involve a defect in glucose transporter rather than insulin receptors (40).

In the pancreatic β -cell GLUT-2, in concert with glucokinase, functions as a glucose sensor that allows the β -cell to recognize modest changes in plasma glucose concentration and appropriately secrete insulin (58, 59). Although the β -cell of the neonate responds to changes in the glycemic level, this process is diminished, in part due to decreased expression and/or function of the immature glucose sensor, and in part due to decreased activity of other metabolic linkages in the β -cell. Thus, the immature glucose sensor in the pancreatic β -cell may contribute to its inability to downregulate insulin secretion during hypoglycemia. There is evidence that this phenomenon is developmentally regulated (59). This is in agreement with reports suggesting that the basal insulin/glucose ratio is significantly higher in the preterm than in the term neonate (55).

Pryds et al. reported some evidence of increased cerebral blood flow in preterm infants to support cerebral metabolism during hypoglycemia (<30 mg/dl) (90). They also reported decreased cerebral blood volume during restoration of hypoglycemia in the preterm neonate (91). They concluded from these observations and the rapidity of adjustment of cerebral blood vessels to alteration in glucose concentration that a cerebral glucose sensor exists in the preterm neonate (92). They suggested that this sensor functions by recruiting brain capillaries to maintain adequate glucose transport to the brain during hypoglycemia.

C. Causes of Hypoglycemia

A number of different classifications have been used to categorize the various causes of hypoglycemia seen in the neonatal period. Table 4 lists many mechanisms known to be associated with hypoglycemia in the human neonate. One or a combination of the following three mechanisms generally causes neonatal hypoglycemia: diminished hepatic glucose production; depletion of glycogen stores; increased rate of glucose utilization. Extreme prematurity is a prime example of hypoglycemia due to primary failure to produce and/or store glycogen. Hypoglycemia secondary to depletion of glycogen stores is evident in the prematurely born AGA and/or SGA neonate as well as the neonate with congenital heart disease. Increased rate of glucose utilization, without hyperinsulinism, may explain the hypoglycemia seen in the perinatally stressed and asphyxiated neonate, cold-stressed neonate, as well as the neonate with congestive heart failure [e.g., hemodynamically significant patent ductus arteriosus (PDA)], and/or sepsis. The common thread in all these conditions is poor peripheral circulation and tissue perfusion associated with hypoxemia and lactic acidosis. This will lead to diminished mobilization of substrates as well as energy-inefficient anaerobic glycolysis. Neonatal hyperinsulinemic syndromes, including the infant of diabetic mother, can be associated with significant and/or persistent neonatal hypoglycemia. Neonates may also be hypoglycemic be-

Table 4 Condition Associated with Hypoglycemia in the Neonate

Mechanism and/or origin	Condition, disease, and/or syndrome
Primary failure to produce and/or store glycogen	Extreme prematurity
Depletion of glycogen stores	Prematurity, intrauterine growth restriction/small for gestational age, postmaturity, and congenital heart disease/congestive heart failure
Increased rate of glucose utilization	Perinatal stress/hypoxia, cold stress, and sepsis
Hyperinsulinemia	Infant of diabetic mother, large for gestational age, Rh incompatibility, following exchange transfusion, malposition of umbilical artery catheter, nesidioblastosis, exposure to beta-adrenergic agonists and others
Inherited diseases	Malformation syndromes (e.g., Beckwith-Wiedemann syndrome), autosomal recessive hyperinsulinemia, inborn errors of carbohydrate, protein and lipid metabolism
Endocrine deficiency	Hypopituitarism, growth hormone deficiency, glucagon deficiency, cortisol deficiency/ACTH unresponsiveness
Newly described syndromes	Specific glucose transporter deficiency (neuroglucopenia during euglycemia), neonatal hyperinsulinemia-hypoglycemia and isoimmune thrombocytopenia association

cause of deficits in intermediary metabolic pathways such as glycogen storage disease type I, fructose 1,6 diphosphatase deficiency, or primary glucagon deficiency, reflecting a series of hereditary metabolic and endocrinological disorders in which hypoglycemia may be the initial or most obvious presenting feature.

V. PRETERM APPROPRIATE FOR GESTATIONAL AGE NEONATES

The appropriate for gestational age neonates born before term may develop hypoglycemia. While the first report of this entity concerned small for gestational age neonates, (19) subsequent studies documented hypoglycemia in the low-birth-weight AGA neonate. In 1968, Raivio and Hallman reported a frequency of 1.4% of hypoglycemia in these neonates (93). Fluge reported that as many as 14% of AGA neonates evidenced neonatal hypoglycemia (94).

The diminished oral and parenteral intake in the low-birth-weight neonate in combination with the decreased concentration of substrates may explain the lower plasma glucose seen in these neonates and their propensity to hypoglycemia. Functionally immature gluconeogenic and glycogenolytic enzyme systems present in the neonate potentiate these difficulties. The relatively increased size of the brain (13% of the body mass in the newborn vs. 2% in the adult) may be responsible for the greater proportion of glucose consumption during periods of fasting. This effect is magnified in the low-birth-weight neonate.

VI. SMALL FOR GESTATIONAL AGE INFANTS

Many centers have reported a relatively high frequency of hypoglycemia in SGA neonates ever since Cornblath et

al. in 1959 described its occurrence in eight infants born to mothers with toxemia (19). Lubchenco and Bard (95), deLeeuw and deVries (96), and others have all substantiated the occurrence of hypoglycemia in these neonates. Toxemia has been repeatedly reported to be associated with hypoglycemia, and its incidence has been shown to be highest (61%) in neonates born to mothers with relatively low urinary estriols, compared to a frequency of 19% in neonates born to mothers with normal estriol levels (96, 97). Reduction in energy reserves in the form of decreased glycogen deposition, combined with increased utilization of substrate, may account for the appearance of hypoglycemia.

Kliegman studied the effect of maternal nutritional deprivation on fetal/neonatal metabolism in dogs (98). Besides reduced fetal weight at term (251 ± 7 vs. 277 ± 7 gms), the growth-retarded pups evidenced lower glucose concentrations after 3, 6, and 9 h of fasting, reduced plasma concentrations of free fatty acids at 9 and 24 h, and lower ketone bodies at 24 h compared to controls. Although the systemic rates of palmitate and alanine turnover were not affected, systemic glucose production was reduced for 3–9 h after birth, which resulted in the observed hypoglycemia. The investigator speculated that reduced rates of gluconeogenesis from alanine and reduced oxidation of fuels such as free fatty acids (FFA) contributed to the hypoglycemia. FFA recycling to triglyceride rather than oxidation contributed to the observed hypoglycemia.

Plasma insulin and blood glucose concentrations were measured in umbilical venous samples from 42 SGA and 68 AGA fetuses by cordocentesis at 17–38 weeks of gestation (99). In the AGA fetus plasma insulin and the insulin/glucose ratio increased exponentially with gestation, suggesting maturation of the pancreas. The major determinant of fetal blood glucose concentration was maternal

blood glucose concentration. The insulin/glucose ratio in the SGA fetuses was lower than in the AGA fetuses, suggesting that hypoinsulinemia in the former was the result of hypoglycemia and pancreatic dysfunction. The degree of SGA status did not correlate with plasma insulin or the insulin/glucose ratio, which suggested to the authors that insulin is not the primary determinant of fetal size.

Following bilateral maternal uterine artery ligation, Bussey et al. studied the sequential changes in plasma glucose, insulin, and glucagon concentrations, hepatic glycogen, and phosphoenolpyruvate carboxykinase (PEPCK) during the first 4 h in growth-retarded rat pups (100). Hypoglycemia was noted in SGA pups compared to control (AGA pups) as well as reduced hepatic glycogen stores at birth. Plasma glucagon rose, but plasma insulin fell. PEPCK levels did not rise either. The investigators concluded that SGA pups developed hypoglycemia because of limited glycogen stores and retarded gluconeogenesis. They speculated that delayed PEPCK induction in these animals may result from inadequate glycogen release at birth or decrease sensitivity to glucagon.

A number of studies have evaluated the intermediary metabolism of substrate available postnatally. A functional delay in the development of PEPCK, thought to be the rate-limiting enzyme of gluconeogenesis, in SGA neonates was suggested by Haymond et al. (101). This was substantiated by Williams et al., who studied the effect of oral alanine feeding on glucose homeostasis in the SGA neonate compared to AGA neonates (102). Oral alanine feeding enhanced plasma glucagon in both groups but stimulated hepatic glucose output only in the AGA infants.

The effect of intravenously administered glucagon on plasma amino acids has been evaluated in various types of neonates including the SGA neonate. SGA neonates in the first hours of life had significantly lower total amino acids compared to a comparable group of AGA neonates, although the response to glucagon in the SGA neonates mimicked the control (AGA) group. It was speculated that the inability of the SGA neonate to extract specific gluconeogenic amino acids could account for the susceptibility to hypoglycemia in these stressed neonates (103).

Twenty-five SGA neonates received 0.5 mg/day glucagon to treat hypoglycemia (104). Twenty of the 25 responded within 3 h with a rise in blood glucose to greater than 72 mg/dl. Five subsequently required hydrocortisone to maintain euglycemia. Rebound hypoglycemia occurred in nine following discontinuation of the glucagon. The response was poor after maternal beta blockade.

Mestyan et al. also evaluated the role of glucagon by measuring 17 amino acids before and during glucagon infusion in normoglycemic and hypoglycemic SGA neonates (105). In the normoglycemic group most amino acid concentrations declined significantly but this did not occur in the SGA neonates who were hypoglycemic. Although the effect was transient, these results reflect the ability of

glucagon to produce acute changes in hepatic glucose homeostasis. This was demonstrated in neonatal lambs between 1 and 3 days of age with infusions of somatostatin alone or who received insulin and glucagon during a 2 h interval. Plasma glucose concentration fell when both insulin and glucagon were suppressed acutely, suggesting that the latter is of importance in maintaining glucose concentration during short-term fasting. It was suggested that the ratio between the two hormones acutely affected glucose homeostasis (106).

The secretion of glucagon and insulin has been evaluated in SGA neonates. Both SGA and AGA neonates, after being fed oral glucose and protein (1 g/kg each after a 4 h fast), had similar secretion of both pancreatic hormones. The investigators speculated that the instability of glucose metabolism in the SGA neonate resulted from the rapid fall of glucose and probably because of a transient deficiency of hepatic gluconeogenic enzymes, but not from altered secretory patterns of the hormones (107).

The adequacy of the hormonal response was reinforced in a study of glucose-infused SGA neonates who were evaluated by stable isotope kinetic analysis. Under stimulation of glucose infusion, the SGA neonate and his AGA counterpart had similar regulatory responses as well as functional integrity in handling glucose during the second day after birth (108).

Using the newborn piglet model, Flecknell et al. studied the effects of an intravenous glucose infusion on glucose homeostasis in normal and growth-restricted newborn piglets using non-steady-state tracer technique (109). Suppression of hepatic glucose output was noted, but hyperglycemia (plasma glucose >180 mg/dl) developed in the majority of study subjects. The mechanism of the hyperglycemia was thought to be failure to increase glucose utilization in response to the glucose infusion.

The possibility of hormonal excess producing growth retardation has been emphasized by Ogata et al. (110). The investigators adapted methodology to produce maternal hyperinsulinemia in a rat model. This resulted in decreased concentrations of glucose and amino acids in both the mother and fetus, which produced retarded fetal growth, limited hepatic glycogen deposition, and delayed neonatal PEPCK induction.

Sann et al. evaluated the effect of hydrocortisone on intravenous glucose tolerance (1 gm/kg) in eight term SGA neonates compared to seven AGA neonates at mean of 41 h of age (111). The rate of glucose disappearance was decreased in the SGA neonates compared to control neonates. Plasma glucose concentrations were similar in both groups, while plasma insulin concentration did not change in the control group. After hydrocortisone administration, plasma insulin concentration increased. The investigators concluded that hydrocortisone induced a reduced peripheral uptake of glucose independent of insulin secretion.

VII. CONGENITAL HEART DISEASE/ CONGESTIVE HEART FAILURE

An inverse relationship has been noted between the concentration of cardiac glycogen and the level of maturity of the neonate, exemplified by the low levels in the offspring of mammalian species more mature at birth (i.e., human, monkey, sheep, etc.). These reserves are rapidly depleted during anoxia (112). Benzing et al. reported on a series of 27 patients in whom the simultaneous occurrence of hypoglycemia and acute congestive heart failure was noted in association with congenital heart disease (113). Reduced dietary intake in association with diminished hepatic glycogen resulted in hypoglycemia. This has been further substantiated by Amatayakul et al., who noted the association of hypoglycemia with congestive heart failure in neonates without significant heart defects (114). The pathophysiology of hypoglycemia in cyanotic congenital heart disease was studied by Haymond et al. (115). Six subjects were evaluated between 13 and 67 months of age. Glucose and alanine turnover studies utilizing stable isotope labeling in these neonates were compared to controls. A subtle defect in hepatic extraction of gluconeogenic substrates was suspected, possibly secondary to decreased hepatic blood flow. It is apparent that the presence of either hypoglycemia or congestive heart failure should be considered when one or the other appears.

The interrelationship of hypoglycemia and pulmonary edema has been emphasized. Unfortunately, it was unclear whether the pulmonary edema was secondary to the hypoglycemia or due to treatment of the hypoglycemia, since D₂₀W was administered through an umbilical venous catheter into a branch of the left pulmonary vein (116).

Nineteen neonates with symptomatic ventricular septal defect (VSD) were examined by means of an intravenous glucose tolerance test (IVGTT) and compared to 14 neonates who were healthy (117). The VSD neonates were growth-retarded with lower weight for age and length for age. Glucose tolerance was similar in both groups. Plasma insulin concentration was low in the VSD neonates but insulin secretion, as measured by C-peptide concentration, was elevated. The authors speculated that increased insulin extraction occurs in the liver, but the mechanism was unknown.

VIII. PERINATAL STRESS/HYPOXIA

Neonates who utilize glucose at an increased rate may be prone to hypoglycemia. Since the low-birth-weight neonate is subject to hypoxia, the combination of decreased substrate availability and increased rate of utilization may result in hypoglycemia. An increased rate of anaerobic glycolysis in combination with an increased rate of glycogenolysis is probably the underlying biochemical mechanism. Two moles of ATP are generated by the Embden

Meyerhof anaerobic pathway, whereas aerobic oxidation results in 36 moles of ATP; thus, 18 times more glucose is required to generate the same amount of ATP. In addition, increased lactate production may result in an associated acidosis. Beard has emphasized the association between hypoxia and hypoglycemia in the low-birth-weight neonate and noted increased metabolic needs out of proportion to substrate availability (118, 119). The difficulties are all accentuated in neonates who are unable to replace substrate from the usual exogenous (oral) sources because of hypoxia or other clinical problems. Metabolic acidosis and lactic acidemia were noted during the first 24 h of life in 4 term and 11 preterm neonates whose Apgar score had been 5 at 1 min after birth and who were fed oral glucose loads (120). Thus, not only may endogenous stores be depleted but also these neonates may be unable to tolerate an exogenous load.

Another complication of perinatal stress is the presence of hyperinsulinism. In a report by Collins and Leonard, hyperinsulinism was noted unequivocally in three SGA neonates and in three who were asphyxiated (121). The cause of the hyperinsulinism was unclear.

Jansen and co-workers undertook a further evaluation of the metabolic effects of neonatal asphyxia (122). Using a rat preparation, they showed that hypoxia drastically altered both metabolic fuel and glucoregulatory hormone availability. They suggested that persistence of the catecholamine surge and tissue hypoxia and acidosis are responsible for the transient surge in glucose and subsequent delay in decrease of insulin and increase of glucagon in the asphyxiated neonatal rat. That is consistent with the clinical observation that the asphyxiated neonate's initial glucose concentration may be elevated and falsely reassuring. However it is not unusual for the neonate to drop his or her glucose concentration to significantly hypoglycemic levels soon after this initial surge. This emphasizes the importance of careful monitoring of the asphyxiated neonate's blood glucose concentration in the first few hours of life, even if the initial values were reassuring.

IX. COLD INJURY AND SEPSIS

Hypoglycemia has been identified in neonates who experience cold injury. Mann and Elliott described 14 neonates who suffered neonatal cold injury following prolonged exposure to environmental temperatures below 90°F (123). Marked hypoglycemia was documented in three of six neonates in whom it was measured. The hypoglycemia was presumed to be the result of free fatty acid elevation secondary to a cold-induced norepinephrine response (124). Recognition of the potential association of hypoglycemia following cold stress should result in parenteral treatment, if necessary, in conjunction with warming of the neonate. In addition, this relationship needs to be considered in the evaluation of blood glucose

levels in neonates with either temperature instability or who are in a suboptimal thermal environment.

Close et al. evaluated the influence of environmental temperature on glucose tolerance and insulin response in the neonatal piglet (125). Temperatures were maintained at 17, 24, and 33°C during which an intravenous infusion of 1 g glucose/kg body weight was administered. Rectal temperatures were maintained in all of the piglets subjected to the two higher temperatures but not the lowest one in which 6 of 18 became hypothermic. A higher glucose disappearance rate was noted— K_G : 2.00 and 2.32%/min was recorded for animals maintaining homeothermic temperatures during 17 and 24°C temperature conditions compared to those kept at thermal neutrality (1.66%/min). The insulin response was comparable. During hypothermia both K_G $0.76 \pm 0.12\%/min$ and the insulin response were decreased. Glucose uptake by skeletal muscle was increased in environmentally cold-exposed homeothermic animals, resulting in an increased metabolic rate.

Neonatal sepsis has been identified with increased frequency in association with hypoglycemia. Yeung noted the association in 20 of 56 neonates with signs of sepsis (126). He suggested that inadequate caloric intake in these infected neonates may predispose to hypoglycemia. The possibility of an increased metabolic rate was considered because these neonates were infused with 100 kcalories/kg/day intravenously. A decreased rate of gluconeogenesis has been documented in laboratory animals following Gram-negative bacterial infection (127). The possibility of increased peripheral utilization because of enhanced insulin sensitivity in sepsis has been considered (128). It is likely that one or more of these factors will operate to produce the resultant hypoglycemia.

X. HYPERINSULINISM: THE INFANT OF THE DIABETIC MOTHER

Hypoglycemia following increased plasma insulin concentration has now been associated with several discrete disorders of the islets. It may be found in the infants of diabetic mothers, neonates with hemolytic diseases of the newborn, neonates with pancreatic nesidioblastosis, discrete or multiple islet cell adenomatosis, and neonates undergoing exchange transfusion. The Beckwith-Wiedemann syndrome should be considered along with other causes of hyperinsulinemic hypoglycemia, beta-sympathomimetic treatment to the mother, following high umbilical artery catheter placement, and following maternal ethanol consumption.

The infant of the diabetic mother (IDM) is the premier metabolic example of the morbidity that may exist in the neonate secondary to maternal disease (i.e., diabetes). Although the IDM may have greater morbidity than the neonate of the nondiabetic woman, many infants of insulin-dependent diabetic women experience an uneventful clinical course, and even more infants of women

with gestational diabetes do well (129). In theory the more closely metabolically controlled the diabetic pregnant patient is, the greater the potential for producing a normal neonate. Over the past decade or so, perinatal mortality, except for congenital anomalies, has approached that for the neonate born to a nondiabetic mother (130, 131). Pedersen originally emphasized the relation between maternal glucose concentration and neonatal hypoglycemia (132). His simplified hypothesis recognized that maternal hyperglycemia parallels fetal hyperglycemia, which stimulates the fetal pancreas resulting in islet cell hypertrophy and β -cell hyperplasia with increased insulin content. After separation of the fetus from the mother, the former no longer is supported by placental glucose transfer, which results in neonatal hypoglycemia.

Hyperinsulinemia in utero affects diverse organ systems, including the placenta. Insulin acts as the primary anabolic hormone of fetal growth and development, resulting in visceromegaly, especially of heart and liver, and macrosomia. In the presence of excess substrate such as glucose, increased fat synthesis and deposition occur during the third trimester. Fetal macrosomia is reflected by increased body fat, muscle mass, and organomegaly (insulin-sensitive tissues) but not an increased size of the brain or kidney (insulin-insensitive tissues) (133, 134).

After delivery there is a rapid fall in plasma glucose concentration with persistently low concentrations of plasma FFA, glycerol, and beta-hydroxybutyrate. In response to an intravenous glucose stimulus, plasma insulin-like activity is increased, as is plasma immunoreactive insulin, determined in the absence of maternal insulin antibodies and plasma C-peptide concentration (135). The insulin response to intravenous arginine is also exaggerated in the infant of a gestationally diabetic mother (136). Certainly the pregnancy of the diabetic mother should be considered to be of high risk. Knowledge of the character of the maternal diabetes, prior pregnancy history, and complications occurring during pregnancy allows the physician caring for the neonate to anticipate many of the potential fetal and neonatal complications that are reported in the infant of the diabetic mother (Table 5).

Factors known to influence the degree of hypoglycemia in the IDM include prior maternal glucose homeostasis and maternal glycemia during delivery. An inadequately controlled pregnant diabetic will have stimulated the fetal pancreas to synthesize excessive insulin, which may be readily released. Administration of intravenous dextrose during the intrapartum period, which results in maternal hyperglycemia (>125 mg/dl), will be reflected in the fetus and will exaggerate the normal postdelivery fall in plasma glucose concentration. In addition, hypoglycemia may persist for 48 h or may develop after 24 h.

Fetal hyperinsulinemia is associated with a suppressed concentration of plasma free fatty acids and/or variably diminished hepatic glucose production in the neonate (Fig. 9). Thus, not only is peripheral glucose uti-

Table 5 Neonatal Morbidities Associated with the Infant of the Diabetic Mother

Respiratory distress
Respiratory distress syndrome
Septal hypertrophy
Small left colon syndrome
Transient hematuria
Transposition of the great vessels
Truncus arteriosus

lization increased due to hyperinsulinemia, but hepatic glucose production is also diminished and other energy substrates are lacking as well.

Other factors that may contribute to the development of hypoglycemia include defective counterregulation by catecholamines and glucagon. The neonate exhibits transitional control of glucose metabolism, which suggests that a multiplicity of factors affect homeostasis. Many of the factors are similar to those that influence homeostasis in the adult. What is different in the neonate are the various stages of maturation that exist. Prior work in conjunction with glucose infusion studies can be summarized to suggest that there is blunted splanchnic (hepatic) responsiveness to insulin in the neonate both in the IDM and the preterm and term neonate of the nondiabetic mother, compared to the adult (32).

What has not been studied, but is of particular interest, are the many contra-insulin hormones that influence metabolism. If insulin is the primary gluco-regulatory hormone, then contra-insulin hormones assist in balancing the effect of insulin and other factors. One should probably evaluate all of the contra-insulin hormones, but those of particular interest in the IDM have been those of the sympathoadrenal neural axis. Many studies have evaluated epinephrine and norepinephrine concentrations in the IDM. The results are quite variable. An early study involved 11 infants of diabetic mothers, only two of whom were gestational diabetics. Urinary excretion of catechol-

amines was measured and compared to that in 10 infants of normal mothers. Urinary norepinephrine and epinephrine concentrations did not increase in the IDM who was severely hypoglycemic, but did increase in the neonate whose mother was mildly hyperglycemic (137).

These results parallel investigations of Stern et al. (138), who suggested that hypoglycemia may be secondary to an adrenal medullary exhaustion phenomenon. This would be secondary to longstanding hypoglycemia in the IDM, which would presumably be secondary to poor control of maternal diabetes. In further studies, Keenan et al. (139) noted that when normal plasma glucose concentration increases, plasma insulin concentration declines, and plasma FFA concentration increases in response to exogenous administration of epinephrine. This confirmed the exhaustion theory. In another series, Artel et al. (140) measured plasma epinephrine and norepinephrine concentrations in the IDM. Elevated concentrations of both hormones were reported, although variation was markedly increased in the IDM. The investigators speculated that hypoglycemia after birth may be secondary to adrenal exhaustion, producing temporary depletion later in the neonatal period.

Figure 9 Glucose production rate (GPR) for the infant of the diabetic mother (chemical- and insulin-dependent diabetic mothers) vs. healthy control. The solid bar indicates the mean rate of production within each group. (From Ref. 32.)

Other factors related to sympathoadrenal activity in the neonate may be of importance. In a continuing evaluation of the transitional nature of neonatal glucose metabolism, both of insulin and contra-insulin factors, epinephrine was infused in two dosages (50 mg or 500 mg/kg/min) in a newborn lamb model and glucose kinetics (turnover) were measured with [6-³H]glucose. The newborn lamb showed a blunted response to the lower dosage of epinephrine infused. The investigators speculated that the newborn lamb evidenced blunted responsiveness to this important contra-insulin stimulus (141, 142). This tendency was reaffirmed by recent data from the same laboratory. It is possible that if this occurs in the diabetic state, it would partially account for the presence of hypoglycemia noted clinically.

Thus, the IDM is a prime example of the potential of glucose disequilibrium in the neonate. Because of the transitional nature of glucose homeostasis in the neonatal period in general, accentuation of the disequilibrium may be enhanced in the IDM secondary to metabolic alterations present in the diabetic mother. A great deal of work is necessary to appreciate fully the operative mechanisms.

XI. Rh INCOMPATIBILITY AND HYPOGLYCEMIA

Hyperinsulinism has been implicated as the cause of the hypoglycemia seen in neonates with severe Rh isoimmunization (143, 144–146). These children are invariably severely affected by their disease, with profound anemia and hepatosplenomegaly at birth. The shock and collapse seen on occasion may be caused primarily by the profound hypoglycemia and, under such circumstances, glucose administration in addition to measures taken to correct the anemia may be critical. The IDM and severely Rh-affected neonate share several pathological hallmarks. In addition to the hyperinsulinism and islet cell hyperplasia, both show almost identical edematous placental changes. Both have excessive islands of extramedullary hematopoiesis in both liver and spleen. Although this latter finding may be the result of insulin stimulation, the precise cause of the hyperinsulinism itself in the Rh-affected neonate is uncertain. It has been suggested that an increase in reduced glutathione resulting from massive hemolysis of red blood cells may act as a stimulus to insulin release.

XII. EXCHANGE TRANSFUSION AND UMBILICAL CATHETER

Hypoglycemia, although not often considered, may be a significant problem following exchange transfusion. In this connection, the exchange blood and its preservatives are more critically important in the neonate, in whom a double-volume washout is being undertaken, than in an

adult who is receiving 450 ml the blood/preservative mixture to be diluted in a total 5 L or more solvent.

Heparinized blood contains no added glucose. Moreover, the heparin, by raising the free fatty acid levels, contributes to the hypoglycemic potential of the transfusion blood, so that under some circumstances (e.g., severe Rh incompatibility with hyperinsulinism) its use would be contraindicated unless a concomitant IV glucose infusion is administered to prevent and/or treat hypoglycemia (147). With citrated blood, acid citrate dextrose (ACD), or citrate phosphate dextrose (CPD), the added dextrose will yield a blood preservative mixture containing as much as 300 mg % glucose. In this situation, although immediate hypoglycemia is not a problem, the high glucose load may result in a reactive insulin response. This response lags behind the glucose infusion so that when the glucose bolus is suddenly terminated at the end of the exchange procedure, a state of hyperinsulinism ensues. Studies documenting this occurrence have shown a precipitous 2 h postexchange fall in blood glucose to levels below that prior to the exchange procedure (148). Once again, the severely Rh-affected neonate is at greatest risk, but even mildly affected and nonerythroblastotic neonates who undergo an exchange transfusion may respond in such a manner. Recognition of this possibility should lead to its detection and treatment.

Another cause of relative hyperinsulinism was reported secondary to malposition of an umbilical artery catheter. In a neonate requiring supplemental oxygen because of increasing respiratory distress, hypoglycemia was relieved only when a high catheter was repositioned from T 11–12 to L 4. Following repositioning of the catheter, the child became euglycemic (149). Malik and Wilson reported on two neonates who developed hyperinsulinism secondary to malposition of the umbilical arterial catheter. Repositioning resulted in creation of the hyperinsulinemia (150). Puri et al. reported on the association of neonatal hypoglycemia associated with position of an umbilical catheter between the 8th and 9th thoracic vertebrae that is the normal position. In this report, the catheter was moved and neonatal hypoglycemia resolved (151). Three neonates were reported whose catheter were placed between the 8th and 10th thoracic vertebrae. They were noted to have hypoglycemia, which responded to catheter withdrawal to the 3rd–4th lumbar region. The investigators speculated that the cause was a high streaming of glucose to the celiac axis. The mechanism of the hypoglycemia was postulated to be excessive insulin secretion following infusion into the celiac axis (152). This was studied using a neonatal lamb model and the clinical suspicion was confirmed. The mechanism was thought to be decreased production of hepatic glucose secondary to the presumed increased portal insulin following high catheter placement (153).

Jacob and Davis studied differences in serum glucose concentrations from different extremities in neonates with

umbilical arterial catheter through which dextrose was being infused. Neonates without catheter had no differences in simultaneous capillary glucose concentrations, obtained from both lower extremities, while neonates with catheters did. Neonates with a high catheter did not. As expected, the highest values were in those extremities into which the catheter was placed. This is another study pointing out the heterogeneity possible in glucose determinations depending on the location from which the blood is taken (154).

XIII. PERSISTENT HYPERINSULINEMIC HYPOGLYCEMIA

Persistent hyperinsulinemic hypoglycemia of infancy (PHHI) consists of persistent neonatal hyperinsulinemia for more than several weeks. Although the infant of the diabetic mother is the premier example of hyperinsulinemia in the newborn, his or her hyperinsulinemia is usually transient and resolves after few or several days. PHHI is a heterogeneous group of disorders and has been given a number of different names in the medical literature (155, 156): leucine-sensitive hypoglycemia, nesidioblastosis (157–159), β -cell hyperplasia, congenital hyperinsulinism, and discrete islet cell adenoma (160, 161), or adenomatosis (162, 163). The term leucine-sensitive hypoglycemia disappeared when leucine was found to function as an insulin secretagogue in patients with PHHI as well as in the healthy infant. Nesidioblastosis (meaning neof ormation of islets) refers to the histological finding of newly formed islets budding from pancreatic ductal cells in histopathological specimens from patients who have PHHI. These findings explain the other names used in the literature to describe the syndrome of PHHI as discussed earlier. However, controlled studies have since shown that these histological findings are not unique to PHHI patients. Similar findings do exist in normal controls at different stages of maturation and are quite prominent in the term neonate (164). Hyperinsulinism without other apparent cause and refractory hypoglycemia should point toward this rare but real possibility. Other diagnostic clues include large for gestational age status; nonketotic hypoglycemia associated with low serum levels of FFA and lactate; low levels of insulin-like growth factor (IGF)-binding protein 1 (suppressed by insulin); glucose/insulin ratio less than 3:1 during hypoglycemia; and a glycemic response to glucagon with a rise of more than 30 mg/dl (this rules out depletion of hepatic glycogen store, which is indicative of hyperinsulinism) (165–167).

Solt'esz et al. have reported on 18 children with hyperinsulinemic hypoglycemia born to nondiabetic mothers (168). Thirteen presented within 3 days of birth, three by 20 months, and two aged 9 years. The diagnosis was established by altered insulin/glucose ratio with corresponding low ketone body levels, as well as lactate, alanine, and glycerol concentrations. The subjects required in-

creased rates of glucose administration (between 9 and 25 mg/kg/min) and had an increased glucose disappearance rate of $KG 7.6 \pm 0.06\%$. The clinical course was quite variable: four cases had transient hyperinsulinemia; two responded to diazoxide; two required both diazoxide and partial pancreatectomy; two responded to surgical excision of an isolated adenoma; five required total pancreatectomy for nesidioblastosis; and two occurred secondary to drug administration. In this series, heterogeneity existed in the clinical courses of this condition.

Aynsley-Green et al. evaluated plasma proinsulin and C-peptide concentrations in five children with hyperinsulinemic hypoglycemia presenting with severe hypoglycemia (169). Data were compared to those from 13 normal neonates. Three neonates and a 9-year-old child required partial or total pancreatectomy. All evidenced elevated proinsulin concentrations and had elevated C peptide concentrations as well. Given the level of glucose concentration present (normal range for normoglycemia but elevated for hypoglycemia), the investigators concluded that the insulin, proinsulin, and C-peptide concentration profile does not provide a reliable indicator for the underlying pathological mechanism.

Both autosomal recessive and autosomal dominant forms of PHHI have been described (170–172). The autosomal recessive form is common in Saudi Arabia, with an incidence of 1:2675, most probably due to high rates of consanguinity in that country. Genetic mapping linked the disorder to chromosome 11p14–15.1 (170). This finding excluded the involvement of glucokinase gene in chromosome 7 and/or GLUT 2 gene on chromosome 3. Of particular interest was that both the insulin gene and the Beckwith-Wiedemann's gene are located on chromosome 11. In 1995, the sulfonylurea receptor (SUR) was cloned and mapped to chromosome 11p15 (173). Subsequently some cases of PHHI were attributed to mutations in the SUR gene (174). Absence of K_{ATP} activity in the pancreatic β -cell has been documented in patients PHHI (175, 176). The absence of this function was attributed in some cases to SUR mutations, but in other cases mutations other than that of the SUR (e.g., inward rectifier K^+ channel defect) were identified as well (176–178). Of clinical relevance is that patients with PHHI who have these two later mutations usually do not respond well to diazoxide therapy (179).

An autosomal dominant form of hyperinsulinism in infancy has been reported in several families (172). These patients usually have a milder variant of the disease than those with the autosomal recessive form. They often present after the neonatal period and respond well to diazoxide therapy. Treatment has been successfully discontinued after 2–14 years of therapy in many patients. A mutation of the glucokinase gene was reported in one family with an autosomal dominant variant of hyperinsulinism (180). Increased rate of insulin secretion was attributed to greater affinity of glucokinase for glucose, leading to higher rates of glycolysis.

Although rare in the neonatal period, insulin-secreting adenomas have been reported in cases of PHHI. They are usually resistant to diazoxide therapy. Focal adenomatous hyperplasia (FoPHHI) as well as diffuse β -cell hyperplasia (DiPHHI) have been described (181). Differentiating between these two variants of PHHI has important implications for therapy. Of interest in the cases of FoPHHI is that a paternal uniparental disomy was confirmed (182). In these cases both alleles in the chromosome 11p15 region were found to be from a paternal origin with loss of maternal alleles. A similar defect was not found in cases of DiPHHI. It is also fascinating to know that uniparental paternal disomy was reported in some cases of Beckwith-Wiedemann syndrome (183). However, it is not yet known why the maternal allelic loss leads to the observed defect.

Reports have described the potential for hypoglycemia after beta-sympathomimetic tocolytic therapy, which has been used increasingly to inhibit the premature onset of labor. A possible explanation of the relationship involves increased pancreatic secretion of insulin in response to a specific glucose concentration (184, 185). A prospective double-blind study of 35 patients in preterm labor with and without ruptured membranes was conducted. Leake et al. evaluated the neonatal metabolic and cardiovascular effects of Ritodrine administration to the mother (186). Patients received intravenous and/or oral ritodrine or a placebo. The shortest time from drug administration to delivery was 6 h. No differences were noted in the Ritodrine vs. the control groups relative to glucose and cardiovascular determinations. The investigators concluded that chronic oral administration did not significantly affect the neonate. In an investigation of the causes of the clinical situation, a neonatal lamb model was used to evaluate the drug (187). Administration of Ritodrine produced both increased insulin secretion from the β -cell and glucose production from the liver. It would follow that the presence of clinical hypoglycemia would depend on the time of administration prior to delivery.

XIV. HYPOGLYCEMIA FOLLOWING MATERNAL ETHANOL CONSUMPTION AND MISCELLANEOUS CAUSES

The association of neonatal hypoglycemia and maternal ethanol ingestion has been reported. Singh et al. evaluated glucose metabolism in neonatal rats exposed to maternal ethanol ingestion (188). Blood glucose concentration, liver glycogen, and plasma insulin concentrations were decreased in ethanol-treated mothers, as was litter size and average fetal body weight. The pups from ethanol-fed mothers evidenced hypoglycemia and hypoinsulinemia. Within 1 h after birth an elevation in blood glucose concentration was followed by a decline to hypoglycemic concentrations. Liver glycogen stores were reduced and they were quickly mobilized. The hypoglycemic tendency

in pups of ethanol-treated mothers disappeared after 4 days.

Witek-Janusek examined the effect of maternal ethanol ingestion on the maternal and neonatal glucose balance in a rat model (189). Controls included an isocaloric liquid pair fed diet or ad libitum rat chow. Blood for glucose concentration and liver was sampled on days 21–22 and pups were studied up to 24 h after birth. Ethanol depressed not only maternal liver glycogen stores but also liver glycogen in the neonatal liver. Ethanol had no effect on plasma insulin concentrations. Postnatal hypoglycemia could be observed following maternal ethanol ingestion. Singh et al. evaluated the combined effect of chronic ethanol ingestion in pregnant rats and three offspring (190). Fetal body weight and liver weight was reduced in fetuses of alcohol-fed mothers. Blood glucose concentrations were also lower, as was liver glycogen.

Isolated instances have been reported that mimic insulin excess and resultant hypoglycemia. Zucker et al. have reported symptomatic neonatal hypoglycemia in association with maternal administration of chlorpropamide (191). This resulted in stimulation of both maternal and fetal β -cells. Because teratogenicity of the drug is a concern, its use is limited, especially since it provides poor control of glucose for the management of diabetes in pregnancy. Benzothiazide (thiazide) diuretics have been implicated in producing insulin secretion (192). It has been suggested that these drugs produce elevated maternal blood glucose concentrations and result in stimulation of the fetal islets with subsequent neonatal hypoglycemia. There is a report of a neonate in whom hypoglycemia may have been due to an insulin-releasing substance, possibly from the gut (193).

Hypoglycemia has been noted in individuals who are sensitive to leucine. This amino acid, among others, is known to be associated with increased insulin release and may be seen following ingestion of milk (194). A fourth defect of leucine metabolism, 3-hydroxy-3-methyl glutaryl CoA lyase deficiency, has been reported. Hypoglycemia was noted along with a characteristic excretory pattern of organic acids, but the exact mechanism resulting in the hypoglycemia was not apparent (195).

Neonatal hypoglycemia has followed administration of salicylates, the suggested mechanism being an uncoupling of mitochondrial oxidative phosphorylation (196). The association of congenital adrenal hyperplasia and hypoglycemia has also been recorded (197). Souto et al. studied the effect of equivalent doses of insulin on the adrenal medulla of neonatal and adult rats (198). Glycemia decreased to 33% of the control values in the adult, while an equivalent dose of insulin to the neonate decreased glycemia to about 50%. Morphological evaluation of the adrenal medulla paralleled the metabolic data. The authors speculated that immaturity of the adrenal chromaffin tissue may be present in the neonate and be involved in hypoglycemic catecholamine counterregulation.

Actavia-Loria et al. reported a survey of the fre-

quency of hypoglycemia in 165 children with primary adrenal insufficiency (199). Of these children, 118 had congenital adrenal hyperplasia, 47% had Addison's disease, and 18% had hypoglycemia. One-half of the episodes occurred in the neonatal period. The episodes of hypoglycemia were isolated in 13 children, 4 neonates with congenital adrenal hyperplasia, and in 1 male with 11 β -OH deficiency. A significant mechanistic correlation was noted between plasma glucose concentration and cortisol concentration during the episodes of hypoglycemia.

Hypoglycemia has been noted secondary to indomethacin therapy in premature neonates with patent ductus arteriosus. The proposed mechanism of indomethacin-mediated hypoglycemia (i.e., lack of prostaglandin inhibition of insulin release) was not confirmed since there were no significant changes in plasma insulin concentration (200).

XV. BECKWITH-WIEDEMANN SYNDROME

In 1964 Beckwith and associates described a syndrome characterized by omphalocele, muscular macroglossia, and visceromegaly (201). Wiedemann almost simultaneously described a similar clinical picture in three siblings (202). The cause of the syndrome remains unclear. On pathologic examination, islet cell hyperplasia of the pancreas has been demonstrated in these neonates. It was subsequently shown that hypoglycemia may be an associated metabolic component of this syndrome, occurring in approximately 50% of cases reported, with hyperinsulinism responsible for both the hypoglycemia and the somatic and visceral growth abnormalities. The hypoglycemia is ultimately self-limiting but may be protracted and difficult to control. In a patient with resistant hypoglycemia and hyperinsulinism, Schiff and co-workers (203) were ultimately able to achieve adequate control of glucose levels with a combination of Susphrine and diazoxide therapy, which suppressed the release of basal and postprandial insulin. The neonate presented at birth with an umbilical hernia, macroglossia, and hepatosplenomegaly as well as hyperinsulinism and severe, persistent hypoglycemia. Normal glucose control was achieved by 1 month of age. At 6 months, somatic growth was normal, hepatosplenomegaly had receded, but the macroglossia was still present. At 2 years of age growth was normal, and the tongue, although still large, could be kept within the mouth without any evidence of malocclusion. Genetic mapping linked the disorder to a defect in chromosome 11p15, as noted earlier (183).

XVI. DEFECTIVE GLUCONEOGENESIS/ GLYCOGENOLYSIS

Hypoglycemia has been noted in neonates unable to sustain normal gluconeogenesis. Glucagon is influential in

hepatic glucose production since it enhances glycogenolysis and gluconeogenesis. A recent report has documented a neonate with isolated glucagon deficiency and neonatal hypoglycemia (204). The diagnosis was based on a low basal glucagon concentration as well as a diminished response to hypoglycemia and alanine infusion, both of which are potent stimulators of glucagon secretion, in a neonate in whom normal insulin secretion was present. Vidnes has reported three neonates with persistent neonatal hypoglycemia, one of whom evidenced an abnormal subcellular distribution of PEPCK in the extramitochondrial fraction (205, 206).

A specific enzymatic deficiency that may affect gluconeogenesis in the neonate is type I glycogen storage disease (glucose-6-phosphatase deficiency). The deficiency is an autosomal recessive genetic defect, which may occasionally present in the neonatal period with severe hypoglycemia and hepatomegaly. A second enzymatic defect, fructose-1,6-diphosphatase deficiency, has also been associated with hypoglycemia (207–209).

Galactosemia may present in neonates who are septic and/or have hepatocellular jaundice. Later (1 month) galactosemic infants may present with cataract formation. In some neonates, hypoglycemic symptoms have been reported and a positive reducing test in the urine (to copper or iron) noted. The usual biochemical defect is in galactose-1-phosphate uridyl transferase. The diagnosis involves the demonstration of a low true glucose concentration (glucose oxidase) in the presence of normal total hexoses, together with determination of the enzymatic defect, which can be analyzed in both red and white blood cells. Exclusion of milk and milk products (lactose) is the treatment of choice. Because early intervention is preventive, routine neonatal screening has been recommended, since it is inherited as an autosomal recessive condition (210).

Hereditary fructose intolerance may be diagnosed in neonates who are old enough to ingest fruits or juices. The major intolerance is due to fructose-1-phosphate accumulation secondary to fructose-1-phosphate aldolase deficiency. The hypoglycemia is secondary to an inhibition of hepatic glucose release and absence of a hyperglycemic response to glucagon following ingestion or parenteral administration of fructose.

Inborn errors of amino acid metabolism that may present as hypoglycemia in the neonatal period include maple syrup urine disease, propionic acidemia, methylmalonic acidemia, tyrosinemia, and/or 3-hydroxy-3-methylglutaryl CoA lyase deficiency. Disorders of fatty acid metabolism that may present as hypoglycemia in the neonatal period include medium-chain and long-chain acyl CoA dehydrogenase deficiency.

XVII. EVALUATION

Current perinatal clinical practice has significantly reduced hypoglycemia associated with conditions such as

the use of glucose infusion during labor, erythroblastosis fetalis, double-volume exchange transfusion, cold stress, and delay of starting enteral feed in the larger neonate or glucose infusion in the low-birth-weight neonate. Many of the clinically observed cases of hypoglycemia occur immediately after birth, as discussed earlier.

As noted with other diagnostic dilemmas in neonatology, a detailed maternal history and thorough physical examination are required to determine the probable cause of neonatal hypoglycemia. Maternal history including family history of diabetes or other glucose intolerance, drug ingestion (chlorpropamide, benzothiadiazide diuretics, salicylates, and or ethanol), blood group incompatibility, pre-eclampsia or pregnancy-induced hypertension, and the rate of dextrose administered to the mother during labor should alert the physician to the potential mechanism of the observed hypoglycemia.

A thorough physical examination of the neonate will indicate if the neonate is AGA, SGA, or LGA, as well as the gestational age. The appearance of the infant of the well-controlled diabetic mother of classes A, B, and C can usually be differentiated from that of the infant of classes D, E, F (who may be SGA). The neonate with Beckwith-Wiedemann is usually obvious, with evidence of a protuberant tongue, umbilical hernia, and macrosomia. Prolonged jaundice and cataracts are suggestive of galactosemia, as are reducing substances in the urine, while unexplained hepatomegaly may indicate glycogen storage disease. Abnormalities, which may indicate central defects, include abnormal genitalia indicative of pituitary abnormalities, and cleft lip and palate.

Treating the underlying condition, providing optimal thermal environment, and supporting the cardiocirculatory system, if indicated, are basic concepts in the management of hypoglycemia. Appropriate laboratory evaluation should include evaluation of the following: glucose, insulin, growth hormone, cortisol, and thyroid function. Evaluation of pH, lactate, pyruvate, and ketones is indicated for glycogen storage disease. Studies are usually performed when hypoglycemia is present or at a time following a fast of at least 3–4 h. Tolerance tests are reserved for confirmation of suspected diagnosis, such as a glucagon tolerance test if glycogen storage disease is suspected. A further clinical evaluation of the neonate, infant, and older child has been detailed by Sperling (211).

XVIII. TREATMENT

Treatment of neonatal hypoglycemia begins with identification of its potential in the neonate at risk, documentation of its existence by appropriate laboratory measurement, and determination of appropriate corrective measures.

Oral administration of nutrients generally is advocated, as either 5% dextrose or formula, in the neonate with mild hypoglycemia (glucose concentration 35–45

mg/dl). It should be used only in the neonate who is able quickly to achieve and maintain a glucose concentration in the euglycemic range during oral feedings. It is unreasonable to expect that oral feedings alone will provide for adequate glucose intake in the neonate whose hypoglycemia does not respond quickly to this approach.

In the case of moderate or severe hypoglycemia, we advocate parenteral (intravenous) treatment with a constant-infusion pump to avoid fluctuations in the rate of infusion that would result in irregular rates of endogenous insulin release. Oral feedings should be allowed as tolerated whenever clinically appropriate. Repeated documentation of blood or plasma glucose concentration should be an integral part of the treatment of any neonate. The glucose infusions should be gradually reduced rather than abruptly terminated so that sudden reactive hypoglycemia is avoided. Once oral feedings are initiated, evaluation of the glucose concentration just before a subsequent feeding provides an analysis of the neonate's status.

Parenteral therapy should begin with 6 mg/kg/min followed by graded increases to achieve euglycemia with the minimal concentration of glucose required. A peripheral vein rather than an umbilical vessel is the preferred route of infusion (153). However, other than in an emergency, rates greater than 15 mg/kg/min should be given only when a central venous line is being used. Rates greater than 25 mg/kg/min are probably contraindicated by either route.

There is disagreement about to the beneficial effect of a glucose bolus prior to the administration of continuous glucose infusion. Most authorities appropriately agree that there is no place for a large bolus (i.e., ≥ 500 mg/kg or 5 ml/kg D₁₀W) in the treatment of hypoglycemia in the neonate, because of the high likelihood of pancreatic β -cell stimulation and rebound hypoglycemia (43). Some investigators (Lilien and Hawdon) recommend a so-called minibolus of 2–3 ml/kg D₁₀W (i.e., ≈ 200 –300 mg/kg) given at a rate of 1 ml/kg/min and followed by continuous glucose infusion at a rate of 5–8 mg/kg/min (Fig. 10) (212, 213). The currently popular approach involves infusion of 2 ml/kg 10% dextrose in H₂O (200 mg/kg) given over 1 min, followed by a continuous dextrose infusion of 8 mg/kg/min (213). However, the concept of the minibolus was challenged based on the potential for hyperosmolar cerebral edema at that extremely rapid administration rate, as reported in older children (214). Others also argued that at this high-administration-rate glucose entry far exceeds glucose uptake; the potential for provoking excessive insulin secretion and inhibition of glucagon secretion may, in fact, aggravate the existing hypoglycemia (215).

Based on this discussion, we recommend the use of a minibolus (200 mg/kg, or 2 ml/kg D₁₀W, over 5–10 min) only in cases of severe hypoglycemia (i.e., glucose concentration ≤ 24 mg/dl), followed by continuous glucose infusion at a rate of 6–8 mg/kg/min. For milder or

Figure 10 Plasma glucose concentrations in neonates treated with 200 mg/kg minibolus followed by 5–8 mg/kg/min constant glucose infusion compared with plasma glucose concentrations of neonates treated with constant infusion alone. (From Ref. 213.)

improving (i.e., partial correction after an initial bolus) hypoglycemia (i.e., glucose concentration of 25–45 mg/dl), a continuous glucose infusion alone at a rate of 5–8 mg/kg/min is an appropriate approach. In all cases blood glucose concentration should be closely monitored every 30–60 min and glucose infusion rate should be gradually adjusted until hypoglycemia resolves. A number of specific agents (e.g., hydrocortisone and glucagon) are usually recommended when continuous glucose infusion at a rate >15 mg/kg/min is not effective in maintaining euglycemia (43).

Calculation of parenteral glucose therapy must include the actual concentration of glucose present in the administered fluids. A hydrated form of dextrose ($C_6H_{12}O_6 \cdot H_2O$) (molecular weight of 198) is used by most manufacturers to prepare the parenteral fluid so that the actual amount of glucose available is approximately 10% less (216). This is of particular concern when very-low-birth-weight or severely hypoglycemic neonates are being treated.

There are increasing reports of the use of lipid infusion to assist in prevention of hypoglycemia. Sann et al. evaluated the effect of oral lipid supplementation on the prevention of neonatal hypoglycemia in 28 low-birth-weight neonates whose mean gestational age was 36 ± 1 weeks and whose birth weight was 1778 ± 230 g compared to a control group of 23 neonates with comparable demographic data (217). Hypoglycemia ≤ 31 mg/dl occurred in 8 of 23 neonates in the control group compared

with 2 of 28 in the supplemented group receiving 2.9 g/day of a solution containing 67% medium chain triglycerides. Prospectively this study showed that lipid supplementation can prevent the occurrence of hypoglycemia in the low-birth-weight neonate.

Treatment with a number of specific agents is indicated when parenteral therapy above 15 mg/kg/min is not effective in maintaining euglycemia. Corticosteroids have been shown to be effective in the therapy of hypoglycemia. Although steroids enhance several glucose-producing reactions, the major effect is probably that of gluconeogenesis from noncarbohydrate (protein) sources and decreased peripheral glucose utilization. Hydrocortisone is given at a dosage of 5 mg/kg/day either intravenously or orally every 12 h, or prednisone is used at a dosage of 2 mg/kg/day orally. As with all forms of therapy, gradual diminution of the dosage administered, in concert with decreasing parenteral concentrations of glucose and increasing oral intake of nutrients, should successfully allow for weaning.

The use of glucagon provides a highly effective method of releasing glycogen from the liver and can be a therapeutic means of assessing whether or not the liver contains adequate stores. Its failure in some growth-retarded neonates is considered to be evidence for a lack of hepatic glycogen stores. In the infant of the diabetic mother, there is often a failure to respond to the usual dosages (30 mg/kg), despite the presence of more than

adequate hepatic glycogen stores. These neonates will frequently respond to higher dosages (300 mg/kg) with a prolonged and sustained hyperglycemia, so that the higher dosage might well be used as initial therapy. Since glucagon may stimulate insulin release, its administration in all probability should be accompanied by an intravenous glucose infusion.

Like glucagon, epinephrine is capable of promoting glycogen to glucose conversion, but in far smaller quantities. For this effect glucagon is the drug of choice. The hyperglycemic potential of epinephrine in blocking glucose uptake by peripheral muscle presupposes an adequate blood level initially and is of little practical benefit in the hypoglycemia state. Epinephrine is a powerful anti-insulin hormone, a fact that explains its success as an effective antihypoglycemic agent in the infant of the diabetic mother as well as in other hyperinsulinemic neonates. The agent most commonly used is a 1:200 epinephrine in aqueous suspension (Sus-Phrine), which can be readily administered subcutaneously (203, 218).

In cases of transient or persistent hyperinsulinism diazoxide, octreotide, calcium channel blockers, and/or partial pancreatectomy have been used as therapeutic modalities (Table 6). It is important to summarize the metabolic signals that lead to insulin gene transcription and then insulin secretion by the pancreatic β -cell, so that the mechanism of action of these therapeutic agents may be understood. Glucose enters the β -cell via the GLUT 2 isoform of glucose transporters. Glycolysis begins with glucokinase, which metabolizes glucose to glucose-6-phosphate. Further glycolysis including interactions in the

tricarboxylic acid (TCA) cycle results in ATP production. Amino acids (AA) and FFA also contribute to ATP production through metabolism in the TCA cycle. Different intermediate signals from glycolysis lead to insulin gene transcription. Increase of the intracellular ATP/ADP ratio activates the SUR. The K_{ATP} channel then closes, the cell membrane depolarizes, and Ca^{2+} influx through the voltage-gated calcium channel (VGCC) triggers insulin secretion. Figure 11 depicts the metabolic signals involved in insulin production and the sites of action for various drugs used in the treatment of PHHI.

Diazoxide, in a dosage of 10–15 mg/kg/day divided every 8 h is the first drug of choice in the hyperinsulinemic neonate who cannot be weaned from intravenous glucose. Diazoxide causes hyperglycemia by stabilizing the β -cell K_{ATP} channel in the open state, thereby inhibiting membrane depolarization and insulin secretion. An intact SUR and inward rectifier K^+ channel are necessary for full action of the drug. Insulin synthesis is uncompromised by this therapy. A secondary hyperglycemic mechanism is via stimulation of catecholamine; this may reduce insulin secretion and counter its actions peripherally as well. A response to diazoxide is usually evident within the first 48 h of therapy. Diazoxide has several important side effects that should be carefully monitored; in some cases the severity of these side effects may necessitate termination of diazoxide therapy. Fluid retention, hypertrichosis, and coarse facial changes have been reported. Diazoxide therapy can result in hyperglycemia and even diabetic ketoacidosis if the infant is unable to secrete insulin appropriately during time of stress. Uricemia, leu-

Table 6 Therapeutic Modalities for the Treatment of Infants and Children with PHHI

Therapy	Mechanism of action	Dosage	Efficacy and side effect
Diazoxide	Opens K_{ATP} channels	5–20 mg/kg/day orally every 8 h	<i>Effective in 22–50% of cases</i> Hypotension, fluid retention, hyperuricemia, hypertrichosis, coarse facial features, leukopenia, thrombocytopenia
Octreotide	Activates a G-protein-coupled inward rectifier K^+ channel	5–40 mg/kg/day subcutaneously every 4–6 h	<i>Effective in 25–80% of cases</i> Abdominal distention, steatorrhea, cholelithiasis, possible suppression of other hormones: growth hormone, thyroid-stimulating hormone, adrenocorticotrophic hormone
Calcium channel blockers	Inhibits Ca^{2+} influx via voltage-gated calcium channels	Nifedipine 0.25–0.7 mg/kg/day orally every 8 h	<i>Case reports suggest efficacy</i> Potential hypotension, lack of long-term experience
Surgery	Reduction of β -cell mass	Surgical removal of 95% of the pancreas	<i>Indicated in cases of failure of medical therapy, effective in 75–95% of cases</i> <i>Immediate:</i> injury to the common bile duct and other surgical complications <i>Long term:</i> failure to achieve euglycemia; diabetes mellitus and exocrine pancreatic insufficiency

Figure 11 Metabolic signals involved in insulin gene transcription and insulin secretion in the β -cell. Dashed lines represent pathways with intermediate steps, glucose transporter isoform 2 (GLUT2), tricarboxylic acid (TCA) cycle. The right side of the cell membrane represents the sites of action for various drugs used in the treatment of PHHI. Diazoxide binds to the sulfonylurea receptor (SUR) and opens the inward rectifier K^+ channel (KIR). Somatostatin analogs bind to the somatostatin receptor (R) and activate a G-protein-coupled inward rectifier K^+ channel (GIRK) with its α , β , and γ subunits. These two drugs serve to hyperpolarize the β -cell membrane, which inhibits Ca^{2+} influx and therefore insulin secretion. Ca^{2+} channel blockers inhibit Ca^{2+} influx through voltage-gated calcium channel (VGCC).

kopenia, and thrombocytopenia are rare side effects of this therapy.

Diazoxide is effective in only 22–50% of the patients with PHHI and it is less likely to work in patients presenting in the immediate neonatal period (219–223).

Somatostatin has a very short half-life (1–3 min) prohibits its clinical use. Somatostatin acts via a G-protein-coupled inward rectifier K^+ channel. The activation of this channel results in hyperpolarization of the β -cell, which inhibits Ca^{2+} influx, thereby inhibiting insulin release (see Fig. 4). The synthetic analog octreotide, however, has a half-life of 1.5 h, and it has been successfully used at intervals of up to 6–8 h in cases of hyperinsulinemia. A starting dosage of 5–10 $\mu\text{g}/\text{kg}/\text{day}$ produces favorable initial responses, but because of the development of tolerance, the dosage sometimes has to be increased to as

much as 40 $\mu\text{g}/\text{kg}/\text{day}$. Although Thornton et al. advocate octreotide use as an adjunct therapy during the pre and postoperative period of partial pancreatectomy, Glaser et al. demonstrated that aggressive octreotide therapy alone was successful in almost 50% of the cases of PHHI that were resistant to other medical therapy (219, 224). The side effects reported during the course of therapy include vomiting, steatorrhea, and abdominal distention; these were self-limiting within the initial few weeks of therapy (165, 225). Asymptomatic cholelithiasis was reported and concerns relative to the effect of octreotide on other hormonal axis require more careful evaluation.

Because Ca^{2+} influx is required for insulin secretion, calcium channel blockers have been used in the treatment of selective cases of hyperinsulinism. Although there are few encouraging case reports in the literature in which

nifedipine was successfully used as adjunct therapy for PHHI, further experience is needed to assess the efficacy of this approach (226).

Surgical intervention is indicated when euglycemia cannot be maintained by medical therapy alone. A 95% pancreatectomy is the surgical procedure of choice. Medical therapy may need to be continued postoperatively, if hypoglycemia persists. If hypoglycemia persists despite added medical therapy, as is the case in 5–25% of the patients, a second surgery would be indicated to remove 99% of the pancreas. Risks associated with surgery other than failure to achieve euglycemia include: injury to the common bile duct, exocrine pancreatic insufficiency, and diabetes mellitus. The later may be transient or persist (219, 227–231).

This review has evaluated the current knowledge of the kinetics of glucose homeostasis in the neonate. Glucose production, glucose utilization, and glucose oxidation have been reviewed in detail. The relationship of the developmental regulation of glucose homeostasis and some of the fundamental differences known to exist in the neonate compared to the adult. The pathophysiological basis and the clinical aspects of neonatal hypoglycemia were discussed. Conditions associated with neonatal hyperinsulinemia, including the infant of the diabetic mother, were also comprehensively reviewed.

Hypoglycemia in Children

Joseph I. Wolfsdorf and David A. Weinstein

Children's Hospital and Harvard Medical School, Boston, Massachusetts, U.S.A.

I. INTRODUCTION

Glucose is normally the predominant fuel for mammalian cells. Because the brain cannot synthesize glucose or store more than a few minutes' supply as glycogen, survival of the brain depends on a continuous supply of glucose (1). Recurrent hypoglycemia during the period of rapid brain growth and differentiation in infancy can result in long-term neurological sequelae, psychomotor retardation, and seizures. Prevention of hypoglycemia and expeditious diagnosis and vigorous treatment are, therefore, essential to prevent the potentially devastating cerebral consequences of hypoglycemia.

Hypoglycemia is most common in the newborn period. During infancy and childhood, it occurs most frequently when nighttime feeding is discontinued and when intercurrent illness interrupts the child's normal feeding pattern, causing periods of relative starvation. Basal energy needs during infancy are high. A full-term newborn baby has a ratio of surface area to body mass more than twice that of an average adult, necessitating a high rate of energy expenditure to maintain body temperature. Also, the infant brain is large relative to body mass and its energy requirement is primarily derived from the oxidation of circulating glucose. To meet the high demand for glucose, the rate of glucose production in infants and young children is two to three times that of older children and mature adults (2). Although the demand for glucose is high, the activity of several liver enzymes involved in energy production is low in the newborn compared to older children and adults. As a consequence, until feeding is well established, maintenance of glucose homeostasis in the newborn period is more precarious than later in childhood.

In the postabsorptive state, the rate of glucose turnover in adults is approximately 2 mg/kg/min (8–10 g/h); whereas the average basal (4–6 h after feeding) rate of glucose turnover is 6 mg/kg/min in newborns, approximately three times the adult rate (2). During prolonged fasting, infants and children cannot sustain the high rate of glucose production. Normal children, 18 months to 9 years of age, fasted for 24 h have a mean whole blood glucose concentration of 52 ± 14 (SD) mg/dl, and 22% have blood glucose concentrations less than 40 mg/dl; blood glucose values conform to a Gaussian pattern of distribution (3). For these reasons, infants and young children are more prone than adolescents and adults to hypoglycemia when normal feeding patterns are disturbed by intercurrent illness.

II. DEFINITION OF HYPOGLYCEMIA

During acute insulin-induced hypoglycemia in normal adults, symptoms appear at an arterialized venous plasma glucose level of approximately 60 mg/dl (3.3 mmol/l) and impairment of brain function occurs at approximately 50 mg/dl (2.8 mmol/l) (4, 5). Comparable levels in venous blood are about 3 mg/dl lower (6). In children, functional changes in the central nervous system (brainstem auditory and somatosensory evoked potentials) occur when the venous plasma glucose concentration falls below 47 mg/dl (2.6 mmol/l) (7). These facts suggest that the physiological threshold is a plasma glucose concentration in the range of 50–60 mg/dl (2.8–3.3 mmol/l). Therefore, for clinical care of children, a venous plasma glucose concentration of 60 mg/dl (3.3 mmol/l) or greater may be regarded as normoglycemia and plasma glucose levels below 50 mg/dl (2.8 mmol/l) as hypoglycemia.

III. OVERVIEW OF FUEL METABOLISM

The physiological mechanisms that normally prevent hypoglycemia ensure that the brain receives a continuous supply of glucose (8). Several tissue-specific glucose transport (GLUT) proteins are responsible for transport of glucose from the extracellular to the intracellular space (Table 1). GLUT-1 and GLUT-3 transporters are found on most cells and are primarily responsible for basal glucose use by the brain and most other body tissues (9). Both GLUT-1 (on glial cells) and GLUT-3 (on neuronal cells) (10) are insulin-independent facilitative glucose transporters. Blood-to-brain glucose transport is a function of the arterial plasma glucose concentration. The supply of glucose to the brain, therefore, is dependent on the precise regulation of systemic glucose balance that maintains the arterial plasma glucose concentration above the critical level that becomes limiting to brain glucose metabolism. None of the glucoregulatory factors, including insulin, modify glucose uptake into the brain. However, chronic exposure to cerebral hypoglycemia results in upregulation of both these transporters (11–13).

Most body tissues, with the exception of the brain, can use free fatty acids (FFA) for oxidative metabolism. Under conditions of fasting, the plasma FFA concentration increases and the uptake and oxidation of glucose decreases. The high rate of tissue oxidation of FFA functionally decreases the use of glucose in accordance with Randle's hypothesis (the glucose–fatty acid cycle) (14). Although FFA are not transported across the blood–brain barrier, β -hydroxybutyrate (BOHB) and acetoacetate (AcAc), the water-soluble products of hepatic β -oxidation of FFA, readily cross the blood–brain barrier (15, 16). In vitro studies in rats have demonstrated that the use of ketones can decrease brain glucose utilization by ~50%. Indirect evidence in humans is consistent with these data (17, 18).

In the interval between meals and during fasting, maintenance of normal plasma glucose concentrations requires adequate endogenous substrate (body fat, hepatic and muscle glycogen, and mobilizable amino acids); intact metabolic and enzymatic pathways; proper hormonal regulation of the mobilization, interconversion, and use of metabolic fuels. An abnormality in any one of these areas may compromise the homeostatic mechanisms that balance the rate of appearance and the rate of disposal of glucose that maintains the plasma glucose concentration in a narrow normal range (19). Glucose is derived from intestinal absorption following digestion of dietary carbohydrate (exogenous glucose delivery) or from endogenous glucose production (glycogenolysis and gluconeogenesis). Gluconeogenesis refers to the formation of glucose from three carbon precursors, including lactate, pyruvate, amino acids (especially alanine and glutamine), and glycerol. The integrated regulatory effects of hormones, neural pathways, and metabolic substrates normally result in the precise matching of glucose utilization

and the sum of exogenous glucose delivery and endogenous glucose production. The key glucoregulatory hormones are insulin, glucagon, and epinephrine. Growth hormone (GH) and cortisol modify the effectiveness of these glucoregulatory hormones.

After feeding, exogenous glucose delivery increases at a rate largely determined by the carbohydrate content of the ingested meal and the rate of gastric emptying. Glucose absorption from the intestine into the portal circulation occurs via a sodium-dependent transport mechanism. The increase in circulating glucose concentration, augmented by incretins (gastric inhibitory polypeptide [GIP] and glucagon-like peptide-1 [GLP-1] secreted by the intestine), stimulates insulin and inhibits glucagon secretion. Increased plasma levels of insulin result in translocation of GLUT-4 transporters from their intracellular location to the cell membrane, thereby enhancing glucose entry into fat and muscle cells (Table 1). More than 80% of ingested glucose enters the systemic circulation; the entire splanchnic bed extracts only 10–20% (20). Over a wide range of carbohydrate consumption in normal individuals, the plasma glucose concentration increases from ~70 mg/dl to \leq 150 mg/dl. Endogenous glucose production is suppressed by high postprandial plasma insulin concentrations, which decrease hepatic glycogenolysis and increase glycogen synthesis. Glucose transported into the liver by GLUT-2 transporters replenishes the hepatic glycogen store. Liver and muscle express high levels of glycogen synthase activity and can store appreciable quantities of glucose as glycogen. In the liver, glucose is also converted to fat, which can be stored in the liver or be transported to other tissues in the form of very-low-density lipoproteins. The increase in plasma insulin concentration also decreases rates of proteolysis and lipolysis, thus decreasing the availability of substrates for gluconeogenesis and ketogenesis, respectively.

Increased metabolism of dietary carbohydrate leads to increased cytosolic citrate, which inhibits activity of carnitine palmitoyltransferase-I (CPT-I) and diverts fatty acids away from oxidation in peripheral tissues and away from β -oxidation and ketogenesis in the liver. With decreased hepatic FFA oxidation, activity of pyruvate carboxylase decreases and 3-carbon substrates are directed away from gluconeogenesis and toward formation of acetyl CoA. A reduction in β -oxidation also results in decreased production of reduced nucleotides, which are necessary for gluconeogenesis. With decreased circulating plasma concentrations of FFA and ketone bodies and increased concentrations of glucose and insulin, GLUT-1, GLUT-3, and GLUT-4 transporters efficiently move glucose out of the circulation and into cells.

Despite a substantial increase in glucose influx into the circulation, the increase in plasma glucose concentration is relatively small after a meal, and plasma glucose and insulin concentrations return to basal levels within 2–3 h. As nutrient absorption is completed, flow of glucose

Table 1 Tissue-Specific Glucose Transporters

Glucose transporter	Distribution	Principal function	K _m for glucose (mmol/L)	Gene location	Regulation
GLUT-1	Wide distribution Brain glial cells Erythrocytes Endothelial cells	Constitutive glucose transporter	20	1p35 → 31.3	Minimal
GLUT-2	Liver Pancreatic β cells Small intestine epithelium Kidney	Glucose-sensing in β cells	42	3q26	Zero to minimal
GLUT-3	Wide distribution CNS neurons Fetal muscle Placenta Kidney	High-affinity glucose transporter	10	12p13	None
GLUT-4	Skeletal muscle Cardiac muscle Adipose cells	Insulin-responsive glucose transporter	2–10	17p13	Regulated by insulin
GLUT-5	Liver Small intestine Sperm Adipose cells Brain Muscle	Fructose transporter; very low affinity for glucose	Not defined	1p31	None

from the gut decreases and eventually stops. Plasma glucose concentration frequently decreases to below the pre-meal value. The relative hypoglycemia, together with the decrease in insulin secretion, triggers release of glucagon, which increases hepatic glucose production (21). The transition from endogenous glucose production to exogenous glucose delivery shortly after a meal and the later transition from exogenous glucose delivery back to endogenous glucose production are finely regulated (21). Hypoglycemia normally does not occur in the interval between meals and glucose delivery to the brain continues unabated (Fig. 1A).

Most of the glucose in the body is normally in the extracellular space; the intracellular glucose concentration is low because glucose is rapidly phosphorylated when it enters cells. The extracellular space is ~25% of body weight in children and adolescents. The total glucose present in a person with a plasma glucose concentration of 90 mg/dl is 1.25 mmol/kg body weight or 225 mg/kg. This is equivalent to ~5% of a teaspoon of glucose/kg body weight. Thus, the total pool size of a 10 year old child (30 kg) is approximately 6.75 g glucose (19).

The amount of glycogen stored in the liver is modest: approximately 5% of the wet weight of the liver. For example, the liver of a 10-year-old child who weighs 30 kg contains about 45 g glycogen. This could, theoretically, satisfy the basal requirement for glucose (~9 g/h) for only

5–6 h. Thus, gluconeogenesis soon plays the major part in maintaining normal blood glucose concentrations (Fig. 1B). In children, the precise fraction of glucose derived from glycogenolysis rather than gluconeogenesis at any point in time during feeding and fasting is unknown.

Muscle can store glucose as glycogen, but lacks the enzyme glucose-6-phosphatase, and, therefore, cannot release free glucose. Red cells lack mitochondria; consequently, glycolysis stops with the formation of lactate. In other cells, glucose can be completely oxidized to carbon dioxide and water. During a fast, muscle can oxidize fatty acids to meet its energy needs and substantially reduce its glucose uptake. Proteolysis in muscle provides the liver with amino acids for gluconeogenesis. Whether or not complete oxidation of glucose occurs depends upon the activity of the enzyme pyruvate dehydrogenase, which is inactivated by products of fatty acid oxidation. The availability of other fuels for oxidation (fatty acids or ketones) affects the activity of pyruvate dehydrogenase and determines whether glucose is completely oxidized to carbon dioxide and water, or is conserved via recycling of lactate, pyruvate, and alanine back to glucose in the liver (glucose–lactate–glucose and glucose–alanine–glucose cycles).

In muscle, glucose is metabolized via glycolysis to pyruvate, which can be reduced to lactate, transaminated to form alanine, or undergo oxidation. Lactate and pyru-

Figure 1 A. Between meals: glucose is from hepatic glycogenolysis; free fatty acids from adipose tissue are an additional source of fuel for muscle. B. Overnight fast: liver glycogen becomes depleted and gluconeogenesis becomes the principal source of glucose. Hepatic ketone production increases and rising plasma ketone body concentrations provide an alternative fuel for brain and muscle. C. Prolonged starvation: Fat-derived fuels are the predominant metabolic substrates. Brain utilization of ketones increases. Glucose is from gluconeogenesis.

vate released from muscle are transported to the liver and serve as gluconeogenic precursors (the Cori or glucose–lactate–glucose cycle). Alanine, glutamine, and other amino acids also flow from muscle to the liver and serve as gluconeogenic precursors. Circulating alanine carbon is largely derived from glucose (glucose–alanine–glucose cycle) (22). Glutamine, the other major amino acid precursor for new glucose formation, is also partially derived from glucose (glucose–glutamine cycle) (23).

Liver and kidney express the critical gluconeogenic enzymes: pyruvate carboxylase, phosphoenolpyruvate carboxykinase (PEPCK), fructose-1,6-bisphosphatase, and glucose-6-phosphatase. Although many tissues have the ability to convert oxaloacetate to glucose-6-phosphate and glycogen, the liver and kidney (owing to the presence of the glucose-6-phosphatase system) are the major organs that produce free glucose that can be released into the circulation. In adults, 40–50% of glucose is derived from gluconeogenesis in the postabsorptive state (after an overnight fast), and this increases to ~90% during a 48–72 h fast (24–26). Thus, in the postabsorptive state, hepatic gluconeogenesis soon plays the major role in maintaining normal blood glucose concentrations. In children and adolescents, the fraction of glucose production from gluconeogenesis is ~50–60% (27) (Fig. 1B).

Over time, the hepatic glycogen store is depleted and all glucose production must be from hepatic and renal gluconeogenesis. Hepatic oxidation of fatty acids produces the energy, reducing equivalents, and metabolic intermediates required to sustain the high rate of hepatic gluconeogenesis that occurs during fasting. FFA are released from adipose tissue stores (lipolysis) and normally are abundant during fasting (28, 29). FFA also provide many tissues (including cardiac and skeletal muscle) with a readily usable energy substrate. A fraction of the FFA undergoes β -oxidation in the liver to form ketone bodies (Fig. 1B,C). High rates of ketone body production are reached during fasting in children. After fasting for 20–22 h, the ketone body turnover rate in young children is comparable to that achieved by adults fasted for several days (30). During fasting, plasma concentrations of ketone bodies increase dramatically as a reflection of increased plasma concentrations of FFA and increased rates of β -oxidation in the liver (28, 31). Within 30 h of fasting, normal children achieve plasma total ketone body concentrations of 5–6 mmol/l, levels that are seen in adult women after fasting for 2.5–3 days and are not achieved in men even after 84 h of fasting (31). Fasting ketonemia provides the brain (which cannot utilize FFA) and other tissues with an alternative source of energy (15, 16, 32). Because the brain can oxidize ketones, it is not solely dependent on glucose as an energy substrate. Normally, the large amounts of ketones generated during fasting results in a decrease in the brain's rate of glucose consumption.

Prolonged fasting ultimately leads to a decrease to about one-half in the basal glucose turnover, resulting in

a gradual decrease in the plasma glucose concentration (33). These metabolic responses to fasting (increased gluconeogenesis, lipolysis, and ketogenesis) are finely regulated by changes in the circulating concentrations of hormones including a decrease in insulin secretion and increased plasma concentrations of glucagon, epinephrine, GH, and cortisol, the latter collectively referred to as the counterregulatory hormones.

In summary, the adaptation to fasting involves a major change in the body's fuel economy. As fasting is prolonged, there is decreased dependence on glucose and increased reliance on the products of fat as the primary source of fuel for energy metabolism (Fig. 1C). A failure to oxidize fatty acids or to synthesize or utilize ketones results in greater utilization of glucose, impaired gluconeogenesis, and inability to conserve glucose, which leads to severe hypoglycemia. Examples of these disorders are discussed in detail later in this chapter.

IV. REGULATION OF INSULIN SECRETION

Insulin secretion is regulated by nutritional, hormonal, metabolic, and autonomic nervous system signals. These signals are transduced by a complex system that involves intracellular glucose metabolism, depolarization of the cell membrane, regulation of free intracellular cytosolic calcium concentration, and the movement of insulin-containing secretory granules to fuse with the plasma membrane to release their contents (Fig. 2) (34). ATP-sensitive potassium channels (K_{ATP} channels) in the plasma membrane, which control the polarity of the β -cell membrane, have a pivotal role in regulating insulin secretion. They are formed from two distinct subunit proteins: the high-affinity sulfonylurea receptor (SUR1) and Kir6.2, a weak inward-rectifier (35). The pore of the channel is formed by Kir6.2 in a tetrameric arrangement. At rest, K_{ATP} channels are normally kept open maintaining a membrane potential of about -70 mV. A rise in the blood glucose concentration increases glucose entry into the cell (via GLUT-2 transport) and the rate of glucose metabolism increases in the β -cell. Intracellular glucose is phosphorylated by glucokinase, the rate-limiting step in glucose metabolism (Fig. 2), and is then metabolized resulting in an increased ratio of ATP/ADP, which leads to closure of K_{ATP} channels, depolarization of the β -cell membrane, and opening of voltage-dependent L-type calcium channels with influx of extracellular calcium. The increase in cytosolic free calcium concentration triggers exocytosis of insulin-containing secretory granules (36).

SUR1 encodes for a 39 exon gene with 17 transmembrane domains and produces a 1581 amino acid product; Kir6.2 encodes for a 390 amino acid protein. These genes are located on adjacent regions of chromosome 11p15.1. The SUR protein forms an octameric complex with four SUR1 subunits surrounding four Kir6.2 centrally located channels. ATP acts directly on Kir6.2 resulting in closure

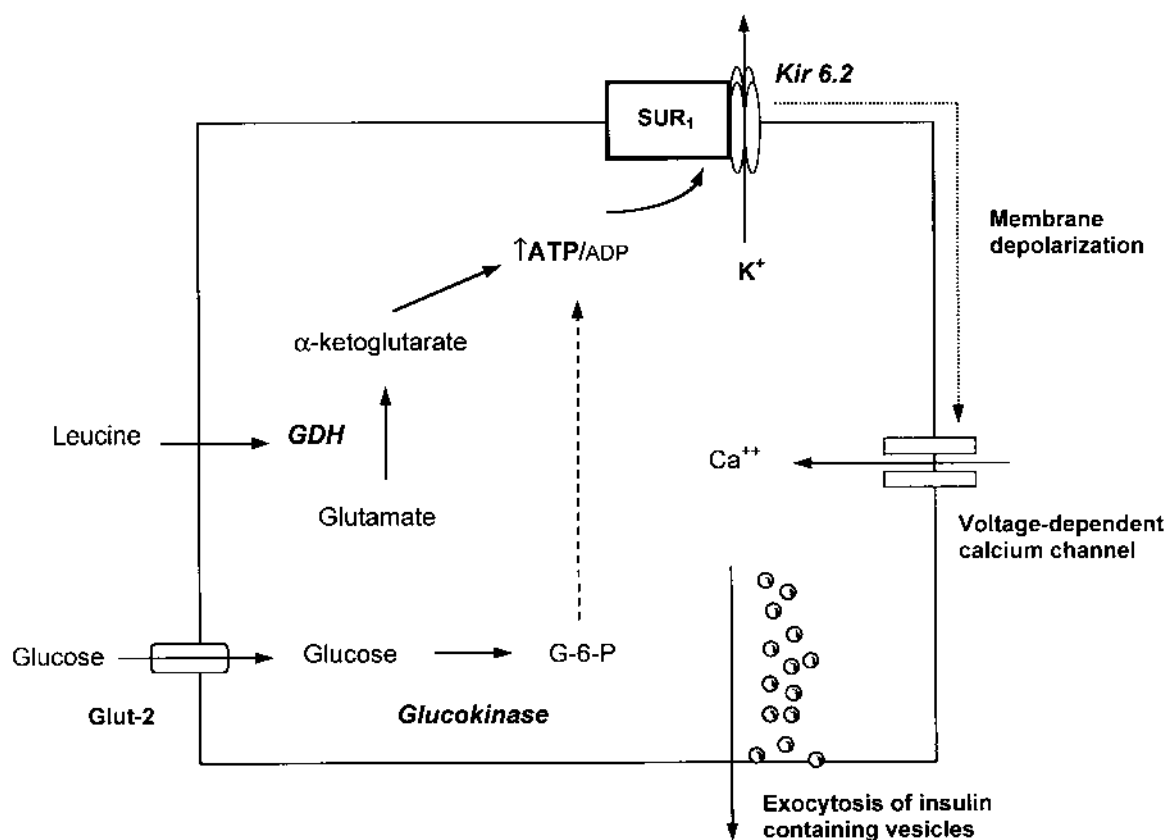

Figure 2 Model of insulin secretion regulation by pancreatic β -cell. Glucose is transported into the β -cell by GLUT-2 and then phosphorylated by glucokinase to glucose-6-phosphate (G-6-P). Glucose metabolism is initiated resulting in an increase in the cytosolic ratio of ATP/ADP, which causes closure of K_{ATP} channels and leads to membrane depolarization and opening of voltage-dependent Ca^{2+} channels. Influx of calcium releases insulin through exocytosis of secretory granules. Leucine stimulates insulin release by allosterically activating glutamate dehydrogenase (GDH), increasing glutamate oxidation, which increases the ATP/ADP ratio and closes K_{ATP} channels.

of the channel, whereas ADP antagonizes the effect via the SUR receptor. Both SUR1 and Kir6.2 are required for the potassium channel to be membrane-bound and functional. Mutations that alter the function of K_{ATP} channels lead to continued membrane depolarization and dysregulation of the voltage-dependent calcium channel, resulting in uncoupling of insulin secretion from glucose metabolism. To date, more than 50 SUR1 mutations have been described; three mutations have been reported in the Kir6.2 component (36, 37).

A constitutive increase in glucokinase activity causes an autosomal dominant form of hyperinsulinism (38). Decreased glucokinase activity causes an unusual form of maturity onset diabetes in youth (MODY-2) characterized by decreased insulin secretion at normal plasma glucose concentrations (39). Other pathways influence the β -cell ATP/ADP ratio and stimulate insulin secretion. For example, leucine stimulates activity of glutamate dehydro-

genase, which converts glutamate to α -ketoglutarate, an intermediary in the Krebs cycle, and results in production of ATP. Glutamate dehydrogenase is constitutively active in patients with the syndrome of hyperinsulinemia and hyperammonemia (40).

V. CLINICAL MANIFESTATIONS OF HYPOGLYCEMIA

The symptoms of hypoglycemia are not specific. Therefore, when a patient's symptoms are suspected to be caused by hypoglycemia, it is essential to measure the blood glucose concentration, confirm that it is low, and demonstrate that administration of glucose promptly relieves the symptoms.

The symptoms of hypoglycemia (Table 2) can be classified into two major categories based on the mecha-

Table 2 Signs and Symptoms of Hypoglycemia

Autonomic	Neuroglycopenic
Sweating	Warmth
Hunger	Fatigue
Paresthesias (tingling, numbness)	Weakness
Tremors	Dizziness
Pallor	Headache
Anxiety	Inability to concentrate
Nausea	Drowsiness
Palpitations	Blurred vision
	Difficulty speaking
	Confusion
	Bizarre behavior
	Loss of coordination
	Difficulty walking
	Coma
	Seizures

nism responsible for their generation: autonomic symptoms result from activation of the autonomic nervous system (both sympathetic and parasympathetic divisions); neuroglycopenic symptoms result from the effects of brain glucose deprivation. The symptoms of hypoglycemia in children are similar to those in adults. In newborn babies and infants hypoglycemia typically manifests as irritability, tremors, feeding difficulty, lethargy, hypotonia, tachypnea, cyanosis, or apnea. Hypoglycemia in this age group is discussed in Chapter 23.

VI. CAUSES OF HYPOGLYCEMIA IN INFANTS AND CHILDREN

The most common cause of hypoglycemia in children is insulin-induced hypoglycemia in individuals with type 1 diabetes mellitus. This is discussed later in this chapter. Almost all cases of hypoglycemia can be classified into one of the five major categories listed in Table 3.

A. Accelerated Starvation (Ketotic Hypoglycemia; Transient Intolerance of Fasting)

So-called ketotic hypoglycemia is the most common non-iatrogenic cause of hypoglycemia in children beyond infancy. Hypoglycemia typically first occurs between 18 months and 5 years of age and remits spontaneously by 8 or 9 years of age. Many children with accelerated starvation are small and thin for their age and have decreased muscle mass. Many were born small for gestational age and may have had transient neonatal hypoglycemia. Hypoglycemia typically occurs during periods of intercurrent illness when food intake is limited by anorexia or vomiting, and occurs in the morning before breakfast. Mani-

festations include neurological symptoms ranging from lethargy to seizures and coma. Sometimes, hypoglycemia occurs in the morning after unusually intense physical exertion on the previous day or after the child has eaten poorly or completely omitted an evening meal.

The precise pathophysiological cause of accelerated starvation is unclear. Serum alanine levels are low at the time of hypoglycemia. Hypoglycemia has been attributed to decreased glucose production because of deficient availability of gluconeogenic substrate, especially alanine from muscle (41). The gluconeogenic pathway is intact, and the serum glucose concentration increases appropriately when alanine is infused at the time of hypoglycemia. However, the cause of the hypoalaninemia is the subject of controversy. It may be the result of a specific defect in protein catabolism or reflect decreased muscle mass. An alternative explanation is that hypoalaninemia is a consequence of decreased muscle glucose uptake in response to decreasing plasma glucose concentrations and increasing levels of FFA and ketone bodies, which would affect flux through the glucose–alanine–glucose cycle (22). The plasma epinephrine response to hypoglycemia is reduced in about half the patients with ketotic hypoglycemia (42). It has been suggested that these children may have a deficient catecholamine response to hypoglycemia that results in increased glucose utilization. This conclusion is suspect in light of new knowledge that recent antecedent hypoglycemia elevates the threshold for autonomic, including epinephrine, and symptomatic responses to subsequent hypoglycemia in healthy individuals (43–45).

After 8–16 h, children with accelerated starvation show the same metabolic pattern as normal healthy children fasted for 24–36 h. In many instances, the differentiation between accelerated starvation and the normal response to fasting is indistinct. Because approximately one-fourth of normal children develop hypoglycemia after a fast of 24–36 h duration (3), accelerated starvation may not be a distinct pathological disorder. Rather, it may represent one end of the spectrum of the normal child's response to starvation (46, 47).

B. Diagnosis

Because ketosis (and ketonuria) is a normal response to fasting and a falling plasma glucose concentration, ketotic hypoglycemia should not be regarded as a specific diagnosis (see section on overview of fuel metabolism). The differential diagnosis of the hypoglycemic child with an appropriately suppressed serum insulin concentration and ketosis is shown in Table 4. Accelerated starvation is a diagnosis of exclusion that should only be made when the other causes of so-called ketotic hypoglycemia have been ruled out.

Children with accelerated starvation typically become hypoglycemic in 12–24 h and have a normal metabolic and hormonal response to fasting. At the time of hypoglycemia, blood ketone body concentrations are raised, there is ketonuria, plasma alanine concentration is low,

Table 3 Causes of Hypoglycemia in Children

Accelerated starvation (so-called ketotic hypoglycemia)
Hyperinsulinism
PHHI
Insulinoma
Beckwith-Wiedemann syndrome
Sulfonylurea ingestion
Factitious
Hormone deficiency
ACTH/cortisol
GH
Hypopituitarism (ACTH/cortisol and GH)
Metabolic defects
Disorders of carbohydrate metabolism
Glycogen synthase deficiency
Glucose-6-phosphatase deficiency (type I glycogen storage disease)
Amylo-1,6-glucosidase deficiency (type III glycogen storage disease)
Phosphorylase deficiency (type VI glycogen storage disease)
Phosphorylase kinase deficiency (type IX glycogen storage disease)
Galactose-1-phosphate uridylyltransferase deficiency (galactosemia)
Fructose-1-phosphate aldolase deficiency (fructose intolerance)
Defects in gluconeogenesis
• Pyruvate carboxylase deficiency
• PEPCK deficiency
• Fructose-1,6-bisphosphatase deficiency
Disorders of fatty acid oxidation and ketone synthesis
Carnitine transport and metabolism
β -oxidation cycle
Electron transfer
Hydroxymethylglutaryl CoA synthase deficiency
Hydroxymethylglutaryl CoA lyase deficiency
Disorders of protein metabolism
Maple syrup urine disease (branched-chain ketoacid decarboxylase deficiency)
Methylmalonic acidemia
Tyrosinemia
Miscellaneous
Nonpancreatic tumor hypoglycemia (IGF-II) (250, 251)
Salicylate intoxication
Reye syndrome
Ethanol intoxication
Malaria
Diarrhea
Malnutrition
Jamaican vomiting sickness (ingestion of unripe ackee)
Reactive hypoglycemia (dumping syndrome) (252, 253)
Carbohydrate-deficient glycoprotein syndrome (254)

and blood lactate and pyruvate levels are normal (48). Plasma insulin levels are appropriately suppressed and the concentrations of counterregulatory hormones are increased. The glycemic response to glucagon (0.03 mg/kg intramuscularly (IM) or intravenously (IV); maximum 1 mg) is normal in the fed state, but blunted at the time of hypoglycemia.

C. Treatment

Treatment consists of educating parents to ensure that the child avoids prolonged periods of fasting. A bedtime snack consisting of both carbohydrate and protein prevents further episodes of hypoglycemia. During intercurrent illness, providing carbohydrate-rich drinks at frequent

Table 4 Differential Diagnosis of Ketotic Hypoglycemia

Liver large
Glycogen storage diseases (types I, III, VI, IX)
Disorders of gluconeogenesis (e.g., fructose 1,6-bisphosphatase)

GH deficiency
Panhypopituitarism
Glycogen synthase deficiency
Short-chain fatty acid oxidation disorders
Organic acidemias (e.g., maple syrup urine disease, methylmalonic acidemia)

intervals during both the day and night can prevent hypoglycemia. Parents are instructed to test urine for ketones during intercurrent illnesses. The appearance of ketonuria precedes the onset of hypoglycemia by several hours. Recently, a new meter (Precision Xtra; Abbott Laboratories, Inc., Bedford, MA, USA) has become available, which accurately measures blood β -hydroxybutyrate concentration on a small drop of blood (49). This may prove quite useful as an alternative method of monitoring the development of ketosis during periods of illness or poor food intake in the child with ketotic hypoglycemia. If the child cannot tolerate oral carbohydrate, intravenous glucose is necessary to avert the development of hypoglycemia.

VII. HYPERINSULINISM

Hyperinsulinism caused by generalized β -cell dysfunction is the most common cause of persistent hypoglycemia in

infants and young children. Islet cell adenomas are rare in children less than 1 year of age. Hyperinsulinism that presents in an older child is more likely to be caused by an insulinoma or by exogenous insulin administration (factitious hypoglycemia) (50).

In the past decade, considerable progress has been made toward elucidating the pathophysiology of the heterogeneous disorders that cause hyperinsulinemic hypoglycemia. Several distinct genetic forms of congenital hyperinsulinism have been described (51). The most common variety is an autosomal recessive defect (52) caused by homozygous mutations in either the SUR1 gene (53, 54) or in the Kir6.2 gene (55, 56). Both genes encode components of the K_{ATP} channel involved in glucose-regulated insulin release, and mutations in these genes result in uncoupling of insulin secretion from glucose metabolism.

The principal clinical and biochemical features of hyperinsulinemic hypoglycemia are summarized in Table 5. Patients with autosomal recessive hyperinsulinism due to SUR/Kir6.2 mutations typically present as macrosomic babies with severe intractable hypoglycemia soon after birth. This disorder is discussed in more detail in Chapter 23.

Unlike the autosomal recessive defects of the K_{ATP} channel that result in diffuse β -cell dysfunction, the sporadic form of hyperinsulinemic hypoglycemia (HHI) can result in either focal or diffuse hyperplasia of β -cells. Focal adenomatous hyperplasia occurs in 30–40% of sporadic cases and is caused by a specific somatic loss of the maternal allele imprinted at 11p15 in a patient harboring an SUR1 mutation on the paternal allele (i.e., hemizygous germline mutation together with maternal loss of heterozygosity of 11p15) (57–60). Two hypotheses have been proposed to explain focal hyperplasia. The loss of heterozygosity may unmask a recessively inherited SUR1 or Kir6.2 mutation located on the paternal allele. An alter-

Table 5 Clinical and Biochemical Features of Hyperinsulinemic Hypoglycemia

Usually less than 12 months of age at presentation
Hypoglycemia soon after feeding (0–5.5 h, average ~2 h)
Urinary ketones negative, trace, or small
Serum insulin $\geq 2 \mu\text{U/ml}$ (15 pmol/l) with plasma glucose $< 45 \text{ mg/dl}$ (2.5 mmol/l)
Increased serum C-peptide concentration
Plasma ketone (β -OH-butyrate and acetoacetate) concentrations inappropriately low
Brisk glycemic response to glucagon $> 30 \text{ mg/dl}$ (1.7 mmol/l)
Parenteral glucose required to maintain normoglycemia is two to four times greater than glucose production rate ($\sim 6 \text{ mg/kg/min}$)
Decreased plasma branched-chain amino acids (valine, leucine, isoleucine)
Decreased IGF-binding protein-1 (IGFBP-1); all other endocrinologic and metabolic abnormalities with fasting hypoglycemia are associated with decreased insulin secretion and increased IGFBP-1 levels
Leucine and/or tolbutamide causes an exaggerated hyperinsulinemic response
GH, cortisol concentrations usually normal but may be inappropriately low if hypoglycemia occurs gradually or is recurrent (blunted counterregulatory hormone responses)

native hypothesis is that this somatic deletion also results in loss of an associated tumor-suppressor gene, H19. H19 normally inhibits the actions of IGF-2; unopposed IGF-2 action could lead to β -cell proliferation (61). The patient with focal adenomatous hyperplasia cannot be differentiated clinically from the patient with diffuse disease. However, pancreatic venous sampling and intraoperative histopathological examination of the pancreas have been successfully used to differentiate between the two (62, 63). If focal disease can be identified, a more limited pancreatectomy can be performed, thereby curing the patient and obviating the risk of postsurgical diabetes mellitus.

Two distinct forms of autosomal dominant hyperinsulinism have been described, both with milder clinical phenotypes than the autosomal recessive form. Patients are not macrosomic at birth and may not present with hypoglycemia until later in childhood or adulthood; hypoglycemia is usually more easily controlled with either diet alone or with diazoxide (64, 65). It responds well to dietary or pharmacological therapy and is generally associated with an excellent prognosis. One form of autosomal dominant hyperinsulinism is caused by an activating mutation in β -cell glucokinase that results in increased affinity of the enzyme for glucose (38). Glucokinase normally has low affinity for glucose and is the rate-limiting step in β -cell glucose metabolism. In the initial description of this disorder, a single base pair change at codon 455 of the gene was found, resulting in substitution of methionine for valine. This alteration increased the activity of the enzyme (a 65% change in enzyme affinity for glucose; K_m 2.9 mM compared to 8.4 mM in wild type). This causes an abnormally low glucose threshold for insulin secretion, 36–45 mg/dl (2.0–2.5 mM). A defect in glucokinase can be missed if the critical sample is obtained when the plasma glucose concentration is below the threshold for insulin secretion. If this diagnosis is suspected, a fasting study with serial measurements of plasma insulin levels may be required to document inappropriate insulin secretion.

A distinct form of mild hyperinsulinism is associated with persistent mild asymptomatic hyperammonemia (blood ammonia levels are in the range of 100–200 μ mol/l or approximately three to six times normal) that is not associated with any abnormality of the amino acids or organic acids characteristic of defects in the urea cycle (40, 66–69). Familial cases with an autosomal dominant pattern of inheritance have been documented; however, the majority of cases have been sporadic. The hypoglycemia may go unrecognized until adulthood. It usually responds well to diet and diazoxide. The syndrome is caused by a gain of function mutation of mitochondrial glutamate dehydrogenase, which causes excessive glutamate oxidation in the β -cell and increased formation of α -ketoglutarate, an intermediary in the Krebs cycle (40). Increased glutamate oxidation increases the ratio of ATP/ADP resulting in unregulated release of insulin. In the

liver, increased glutamate oxidation decreases the glutamate concentration and results in decreased synthesis of N-acetylglutamate, an allosteric activator of carbamoyl phosphate synthetase, which catalyzes the first step in ureagenesis (40).

Despite the extraordinary advances in understanding of the pathophysiology of hyperinsulinism, only 30–50% of patients have a definable genetic abnormality (37, 70). It is likely that other abnormalities will be revealed as the search continues for new defects in the secretory apparatus, including defects in the intracellular control of calcium signaling of exocytosis (70).

A. Diagnosis

Hyperinsulinism should be considered in any infant or child with hypoketotic hypoglycemia (Table 5). Hyperinsulinism is the probable diagnosis in a child with hypoglycemia whose concomitant serum insulin level is >2 μ U/ml. Malicious insulin administration should be suspected if severe hypoglycemia is associated with very high serum insulin (>100 μ U/ml), and is confirmed by finding concomitantly low or suppressed serum C-peptide levels.

Reliable noninvasive methods are still not available to differentiate among an adenoma, focal adenomatous hyperplasia, and diffuse β -cell dysfunction. Sonographic and computerized axial tomography (CT) are both insensitive imaging modalities. For patients who fail to respond to pharmacological therapy (especially in those without a family history of hyperinsulinism), more extensive evaluation at a specialized center is recommended before undertaking a 95–99% pancreatectomy. The type and location of the pancreatic lesion (diffuse disease vs. focal adenomatous hyperplasia) can be determined by preoperative pancreatic catheterization and intraoperative histopathological studies of the pancreas (evaluation of β -cell nuclear radius and cell density) (62, 71). Armed with this information, the surgeon may be able to choose between a partial pancreatectomy for a focal lesion and a near-total pancreatectomy for a diffuse lesion. It has recently been shown that in neonates with hyperinsulinism about half may have focal islet-cell hyperplasia that can be treated with partial pancreatectomy (63).

B. Treatment

The goal of therapy is to prevent hypoglycemia in order to protect the developing brain from damage. Successful treatment should maintain the plasma glucose concentration above 60 mg/dl (3.3 mmol/l) on a feeding schedule appropriate for the age of the child. For example, for up to 12 h in infants up to 1 year of age, or 16 h or more in older children. Prompt effective treatment is necessary to minimize the risk of long-term adverse neurological sequelae (72).

Oral diazoxide, which opens normal K_{ATP} channels and thereby suppresses insulin secretion, should be given

a trial starting at a dosage of 10 mg/kg per day (15–25 mg/kg per day in three doses at 8 h intervals) (70). If no effect is observed at a dosage of 25 mg/kg per day, it is not worthwhile to increase the dose further because this will cause worsening of side effects (edema, hypertrichosis) without improving efficacy. The effect of diazoxide may be potentiated by the addition of a thiazide diuretic (chlorothiazide 7–10 mg/kg per day divided twice daily) which acts synergistically with diazoxide (activates potassium channels by a different mechanism) and decreases edema (70). Diazoxide is ineffective in infants whose hyperinsulinism is caused by mutations resulting in functional inactivation of the K_{ATP} channel.

A long-acting injectable somatostatin analog (Octreotide) may be successful in maintaining normoglycemia in up to 50% of cases of congenital hyperinsulinism. Octreotide inhibits insulin secretion by decreasing intracellular translocation of calcium ions into β cells and through a direct effect on secretory granules. It may also mediate G-protein activity in the potassium channel (73). The starting dosage is 5 μ g/kg every 6–8 h. If glucose is not maintained ≥ 60 mg/dl, the dosage of Octreotide is increased up to a maximum of 40–60 μ g/kg daily, divided into three to six doses. Gastrointestinal side effects usually limit the tolerable dosage of Octreotide. Because of the marked variability of response to Octreotide, the therapeutic regimen has to be adapted for each individual patient and its effects closely monitored (74).

More recently, nifedipine (a calcium channel blocker) has been used to treat HHI that is unresponsive to conventional therapy (75–78). Experience with its use is still very limited. However, after failure of diazoxide and/or somatostatin analog to restore euglycemia, nifedipine (0.7–2.5 mg/kg/day) has been used successfully to maintain normoglycemia in at least three patients (76, 77). The clinical response to this drug is highly variable and it is currently not possible to predict which children will respond without a trial.

Continuous subcutaneous (SC) infusions of Octreotide (5–20 μ g/kg/day) or glucagon (1–10 μ g/kg/hour) IV or SC can be used to stabilize the hypoglycemia in patients prior to surgery. They should be used when the orally administered drugs have been shown not to be effective, particularly if the child remains dependent on a glucose infusion to maintain normoglycemia. When used in high dosages, both hormones cause tachyphylaxis. Many infants fail to respond to medical therapy and require a 95–99% subtotal pancreatectomy to restore normoglycemia (79).

VIII. HORMONE DEFICIENCY

A. ACTH/Cortisol Deficiency

Cortisol limits glucose utilization in several tissues, including skeletal muscle, by directly opposing the action

of insulin and, secondarily, by promoting lipolysis. It stimulates protein breakdown and increases release of gluconeogenic precursors from muscle and fat. Cortisol stimulates hepatic gluconeogenesis and glycogen synthesis and exerts permissive effects on the gluconeogenic and glycogenolytic effects of glucagon and epinephrine. As a result of all these effects, cortisol tends to raise the plasma glucose concentration.

Hypoglycemia is an uncommon presentation of primary adrenal failure. Nevertheless, adrenocortical insufficiency should be considered in the differential diagnosis of patients who present with hypoglycemia and ketosis. In infancy and early childhood, adrenocortical insufficiency may be secondary to congenital adrenal hypoplasia or congenital adrenal hyperplasia (rarely). In older children, adrenocortical insufficiency is more likely to be caused by Addison's disease. ACTH deficiency or panhypopituitarism can present with hypoglycemia in infancy or in later childhood. Hypoglycemia caused by isolated deficiency of ACTH is rare (80, 81); it is more common in children with multiple pituitary hormone (including GH and ACTH) deficiencies (82).

B. Diagnosis

A serum cortisol concentration < 10 μ g/dl at the time of hypoglycemia should suggest the diagnosis. The diagnosis is confirmed by definitive tests that evaluate the hypothalamic-pituitary-adrenal axis.

Treatment consists of physiological replacement of cortisol and mineralocorticoids (when necessary).

C. Hypopituitarism (Isolated GH Deficiency, Multiple Pituitary Hormone Deficiencies)

GH decreases sensitivity to insulin, stimulates lipolysis, and decreases glucose utilization. Congenital hypopituitarism often presents in the newborn period with hypoglycemia, persistent hyperbilirubinemia, and a microphallus (83). About 20% of children with isolated GH deficiency or multiple anterior pituitary hormone deficiencies present with fasting hypoglycemia and ketosis (84). The occurrence of hypoglycemia in children with GH deficiency is inversely related to age (84, 85). The combination of low serum GH and cortisol concentrations at the time of hypoglycemia suggests hypopituitarism. However, serum GH levels during spontaneous hypoglycemia do not correlate well with GH levels obtained by stimulation tests of pituitary GH secretory reserve. Therefore, a single low serum GH concentration cannot be relied on to make the diagnosis of GH deficiency (86). Patients with insulin-like growth factor 1 (IGF-1) deficiency (Laron syndrome) have high GH levels, but are otherwise indistinguishable from patients with isolated GH deficiency. These patients are prone to symptomatic hypoglycemia in infancy (87); the tendency to develop hypoglycemia ameliorates with advancing age. Pituitary GH secretory reserve should be

formally tested if there is any suspicion of GH insufficiency.

Treatment of panhypopituitarism consists of replacing thyroxine, cortisol, and GH.

IX. DISORDERS OF GLYCOGEN SYNTHESIS AND GLYCOGEN DEGRADATION

A. Glycogen Synthase Deficiency

This is a rare autosomal recessive disorder caused by mutations in the human liver glycogen synthase (GYS2) gene (88) on chromosome 12p12.2, resulting in lack of glycogen synthase activity in the liver. Because dietary carbohydrate cannot be stored as glycogen, glucose is preferentially converted to lactate. The disorder causes a unique metabolic disturbance characterized by fasting hypoglycemia and hyperketonemia alternating with daytime hyperglycemia and hyperlacticacidemia after meals. The glycogen content of the liver is markedly decreased (0.5 g/100 g wet weight 4–6 h after a meal); the liver is not enlarged. The disorder should be considered in children who have hypoglycemia and ketonuria before the first meal of the day (Table 4) (89).

The goal of treatment is to prevent hypoglycemia and ketosis during the night and hyperglycemia and hyperlacticacidemia during the day. Fasting hypoglycemia is prevented by administration of uncooked cornstarch at bedtime. During the day, patients are fed frequently (e.g., every 4 h). The diet should contain increased amounts of protein to provide substrate for gluconeogenesis (90) and a correspondingly reduced amount of carbohydrate to minimize postprandial hyperglycemia and hyperlacticacidemia (89).

B. Glucose-6-Phosphatase Deficiency (Type I Glycogen Storage Disease)

Type I glycogen storage disease (GSD-I) is an autosomal recessive disease that results from lack of glucose-6-phosphatase activity, the enzyme that catalyzes the final step in the production of glucose from glucose-6-phosphate (91) (Fig. 3). At least 30 different mutations in the gene encoding glucose-6-phosphatase on chromosome 17q21 have been found in patients with GSD-Ia (92). Glucose production both from glycogenolysis and gluconeogenesis is severely impaired, resulting in postprandial hypoglycemia and increased production of lactic acid, uric acid, and triglycerides (Fig. 3). Glycogen and fat accumulate in the liver, resulting in hepatomegaly and a protuberant abdomen. Symptomatic hypoglycemia may be detected soon after birth; however, most infants are asymptomatic as long as they receive frequent feedings containing sufficient glucose to prevent hypoglycemia. Symptoms of hypoglycemia usually appear when the interval between feedings increases and the infant begins to sleep through the night. Characteristic manifestations in untreated pa-

tients are a progressive decrease in linear growth, muscle wasting, delayed motor development, and a cushingoid appearance (93). The kidneys are enlarged; renal tubular dysfunction and glomerular hyperfiltration are common in childhood. Increased urinary albumin excretion may be observed in adolescents (94). More severe renal injury (proteinuria, hypertension, decreased creatinine clearance) due to focal segmental glomerulosclerosis and interstitial fibrosis, and hypercalciuria and nephrocalcinosis are common in young adults (95, 96). Inadequate therapy causes severe retardation of physical growth and delayed puberty. Hepatic adenomas usually develop in the second and third decades of life, and may undergo malignant degeneration or hemorrhage (97).

Patients with type Ib glycogen storage disease (deficiency of the glucose-6-phosphate transporter required to move glucose-6-phosphate across the microsomal membrane into the lumen of the endoplasmic reticulum where it is exposed to the hydrolytic function of the glucose-6-phosphatase enzyme system) have similar clinical manifestations (98). In addition, they have either constant or cyclic neutropenia associated with recurrent bacterial infections. Neutropenia of varying severity is a consequence of disturbed myeloid maturation and is accompanied by functional defects of circulating neutrophils and monocytes (99). Some patients develop an inflammatory bowel disease resembling Crohn's disease that is responsive to treatment with granulocyte colony-stimulating factor (GCSF) (100).

C. Diagnosis

In infancy, severe hypoglycemia accompanied by marked hyperlacticacidemia develops 3–4 h after a feed. The serum is often cloudy or milky with very high triglyceride and moderately increased levels of cholesterol. Serum uric acid is increased and serum aspartate aminotransferase (AST) and alanine aminotransferase (ALT) levels are moderately elevated. Glucagon causes either no or only a small increase in blood glucose, whereas the already elevated blood lactate level increases further. Lack of glucose-6-phosphatase activity on a liver biopsy specimen confirms the diagnosis. In many patients mutational analysis can be used to confirm the diagnosis and obviate the need to perform liver biopsy.

Treatment consists of providing a continuous dietary source of glucose at a rate that prevents the blood glucose level from falling below the threshold for glucose counterregulation, approximately 70 mg/dl. When hypoglycemia is prevented by providing an appropriate amount of glucose throughout the day and night, the biochemical abnormalities are ameliorated, liver size decreases, the bleeding tendency is reversed, and growth improves (101). The amount of glucose required varies among patients, but can be approximated, initially, by using the formula for calculating basal glucose production rate as a guide:

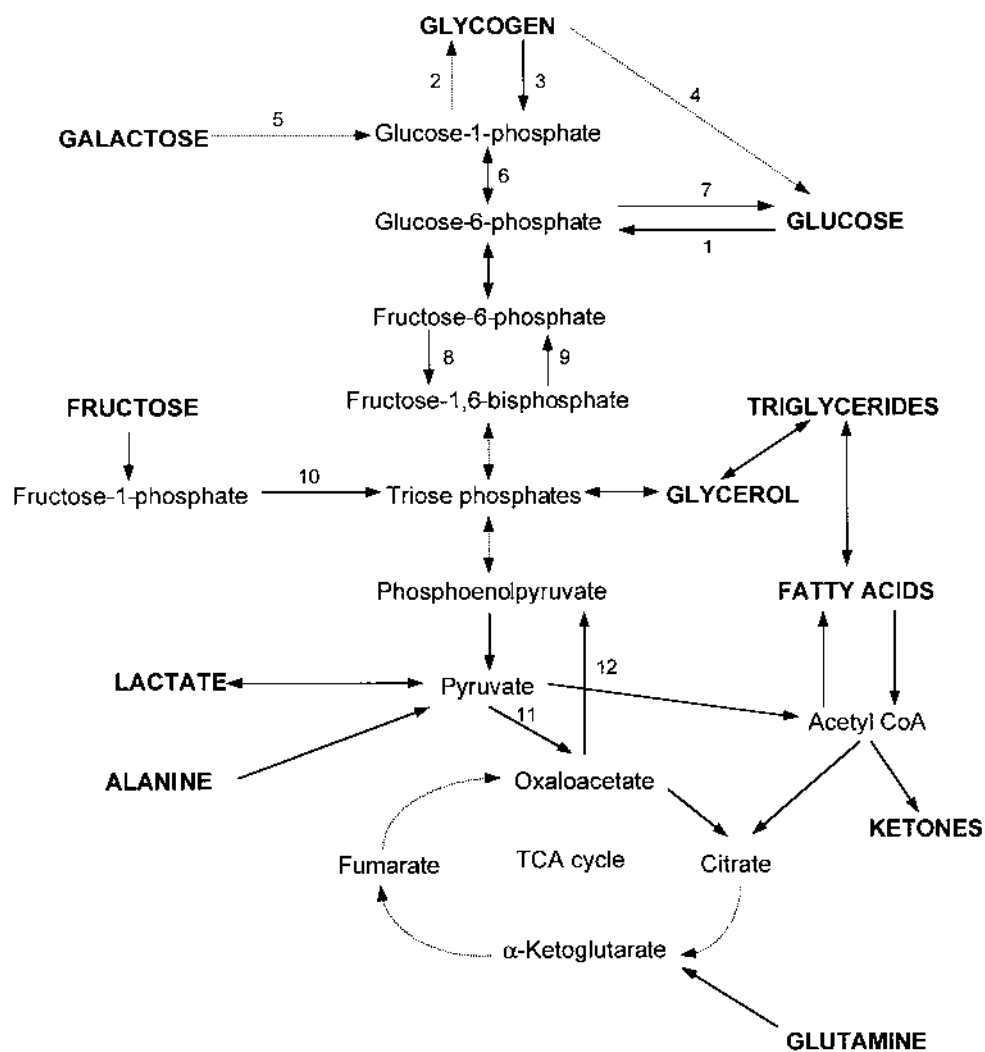

Figure 3 Schematic outline of glucose metabolism shows pathways of glycogen synthesis, glycogen degradation, glycolysis, and gluconeogenesis. Key enzymes are designated by number. 1, hexokinase/glucokinase; 2, glycogen synthase; 3, phosphorylase; 4, Amylo-1,6-glucosidase (glycogen debrancher); 5, galactose-1-phosphate uridyl transferase; 6, phosphoglucomutase; 7, glucose-6-phosphatase; 8, phosphofruktokinase; 9, fructose-1,6-bisphosphatase; 10, fructose-1-phosphate aldolase; 11, pyruvate carboxylase; 12, phosphoenolpyruvate carboxykinase.

$$y = 0.0014x^3 - 0.214x^2 + 10.411x - 9.084$$

where $y = \text{mg glucose/min}$, and $x = \text{body weight in kg}$ (2). Glucose itself or glucose-containing polymers can be given intermittently during the day and continuously (via a nasogastric tube or gastrostomy) at night. As an alternative, after 6–8 months of age, intermittent feedings of uncooked cornstarch can be used as the source of continuous glucose administration (102). Orally administered uncooked cornstarch appears to act as an intestinal reservoir of glucose that is slowly absorbed into the circulation. It is given in a slurry of water or artificially flavored drink (or in milk or lactose-free formula for infants)

at 3–5 h intervals during the day and 4 or 5 h intervals overnight (103–105).

D. Amylo-1,6-Glucosidase Deficiency (Type III Glycogen Storage Disease; Glycogen Debranching Enzyme Deficiency)

The glycogen debrancher enzyme (GDE) gene is on chromosome 1p21 (106). The disorder is transmitted as an autosomal recessive trait. Absence of GDE activity permits breakdown of glycogen to proceed until the outermost branch points are reached. This leaves a limit dex-

trin, which consists of the core of the molecule bearing short branches about four glucose units in length. Some 80–85% of patients with GSD III lack GDE activity (deficiency of transferase and glucosidase activities) in both liver and muscle (GDE-IIIa) (91) and show clinical evidence of hepatic dysfunction and myopathy. About 15% of patients have GDE deficiency only in the liver (GSD IIIb) (91). In rare cases, there is selective loss of only one of the two GDE activities (glucosidase [type IIIc] or transferase [type IIId]) (107, 108). GSD types IIIa and IIIb have different prognoses and outcomes. Myopathy and cardiomyopathy are common in GSD IIIa and can lead to early death or debilitation in adult life. Muscle involvement can be inferred from high plasma creatine kinase concentrations.

Several distinct clinical features differentiate type III from type I GSD. Because glucose can be produced from 1,4 segments beyond the outermost branch points and from gluconeogenesis, patients with GDE deficiency are able to tolerate longer periods of fasting and develop less severe hypoglycemia than patients with glucose-6-phosphatase deficiency. Infants who are fed frequently may not have symptoms. Fasting causes hypoglycemia with ketosis (as a result of an accelerated transition to the starving state) (109), mild hypercholesterolemia, and hypertriglyceridemia, without elevation of blood lactate and serum uric acid concentrations. Liver enzyme levels (AST, ALT, alkaline phosphatase, lactic dehydrogenase [LDH]) are consistently elevated in children, but decline at puberty concomitant with a decrease in liver size and may be normal in adults (110). Patients frequently present with growth failure and hepatomegaly, which may be associated with an enlarged spleen at 4–6 years of age in patients who have hepatic fibrosis. The kidneys are not enlarged, nor does renal dysfunction occur. Untreated infants and children have a decreased rate of linear growth and puberty is delayed. The enzyme is lacking in muscle in about 85% of patients; however, weakness is usually minimal and not clinically significant in childhood. A subset of patients primarily manifest myopathic symptoms (usually in their third and fourth decades), and myopathy may be progressive. Abnormal glycogen (limit dextrin) may also accumulate in the heart. Subclinical evidence of cardiac involvement is common and manifests as ventricular hypertrophy on electrocardiography (ECG) and an abnormal echocardiograph (111). Some patients develop a cardiomyopathy similar to hypertrophic obstructive cardiomyopathy (112). Hepatic adenomata occur less frequently in patients with GSD III than in GSD I; and the transformation of an adenoma into a hepatocellular carcinoma is rare. With the exception of myopathy, symptoms and signs characteristically ameliorate with increasing age. The size of the liver tends to decrease to normal during puberty; however, biopsy usually shows hepatic fibrosis and some adult patients develop cirrhosis and its complications (113).

After an overnight fast, the low blood glucose and normal blood lactate concentrations do not increase after administration of glucagon (0.03 mg/kg, maximum dose 1 mg IM or IV). When the test is repeated 2 h after a high-carbohydrate meal, which lengthens the outer branches of glycogen, a glycemic response does occur. Definitive diagnosis and subtyping require a biopsy of both liver and muscle for assay of enzyme activity.

As in type I GSD, continuous provision of an adequate amount of glucose, using uncooked cornstarch, combined with a normal intake of total calories, protein, and other nutrients corrects the clinical and biochemical disorder and restores normal growth. Uncooked cornstarch, 1.75 g/kg at 6 h intervals (e.g. at midnight, 6 a.m., etc.) maintains normoglycemia, increases growth velocity, and decreases serum aminotransferase concentrations (114, 115).

For patients with type III disease who have significant growth retardation and myopathy, continuous nocturnal feeding of a nutrient mixture composed of glucose, glucose oligosaccharides, and amino acids combined with meals that have a high protein content has been shown to improve muscle strength (116). The composition of the diet should be 55–60% carbohydrates, 15–20% protein, and 20–30% fat. Milk products and fruits can be allowed without restriction, as galactose and fructose can be normally converted to glucose.

E. Hepatic Phosphorylase Complex Deficiency

The glycogen storage diseases associated with a reduction in liver phosphorylase activity are a heterogeneous group of disorders that includes autosomal recessive liver glycogen phosphorylase deficiency (type VI or Hers' disease), an autosomal recessive phosphorylase kinase b deficiency (type VIII), and X-linked phosphorylase kinase deficiency (type IX) (93). They are all mild forms of hepatomegalic glycogenosis without hyperlacticacidemia or hyperuricemia.

These disorders present in infancy or early childhood and are characterized by mild to moderate hypoglycemia, ketosis, growth retardation, and prominent hepatomegaly. Blood levels of lactic acid and uric acid are normal. The heart and skeletal muscle are not affected. The clinical course is benign. Symptoms remit and hepatomegaly decreases at puberty. The prognosis is excellent.

F. Phosphorylase Kinase Deficiency

This is the most common disorder in this group, accounting for about 25% of all cases of GSD and occurs with a frequency of approximately 1 in 100,000 births (91, 117). X-linked liver glycogenosis (XLG) is the most common type of phosphorylase kinase (PHK) deficiency and is usually a mild disease. Patients seldom have symptomatic hypoglycemia during infancy unless they fast for a pro-

longed period of time, in which case they can develop hyperketosis similar to, but usually milder than, that seen in type III GSD. Metabolic acidosis is rare. The disorder is usually discovered in early childhood when an enlarged liver and protuberant abdomen are noted during a physical examination. Physical growth may be retarded, and motor development may be delayed as a consequence of muscular hypotonia in the rare case with reduced enzyme activity in muscle as well as liver. Hypoglycemia is unusual and blood lactate and uric acid levels are normal. Mild hypertriglyceridemia, hypercholesterolemia, and elevated serum AST and ALT levels may be present. Functional tests are not especially useful in evaluating these patients. The administration of glucagon after an overnight fast usually elicits a brisk glycemic response without a rise in the blood lactate level. The glycemic response to glucagon cannot be used to differentiate between phosphorylase kinase deficiency and lack of phosphorylase itself. The enlarged liver regresses when patients reach puberty. With increasing age, clinical and biochemical abnormalities gradually disappear, and most adult patients are asymptomatic despite persistent PHK deficiency.

Liver phosphorylase deficiency can be difficult to diagnose biochemically and difficult to differentiate from deficiency of phosphorylase kinase. Mutation analysis may aid in the laboratory diagnosis of deficiencies of the liver phosphorylase system. Definitive diagnosis of phosphorylase kinase b deficiency requires demonstration of the enzymatic defect in affected tissues.

Most patients do not require treatment; however prolonged fasting should be avoided. For the minority of patients who are prone to fasting hypoglycemia during childhood, a late night snack will usually suffice to prevent morning hypoglycemia. In the unusual patient who experiences overnight hypoglycemia and ketosis, uncooked cornstarch, 2 g/kg at bedtime, prevents hypoglycemia and ketosis (118).

X. DISORDERS OF GLUCONEOGENESIS

Disorders of gluconeogenesis may be caused by deficiency of one of the key gluconeogenic enzymes (pyruvate carboxylase, phosphoenolpyruvate carboxykinase, fructose-1,6-bisphosphatase, and glucose-6-phosphatase) (Fig. 3). In addition to these inborn errors of metabolism, gluconeogenesis is impaired in hereditary fructose intolerance, by ingestion of ethanol, in children with Jamaican vomiting sickness, falciparum malaria, severe diarrhea, and in salicylate intoxication. Hypoglycemia caused by disorders of gluconeogenesis is characteristically accompanied by hyperlacticacidemia and hyperalaninemia.

A. Phosphoenolpyruvate Carboxykinase Deficiency

PEPCK is a unidirectional rate-limiting enzyme of gluconeogenesis that converts oxaloacetate to phosphoenol-

pyruvate (Fig. 3). Hypoglycemia is seen in infancy and may be severe. Fatty infiltration of the liver, kidney, and other organs occurs because there is increased formation of acetyl CoA. Laboratory evaluation reveals high concentrations of lactate and pyruvate, a normal lactate/pyruvate ratio, and ketosis. The definitive diagnosis of PEPCK deficiency depends on the demonstration of impaired enzyme activity on a liver biopsy. Treatment consists of frequent feedings and avoiding fasting.

B. Fructose-1,6-Bisphosphatase Deficiency

The block in gluconeogenesis resulting from failure to convert fructose-1,6-bisphosphate to fructose-6-phosphate causes fasting hypoglycemia and lactic acidosis (Fig. 3). Hypoglycemia occurs during fasting and intercurrent illness and is associated with ketosis, hypertriglyceridemia, and hyperuricemia. In the immediate postprandial period, glucagon elicits a glycemic response (119). The biochemical abnormalities caused by fructose-1,6-bisphosphatase deficiency are similar to glucose-6-phosphatase deficiency. Affected children typically fail to thrive. Hepatomegaly is caused by fatty infiltration of the liver. Diagnosis is based on demonstrating decreased enzyme activity in the liver. Treatment consists of eliminating dietary fructose and sucrose and avoiding prolonged fasts. During intercurrent illness, intravenous glucose must be given to arrest catabolism.

C. Hereditary Fructose Intolerance

This rare disorder is caused by deficiency of fructose-1-phosphate aldolase (Fig. 3). Nursing infants are asymptomatic until fruits and juices are added to their diet. It usually presents following the introduction of a commercial formula containing sucrose, or at the time of weaning when fructose or sucrose are ingested for the first time. Fructose causes vomiting, diarrhea, and hypoglycemia. Chronic exposure to fructose causes hepatomegaly, jaundice, failure to thrive, and renal tubular dysfunction with aminoaciduria. Older children have an aversion to sweets. Fructose-1-phosphate accumulates in the liver and acutely inhibits glycogenolysis via the phosphorylase system and gluconeogenesis at the level of fructose-1,6-bisphosphatase (120). Chronic fructose intoxication can occur after infancy without causing symptoms of acute fructose intoxication and can be expressed as an apparently isolated, reversible retardation of somatic growth. The diagnosis is suggested by fructosuria after meals; a fructose tolerance test results in hypoglycemia. Traditionally, the diagnosis has been made by intravenous fructose challenge or by liver biopsy, both difficult and risky invasive tests. Identification of mutations of the aldolase B gene by analysis of DNA from blood leukocytes is now possible, allowing for the potential of a noninvasive diagnosis (121).

D. Alcohol Intoxication

Ingestion of alcohol by children and adolescents can cause hypoglycemia several hours after its consumption as a result of inhibition of gluconeogenesis (122). Ethanol inhibits gluconeogenesis because its metabolism by alcohol dehydrogenase depletes hepatic nicotinamide adenine dinucleotide, a cofactor critical to the entry of most precursors into the gluconeogenic pathway. It does not inhibit glycogenolysis (123). Ethanol also inhibits cortisol and GH responses to hypoglycemia (122). When hepatic glycogen stores are adequate, ethanol does not cause hypoglycemia. However, severe hypoglycemia occurs when glycogen is depleted as a result of ethanol consumption without food, or after accidental alcohol ingestion after an overnight fast in a young child. Glucagon cannot raise the blood glucose level; treatment of ethanol-induced hypoglycemia should always be with administration of intravenous glucose.

E. Salicylate Poisoning

High dosages of salicylates can lower the plasma glucose concentration (124). Both hyperinsulinemia and reduced gluconeogenesis have been observed following acute ingestion of aspirin (124). However, the precise mechanism causing hypoglycemia is unclear. Salicylates may decrease gluconeogenesis via their ability to uncouple oxidative phosphorylation.

F. Malaria

Hypoglycemia is common in children with severe falciparum malaria in the absence of treatment with quinine (125–128). Impaired gluconeogenesis is suggested by the presence of high blood levels of ketones, lactate, and alanine at the time of hypoglycemia. Gluconeogenesis appears to be limited by an insufficient supply of precursors and is unable to compensate for the decreased availability of glucose from glycogen (129). Hypoglycemia has also been described during treatment with quinine and has been attributed to quinine's hyperinsulinemic effect (124). It has been suggested that the frequency of hypoglycemia in malaria may be no higher than in other serious illnesses associated with severe calorie deprivation (128). Treatment of hypoglycemia associated with malaria is with intravenous glucose.

G. Reye Syndrome

This syndrome typically follows viral infections with varicella and influenza A and B. Aspirin has been implicated in its pathogenesis. It is characterized by recurrent vomiting, an altered level of consciousness, hyperpnea, and hypoglycemia that is mainly the result of altered gluconeogenesis (130). Hypoglycemia occurs most often in children less than 5 years of age. Increased plasma levels of ammonia and free fatty acids suggest impaired urea-

genesis and fatty acid oxidation (131, 132). Recurrent episodes that mimic Reye syndrome should raise suspicion for a fatty acid oxidation defect (see Sec. XIII). Treatment is supportive (133, 134).

H. Diarrhea and Malnutrition

In developing countries, hypoglycemia is a common complication of infectious diarrhea in both well-nourished and poorly nourished children (135–137) and is a major cause of death (138). Children with kwashiorkor frequently suffer from severe hypoglycemia (139–141). Infants with acquired monosaccharide intolerance after an episode of gastroenteritis are also at increased risk for severe and even fatal hypoglycemia when fed a carbohydrate-free diet (142, 143).

Depletion of hepatic glycogen together with hepatic steatosis is observed in children with fatal hypoglycemia and diarrhea (144). Serum insulin levels are appropriately suppressed and glucose counterregulatory hormone concentrations are appropriately elevated in children with diarrhea and hypoglycemia, whereas gluconeogenic substrates are low suggesting that the hypoglycemia may be due to failure of gluconeogenesis (138). Reduced availability of fat-derived fuels (FFA and ketones) may play an important role in the development of hypoglycemia. In children who developed hypoglycemia during acute diarrheal illness, β -hydroxybutyrate concentrations were not significantly higher than in normoglycemic children with diarrhea, suggesting deficient generation of ketones, either because fat stores were diminished as a result of malnutrition or because the oxidation of fat was impaired (138). If fatty acids are less available (as may occur in malnutrition) or when oxidation of fatty acids is defective (e.g., as a result of acquired carnitine deficiency), hypoglycemia is more likely to occur because body tissues and brain (secondary to hypoketonemia) are more dependent on glucose. The failure of gluconeogenesis in diarrheal illness, therefore, may be a consequence of depleted fat stores, defective fatty acid oxidation and ketogenesis, or a defect in the hepatic enzymatic pathways required for gluconeogenesis (145).

Frequent feeding of children during diarrhea may help to prevent hypoglycemia. When patients with diarrhea require parenteral therapy, dextrose-containing electrolyte solutions should be used and the child's blood glucose level must be carefully monitored.

XI. DISORDERS OF AMINO ACID METABOLISM

Several disorders of amino acid metabolism result in hypoglycemia with organic aciduria. These patients typically have a delay in growth and development, recurrent vomiting, and may have hepatomegaly. Laboratory features include hyperammonemia and hyperchloremic metabolic

acidosis. Diagnosis depends on identification of specific organic acids in the urine and analysis of liver biopsy specimens or cultured fibroblasts (146).

A. Methylmalonic Acidemia

Methylmalonic acidemia results from a deficiency of methylmalonyl-CoA mutase, a cobalamin-dependent enzyme involved in the carboxylation of propionyl-CoA. Patients typically present in the newborn period with ketoacidosis, hyperammonemia, hypoglycemia, and acute encephalopathy. Hypoglycemia is due to impaired gluconeogenesis (147). Asymptomatic and benign variants are also detected by the analysis of urine organic acids. Plasma amino acid profile shows an increased concentration of glycine.

B. 3-Hydroxy-3-Methyl Glutaric Acidemia

3-Hydroxy-3-methylglutaryl CoA lyase catalyzes the last step of leucine degradation and ketogenesis. Deficiency of this enzyme results in a clinical presentation that includes episodes of hypoketotic hypoglycemia, fatty liver, coma, and mental delay (148).

C. Maple Syrup Urine Disease

Maple syrup urine disease (MSUD) is caused by a deficiency of branched-chain keto acid dehydrogenase, the enzyme that decarboxylates α -keto acids of leucine, isoleucine, and valine (149). The classic clinical presentation consists of failure to thrive, acidosis, hypoglycemia, and neurological symptoms with rapid deterioration when left untreated. The pathogenesis of hypoglycemia is not entirely clear, although it appears to result from defective gluconeogenesis (150). The levels of the branched-chain amino acids (leucine, isoleucine, and valine), particularly leucine, are elevated in plasma and urine. Increased plasma and urine concentrations of leucine, isoleucine, and valine with accumulation of branched-chain keto acids and 2-hydroxy acids are essential for making the diagnosis. Additional metabolites of the branched-chain amino acids may be detected. The enzymatic defect can be detected in leukocytes. Treatment consists of a diet restricted in the precursors to the enzyme defect, avoidance of and aggressive treatment of catabolic states, and supplementation with carnitine and vitamin cofactors. Treatment of acute episodes includes the administration of glucose with or without insulin to increase removal of branched-chain amino acids through enhanced protein synthesis. Long-term treatment requires limiting protein intake.

D. Hereditary Tyrosinemia (Tyrosinemia Type I)

This disorder is caused by deficiency of fumarylacetoacetate hydrolase. Infants present with vomiting, diarrhea,

and failure to thrive. Liver disease and hypoglycemia are consistent findings. A large amount of succinylacetone is excreted in the urine. Diagnosis is confirmed by measurement of fumarylacetoacetate hydrolase in the liver. Treatment consists of a diet low in tyrosine and phenylalanine in addition to the administration of 2-(2-nitro-4[trifluoromethyl] benzoyl)-1,3-cyclohexandione. Liver transplant is an effective therapy.

XII. MISCELLANEOUS CAUSES OF HYPOGLYCEMIA

A. Galactosemia

Galactosemia is caused by deficiency of galactose-1-phosphate uridyl transferase (Fig. 3), resulting in an inability to convert galactose-1-phosphate to glucose-1-phosphate (151). A defect in UDP-galactose-4-epimerase may cause a similar presentation (152). Hypoglycemia occurs following milk feedings. Although the precise mechanism causing hypoglycemia is unclear, there is evidence suggesting that the accumulation of galactose-1-phosphate inhibits phosphoglucomutase activity, thereby causing inhibition of glycogenolysis (153). Patients may present with neonatal *Escherichia coli* sepsis, diarrhea, vomiting, failure to thrive, hepatomegaly, jaundice, ascites, cataracts, and mental retardation. The urine contains a reducing substance that is not glucose (urine gives a positive Clinitest reaction but is negative with Clinistix) while the patient is receiving galactose. The increased concentration of galactose-1-phosphate leads to intellectual impairment, cataracts, hepatic dysfunction, renal tubular disease (Fanconi's syndrome), and ovarian failure (154). Diagnosis is confirmed by identifying a marked increase in blood levels of galactose and galactose-1-phosphate and near-absent galactose-1-phosphate uridyl transferase activity in red blood cells (155). Treatment consists of eliminating galactose from the diet.

B. Liver Disease

Fasting hypoglycemia may occur in patients with a variety of diseases and ingestion of various agents that cause extensive damage to the liver parenchyma resulting in fulminant hepatic necrosis and liver failure (156). Hypoglycemia results from impaired glycogenolysis and gluconeogenesis. Treatment is supportive.

C. Jamaican Vomiting Sickness

The unripe ackee fruit of the *Blighia surpida* tree contains a water-soluble toxin, hypoglycin, which produces vomiting, central nervous system depression, acute fatty liver, and severe hypoglycemia. Hypoglycemia is caused by hypoglycin A, which inhibits gluconeogenesis secondary to its interference with oxidation of long chain fatty acids (157). The disease is endemic in Jamaica where ackee is

part of the diet of the poor. It has been reported in the United States resulting from the consumption of canned ackee (158).

D. Glucose Transporters

Hypoglycorrhachia despite normal plasma glucose concentrations has been described in infants with a seizure disorder, developmental delay and acquired microcephaly, caused by a defect in the blood–brain GLUT-1. Glucose and lactate concentrations in the cerebrospinal fluid are low. Two distinct classes of mutations cause the functional defect of glucose transport: hemizygoty of GLUT-1 and nonsense mutations resulting in truncation of the GLUT-1 protein (159). Treatment is with a ketogenic diet to provide the brain with an alternative fuel source (160).

XIII. DISORDERS OF CARNITINE METABOLISM, FATTY ACID β -OXIDATION, AND KETONE SYNTHESIS

Disorders of carnitine metabolism and fatty acid β -oxidation are characterized by impaired ability to metabolize free fatty acids to acetyl CoA in various tissues and to synthesize ketones in the liver. During periods of fasting, mitochondrial oxidation of fatty acids becomes the major source of energy. Fatty acids with a chain length of ≤ 18 carbons undergo a series of reactions that produce acetyl CoA, a Krebs cycle intermediate and a precursor of hepatic ketone body synthesis. Normally, ketones are an alternative source of fuel for a variety of tissues, thereby conserving glucose for oxidation by the brain and heart. The paucity of ketones in fatty acid β -oxidation (FAO) disorders results in continued dependence on and utilization of glucose. FAO disorders result in the inability to maintain fasting plasma glucose concentrations and accumulation of intermediates of β -oxidation, which cause encephalopathy, arrhythmias, cardiac arrest, and sudden death (161, 162).

The oxidation of fatty acids begins with the formation of acyl-coenzyme A, which is transported across the mitochondrial membrane by a carnitine-mediated transport mechanism. Within the mitochondrion, carnitine is removed and four reactions, catalyzed by membrane bound enzymes, result in sequential removal of two carbon moieties (Fig. 4). Although defects in the formation of CoA esters, transport, or β -oxidation all result in impaired energy metabolism, there is a wide spectrum of clinical phenotypes. To date, at least 22 distinct disorders of fatty acid oxidation or transport have been described. Clinical manifestations may appear at any age between birth and adulthood; 69% of patients manifest symptoms before 1 year of age (163). Clinical manifestations usually occur during periods of catabolic stress or reduced caloric consumption (164). Symptoms of an acute metabolic crisis vary in se-

verity and include nausea, vomiting, lethargy, confusion, coma, seizures, or sudden death. Patients may have hypoglycemia (usually, but not always, hypoketotic), liver disease ranging in severity from increased serum transaminase levels to fulminant hepatic failure, skeletal myopathy, or cardiac dysfunction caused by cardiomyopathy (Tables 6, 7).

Approximately one-third of patients with FAO disorders present in the newborn period with lethargy, hypotonia, and neurological depression (163). Dysmorphic features (including facial dysmorphisms, renal dysplasia or cysts, and developmental brain malformations caused by defects in neuronal migration) have been observed in multiple acyl-CoA deficiency (MAD [glutaric acidemia type II]) (165) and in CPT-II deficiency (166). Other disorders that may present in the neonatal period, but are not typically associated with dysmorphology, include translocase deficiency, trifunctional protein deficiency, CPT-I deficiency, and very-long-chain acyl-CoA dehydrogenase (VLCAD) deficiency. Cardiac manifestations, including conduction disturbances and arrhythmias, are common in all of the disorders that present in the newborn period. Although hypoglycemia is a feature of these disorders, severely ill infants usually die within a few days of birth despite treatment of hypoglycemia (167, 168). About 5% of cases of sudden infant death syndrome (SIDS) are believed to be caused by defects in carnitine transport and/or FAO, including deficiencies of medium-chain acyl-CoA dehydrogenase (MCAD), VLCAD, long-chain hydroxyacyl-CoA dehydrogenase (LCHAD), MAD, and carnitine transport defects (169).

In infancy and childhood, hypoglycemia is the most common presenting abnormality; more than 80% of patients have a low plasma glucose concentration at diagnosis (163). Hypoglycemia is classically associated with hypoketosis; however, enough ketones may be formed in patients with the short-chain fatty acid disorders that patients may appear to have abundant (appropriate) urinary ketones at the time of presentation with hypoglycemia. Moderate hepatomegaly at presentation is caused by fatty infiltration (micro- and macrovesicular steatosis), which may lead to the erroneous impression that the patient has a glycogen storage disease or Reye syndrome. The hepatomegaly rapidly resolves with treatment. In addition to hypoglycemia, most patients show evidence of hepatic dysfunction during episodes of acute metabolic decompensation (161, 164). A clinical picture similar to Reye's syndrome (hepatomegaly, neurological depression, hyperammonemia) is present in about 30% of patients (163). A moderate increase in serum transaminase concentrations (100–800 U/L) is common, and patients with MAD and translocase deficiency may present with frank hepatic failure. The mitochondria may be abnormal in shape and size in both disorders. However, electron microscopy may reveal differences: dense condensation of mitochondria with inclusion bodies in fatty acid oxidation defects compared with mitochondrial swelling in Reye syndrome (170).

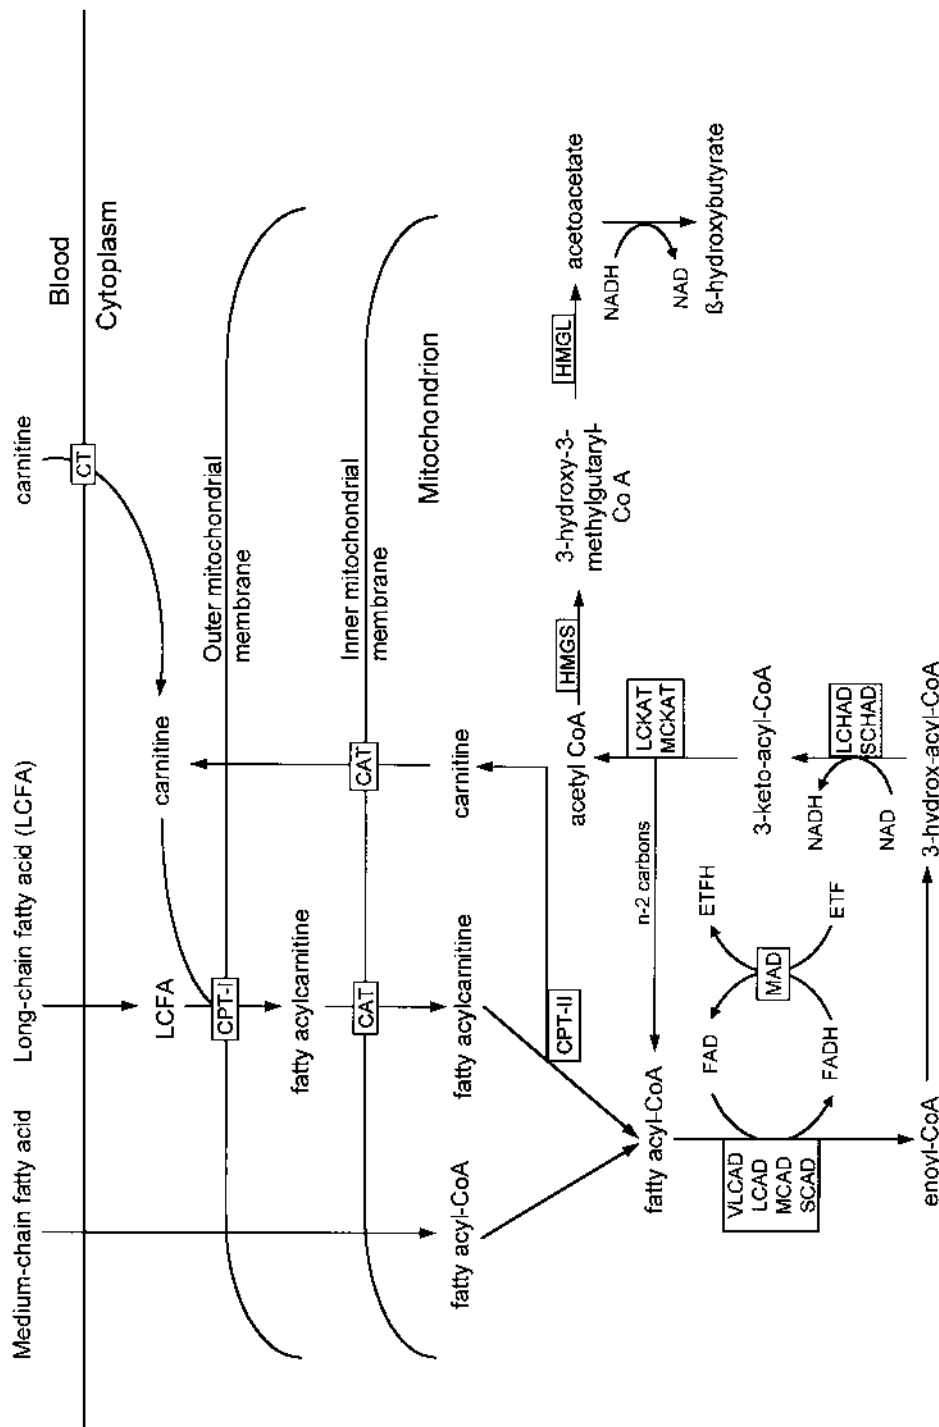

Figure 4 Schema of carnitine metabolism, fatty acid β -oxidation, and ketone synthesis. Reactions associated with known metabolic defects are shown in shaded boxes. CAT, carnitine-acylcarnitine translocase; CPT, carnitine transporter; ETF(H), electron transfer flavoprotein (reduced); FAD(H), flavin adenine dinucleotide (reduced); HMGL, 3-hydroxy-3-methylglutaryl-CoA lyase; HMGS, 3-hydroxy-3-methylglutaryl-CoA synthetase; LCFA, long-chain fatty acid; LCKAT, long-chain 3-ketoacyl-CoA thiolase; MCKAT, medium-chain 3-ketoacyl-CoA thiolase; NAD(H), nicotinamide adenine dinucleotide (reduced).

Table 6 Disorders of Carnitine Metabolism

Enzyme deficiency	CT	CAT	CPT-I	CPT-II
Clinical				
Fasting intolerance	+	+	+	+
Acute episodes	+	+	+	+
Coma/seizures	+	+	+	+
Muscle weakness/myopathy	+	+	+	+
Muscle pain/myoglobinuria				+
Cardiomyopathy/arrhythmia	+	+		±

Patients with defects in carnitine transport and metabolism (other than CPT-I deficiency) or in the oxidation of longer chain fatty acids (long-chain acyl-CoA dehydrogenase [LCAD], VLCAD, LCHAD, MAD deficiency) characteristically have hypertrophic or dilated cardiomyopathy (161, 164, 171). Patients often present with congestive heart failure or cardiac arrest. Arrhythmias have been reported without cardiomyopathy. Conduction disturbances are thought to be due to accumulation of toxic intermediates and can occur before the development of severe hypoglycemia. Cardiac presentations have not been described with CPT-I or MCAD deficiency.

Muscle symptoms are the hallmark of FAO defects that present in adulthood. Progressive muscle weakness, episodic muscle pain, rhabdomyolysis, and myoglobinuria after strenuous physical activity occur in adults with CPT-II, translocase, LCHAD, and VLCAD deficiency (Tables 6, 7). Symptoms may occur after prolonged exercise or exposure to cold, during fasting or an intercurrent infection. Hypoglycemia and alterations in mental status are unusual in the late onset disorders.

The characteristic biochemical features of disorders of carnitine metabolism and FAO are summarized in Tables 6 and 7. Acute metabolic crises are frequently, but not invariably, associated with hypoglycemia and metabolic acidosis. Hypoglycemia results from a combination of failure to decrease utilization of glucose (because of the absence of an alternative energy source) and impaired gluconeogenesis. Metabolic acidosis is accompanied by an increased anion gap. Mild to marked hyperammonemia may occur as a result of secondary inhibition of *n*-acetylglutamate synthesis in the urea cycle. Hepatic dysfunction generally manifests with increases in serum AST and ALT concentrations. When muscle is affected, serum creatine kinase (CK) increases during symptomatic episodes. The cause of the increased serum uric acid level is unclear.

Urinalysis shows an inappropriately low level of ketonuria relative to the duration of fasting and/or degree of hypoglycemia. Ketones are rarely completely absent from the urine. Note, however, that ketonuria is abundant in patients with defects limited to the oxidation of short chain fatty acids (short-chain acyl-CoA dehydrogenase [SCAD] and short-chain hydroxyacyl-CoA dehydrogenase [SCHAD] deficiency). In these disorders, most of the long-chain fatty acid is oxidized to ketones without difficulty; only the metabolism of the short-chain remnants is impaired.

Quantitative assays of plasma carnitine concentrations measure total carnitine as well as free carnitine and bound (or esterified) carnitine. Normally, the free fraction makes up about 80% of total carnitine. Carnitine transport defects are rare and are characterized by extremely low total and free carnitine levels in blood and urine (generally $<10 \mu\text{mol/l}$). Carnitine loading (for example, with 100 mg/kg) raises the blood level of carnitine, but produces an inappropriate carnitinuria. Secondary carnitine defi-

ciency is much more common. A low level of total plasma carnitine is usually the result of an inadequate supply of dietary carnitine, and the ratio of the free and esterified fractions to total carnitine generally remains intact. A low free/total carnitine ratio can occur for a number of reasons including physiological ketosis (when acetyl CoA binds free carnitine to form acetylcarnitine), and with certain medications (e.g., valproate binds carnitine forming valproylcarnitine). In disorders of FAO, carnitine binds with intermediate compounds in the pathway (e.g., octanoylcarnitine), resulting in decreased total and free carnitine and increased esterified fractions.

A. Diagnosis

All children with hypoglycemia should be screened for FAO disorders. Failure to make the correct diagnosis in a timely fashion increases the risk of hepatic failure or sudden death. During an episode of hypoglycemia, screening for a FAO defect should routinely include urinalysis for measurement of ketones and an analysis of urinary organic acids. Urinary ketones are usually inappropriately low for the degree of hypoglycemia; complete absence of ketones is unusual. Hypoketosis (unless clearly explained by hyperinsulinism) always warrants an investigation for FAO defects. A moderate or large amount of urinary ketones does not exclude the diagnosis of an FAO disorder.

Analysis of urine organic acids by gas chromatography/mass spectrometry is the most useful method to screen for FAO disorders. The urinary excretion of ketones is reduced (except in SCAD and SCHAD deficiencies). In all defects characterized by impaired β -oxidation of fatty acids, intermediate compounds accumulate and undergo ω -oxidation, resulting in the production of dicarboxylic acids (adipic, suberic, and sebacic acids, corresponding to the saturated fatty acids hexanoate, octanoate, and decanoate, respectively). The excretion of dicarboxylic acids is not necessarily pathological since this may occur to a limited degree during physiological ketosis. Also, patients receiving medium-chain triglycerides (MCT; e.g., in a formula), have dicarboxylic aciduria. Defects in carnitine transport and metabolism do not directly disrupt β -oxidation and are not generally associated with dicarboxylic aciduria. In 3-hydroxy-3-methylglutaryl-CoA lyase deficiency, only adipic acid is found in urine during a metabolic crisis. Other metabolites in the organic acid analysis can help to identify the particular site of the metabolic block.

Glycine and carnitine are normal cellular constituents that displace CoA from organic acyl and fatty acyl intermediates, producing acylglycines and acylcarnitines, respectively. The former is analyzed in urine, the latter in plasma or in blood filter paper specimens (172). Certain compounds have a higher affinity for glycine, others for carnitine. The specific pattern of unusual compounds identified by these techniques, in concert with the urine organic acid findings, increases the likelihood of making a

specific diagnosis. Quantitative free fatty acid profiles allow direct analysis of all fatty acid intermediates and appears to be the most sensitive test for diagnosing disorders of FAO (162). Because deficiency of carnitine and disorders of carnitine transport do not cause abnormal patterns of fatty acyl-CoA intermediates, measurement of total, free, and esterified carnitine concentrations should be included in the work-up of any patient with a suspected FAO disorder.

The importance of obtaining diagnostic specimens during the acute catabolic phase of illness (or as soon as possible after the patient has been treated) cannot be overstated. Once treatment is begun with oral and/or intravenous glucose, fatty acid flux through the defective pathway decreases so that the characteristic biochemical abnormalities necessary for establishing a diagnosis may no longer be evident. As a consequence, specimens obtained once treatment is well underway may be normal, necessitating a more invasive and potentially dangerous approach to investigating these patients.

Several American states and European regions are using tandem mass spectrometry to screen for FAO disorders and CPT-II deficiency on filter paper blood specimens obtained during the newborn period (173, 174).

There are several options for investigating the asymptomatic patient who has a history suggestive of a defect in carnitine metabolism or FAO. Plasma acylcarnitine and urinary acylglycine should be obtained in the morning after a routine overnight fast of 8–10 h duration when the child is well. Arrangements can be made for diagnostic blood and urine specimens to be obtained when the patient is under catabolic stress (e.g., during a fever or intercurrent illness). The patient can be admitted to the hospital to monitor the response to fasting (29, 175). However, because of the potential hazard of inducing an arrhythmia, hepatic failure, or sudden death, a monitored fast should be performed as a last resort in the child with undiagnosed hypoglycemia in whom all noninvasive methods have failed to yield a diagnosis. A supervised oral fat load is a practical *in vivo* test to identify defects affecting longer-chain fatty acid metabolism (176). In all cases of potential carnitine transport defects and FAO defects, especially in very young patients or when it is inappropriate for a patient to fast or undergo a provocative study, skin fibroblasts may be obtained for FAO studies and for direct enzyme analysis. In addition, mutational analysis can be performed for diseases with common mutations (e.g., MCAD and LCHAD deficiency).

B. Treatment

The specific treatment of diseases of carnitine metabolism and defects of FAO depends upon the individual defect. The primary recommendation for all disorders of FAO is to avoid prolonged fasting and ensure a regular feeding regimen when patients are at risk for acute decompensation. Provision of a continuous exogenous source of car-

bohydrate obviates dependence on fatty acids and ketones for energy. During intercurrent illnesses, or when calorie intake decreases for any reason, patients should be fed every 4 h around the clock until a normal diet is resumed and symptoms of the illness abate. When vomiting prevents dependable consumption of food or fluids, 10% dextrose solution must be given intravenously at a rate approximately 1.5 times the hepatic glucose production rate to inhibit glucose counterregulation.

Dietary therapy for defects of FAO is controversial. For the young child (above 1 year of age) who is otherwise well, raw cornstarch at night decreases the need for fatty acids as a source of energy. Restriction of fat has been used; however, overzealous fat restriction may lead to deficiencies of essential fatty acids. In defects of long-chain fat oxidation, supplemental dietary medium-chain triglycerides allows ketone synthesis to occur. The availability of fat as a substrate for energy may be of therapeutic benefit even during an acute metabolic crisis.

Carnitine supplementation (usually 100 mg/kg/day) is indicated for carnitine transport defects. Whether carnitine supplementation is beneficial for other defects of FAO is controversial. It is postulated that carnitine displaces coenzyme A bound to toxic intermediates. The liberated CoA is free to participate in other metabolic reactions, allowing excretion of the acylcarnitines.

Patients with later-onset MAD deficiency (i.e., glutaric acidemia type II) may respond to high-dosage (100–200 mg/kg/day) riboflavin supplementation.

Because defects in carnitine metabolism and FAO may be asymptomatic, the siblings of probands should be screened and parents should be counseled regarding the autosomal recessive pattern of inheritance of these diseases. Prenatal diagnosis may be available depending on the specific disorder.

XIV. DETERMINING THE CAUSE OF HYPOGLYCEMIA

The cause of hypoglycemia is often readily apparent; for example, in the child with type 1 diabetes mellitus treated with insulin or when hypoglycemia occurs in a child with fulminant hepatitis or Reye's syndrome. When the cause of hypoglycemia is not obvious, following the diagnostic approach outlined below will usually lead to the specific cause. Determining the cause begins with a detailed history and physical examination. Important features of the history and physical examination are shown in Tables 8 and 9, and a diagnostic algorithm based on key clinical and biochemical features is shown in Figure 5. Infants with hyperinsulinism who do not present in the newborn period usually present within the first 6–12 months of life. Mild forms of congenital hyperinsulinism may present for the first time in childhood or adolescence. When hyperinsulinemic hypoglycemia presents after infancy, one should suspect an islet cell adenoma (often part of mul-

Table 8 History

Birth weight, gestational age, maternal health and medications
Symptoms of hypoglycemia at birth or during neonatal period
Prolonged neonatal jaundice
Age at onset of symptoms
Family history of hypoglycemia
History of consanguinity
Frequency of hypoglycemia
Temporal relationship to feedings
<4 h suggests a defect in glycogenolysis or hyperinsulinism
10–12 h suggests a defect in gluconeogenesis or fatty acid β -oxidation
Specific content of feedings and relationship to onset of symptoms
Food intolerance or aversion
Unexplained infant deaths or SIDS in family; Reye's syndrome, cardiomyopathy, myopathy
Potential drug exposure (oral hypoglycemic agents, insulin)
Hypoglycemia after an adult party: alcohol ingestion
Recurrent "pneumonia": episodes of hyperventilation from metabolic acidosis
Unusual odors, especially when sick

multiple endocrine neoplasia type 1 syndrome). Growth hormone and/or cortisol deficiency usually presents in the newborn period or in early childhood. Accelerated starvation usually presents at 18 months to 5 years old. Hepatomegaly, ketosis, and metabolic acidosis suggests an inborn error of metabolism, which may present either in the neonatal period or later in infancy, usually precipitated by cessation of overnight feeding or an infection that interrupts the child's normal feeding pattern and causes catabolic stress.

Glucose meters are widely used in newborn nurseries and in emergency departments to screen for hypoglycemia. These instruments are not consistently reliable at low blood glucose concentrations; therefore, any value below 60 mg/dl (3.3 mmol/l) should be confirmed by a laboratory measurement of the plasma glucose concentration (177). In addition, a simultaneous so-called critical blood sample should be obtained for the measurement of hormones, metabolic substrates, and serum chemistries (see Table 10).

The first urine sample obtained after the episode of hypoglycemia should be tested for the presence of ketones (ketotic vs. nonketotic hypoglycemia), reducing sugars (suggest galactosemia or fructose intolerance), and glucose using a glucose-specific method. An aliquot should be saved and frozen for possible later analysis of amino acids, organic acids, and acylglycines after the initial laboratory investigations have been completed.

The initial laboratory evaluation should include measurement of serum insulin to determine whether the hypoglycemia is associated with a normal (suppressed) or an inappropriately increased serum insulin concentration, and measurement of urinary ketones to determine if the hypoglycemia is associated with ketosis. Absence of urinary ketones or their presence in only trace or small amounts (i.e., nonketotic or hypoketotic hypoglycemia), is characteristic of hyperinsulinism and disorders of carnitine metabolism and FAO and/or ketogenesis. The serum C-peptide concentration is low or undetectable when hyperinsulinism is caused by exogenous insulin administration. If the serum insulin concentration is appropriately suppressed ($<2 \mu\text{U/ml}$ with a highly sensitive insulin assay), the diagnosis is likely to be a disorder of FAO. Encephalopathy is common at the time of acute metabolic decompensation; the liver may be moderately enlarged from acute fatty infiltration (microvesicular steatosis), and liver enzymes (AST, ALT) and plasma ammonia levels are increased during acute episodes of catabolic stress (164). If a disorder of FAO is suspected, plasma total and esterified carnitine, plasma (or filter paper) acylcarnitines (172), and plasma free fatty acids should be measured, and urine analyzed for organic acids and acylglycines (178).

Ketosis with hypoglycemia is a normal physiological response to a falling blood glucose concentration. The differential diagnosis of the hypoglycemic child with an appropriately suppressed serum insulin concentration and ketosis (Table 5) can be further delineated depending on whether or not the liver is large (Fig. 5). Elevated levels of GH and cortisol exclude deficiency of these counter-regulatory hormones and obviate the need for further testing. On the other hand, random values that appear to be inappropriately low during a spontaneous episode of hypoglycemia do not constitute definitive evidence of deficient secretion. Specific testing must be performed.

A large liver suggests a glycogen storage disease or disorder of gluconeogenesis (e.g., fructose 1,6-bisphosphatase deficiency). The liver size is normal in patients with accelerated starvation, cortisol deficiency, GH deficiency, glycogen synthase deficiency, maple syrup urine disease, and the other conditions listed in Table 3. Transient enlargement of the liver during an acute metabolic crisis can occur in organic acidemia, FAO defects, and in disorders of carnitine metabolism, and results from acute fatty deposition in the cytosol associated with impaired mitochondrial function.

A specific diagnosis of the cause of the hypoglycemia usually is evident from the analysis of the results of the so-called critical blood sample obtained at the time of hypoglycemia (Table 10) and application of the diagnostic algorithm shown in Figure 5. However, if the laboratory data required to make a diagnosis are not available, it may be necessary to perform a comprehensive evaluation of intermediary metabolism by reproducing the conditions

Table 9 Findings on Physical Examination

Examination	Possible causes
Short stature; growth failure	GH deficiency, hypopituitarism
Microphallus	GH deficiency, hypopituitarism
Midline facial defects	GH deficiency, hypopituitarism

Gallop or murmur	Disorder of carnitine transport or metabolism
Cardiomyopathy	

that caused the hypoglycemia. This involves measurement of hormones and metabolic substrates that reflect carbohydrate, fat, and amino acid metabolism during a monitored fast of specified duration depending on the age of the child (175). Fasting may be hazardous and can even be lethal in patients with a disorder of FAO. Before subjecting any child to a monitored fast, one should first attempt to rule out a disorder of FAO by measuring non-fasting plasma acylcarnitines (by tandem mass spectrometry if available) (172) and urinary acylglycines (178).

XV. TREATMENT

Immediately after the critical blood sample has been obtained, 0.3 g/kg glucose is injected intravenously over 10 min to restore the plasma glucose concentration to normal. A continuous infusion of 10% dextrose solution at a rate of $\sim 6\text{--}8$ mg/kg/min is given to maintain normoglycemia. This rate of glucose infusion is usually sufficient to reverse catabolism. The plasma glucose concentration is monitored and the infusion rate adjusted to maintain a level of ~ 80 mg/dl (4.5 mmol/l). Valuable diagnostic information can be obtained from the response to treatment. Infants and children with hyperinsulinism characteristi-

cally require considerably higher rates (14.5 ± 1.7 mg/kg/min) of glucose infusion to prevent hypoglycemia (179). In disorders of FAO, administration of glucose at $\sim 1.5 \times$ basal glucose production (10 mg/kg/min) stimulates insulin secretion, inhibits lipolysis, and reverses the acute metabolic disorder and leads to a decrease in liver size to normal over several days.

XVI. HYPOGLYCEMIA AND DIABETES MELLITUS

Hypoglycemia is the most frequent acute complication of the treatment of diabetes mellitus in children and adolescents and is the principal factor that limits attempts to intensify treatment aimed at achieving near-normal glycemic control (180, 181). Patients with type 1 diabetes mellitus are susceptible to hypoglycemia for many reasons, including the nonphysiological nature of insulin replacement therapy, inconsistencies in food intake and exercise, and defective counterregulatory hormone responses to hypoglycemia (Table 11). Because the glucagon response to hypoglycemia is lost early in the course of the disease (182, 183), patients with diabetes mellitus are dependent on sympathoadrenal responses (8) to prevent or

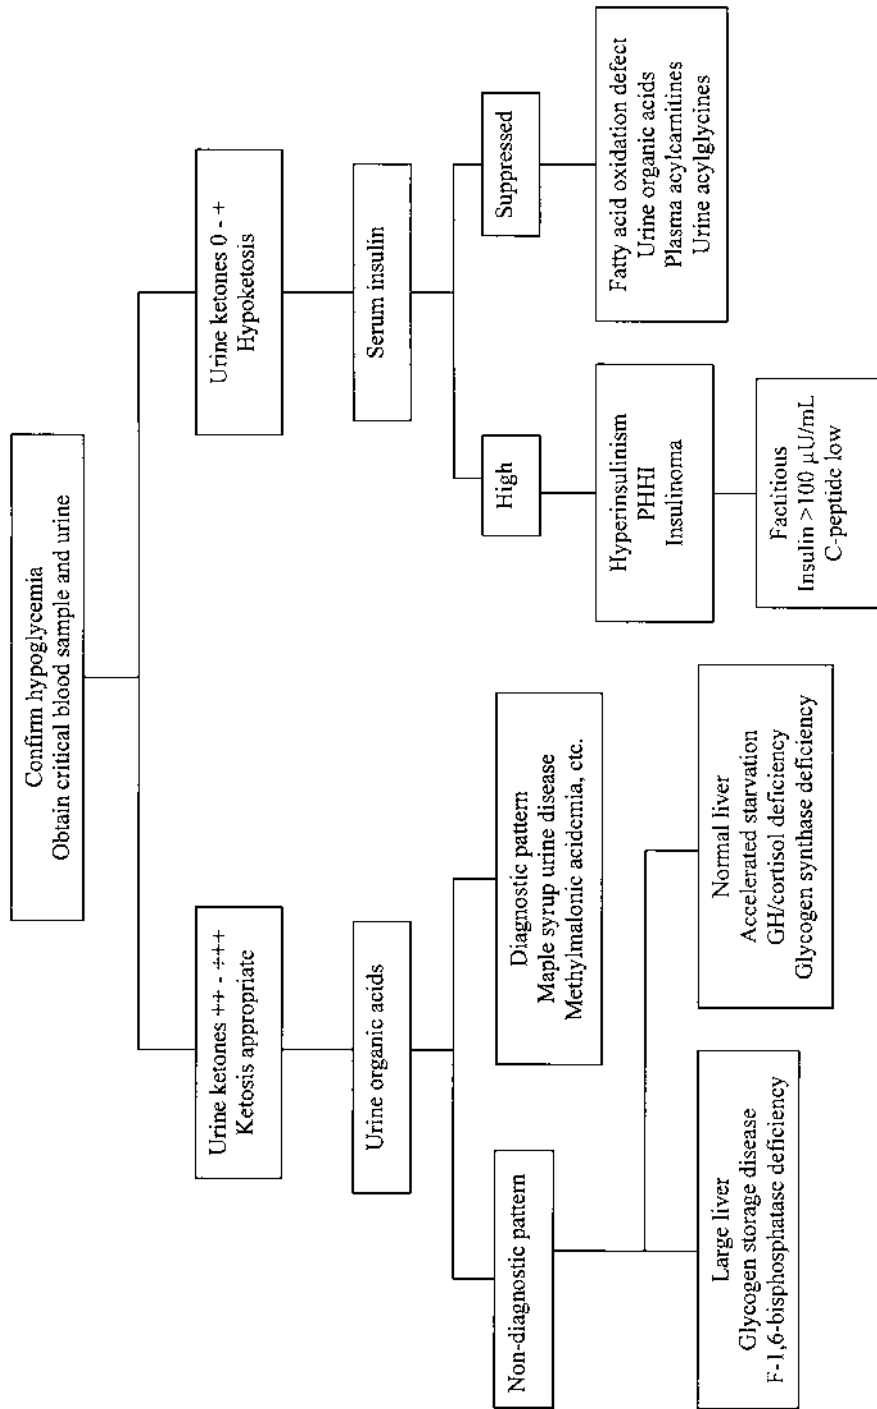

Figure 5 Algorithm for diagnosis of hypoglycemia.

correct hypoglycemia. Mild hypoglycemia itself reduces epinephrine responses and symptomatic awareness of subsequent episodes of hypoglycemia (43, 184, 185).

A. Causes of Hypoglycemia in Diabetes Mellitus

Patient errors relating to insulin dosage, decreased food intake, or unplanned exercise account for 50–85% of episodes of hypoglycemia in children and adolescents (186–191). After years of living with diabetes, some patients and/or their parents conduct their routine diabetes self-care practices without thinking about the intricate interplay among insulin, food, and exercise (192).

B. Symptoms and Signs

Symptoms of hypoglycemia are caused by neuronal deprivation of glucose and are autonomic (adrenergic), neuroglycopenic, or a combination of the two. The most common signs and symptoms of hypoglycemia in diabetic children are pallor, weakness, tremor, hunger, fatigue, drowsiness, sweating, and headache (186, 193). In contrast to adolescents, autonomic symptoms are less common in children younger than 6 years old whose symptoms are more often neuroglycopenic or nonspecific in nature (193). Symptoms of hypoglycemia experienced by adults with diabetes have been categorized into subgroups: autonomic (sweating, palpitations, shaking, hunger), neuroglycopenic (confusion, drowsiness, odd behavior, speech difficulty, incoordination), and nonspecific malaise (hunger and headache) (194).

Manifestations of hypoglycemia in young children with diabetes mellitus tend to differ from those of insulin-treated adults. In young children, behavioral changes are often the primary manifestation of hypoglycemia. This difference has important implications for parent education on hypoglycemia. Also, autonomic and neuroglycopenic symptoms reported by children and their parents tend to cluster. This contrasts with adult patients who are usually able to differentiate between these two types of symptoms. In children, the coalescence of autonomic and neurogly-

copenic symptoms may indicate that both types of symptom are generated at similar glyceic thresholds. Both parents and children report a coherent cluster of symptoms related to behavioral change during hypoglycemia. Behavioral changes, therefore, are important premonitory signs of hypoglycemia in young children (195).

Hypoglycemia is classified in terms of its severity as mild, moderate, or severe; most episodes are mild (193). Parents are most often alerted to the presence of hypoglycemia in a very young child by noting pallor, drowsiness, or unexplained irritability. Cognitive deficits usually do not accompany mild reactions, and older children are able to treat themselves. Mild symptoms abate within 10–15 min after an appropriate dose of rapidly absorbed carbohydrate. Moderate hypoglycemia has neuroglycopenic as well as adrenergic symptoms: headache, mood changes, irritability, decreased attentiveness, and drowsiness. Young patients typically require assistance with treatment because they are often confused and have impaired judgment; weakness and poor coordination may make it difficult to treat oneself. Moderate reactions produce longer-lasting symptoms and may require a second dose of rapidly absorbed carbohydrate. Severe hypoglycemia is characterized by unresponsiveness, unconsciousness, or convulsions and requires emergency treatment with parenteral glucagon administered or intravenous glucose given by an emergency medical technician in the field or in a hospital emergency department. The definition of severe hypoglycemia in the Diabetes Control and Complications Trial (DCCT) was symptoms consistent with hypoglycemia requiring the assistance of another person for treatment, associated with a blood glucose concentration less than 50 mg/dl or prompt recovery after oral carbohydrate, SC glucagon, or IV glucose (181).

Patients with longer duration of diabetes describe a change in their symptomatology over time, characterized by reduced occurrence of autonomic symptoms and increased frequency of neuroglycopenic symptoms (drowsiness, difficulty concentrating, lack of coordination). Patients must learn to recognize the change in symptoms to prevent severe episodes (196). Furthermore, the blood glucose concentration at which symptoms occur varies

Table 11 Causes of Hypoglycemia in Diabetes Mellitus

Insulin errors (inadvertent or deliberate)
Reversal of morning and evening dose
Reversal of short- or rapid-acting insulin and intermediate-acting insulin
Improper timing of insulin in relation to food
Excessive insulin dosage
Surreptitious insulin administration, suicide gesture, or attempt
Erratic or altered absorption
Inadvertent intramuscular injection
More rapid absorption from exercising limbs
Unpredictable absorption from lipohypertrophy at injection sites
More rapid absorption after sauna, hot bath, sunbathing
Diet
Omission or reduced size of meals or snacks
Delayed snacks or meals
Eating disorders
Gastroparesis
Malabsorption (e.g., gluten enteropathy)
Exercise
Unplanned physical activity
Prolonged duration and/or increased intensity of physical activity
Failure to reduce the dose of intermediate-acting insulin to combat the so-called lag effect of exercise
Alcohol and/or drugs
Impaired gluconeogenesis from excessive consumption of ethanol
Impaired cognition from use of ethanol, marijuana, cocaine, other recreational drugs
Hypoglycemia-associated autonomic failure
Unawareness of hypoglycemia
Defective glucose counterregulation
Miscellaneous uncommon causes of hypoglycemia
Adrenocortical insufficiency
Hypothyroidism
Growth hormone deficiency
Renal failure
Decreased insulin requirement in first trimester of pregnancy
Insulin antibodies

among patients. This threshold may also vary in the same individual in parallel with antecedent glyceemic control. For example, children with long-standing hyperglycemia as a result of poor diabetes control experience symptoms of hypoglycemia at higher blood glucose concentrations than children with good glyceemic control, similar to adults with diabetes (197).

C. Impact of Hypoglycemia

Occasional, mild symptomatic hypoglycemia may be the price to pay for near-normal glyceemic control (198–202).

However, it is important to appreciate that cognitive function deteriorates at low blood glucose levels even in the absence of typical symptoms (203, 204). Moderate and severe hypoglycemia is disabling, affects school performance, and makes driving a car or operating dangerous machinery extremely hazardous (203, 205–207). The utmost effort should be made to avoid such events. Repeated or prolonged severe hypoglycemia can cause permanent central nervous system damage (208), especially in very young children (209). Fortunately, hypoglycemia is an unusual cause of death in children with type 1 diabetes (210). Although diabetes is not typically associated with reduced intelligence in children, subtle neurocognitive impairments may result if onset occurs before 5 years (211) or the child has seizures from hypoglycemia (212, 213). The neurocognitive sequelae of intensive diabetes management in children whose brains are still developing are still largely unknown. Preliminary findings suggest poorer memory skills, presumably the consequence of recurrent and severe hypoglycemia (214).

The confidence of the patient and members of the patient's family is often shaken after an episode of severe hypoglycemia. The fear of hypoglycemia may cause the patient or family to change its diabetes management strategies in an effort to avoid subsequent episodes of hypoglycemia. The fear of hypoglycemia, therefore, can become a barrier to attaining and maintaining optimal glyceemic control. Examples of altered patient behaviors that result in worsening metabolic control include chronic overeating or selection of inadequate dosages of insulin to maintain higher blood glucose levels perceived as being safe (215–217). Concern about nocturnal hypoglycemia causes more anxiety for some parents than any other aspect of diabetes, including the fear of long-term complications. Parents may fear that an episode of severe hypoglycemia during the night may not be treated in a timely fashion or that an episode could go entirely undetected and lead to permanent brain damage or death (218).

D. Frequency of Hypoglycemia

The true frequency of mild (self-treated) symptomatic hypoglycemia is almost impossible to ascertain because mild episodes are quickly forgotten and/or are not recorded. In a random sample of 47 children attending a diabetes clinic, the average incidence of symptomatic hypoglycemia was once every 33 days (range, 0–5.2 times per month), and occurred more frequently in children with the lowest glycosylated hemoglobin levels (199). In a 12 month population-based study, Aman et al. found that mild episodes (managed by the child without assistance) occurred in 97% of children and occurred at least once a week in 53% (186). More recently, Tupola et al. (193) prospectively examined the frequency of hypoglycemia (blood glucose <3 mmol/l [54 mg/dl]) in 161 children and adolescents predominantly treated with multiple doses of insulin, who were asked to document hypoglycemia epi-

sodes in a 3 month diary. Fifty-two percent of the clinic population experienced episodes of hypoglycemia (0.6 hypoglycemia events per patient per month), most of which (77%) were mild.

The literature is replete with reports of the frequency of severe hypoglycemia in children and adolescents with diabetes (187–191, 198, 200, 201, 219–228). However, various methods of collecting data and different definitions of hypoglycemia and methods of insulin replacement make comparisons among the reports difficult (229). For example, in some studies, severe hypoglycemia is defined as loss of consciousness, whereas others include children who required assistance with treatment. In young children, all episodes of hypoglycemia require the assistance of a third party for treatment regardless of the severity of the symptoms. It is not surprising, therefore, that the reported incidence of moderate or severe hypoglycemia in the pediatric diabetes population varies widely. The incidence of severe hypoglycemia can be assessed with some reliability by defining severe hypoglycemia as requiring the assistance of another person, irrespective of whether it induces loss of consciousness or convulsions. The incidence of severe hypoglycemia varies from 3.1 (227) to 134 episodes per 100 patient-years (202); most studies document a range of 10–40 episodes per 100 patient-years (229, 230). The adolescent cohort of the DCCT had a frequency of severe hypoglycemia of 27.8 and 85.7 episodes per 100 patient-years for the conventional and intensive treatment groups, respectively (201). It is also likely that severe hypoglycemia in pediatric studies has been underreported. This is suggested by the fact that the rate of severe hypoglycemia in conventionally treated adolescents in the year before the DCCT started was 15.7 per 100 patient-years, but increased to 27.8 per 100 patient-years during the course of the study, whereas hemoglobin A1c did not decrease ($9.20 \pm 1.8\%$ before and $9.76 \pm 0.12\%$ during the study) (181, 201).

Many, but not all, studies have found an increased frequency of severe hypoglycemia in younger children (191, 200, 222, 223, 225, 228) and in association with lower hemoglobin A1c concentrations (188, 189, 198, 200, 201, 222, 223, 225, 227). Other factors associated with a higher risk of moderate and severe hypoglycemia are a prior history of severe hypoglycemia (181, 189, 221, 225), relatively higher doses of insulin and low C-peptide secretion (181, 221, 225, 227), longer duration of diabetes (190, 223, 226), and male gender (181, 220).

E. Nocturnal Hypoglycemia

Hypoglycemia, often asymptomatic, frequently occurs during sleep. Moderate and severe (with coma and seizures) hypoglycemia are more common during the night and early morning (before breakfast) than during the daytime (223, 231). In the DCCT, 55% of severe hypoglycemia events occurred during sleep and 43% occurred between midnight and 8 a.m. (181, 231).

Studies of diabetic children and adolescents, in hospital or at home, in which blood glucose concentrations were measured frequently during the night, show a high incidence (14–47%) of asymptomatic hypoglycemia. Such episodes during sleep often exceed 4 h in duration (232–238). Up to half these episodes may be undetected because the subject does not wake from sleep. The incidence of hypoglycemia on any given night may be affected by numerous factors, including the insulin regimen, the timing and content of meals and snacks, and antecedent physical activity. The highest frequency of asymptomatic nocturnal hypoglycemia occurs in children less than 10 years old (234, 236–238). Low blood glucose concentrations in the early morning (before breakfast) are associated with a higher frequency of preceding nocturnal hypoglycemia. Knowledge of this fact is useful in counseling patients to modify the evening insulin regimen and bedtime snack to prevent more severe nocturnal hypoglycemia.

Sleep impairs counterregulatory hormone responses to hypoglycemia in normal subjects and in patients with diabetes mellitus (239). Because a rise in plasma epinephrine levels is normally the main hormonal defense against hypoglycemia, impaired counterregulatory hormone responses to hypoglycemia explain the increased susceptibility to hypoglycemia during sleep. This phenomenon explains the high frequency of nocturnal hypoglycemia. Asymptomatic nocturnal hypoglycemia may itself result in further deficits in counterregulatory hormone responses (240). Thus, impaired defenses against hypoglycemia during sleep may contribute to the vicious cycle of hypoglycemia, impaired counterregulatory responses, and unawareness of hypoglycemia either awake or asleep. Recurrent asymptomatic nocturnal hypoglycemia is an important cause of hypoglycemia unawareness, which, in turn, leads to more frequent and severe hypoglycemia because of failure to experience autonomic warning symptoms before the onset of neuroglycopenia (180).

F. Treatment

Most episodes of symptomatic hypoglycemia are self-treated (except in pre-school-age children) with rapidly absorbed carbohydrate such as glucose tablets, juices, soft drinks, candy, crackers, milk. Glucose tablets raise blood glucose levels more rapidly than do orange juice or milk, and the dosage is easily calibrated (241). Glucose tablets are the treatment of choice for children old enough to chew and swallow large tablets safely. The recommended dosage is 0.3 g glucose/kg body weight. The glycemic response to oral glucose usually lasts less than 2 h (242). Therefore, unless a scheduled meal or snack is due within an hour of the event, following treatment with oral glucose the patient should be given either a mixed snack containing both carbohydrate and protein or a meal.

Severe reactions (unresponsiveness, unconsciousness, or convulsions) require emergency treatment with paren-

teral glucagon (IM or SC). Buccal and rectal administration of glucose is ineffective (243). Parenteral glucagon is as effective in treating severe hypoglycemia in children (244) as it is in adults (242, 245). Glucagon raises blood glucose levels within 5–15 min and usually relieves symptoms of hypoglycemia (242, 245). Symptoms of experimentally induced hypoglycemia in diabetic children are relieved within 10 min of giving glucagon by either SC or IM injection. Mean blood glucose and plasma glucagon levels are slightly but not significantly higher after IM than SC injection (244). Both 10 $\mu\text{g}/\text{kg}$ and 20 $\mu\text{g}/\text{kg}$ of glucagon relieve clinical signs and symptoms, but the increment in blood glucose concentration after 10 min is less after the 10 $\mu\text{g}/\text{kg}$ dose (1.1 ± 0.3 vs. 1.7 ± 0.7 mmol/l). However, after 20 and 30 min the differences in blood glucose concentrations are not significant. Nausea and/or vomiting can be expected to occur after the injection in a minority of children who receive a dose of 20 $\mu\text{g}/\text{kg}$, but usually do not occur after receiving 10 $\mu\text{g}/\text{kg}$. Excessively high plasma glucagon levels are more likely to cause nausea and/or vomiting. The recommended dose, therefore, is 15 $\mu\text{g}/\text{kg}$ to a maximum of 1.0 mg. In diabetic children (244) and in healthy adults (245) there appears to be no important difference between the effects of glucagon injected SC or IM. The plasma glucagon levels attained are higher than those in peripheral venous or portal blood of healthy adults during insulin-induced hypoglycemia, and are probably higher than is necessary for maximal effect. The increase in blood glucose concentration after glucagon administration is sustained for at least 30 min; it is therefore not necessary to repeat the dose or force the child to eat or drink for at least 30 min. Intranasal glucagon has a similar effect, but is not available in the United States (246). In an emergency department or hospital, the preferred treatment is intravenous glucose (0.3 g/kg). Because the glycemic response is transient after bolus administration of glucose, the patient should continue to receive intravenous glucose infusion until she or he is able to swallow safely.

If severe hypoglycemia was prolonged and the patient had a seizure, complete recovery of normal mental and neurological function may take many hours despite restoration of a normal blood glucose level (247). Permanent hemiparesis, or other neurological sequelae, is rare (248, 249). The postictal period may be complicated by headache, lethargy, nausea, vomiting, and aching muscles.

Diabetes in the Child and Adolescent

Arlan L. Rosenbloom and Janet H. Silverstein

University of Florida College of Medicine, Gainesville, Florida, U.S.A.

I. INTRODUCTION

Until the 1970s, the care and investigation of childhood diabetes were pursued by internists, pediatricians, nephrologists, and general physicians. In 1971 it was estimated that visits for diabetes by those 0–15 years of age were equally divided among internists, general physicians, and general pediatricians (1). At that time there were few pediatric endocrinologists, virtually none in private practice, and most of them did not consider diabetes to be an endocrine disorder. The third (1965) edition of what was then the only textbook of pediatric endocrinology devotes a short paragraph to diabetes mellitus as one of half a dozen causes of hyperglycemia (2). By 1993, pediatric endocrinologists accounted for 35% of all visits of 0–21-year-old diabetes patients and nearly half of these were to private practicing pediatric endocrinologists; the remainder included 37% to internists (most likely the older adolescents and young adults) and 28% to general pediatricians (3). In pediatric endocrinology practice, diabetes now accounts for 50–60% of the workload (3). The movement of diabetology into mainstream pediatric endocrinology has multiple causes beyond the clinical importance and challenge of the problem, including the scientific excitement about diabetes research (and its funding), the extensive endocrine physiology that diabetes affects, and the inclusion of diabetes in the accreditation requirements of training programs and board certification for pediatric endocrinology.

This history deserves consideration and reflection because we are presently engaged in a comparable revolution in what is considered to be within the purview of pediatric endocrinology. The contemporary epidemic of type 2 diabetes in youth has confronted pediatric diabetes specialists with a major responsibility for a condition previously rare in the pediatric age group. Furthermore, pediatric endocrinologists have had to reconsider the associated problem of obesity, which has long been a frequent

reason for referral to the endocrine clinic, but rarely dealt with after ruling out unusual syndromic or medical causes. As they earlier did for diabetes, pediatric diabetologists are becoming involved in creating teams to deal with this difficult and growing clinical challenge of obesity and type 2 diabetes.

II. DIAGNOSIS AND CLASSIFICATION

The diagnosis of diabetes includes a wide variety of diseases characterized by hyperglycemia. Because insulin is the only physiologically significant hypoglycemic hormone, hyperglycemia is the result of either impaired secretion of insulin from the beta cells of the pancreas (type 1 diabetes) or resistance to the effect of insulin in the liver, muscle, and fat cells exceeding a limited capacity of the pancreas to compensate (type 2 diabetes). Criteria for the diagnosis of diabetes have recently been revised and categories of impaired glucose tolerance and impaired fasting glucose added, reflecting the recognition that these pre-clinical glucose intolerance states are associated with increased cardiovascular morbidity (4). Table 1 lists the current recommendations of the American Diabetes Association (4). There is no reason to apply different criteria with children and adolescents.

In 1997 the American Diabetes Association published revisions of the classification of diabetes, based on etiology, and these were modified in 1999 (4). Early taxonomy had the common forms of diabetes separated by age of onset (juvenile and maturity or adult), which a 1979 report of the U.S. National Diabetes Data Group revised to emphasize treatment, using the terms insulin-dependent (IDDM) and noninsulin-dependent diabetes (NIDDM) for the principal forms (5). Contemporary understanding of the pathogenesis of various forms of diabetes has made this classification based on treatment inappropriate. Table 2 is adapted from the classification published by the ADA expert committee (4).

A. Type 1 Diabetes

Diabetes occurring in childhood remains predominantly immune-mediated type 1 disease associated with histocompatibility locus (HLA) specificities. Type 1 diabetes will be discussed in detail in the next section. Idiopathic type 1 diabetes may be difficult to differentiate from the immune-mediated form. Many, if not most, African-American patients who have type 1 disease without evidence of autoimmunity have what has been termed atypical diabetes mellitus (ADM) or Flatbush diabetes (6, 7). This condition has its onset throughout childhood and rarely past age 40, and is not associated with HLA specificities. Further characteristics are described in Table 3.

B. Type 2 Diabetes

Type 2 diabetes in childhood and adolescence now accounts for 10–50% of new patients with diabetes in this age group, depending on the ethnic/racial mix of the population served (8). Detailed discussion of this form of diabetes is in a subsequent section and the characteristics are listed in Table 3.

C. Maturity-Onset Diabetes of the Young

This is a stable form of youth-onset (under 25 years of age) diabetes inherited in an autosomal dominant fashion and affecting almost exclusively white patients (Table 3). Six molecular causes of MODY have been identified, affecting beta-cell function. Its frequency among patients with diabetes is reported to vary from <0.2 to 5% in various populations (9).

D. Mitochondrial Mutations

Diabetes and deafness may be associated as a result of mutations in mitochondrial DNA (10–12).

Table 1 Criteria for the Diagnosis of Diabetes

Symptoms plus random plasma glucose concentration >200 mg/dl (11 mmol/l), *or*
 Fasting plasma glucose >126 mg/dl (7 mmol/l), *or*
 2 h plasma glucose >200 mg/dl (11 mmol/l) during oral glucose tolerance test (OGTT). The test should be performed using a glucose load containing the equivalent of 75 g anhydrous glucose dissolved in water for those weighing >43 kg and 1.75 g/kg for those weighing <43 kg.

In the absence of marked hyperglycemia with decompensation, these criteria should be confirmed by repeat testing on a different day. OGTT is not recommended for routine clinical use.

Impaired glucose tolerance = 2 h plasma glucose 140–200 mg/dl
 Impaired fasting glucose = 110–125 mg/dl

Table 2 Classification of Causes of Diabetes Mellitus

I. Type 1 diabetes^a (β -cell destruction), usually leading to absolute insulin deficiency

A. Immune-mediated
 B. Idiopathic

II. Type 2 diabetes^a: may range from predominantly insulin resistance with relative insulin deficiency to a predominantly secretory defect with insulin resistance

III. Other specific types

A. Genetic defects of β -cell function

1. Maturity-onset diabetes of the young
2. Mitochondrial defects

B. Genetic defects in insulin action

1. Type A insulin resistance
2. Leprechaunism
3. Rabson-Mendenhall syndrome
4. Lipotrophic diabetes

C. Diseases of the exocrine pancreas

1. Pancreatitis
2. Trauma/pancreatectomy
3. Neoplasia
4. Cystic fibrosis
5. Hemochromatosis
6. Fibrocalculous pancreatopathy

D. Endocrinopathies

1. Acromegaly
2. Cushing syndrome
3. Glucagonoma
4. Pheochromocytoma
5. Hyperthyroidism
6. Somatostatinoma
7. Aldosteronoma

E. Drug- or chemical-induced

1. Vacor
2. Pentamidine
3. Nicotinic acid
4. Glucocorticoids
5. Thyroid hormone
6. Diazoxide
7. β -adrenergic agonists
8. Thiazides
9. Dilantin
10. α -Interferon

F. Infections

1. Congenital rubella
2. Cytomegalovirus

G. Uncommon forms

1. “Stiff-man” syndrome
2. Anti-insulin receptor antibodies

Table 2 Continued

H. Other genetic syndromes sometimes associated with diabetes
1. Down syndrome
2. Klinefelter syndrome
3. Turner syndrome
4. Wolfram syndrome
5. Friedreich ataxia
6. Huntington chorea
7. Laurence-Moon-Biedl syndrome
8. Myotonic dystrophy
9. Porphyria
10. Prader-Willi syndrome
IV. Gestational diabetes mellitus

^aPatients with any form of diabetes may require insulin treatment at some stage of their disease. Such use of insulin does not, of itself, classify the patient's disease.

E. Genetic Defects in Insulin Action

Genetically determined abnormalities of insulin action are very rare as a cause of diabetes, ranging from mild hyperinsulinemia with modest hyperglycemia to severe diabetes (13). The structure and function of the insulin receptor are intact in the insulin resistance of lipotrophic diabetes, indicating that the defect lies in postreceptor transduction (14).

F. Diseases of the Exocrine Pancreas

Diffuse injury to the pancreas needs to be relatively extensive to result in diabetes, because of the small volume

occupied by the beta cells, with the exception of carcinoma involving the pancreas, which is a condition not seen in children. With improved survival, increasing numbers of patients with cystic fibrosis are developing diabetes (15).

G. Endocrinopathies

Diabetes has been described in adults with hormone excess syndromes including acromegaly, Cushing syndrome, glucagonoma, and pheochromocytoma (16). There has been recent concern about the use of pharmacological doses of growth hormone in children who do not have growth hormone deficiency, which may be increasing the risk for type 2 diabetes (17, 18).

H. Drug- or Chemical-Induced Diabetes

A large number of drugs used in pediatric care can impair insulin secretion, increase gluconeogenesis, or increase insulin resistance, resulting in hyperglycemia or the precipitation of diabetes in a susceptible individual (19, 20). The rat poison, Vacor, and pentamidine given intravenously can permanently destroy beta cells (21–24). Other drugs can impair insulin action, probably the most common being glucocorticoids (19, 20).

I. Infections

Numerous viruses have been implicated in the induction of diabetes, but the strongest evidence of direct causation comes from the experience with congenital rubella (25) which is, fortunately, now rarely seen.

Table 3 Classification of the Types of Diabetes Seen in Children

	Type 1	ADM	MODY	Type 2
Age at onset	Throughout childhood	Pubertal	Pubertal	Pubertal
Predominant race or ethnic distribution	All (low frequency in Asians)	African American (AA)	White	Nonwhite Hispanic, AA, Native American
Onset	Acute, severe	Acute, severe	Subtle	Subtle to severe
Islet autoimmunity	Present	Absent	Absent	Unusual
Insulin secretion	Very low	Moderately low	Variable	Variable
Insulin sensitivity	Normal (with BG ^b control)	Normal	Normal	Decreased
Ketosis, DKA at onset	Up to 40%	Common	Rare	Up to 33%
Obesity	As in population	As in population	Uncommon	>90%
Proportion of diabetes	~70–80% ^a	<10%	<5%	20–25% ^a
Percentage of probands with affected first-degree relative	5–10%	>75%	100%	~80%
Mode of inheritance	Nonmendelian, generally sporadic	Autosomal dominant	Autosomal dominant	Nonmendelian, strongly familial

^aThe proportion of pediatric diabetes patients having type 2 diabetes will vary with racial/ethnic mix of the population and it is increasing.

^bBG = blood glucose.

Source: Adapted from Ref. 26.

The distinctions indicated by the typical features in Table 3 are not always as certain as one would like. There are a number of reasons for difficulties in classification. With the increased frequency of obesity in childhood, a substantial number of newly diagnosed type 1 patients and ADM patients will be obese, raising the question of type 2 disease. Because some type 2 patients and almost all ADM have ketoacidosis, this feature is not helpful for differentiating non-type 1 from type 1 diabetes. The specificity of a family history of type 2 disease is low because of the high frequency of this disorder in the general population, particularly in populations of nonwhite heritage. Furthermore, a family history of type 2 diabetes is three times as likely with type 1 diabetes as in the general population; conversely, type 1 diabetes is more frequent in the relatives of patients with type 2 disease. Genetic interaction between type 1 and type 2 diabetes is further suggested by HLA haplotype interaction and the finding of islet autoimmunity markers at onset in some children and adults with typical type 2 disease (27). Insulin or C-peptide measurements at the onset of diabetes may not be helpful because of the recovery phase of autoimmune diabetes indicating reasonable beta cell function and, conversely, glucose toxicity/lipotoxicity in nonautoimmune diabetes, which may impair insulin secretion at the time of testing.

A study of 700 newly diagnosed 5–19-year-old patients from three university centers in Florida over a 5 year period indicated that 3% of those initially classified as having type 1 diabetes (17/605) were later classified as having type 2 disease; 8% of those initially diagnosed as type 2 disease were subsequently reclassified as having type 1 diabetes (6/77) (28). Most of the 17 originally considered to have type 1 disease and later determined to have type 2 diabetes were diagnosed with ketosis or in ketoacidosis. Those six with an initial diagnosis of type 2 diabetes who were subsequently considered to have type 1 disease were, typically, overweight youngsters without diabetes-related antibodies; however, over the next few years they had a clinical course most consistent with type 1 disease. In this relatively sophisticated clinical setting, the proportion of patients in whom classification may be problematic is less than 5% of newly diagnosed children and youth.

Table 4 summarizes clinical characteristics that are helpful in differentiating type 1 and type 2 diabetes in children and adolescents. In those with acute onset who are not obese, and not African-American, type 1 diabetes is highly likely and further testing is not necessary. Non-obese African-American youngsters with acute-onset diabetes who have a three-generation family history of diabetes indicative of autosomal dominant transmission and do not have islet autoimmunity markers are very likely to have ADM. Islet cell autoimmunity testing should be considered in obese patients who have acute onset; if this is not practical or if the patient has acanthosis nigricans, the ability to reduce and stop the acutely required insulin over

the first several months, with weight reduction, exercise, and oral hypoglycemic therapy as necessary, will clarify the diagnosis.

With insidious onset, obese individuals can be considered to have type 2 disease. If the patient is lean, islet autoantibody testing will be helpful and, if results are positive, indicate early detection of type 1 diabetes. Absence of islet cell autoimmunity in the lean individual may indicate MODY, in which case testing of family members will be productive; the pattern of autosomal dominant transmission may not emerge unless apparently unaffected family members are tested. Fasting C-peptide or insulin measurements may be of value, with elevated levels indicative of type 2 diabetes; repeated testing after 1 year or more may be needed for those who have normal results.

III. TYPE 1 DIABETES

A. Epidemiology

The terminology used in discussing the epidemiology of disease includes the following (29):

Incidence: The number of cases diagnosed in a given period of time, within a population or segment thereof, such as males and females, 10–20-year-olds, and so on. For chronic diseases such as diabetes, this is usually expressed as new cases per 100,000 population per year.

Prevalence: The number of cases within a population or a specific segment of the population at any time. This is a cross-section and is usually expressed as number of cases per 1000 individuals.

Frequency: This nonspecific term can denote either prevalence or incidence, or both, depending on how it is used.

Epidemic: A greater number of cases than expected.

The past 20 years have seen a phenomenal increase in knowledge about the epidemiological patterns of type 1 diabetes, which was anticipated to provide insight into the critical environmental contribution to the development of this disease (30). This information has heightened the appreciation of the likely complexity and importance of environmental causation, while casting little light on what those environmental factors might be. The Multi-National Project for Childhood Diabetes (DiaMonde) study was initiated by the World Health Organization in 1990 to investigate and monitor the patterns of incidence of type 1 diabetes (31). This remarkable study encompasses surveillance of 4.5% of the world's population 14 years of age and under, representing probably the largest standardized survey undertaken for any disease (32).

From 1990 to 1994, a total of nearly 20,000 cases of type 1 diabetes in children ≤ 14 years were diagnosed in the 75 million sample population, and incidence rates calculated per 100,000. There was a >350 fold variation in incidence among the 100 populations studied, from 0.1:100,000 per year in China and Venezuela to 36.8:100,000

Table 4 Differentiating Type 1 from Type 2 Diabetes in Children and Adolescents

Characteristics	Type 1	Type 2	Comment
Demographics			
Family history	3%–5%	74%–100%	Extensive family history suggests T2; T2 affects minorities disproportionately.
Age or pubertal status	Variable	>10 or pubertal ^a	Type 1 can occur at any age; only 10% of type 2 children are younger than 10 or prepubertal.
Gender	F = M	F > M	Some gender difference in T2 may reflect differences in use of medical care.
Presentation			
Asymptomatic	Rare	Common	Type 2 often detected incidentally on routine physical exam.
Symptom duration	Days or weeks	Weeks or months	Predominant symptoms are polyuria, polydipsia, polyphagia, and nocturia.
Weight loss	Common	Common	Type 2 children lose more pounds; type 1 usually lose greater percentage of body weight.
HHS	Very rare	Occurs	Type 2 can develop severe, fatal dehydration, and electrolyte disturbance.
Physical findings			
BMI at diagnosis	≤75 percentile	≤85 percentile	Those with BMI 75–85th percentile often present greatest diagnostic challenge.
Acanthosis	No	Common	Useful marker in hyperglycemic child.
Biochemical findings at diagnosis			
Hyperglycemia	Variable	Variable	Degree of hyperglycemia at diagnosis is not useful in delineating diabetes type.
Ketosis and ketonuria	Common	Common	Not useful for diagnosis of diabetes type.
Acidosis	Common	Moderately common	Not useful for diagnosis of diabetes type.
Other markers			
HbA _{1c}	Elevated	Elevated	Not useful for diagnosis of diabetes type.
Insulin or C-peptide/serum	Low (may be nl early)	Normal-high	Hyperinsulinism reflects insulin resistance. Low levels may be found in type 2 at diagnosis, repeat 3–6 months after diagnosis may be elevated.
Autoimmune markers	Common	Uncommon	Includes anti-islet cell and anti-GAD antibodies; absence does not rule out T1.

^aOccasionally in 8–10-year-old group and as young as 4 years.

Source: Adapted from Hale DE. Type 2 diabetes: an increasing pediatric problem.

per year in Sardinia and 36.5:100,000 per year in Finland. Very high incidence, considered ≥ 20 :100,000 per year, was also found in Sweden, Norway, Portugal, the United Kingdom, Canada, and New Zealand. When the population was divided into 5 year age groups, incidence increased with age and was highest among those 10–14 years old. Wide variation was seen between neighboring areas in Europe and North America. For example, the rate in Estonia (10.5:100,000) is less than one-third that of Finland. In North America, Alberta and Prince Edward Island have comparable rates of 24 and 24.5:100,000, whereas US rates vary from 11.7:100,000 in Chicago to 17.8:100,000 in Pennsylvania. While the rate in Puerto Rico, 17.4:100,000 is virtually identical to that in Pennsylvania, that in neighboring and ethnically similar Cuba

is only 2.9:100,000 (32). The prevalence of type 1 diabetes is estimated to be 1.7–2.5:1000 in the school-age population younger than 18 years in the United States (33).

Migrant populations provide an interesting perspective on environmental contributions to the development of type 1 diabetes. A number of observations have indicated that susceptibility is affected by environmental change. Japanese living in Hawaii are five times more likely to have type 1 diabetes than those in Japan, a country with a very low incidence of type 1 diabetes. Ethnic French and Italian children in Montreal have twice the incidence of diabetes as those in their native lands (34–36). Israeli children in Canada have a fourfold greater incidence than those in Israel (32). Indian children migrating from South

Africa, where type 1 diabetes in the Indian population is very low, to England had incidence rates comparable to those of English children in the community (33).

There is considerable evidence for an increasing frequency of type 1 diabetes, which is a further profound argument for environmental influences. The temporal trend has been one of steadily increasing incidence in northern European countries (38, 39); Sweden and Norway have reported a 3.3% annual increase while Finland has reported a 2.4% annual rise in incidence (40, 41). Epidemics have been described outside Europe, one striking report being a single year nearly sixfold increase in the Virgin Islands in 1984 (42). There is also evidence that the average age of onset of diabetes is decreasing (43). Consistent with the occasional observation of an epidemic increase in type 1 diabetes, modest seasonality has been documented, with a summertime dip that occurs in both northern and southern parts of the United States (38, 44, 45).

B. Etiology and Prevention

Type 1 diabetes is an autoimmune disease with a long preclinical course. Patients who are genetically predisposed are exposed to an environmental trigger that initiates autoimmune destruction of beta cells. This results in the release of antigens that had previously not been seen by the immune system, resulting in production of antibodies to these antigens. The appearance of insulin autoantibodies, islet cell antibodies, glutamic acid decarboxylase (GAD₆₅) antibodies, and antibodies to tyrosine phosphatase (IA-2 or ICA512) indicates ongoing autoimmune disease. These antibodies may be present in the serum for several years before the development of overt diabetes. As the autoimmune process continues, there is gradual loss of beta-cell mass. The first demonstrable abnormality is loss of first-phase insulin release (FPIR) during intravenous glucose tolerance testing (IVGTT). This is followed by abnormal results of oral glucose tolerance testing and, finally, overt diabetes (46).

The presence of immune markers before the onset of diabetes has allowed for the development of prediction models to determine who is at risk for developing disease. The immunoassays (GAD₆₅, IA-2) are more easily applied for large-scale use than previous assays for islet cell autoimmunity, have a high predictive value for type 1 diabetes, and are more reproducible than islet-cell antibody assays. GAD₆₅ antibodies are present in 80% of relatives with newly diagnosed diabetes and IA-2 are present in 50–60% of patients at diabetes onset (46). Multiple autoantibodies to islet antigens confer a cumulative risk of 75–90% over 5–10 years of follow-up in first-degree relatives (47–49). Other risk factors include young age, high-titer antibodies, low first-phase insulin response to IVGTT, and high-risk HLA (DR3/4, DQB0302/DQB0201) (50, 51). The persistent loss of FPIR secretion during IVGTT pre-

dicts progression to overt diabetes over the next 5 years in >85% (52).

Because of this ability to predict diabetes, several trials designed to prevent the disease in high-risk individuals have been initiated. Initial studies were aimed at treatment of newly diagnosed patients with immunosuppressive agents. Cyclosporine appeared promising: there was increased frequency and duration of clinical remission as determined by residual C-peptide secretion, but remission was not long lived and the effect was lost when the cyclosporine was discontinued (53). Furthermore, reports of cyclosporine-induced nephrotoxicity led to concern about the relative risk/benefit ratio of this form of therapy and studies were stopped (54). Azathioprine was also used in patients with newly diagnosed diabetes. Again, the increased C-peptide levels seen in treated patients compared to controls was a short-lived effect despite continued use of the immunosuppressive agent. Predictors of success with these agents were older age, lack of ketoacidosis at diagnosis, early initiation of treatment, and higher C-peptide levels at diabetes onset (55). Treatment with high-dose insulin using the Biostator, a device that measured venous blood glucose every few minutes and provided intravenous insulin to maintain normoglycemia, was as effective in preserving C-peptide as was azathioprine. However, as with the immunosuppressive agents, the results were transient (56). Because of the lack of adequate efficacy to justify the potential toxicities of the immunosuppressive agents used, efforts were made to design trials using safer agents and to initiate treatment at an earlier stage of the disease (i.e., before the appearance of diabetes).

1. North American Diabetes Prevention Trial 1

The North American Diabetes Prevention Trial 1 (DPT-1) was designed to determine if antigen-based therapy could prevent diabetes in at-risk individuals. Insulin was used as the antigen, based on studies showing that low-dose parenteral insulin given to ICA-positive relatives with low FPIR resulted in reduced development of diabetes compared to controls who refused insulin prophylaxis (57). In the DPT-1, patients with ICA were considered high risk if they had low FPIR to IVGTT (>50% risk of developing diabetes over 5 years) and were randomized to receive low-dose subcutaneous insulin or no intervention. Subjects with ICA and normal FPIR were assigned to the intermediate-risk group (25–50% chance of developing diabetes over 5 years) and were randomly assigned to receive oral insulin or placebo. The study revealed no differences in development of diabetes between the high-risk insulin-treated group and controls (58). Enrollment for the oral insulin arm of the study is expected to be complete by 2003. Regardless of the outcome of this large multicenter trial, this undertaking has resulted in the formation of an integrated network with core laboratories providing standardized testing and a centralized data/statistical cen-

ter, providing a framework for future multicenter intervention trials.

2. Nicotinamide

Nicotinamide is a free radical scavenger that interferes with the autoimmune destruction of beta cells, primarily by acting as an antioxidant. Nicotinamide therapy restores cellular NAD⁺ levels, helps to prevent damage from inflammatory macrophages, and promotes increased beta-cell regenerative capacity (59, 60). Animal models have shown nicotinamide to be effective in preventing diabetes. Because nicotinamide is a safe drug, its initial positive results in animal models, as well as in population based studies in New Zealand (below), made it an attractive candidate for diabetes prevention trials.

Nicotinamide decreased the incidence of type 1 diabetes by 41% in a study involving 80,000 5–7-year-old New Zealand school children (61, 62). Among the 20,000 children tested for ICA, 185 were positive and 173 of them accepted treatment with nicotinamide for upwards of 7 years; the incidence of type 1 diabetes in the treated group was ~7:100,000, which was significantly lower than the 16–18:100,000 per year incidence in the background population. These findings led to the initiation of a large European multicenter study, the European Nicotinamide Diabetes Intervention Trial (ENDIT). This trial is a double-blind placebo-controlled study enrolling first-degree relatives who have islet cell antibodies. Enrollment began in 1994 and was completed in 1998. Final results are anticipated in 2003. ENDIT screened 50,000 first-degree relatives of children with type 1 diabetes. Of these, 552 subjects had islet cell antibodies with normal oral glucose testing. The interim analysis demonstrated that none of the criteria for stopping the study had been met: there was neither a higher nor lower incidence of diabetes in the nicotinamide group, using a *p* value <0.0001 (63).

The Deutsche Nicotinamide Intervention Study (DENIS) was a randomized placebo-controlled trial comparing nicotinamide with placebo in 2415 siblings of children with type 1 diabetes from Germany and Austria. Of those screened, 164 siblings had islet cell antibody titers and, of those, 68 agreed to be randomized to receive nicotinamide or placebo. The study was terminated early (after 2 years) because of failure to demonstrate efficacy of nicotinamide over placebo. Indeed, FPIR during IVGTT was decreased in the nicotinamide group at 2 years compared to the placebo group, in which it remained stable (64).

3. Environmental Triggers

The importance of environmental factors in the initiation of the autoimmune response that ultimately results in diabetes is suggested by the observations that only 30% of identical monozygotic twins are concordant for type 1 diabetes and the incidence of diabetes is rising, with a decrease in mean age of onset, despite a stable genetic pool

(65–67). Several agents have been implicated, but only those figuring in preventive trials will be discussed here. Particularly interesting is the report that vitamin D supplementation of a large group of infants in northern Finland was associated with a relative risk of 0.16 compared to those who did not receive vitamin D (relative risk = 1) (68). Many other factors have been linked to increased risk of diabetes, including perinatal insult, exposure to nitrosamine (69–71), and lack of exposure to early infection (72).

a. Cow's Milk. One of the proposed triggers of diabetes is cow's milk, thought to be due to the structural similarity of a 17 aminoacid fragment (ABBOS) of bovine serum albumin to an islet antigen (ICA 69). This structural similarity invoked the concept of molecular mimicry as the mechanism for autoimmune destruction of beta cells. This hypothesis is controversial, however, with conflicting studies reported. Although Karjalainen et al. found antibodies to bovine serum albumin in children with new-onset diabetes, but not controls (73), the Diabetes Autoimmunity Study of the Young (DAISY) found no association between islet autoimmunity and early cow's milk exposure (74). The Trial to Reduce Type 1 Diabetes in the Genetically at Risk (TRIGR) was designed to test the hypothesis that avoidance of nutritional cow's milk proteins for at least the first 6 months of life would reduce diabetes in the high-risk population. Infants with high-risk HLA genotypes DQB10302 and/or DQB10201 and who were negative for the protective genotypes DQB10602, 0603, or 030 were offered enrollment. Two hundred thirty-four infants have been randomized. Mothers were encouraged to breastfeed. The intervention group received a caseine hydrolysate formula after full breastfeeding, whereas the control group received the cow's-milk-containing formula. The intervention group was advised to avoid beef and cow's milk products in the diet. Fifteen percent of the infants dropped out of the study before 8 months and those infants randomized into the intervention group remained breastfed longer than did those in the control group (8.1 vs 7.2 months). Antibodies to IA-2, insulin, GAD, and islet cell cytoplasm were measured in 173 children at 2 years of age. At least one autoantibody was present in 3.6% of the caseine hydrolysate group and 11.2% of the control group (75). This 10 year prospective trial is not yet complete.

b. Viral Agents/Vaccines. Maternal infection with enterovirus has been reported to increase diabetes risk in the offspring. Studies from Sweden and Finland found increased IgM antibodies to enterovirus in pregnant women whose children subsequently developed diabetes compared to control women (76, 77). Molecular mimicry between the P2-D protein of coxsackievirus and the GAD protein make this an attractive hypothesis. Other viruses implicated have been rubella (acquired in utero), chickenpox, mumps, measles, ECHO, and rotavirus (78, 79). Immunization with diphtheria–pertussis–tetanus and with

Hemophilus influenzae vaccines has also been reportedly associated with increased incidence of type 1 diabetes (80). An expert panel of the National Institutes of Health found no evidence for a relationship between immunizations and diabetes, however.

One approach to diabetes prevention is to shield those who are genetically at risk from potential initiators of pancreatic autoimmunity. The Pediatric Assessment of Newborns for Diabetes Autoimmunity (PANDA) study is a pilot effort in which infants have filter-paper HLA typing done at birth with the rest of the standard neonatal screening (81). Those babies with highest HLA risk haplotypes (DR3 and DR4, DQA0302/501 and DQB0301, 0201) have blood drawn for determination of islet cell antibodies. The families keep records of foods eaten, immunizations, and illnesses and the subjects are tested for islet autoantibodies every 6 months in the initial few years, and then annually. Correlations of the appearance of islet autoimmunity with history of environmental exposure may help to identify the environmental factors that trigger the autoimmune cascade to permit specific preventive intervention.

C. Clinical Picture

Children with type 1 diabetes mellitus are typically diagnosed because of symptoms of polyuria, polydipsia, and weight loss. The classic sign of polyphagia is frequently absent in children, and they are likely to have loss of appetite, presumably because their ketosis results in anorexia. Preschool children often have a shorter duration of symptoms and are more likely to have ketoacidosis with vomiting and lethargy at diabetes diagnosis than are older children. Enuresis in a previously toilet-trained child, or nocturia, may be the first clue to polyuria. Loss of weight despite increased dietary intake is due to tissue catabolism, with gluconeogenesis and urinary glucose loss.

Pyogenic skin infections, candidal diaper rash in babies and toddlers, monilial vaginitis in teenage girls, or dysuria may be present at the time of diagnosis. These findings are rarely isolated features of diabetes in children, and careful history will invariably reveal the coexistence of polyuria and polydipsia. The dehydration associated with polyuria may result in nonspecific symptoms of constipation, headache, and abdominal pain, often interpreted as a viral syndrome, or gastroenteritis if there is vomiting. Ketoacidosis (DKA) is present in 15–40% of newly diagnosed children, depending on the sociodemographic characteristics of the population. Clinical features of DKA are listed in Chapter 27. Vomiting without diarrhea, and continued high urine output despite circumstances associated with dehydration, indicate diabetes.

Children in whom diabetes must be considered may, for practical purposes, be divided into three general categories: those who have typical signs and symptoms of diabetes: polyuria, polydipsia, and weight loss; those who

have glucosuria, without hyperglycemia; and those with transient hyperglycemia.

Renal glucosuria may be an isolated congenital disorder, a feature of Fanconi's syndrome and other renal tubular disorders, due to severe heavy metal intoxication, ingestion of certain drugs (e.g., outdated tetracycline), or result from inborn errors of metabolism such as cystinosis. When vomiting, diarrhea, or inadequate intake of food occurs in any of these conditions, starvation ketosis may ensue and simulate diabetic ketoacidosis. The absence of hyperglycemia eliminates the possibility of diabetes. Stress of illness, especially in toddlers, may be associated with glucosuria and moderate hyperglycemia. Blood glucose levels usually do not exceed 300–400 mg/dl (17–20 mmol/l), but values up to 800 mg/dl (44 mmol/l) have been reported. This usually occurs in the context of acute exacerbation of asthma or during a hospital admission for infection or other serious illness. The hyperglycemia is usually transient and blood glucose levels normalize with resolution of illness. A similar clinical picture can be seen with glucocorticoid administration (19, 20). The presence of ICA, IA-2, IAA, or GAD antibodies with stress- or glucocorticoid-induced hyperglycemia may indicate limited beta-cell reserve and risk for future development of diabetes (46). Thus, autoantibodies against islet antigens should be measured in all instances of stress hyperglycemia.

D. Complications

Insulin replacement makes it possible for the child with diabetes to attain a level of metabolic control that permits day-to-day functioning in school, play, and at home, with only occasional episodes of mild to moderate hypoglycemia and avoidance of ketoacidosis, despite high average blood sugar concentrations. Awareness that this was the typical situation was limited until the advance of self-monitoring blood glucose and measurement of glycohemoglobin (HbA1c) (82, 83). These advances, and the improvement in insulins and delivery systems, have made it possible to attain a level of glucose control that will reduce the risk of long-term complications, as demonstrated in the Diabetes Control and Complications Trial (84). The contemporary goals of treatment of type 1 diabetes in children, therefore, include the traditional maintenance of a reasonably normal lifestyle and avoidance of the acute complications (see Chapter 26), but with the attainment of near-normal glycemia to reduce the risk of long-term complications involving both microvascular and macrovascular disease. Microvascular disease is responsible for retinopathy, nephropathy, and neuropathy. Macrovascular complications affecting coronary, carotid, and other major vessels are increasingly recognized as beginning during childhood. Of particular interest in children have been skeletal, joint, and skin complications, and the effects of diabetes on growth and development.

1. Skeletal, Joint, and Skin Problems

a. Skeleton. Early studies of bone density, using single-photon absorptiometry, which detects the transmission of radiation from a ^{125}I crystal through the bones of the forearm, described more than 10% loss of bone density in nearly one-half of girls and one-third of boys with type 1 diabetes. This was much more severe in white than in black children, similar to the situation for adult osteopenia in women, and was only seen during the first 5 years of diabetes (85). When spine bone density was examined by computed tomography (CT) scan, a slight but significant decrease was found, which was entirely caused by weight differences between patients and controls (86, 87). More recent study of the lumbar spine in children and adolescents with diabetes, using dual energy x-ray absorptiometry (DEXA), also noted that bone mineral density was highly dependent on stature. There was no abnormality during the first several years of diabetes and no abnormalities in the calcium/phosphorus hormone and metabolic profile (88). Studies of the femoral neck and lumbar spine in 88 younger Spanish adults with young onset type 1 diabetes confirmed no significant osteopenia associated with diabetes (89).

Two recent studies from Venezuela using DEXA examination of the lumbar spine and femoral neck in 26 children with a mean duration of diabetes of 4.3 years are consistent with the initial studies using single-photon absorptiometry of the forearm. Children were compared to controls and restudied after 1 year. There were no significant differences in femoral neck densities or total body densities, but lumbar spine had significantly less bone mineral density in those with diabetes. This did not correlate with duration of diabetes or degree of diabetes control as determined by HbA1c concentration. A variety of measures of bone turnover indicated lower activity in the patients (90). A further study of 23 prepubertal children with an average 6 month diabetes duration also revealed decrease in lumbar spine density and decreased bone formation markers, indicating very early changes (91).

The practical significance of these findings and their consistency remain uncertain. Calcium loss in the urine is characteristic of poorly controlled diabetes (92, 93), but no studies have established a relationship between level of control and bone mineral density. With longstanding diabetes in adults, there is no epidemiological evidence of increased fracture risk (94).

b. Joints. Limited joint mobility (LJM) is the earliest clinically apparent long-term complication of type 1 diabetes in childhood and, following its initial description in 1974, was recognized to be a common feature of both type 1 and type 2 diabetes (95, 96). LJM was described as bilateral, painless, but obvious, contracture of the finger joints and large joints, with thick tight waxy skin and short stature in three older teenagers with longstanding diabetes and early microvascular complications (95).

Milder expression was subsequently recognized as affecting ~30% of youngsters with diabetes, one-third of whom had involvement of more than two fingers or one finger and one large joint bilaterally. Variation in prevalence among various reports is related to the examination technique, criteria, age of the patients, and duration of diabetes. In older adult patients, examination is confounded by the presence of finger contracture related to age, occupation, and non-diabetes-associated problems such as osteoarthritis. It may also be related to other conditions involving the finger joints that are more common in diabetes, such as flexor tenosynovitis, carpal tunnel syndrome, and Dupuytren disease, which are conditions not seen in pediatric patients. It is rare to see bilateral finger contractures in children with diabetes that are not due to LJM, except for the unusual bilateral trauma of the finger or familial camptodactyly of the fifth fingers.

Changes begin in the metacarpophalangeal and proximal interphalangeal joints of the fifth finger and extend radially, with involvement of the distal interphalangeal joints as well. Involvement of larger joints includes particularly the wrist and elbow, but also ankles and the cervical and thoracolumbar spine. The limitation is painless and only mildly disabling when severe. A simple examination method is to have the patient attempt to approximate palmar surfaces of the interphalangeal joints (Fig. 1). Passive examination is essential to confirm that inability to do so is due to LJM. The examiner extends the proximal interphalangeal and distal interphalangeal joints (expected 180 degrees). There may be a sense of resistance to the permitted movement. The metacarpophalangeal joints should extend to >60 degrees and the wrists and elbows to >70 and >180 degrees, respectively. Cervical spine lateral flexion should permit ear to shoulder juxtaposition and thoracolumbar spine lateral flexion should be to at least 35 degrees in young persons. Equivocal or unilateral findings are considered to reflect no limitation (97). There is no associated muscle atrophy or evidence of neuropathy. Involvement of the cervical spine has been found to complicate endotracheal intubation for anesthesia (98).

Diminished pulmonary capacity has also been documented, but it is uncertain whether this is the result of decreased pulmonary compliance or limitation of the thoracic joints (99). Thick, tight, waxy skin, described in the initial patients, was most prominent over the dorsum of the hands and forearms and occurred in one-third of those described later, but only in those who had more than mild changes in the joints (96). Skin biopsy specimens have shown active fibroblasts and extensive collagen polymerization in the rough endoplasmic reticulum. There is a predominance of large fibers that has been found in patients with diabetes whether or not they have had thick skin; this is quite different from the bimodality of collagen fiber sizes seen in scleroderma (100). Radiographic examination of the joints is normal, but there is periarticular thickening that can be quantitated (101).

Figure 1 Inability to approximate the palmar surfaces of the fingers in a 14-year-old girl with diabetes for 7 years.

Attained age seems more important than duration of diabetes or age of onset of diabetes in the evolution of LJM. With rare exception, LJM appears after the age of 10 years. The interval between the detection of mild LJM and progression to moderate or severe changes in those who progress beyond mild changes ranges from a few months to 4 years, following which stabilization occurs (102).

The biochemical basis for LJM is likely to be glycation of protein with the formation of advanced glycation end-products (AGE). This results in increased stiffness of the periarticular and skin collagen with decreased range of motion. Increased accumulation of relatively insoluble dermal collagen resistant to enzymatic digestion has long been recognized as a characteristic of connective tissue aging in both type 1 and type 2 diabetes (103). Fluorescence of skin collagen reflects the accumulation of stable end-products of the glycation reaction, with increased cross-linking, dehydration, and condensation of collagen. Such fluorescence increases linearly with age but with abnormal rapidity in patients with type 1 diabetes, correlating with the presence of retinopathy, nephropathy, and LJM (104).

As might be expected, the presence of LJM is associated with increased risk for the development of microvascular (MVC) disease. The initial report of the prevalence of LJM included seven patients with severe changes, of whom five had clinically apparent retinopathy before the age of 18 years (96). In a longitudinal study of 169 patients with diabetes duration >4.5 years, which was the shortest duration at which complications were noted, LJM was associated with an 83% risk for retinopathy, whereas the absence of LJM was associated with a 25% risk after 16 years of diabetes (Fig. 2). The severity of microvascular changes also corresponded with the severity of LJM (97). In a later study of 311 patients aged 6–27 years undergoing fluorescein angiographic examination, 43% of those with LJM and >4 years duration of diabetes had >10 microaneurysms compared to 15% without LJM (105). In another large series, LJM was associated with a 4.3-fold relative risk of clinical neuropathy in those with type 1 diabetes (106). Histopathological changes in renal biopsy specimens from patients without clinically detectable nephropathy also correlate highly with LJM (107).

Although cross-sectional studies had shown no relationship to diabetes control as measured by HbA_{1c}, a longitudinal study of average HbA_{1c} from onset of diabetes revealed a correlation between long-term metabolic control and the development of LJM. For every unit increase in average HbA_{1c} there was an approximately 46% increase in the risk of developing LJM (108).

The impression that LJM had markedly decreased in prevalence and severity since the initial recognition in the 1970s has been confirmed by a recent report comparing subjects examined in 1998 using the same examination methods in the same setting as those examined in 1976–1978. Documented was a >fourfold reduction, from 31% to 7%, in frequency of LJM over this 20 year period, with a marked decrease in the proportion having moderate or severe LJM (9% vs. 35%). This reduction in the prevalence and severity of LJM was considered to be most likely the result of improved glucose control during this era (109). These study results are pertinent to the question of the importance of prepubertal duration and control of diabetes for the development of long-term microvascular complications. Even for the youngest age group studied or those with the shortest duration of diabetes, there was a marked decrease in the prevalence of LJM between the two eras, suggesting that improved control from the first years of childhood diabetes will reduce long-term complication risks.

c. Skin. Necrobiosis lipoidica diabetorum is a rarely seen pretibial lesion characterized by round or oval indurated plaques, with central atrophy and eventual ulceration. Unless they become infected, the lesions are painless. The relationship to diabetes control is uncertain, but there is an association with smoking, proteinuria, and retinopathy (110). Because these lesions do not heal well, trauma should be avoided and infection vigorously treated.

Figure 2 Actuarial analysis of risk for development of microvascular complications with and without limited joint mobility, based on longitudinal study of 169 patients with diabetes duration ≥ 4.5 years followed from before the development of LJM or microvascular disease. (From Ref. 97.)

Lipoatrophy, seen as indentation or atrophy of the subcutaneous tissue resulting from insulin injection, has become uncommon with the generalized use of recombinant-derived human insulin. It is presumed that the impurities in animal extract insulin or the foreign nature of that insulin led to the problem. It was thought to be immune mediated, frequently following dermatomes and occurring symmetrically, distal from the actual injection sites. The lesions tended to resolve after a few years and were thought to be IgE mediated. Mild atrophy is still seen occasionally with the contemporary insulin, affecting $\sim 3\%$ of patients 1–19 years old in one study (111). Giving insulin injections around the edges of the atrophic area may be helpful.

Lipohypertrophy, which always occurs at the site of injection, is a local reaction to repeated injection trauma, usually from inadequate site rotation, with scarring and decreased sensitivity to pain. The lesion can occur quite early, however, and may not be abolished by site rotation (112). Unlike lipoatrophy, lipohypertrophy continues to be frequent with improved insulin forms, present to some degree in as many as half of patients under 20 years of age (112). Both lipoatrophy and lipohypertrophy are associated with greater insulin antibody concentrations (111). The cosmetic effect is problematic, but most important is the possibility of varying absorption of insulin from areas of hypertrophy, resulting in erratic glycemic control.

2. Cataracts

Cataracts occur rarely during recovery from ketoacidosis, typically in the newly diagnosed patient; they usually disappear rapidly but may persist and require surgical removal (113). In contrast to these sugar cataracts, subcapsular juvenile cataracts, associated with chronic hyperglycemia and caused by sorbitol accumulation, do not regress and always require removal.

3. Growth Failure and Delayed Sexual Maturation

Insulin has important influence on normal growth and development, largely through effects on anabolism and the growth hormone–insulin-like growth factor I (GH–IGF-1) axis. Before the contemporary era of self blood glucose monitoring and more physiological insulin administration, modest growth retardation and delayed puberty were frequently seen in the pediatric diabetes clinic. Nonetheless, despite the generally nonphysiological traditional means of treating diabetes, most children with diabetes did not have serious growth or maturational delay problems. In twin pairs discordant for diabetes, the development of diabetes before the onset of puberty was associated with invariably shorter stature than that of the nonaffected twin (114). More contemporary studies demonstrate normal timing of puberty, with reduced growth and adult height even with modern therapeutic regimens, although these deviations are not substantial (115, 116).

Analyzing the stature of 142 patients with diabetes onset at least 2 years before puberty and with duration longer than 3 years, which provided sufficient time for a growth-inhibiting effect, Rosenbloom et al. in 1982 (117) found that 37% of 68 patients without LJM were below the 25th percentile of NCHS data. The 74 with LJM had four times the proportion with stature below the 25th percentile for age (77%), with no difference between the 31 with mild changes (involving one or two interphalangeal joints, one large joint, or only the metacarpophalangeal joints bilaterally) and those with more severe limitation ($n = 43$). When a similar group of children was examined in 1998, using the same criteria, only 22% of the 157 without LJM were below the contemporary NCHS 25th percentile and only 33% of the 18 with LJM were (118). Thus, contemporary diabetes control methods were resulting in improved growth along with the reduction in frequency of LJM. It will be recalled that the initial patients described with severe LJM had growth failure and delayed puberty (95, 96).

Insulin deficiency is associated with manifold changes in the GH-IGF-I axis. Deficiency of portal insulin delivery to the liver results in reduced circulating GH-binding protein, the extracellular domain of the cell surface receptor for GH, with GH resistance and diminished IGF-I production (119, 120). The deficiency in insulin also results in decreased production of IGF binding protein-3 (IGFBP-3), which is the principal binding protein for circulating IGF-I, and increased production of IGFBP-1 and IGFBP-2 (121). These latter BPs, unlike IGFBP-3, do not deliver their bound IGF-I to tissues. Furthermore, there is increased proteolysis of IGFBP-3, decreasing its viability in the circulation. In addition to the GH resistance, reflected in the lower concentrations of circulating GHBP, there may be postreceptor defects in GH action mediated by the insulin deficiency as well. Diminished circulating total and free IGF-I levels are associated with GH hypersecretion because of the absence of negative feedback from IGF-I. This hypersomatotropism increases glycemia and decreases insulin sensitivity, but is reversible with adequate insulin replacement (122).

Growth failure and maturational delay with hepatomegaly and abdominal distention in insulin-treated children was first described by Mauriac in 1930 (123). The regression of hepatomegaly in 13 such patients, following transfer from regular insulin to protamine zinc insulin, was noted in 1936 (124). Hepatomegaly was apparently a common complication in children in the era when only short-acting insulin was available and aglycosuria was the objective. This was exemplified in a series from the Joslin Clinic in the late 1930s, of 60 youngsters with hepatomegaly, growth failure, delayed sexual maturation, and severe uncontrollable diabetes with frequent hypoglycemia and ketoacidosis (125). Improvement was associated with the change to long-acting protamine zinc insulin.

There appear to be two forms of the Mauriac syndrome. In one form there is associated cushingoid obesity

and documented wide fluctuation between hyper- and hypoglycemia. This is suggestive of a pattern of over- and underinsulinization, which would be expected with treatment using only soluble insulin, with secondary hyperadrenalism. Periods of overinsulinization would appear to be essential for the development of obesity in this form of the syndrome, and for the induction of hyperadrenalism. In addition to the Joslin series, an impressive North American case was reported in 1962 of a 13.5-year-old girl with extremes of blood glucose from 1 to 29 mmol/l, hypertension, edema, hepatomegaly, marked growth failure, sexual immaturity, cushingoid obesity, retarded bone age, hyperlipidemia, and osteoporosis. When her insulin dosage was reduced from 65 units a day (40 NPH/25 soluble) to 20 NPH daily, she had complete clearing of the abnormalities, catch-up growth, and sexual maturation (126). More recent reports are of patients with Mauriac syndrome who are not obese and without a history of alternating hypoglycemia and ketoacidosis; these patients are unmistakably inadequately insulinized continuously (127–129).

Associated autoimmune problems that can result in growth failure include hypothyroidism and celiac disease. Approximately 20% of girls and 15% of boys with type 1 diabetes have evidence of autoimmune thyroid disease, determined by the presence of thyroid autoantibodies (130). Such autoantibodies should be tested for in all youngsters with type 1 diabetes. Those with positive results should have an annual determination of thyroid-stimulating hormone (TSH) level. Celiac disease has been described in 5–8% of children with type 1 diabetes; tissue transglutaminase antibodies should be sought in children with growth failure without obvious cause, even in the absence of diarrhea (131).

Eating disorders are more common in children with diabetes than in the general population and should be considered in the assessment of any child who is not gaining weight or growing normally. Adolescent girls with diabetes are 2.4 times more likely than those without diabetes to have clinical eating disorders and 1.9 times more likely to have a subclinical eating disorder. Mean HbA1c levels were higher in adolescents with diabetes who had an eating disorder than in those who did not (132).

4. Microvascular Complications

a. Pathogenesis. The hallmark of microvascular disease is thickened capillary basement membrane with alterations in membrane permeability and occlusion of small blood vessels. Several theories explain these findings.

Protein glycation. It has been well documented that improved glycemic control is associated with decrease in microvascular disease and its progression (84). This suggests that excess glucose *per se* has deleterious effects on tissues. Some of these effects appear to be through binding to collagen by posttranslational nonenzymatic means.

The amidori glycation products undergo slow (nonenzymatic) chemical rearrangements to form irreversible AGE. These AGE accumulate in the extracellular matrix and vascular intracellular proteins to cause structural tissue alterations with progressive occlusion of blood vessels. This glycation may alter the charge of the proteoglycan component of the basement membrane, resulting in leakage of negatively charged proteins from the plasma. The pores in glomeruli may also undergo alterations in size, resulting in protein leakage. The increased basement membrane thickening found in microvascular disease may be due to this glycation process, with accumulation of proteins that are not degradable. The nonenzymatic glycation of hemoglobin is an example of protein glycation and has been used as an indicator of glycemic control since the late 1970s.

Amidori products may be involved in induction of strand breakage in DNA by interfering with gene transcription. This may explain the hyperglycemic memory observed in the EDIC study 4 years after the conclusion of the Diabetes Control and Complication Trials (DCCT). Although the mean HbA1c levels 4 years after conclusion of the DCCT were similar between the former intensive and former conventional groups (8.38% vs 8.45%), the rate of worsening of retinopathy by three steps or more was lower in the former intensive therapy group than in the former conventional group (84). The prevalence of micro-albuminuria (defined below) was 13.6% for the former conventional treatment group compared to 8.1% in the former intensive treatment group at study closeout; 9.9% of the former conventional group had albuminuria at years 3 and 4 compared to only 1.3% of patients in the former intensive group.

Polyol pathway. Sorbitol (glucose alcohol) is formed enzymatically from glucose by the enzyme aldose reductase. The higher the blood sugar concentration, the more the sorbitol accumulation in a number of tissues, including lens and nerve. This influx of glucose into the polyol pathway is associated with decreased myoinositol uptake and decreased sodium/potassium/ATPase activity. These changes have been related to increased permeability and increased pressure and leakage in blood vessels, which may be related to the increased release of vasoconstrictive prostaglandins and decreased release of nitric oxide that mediates endothelium relaxation. The overall effect of these metabolic abnormalities is decreased vessel wall elasticity and microvascular hypertension (133).

Abnormalities in the coagulation system. Elevated fibrinogen levels and other antithrombotic factors may result in increased platelet stickiness. Increased prostaglandin metabolism increases coagulopathy, resulting in increased red blood cell aggregation and blockage of small capillaries (134).

b. Nephropathy. Micro-albuminuria, defined as urinary albumin excretion rates of 20–200 $\mu\text{g}/\text{min}$ or 30–300 $\text{mg}/24\text{ h}$, is predictive of renal and cardiovascular

disease (135). Concentration above 300 mg/g is considered overt diabetic nephropathy. HbA1c levels, albumin excretion rate, low-density lipoprotein cholesterol, and body mass index were risk factors for the development of micro-albuminuria in 12.6% of 1134 men and women with type 1 diabetes aged 15–60 years during 7 years of follow-up in the EURO DIAB Prospective Complications Study (136).

The prevalence and progression of micro-albuminuria and of clinical proteinuria were studied in 361 children with type 1 diabetes over the course of 12 years, with the conclusion that micro-albuminuria was rare before adolescence. The incidence of micro-albuminuria, however, increased between the ages of 10 and 18 years with 30.9% of males and 40.4% of females having one or more episodes of micro-albuminuria (137).

A study of 101 normal albuminuric children and adolescents with diabetes found that 11% developed persistent micro-albuminuria during 8 years of follow-up. The odds ratio for the occurrence of micro-albuminuria with elevated vascular endothelial growth factor serum levels was 4.1, indicating that persistently increased serum levels of vascular endothelial growth factor may help to identify patients who are predisposed to persistent albuminuria (138).

In Denmark, high HbA1c and high baseline albumin excretion rates predicted the development of persistent albuminuria over 6 years in 12.8% of 339 children and adolescents with type 1 diabetes (139). These results showed a higher incidence than in a large American cross-sectional survey of 702 children and adolescents with an average diabetes duration of 7.6 years. In this study, albumin excretion rate $\geq 15\ \mu\text{g}/\text{min}$ measured on at least two of three urine collections was defined as micro-albuminuria, which increased from 5.1% to 11.6% after 10 years of diabetes duration and completion of puberty. Maternal hypertension was a significant risk factor, but patients' BP was not, and HbA1c had a borderline effect (140). These findings contrast with other studies in which there is strong association between progression of micro-albuminuria and HbA1c values. A 4 year follow-up of 279 patients with type 1 diabetes found that the rate of progression was 1.3:100 person years in those with HbA1c levels $< 8\%$, whereas it was 5.1:100 person years with HbA1c levels between 8 and 9%, 4.2 between 9 and 10%, and 6.7:100 person years if HbA1c was $> 10\%$. The risk of progression rose steeply between HbA1c values of 7.5 and 8.5%, emphasizing the importance of improved glycemic control, especially of maintaining HbA1c values below 8.5% (141).

The Pittsburgh Epidemiology of Diabetes Complications (EDC) study is an observational prospective study of 589 patients with onset of type 1 diabetes before the age of 17 years. Baseline low-density lipoprotein (LDL) levels ≥ 130 , triglycerides ≥ 150 , systolic blood pressure ≥ 130 , and diastolic blood pressure ≥ 85 conferred relative

risks of 2.2, 3.2, 2.3, and 2.5, respectively, for developing nephropathy over 10 years (142).

Homocysteine elevation has been considered a risk factor for premature cardiovascular disease. Young patients with type 1 diabetes diagnosed before the age of 12 years and with duration of disease longer than 7 years who had albumin excretion rates $>70 \mu\text{g}/\text{min}$ had elevated homocysteine levels, indicating an association of diabetic nephropathy with premature cardiovascular disease (143).

Annual testing of the urine for albumin is recommended for children from puberty and with 3–5 years of diabetes. The most convenient way to assess albuminuria is with the urinary albumin/creatinine ratio obtained on a spot urine sample. Micro-albuminuria in a single specimen may not indicate fixed disease. It is important to repeat the test on at least one other occasion in a random urine sample. A timed 12 h or 24 h urine specimen is preferable. It is also important to differentiate orthostatic proteinuria from that due to diabetic renal disease. With orthostatic proteinuria, a first void morning urine should not contain abnormal concentration of albumin, whereas a late afternoon urine often will.

The DCCT demonstrated that micro-albuminuria and overt nephropathy can be delayed or prevented by intensive diabetes treatment (84). However, the United Kingdom Prospective Diabetes Study (UKPDS) and other studies have shown that blood pressure control is as important as glycemic control in prevention of nephropathy and in decreasing the rate of decline of glomerular filtration rate (GFR) in established disease (144). ACE inhibitors decrease albumin excretion rate in patients with hypertension as well as in nonhypertensive patients (145). Children and adolescents with micro-albuminuria have higher blood pressures than those with normal albuminuria (146–150). Because of this increased risk for development of nephropathy, it is essential to pay close attention to maintaining blood pressure at normal or near normal values.

The treatment of choice for nephropathy has been ACE inhibition, which is effective whether or not the patient has hypertension. In addition to their antihypertensive effects, ACE inhibitors increase afferent vessel dilatation, thereby decreasing elevated intraglomerular pressure, a hallmark of diabetic nephropathy. The role of low-protein diets in treatment of micro-albuminuria has been debated for several years; there are no long-term studies in children. Studies in adults have shown that protein restriction slows the rate of decline of glomerular filtration rate (151). The albumin excretion rate has been decreased in adults with micro-albuminuria with the low protein diet (152). A low-protein diet of 0.8 g/kg body weight may be helpful in decreasing albuminuria and slowing the decline in renal function (153). Thus, high protein intake should be avoided in children with micro-albuminuria. Because of the importance of adequate dietary protein in the growing child, however, protein restriction below 15% of total daily calories is not justified.

Adolescents should be counseled to avoid smoking; nicotine has profound vasoconstrictive effects that have been associated with progression of nephropathy in adults with type 1 diabetes (154).

c. Retinopathy. Retinopathy is the most common microvascular disease in children and adolescents with type 1 diabetes. It is broadly defined to include background retinopathy, with the presence of microaneurysms only or microaneurysms and occasional dot blot hemorrhages, and proliferative retinopathy, with growth of new vessels, glia, and fibrous tissue. Fluorescein angiography is used to document severity of retinopathy by showing areas of retinal ischemia, proliferation of new blood vessels, and permeability of the retinal vessels.

At diabetes diagnosis, there is increased blood flow through the retina. Early on, poor metabolic control may be associated with leakage of injected fluorescein in the vitreous (155, 156), with reversal by improved metabolic control. Anatomical disease begins as background non-proliferative changes within the retina resulting from increased vascular permeability and capillary and arteriolar occlusion. The increased permeability results in edema and the formation of hard exudates, whereas the occlusion results in formation of microaneurysms, hemorrhages, soft exudates, and capillary dropout. The growth of new blood vessels, glia, and fibrous tissue in front of the retina can result in vitreous hemorrhage and retinal detachment from shrinkage of the proliferating tissue.

Although retinopathy has been reported to be present at onset of diabetes (105), it usually is not recognized before 5–10 years' duration. By that time, 20–30% of patients will have background retinopathy, 30–50% after 10–15 years diabetes duration, and 70–80% after 15 years. The progression to blindness is not uniform and varies between 20 and 55% in different series (157). Diabetes accounts for 10–20% of all cases of blindness in adults (158).

The incidence of retinopathy in 764 patients >15 years of age in the EURO DIAB prospective complications study was 56% after 7 years of follow-up. Risk factors for development of retinopathy included albumin excretion rate, cholesterol, triglycerides, and waist-to-hip ratio. In contrast to other studies, there was no association between retinopathy and blood pressure, cardiovascular disease, or smoking in this study (159).

In a cross-sectional study of 725 African-Americans in New Jersey, 3% had macular edema and 20.6% had retinal hard exudates. The severity of retinopathy correlated with the presence of proteinuria, higher LDL cholesterol levels, systolic hypertension, poor glycemic control, and longer duration of disease. Hyperglycemia was strongly associated with retinopathy. Those patients whose HbA_{1c} values were in the highest quartile were three times more likely to have retinopathy than those in the lowest quartile. Patients with renal disease were three times more likely to have retinopathy and 10 times more

likely to have proliferative retinopathy than those without renal disease. Patients in the highest quartile of systolic blood pressure were three times more likely to have proliferative retinopathy than patients in the lowest quartile (160, 161).

The Pittsburgh EDC found that systolic BP ≥ 120 mmHg conferred a relative risk (RR) of 1.6 for the development of proliferative retinopathy and RR was 2.7 if systolic BP ≥ 130 ; diastolic BP >79 mmHg conferred RR of 1.8, if ≥ 85 RR was 2.4, and if ≥ 90 mmHg, the relative risk of proliferative retinopathy was 4.6 in this population (142). Thus, it is important to maintain blood pressure near normal, because systolic blood pressures above 120 mmHg conferred increased risk of proliferative retinopathy.

Homocysteine concentrations, which, as noted above, are elevated with cardiovascular disease, were higher in adolescents with proliferative retinopathy, further indicating a link between presence of microvascular complications and later onset of macrovascular disease (143).

Because retinopathy is rare before puberty, it is recommended that children begin regular ophthalmological evaluation at the age of 9–10 years and following 3–5 years of diabetes. Once criteria for ophthalmological evaluation have been met, all children with diabetes should be evaluated by an ophthalmologist with serial fundus photographs at annual intervals and photocoagulation performed with the development of proliferative retinopathy. ACE inhibitors have been shown to slow the progression of retinopathy in patients with and without hypertension; thus, the presence of retinopathy is an indication for initiation of such therapy (162, 163).

The use of retinal photocoagulation has markedly improved the prognosis for vision in patients with proliferative retinopathy (164, 165). Although the mechanism of action is uncertain, it is thought that the photocoagulation destroys ischemic retinal tissue, thus removing the stimulus for neovascularization. Laser therapy is also used for macular edema by destroying leaking microaneurysms and dilated capillaries. In cases of proliferative retinopathy, panretinal photocoagulation will destroy retinal tissue outside the macula and optic nerve so that the remaining retina is not ischemic and will, therefore, not produce the growth factors that result in proliferative diabetic retinopathy. The panretinal photocoagulation has the adverse effects of compromising color discrimination, visual fields, and night vision. In the case of vitreous hemorrhage or detached retina, vitrectomy can be used to remove the blood from the vitreous or to reattach a retina in the process of detaching.

d. Neuropathy. Although symptomatic neuropathy is uncommonly seen in children and adolescents with diabetes, findings of sensory and autonomic motor nerve impairment can be demonstrated in young people. Peripheral neuropathy, including motor and sensory disturbances, as well as autonomic neuropathies, including gas-

trointestinal, cardiovascular, vasomotor instability, and hypoglycemia unawareness, have been described in childhood and adolescence.

The pathogenesis of neuropathy in diabetes is likely multifactorial. The aldose reductase system is present in the lens and peripheral nerves and is responsible for metabolism of glucose to sorbitol. High glucose levels will accelerate the synthesis of sorbitol, which is not freely diffusible. The sorbitol thus remains as an osmolar force within the nerve, causing swelling and possible destruction. Myoinositol, a component of neuronal cell membranes, and therefore involved in the control of neural transmission, has been found to be decreased in animals and humans with diabetes. In addition, the basement membrane of the Schwann's cell is thickened and the vasa nervorum has capillary and arteriolar wall thickening by basement membrane accumulation, as part of the generalized microvascular disease of diabetes. Biopsy of affected nerves has shown numerous thrombosed vessels, axonal loss, and a characteristic segmental demyelination.

Peripheral neuropathy. Clinical symptoms of peripheral neuropathy include numbness and paresthesias, especially pain and burning in the lower extremities, which is much worse at night. Usually a decrease in vibratory sense is the first clinical sign of neuropathy, followed by loss of ankle jerks and later by loss of pin prick sensation in a stocking distribution (166). These symptoms are commonly accompanied by anorexia with early satiety and postprandial vomiting due to gastroparesis from autonomic neuropathy. It is possible that undernutrition contributes to the neuropathy (167). The Pittsburgh EDC study found that 3% of 65 children under 18 years of age had neuropathy based on history and physical examination (168). Subclinical neuropathy, assessed by decreased motor nerve conduction velocities and sensory changes, is much more common, however, occurring in as many as 50–72% of adolescents (169). Neuropathy has been correlated with hyperlipidemia and smoking (168) and with LJM (106), but no relationship has been demonstrated between the presence of motor or sensory nerve conduction abnormalities and micro-albuminuria or retinopathy (170, 171). A recent study of 339 patients who were followed for 6 years found that neuropathy, determined by decreased vibration perception threshold, occurred in 62.5% of patients. Risk markers were male gender, age, and increased albumin excretion rate (140).

The Pittsburgh EDC study found the relative risk of developing peripheral neuropathy to be 2.2 if LDL cholesterol was >129 mg/dl and 1.5 if LDL cholesterol was >99 mg/dl. Triglyceride levels >140 mg/dl likewise conferred a 1.5 relative risk. Systolic blood pressure >130 mmHg was associated with a relative risk of 4.0 and diastolic blood pressure >85 mmHg with a 2.0 relative risk. Glycemic control was not evaluated in this report (142).

Improved metabolic control may result in resolution of sensory and motor nerve velocities as well as the sen-

sory and gastrointestinal symptoms. The DCCT showed that intensive diabetes therapy decreased clinical neuropathy by 60% (172). Peripheral motor and sensory nerve conduction velocities were significantly faster after 5 years of intensive therapy than after conventional treatment in the adolescent cohort (84).

Autonomic neuropathy. Autonomic neuropathy most commonly results in gastroparesis, cardiovascular reflex loss, and hypoglycemic unawareness. Diabetic gastroparesis is associated with decreased gastric motility and delayed emptying time. Affected patients often complain of bloating and feelings of satiety following intake of small amounts of food and they often have anorexia and weight loss. There are some reports of resolution of gastroparesis with improved metabolic control (173, 174). Diagnosis can be made using technetium-coated egg in a gastric-emptying study. Use of metoclopramide or erythromycin may result in increased motility with resolution of symptoms. Diabetic diarrhea is watery, most frequent at night or following meals, and can result in fecal incontinence (175).

Autonomic neuropathy of the cardiovascular system results in persistent tachycardia with a fixed heart rate in response to standing, Valsalva maneuver, and inspiration. Because of this, there is an inability to increase cardiac output resulting in hypotension with standing or exercise, and hypersensitivity to catecholamines. Patients with this neuropathy will frequently have a lower blood pressure when sitting or standing than when supine.

Loss of awareness of hypoglycemia is the loss of the catecholamine-induced symptoms of sweating, tachycardia, nausea, sense of fear, and tremulousness that normally accompany severe drops in the blood glucose level.

5. Macrovascular Disease and Hyperlipidemia

Diabetes mellitus is a strong risk factor for cardiovascular disease, conferring a two- to fourfold increased risk (176–178). Risk factors that independently increase cardiovascular risk in people with diabetes include smoking, hypertension, dyslipidemia (179), renal dysfunction (179), and hyperglycemia (180–184). The Pathological Determinants of Atherosclerosis in Youth (PDAY) study of more than 3000 people who died between the ages of 15 and 34 evaluated risk factors for coronary heart disease by correlating pathological findings of fatty streaks and lipid-laden plaques to blood lipid values, smoking, hypertension, and tendency towards diabetes. There was a strong association of extent of disease with smoking, as measured by serum thiocyanate concentrations. All the aortas and about half of the right coronary arteries in the 15–19 year age group already had lesions. On average, 7% of the aortas and 12% of the right coronary arteries had raised lesions or advanced lesions of atherosclerosis at the young age of 15–19 years. The percentage of intimal surface involved with lesions in both the aorta and right coronary artery was positively associated with very-

low-density lipoproteins (VLDL) and LDL cholesterol, with a 5% increase in surface involvement with each 1 standard deviation increase of LDL and VLDL cholesterol levels. Conversely, a 1 standard deviation increase in HDL was associated with a 3% decrease in intimal surface involvement. HbA1c concentration was associated with more extensive and more advanced atherosclerosis in the aorta and right coronary artery, primarily in people between the ages of 25 and 34 years of age. The prevalence of raised lesions involving 5% or more of the intimal surface was twice as great in both the aorta and right coronary artery of people with hypertension throughout the entire 15–34 year age span (185).

The Bogalusa heart study reported a study of 43 people aged 2–39 years who died from accidents or homicide and in whom premortem data were available. Half of the children 2–15 years of age had fatty streak lesions in the coronary arteries and 8% had fibrous plaques in their coronary arteries. These atherosclerotic lesions correlated with body mass index (BMI), systolic and diastolic blood pressure, total and LDL cholesterol, and triglycerides (186). It is thus important to address each of the risk factors for cardiovascular disease in order to decrease the risk of cardiovascular disease early in children with type 1 diabetes because the atherosclerotic process is already present in childhood. The increased cardiovascular risk in type 1 diabetes may be due to a number of factors, including endothelial dysfunction and increased arterial stiffness (187), and loss of endothelial integrity. Cardiomyopathy, consisting of interstitial fibrosis, has been described in adults with type 1 diabetes but is rare in children. The heart is subject to both microvascular disease, with microaneurysms and thickened capillary basement membrane, and macrovascular disease, with accelerated atherosclerosis.

Recent studies have found higher levels of endothelin-1 (an indicator of endothelial damage) in patients with diabetes and hyperlipidemia than in controls; those patients with diabetes who had vascular complications had significantly higher endothelin-1 levels than did patients without complications. The patients with diabetes complications also had significantly higher apolipoprotein B levels than did healthy controls. Patients without microvascular or macrovascular disease had levels similar to those of controls. Thus, it is possible that the susceptibility to the development of atherosclerosis might be attributed to the relationship between elevated lipid levels and endothelin-1 (188).

The Heart Outcome Prevention Evaluation (HOPE) study was a cohort study of 5545 individuals aged 55 years or more with a history of cardiovascular disease or with diabetes mellitus and at least one cardiovascular risk factor. Of the 3498 subjects in the latter category, microalbuminuria increased the relative risk of major cardiovascular events (relative risk 1.83), all-cause death (relative risk 2.09), and hospitalization for congestive heart

failure (relative risk 3.23). Any degree of albuminuria was a risk factor for cardiovascular disease, the risk increasing with the albumin/creatinine ratio. The use of the ACE inhibitor ramipril resulted in significant risk reduction of 25% for myocardial infarction, 37% for cardiovascular deaths, 33% for stroke, and 24% for all causes of mortality. ACE inhibition also reduced the risk of overt nephropathy by 22% and dialysis by 15%. Ramipril not only works by decreasing blood pressure but it also has anti-thrombotic effects, reducing collagen-induced platelet aggregation by 18% and ADP-induced platelet aggregation by 39% (189). In addition, ACE inhibitors have effects on endothelium and fibrinolysis that are beneficial in preventing plaque rupture and subsequent thrombosis, which are two key events in the acute formation and progression of atherosclerotic disease (190).

Similar to the findings of the UKPDS in adults with type 2 diabetes, the Pittsburgh EDC found a strong correlation between lipid levels and risk of cardiovascular disease in their 10 year study of patients with diabetes diagnosis in adolescence or earlier. They showed a relative risk of 2.3 for LDL cholesterol levels ≥ 130 mg/dl, and a relative risk of 1.8 for patients whose LDL levels were ≥ 100 mg/dl compared to those whose levels are lower. Triglycerides also conferred risk for cardiovascular disease with the relative risk being 2.5 for triglyceride levels ≥ 90 mg/dl and 3.3 if the levels were ≥ 150 mg/dl. Systolic blood pressure conferred additional risk with levels of ≥ 110 mmHg conferring a relative risk of 1.8, 120–129 mmHg, 2.5, and ≥ 130 mmHg 5.6. Any diastolic blood pressure >80 conferred additional risks but the relative risk was extremely high, 4.2, with diastolic blood pressures ≥ 90 (142).

The recommended treatment for adults with diabetes is to intervene when LDL cholesterol is >100 mg/dl and triglycerides >140 mg/dl. The data indicating that fatty streaks and atherosclerotic plaques are present during childhood indicate that the process begins early and, therefore, intervention should also begin early. Initial efforts at improving metabolic control with recommendations for diet and exercise should be initiated when lipid levels exceed target. If, after 3 months, fasting lipid profiles are not decreasing, pharmacological therapy should be considered. In our practice we have used HMG Co-A inhibitors (statins) with good success and few adverse reactions.

Triglycerides, too, should be vigorously treated. In some patients optimal blood glucose levels will not be achieved despite intensive attempts to maximize glycaemic control, resulting in isolated hypertriglyceridemia. In those instances, agents targeted at lowering triglyceride levels, such as gemfibrozil, should be considered.

6. Hypertension

The UKPDS showed that above a baseline systolic blood pressure of 110 mmHg, the higher the blood pressure, the

greater the risk of cardiovascular disease (191). The Hypertension Optimal Therapy (HOT) study compared the outcomes of maintaining diastolic blood pressure to goals of ≤ 90 mmHg, ≤ 85 mmHg, or ≤ 80 mmHg. In the 15,001 patients with diabetes mellitus at baseline, the rate of major cardiovascular events, defined as myocardial infarction, stroke, or death due to any cardiovascular event, revealed that the group randomized to maintain a diastolic blood pressure ≤ 80 mmHg had half the risk of major cardiovascular events compared to the group randomized to a blood pressure ≤ 90 mmHg. This differs from the results seen in the group without diabetes, in which the risk reduction was only 10% for the lower compared to the higher blood pressure readings (192), indicating that diabetes conferred an additional risk for cardiovascular disease.

These studies have led to the recommendations that hypertension should be treated to maintain a blood pressure of 130/80 mmHg or less and, as albumin excretion rate is an additional risk factor for cardiovascular disease (>20 mg/min, 30 mg/day, or 30 mg/g creatinine), blood pressure should be treated to a level of 120/75 mmHg or below in those with elevated albumin excretion rates (193).

IV. TYPE 2 DIABETES

A. Epidemiology

The definitions of incidence, prevalence, frequency, and epidemic have been provided in the preceding section on epidemiology of type 1 diabetes. Beginning around 1990, pediatric endocrinologists, who had been aware for decades of a small proportion of their diabetes patients having type 2 disease (194), noticed a sharp increase in the numbers of such patients (195). This was predominantly, but not exclusively, in the African-American and Hispanic-American population, and Native American youth were reported to have a 1% prevalence of type 2 diabetes as early as 1979 (196).

There seems little argument that type 2 diabetes in children and adolescents has become an epidemic. The first recognition of a substantial prevalence was among Pima Indian 15–24-year-olds, 9:1000 (0.9%) having diabetes associated with obesity and long-term complications (196). This was in a population in which 50% of adults have type 2 diabetes. Half of these youngsters had ketoacidosis. By the 1990s, 5% of 15–19-year-olds and 2.2% of 10–14-year-olds (previously 0%) had type 2 diabetes (197). Among First Nations children and youth in Canada, the frequency of type 2 diabetes is comparable to that of type 1 diabetes in the white population (198).

A study in Cincinnati reviewed 1027 consecutive records of children 0–19 years old diagnosed with diabetes and found that the proportion diagnosed as having type 2 increased from 2–4% between 1982 and 1992, to

16% in 1994 (199). It is interesting that this percentage was stable for over 20 years, Knowles having reported that approximately 3.5% of patients in this clinic had type 2 disease in 1971 (194). Thirty-three percent of those in the 10–19 year age group newly diagnosed in 1994 had type 2 disease. The estimated age-specific incidence for the community was 7.2:100,000, which is approximately half the incidence rate for type 1 diabetes in childhood, and a 10-fold increase from 1982 (30). In this study and also in a study from Arkansas, African-Americans accounted for 70–75% of the individuals with type 2 diabetes (200). It is estimated that one-third of Mexican-Americans with diabetes in southern California and over two-thirds of those in south Texas have type 2 disease (201, 202).

In Native North Americans four to six times as many females as males are affected, but among African-American and Mexican-American groups with type 2 diabetes, sex ratio has been far less skewed. It varies from 1.7 females for every male among African-Americans to nearly 1:1 among Mexican-Americans (203).

A study of 682 5–19-year-olds diagnosed between January 1, 1994, and December 31, 1998, at the three University-based diabetes centers in Florida found that 14% of the patients had type 2 disease. While 47% of type 1 patients were female, 63% of type 2 patients were. In contrast to the studies from Arkansas and Cincinnati, African-Americans were only 46% of those with type 2 diabetes while 22% were Hispanic, and the rest non-Hispanic whites. The risk for type 2 diabetes was three times greater for African-American youngsters and 3.5 times greater for Hispanics than for whites. During the initial year of the study, 8.7% of newly diagnosed patients were eventually classified as having type 2 disease, whereas in the last year of the study 19% were thus classified. This indicates a twofold increase in the proportion of new diabetes patients in this age group having type 2 disease over the relatively brief period of 5 years (28).

The recognition of an epidemic of type 2 diabetes is not unique to North America. Libyan Arabs are reported to have an age-specific incidence for the 15–19-year-old group of 6:100,000, increasing to 26:100,000 for the 20–24 year age group. Overall, this represents greater than twice the incidence for type 1 diabetes in males and over four times the incidence of type 1 diabetes in females (204). Among Hong Kong Chinese, type 2 diabetes accounts for >90% of young-onset diabetes and is strongly familial and associated with obesity (205). As with the Chinese, the Japanese have a very low incidence of type 1 diabetes. Annual urine testing for glucose of school-children in the Tokyo area has been carried out since 1975, followed by oral glucose tolerance testing for those with glucosuria. In the 12–15 year age group, there has been a doubling of incidence of type 2 diabetes from 7.2 to 13.9:100,000 paralleling increasing obesity rates (206). Other reports indicate that obese youth who are Bangla-

deshi (207), Australian aborigines (208), New Zealand Maoris (209), or East Indians or Arabs living in the United Kingdom (210) are also being observed with type 2 diabetes. Five obese adolescents aged 13–15 years with type 2 diabetes are the first white youngsters reported from England, and this problem is expected to be more prevalent with the epidemic of childhood obesity in that country (211).

A constant in the emergence of type 2 diabetes in young patients has been the association with obesity and increasing rates of that seminal condition. The U.S. National Health and Nutrition Examination Survey conducted between 1988 and 1994 found that 20% of children 12–17 years of age had BMIs above the 85th percentile for age (the definition of overweight), and that, depending on ethnicity, 8–17% were obese with a BMI >95th percentile. Not only was there a doubling of the frequency of childhood obesity since 1980 but the severity of obesity was also greater (212).

In a 20-year biracial community-based study in Louisiana (the Bogalusa heart study) of 11,564 5–24-year-olds from 1973 to 1994, there was a mean weight increase of 0.2 kg/year along with increased skinfold thickness. Overweight as defined above increased from 15 to 30%, and obesity from 5 to 11% in 5–14-year-olds and increased 5–15% in 15–17-year-olds. The increases in the second 10 years of the study were 50% greater than those in the first 10 years (213). In the National Longitudinal Survey of Youth, a prospective cohort study of 8270 children aged 4–12 years, there was a significant increase in overweight and obesity between 1986 and 1998. The prevalence rates in 1998 for overweight were 38% for African-Americans and Hispanics, and 26% for whites, while 22% of African-Americans and Hispanics and 12% of whites were obese (214).

The epidemic of obesity is also international. Similar trends to those in the United States have been reported for Japan (206) and the United Kingdom (215). In Russia, 6% of ~7000 6–18-year-olds examined in 1992 were obese and 10% were overweight, using US BMI reference data (216). In China, 3.6% of ~3000 6–18-year-olds examined in 1993 were obese and another 3.4% overweight (216). In 1996, in the United Kingdom, 22% of 6-year-olds were overweight, and 10% were obese; by age 15, 31% were overweight and 17% obese. Numerous studies in Europe have indicated that the highest rates of childhood obesity occur in Eastern European countries, particularly Hungary, and in the southern European countries of Italy, Spain, and Greece (217).

B. Etiology

The recent increase in type 2 diabetes prevalence in young patients has been so rapid that it must be explained by changes in the environment, most obviously increasing obesity rates (218, 219). Nonetheless, not all or even a majority of obese youngsters develop type 2 diabetes, em-

phasizing the importance of genetic factors. The *thrifty genotype* hypothesis, advanced nearly 40 years ago and recently updated (220, 221), explains the insulin resistance and relative beta-cell insufficiency associated with the development of obesity and type 2 diabetes as an adaptation for conserving energy and surviving famine. Until the modern era of continuous feasting, such a genotype would have had great survival advantage.

Numerous studies have demonstrated either insulin resistance preceding the development of type 2 diabetes or that limited pancreatic beta-cell capability to respond to the increased insulin requirements associated with obesity is the basic lesion (222–228).

Insulin resistance can be defined as the impaired ability to respond to physiological effects of insulin on glucose, lipid, and protein metabolism. Normal glycemic control requires the sensing of glucose concentration by the beta cells, the synthesis and release of insulin, binding of insulin to its receptors, and postreceptor insulin activation. This results in increased glucose uptake by muscles, fat, and liver tissue with decreased glucose production by the liver. In type 2 diabetes, there is peripheral insulin resistance in muscle and fat tissue, together with decreased pancreatic insulin secretion, and increased hepatic glucose output (Fig. 3). Note that both insulin resistance and impaired beta-cell function are required for the development of type 2 diabetes in this model (229).

1. Role of Fetal and Childhood Nutrition

The association of lower birth weight, smaller head circumference, and thinness at birth with impaired glucose tolerance or type 2 diabetes and insulin resistance in adults has suggested in utero programming that limited β -cell capacity and induced insulin resistance in peripheral tissues (230, 231). The maternal undernutrition that led to low birth weight was thought to impair development of the endocrine pancreas. The effect of fetal undernutrition on adult glucose tolerance has been confirmed in large

studies in Sweden and the United States (232, 233). Glucose intolerance was also found in adults who were the offspring of mothers who had starved during the last trimester of pregnancy during the Dutch famine of World War II (234).

Low birth weight has also been associated with increased cortisol axis activity in adults. South African non-obese 20-year-olds who had been underweight for gestational age had greater plasma cortisol response to adrenocorticotropin (ACTH), higher blood pressure, and impaired glucose tolerance compared to normal-birth-weight controls (235).

Three studies of young subjects from high-risk populations are consistent with reports of the effect of fetal nutrition on the risk for insulin resistance syndrome (type 2 diabetes, hypertension, hyperlipidemia) in adulthood. Current weight correlated with birth weight among 3061 Pima Indians aged 5–29 years, and 2 h glucose concentrations had a U-shaped relationship with birth weight in those >10 years old, regardless of current weight. Thus, higher blood glucose levels occurred in those with greater than normal and less than normal birth weight, unrelated to their current weight. The 2272 subjects without diabetes had negative correlations between birth weight and insulin concentrations at baseline and at 2 h, and insulin resistance. These findings supported the hypothesis of a survival advantage for insulin resistance in low-birth-weight babies (236).

In a study of 477 8-year-old Indian children, insulin resistance variables and plasma total and LDL cholesterol concentrations were strongly related to current weight. Lower birth weight was associated with elevated systolic BP, fasting plasma insulin and 32–33 split proinsulin concentrations, plasma lipids, glucose and insulin concentrations 30 min after glucose, and calculated insulin resistance. Children who had low birth weight but high fat mass at 8 years had the highest risk of insulin resistance syndrome variables and hyperlipidemia (237). Low-birth-weight white and African-American children ($n = 139$)

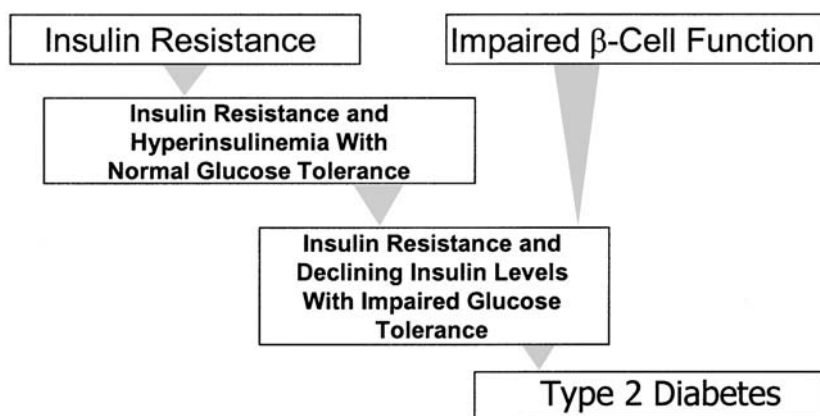

Figure 3 Development of type 2 diabetes. (Adapted from Ref. 229.)

were studied when they were aged 4–14 years. There were significant differences between the two races in the effect of low birth weight on visceral fat mass as measured by DEXA and CT, fasting insulin, acute insulin response and beta cell function, and HDL cholesterol concentrations, indicative of the genetic differences suggested by the thrifty genotype hypothesis (238).

The *thrifty phenotype* hypothesis has emerged from these studies indicating an effect of fetal nutrition on later glucose tolerance and other manifestations of insulin sensitivity. This hypothesis states that poor nutrition in fetal and early infant life would be detrimental to the development and function of the β -cells and insulin-sensitive tissues, primarily muscle, leading to insulin resistance. With obesity in later life, type 2 diabetes would develop. These findings could also be interpreted as a reflection of the *thrifty genotype*: that defective insulin action in utero results in decreased fetal growth and obesity-induced impaired glucose tolerance in later childhood or adulthood (26).

Genetic factors affecting birthweight and glucose metabolism are of interest in this regard. The polymorphism of the variable number of tandem repeats (VNTR) locus of the insulin chain is associated with decreased body length, weight, and head circumference at birth (239). Decreased birthweight has been associated with heterozygosity for a mutation in the glucokinase gene (240). Finally, the glucose transporter 4 (GLUT4) expression is impaired in young adults with insulin resistance who were undernourished in utero (241).

2. Maternal Diabetes

The influence of the diabetic intrauterine environment on the risk of type 2 diabetes in children was first appreciated from studies in the Pima Indian population. The prevalence of diabetes in the offspring of Pima women with diabetes during pregnancy is significantly greater than in nondiabetic mothers or those who develop diabetes after delivery (242). In another population, fetal β -cell function was assessed in 88 pregnancies with pregestational or gestational diabetes by measuring amniotic fluid insulin (AFI) concentration at 32–38 weeks' gestation. The offspring had oral glucose tolerance testing done annually from 18 months of age. Only 1 of 27 adolescents with normal AFI had impaired glucose tolerance, in contrast to one-third of those with elevated AFI (243). These studies suggest a generation-to-generation accumulation of risk for type 2 diabetes that further increases the public health concern about the epidemic of this disease in young persons (244).

3. Role of Puberty

In all reports of type 2 diabetes in childhood, the mean age at diagnosis is \sim 13.5 years, corresponding to the time of peak adolescent growth and development (198–203). Puberty is associated with relative insulin resistance, re-

flected in a two- to threefold increase in the peak insulin response to oral or intravenous glucose (245). Insulin-mediated glucose disposal is a mean 30% lower in adolescents than in prepubertal children or young adults (246). The physiological insulin resistance of puberty is of no consequence in the presence of adequate beta-cell function. The cause of this physiological resistance is likely to be increased activity of the GH-IGF axis, which is transitory and coincides with the physiological insulin resistance of adolescence (8).

4. Role of Obesity

The insulin resistance associated with obesity is the fundamental problem in type 2 diabetes in children and adolescents, as it is in adults. Total obesity accounts for approximately 55% of the variance in insulin sensitivity (246). That obese children have hyperinsulinism has been known for over 30 years (247, 248). Obese children have \sim 40% lower insulin-stimulated glucose metabolism than nonobese children (246). African-American 5–10-year-olds, especially girls, have reduced insulin sensitivity in proportion to increases in blood pressure, triglycerides, subcutaneous fat, percentage of total body fat, and stage of sexual maturation (249). The amount of visceral fat in obese adolescents correlates directly with basal and glucose-stimulated insulinemia and inversely with insulin sensitivity (250). Insulin-stimulated glucose metabolism and fasting insulinemia decrease with increasing BMI (246).

Glucose tolerance testing was carried out in 720 Pima Indians aged 10–39 years, including 325 who had been exclusively bottlefed as infants, 144 who were exclusively breastfed, and the rest who had been partially breastfed for the first 2 months of life. Those exclusively breastfed had significantly lower rates of type 2 diabetes than those exclusively bottlefed for each age decade, with an odds ratio for type 2 diabetes in exclusively breastfed individuals of 0.41 (251). Prolonged breastfeeding has been noted in a large study of nearly 10,000 5–6-year-old German children to markedly reduce the risk of overweight; 3.8% of those exclusively breastfed for 2 months were overweight vs. 0.8% of those breastfed for longer than 12 months (252). Lower insulin responses occur in breastfed versus bottlefed infants and breastfed infants have lower energy and protein intake. Association has been made between early high protein intake and later obesity. Breastfeeding results in a more appropriate caloric intake at a critical stage in development, whereas bottlefeeding is more likely to be associated with overfeeding and obesity. The typical overweight of the bottlefed infant may contribute to insulin resistance and obesity in adolescence and young adulthood.

5. Polycystic Ovarian Syndrome and Premature Adrenarche

There is increasing recognition of polycystic ovarian syndrome (PCOS) in the adolescent population (253). Girls

with PCOS are reported to have ~40% reduction in insulin-stimulated glucose disposal compared to nonhyperandrogenic control subjects (254, 255). Premature adrenarche, which has been thought to be a benign condition, is now recognized as a risk factor for ovarian hyperandrogenism and PCOS (256). Affected children are also more likely to have been born small for gestational age, indicating another aspect of the association of insulin resistance and intrauterine undernutrition (257, 258).

6. Racial and Familial Influences

A racial difference in the insulin responses to various stimuli parallels the ethnic/racial differential in type 2 diabetes frequency. Greater insulin responses to oral glucose are seen in African-American (AA) children and adolescents than in European-American (EA) children after adjustments are made for weight, age, ponderal (obesity) index, and pubertal stage. This is indicative of compensated insulin resistance in the AA youngsters (259, 260). Both prepubertal and pubertal AA children have higher fasting and stimulated insulin concentrations during glucose clamp studies than do EA youngsters (261). Lipolysis is also significantly less in AA children than in EA children, suggesting an energy conservation phenotype that would have survival value in times of famine but be detrimental with excess nutrition (thrifty genotype) (262).

Prepubertal children who have a family history of type 2 diabetes have lower insulin-stimulated glucose disposal and nonoxidative glucose disposal than do those without such a family history, indicating that family history of type 2 diabetes is a risk factor for insulin resistance in children, as in adults (263).

7. Genetic Considerations

The evidence that type 2 diabetes is a genetic disease includes the family clustering and segregation analyses that indicate that siblings of affected individuals have 3.5 times the general population risk of developing type 2 diabetes; studies of monozygotic twins that indicate a concordance of 80–100%, greater than twice the concordance in dizygotic twins and in monozygotic twins for type 1 diabetes; and the previously noted variations in insulin sensitivity and frequency of type 2 diabetes by ethnic origin (264). With rare exceptions, type 2 diabetes in children and adolescents, as in adults, is polygenic. The rare monogenic (autosomal dominant and mitochondrial) forms, however, provide insights for the study of typical type 2 disease (265).

Autosomal dominant forms include MODY and ADM. Molecular defects in 6 genes have been identified in families with MODY, affecting hepatocyte nuclear factors, glucokinase, and insulin promoter factor-1. Over 200 different mutations have been described. A glucokinase mutation has been identified in 1 of 10 ADM families studied as well (9).

In mitochondrial forms, disease transmission is exclusively from the mother because mitochondria are inherited via the cytoplasm of the ovum. The diabetes is usually indistinguishable from typical type 2 diabetes. In addition to the diabetes, affected individuals may also have sensorineural hearing loss, cardiomyopathy, optic neuropathy, myopathy, encephalopathy, lactic acidosis, stroke-like syndrome, or epilepsy (10–12).

The identification of type 2 diabetes susceptibility genes involves choosing between two general approaches: the candidate gene approach and the genome scan approach. In the candidate gene approach, there is a problem identifying or choosing an appropriate candidate, or the candidate may be unknown at the time of the study, as was the case with the MODY genes. In the genome scan approach, the entire genome is examined for linkages within families or associations within populations. In these analyses, microsatellites are particularly useful and microassays of mRNA are able to identify gene patterns that are over- or underexpressed in specific disease states. Figure 4 illustrates possible candidate genes in the beta cell–target cell interaction.

More than 20 loci have been linked to or associated with type 2 diabetes in adults, the most important being *NIDDM1*, described among Mexican-American sibships in Starr County Texas. This county, which is 97% Mexican-American, has the highest disease-specific diabetes mortality in Texas. The gene pool is 31% Native American. Some 474 autosomal markers and 16 X-linked markers were examined in 170 affected sibships involving 300 affected sibs and 78 unaffected sibs. Identified as linked to type 2 diabetes was the *NIDDM1* site on chromosome 2, accounting for ~30% of family clustering. This was equal in importance, therefore, to the linkage with HLA in type 1 diabetes (267). This linkage was not identified in other populations, including non-Hispanic white, Japanese, French, Sardinian, and Finnish (264). The Calpain gene in the *NIDDM1* region of chromosome 2 was subsequently found to be associated with type 2 diabetes in several of these populations, linked to different loci (268).

Calpains are calcium-activated neutral proteases ubiquitously expressed from fetal life through adulthood, which function in signaling, proliferation, differentiation, and insulin-induced downregulation of IRS-1. Multiple polymorphisms of the gene encoding Calpain-10, encoded by the *CAPN10* gene within the *NIDDM1* region, have been found to be associated with type 2 diabetes. The highest-risk combination of polymorphisms give odds ratios of 2.8–3.6 in Mexican-Americans, 2.6 in Finns, and 5.0 in Germans (268). Nondiabetic Pima Indians who are homozygous for a common polymorphism of *CAPN10* have reduced insulin-mediated glucose turnover as the result of decreased glucose oxidation rates (269).

Figure 5 summarizes the factors that have been discussed in the development of type 2 diabetes.

Figure 4 Beta-cell candidate genes in diabetes mellitus include GLUT2 (glucose transporter 2), which is responsible for the facilitative uptake of glucose by beta-cells; glucokinase (GCK), which is the beta-cell glucose sensor; mitochondrial genes that provide power to the beta cell (an increased ratio of ATP to ADP + Pi $\frac{[ATP]}{[ADP] + [Pi]}$); the ATP-sensitive potassium (K^+) channel (sulfonylurea receptor [SUR]); GLP-1 R (the beta-cell glucagon-like peptide-1 receptor) that responds to GLP from the gastrointestinal tract; insulin; PCII (prohormone convertase II, an example of an insulin-processing protein); and amylin, which is cosecreted with insulin. At the target cell (muscle, fat, or liver), candidate genes include the insulin receptor; intracellular proteins that are phosphorylated (insulin receptor substrate-1 [IRS1]); GLUT1; hexokinase II, which catalyzes the conversion of glucose to glucose-6-phosphate; glycogen synthase (GYS), which regulates glycogen production; and the regulatory subunit of phosphorylase (PHOSP) that regulates glycogen breakdown. GLUT4 is also a candidate gene, but GLUT4 is expressed only in muscle and fat tissues and is not expressed in the liver. (From Ref. 266.)

C. Clinical Features

The most striking difference between type 1 and type 2 diabetes is that in type 2 diabetes hyperglycemia/diabetes is one of many manifestations of the insulin resistance syndrome (diabesity syndrome, syndrome X, or the metabolic syndrome) (see Fig. 6). Common type 1 diabetes is, on the other hand, until the development of long-term complications, a unitary hormone deficiency state (although other autoimmune mediated deficiencies, such as thyroid, may develop).

Insulin resistance is a pathogenic factor in the devel-

opment of a broad spectrum of clinical conditions. These include hypertension, atherosclerosis, dyslipidemia, decreased fibrinolytic activity, impaired glucose tolerance type 2 diabetes, acanthosis nigricans, hyperuricemia, polycystic ovary disease, and obesity, which is the core abnormality (270).

In addition to the metabolic effects related to insulin resistance, obesity has deleterious associations in childhood and adolescence that increase morbidity and contribute to cardiovascular risk. This increased risk has been documented to be the result of the persistence of obesity into adulthood, rather than specific effects during child-

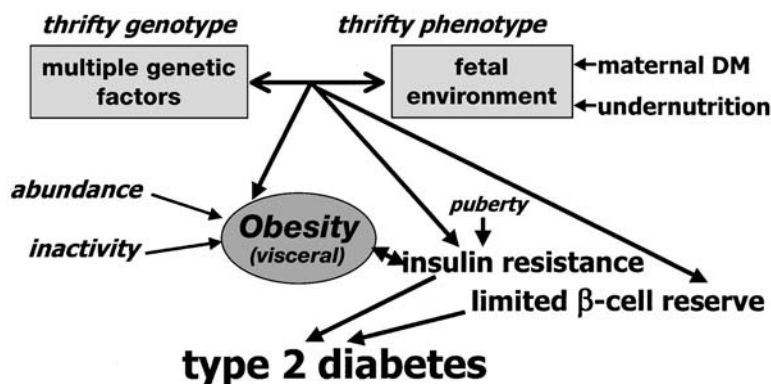

Figure 5 Factors in the development of type 2 diabetes.

hood (271, 272). Childhood obesity has been associated with elevated C-reactive protein and white blood cell counts, which are inflammatory indicators implicated in adult cardiovascular disease (273), proteinuria and focal segmental glomerular sclerosis (274), obstructive sleep apnea and other respiratory problems (275), hepatic steatosis (276), and orthopedic problems (275).

Lipoprotein abnormalities noted in type 2 diabetes include hypertriglyceridemia, elevated VLDL, elevated LDL-cholesterol, elevated lipoprotein (a), decreased high-density lipoprotein (HDL) cholesterol, increased small dense LDL particles, decreased lipoprotein lipase activity, increased lipoprotein glycation, and increased lipoprotein oxidation. The mechanism for this hyperlipidemia pattern is as follows. Fat cells, which are sensitive to insulin, store triglyceride and suppress hormone-sensitive lipase, the enzyme that breaks down triglycerides to release free fatty acids. Insulin also provides glucose to the fat cells for forming glycerol, the triglyceride backbone. With insulin resistance, there is abnormal breakdown of triglyceride and release of free fatty acids and glycerol, the latter contributing to gluconeogenesis. The free fatty acids cause insulin resistance in muscle tissue. In the liver, they are

reconverted to triglyceride, driving the production of LDL, which is the lipoprotein carrier of triglycerides, and the other dyslipidemic changes follow. The hyperinsulinemia of the insulin resistance state further drives the synthesis of fatty acids from glucose in the liver (277).

In adults there is a strong association between the level of hyperglycemia and risk factors for macrovascular disease. Dyslipidemia is one of several factors that accelerate atherosclerosis in type 2 diabetes. Additional factors described include oxidative stress, glycation of numerous vascular proteins, defective endothelium-dependent vasodilatation, and abnormalities of platelet function and coagulation (increased fibrinogen, increased plasminogen activator inhibitor-1, decreased antithrombin III and other anticoagulant and proteins, elevated factors VII and VIII, elevated vascular adhesion molecule 1, increased platelet adhesiveness and aggregation, decreased platelet nitric oxide [NO] production [NO mediates vasodilatation], decreased platelet prostacyclin production, and glycation of platelet proteins) (278).

Hypertension is estimated to account for 35–75% of diabetes complications involving both the microvasculature and macrovasculature (279). Diabetes or impaired glucose tolerance doubles the risk of developing hypertension (280). There is emerging evidence of a genetic predisposition to hypertension and type 2 diabetes related to the angiotensin-converting enzyme genotype (281). The hypertension in type 2 diabetes is due to volume expansion and increased vascular resistance, with reduced NO-mediated vasodilatation and increased activity of the renin-angiotensin system (278).

Acanthosis nigricans (AN) is an indicator of insulin resistance, prominent in genetic insulin resistance syndromes not associated with obesity. The frequency of AN in obese adolescents varies greatly by ethnicity: ~90% in Native Americans, ~50% in African-Americans, ~15% in Hispanic-Americans, and <5% in non-Hispanic whites. As an indicator of hyperinsulinism, AN also varies by ethnicity inversely to its frequency of association with

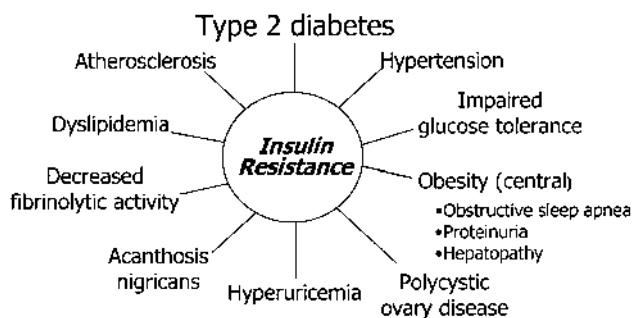

Figure 6 Insulin resistance: associated conditions. (Adapted from Consensus Development Conference of the American Diabetes Association, Diabetes Care, 1997.)

obesity (282). In a study of 139 overweight 6–10-year-olds, AN was present in 50% of African-Americans and 8.2% of whites. Half of those with fasting hyperinsulinemia did not have AN. AN was not considered a reliable marker for hyperinsulinemia in overweight children, despite its presence in a child with diabetes being a diagnostic indicator of type 2 disease (283).

D. Prevention

The concept of prevention of type 2 diabetes arises naturally from the appreciation of its environmental causation. Primary prevention would involve intervention to prevent obesity or to correct obesity before the development of other features of the insulin resistance syndrome. Prevention of obesity is a societal challenge. From the individual physician standpoint, the major question is, "Who should be tested?" (8). The importance of primary prevention of obesity lies in the recognition that preclinical impairment of glucose tolerance as the result of obesity-induced insulin resistance conveys cardiovascular risk; a substantial number of severely obese adolescents have impaired glucose tolerance (284). Considerations of testing for type 2 diabetes in children began with the assumption that this will be done in obese individuals, making the determination of obesity the screening test. The testing for hyperglycemia then becomes a case-finding exercise (285). The justifications for case finding include:

1. That the condition tested for is sufficiently common to provide a reasonable yield
2. That the condition is serious in terms of morbidity and mortality
3. That the condition has a prolonged latency without symptoms during which abnormality can be detected
4. That a test is available that is sensitive (few false-negative results) and accurate with acceptable specificity (a minimum number of false-positive results)
5. That an intervention is available to prevent or delay disease onset or more effectively treat the condition if it is detected in the latency phase

The first three conditions are unquestionably met by type 2 diabetes in children. The fourth criterion is met by plasma glucose measurement, with sensitivity and specificity dependent upon the circumstances of measurement. The last criterion, however, is extremely challenging, as discussed below.

A consensus panel of the American Diabetes Association (8) has recommended criteria for testing children. They should be overweight (BMI >85th percentile for age and sex (Figs. 17 and 27 in Chapter 43), weight for height >85th percentile, or weight >120% of ideal for height). Additionally, they should have two other risk factors, which were considered to be: family history of type 2 diabetes in first or second degree relatives; being of Amer-

ican Indian, African-American, Hispanic, or Asian/Pacific Islander race/ethnicity; and signs of insulin resistance or conditions associated with insulin resistance (acanthosis nigricans, hypertension, dyslipidemia, PCOS). It was recommended that testing begin at age 10 or at the onset of puberty if puberty occurs at a younger age and that repeat testing be done every two years, with fasting plasma glucose as the preferred test.

These criteria were not evidence based, which is why the consensus panel provided the disclaimer that clinical judgment should be used to test for diabetes in high-risk patients who do not meet these criteria. One might also take issue with the suggestion to use fasting plasma glucose. This was considered preferable because of its lower cost and greater convenience: 2 h plasma glucose increases earlier in the course of the development of type 2 diabetes, making it a more sensitive measure. Fasting hyperglycemia is an advanced stage of type 2 diabetes, and therefore highly specific but relatively insensitive as a testing method. Random plasma glucose concentration can be measured in those who have taken food shortly before testing, with a glucose concentration ≥ 7.8 mmol/L (140 mg/dL) serving as an indication for further testing.

The need for primary prevention efforts in childhood has been the subject of wide publicity for the past several years, with recognition of the epidemic of obesity (286–291). Obesity is associated with diminished school performance due to sleep apnea, torpor associated with physical inactivity, and social stigmatization. Secondary prevention of obesity is rarely successful beyond the short term. Intervention in adult populations indicates the enormous difficulty in altering lifestyle and dietary habits. The challenge for the pediatrician and society is to counter eating and entertainment trends that provide popular social outlets and are highly attractive, heavily promoted, and readily available. Financially stressed school systems often sabotage community efforts by providing fast food concessions and soft drink and snack vending machines in exchange for financial support from the vendors. Food service in middle and high schools typically includes high-fat, high-calorie foods such as pizza and french fries. There are inadequate opportunities for noncompetitive sports permitting participation of all youngsters, such as aerobics and dance, and there has been a sharp reduction in compulsory physical education programs. For some minority youngsters, there is the additional problem of a lack of safe environments in which to be physically active, and lack of funding for afterschool programs. Finally, school curricula have not effectively incorporated healthy lifestyle training.

A number of school-based and community-based programs have been developed targeting high-risk populations (290–295). School-based programs attempt to modify the food provided in school meals, incorporate healthy lifestyle training into classroom education, and create a school environment that promotes physical activity. Pre-

school and kindergarten through sixth grade programs encourage family involvement; high-school-based programs focus on social networks and peer pressure in an effort to promote behavior change and reduce risk factors. Short-term behavioral change has occurred with these programs, but longer-term studies are needed to determine whether these changes persist and reduce the risk for type 2 diabetes.

Before the contemporary epidemic of type 2 diabetes, we had noted the occasional obese African-American teenager attending our diabetes adventure camp program and rapidly becoming normoglycemic with vigorous exercise, permitting withdrawal of insulin. This phenomenon has been documented in 1 week summer camp programs for North American Indian youth with type 2 diabetes, who are able to achieve normoglycemia after 5 days of increased physical activity. Unfortunately, the behaviors of camp are not maintained, and most of the youngsters return to poor glycemic control at home (292, 296). Programs are in place that emphasize nutrition and exercise in schools, including those on Indian reservations throughout the United States, but their effectiveness has yet to be documented (294, 297).

The health-care system is increasing its appreciation of the magnitude of the obesity/type 2 diabetes problem. All who have contact with at-risk families need to emphasize the importance of intervention. Parent training by pediatricians, WIC and county health-department nurses, and other health personnel should continue to promote prolonged breastfeeding, which, in addition to its other many benefits, reduces the risk of obesity in childhood (251, 252). Parents also need to know that a fat baby is not a more healthy baby: candy, potato chips, and other foods with high caloric density and low nutritional value should not be used as rewards. Because children with normal-weight parents have a much lower risk of overweight (<7% vs. 40% with one overweight parent; and 80% with two overweight parents) obesity prevention is important for the whole family. It will not work for any one member by himself or herself (298). Physical activity must also be a family investment, with habits such as using stairs instead of elevators or escalators, walking or bicycling to school and to shop, and engaging in physically demanding chores such as yardwork. The most effective single thing that can be done to increase children's physical activity is to turn off the television set (299). It is also important that meals be taken on schedule, in one place, with no other activity going on.

Studies in adults have shown improved glucose tolerance or reduction in the rate of development of type 2 diabetes for up to several years as a result of lifestyle interventions, including individualized counseling for weight reduction, reduced total and saturated fat intake, increased fiber intake, and exercise (300–302). Among the most sustained efforts was a 13 year project involving six communities, The Minnesota Heart Health Program.

This included adult education classes for weight control, exercise promotion, and cholesterol reduction; a worksite weight control program; a home correspondence course for weight loss; and a weight gain prevention program. Despite this intensive effort, there was a strong upward trend in weight even when all potentially confounding variables were considered (303). Intervention with children, particularly preadolescents, should be more effective. In one study of family-based intervention involving 113 families, children had greater relative weight loss and better maintenance than the adults with one-third of children remaining nonobese after 10 years (304). In another study involving 24 families, including children 8–12 years old, the intervention was a 10–12 session behavioral modification. Two-thirds of the families completed the treatment program and those children who completed it lost weight. Weight loss was not maintained during 4–13 months of follow-up, however (298). Even modest successes in the reported studies have to be interpreted with caution, because these are selected study populations.

Diabetes prevention programs have to be designed with an understanding of the health beliefs and behaviors of the community. For example, American Indian youth with family members who had diabetes did not relate the complications of retinopathy or amputation to this problem in one study. Over half of the youth thought that diabetes was caused by bad blood, and greater than one-third attributed it to general weakness (305).

No medications are currently approved for the reduction of body weight in children. Medications that have been effective in adults do not result in maintenance of weight loss when the drugs are stopped. The only study of medical intervention for obesity in adolescents has been with metformin. Twenty-nine black and white adolescents aged 12–19 years with BMI >30 kg/m², with elevated fasting insulin concentrations (>15 uU/ml), a family history of type 2 diabetes, and normal fasting glucose and HbA1c were randomized to receive metformin 500 mg twice daily or placebo for 6 months. Controls had an increase in BMI of 0.23 SD and metformin-treated subjects a decrease of 0.12 SD, a significant difference. There was also a significant decrease in fasting glucose concentrations and insulin levels in metformin-treated youngsters compared with controls. Transient abdominal discomfort or diarrhea occurred in 40% of those taking metformin (306). In adults, lifestyle intervention was more effective than metformin in preventing progression from impaired glucose tolerance to type 2 diabetes (302).

There are limited data and no guidelines for surgical treatment of obesity in children and adolescents. A report in 1975 indicated a median weight loss of ~25% 3 years after gastric bypass or gastroplasty in 18 morbidly obese adolescents (307). A report 5 years later of 30 patients <20 years of age described average weight loss of 40 kg after 3 years and 26 kg 5 years after gastric bypass or gastroplasty. Major postoperative complications occurred

in one-third and there was one postoperative death from anastomosis leakage (308). In 2001, 1 year follow-up of 10 adolescents age 17 years or younger who had undergone gastric bypass surgery by newer techniques was reported. There were no postoperative complications. Morbidities from obesity resolved in seven, including sleep apnea, hypertension, dyspnea, vertebral compression fracture, and refusal to attend school. Nine of the youngsters had >30 kg weight loss. Incisional hernia, gallstones, or small bowel obstruction required surgery in four of the individuals. Medical complications included mild iron deficiency anemia and transient folate deficiency (309).

E. Treatment

1. Challenges

The treatment challenges of type 2 diabetes in children and adolescents differ greatly from those of type 1 diabetes, due largely to the nature of the disease and those most likely affected. While type 1 diabetes is distributed throughout the population, type 2 diabetes disproportionately affects families with fewer resources, paralleling the distribution of obesity in the population. Whereas type 1 diabetes occurs throughout childhood, usually during the time when parental influence predominates, type 2 diabetes affects mostly those in adolescence or beyond, when peer influence is most important. There is also a large difference in family experience, with only ~5% of families with a child with type 1 diabetes having affected family members; 90% or more of youth with type 2 diabetes have family experience. These family members have typically failed to control their weight and glycemia, developing complications and creating an aura of despair and futility. Treatment priorities are also different between type 1 and type 2 diabetes. Extensive lifestyle modification, beyond insulin administration and glucose monitoring, is only required by those patients with type 1 disease who are overweight and inactive. However, the emphasis is on lifestyle modification in all those with type 2 diabetes and secondarily on glucose monitoring and hypoglycemic medication. Finally, technological innovation has revolutionized management of type 1 diabetes with improved insulin purity and delivery, self blood glucose monitoring, and the development of insulin analogs, with an artificial pancreas on the horizon and the likelihood that there will be islet cell replacement.

Technological advances have, however, been the underlying cause of the problem of type 2 diabetes, with advances in home entertainment systems, labor-saving devices, and transportation, and food preparation making calorically dense food increasingly available, desirable, and inexpensive.

2. Treatment Goals

The goals of treatment are to promote weight loss, normalize glycemia and HbA1c, control or prevent hyperten-

sion and hyperlipidemia, reduce acanthosis nigricans, and increase exercise capability.

Treatment is more important than might be indicated by the level of glycemia in some patients, because of the multitude of cardiovascular risk factors associated with insulin resistance. Just as in adults with newly diagnosed type 2 diabetes, young patients may already have evidence of complications, reflecting a prolonged period of impaired glucose tolerance. Among 100 Pima Indian children and adolescents with type 2 diabetes, 7% had high cholesterol (≥ 200 mg/dl), 18% had hypertension (BP $\geq 140/90$, now considered far too high a cut off), and 22% had micro-albuminuria (albumin/creatinine ≥ 30) at the time of diagnosis. Ten years later, while still in their 20s, they had mean HbA1c of 12% indicative of poor control, 60% had micro-albuminuria, and 17% had macro-albuminuria (albumin/creatinine ≥ 300) (310). Japanese investigators have described a high risk of renal failure in those who develop diabetes under 30 years of age (311).

Reduction in the risk of complications may require more stringent glycemic control in the insulin resistance state of type 2 diabetes than is required in type 1 diabetes, with diligent attention to comorbidities. In the UKPDS there was a 25% decrease in the risk of microvascular complications when the average HbA1c decreased from 7.9 to 7.0% (312). Reduction in BP to below 144/82 resulted in a more dramatic decrease of 37% in the risk for microvascular disease, 44% decrease in stroke occurrence, and 36% decrease in heart failure (313).

3. Changing Behavior

The behavioral changes and motivation required are so extensive that the treatment team requires a psychologist or social worker. One of the simplest changes to make is to eliminate the frequent consumption of high-calorie soft drinks, sweetened tea, and juices, substituting water, diet soft drinks, and artificial sweeteners for tea or Kool-Aid (314). Daily exercise should be documented in an attempt to break the vicious cycle of increased weight producing increased torpor, resulting in decreased activity and increased weight. As noted above, the most effective single method for doing this is turning off the television. A relatively small reduction in weight, accomplished by an increase in activity, can restore euglycemia and decrease hyperinsulinemia, as in the camp experience.

The stages of change are outlined in Table 5 (315).

4. Hypoglycemic Agents

Pharmacological therapy can decrease insulin resistance, increase insulin secretion, slow postprandial glucose absorption, or, in the case of insulin injection, supplement inadequate secretion of insulin (Table 6).

a. Biguanides. The biguanides act on insulin receptors in the liver to reduce hepatic glucose production and in muscle and fat tissue to enhance insulin-stimulated glucose uptake. They have an anorexic effect that can pro-

Table 5 Stages of Change

Concept	Definition	Application
1. Precontemplation	Unaware of problem; has no intention of changing in the near future (next 6 months) and may deny need for change. "Everyone in our family is big."	Increase awareness of need for change, personalize information on risks, benefits
2. Contemplation	Thinking about change, in the near future; knows there is an issue but is not ready to change; there may be intent to change in the next 6 months. "I've heard that some overweight kids are getting diabetes. But I don't think I can handle going on a diet."	Motivate, encourage to make specific plans
3. Preparation	Making a plan to change; knows what s/he wants to do; is seeking more information, planning, even starting to change; may tell family and friends; there is an intent to change in the near future. "I found out that if I lose some weight, this smudge on my neck will fade. I've talked to my Mom about it . . ."	Assist in developing concrete action plans, setting gradual goals
4. Action	Implementation of specific action plans; making changes in the environment to support the change. Relapse is normal. This stage may last as long as 6 months. "I'm walking three times a week for half an hour. I've quit drinking sodas . . ."	Assist with feedback, problem solving, social support, reinforcement
5. Maintenance	Continuation of desirable actions; or repeating periodic recommended step(s); may last 6 months to 5 years; some add a sixth stage, termination; "I lost 10 pounds. The smudge on my neck went away. I am going to keep on walking and eating better."	Assist in coping, reminders, finding alternatives, avoiding relapses (as apply)

mote weight loss. As noted above, metformin has also been used for this purpose. It has also been used to reduce acanthosis and ovarian hyperandrogenism. Long-term use is associated with a 1–2% reduction in HbA1c, but a high rate of side effects, including transient abdominal pain, diarrhea, and nausea, limits compliance in adolescents (316). Metformin must not be given to patients with renal

impairment or who have hepatic disease, cardiac or respiratory insufficiency, or who are undergoing radiographic contrast studies, because of the risk of lactic acidosis.

Metformin is the only oral hypoglycemic agent for which there are available pediatric data. Eighty previously untreated patients age 8–16 years were randomized to receive metformin or placebo in a multicenter study. Dosage

Table 6 Effects of Drug Action in Diabetes

Drug type	Action	Effect on BG ^a	Risk of low BG ^a	Weight increase	Lipid decrease
Biguanides (metformin)	↓ Hepatic glucose output ↑ Hepatic insulin sensitivity	++	0	0	+
Sulfonylureas	↑ Insulin secretion and sensitivity	++	+	+	0
Metiglinide (repaglinide)	Short-term ↑ insulin secretion	++	+	+	0
Glucosidase inhibitors (acarbose, miglitol)	Slow hydrolysis and absorption of complex CHO	+	0	0	+
Thiazolidinediones (rosi-, pioglitazone)	↑ Insulin sensitivity in muscle and fat tissue	++	0	+/-	+
Insulin	↓ Hepatic glucose output ↓ Hepatic glucose output; overcomes insulin resistance	+++	+	++	+

^aBG = blood glucose.

began at 500 mg twice daily and increased to 2000 mg/day over 2 weeks. Rescue criteria resulted in few placebo cases remaining by 16 weeks of the study. At 4 months or longer, the mean fasting glucose change from baseline was a decrease of 44 mg/dl with metformin and an increase of 20 mg/dl with placebo. The adjusted mean HbA1c with metformin was 7.5% and with placebo 8.6%. With metformin, there was no weight gain, and modest decrease in some patients, and lipid profiles improved. No serious adverse events were recorded (317).

When metformin is not being effective, it is important to take an in-depth history of medication intake, including refill history from the pharmacy, which may demonstrate that the medication is not being taken. Metformin may normalize ovulatory abnormalities in girls with PCOS or ovarian hyperandrogenism, increasing their pregnancy risk.

b. Sulfonylurea and Metiglinide/Repaglinide. This group of drugs increases insulin secretion and is thus most useful when there is residual beta-cell function. The sulfonylureas bind to specific receptors on the K⁺/ATP channel complex, while metiglinide and repaglinide bind to a separate site on the complex (Fig. 7). Activating ATP or binding by these drugs causes K⁺ channels to close, with resultant membrane depolarization, allowing calcium influx and insulin release. ATP-binding sites equilibrate rapidly; sulfonylurea sites do so slowly with prolongation of binding, which explains the sustained effects of traditional sulfonylureas. Metiglinide has an intermediate equilibration and binding duration, explaining its use for more rapid stimulation of insulin secretion and need for premeal dosing (318). The major adverse effects of the sulfonylureas have been hypoglycemia, which, as noted above, can be prolonged, and weight gain, which is particularly troublesome for adolescent patients.

c. Glucosidase Inhibitors. Alpha-glucosidase inhibitors such as acarbose and miglitol reduce the absorption of carbohydrates in the upper small intestine by the inhibition of oligosaccharide breakdown, delaying absorption in the lower small intestine. This results in reduction in postprandial glycemia. Long-term use of glucosidase inhibitors is associated with a reduction in HbA1c of 0.5–1% (319). Flatulence associated with the use of these agents makes them unacceptable to young patients.

d. Thiazolidinediones. These drugs act directly on muscle, adipose tissue, and liver to increase insulin sensitivity, and are, therefore, considered specific agents for the manifold problems of the insulin sensitivity syndrome. They bind to nuclear proteins, activating peroxisome proliferator activator receptors (PPAR), which are orphan steroid receptors particularly abundant in adipocytes, thus increasing formation of proteins involved in the nuclear-based actions of insulin. These include cell growth, adipose cell differentiation, regulation of insulin receptor activity, and glucose transport into cells. Long-term treatment with thiazolidinediones has been associated with a

reduction in HbA1c of 0.5–1.3% (320). Side effects have included edema, weight gain, and anemia. The original member of this group of drugs, troglitazone, was associated with liver enzyme elevations in ~1% of those taking the drug, with mortality in some who had existing liver problems. For these reasons it was withdrawn from the market. The newer thiazolidinediones, rosiglitazone and pioglitazone, have not been shown to have significant hepatotoxicity.

The binding of thiazolidinediones to PPAR γ receptors is ubiquitous and includes arterial walls that contain muscle, affecting the growth of muscle cells and their migration in response to growth factors (321). These drugs also improve lipid profiles, decreasing LDL-cholesterol and triglycerides, while increasing HDL-cholesterol. These effects on vascular muscle and lipids could be important for the reduction of macrovascular disease associated with type 2 diabetes (322).

Although studies are in progress, there is no published data yet on the use of rosiglitazone and pioglitazone in children.

e. Insulin. The development of type 2 diabetes is an indicator of limited beta-cell function, estimated to be ~50% by the time of diagnosis in adults, most of whom will be insulin-requiring by 6 or 7 years later (323). Despite the insulin resistance, relatively low dosages of supplemental insulin (a few units) may be sufficient to maintain euglycemia. The newly available long-acting insulin analog without peak effects, insulin glargine, may be especially useful for type 2 diabetes in combination with premeal megilitinide, particularly in individuals unwilling to take metformin. Hypoglycemia has not been a common side effect of insulin in type 2 diabetes, but weight gain is an important adverse effect. All patients with type 2 diabetes eventually require treatment with insulin because of continuing loss of beta-cell function.

f. Treatment Recommendations. Treatment decisions are based on symptoms, severity of hyperglycemia, the presence or absence of ketosis/ketoacidosis (DKA), or dehydration. Dehydration signs may be less obvious in the obese. Symptomatic youngsters with type 2 diabetes, in addition to frequently having ketoacidosis at onset, are at particular risk for the hyperglycemic hyperosmolar state (HHS) which carries a high mortality (324). Acute management of DKA is discussed in Chapter 27. A treatment decision tree for outpatient management is given in Figure 8 (328).

Metformin should be the first oral agent used, because it is associated with HbA1c reductions similar to those resulting from use of sulfonylureas, without the risk of hypoglycemia and without weight gain. Furthermore, there may be greater effect on reducing LDL cholesterol and triglyceride levels. If there is failure of monotherapy using metformin over 3–6 months, sulfonylurea, metiglinide, or insulin can be added. Thiazolidinediones may

Figure 7 Insulin secretory control mechanism affected by sulfonylurea and metiglinide.

be used in older adolescents. Combination formulations may result in better compliance.

It is important to counsel adolescents with type 2 diabetes about sexuality and pregnancy, and provide contraceptive advice, as necessary. Metformin and thiazolidinediones may restore normal periods (326), and none of these oral agents should be used during pregnancy.

Although routine self-monitoring of blood glucose may not be needed as frequently as with type 1 diabetes, frequent monitoring is needed during periods of acute illness, during dosage adjustment, or with symptoms that indicate hyper- or hypoglycemia. It is also necessary to monitor for asymptomatic hypoglycemia in individuals who are taking insulin or sulfonylureas. The frequency of routine self-monitoring of blood glucose needs to be individualized, but should include a combination of fasting and postprandial measurements.

Assessments of HbA_{1c} concentration should be done at least twice a year and, if metabolic control is unsatisfactory and requires treatment adjustment, every 3 months. The involvement of a dietitian with skill in the management of nutritional problems in children with diabetes is essential. Dietary recommendations need to be culturally appropriate, sensitive to family style and resources, and understood by all caregivers.

g. Treating Comorbidities. Hypertension is an independent risk factor for the development of albuminuria, retinopathy, and cardiovascular disease in type 2 diabetes in adults. Its importance is emphasized by the experience of the UKPDS, in which hypertension control was more important than blood glucose control in reducing the risk of cardiovascular disease (313). Blood pressure should be measured at diagnosis and at least quarterly and compared to standards appropriate for age and height percentiles, as

noted in the tables in Chapter 38 (327). Elevations must be treated aggressively if there is persistent elevation above the usual percentile for the child or above the 90th percentile for either systolic or diastolic pressure. Angiotensin-converting enzyme inhibitors (ACEI) are the initial drug of choice. As with type 1 diabetes, many physicians use ACEI prophylactically.

Lipid levels and urine albumin excretion should be measured shortly after diagnosis and annually, or more often if there is abnormality and if treatment effects need monitoring. Exercise, weight loss, and glycemic control may be sufficient to correct hyperlipidemia. Dietary recommendations should be for the reduced-fat diet consistent with step 1 American Heart Association guidelines. Lipid-lowering medications should be added if lipid levels do not normalize after 2–3 months of dietary and diabetes control efforts. HMG CoA reductase inhibitors (statins) are the most commonly used lipid-lowering agents in children; they are contraindicated in pregnancy or if there is risk of pregnancy (328).

Unlike the recommendations for type 1 diabetes, in which is recommended that regular monitoring for complications not begin until adolescence and several years of diabetes, monitoring lipids and urinary albumin excretion, and examining the retina in those with type 2 diabetes, should begin at the time of diagnosis (8).

V. OTHER TYPES OF DIABETES

A. Cystic-Fibrosis-Related Diabetes

Cystic-fibrosis-related diabetes (CFRD) occurs in a substantial percentage of patients with CF and impaired glucose tolerance can be seen in most adolescents, which is

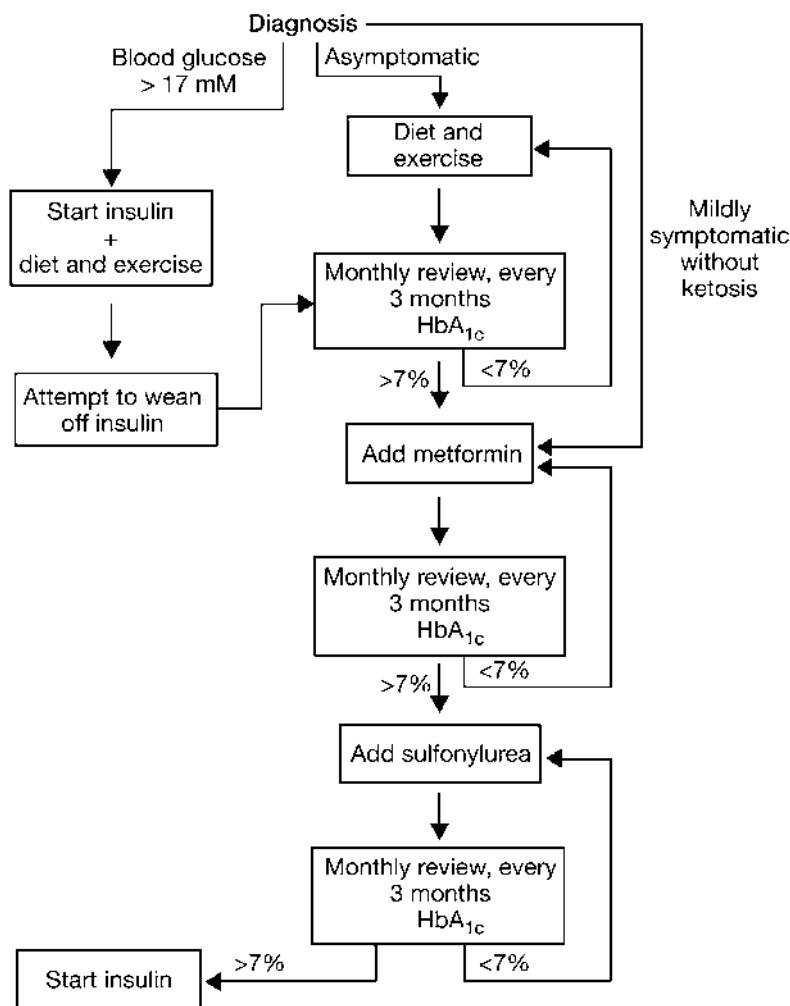

Figure 8 Treatment decision tree for outpatient management of type 2 diabetes.

the result of progressive pancreatic damage (329). Earlier reports suggested a prevalence of 2.5–7.6% in North America (330–332), but more recent reports indicate prevalences of 10–15% for overt diabetes (333–337). These rates continue to increase with the increase in longevity of patients with CF.

Pancreatic involvement beginning in utero progresses throughout life (338, 339). It eventually results in impaired insulin secretion in the vast majority of CF patients who have pancreatic exocrine deficiency, even in the presence of normal glucose tolerance (332, 340–343). The development of CFRD is considered an indicator of deterioration in the clinical state (330, 344, 345). Decrease in pulmonary function has been noted 2–4 years before the onset of CFRD, with improvement with insulin therapy (346). The course of CFRD is complicated by the need for high caloric intake to counter malabsorption and catabolism, the intermittent use of glucocorticoids, and re-

current infection. The diabetes has features of type 1 and type 2 disease, with insulin dependency and resistance (15, 335, 347, 348).

A recent report noted impaired glucose tolerance in 20% of 18 children with cystic fibrosis aged 9.5–15 years who were studied for the relationship of insulin secretion, IGF axis, and growth. However, impaired insulin secretion was present in 65% and was related to poor linear growth. It was considered that the increased demands for insulin during the pubertal growth period could indicate the need for treatment of growing children before the appearance of overt diabetes (349).

B. Infantile Diabetes

1. Transient Diabetes of the Newborn

This rare condition occurs from the first few hours to 6 weeks of life in small for gestational age infants who ap-

pear hyperalert with marked subcutaneous wasting (350). Onset is sudden, with severe dehydration in the absence of vomiting or diarrhea. Histological appearance of the pancreas has been reported as normal (351, 352), showing decrease in islet cells (353, 354) or increased numbers of islets (355). Approximately one-third of reported patients have a family history of type 1 diabetes (350) and have siblings who have been reported with transient diabetes of the newborn (356–358). Insulin may be required for a few days to a few months. Some infants may have permanent diabetes and a number have been reported to develop diabetes 8–20 years later (359–363).

2. Pancreatic Dysgenesis/Agenesis

Infants with transient diabetes who subsequently develop permanent diabetes (358–363) are thought to have dysgenesis of the pancreas. In one of these patients, no evidence of islet cell or other organ-specific autoimmunity was detected (361).

Only a few patients with severe pancreatic dysgenesis or agenesis have been reported, with permanent neonatal diabetes. Some have not survived, particularly those with associated anomalies such as gallbladder achalasia, diaphragmatic hernia, and cardiac defects (364, 365). Several infants without associated anomalies have survived, including siblings from our clinic, both with onset at 4 months of age, who are now in their mid-30s and have long-term complications (366–368). Such patients have exocrine and endocrine deficiency.

I. INTRODUCTION

Three distinct aspects of diabetes management have occupied the minds of physicians and researchers for decades: the *control* of the disease, its *prevention*, and its *cure*. Simultaneous with significant advancements in the control of the metabolic disturbances of diabetes and its complications, immense efforts have recently been carried out through large-scale clinical trials to find a strategy to prevent the disease in susceptible individuals, and, through arduous bench, animal, and clinical research, to find a definitive cure. These latter two objectives have been elusive, but as more people and resources are committed to this endeavor their attainment looks closer.

Since the first recognition of diabetes as a clinical entity, utmost attention has been paid to its control. Initial efforts were directed toward amelioration of the symptoms of polyuria and polydipsia, which would lead to severe cachectic states and eventually to death within weeks or months. Severe dietary restriction, especially in the intake of sugars and other carbohydrates, high-fat diets, and even complete starvation were the only available strategies to achieve that goal before the discovery of insulin. This therapeutic approach did not prevent death as an almost immediate outcome of the disease and, surely enough, contributed to the progression through the final stages of the disease.

The discovery of insulin by Banting and Best in 1922 divided the history of diabetes in two. When injections of pancreas extracts started to be used as management for this disease, the expectations of the outcome changed drastically. Survival beyond the first months after diagnosis was now possible, starvation was not necessary, and patients could recover from their initial cachexia. Progressive refinement by the pharmaceutical industry

lead to improved purification techniques, which helped to circumvent initial problems with nonpurified pancreas extracts such as local and generalized reactions and immune-mediated inactivation of insulin through antibody production. Years of research and sophistication of molecular engineering have led to the production of human insulin through recombinant DNA technology and the design of insulin analogs with particular pharmacokinetic profiles that allow extrarapid or retarded insulin action of injected insulin.

II. METABOLIC DISTURBANCES AS A CONSEQUENCE OF INSULIN DEFICIENCY

The hormone insulin has pervasive effects on overall energy homeostasis. Although diabetes mellitus is usually considered a disease of carbohydrate metabolism, in fact, equally serious alterations are present in the area of lipid and protein metabolism. The actions of insulin referable to carbohydrate metabolism are multifold. Insulin promotes the translocation of glucose from the intravascular space to the intracellular space by activation of insulin receptors that promote glucose transport. Intracellularly, insulin promotes the utilization of glucose as a direct energy source, or storage of glucose as glycogen (primarily in the liver, muscle and kidney), or converted into lipids with accumulation within the cell via the lipid synthesis pathway. Insulin also inhibits the release of glucose from the liver, promoting hepatic glucose storage. The actions of insulin on lipid metabolism include the transfer of so-called excess dietary carbohydrate calories into the lipid synthesis and storage pool and the inhibition of lipid mobilization from adipose tissue stores. Insulin has both di-

rect and indirect effects on protein metabolism. The insulin molecule, apparently through specialized cell membrane receptors, works in a coordinated fashion with pituitary growth hormone to stimulate amino acid uptake into cells and promote cell growth and multiplication. Insulin promotes glycolysis and inhibits gluconeogenesis indirectly.

Insulin release is stimulated by dietary intake (glucose, amino acids and, to a much lesser extent, fats and ketones). The body energy metabolism is under the direct control of insulin during the prandial and immediate postprandial periods, whereas it is probably under the control of glucagon and epinephrine in the distal postprandial periods, growth hormone and cortisol being added during intervals of fasting. The overall effect in the normal healthy individual is very narrow variations in the concentration of all nutrients throughout the course of each day, despite feasting and fasting cycles. These well-regulated nutrient concentrations include glucose, amino acids, triglyceride, cholesterol, ketone bodies, and a number of energy intermediates such as lactate, pyruvate, and glycerol. The extremes of both hyper- and hypoglycemia are avoided, as are significant variations in lipid and protein concentration.

The deficiency of insulin results in a reversal of all these normal patterns. Hyperglycemia results as a consequence of impaired peripheral glucose uptake and increased hepatic glucose production, from an increased rate of both glycogenolysis and gluconeogenesis.

Hyperlipidemia results from a marked increase in the mobilization of preformed fat in adipose tissues, and ketonuria results if this process continues unabated, without intervention of insulin therapy. The concentration of several counterregulatory hormones is increased, including growth hormone, adrenocorticotrophic hormone (corticotropin), cortisol, glucagon, and, in extreme stress, the catecholamines. Insulin deficiency and counterregulatory hormone excess combine to complicate the metabolic picture further, exacerbating hyperglycemia, hyperlipidemia, and ketogenesis. This leads to an increased rate of proteolysis and gluconeogenesis, placing the individual in negative nitrogen balance (1, 2). Acidosis, which is an additional complicating factor, ensues as the result of direct and indirect effect of insulin deficiency. Increased serum ketone concentration is the main cause of acidosis in insulin deficiency. Two additional sources of acidosis in the individual with moderate to severe fluid deficit are build-up of excretable organic acids resulting from decreased renal clearance and accumulation of lactic acid resulting from anaerobic metabolism of peripheral tissues.

III. MANAGEMENT

We are currently in the midst of changes in the strategies, techniques and objectives of diabetes management. There are continual improvements in techniques used for short-

and intermediate-term assessment of metabolic control using capillary blood glucose monitoring and measurements of glycosylated proteins, particularly glycosylated hemoglobin, as well as attempts to standardize their laboratory measurements. The widespread utilization of these monitoring techniques has provided the patient and the therapeutic team with quantitative means of assessing metabolic status over time. There have been also advancements in other areas, since the improvement in the purification of pork insulin and the introduction of human insulin produced by DNA technology. More recently, beef insulin has been taken off the US market and there is widespread use of insulin analogs. The latter may allow much more precise tailoring of an individual patient's insulin therapeutic needs based on the individual's lifestyle (3, 4). An improvement of insulin infusion devices, both external and implanted, also provides the potential for more physiological insulin delivery (5). Ultrasound-enhanced transdermal delivery of insulin and oral insulin therapy is appearing as a possible way to treat diabetic patients. Trials of inhaled insulin are currently underway (6–10).

With these methodological advances has come an increasing interest in attempting to normalize energy metabolism, with the anticipation that this will eliminate or reduce the serious vascular complications of diabetes. This increasingly popular therapeutic movement has been improperly referred to as intensive insulin therapy rather than the more appropriate intensive diabetes therapy (11). Unfortunately, many, both physicians and patients have concluded that the way to improve diabetes management is simply to give insulin more often. This is a serious misconception. Intensive diabetes therapy also includes the need for intensive blood glucose monitoring and close attention to the patient's dietary regimen. Successful therapeutic management of the child and adolescent with diabetes mellitus requires a highly integrated four-pronged approach: insulin administration, dietary management, physical activity, and education and emotional support (12–15).

IV. INSULIN THERAPY

A. Insulin Requirements

Initial insulin requirements are approximately 1.0 unit/kg/day. A partial remission, referred to as the honeymoon period, is identified as a decline in insulin requirement below 0.5 units/kg/day associated with very good metabolic control as measured by near-normal glycosylated hemoglobin levels. This occurs in more than 65% of all newly diagnosed patients during the first several weeks after diagnosis, with the nadir in insulin requirement reached on average between 12 and 16 weeks after diagnosis. During this period, insulin doses must be carefully adjusted downward to prevent hypoglycemia. In some cases the evening dose can be entirely eliminated.

This is particularly true in children under 6 years of age. We believe that the duration of this remission period is usually longer than experienced in the past and in some cases may last longer than 2 years before increasing insulin needs are again expressed. The maintenance of some residual C-peptide secretion by intensive therapy must be a goal of treatment in view of the beneficial effects on the prevention of microvascular complications seen in the Diabetes Control and Complications Trial (DCCT) (16). Eventually, in all patients, insulin requirements begin to climb after the nadir of remission and generally plateau at about 0.8 units/kg/day in the preadolescent and somewhat above 1.0 units/kg/day in the adolescent. Pubertal development is associated with increased insulin requirements secondary to insulin resistance induced by changes in the hormonal milieu. It is not infrequent to find adolescent patients who require 1.5–1.8 units/kg/day to maintain target hemoglobin A1c (HbA1c) levels (17).

B. Available Insulin Preparations and Insulin Management Strategies

The last 20 years have witnessed major changes in all aspects of insulin treatment. Improvement in manufacturing techniques has resulted in a remarkably increased purity of commercially available insulin preparations. Mixed beef and pork insulin, formerly the standard of therapy, has been removed from the marketplace for the most part. Highly purified pork insulin is currently available in some but not all countries. Human insulins produced by recombinant DNA technologies are the most frequently available choices. New synthetic insulin analogs have been engineered to provide either extra-rapid action or prolonged, peakless pharmacokinetics.

Human insulin has been thought to have both theoretical and practical advantages and has been the insulin of choice. Two issues have raised concern about this apparently reasonable conclusion. Several investigators, particularly Europeans, have reported that severe hypoglycemia, usually without typical hypoglycemic symptoms, is far more common in patients treated with human insulin preparations. This suggests that there is something uniquely different about the body's response to human insulin that increases the likelihood of hypoglycemia. The controversy remains unresolved, with most studies not supportive of a uniquely dangerous hypoglycemic potential for human insulin (18, 19). The second issue has to do with the time course of human insulin. It relates to our own experience and decision to prefer pork insulin, especially in children under 10 years of age. All the human insulin preparations appear to have a quicker onset time and a shorter duration of effect than the comparable pork insulin preparations (20). Diabetes in very young children can be controlled using a split-dose regimen of NPH insulin plus lispro or regular insulin given before breakfast and before the evening meal using pork NPH. When using this schedule with human insulin, the shorter time course

of human NPH, particularly overnight, did not provide adequate glucose control. Raising the dosage increased the likelihood of nocturnal hypoglycemia. If a two injection/day regimen is used, we recommend highly purified pork NPH insulin, which provides better and more prolonged coverage especially through the night. Insulin antibody formation is the same whether pure pork or human insulins are used. Although we still support the use of pork insulin, we have recently faced the problem of decreased availability of these preparations. For this reason and where flexibility of schedule is needed, we recommend using alternative insulin injection regimens that circumvent the problem of poor overnight coverage. One such regimen involves the administration of human NPH insulin before breakfast and before the bedtime snack. We have found human ultralente insulin useful only in the context of a four shot/day regimen when it can provide basal coverage, but with significant variation in its effect.

The use in the near future of long-acting insulin analogs may provide another strategy to avoid this problem, as discussed below. A fast-acting insulin analog is also given before breakfast and before dinner and, if necessary, with a bedtime snack. Regular insulin was, until not too long ago, the only fast-acting insulin available. The introduction of insulin lispro, an extra-rapid acting insulin analog, in the last decade has broadened the repertoire of therapeutic options. Insulin lispro is synthetically produced by recombinant DNA technology, introducing a reversal of the natural occurring sequence of proline and lysine in positions B-28 and B-29, respectively to LysB28, ProB29. It is highly homologous with human insulin, yet it does not self-associate into dimers as does human insulin. The stabilized hexamer complexes of insulin lispro immediately dissociate into monomeric subunits upon injection into the subcutaneous tissue. This characteristic confers on insulin lispro at least three differences compared to human regular insulin: the action starts earlier (10–15 min), the peak insulin concentration in plasma is higher (more than double), and the duration of action is shorter (less than 4 h). A similar pharmacokinetic profile is found in insulin aspart, another analog also produced by recombinant DNA technology substituting proline in position B28 with Aspartate (21–23).

These rapid analogs provide a more precise action profile at mealtimes. Our current practice in the treatment of the great majority of school-age patients involves three insulin shots: human or pork NPH plus insulin lispro before breakfast, insulin lispro before supper, and human or pork NPH insulin before bedtime snack. Variations in this basic regimen are designed depending on the need. They include, but are not limited to, substitution of regular insulin for insulin lispro; the use of an insulin injection (either regular or lispro) before lunch or lispro before an afternoon snack; and the use of fast-acting insulin in conjunction with the bedtime dose of NPH insulin, depending on the blood glucose and the size of the snack. Advan-

tages of these short-acting analogs include lower postprandial blood glucose levels, less hypoglycemia, and thus better hypoglycemia awareness and counterregulation in response to low blood sugar levels. An additional advantage in pediatric patients, especially infants, is that medication can be given after eating due to these agents' rapid initiation of action. This allows dosing adjustments depending on the food intake, which in infants is very frequently unpredictable. More recently, long-acting insulin analogs have been synthesized with the idea of providing peakless basal insulin concentrations. Also produced by recombinant DNA technology, these analogs are designed to have a longer period of action by changing their isoelectric point (i.e., insulin glargine) or by promoting their binding to serum proteins such as albumin (fatty acid acylated insulins) (21).

Insulin glargine has already been approved by the Food and Drug Administration (FDA) and became available a few months before completion of this chapter. Two arginine molecules are added at the C-terminus of the B-chain. With these two extra positive charges, the isoelectric point changes and creates a molecule that is soluble at a more acidic pH and less soluble at the physiological pH of subcutaneous tissue. Another modification of the molecule, a substitution of Asparagine in position 21 of the A-chain by Glycine, is intended to protect it from deamidation and dimerization that would otherwise occur in the acidic solution in which it is formulated. The acidity of its formulation (pH 4.0) allows insulin glargine to remain soluble. Once injected in the subcutaneous tissue, the solution is neutralized and forms microprecipitates from which insulin glargine is slowly released, providing virtually no peak concentrations and duration of action for at least 24 h (24). Disadvantages of this type of insulin include the fact that it cannot be mixed with any other type of insulin. Therefore, two separate injections must be given when the action of a rapid action insulin is needed at the same time. The acidic pH of the preparation seems to be responsible for a burning sensation at the injection site for some patients. Large multicenter trials of the effectiveness of these newer analogs in the pediatric population are soon to be initiated in the United States.

It should be possible in the near future to tailor the individual patient's insulin management carefully to his or her lifestyle and changing requirements. The availability of this new family of synthetic insulins will make the demise of animal insulin less painful for all of us. Premixed insulins, such as 70/30 or 75/25 H are used only in patients with compliance problems because of the inability to adjust doses according to planned food intake, meal plans, or ambient blood sugar levels.

C. Insulin Dosage Adjustments

By applying glucose goals derived from self-monitoring of blood glucose, insulin adjustments are made as necessary to attempt continually to bring the patient's glucose

variation into the target range. Diet and exercise alterations are also considered and applied as necessary. We use a 10% rule for insulin changes: By summing the total insulin dose and dividing by 10, one obtains the number of units of insulin that is generally safe to increase or decrease in a patient who requires change. However, a maximum increase is 6 units (total insulin dose of 60 units). If the patient's blood glucose levels are generally high throughout, then the distribution of the increase follows the current distribution: usually two-thirds added to the morning and one-third to the evening dosage. On the other hand, if the patient is persistently out of range at a particular time, for example before dinner, then the dose modification applies only to the morning or lunch-time insulin and the amount is determined by calculating 10% of the morning dose. The distribution between NPH insulin and regular insulin or insulin lispro depends upon both the pre- and postprandial blood glucose levels. In the asymptomatic patient, we prefer to make insulin adjustments relatively slowly, after 3–5 days on a particular dose. On the other hand, if the patient is symptomatic and/or ketonuric, one must be more aggressive in moving toward a more acceptable blood glucose excursion. Most patients are provided with insulin scales for their short-acting insulin doses that can be used in anticipation of planned activity, food intake, and to correct current hyperglycemia.

V. INTENSIVE DIABETES THERAPY

There has been a gradual movement toward intensification of diabetes management, climaxed by the results of the DCCT. The term "intensive insulin therapy" has unfortunately become embedded in our terminology and to the uninitiated may be interpreted to mean that overall diabetes management can be improved simply by increasing the frequency of insulin administration. The proper message, of course, is that improved results are accomplished in the great majority of patients only with intensification of all aspects of management. The therapeutic set of the diabetes team, with full cooperation of the patient and family, is directed toward achieving either optimal management utilizing whatever resources are available or something less. The concept of conventional vs. intensive management must be set aside. We must undertake to do the very best we can with each patient, understanding that there are major differences in resources and abilities as well as many barriers to the achievement of metabolic near-normality (25–28). Intensive diabetes therapy almost always includes frequent insulin injections or continuous insulin infusion.

A. Continuous Subcutaneous Insulin Therapy

In the early days of insulin pumps in the 1980s, we developed extensive pump experience with our adolescent patients. Their initial metabolic response was gratifying in

terms of decreasing glycosylated hemoglobin and blood glucoses. As we evaluated these patients over time, however, the enthusiasm for living with a pump declined and their compliance with the intensive therapeutic regimen diminished. Thus, the early successes were lost. At that time we concluded that the rigors of insulin pump therapy with the available pumps were such that few children or adolescents would adapt successfully to it. We essentially discontinued pump use in our general clinic population (29). More recently, however, advances in delivery systems have made pump therapy much easier for the patient, with more reliable insulin delivery and less complications. The potential for success with pump therapy has been demonstrated in carefully selected patients who are either very mature and have made a clear commitment to improved health or have very dedicated families.

Determining patient eligibility for continuous subcutaneous insulin infusion (CSII) therapy has been a subject of controversy. Among the factors involved are the age of the patient, the degree of prior glycemic control and multiple psychological, familial, cultural, and socioeconomic issues. The American Diabetes Association suggests four basic conditions that should be met by the patient to increase the chances of obtaining benefit from CSII: motivation, willingness to work in conjunction with the health care team, demonstrated understanding of the technical aspects of correct use of the pump, and ability to obtain and interpret data to make decisions regarding pump programming (30, 31). Patient's age and the degree of prior glycemic control are major factors accounting for the heterogeneity of eligibility criteria for CSII in different centers. Some centers have been more liberal with the use of insulin pumps in younger patients including young children and even infants, while others prefer to reserve this mode of therapy for older children, adolescents, and young adults capable of independent decision-making. The involvement of parents or caregivers is a *sine qua non* in the former group. The parental share of responsibility approaches 100% in the youngest patients, and should decrease in the older ones, although at least a certain degree of supervision continues to be highly recommended in the latter. Improvement of glycemic control achieved by adolescent patients with the participation of their parents or responsible adults decreases significantly when these patients are left on their own (32). This most probably reflects a decrease in the frequency of blood glucose monitoring and/or failure to give premeal insulin boluses. Poor judgment at the time of deciding on pump programming and bolus calculation according to the blood sugar level, the food to be eaten, and the amount of exercise predicted for the next minutes or hours would be additional concerns in some adolescents managed through CSII without parental involvement.

Our most recent experience with CSII (33) showed that metabolic control improved in patients switched from multiple daily insulin injections (MDI) to CSII as mani-

festated by a decrease of 0.5% of HbA1c at 3 and 6 months after initiation. HbA1c levels at 9 and 12 months after initiation of CSII were not significantly different from baseline. A similar difference in Hb1Ac levels was observed between patients managed with MDI and those receiving CSII during the same observation period, with lower HbA1c levels in the latter. The patients who had worsening of their diabetic control when switched to CSII were older than the patients whose condition improved. They also had higher baseline levels of HbA1c. We found that the patients more likely to experience improved metabolic control are those with better control to begin with than patients in poorer control who are older adolescents and whose condition tends to worsen.

A beneficial effect of CSII found by us and others is the reduction in the frequency of severe hypoglycemia. We have not seen an increase in body weight in patients managed with CSII, as would be expected according to the results of DCCT. Despite the lack of improvement in metabolic control in older adolescents with poorer control, reduction in the frequency of DKA has been reported (34).

Approximately one-third of DCCT's intensively managed patients were using an insulin infusion device. The general experience did not clearly document a benefit of either pump or MDI therapy. Since then, uncontrolled studies have suggested improved glycemic control and less hypoglycemia in children and adolescents in CSII (35), although similar results are not universally reported (36). Our own experience suggests that CSII does not improve glycemic control in those with high HbA1cs but can improve quality of life. The biggest risk is exaggerated expectations of pump therapy.

VI. SOMOGYI EFFECT AND DAWN PHENOMENON

A very common management problem is illustrated by the child whose fasting blood glucose levels are consistently elevated. The usual strategy is to increase the evening NPH insulin until these levels are satisfactory. The common complication of this technique is that nocturnal hypoglycemia may be induced, leading to the Somogyi reaction and rebound hyperglycemia the next morning. This is particularly true with human insulin because of its shorter duration time. This hypoglycemia is masked by counterregulation or waning of insulin action. If fasting glucose levels are high, with NPH given at bedtime the addition of lispro at this time may be beneficial. In essentially all patients, excluding some toddlers, a minimum program of three injections per day program is needed. This is due to the need to continue covering the postprandial glucose rise after dinner with regular insulin or insulin lispro and administration of lispro as late as possible. This change has been frequently successful and surprisingly well accepted by most patients and parents (37, 38).

Elevated plasma glucose concentrations in the morning (after 5 am), without preceding hypoglycemia characterize the so-called dawn phenomenon. This occurs as a result of increased insulin requirements in the early morning, which could be related to either increased insulin clearance or decreased insulin action. An early-morning surge of growth hormone, one of the insulin-counterregulatory hormones, has been hypothesized as a causal factor. Whether long-acting insulin analogs are able to avoid this morning rise in blood glucose levels as a result of the dawn phenomenon in children and adolescents remains to be demonstrated in larger-scale pediatric trials. The once-popular concept of the Somogyi effect is unlikely to explain early-morning hyperglycemia, although counterregulation can account for past hypoglycemic euglycemia. Rebound hyperglycemia probably only occurs after active food therapy of low blood sugar (although this is not well reported in children).

VII. DIETARY MANAGEMENT

As stated above, the nutritional component is one of the cornerstones of diabetes management. Recommendations on nutritional intervention in diabetes have changed over the years. Before the discovery of insulin, the concept of dietary management relied on severe restriction of caloric intake leading to starvation diets. This was followed by low-carbohydrate–high-fat diets and, most recently, higher-carbohydrate–lower-fat diets (see Table 1). Our own recommendations since the early 1970s have been 50–55% carbohydrate, 15–20% protein, and 30% fat with limitation of saturated fat and cholesterol to <10%.

The design of nutritional strategies for the management of diabetes must be based on the procurement of basic goals, including the maintenance of near-normal glucose and lipid levels; the delivery of adequate amount of calories to achieve normal growth and development in children, and to avoid weight loss or excessive weight

gain in all patients; and the prevention of nutrition-related complications such as hypoglycemia, renal disease, cardiovascular disease, hypertension, and autonomic neuropathy. Therefore, diabetic patients should have individually designed meal plans based on their needs and goals, taking into consideration cultural, ethnic, and financial issues. This clearly opposes the obsolete concept of a unique diabetic or American Diabetes Association diet. Furthermore, the term *diet* should be avoided, given its connotation of imposed and punitive restriction.

The food plan for a diabetic child, as well as that of any healthy child, should be balanced. It should contain adequate amounts of carbohydrates, protein, fat, minerals, vitamins, fiber, and water. Current recommendations suggest that carbohydrates should provide 55–60% of the total caloric intake; no more than 30% of the calories should come from fat; and 10–20% should derive from protein. It is evident from Table 1 that carbohydrate intake has become less restricted according to recent recommendations. Carbohydrates are mainly of two kinds: complex carbohydrates, or starches; and simple sugars. Great emphasis has been given in the past to the avoidance of simple sugar intake in diabetic individuals. Although this continues to be true, the restriction need not be as severe as originally proposed. Simple sugars naturally occurring in fruits (fructose) and milk (galactose), for instance, should be allowed in the meal plan. Fructose induces a smaller rise in blood sugar than isocaloric amounts of sucrose or other carbohydrates; however, it may induce an undesirable increase in serum cholesterol and low-density lipoprotein (LDL) cholesterol. Therefore, its intake in diabetic individuals should be moderate and its use as a sweetener should be considered as not advantageous. Sucrose may also be part of the meal plan, as long as it is not abused and is part of a meal rather than eaten alone. Glycemic excursions after ingestion of sucrose have been found to be of similar magnitude to those occurring after intake of white bread, refined rice, and cooked potatoes. Therefore, more attention has been paid to the total amount of carbohydrate and not the source of carbohydrate. Less attention has been paid to patient factors that affect absorption of the carbohydrate, such as the rapid absorption in the liquid state or delay when eaten with fat or fiber.

Within the 30% of calories coming from fat, it is accepted that less than 10% could come from saturated fat, another 10% from polyunsaturated fat, and yet another 10% or more from monounsaturated fat. Because LDL cholesterol is a major risk factor for both micro- and macrovascular disease in patients with type 1 diabetes (39, 40), we advise that more attention be paid to the fat content of the diet. This is in addition to the importance of the role of fat in influencing glycemic excursions after a meal.

Limitations of protein content in the meals prior to albuminuria have been recommended because of the detrimental effect of protein excesses in animals. Although

Table 1 Historical Perspective on Nutrition Recommendations

Year	Distribution of calories		
	% Carbohydrate	% Protein	% Fat
Before 1921	Starvation diets		
1921	20	10	70
1950	40	20	40
1971	45	20	35
1986	Up to 60	12–20	<30
1994	^a	10–20	^{a,b}

^aBased on nutritional assessment and treatment goals.

^bLess than 10% from saturated fats.

Source: Ref. 38a.

this effect has not yet been proven in children and adolescents, preventing protein overload to the kidneys appears to be prevalent.

Food exchange lists have been created to deal with the heterogeneity of nutrient composition of different foods, so as to provide some standardization when designing a meal plan. These lists group certain foods together based on similarities in their composition. The carbohydrate group includes several lists: starch, fruit, milk (skim, reduced fat, whole), other carbohydrates, and vegetables. The meat and meat substitute group also includes several lists: very lean, lean, medium fat, and high fat. The fat group includes lists of monounsaturated fats, polyunsaturated fats, and saturated fats. These lists are not a dietary formulation *per se*. The meal plan should be individually tailored by a skilled dietician for each patient. This can be made on the basis of the exchange lists to help the patient understand better the rationale for the prescription, and to make it easier when making decisions about food choices and alternatives.

A balanced diet must provide adequate amounts and proportions of all macronutrients and micronutrients. The food exchange list system is a tool to help accomplish this goal; however, tailoring insulin needs according to food exchanges and vice versa is not a straightforward task. Because more than 90% of the calories from carbohydrates end up as glucose (compared to far fewer of the calories from protein and fat), carbohydrate is considered the main dietary driver for blood glucose concentration. Carbohydrate counting has been suggested as a means to assist diabetic patients in designing their meal plan, especially when their glycemic control has proven inadequate through other ways of meal planning or no meal planning at all. Such counting offers the possibility of calculating, by a simple mathematical operation that involves initial training and attainment of skills, the amount of insulin that should be given to cover the predicted blood glucose rise after a certain food is eaten. This approach has proven particularly useful to calculate insulin boluses to cover meals in patients receiving insulin through an infusion pump. However, it should not be limited to this mode of insulin delivery. In addition, when teaching carbohydrate counting, the importance of stabilizing the other meal constituents should not be forgotten.

VIII. EXERCISE AS A THERAPEUTIC MODALITY

An increasing body of scientific data suggests, but does not definitively prove, that physical fitness is beneficial and highly desirable for the patient with diabetes mellitus (41–45).

We have taken on faith that this is true and, consequently, recommend to our patients that they incorporate a regular exercise program into their daily lives. Exercise increases glucose utilization, and highly fit muscles have

an increased sensitivity to insulin and, consequently, glucose uptake. Our clinical observations include the following. Highly fit children and adolescents with diabetes usually require less insulin per level of metabolic control. These individuals are generally in better metabolic control than their relatively unfit diabetic peers. The physically fit individual, particularly the competitive athlete, usually has a better self-image and a better appreciation of the importance of good diabetes management. Episodic exercise, as opposed to regular exercise that leads to an improved level of physical fitness, may be dangerous in terms of both hypoglycemia or the induction of diabetic ketoacidosis in very poorly controlled patients. Our long-term diabetes complication studies indicate that persons who participate in competitive athletics during high school and college had a significant reduction in both diabetes-related morbidity and mortality when evaluated 10–30 years later.

Our recommendation to our patients is that they undertake a daily exercise regimen (7 days per week) that involves a fairly vigorous level of exercise for approximately 1 h each day. This is usually most easily achieved by participating in competitive programs at school. If this is neither possible nor desirable, other entirely satisfactory exercise activities can be substituted: vigorous walking, jogging, swimming, aerobic dancing, tennis, and golf. The patients must understand the effects of exercise on blood glucose and be ready to make necessary adjustment in his or her insulin dosage or diet. In general, we prefer to increase caloric intake before exercise rather than reduce insulin in the normal-weight child, although either or both may be satisfactory solutions to problems of hypoglycemia associated with exercise. The very poorly controlled patient who desires to embark on an exercise program should be encouraged to improve overall metabolic control by increasing insulin dosage beforehand.

IX. EDUCATION AND EMOTIONAL SUPPORT

The importance of education as part of the integral management of diabetes cannot be overemphasized. Education should start at the very moment when the diagnosis of diabetes is made. However, the initial phase of shock experienced by parents in response to the new diagnosis in their child may interfere with their understanding of basic principles. For this reason a well-balanced combination of emotional support and objective teaching is essential for the success of the initial education process. Previous misconceptions about diabetes that patients and their families may have when they are first faced with this diagnosis should be clearly addressed. When the child presents in severe diabetic ketoacidosis, starting the education process should be deferred until the parents see signs of recovery and the child is able to participate in a teaching conversation depending on his or her age. However, the diabetes

management team should be readily available to answer questions from family members during this critical period, to soothe their fears and to start building a nurturing relationship. That opportunity can be used to explain in very basic language the pathophysiology of DKA and the reason for the clinical manifestations during the days prior to the diagnosis and at presentation. This will help the family to recognize later the signs of decompensation that need to be avoided.

The education process may start immediately when the newly diagnosed child does not present in DKA or comes with a very mild DKA. Doing this initial education when the child is an inpatient or an outpatient depends on several considerations: resources available to the diabetes management team, third-party reimbursement issues, and patient-related issues. Several investigators have addressed the question of differences in the outcome when comparing inpatient and outpatient education in the newly diagnosed patient. Initial retrospective studies by Lee, Chase, and Swift suggested that the patients who received outpatient education at the time of diagnosis had lower rate of hospital readmission for diabetes-related problems than those who received inpatient education (46–48).

In a prospective study comparing the outpatient education programs at Texas Children's Hospital (Houston, TX) and Denver Children's Hospital (Denver, CO), with the inpatient education program at Children's Hospital of Pittsburgh (Pittsburgh, PA), no significant differences were found in the outcome of multiple variables among the two approaches. The outcome measures considered in this study included rates of hospital readmissions and/or emergency room visits, knowledge test scores, sharing of responsibilities, adherence to the diabetes regimen, family functioning scores, coping skills, and perceptions of quality of life. Because very sick patients are always hospitalized initially, the problems with these studies are that they may be comparing outcomes in milder and more severe onset (49–51).

In our service we usually provide this initial education to the patient and the family in the hospital on an inpatient basis. Attempts to move to an outpatient setting have encountered obstacles, especially in terms of reimbursement by third-party payers.

Both inpatient and outpatient approaches have advantages and disadvantages, as listed in Table 2.

X. THE THERAPEUTIC TEAM

Medical care of the child with diabetes is different from that of patients with most other diseases handled by the pediatrician. The primary focus is on education. A major responsibility for the physician is to ensure that the patient and family members are well educated about the diversity of problems associated with diabetes. This cannot be a one-time experience: it must be a constantly renewed and continuing activity. However, attainment of the knowl-

Table 2 Advantages and Disadvantages of Inpatient and Outpatient Diabetes Education

Inpatient setting	
Advantages	
	Interaction between patient and family with the team in one place and during a few days.
	Supervised environment, rapid response to possible complications. Patients/family may feel safer.
	Fewer trips for patient/family for medical facility.
	Fewer difficulties in team member reimbursement.
	Less reticence in early initiation of tight metabolic control.
Disadvantages	
	Hospital stay increases general cost.
	Less comfort for patient and family.
	Removal of child from home environment.
Outpatient setting	
Advantages	
	Change is reduced because hospital stay is avoided.
	Family starts building self-confidence early in the process.
Disadvantages	
	Needs well-mounted and coordinated infrastructure of outpatient resources, including sufficient well-trained personnel on 24 h call.
	If families cannot commute from home, housing at no cost to family must be available.

edge is only half of the battle. The knowledge gained about insulin administration, the utilization of monitoring information, dietary principles, and the incorporation of exercise into daily life must be accepted by the patient, with adherence to the therapeutic regimen as a personal commitment for improved health. Each patient and family has their own unique barriers to full acceptance and incorporation of the recommended therapeutic regimen. Although most of these barriers are in the psychological sphere, other factors, such as peer group pressures, financial problems, or unavailability of parents at appropriate times, may make the recommended therapeutic regimen difficult, if not impossible, to follow.

The physician diabetologist must serve as captain of the therapeutic team. It is his or her responsibility to assess the unique characteristics of each patient and family and to determine the general therapeutic strategies to be used in an attempt to help the child achieve and maintain good health. Several other team members are essential for the creation of an effective diabetes therapeutic program. The diabetes nurse educator plays a pivotal role. Although the experienced physician must always be involved in reinforcing the educational components of therapy, it is unlikely that he or she has sufficient time to carry the primary educational activities. The nurse educator must become involved with the family as early as possible, usually at the initial diagnosis. It is clear from a number of

studies that this is not an optimal time for teaching because of the family's shock at the diagnosis of diabetes. However, we believe it important to begin this process and ensure that the family has at least rudimentary survival skills when the child is discharged from the hospital 3–5 days later. The educational process continues at each clinic visit and, if necessary, special educational sessions are set up with the diabetes educator outside the normal clinic schedule.

The dietitian assesses the family's knowledge of food and nutrition at the initial visit and begins constructing a diet appropriate to the particular child. At least an annual review of the patient's nutritional status by the dietitian is desirable. Specific issues about the appropriateness of particular food substances and insulin coverage can usually be handled by telephone consultation or at clinic visits.

The psychiatric social worker plays a special role in the diabetes therapeutic team. It is the social worker's responsibility to assess the strengths and weaknesses of the family as they relate to emotional issues, economic and community support, educational activities, and other issues. Usually the social worker's assessment and recommendations determine whether other professionals, such as clinical psychologists and psychiatrists, become promptly involved with the family. The appearance of psychiatric problems over time as a consequence of stresses of the disorder also calls for the social worker's reinvolvement. The social worker can be particularly useful in families with limited financial resources, helping them to obtain support for diabetes medications and supplies, and transportation to clinic appointments.

The core diabetes therapeutic team includes the physician diabetologist, diabetes nurse educator, dietitian, and psychiatric social worker. However, the central member of the team is the patient. The patient, when old enough to be involved in a meaningful way in decisions, or the parents of the younger child, must be incorporated from the beginning in planning therapeutic strategies and all other major decisions. It is not therapeutically meaningful to insist on an insulin therapy of three to four injections daily or using an insulin pump and a monitoring program of four glucose determinations daily when the patient frequently misses some injections of insulin and/or refuses any monitoring. Although one continues to try to educate the patient and the family about the importance of a more comprehensive approach at the same time, it is essential to deal with reality. Most patients understand and appreciate the responsibility being placed upon them as part of the therapeutic team and respond maturely and appropriately to it.

The need for the diabetes therapeutic team cannot be minimized. Creative new ways must be found to make these resources available to all children and adolescents with diabetes mellitus. University diabetes centers must provide the leadership and direction for the development of networks of diabetes therapeutic programs across ge-

ographic areas, involving small communities with apparently limited diabetes-related resources. The local family physician or pediatrician must be incorporated into the therapeutic team and given encouragement for periodic re-education to function locally as the diabetes leader. In every community, it should be possible to identify nurses and dietitians who are willing to accept increased responsibility with appropriate, specifically pediatric diabetes training to become the local diabetes educator or special diabetes dietitian. The university-based diabetes center or speciality clinic must be able to provide outreach to the local community diabetes program by providing periodic visiting specialists, local patient and professional teaching conferences, and referral services for especially difficult management problems.

Opportunities for educational renewal by local team members must be available on a periodic basis. Such a networking program should provide the benefits of diabetes team management to the great majority of children and adolescents with type 1 diabetes. Although the initial costs of such a program will clearly be greater than for current management activities, the long-term reduction in vascular complications will greatly reduce the health care costs associated with visual loss, end-stage renal disease, peripheral vascular disease, heart attacks, and strokes.

XI. THERAPEUTIC OBJECTIVES AND MONITORING REQUIREMENTS

It is the therapeutic goal of all of us to put our patients right. We would like to be able to provide such comprehensive management to our patients with diabetes mellitus that they are metabolically normal, physically and emotionally healthy, and free of diabetes-related complications, both acute and chronic, as they go through life. Unfortunately, even with the advances of the DCCT, this is not now possible. We regularly find ourselves making therapeutic compromises between what we and the patients would like to achieve and what is reasonable within their personal situations. Table 3 lists the principles of diabetes therapy as they have evolved over the last several years in the diabetes clinic at Children's Hospital of Pittsburgh.

Certainly a primary therapeutic objective is to eliminate the obvious symptoms of poorly controlled diabetes, including polyuria, polydipsia, and polyphagia. Conversely, both serious and frequent mild hypoglycemia should be avoided. Careful attention to physical growth and sexual maturation is important. Inadequate insulin therapy results in slow growth and delayed maturation. Unfortunately, the achievement of these important therapeutic goals is not enough. Many patients deny symptoms of either hyper- or hypoglycemia and are able to maintain normal growth and maturation while maintaining blood glucose and glycosylated hemoglobin levels that are persistently too high.

Table 3 Principles of Diabetic Therapy

Elimination of the clinical features of inadequately controlled diabetes, including polyuria, polydipsia, and polyphagia.
Prevention of diabetic ketoacidosis.
Avoidance of hypoglycemia.
Maintenance of normal growth and sexual maturation.
Prevention of obesity.
Early detection of associated diseases. A number of autoimmune diseases (such as Hashimoto's thyroiditis) and celiac disease occur with increased frequency in patients with IDDM. Routine surveillance is important to detect these conditions in the early stages.
Prevention of hyperlipidemia.
Prevention of emotional disorders. The chronic and unrelenting demands of the disease and the therapeutic regimentation necessary to achieve reasonable control result in behavioral disability in a large number of families. The therapeutic program should be designed to prevent such problems or provide prompt and effective therapy as required.
Prevention of chronic vascular complications of diabetes.

Specific therapeutic objectives are presented in Table 4. Based on the DCCT results, primary therapeutic emphasis should be placed on achieving a near-normal metabolic status while avoiding the known complications of this approach, including hypoglycemia and excessive weight gain. The primary biochemical guides to management include glycosylated hemoglobin measurements obtained every 3 months and self-monitoring for blood glucose carried out at least four times daily. A number of commercial techniques are available for determination of glycosylated hemoglobin. It is imperative that the physician be well acquainted with his or her own laboratory assay, its normal range, and any special peculiarities of the assay. The currently used assays measure either glycated Hb or HbA1c. The DCCT used a highly standardized method for measuring HbA1c that had a higher limit of normal of 6.05% to which all other assays should be standardized. This was the therapeutic goal of the intensively managed patients, a goal achieved in only about 5%. At the close of the study, the mean HbA1c in the intensively managed adults was 7.1%, compared with 9% in the conventionally treated cohort. In those individuals who entered the study as adolescents, mean values were approximately 1% higher with the intensively treated adolescents, with a mean of 8.1% and the conventional at 9.8%. Because the effectiveness of the management appears to be comparable in both adults and adolescents, in terms of minimizing rates of progression of vascular change, it seems reasonable to use the HbA1c value of 8.0% as a maximum therapeutic goal for adolescents participating in an optimized management program. Different

assays have different normal ranges and may not read parallel to each other despite excellent statistical correlations.

There were no patients younger than 13 years of age at entry in to the DCCT, and at the conclusion of the study, there were no individuals under 20 years of age. One must therefore translate the conclusions of the DCCT to younger children with extreme caution. It is our view that although the general principle of moving all patients toward physiological homeostasis should be embraced,

Table 4 Specific Monitoring and Objectives

-
1. Glycosylated hemoglobin (total HbA1 or HbA1c) should be obtained at least every 3 months; the goal in patients participating in an optimized management program should be an HbA1c of 8% (the average of adolescents in the DCCT) or lower in older patients.
 2. Self-monitoring for blood glucose should be carried out daily before each meal and at bedtime, and at 3:00 a.m. three or four times per month; the blood glucose goals in optimized patients should be in the range of 80–120 mg/dl in the fasting state and 80–140 mg/dl at other times. (See text for goals for younger patients.)
 3. Urine testing: daily dipstick testing for glucose and ketones of the first voided urine in the morning unless blood sugar is measured more often at night; presence of ketonuria should lead to prompt consultation with the therapeutic team; minimal or no glycosuria or ketonuria is the goal.
 4. Urine testing for albumin: dipstick screening testing for albuminuria should be performed on a single voided specimen at each clinic visit; presence of albuminuria should promptly lead to assessment of an overnight or 24 h urine collection; in the absence of postural proteinuria, overt proteinuria should result in a detailed renal evaluation and appropriate therapeutic intervention; microalbumin methods are now becoming available and are recommended for routine assessment; a timed overnight specimen is more convenient as it decreases the chances of detection of postural proteinuria. Spot urine albumin/creatinine ratios are more costly and introduce two variables.
 5. Blood lipids: Blood should be obtained annually for determination of total cholesterol, HDL, LDL, very-low-density lipoproteins, and triglycerides; the lipid fractions should be between the normal range for nondiabetic children and adolescents. If the LDL level is greater than 100–110 mg/dl, a fasting level should be measured. Increases may reflect inadequate diabetes management or genetic lipid alterations.
 6. Thyroid function should be assessed annually by determination of TSH; thyroid antibodies should be obtained in the presence of a goiter.
 7. Poor growth, erratic glycemic control, or abdominal symptoms may be indicative of celiac disease and transglutaminase antibodies should be measured. The need for routine screening remains controversial.
-

glycemic goals may have to be higher in the preadolescent, particularly the preschooler. It is important to focus on blood glucose variation in these two younger groups, with a significant emphasis on avoiding hypoglycemia in preschoolers (52).

Because of the impossibility of monitoring amino acid and lipid fluctuations on a day-to-day basis, blood glucose measurements have traditionally been the sole modality to assess and manipulate insulin and food therapies. It is important to recognize that although monitoring is "glucocentric," our therapy should be global in terms of insulin action. Routine frequent self-monitoring for blood glucose is an essential component of good diabetes management. We recommend that, at a minimum, the patient measure blood glucose before each meal and at bedtime. In addition, periodical blood glucose determination at 2–3 a.m. should be obtained to document whether hypoglycemia is occurring during sleep. It is obvious that postprandial blood glucose determinations should be obtained under certain circumstances. It is also important to document symptomatic hypoglycemia by promptly performing a blood glucose test. During illness, blood glucose monitoring should be more frequent, as well as ketone checks. Although there is a general correlation between the frequency of blood glucose determinations and control, this is true only if the individual uses this information to make informed decisions regarding alteration in insulin dosage or other aspects of management. Recording of the blood glucose levels on a log sheet or computer can be useful in this regard. A single determination of blood glucose at any one time gives valuable information that may lead to immediate therapeutic decisions. However, the other half of the information lies in the analysis of patterns appearing day to day when multiple measurements are reviewed as a whole. For instance, finding a significantly low blood sugar level in the mid-morning might prompt immediate management of hypoglycemia with the use of a fast-acting carbohydrate such as glucose tablets or orange juice. However, the recognition of a pattern of low blood sugar levels in the mid-morning over several consecutive days would call for its prevention by a decrease in the prebreakfast fast-acting insulin dosage, an adjustment in the content of breakfast, or both, to avoid this hypoglycemia on a continuous basis.

Although it is difficult for US patients to measure blood glucose values at school before lunch, we insist that prelunch values be obtained routinely to assess properly the need for regular insulin in the morning injection. Schools should make this as easy as possible for the patient. There are major advantages to the use of meters with extensive memory capacity, primarily to cross-check the patient's accuracy in the recording of blood glucose results. However, the meter memory should not be used as an excuse for not recording the daily results in a format available for review by the parent as well as the team, at and between outpatient visits.

The DCCT blood glucose goals should be adopted for adolescent patients who have made a commitment to optimize management. The blood glucose goals are to achieve a normal fasting blood glucose level in the range of 80–120 mg/dl (or 80–140 with meters calibrated to serum). Any other daytime determination should fall in the range of 80–140 mg/dl, with 3 a.m. values in excess of 70 mg/dl. The DCCT results, based on seven-point glucose profiles performed once monthly, gave a mean daily blood glucose level of 153 mg/dl in the intensively management cohort compared with 230 mg/dl in the conventionally treated group. The results, although documenting the improved status of the intensively managed patients, further illustrates the difficulty in achieving blood glucose goals close to the normal range. We are pleased if our patients met the agreed goals about 80% of the time.

Pediatric diabetologists are currently attempting to come to grips with issues surrounding the general implementation of DCCT guidelines in the younger child. In the preadolescent (6–13 years of age) preprandial fasting levels should be moved as close as possible to adolescent blood glucose goals: 80–140 mg/dl. This should be done as soon as patients can reliably detect and respond to hypoglycemic symptoms. Some preadolescent patients are stable and have predictable enough blood glucose excursions that careful management adjustments can be made to bring them into line with adolescent recommendations. For the preschool child we strongly recommend that higher blood glucose goals be implemented to minimize the danger of hypoglycemia. Our specific recommendations are for fasting blood glucose levels in the 100–180 mg/dl range and postprandial values in the 100–200 mg/dl range in toddlers, and 80–180 mg/dl for 3–6 years. Allowable glycosylated hemoglobin results may be 1–1.5% higher than those of the adolescent if frequent hypoglycemia cannot be avoided.

With the widespread acceptance of routine self-monitoring of blood glucose, urine glucose testing has largely been relegated to an assay of historical interest only. We think that this is a mistake. The value of assessing night time control is significant and can be achieved by routine daily testing for urine glucose and ketones in the first voided morning urine. A dipstick method is used to measure both glucose and ketones. The presence of ketonuria is always of importance. Ketonuria associated with negative or minimal glucose spill is suggestive of nighttime hypoglycemia. The combination of high urinary glucose and ketones must be considered a strong indication of impending serious metabolic deterioration that requires careful follow-up. Under these circumstances, each successive voiding should be checked until ketonuria is clear. Communication with the therapeutic team is necessary to alter management as needed to prevent progression to DKA.

Urine protein determination is an essential component of routine management. A freshly voided specimen should

be checked at each visit using one of the microalbumin screening methods. More sensitive methods for albumin determination to detect microalbuminuria can detect that protein levels of 30–300 mg/24 h may be indicative of impending, progressive renal disease. If positive, overt proteinuria should be assessed using a protein dipstick method that becomes positive with a urine albumin concentration of about 300 mg/l or total protein level of 500. Proteinuria at this level or higher, if related to diabetes renal damage, is indicative of significant and serious pathology once infection is excluded. A carefully obtained 24 h urine specimen or a timed overnight urine specimen obtained the morning before the clinic or office visit is possibly easier and more helpful in excluding orthostatic proteinuria. A spot urine albumin/creatinine ratio is the most convenient, but also the most costly and erratic assessment of microalbuminuria; it does not exclude orthostatic proteinuria.

Patients with poorly controlled diabetes mellitus frequently have elevations in several of the blood lipid fractions. As a component of assessment of control, we recommend that nonfasting lipids be screened annually for the determination of total cholesterol, LDL, high-density lipoproteins (HDL), and triglycerides. Total cholesterol values should be below 160 mg/dl, LDL below 100–110 mg/dl, and triglycerides below 140 mg/dl. If any levels are elevated, this should be confirmed on a fasting specimen. Elevated lipid values may be a result of either inadequate diabetes management or one of the forms of genetic hyperlipidemia. If the patient's diabetes control is unsatisfactory, the first objective should be to improve overall diabetes management and determine whether the elevated lipid fractions return toward the normal range. If persistent hyperlipidemia is identified in individuals with satisfactory diabetes control, then an evaluation for genetic hyperlipidemia should follow. Strict diet or pharmacological therapy with lipid-lowering agents may be necessary.

Thyroid disease is commonly seen in association with IDDM. Hashimoto's thyroiditis, an autoimmune destructive process, appears to share many similarities with the mechanism of β -cell destruction leading to IDDM. In our experience, approximately 40% of our patients, particularly during the adolescent years, have evidence of Hashimoto's thyroiditis, including goiter and/or elevations in thyroid antibodies. Approximately 10% of these patients develop hypothyroidism; a significantly smaller number develop hyperthyroidism. Timely diagnosis and appropriate management of these conditions are obviously important to the patient's well-being. Careful examination of the patient's neck should be a part of each clinic visit, and assessment of thyroid function should occur as specifically indicated or on an annual basis. We recommend annual screening with measurement of thyroid-stimulating hormone (TSH). In the patient whose TSH level is abnormally elevated or in whom a goiter or signs or symp-

toms of hypothyroidism are present, measurement of free thyroxine (free T4) and thyroid antibodies are also indicated; thyroglobulin antibodies (TG-Ab) and thyroid peroxidase antibodies (TPO-Ab). Measurement of thyrotropin receptor antibodies (TR-Ab) is indicated when a hyperthyroid state is suspected as a work-up to rule out Graves' disease. Unexplained persistent hypoglycemia may be a subtle manifestation of hypothyroidism; conversely, unexplained persistent hyperglycemia may be a subtle manifestation of a hyperthyroid state.

Another relatively common association has been documented between type 1 diabetes mellitus and celiac disease. The prevalence of celiac disease using screening tests among type 1 diabetics has been calculated by different authors in Europe, Australia, and the United States showing rates between 1.0 and 7.8% (53–55). Based on this, it has been suggested that all patients with type 1 diabetes be screened for celiac disease. However, this recommendation remains controversial. The measurement of tissue transglutaminase antibodies is currently accepted as the most sensitive test to screen for celiac disease. The diagnosis, when suspected, is confirmed only with biopsy. We do not routinely perform "universal" screening for celiac disease in all our diabetic patients, but we certainly request measurement of transglutaminase antibodies in those patients who display poor linear growth, weight loss, or poor weight gain not clearly explainable by their degree of metabolic control, and obviously in patients showing signs or symptoms of the disease. A similar genetic background, especially the high frequency of HLA-DR3 genotypes, has been postulated as the explanation for the simultaneous occurrence of type 1 diabetes mellitus and celiac disease (56). Gluten, the protein responsible for celiac disease, has also been suggested as a possible determinant for islet autoimmunity (57).

XII. CONSULTATIONS AND REFERRALS

For the child and adolescent with diabetes mellitus, there may be several occasions on which the advice of physicians outside the therapeutic team is especially valuable. According to current guidelines, children with type 1 diabetes of at least 5 years' duration, as well as all patients during their adolescent years, undergo a thorough retinal exam through dilated pupils performed by an ophthalmologist or a trained optometrist on an annual basis. Many advocate waiting until 8 years of diabetes duration in the prepubertal child in good control, but doing the exam after 2 years in patients with poorly controlled disease. Ideally the eye specialist should have experience in detecting early diabetic retinal changes. Fundus photography, either stereo color photography or fluorescein angiography, may be appropriate as a more sensitive assessment during the adolescent years. The detection of vascular changes in the eye by either the family physician or diabetologist should promptly result in referral to an

ophthalmologist. Although in most cases the ophthalmologist provides no therapeutic intervention at that time, the visit may provide an opportunity for the therapeutic team to re-emphasize the importance of good diabetes management. Adolescent girls should be referred to a gynecologist or adolescent medicine clinic when they become sexually active.

The stress of diabetes and its management requirements exact a heavy toll in terms of behavioral problems and disabilities. In prospective studies carried out in our institution, nearly 50% of our patients experience significant psychopathology during adolescence (58). In most cases, this was pathological depression, requiring professional intervention. Other problems include antisocial acting-out behaviors, eating disorders, and adjustment problems. It is essential for all therapeutic team members to be sensitive to behavioral issues and be prepared for referral to colleagues in psychiatry or psychology if necessary. There is a natural reticence on the part of most patients and families to accept psychiatric referrals. By including the behavioral scientist as an integral member of the therapeutic team from the beginning, and emphasizing the importance of psychological well-being as part of the management of the patient with diabetes, the likelihood of family cooperation, if active intervention therapy is needed, is increased.

Annual evaluation of possible renal involvement is also advised. Measurement of microalbuminuria is recommended on an annual basis in patients who have had diabetes for at least 5 years or those who are reaching puberty, and after 2 years if the disease is poorly controlled. Albumin excretion rate above $21 \mu\text{g}/\text{min}$ should be confirmed by repetition of the test within the following few weeks or months. A persistent overt proteinuria should ideally prompt the referral of the patient to a nephrologist. If the patient has not had poor glycemic control, causes other than diabetes should be excluded.

Eventually the patient evaluated by the pediatric diabetes specialist must be referred for adult care based on age. It is our preference to continue to work with these patients through adolescence; high school or college graduation is a natural time to terminate this therapeutic relationship and hand the patient's case over to an adult diabetologist. All too often the young adult diabetic, following high school graduation and either entry into the work force or departure from home for university, is lost from the healthcare system and may not return for several years. Unfortunately the return is frequently precipitated by an acute event, such as retinal hemorrhage or other diabetic complications. It is not enough simply to refer the patient to the family doctor and assume that proper future management will be arranged locally. These patients deserve the opportunity to continue in a therapeutic environment characterized by the diabetes therapeutic team and led by a skilled internist or diabetologist. Assuring that this connection is made will go a long way

toward minimizing serious complications during patients' young adult years.

XIII. CLINICAL ASSESSMENT AND THERAPEUTIC DECISION-MAKING

Children and adolescents with insulin-dependent diabetes mellitus require regular physical, biochemical, and emotional assessment and modification in all aspects of management to meet their changing needs and individual lifestyle requirements. Because of the complexity of this problem, we are convinced that this process should be carried out in a setting in which the talents of several diabetes therapeutic team members can be brought to bear on the situation of the patient and family.

We recommend that routine care involve a full clinic visit at a minimum of 3 month intervals, with interim visits with the nurse educator or dietitian as required. The physician's routine evaluation should include a careful review of general health and diabetes management issues in the interval since the last examination. Frequency, severity and management of hypoglycemia should be specifically investigated. Symptoms of hyperglycemia, such as nocturia or urinary frequency, should be documented. Dietary management should be reviewed by the physician, and specific dietary problems should be referred to the dietitian. An evaluation of physical activity should be obtained and the patient encouraged to participate in daily exercise to achieve superior physical fitness and assistance with dose adjustment made. Psychological issues should be reviewed, including how the patient is handling the personal problems of diabetes and its management, school performance, and interpersonal relationships at school and at home. Issues of sexuality and drug and alcohol abuse should be approached directly in a nonjudgmental fashion. Sexually active girls should be referred to a gynecologist for additional counseling.

Physical examination should be complete. Height and weight measurements should be transferred to a standard percentile growth grid in which assessment of growth parameters over time can be followed accurately. A declining growth rate or inadequate weight gain should result in careful review to determine whether this is a reflection of inadequate diabetes management or another problem. In the adolescent patient, the physical examination should include determination of Tanner staging and information about menses in girls. Blood pressure should be carefully obtained with the patient in a relaxed state. Even moderate elevations above the appropriate blood pressure range for the age should lead to additional determinations during the visit and, if necessary, periodically by the school nurse or even with use of an ambulatory monitor. Persistent hypertension is a serious problem in the diabetic patient and must be aggressively evaluated and treated. The diabetologist should be comfortable and confident in carrying out a routine ophthalmological examination looking for early

changes indicative of background retinopathy. Insulin injection sites should be carefully examined. Lipohypertrophy may result in impairment of insulin absorption and contribute to inadequate management.

A major portion of the routine visit is review of the patient-generated blood glucose records by the diabetologist. This is an opportunity to teach about diabetes therapeutics and encourage the patient's and parents' participation in therapeutic decision-making. The individual's blood glucose goals in the fasting and postprandial state are reviewed, and an assessment of the interim performance provided. The focus is on insulin adjustments, but the integration of diet and physical activity must also be emphasized in these discussions. Any therapeutic changes must be followed by a telephone conversation between the patient and the therapeutic team, which may include faxing the most recent blood glucose results to a member of the therapeutic team. The results of the biochemical assessment are shared with the family and referring physician by letter within days of the clinic visit. Elevations in glycosylated hemoglobin levels, for example, may dictate more vigorous therapeutic changes than the initial review of the patient's blood glucose record would suggest. When biochemical therapeutic goals are met, congratulations are due to the patient and family, with encouragement to keep up the good work. Lack of achievement of goals should not be presented in a negative or punitive fashion but rather as encouragement to the patient and family to try even harder in the future with the assistance of the therapeutic team.

Diabetic Ketoacidosis

Dorothy J. Becker, Allan L. Drash, and Oscar Escobar

University of Pittsburgh School of Medicine and Children's Hospital of Pittsburgh, Pittsburgh, Pennsylvania, U.S.A.

I. INTRODUCTION

Diabetic ketoacidosis (DKA) is a potential complication in every patient with type 1 or insulin-dependent diabetes mellitus (IDDM). It is an inevitable consequence of untreated or inadequately controlled IDDM, and may be part of the initial presentation. Ketoacidosis is the most common cause of rehospitalization in the child with known type 1 diabetes or atypical or type 1½ diabetes.

DKA is a serious, life-threatening acute metabolic complication of IDDM. The frequency of DKA in our center and others in the United States is declining, both as the presenting feature of IDDM and as a later-recurring problem. There appears to be considerable variation in the frequency of DKA in children and adults in different geographic areas of the world. Although these data are poorly documented and scanty, physicians from Israel and parts of Europe report that DKA is uncommon in their countries. However, DKA remains a major frequent problem in diabetic children in many parts of the world including the United States. From our experience at Children's Hospital of Pittsburgh, DKA (defined as a serum bicarbonate level less than 18 mEq/l and/or pH equal to or less than 7.3), as the new presenting feature of newly diagnosed patients has declined from 80% of cases in the 1950s to 55% of cases in the early 1980s and to 40% among whites in the late 1990s. However, there was no change in the frequency of DKA among black patients. DKA is more frequent and more severe in children <6 years of age (64%), with one-third of these presenting with impaired levels of consciousness in the youngest children, in contrast to 9% in the older age groups (1).

The severity of DKA in these children also appears to have lessened. Severe acidosis with dehydration has been more common in our newly diagnosed girls than boys, and is associated with higher mean glycosylated hemoglobin and serum cholesterol levels. They also had a greater frequency of evidence of infection or pre-existing

infection. The reason for gender differences in DKA is not apparent (2).

Despite improvement in therapy, DKA remains a major cause of death in IDDM around the world and, until the 1980s, was the most common cause of death in the diabetic patient under 20 years of age (3). Although there was some decline during that period, within our own institution deaths have become extremely rare and have occurred only in patients transferred from other hospitals in a moribund state. This suggests that with improved therapy and more rapid diagnosis, death from DKA may be preventable. There is little new data regarding DKA mortality in the United States (3). The overall mortality rate due to DKA was approximately 7% in the United States and the United Kingdom, with reports ranging from 1 to 19% before 1980 (4). Approximately 65% of all DKA admissions reported in this study occurred in children and adolescents. However, the mortality was far higher in adults, with death mostly resulting from complications of myocardial infarction and cerebral vascular accident.

It is hoped that with increasing understanding of the pathogenesis of this disorder and careful therapy, together with education of the physician and patient population, the overall morbidity and mortality rates of this acute complication can be appreciably lessened in the future.

II. PRESENTATION AND CLINICAL FEATURES

Insulin deficiency results in a series of understandable and predictable metabolic events, which have associated clinical concomitants. The pathogenesis of these events is described later. In patients with new-onset diabetes, presumably there is a gradual drop in the release of insulin from the β cells with an associated impairment in the metabolism of energy intermediates, including carbohydrates, fat, and protein. The first recognizable symptoms are as-

sociated with postprandial hyperglycemia and glycosuria, because the concomitant hyperlipidemia and alterations in protein metabolism are not yet clinically evident (5). Thus, the classic initial features of IDDM include polyuria, polydipsia, polyphagia, and visual disturbances, all associated with hyperglycemia. This condition progresses to a catabolic state with fatigue and weight loss due to muscle proteolysis and lipolysis. The abnormal fat metabolism results in hypercholesterolemia and ketosis. If the diagnosis of IDDM or of poor control of IDDM is not made at this phase, the symptoms progress to vomiting, abdominal pain, anorexia, dehydration, so-called sighing respiration, and, later, impairment of the central nervous system (CNS) or coma. In our experience, most patients have a clinical course of approximately 4–8 weeks before development of DKA. In some cases, the symptoms have been identified for only a few days and, in previously diagnosed patients, often for only few hours prior to their presentation with severe metabolic derangement.

Very severe DKA is seen most commonly in the infant and toddler. It declines in frequency with the presentation of IDDM in the older child (1). Hyperosmolar diabetic coma (severe hyperglycemia with no ketosis) also occurs more often in the younger child (6). The degree of metabolic derangement in DKA can vary widely from severe uncompensated metabolic acidosis to diabetic ketosis in which there is hyperglycemia and ketonemia with ketonuria and normal acid–base balance. Diabetic ketosis occurs in approximately 50% of our patients. Although the clinical presentation of patients usually parallels the severity of the biochemical changes, one frequently sees patients who are in surprisingly good clinical condition relative to the severity of their metabolic derangement. One also sees patients who are in poor clinical condition with marked dehydration relative to the mildness of metabolic acidosis.

The biochemical alterations of DKA are hyperglycemia, dehydration, ketosis, acidosis, and electrolyte disturbance. Often a linear relationship exists between the concentration of blood glucose and the severity of the metabolic acidosis. Exceptions at either extreme occur frequently. Thus, patients may have severe hyperglycemia and hypernatremia with resultant hyperosmolality and minimal or no ketosis. Hyperosmolar diabetic coma, which is a rare complication of diabetes in childhood, is at one extreme of this biochemical derangement with marked hyperglycemia but no ketosis and little acidosis. Conversely, a number of children have severe metabolic acidosis and only mild to moderate hyperglycemia with blood glucose levels in the range of 200–300 mg/dl. These patients usually have an acute onset with severe vomiting and frequently have previously diagnosed diabetes. We consider any patient to have DKA whose serum bicarbonate level is less than 18 mEq/l, irrespective of serum pH (i.e., whether or not the acidosis is compensated). We define a serum pH of less than 7.2 in a diabetic

patient as severe ketoacidosis. Hyperlipidemia is almost invariably present in patients with DKA with elevations in both serum cholesterol and triglyceride concentrations. Increases or decreases in the serum levels of electrolytes, blood urea nitrogen (BUN), and creatinine also occur, depending upon the degree of dehydration, acidosis, and vomiting. The hemoglobin value, hematocrit, and white blood cell count may likewise be high.

Although the serum sodium concentration is usually high when associated with severe dehydration, it may be mildly or moderately depressed. The depressed sodium level results from both excessive urinary losses and movement of sodium from the extracellular space into the intracellular space, secondary to the hyperosmolality associated with hyperglycemia. Serum sodium may also be spuriously low in association with the concomitant hyperlipidemia with increased fat displacing plasma water (7). Most clinical laboratories today displace these circulating lipids by ultracentrifugation, and it is important to determine whether or not hyperlipidemia has been allowed for in each laboratory (8). Serum potassium levels are usually initially normal or even elevated, depending upon the degree of acidosis and dehydration. This occurs despite severe total body potassium deficit with markedly diminished intracellular concentrations of potassium. During therapy, even with adequate replacement of potassium, there is usually a decline in the serum concentrations of potassium (9). Like potassium concentration, the concentration of phosphorus in the blood is variable at presentation but usually drops markedly during therapy because of excessive urinary losses with an associated total body phosphorus deficit (9). Reduction of the intracellular phosphate content is associated with a loss of 2,3-diphosphoglycerate (2,3-DPG), which is most important in the red blood cells. Thus, 2,3-DPG, which controls the oxygen affinity of hemoglobin, may be important in oxygen transfer at the tissue level (10). However, this subject is highly controversial. Although severe hypophosphatemia frequently occurs during therapy in DKA, identifiable associated complications have not been reported in this condition. The clinical effect of hypophosphatemia is therefore not yet clear in DKA (11).

Routine urinary test findings in DKA indicate glucosuria and ketonuria. Proteinuria and hyaline casts are frequently found at presentation. Both findings depend on the degree of dehydration. The glycosylated hemoglobin concentrations in DKA are variable and probably depend on both the prior duration and severity of hyperglycemia.

III. PATHOGENESIS

A. Insulin Deficiency

The pathophysiology and presenting features of DKA are the subject of a number of reviews (12–14). Ketoacidosis in the newly diagnosed diabetic patient may have a fairly

extensive prodrome consisting of the classic symptoms of polydipsia, polyuria, and polyphagia, or it may develop within a few hours in an insulin-treated diabetic child who had otherwise previously been in good health. The first case appears associated with relative insulin deficiency due to failure of insulin secretion by the pancreatic β cells, although circulating levels may be detectable in the low-normal or, in the face of obesity, even the normal range at the time of presentation. Circulating insulin levels are lower than the body's requirement at that time (5,15). In the insulin-treated diabetic child, the cause is usually absolute insulin deficiency with frequently very low circulating free insulin levels when measured on presentation (despite a history of not missing insulin injections). However, insulin deficiency may also be relative to increased insulin requirements (12).

Reasons for the apparently greater requirement for insulin may be infection, dehydration, physical or emotional stress with overproduction of counterregulatory hormones, insulin antagonism by elevation of free fatty acid levels, and diminished number of insulin receptors associated with acidosis. Circulating insulin antibodies are usually of low affinity and are an unlikely cause of an acute reduction of insulin action.

The absolute or relative insulin deficiency produces a situation of acute intracellular starvation in most of the cells of the body. The accompanying metabolic changes in diabetic ketoacidosis are thus very similar to those found in prolonged starvation. The major effects are those of insulin deficiency, which is accompanied by an acute elevation of the counterregulatory hormones, presumably stimulated by the insulin deficit and its metabolic consequences (16). The metabolic consequences of the insulin deficit are enhanced glycogenolysis and gluconeogenesis resulting in greater hepatic glucose output, increased lipolysis, and reduction of peripheral glucose utilization, lipogenesis, and protein synthesis.

B. Counterregulatory Hormones

As suggested previously, absolute insulin deficiency, per se, does not account for the development of ketoacidosis in the majority of patients. Even when insulin therapy is omitted, ketoacidosis is not precipitated without the concomitant increment of some, if not all, the counterregulatory hormones (12). These hormones—glucagon, catecholamines, cortisol, and growth hormone—which are also known as the stress hormones, antagonize the action of insulin on carbohydrate, protein, and fat metabolism. In DKA of both adults and children there is almost invariably an elevation of at least three, if not all, of the counterregulatory hormones. The most important for the development of ketogenesis appear to be glucagon and catecholamines because of the rapid onset of their metabolic effect (12,17). The actions of glucagon include the following: glycogenolysis; elevated gluconeogenesis; enhanced ketogenesis, by suppression of malonyl CoA,

which regulates the carnitine acyl transferase enzymes; and proteolysis (18,19). Catecholamine actions are as follows: lipolysis by stimulation of lipase, gluconeogenesis, possible ketogenesis, and reduction of peripheral glucose utilization (18).

Cortisol and growth hormone excesses, both of which occur in DKA, have much slower actions but play an important role in the pathogenesis of DKA after a number of hours (12,18). The actions of increased circulating cortisol are catabolism of protein, reduction of peripheral utilization of glucose, augmentation of both gluconeogenesis and ketogenesis, along with some lipolysis. The effects of growth hormone elevation are lipolysis, gluconeogenesis (by an undefined mechanism), augmentation of ketogenesis, and reduction of peripheral glucose utilization.

C. Mechanism of Hyperglycemia

The degree of hyperglycemia in DKA varies and does not necessarily correlate with the severity of acidosis. The major source of blood glucose elevation is the continued hepatic glucose output due initially to glycogenolysis. Later it is due to continued gluconeogenesis stimulated by the combination of insulin deficiency and glucagon and catecholamine excess, augmented by the action of cortisol and growth hormone (20,21). Superimposed on the elevated glucose output is the reduction of peripheral glucose utilization caused by the absolute or relative insulin deficiency as well as the catecholamine action on muscle and adipose tissue (22).

Most of the glucose formed is excreted in the urine, resulting in a major caloric loss. As long as there is normal renal function, the circulating blood glucose does not increase much above 300–400 mg/100 ml. However, once severe dehydration ensues owing to osmotic diuresis, the diminished glomerular filtration rate prevents further excretion of glucose and the serum glucose level increases markedly. The more dehydrated the patient, the higher the serum glucose level (23). However, some patients exhibit initially very high serum glucose levels without concomitant dehydration. This occurs when thirst is quenched with sugar-containing fluids, resulting in extremely large glucose loads that can be partially excreted by the kidney without insulin therapy.

D. Mechanism of Hyperlipidemia

DKA is associated almost invariably with hypertriglyceridemia and elevated circulating nonesterified fatty acids (NEFA). The major source of these lipids is lipolysis of the adipose tissue due to stimulation of lipase caused by a combination of insulin deficiency and catecholamine, cortisol, and growth hormone excess (24). Another major source of serum triglycerides and NEFA may be the hepatocytes (25). As a result of extensive lipolysis, the serum in DKA may be extremely turbid, with increased vis-

cosity and the danger of sludging in small blood vessels. A major complicating factor caused by severe hyperlipidemia is the spuriously low measurement of plasma electrolytes due to displacement of plasma water by the lipids. Thus, severe hyponatremia may be an artifact of hyperlipidemia unless the lipid is extracted prior to analysis (7,8).

E. Aminoacidemia

Because DKA is a catabolic condition, with reduced protein synthesis and continued proteolysis associated with both insulin deficiency and cortisol and glucagon excess, it causes increased concentrations of circulating branch-chain aminoacids (i.e., leucine, isoleucine, and valine). By contrast, the gluconeogenic aminoacid concentrations, particularly those of alanine and glutamine, are diminished because of greater hepatic uptake (26,27).

F. Mechanism of Ketogenesis

The liver is the sole source of ketone-body production. Acetoacetate and β -hydroxybutyrate are metabolized from the increased circulating NEFA delivered from the adipose cells. The liver is set in the ketogenic mode by a combination of insulin deficiency and glucagon excess. The higher ketone body production is controlled by the rate of lipolysis and thus by the substrate availability, and to a minor extent by the supply of ketogenic aminoacids, which are leucine and isoleucine. Continued gluconeogenesis, stimulated by glucagon with possibly an additive action of catecholamines and cortisol, produces sufficient NAD for ketone production. The long-chain fatty acids are transported into the mitochondria after combining with carnitine by the action of two carnitine acyl transferase enzymes. Sequential β -oxidation results in the formation of acetoacetate that is in equilibrium with β -hydroxybutyrate. Acetone may be formed by spontaneous decarboxylation of acetoacetate and excreted through the lungs or kidneys. Under the condition of severe acidosis, particularly that associated with hypoxia or lactic acidosis, most of the ketone bodies exist as β -hydroxybutyrate. This finding is important because β -hydroxybutyrate does not react with nitroprusside when the serum and urine are tested for ketones. Only acetoacetate will give the classic purple color. As the acidosis resolves, β -hydroxybutyrate is converted to acetoacetate and may give the impression of an increased production of ketones if one is not aware of this so-called factitious increased ketosis. The production of acetoacetate occurs at a time when there is an actual reduction in the total plasma ketone body concentration (28). New meters appearing on the market measure serum β -hydroxybutyrate and thus circumvent this problem.

Two studies have shown that the hepatic overproduction of ketone bodies alone cannot account for the huge increase in the circulating ketone concentration in DKA

(29,30). It is suggested that a reduction in ketone body clearance and utilization is also necessary to explain the severe ketoacidosis. Insulin deficiency and catecholamine excess have been shown to lessen peripheral ketone body utilization, particularly by muscle. Excretion of ketone bodies through the lungs and kidneys is not sufficient to compensate for the greater hepatic production and lesser muscle utilization, particularly when glomerular filtration is diminished due to dehydration.

G. Mechanism of the Metabolic Acidosis

In children with DKA, the major cause of acidosis is the accumulation of ketone bodies. β -Hydroxybutyrate and acetoacetate both are strong acids and contribute to the classic anion gap found in DKA (31). When severe dehydration is found with peripheral vascular shutdown and anoxia, an accumulation of lactic acid with lactic acidosis contributes to the general metabolic acidosis (32). Patients with DKA usually have a normochloremic acidosis with an elevated anion gap. However, during therapy, despite continued excretion of the ketone bodies, acidosis frequently persists with the appearance of hyperchloremia and disappearance of the anion gap. Excretion of ketone bodies is not associated with a rise in serum bicarbonate concentration, suggesting the loss of a great deal of alkali together with the ketones in the urine. However, it is likely that the apparent loss of bicarbonate may also occur on a dilutional basis or may be associated with alterations in anion distribution. It is thought that the administration of chlorides during rehydration can only partially account for the hyperchloremia, and that there is increased renal tubular chloride reabsorption. The associated lack of adequate amounts of alkali causes the persistent metabolic acidosis. Serum electrolyte balance is maintained by elevated chloride concentration (33).

H. Effects of Renal Function

1. Water Loss

A major effect of uncontrolled diabetes is osmotic diuresis associated with glucosuria. This water loss results in severe dehydration and, eventually, reduced glomerular filtration. If the decrease in plasma volume is severe, diminished peripheral circulation, shock, and, occasionally, renal tubular necrosis can result.

2. Electrolyte Loss

The glycosuria of DKA classically is accompanied by a loss of sodium, potassium, calcium, phosphate, and magnesium in the urine. The loss of sodium, calcium, and phosphate is apparently related to both insulin deficiency and glucagon excess, which have a direct effect on the renal tubules. The contraction of the intravascular circulating volume together with the sodium loss stimulates

both aldosterone and ADH secretion. Aldosterone's action on the tubules may account for some of the potassium loss. However, most of the potassium and phosphate loss is due to movement of these cations from the intracellular space into the intravascular space and into the urine due to insulin deficiency. Glucagon excess may induce resistance to the sodium-retaining actions of mineralocorticoids so that circulating aldosterone does not exert its sodium-retaining action (34,35). High levels of ADH add to the Na excretion in the urine, contributing to the total body sodium deficit. As mentioned previously, the alkali loss through the kidney associated with the excretion of ketone bodies can result in a total body bicarbonate deficit that must be replenished. As mentioned previously, sodium moves from the intravascular to extravascular space in the face of severe hyperglycemia. An approximate formula to calculate this effect is a decrease of sodium in the serum of 1.6 mE/l for every 100 mg increase in serum glucose above normal.

I. Effects on the Brain

Changes in the level of consciousness are a hallmark of severe DKA. These changes can vary from lethargy to stupor and coma. Even when there is not clinical change in the level of consciousness, DKA, particularly when associated with severe hyperosmolarity, is associated with major electroencephalographic (EEG) abnormalities that are usually reversible (36). Alterations in the level of consciousness appear to be more closely associated with hyperosmolarity due to hyperglycemia, with or without hypernatremia. If there is severe ketoacidosis and dehydration, there may be relative cerebral anoxia, which can also contribute to changes in the level of consciousness. Severe phosphate loss will result in deficiency of 2,3-DPG. This loss results in increased oxygen affinity of hemoglobin and relatively decreased delivery of oxygen to the tissues (i.e., a shift of the Bohr curve to the left) (10). When a patient is severely acidotic the Bohr curve is effectively shifted to the right. Thus acidosis and 2,3-DPG reduction counterbalance each other. Severe phosphate depletion without severe acidosis shifts the Bohr curve to the left and, theoretically, is associated with tissue anoxia. However, measurements of oxygen partial pressure in peripheral tissues were not abnormal in a series of studies, but the effect in the brain has not been well studied.

J. Hyperosmolar Nonketotic Coma

In pediatric practice, hyperosmolar nonketotic coma is an unusual condition that occurs mainly in very young or mentally retarded children (6). It is assumed that these patients are unable to obtain access to sufficient water to prevent severe dehydration. This condition occurs in the presence of a relative insulin deficiency, resulting in excessive glucose production and an osmotic diuresis. How-

ever, there appears to be enough insulin to suppress lipolysis and thus prevent an excess production of ketone bodies. There is assumed to be an unexplained limitation to the output of glucagon that would usually occur in a stress situation and stimulate ketogenesis. Coma in these patients is associated with severe hyperosmolarity, metabolic acidosis, and high incidence of death associated with cerebral edema. It should be remembered that an equal degree of hyperosmolarity could occur in the presence of ketoacidosis with similar detrimental effects.

IV. CAUSES OF DIABETIC KETOACIDOSIS

In both newly diagnosed patients and insulin-treated patients with diabetes, DKA is usually associated with a precipitating factor, making the relative insulin deficiency functionally absolute. In the known diabetic, the most common precipitating cause is disruption of insulin delivery by omitting injections, malfunction of an insulin pump, or inappropriate decreases of doses during illness. In contrast, in newly diagnosed patients DKA is often precipitated by an acute infection that carries with it an increase in the insulin requirement. Relatively routine pediatric illnesses such as flu, otitis media, and gastroenteritis may rapidly induce ketosis and subsequent acidosis in a previously apparently healthy child. Acute infection is a less common precipitant in known diabetic children. It occurs only in the face of inadequate insulin delivery. The progression to DKA usually suggests that prompt intervention at home was not accomplished, often because of failure to recognize the early deterioration. The mild insulin deficiency results in acute DKA only if it is accompanied by an increase in the counterregulatory hormones, particularly glucagon. Less common precipitating causes of DKA after diagnosis are physical and mental stress. In most diabetic children the occurrence of DKA after diagnosis is not common. A small group of patients has recurrent DKA in response to emotional stress. It has long been held that this response seems related to an acute rise in catecholamine secretion, with an accompanying rise in free fatty acid (FFA) production due to lipolysis and subsequent ketogenesis. This response can occur within hours in a previously apparently healthy person.

Our recent experience suggests that this phenomenon is rare in the majority of children with recurrent DKA. These children appear to have an excessive biochemical response to stress or a defect in the clearance rates of related hormones or substrates. Such patients are referred to as psychogenic diabetics and are often adolescents from disorganized homes. Like the rapid onset of DKA in these children, the response to medical therapy is unusually prompt. Our institution of measurements of free insulin levels has revealed that a more common mechanism of this recurrent DKA is failure to receive insulin, even sometimes when a parent claims to have administered the injection. The problem will recur unless underlying be-

havioral problems are identified and resolved. Exercise can also precipitate acute ketoacidosis in a patient who is already partially decompensated due to underinsulinization. Again, this is presumed to be related to an elevation of catecholamines and glucagon levels in excess of available insulin.

V. DIFFERENTIAL DIAGNOSIS

If the patient has known history of diabetes, the differential diagnosis of alterations in consciousness is between DKA and hypoglycemia. Measurement of blood glucose levels by a blood glucose monitor and serum or urine ketones should give the accurate diagnosis (remembering that hypoglycemia can induce ketosis).

Because patients with ketoacidosis often have abdominal pain with vomiting, an acute abdomen must enter the differential diagnosis. A patient with diabetes may have an acute abdomen most commonly from appendicitis, and this can coexist with DKA.

Severe gastroenteritis with hypernatremia and acidosis is occasionally associated with ketoacidosis due to inhibition of insulin secretion, with accompanying hyperglycemia and ketosis. Such patients have temporary diabetes and sometimes may require a few doses of very small amounts of insulin. Some drugs induce nondiabetic ketoacidosis, the most common being salicylate intoxication in children. In addition, high dosages of diazoxide or salbutamol have been reported to induce nondiabetic ketoacidosis. Chronic alcoholism associated with reduced food intake can cause severe hyperketonemia with acidosis. However, alcoholism is usually associated with hypoglycemia.

VI. CLINICAL ASSESSMENT

Most of the diagnostic signs and symptoms of DKA are sequelae of the metabolic disorder with clear pathogenesis. The only feature that is not fully explained is the devastating effect of DKA on the CNS. Patients will almost always present with polyuria and polydipsia of variable duration. These symptoms eventually result in dehydration with consequent hypovolemia, tachycardia, and shock. Ketosis is usually accompanied by abdominal pain, nausea, and vomiting, the mechanism of which is totally unclear. DKA typically causes hyperventilation (Kussmaul breathing), which is deep sighing ventilation with a long air column. If the patient is extremely acidotic (pH < 7.0), CNS depression often occurs and the respiratory rate may fall in association with carbon dioxide retention. When acidosis is severe, the serum potassium level may be high. However, because of insulin deficiency, there is a great deal of intracellular potassium loss due mainly to potassium diuresis, which accounts for gastric stasis, ileus,

muscle weakness and cramps, and the risk for cardiac arrhythmia. The loss of intracellular magnesium and phosphate may add to these symptoms (37).

The presenting abdominal symptoms and signs may be similar to those of an acute abdomen. Because of the frequent increase in serum amylase levels in DKA, a number of workers have suggested an association of DKA with acute pancreatitis in some of these patients. However, serum amylase levels increase in approximately 70% of patients with DKA, most of whom have no clinical evidence of pancreatitis. The raised serum amylase levels are usually associated with severe hyperglycemia, and the origin of the enzyme is likely to be the salivary glands (38). Because DKA is often precipitated by infection, accompanying signs and symptoms should be sought. It is important to note that even in the absence of infection, pyrexia is rare in association with DKA, and leukocytosis frequently occurs despite the absence of infection.

Reports indicate that approximately 10% of patients with DKA are comatose and coma is associated with a greater mortality risk. We have noted that the incidence of coma is diminishing at our center because of earlier recognition of decompensating diabetes. Disturbances in the level of consciousness are more common, varying from lethargy to disorientation and agitation. Cerebral edema at presentation is unusual but may occur, and the mechanism of CNS abnormalities appears to be related mainly to the degree of hyperosmolarity.

Initial clinical assessment of the patient should be made rapidly and should include state of hydration; blood pressure and cardiac output; renal function (polyuria or anuria); cerebral function, including a very careful evaluation of the optic discs for papilledema; and complicating and precipitating factors.

Immediately after the clinical assessment, baseline biochemical evaluation of the patient should be made prior to initiation of insulin therapy. This evaluation should include:

1. Urinalysis for glucose and ketones, recognizing that interfering substances such as salicylates, antibiotics, and degraded strips may possibly give false-negative or false-positive results for acetonuria (39).
2. Serum glucose level using a sensitive laboratory technique after screening with one of the available bedside blood glucose monitors.
3. Serum electrolyte levels.
4. Values of arterial or venous gases. In our experience, we have not found measurement of arterial gases necessary for monitoring patients, and we have used venous blood unless there is peripheral vascular collapse. The measurement of blood gases should include pH, PCO₂, and bicarbonate.
5. Plasma osmolarity should be measured or calculated using the formula:

$$\text{Osm (serum)} = 2 \times \text{Na (mEq/l)} \\ + \frac{\text{Glucose (mg/dl)}}{18} + \frac{\text{BUN (mg/dl)}}{2.8}$$

6. Serum or plasma ketone levels should be measured using an Acetest tablet or a meter.
7. BUN and creatinine levels.
8. Calcium and phosphorus values.
9. Serum amylase level (if indicated).
10. Hemoglobin value, hematocrit, and white blood cell count.
11. Microscopic examination of the urine.

VII. THERAPY

The development of DKA is usually relatively slow and should be corrected relatively slowly. The only indication for very rapid correction is impending or actual shock. This maxim is probably even more important in treatment of children than of adults.

A. Rehydration

Because a major feature of DKA is water loss associated with loss of electrolytes, rehydration is the cornerstone of therapy. It is probably more important in the early stages of therapy than insulin delivery. An initial 1 h bolus of 10–20 cc/kg 0.9% normal saline should be given prior to the administration of insulin while awaiting report of laboratory results and assessing fluid losses. The most common fluid used is normal saline without the addition of potassium until urine excretion has been confirmed and serum potassium levels have been measured. Ringers' lactate, while effective, is less than optimal because of possible delay in lactate metabolism by the liver. The advantage of this initial hour or even 2 h of rehydration is that it allows one to assess the degree of dehydration and rate of blood glucose decrement associated with volume expansion rather than insulin action. Rehydration is very useful in the child in whom the degree of dehydration is not apparent based on clinical assessment. Some of the plasma glucose reduction during this period is probably caused by improved insulin action in previously treated patients, or elimination of a large oral glucose load by improved renal function in the face of enhanced glomerular filtration rate. The fluid deficit is calculated according to the body weight, and the deficit is corrected over 24 h with one-half the correction over the first 8 h. It is extremely important to assess water balance continually in the patient with an actual measurement of the total fluid infused or taken orally and the total urine volume lost.

The initial fluid rate required should be between 10 and 20 ml/kg/h depending on the patient's hydration and hemodynamic status. Excessive infusion should be avoided unless it is needed for correction of hypotension

and shock. Excessively rapid rehydration with volumes above this is thought by some (40,41) but not all (42,43) to be related to the development of cerebral edema. Unless severe hyperosmolality or hyponatremia persists after the first hour, the rehydration fluid is changed to half-normal saline in order to supply maintenance fluid, correct the deficit, and replace continual losses. Fluid status must be reassessed on a regular basis; fluid requirements should not be calculated based on the initial status without reevaluation.

Maintenance and replacement fluid volumes can be calculated on a weight or surface area basis, with allowances made for age (Fig. 1). Most of the rehydration treatment should be administered intravenously and oral fluids should be avoided in the very ill patient, particularly if there has been prior vomiting. Even when oral fluids are tolerated, gastric stasis and ileus may prevent rapid absorption of fluids and make it difficult to calculate actual delivery to the intravascular space. Composition of the rehydration fluids depends on the patient's serum sodium and potassium levels and the serum osmolality. In general, one should attempt to rehydrate, at least initially, with iso-osmolar solutions. As the serum osmolality diminishes, some free water should be administered. There is almost never an indication for administration of intravenous fluids that do not contain sodium. In contrast, hyponatremia, which may occur during therapy, may require continuation or reinstitution of 0.9% normal saline therapy. The aim should be to reduce the serum osmolality slowly by constant administration of solutions containing sodium (unless the serum sodium levels rise), and later to add glucose (see following section). The concentration of K^+ usually should not exceed 40 mEq/l but in rare circumstances up to 80 mEq/l may be required. Maintenance and replacement fluid volumes can be calculated according to body weight in kilograms (Fig. 1).

There are some differences of opinion as to whether the rehydration period should be 24, 36, or 48 h in duration. In our experience, a period longer than 24 h with very slow correction of hydration results in persistent acidosis. However, if there is severe hyperosmolality, a 36–48 h rehydration period should be calculated.

B. Insulin

For many years, the conventional mode of insulin therapy in DKA was intermittent subcutaneous injections of crystalline insulin. Fairly high doses (100–200 units) were recommended, particularly in adults (44). In children, the tendency was to use slightly lower doses, although these would still be considered high compared with the low doses currently shown to be effective. Since the mid-1970s, a number of studies in both adults and children have shown that low-dose intravenous or intramuscular insulin delivery corrects the hyperglycemia and ketoacidosis in DKA as rapidly and effectively as the previously used high doses. With lower insulin doses, more physio-

Maintenance Fluid		Deficit (10% dehydration)
Fluid	$\left\{ \begin{array}{l} 100 \text{ ml/kg} \\ 50 \text{ ml/kg} \\ 20 \text{ ml/kg} \end{array} \right.$	100 ml/kg
Na	3 mEq/kg	6 mEq/kg
K	2 mEq/kg	5 mEq/kg

Thus, a 30-kg patient with 10% dehydration would need:

	Maintenance	Deficit	Total
Fluids	1700 ml	3000 ml	4700 ml
Na	90 mEq	180 mEq	270 mEq
K	60 mEq	150 mEq	210 mEq

Fluids could be given according to the following procedure:

Hour	ml/kg/hr	Fluid composition	
1st	15	Normal saline	
2nd	10	Half-normal saline plus 40 mEq KCl/L	} Add 5% glucose when necessary
3 rd -8th	8	Half-normal saline plus 30 mEq KCl/L	
9 th -24th	5	Quarter-normal saline plus 20-30 mEq KCl/L	

Figure 1 Calculation of maintenance fluid levels.

logical circulating insulin levels are achieved, and hypoglycemia, hypokalemia, and hypophosphatemia have been shown to occur less frequently in comparative studies (45,46). Thus, low-dose insulin therapy compared to that used in adults is the treatment of choice in children with DKA because this level of insulin delivery achieves its goal in the majority of cases (47,48). Occasionally, a patient appears to have a greater than usual degree of insulin resistance, requiring slightly higher doses for reversal of the ketoacidotic state.

The choice of insulin delivery route should depend on the condition of the patient and the facilities available. If DKA is very mild with minimal acidosis and dehydration, the subcutaneous route is convenient and effective, especially if the patient does not require intravenous rehydration. The dosage regimen is approximately 0.25 units/kg regular insulin given every 4–6 h prior to meals. Regular insulin given subcutaneously delivers therapeutic doses for approximately 4 h, with the duration of action being 6 h at most. Therefore, patients must receive insulin at least every 4–6 h, even during the night, and if they are not eating, in order to prevent recurrent ketosis. The dose given during the night can be decreased slightly if ketosis is nearly cleared and should always be accompanied by a small meal.

If the patient is significantly dehydrated, subcutaneous insulin is poorly and irregularly absorbed. Under these circumstances, the intravenous route is preferred for insulin delivery by means of a continuous infusion of 0.1 units/kg/h after an initial loading bolus of 0.1 units/kg.

Although some investigators believe that a loading dose is not necessary (49), it seems logical to achieve physiological insulin levels immediately, particularly in the patient who has not had prior insulin therapy. The insulin is delivered in a fairly concentrated solution (approximately 1 unit/ml in normal saline) with the infusion controlled by a syringe pump through a line, which is connected piggyback to the rehydration intravenous infusion set using as short tubing as possible. A change of the syringe or infusion bag every 12 or 24 h and the use of concentrated solution of insulin minimize the problems of insulin adherence to the plastic of the infusion system. Thus, the use of albumin has not been necessary (50). Mixing insulin in the rehydration fluid directly is dangerous because the delivery rate will depend on the rate of rehydration rather than on insulin need. In addition, these dilute solutions of insulin have a greater propensity for loss of insulin onto the surface of the infusion apparatus.

The advantage of the intravenous delivery of insulin is the smooth pattern of circulating insulin levels achieved. The physician is able to increase or decrease the amount of insulin delivered with immediate effect, since intravenous insulin has a half life of 3–8 min. Contrary to popular belief, the patient does not require greater vigilance from a biochemical standpoint when insulin is infused intravenously. The same care is needed irrespective of the route of insulin delivery. However, greater care is required to ensure that the intravenous delivery system and the pump are working effectively. A number of clinicians believe that constant intravenous infusion of in-

sulin should not be used in community hospitals that do not have adequate facilities, particularly the use of some type of pump system. The use of intravenous insulin boluses should be discouraged, as it results in supraphysiological levels with a rapid decline, possibly stimulating an enhanced secretion of counterregulatory hormones (47,51).

Intramuscular insulin delivery with a loading dose of 0.25 units/kg followed by 0.1 units/kg/h has been used with the same success as the continuous intravenous routes (52). The disadvantage of this mode of therapy is the repeated pain of an intramuscular injection, which is avoided with the use of intravenous routes.

The amount of insulin given initially should be tailored so that the drop in blood glucose level is approximately, but no more than, 100 mg/dl/h. If the blood glucose level drops more rapidly than this rate after the first 2 h of rehydration, the insulin dose should be reduced. If it drops to less than 75 mg/dl/h, the insulin dose rarely may have to be increased. In general, as long as there is ketosis, it is preferable to add 5% dextrose water to the hydration solution to prevent excessive glucose decrements once the serum glucose is below 500 mg/dl, but this is rarely needed.

Continuous intravenous insulin is administered until the acidosis is corrected, the hyperglycemia under control, and ketonemia virtually absent. Ketonuria will persist for some time after correction of metabolic acidosis. If a patient is able to eat meals prior to achievement of these goals, a small increment of insulin should be given to cover the anticipated hyperglycemia. A dose of subcutaneous insulin (0.1–0.25 units/kg, depending on the ambient blood glucose level, ketosis, and appetite) should be given approximately 30 min prior to the discontinuation of intravenous insulin. The patient should then be given subcutaneous insulin, 0.2–0.25 units/kg every 4–6 h. The next 24 h should be used to evaluate the patient's total dose requirements. Thereafter, a regimen of intermediate-acting plus short-acting insulin can be started, with the total long-acting dose requirement approximately close to the previous day's total crystalline insulin dose. Short-acting insulin is given as needed, starting with approximately the same dose of short-acting insulin as had been used in a single injection on the prior day.

C. Potassium

Potassium should be started when the initial insulin dose is given, unless severe hyperkalemia ($K^+ > 6$ mEq/l) is present. Potassium is given prophylactically to prevent dangerous hypokalemia from occurring with the movement of serum potassium back into the cells or into the urine. Electrocardiographic (ECG) monitoring is very useful in indicating hyperkalemia and hypokalemia, by demonstrating peaked T waves in the former and U waves in the latter. Intracellular potassium deficiency, even when it occurs without accompanying hypokalemia, can result in

gastric stasis, ileus, and arrhythmia. Failure to replace potassium was a frequent cause of death in DKA in the past and is required even when low-dose insulin therapy is used. If bicarbonate is administered, a greater amount of potassium may be needed. In all dehydrated patients, potassium should be started at a rate of 20–40 mEq/l with the intravenous rehydration fluid. If, despite this therapy, the plasma potassium levels drop into the hypokalemic range ($K^+ < 3.5$ mEq/l), a higher concentration even up to 60 and rarely 80 mEq/l may be necessary. Hourly serum potassium monitoring is required until the patient is stable (usually 6–8 h) and thereafter the frequency can be decreased. Under most circumstances, it is safe to give the potassium in the form of potassium chloride: it is unlikely that the additional chloride administration will significantly contribute to the degree of hyperchloremia that is sometimes seen. If necessary, half the potassium can be given as potassium chloride and the other one-half as potassium phosphate (see discussion below). It should be remembered that 80% of the administered potassium can be lost in the urine during the first 24 h, and continued oral potassium supplementation in the diet is recommended after an episode of ketoacidosis. Most normal diets contain enough potassium to replenish the body's stores.

D. Phosphate

Phosphate is lost from the intracellular space by the same mechanism as that causing potassium depletion. The institution of insulin therapy causes a drop in serum phosphate in the majority of patients, resulting occasionally in severe hypophosphatemia. The inclusion of phosphate in the rehydration solution is a subject of continued controversy. The administration of phosphate supplements in the treatment of DKA can prevent early but not late hypophosphatemia and has been reported to maintain normal 2,3 DPG levels, although this has not been shown to be associated with improved peripheral oxygen delivery (10). Although there is one report of phosphate therapy improving the level of consciousness in patients with DKA (53), such is not the case in our experience (11). High-dosage phosphorus supplementation, in children particularly, which is a risk in dehydrated patient requiring large fluid volumes, is associated with the development of severe hypocalcemia and tetany (54). By contrast, low-dosage phosphate therapy in our studies does not prevent late hypophosphatemia because most of the supplement is lost in the urine, particularly in patients with severe initial acidosis who require bicarbonate therapy (11). Total serum calcium, but not ionized serum calcium, is diminished in many ill patients with DKA even without the use of phosphate supplements (11). Because the severe complications of hypophosphatemia are rarely, if ever, described in children with DKA, and because the benefits of phosphate therapy are not demonstrated conclusively, many pediatricians believe that there is at present no indication for

routine phosphate therapy because of the concomitant risk of hypocalcemia. However, others hold that severe hypophosphatemia per se may be dangerous and that careful supplementation with phosphate with continuous monitoring of serum calcium and phosphorus levels and clinical signs of hypocalcemia is a logical form of therapy. In the severely ill patient with DKA, a rational approach is administration of half the potassium as potassium chloride and the other half as potassium phosphate once the serum phosphorus level starts falling below 3 mg/dl. Phosphate should preferably be given independent of potassium needs as a sodium phosphate solution in a dosage of approximately 4 mM/kg over 12 h. Dietary phosphate supplements may need to be continued after intravenous rehydration has stopped, in order to correct the total body phosphate deficit and maintain normal intracellular levels of 2,3 DPG.

E. Magnesium

Although magnesium loss in the urine with intracellular depletion has been documented in DKA, its clinical effects are not clear (37). Thus the replacement of magnesium in the rehydration fluid is not commonly carried out. However, severe magnesium depletion can be associated with transient hypoparathyroidism and hypocalcemia. Improvement in resistant hypocalcemia and carpopedal spasm has been reported in one child with DKA after magnesium supplementation (54).

F. Bicarbonate

Bicarbonate administration is, perhaps, one of the most controversial areas in the therapy of DKA (55). It is agreed that severe acidosis, particularly in very young children, should be treated with bicarbonate because the risk of arrhythmia, reduced cardiac contractility, and possible contribution to circulatory collapse and insulin resistance. The most important danger is impaired ventilatory capacity. There is a debate about the definition of severe acidosis. The reason for avoiding the use of bicarbonate is its potential effect on cerebrospinal fluid pH (56), the production of severe hypokalemia (55), the possibility of hypophosphatemia (11), and the excessively rapid shift of the oxygen dissociation curve to the left. This would result in reduced tissue oxygenation, particularly in the presence of diminished 2,3 DPG (55), and the possibility of persistent ketosis as shown in a small-human and animal study (57). Because the paradoxical drop in CNS pH occurs in patients given bicarbonate and in those not given bicarbonate (58), this danger has been de-emphasized recently. However, the effect of bicarbonate administration on CNS oxygen tension, and its possible role in the production of cerebral edema in dogs, have made a number of physicians very cautious about its use (59). This concern has been emphasized by the identification of treatment of DKA with bicarbonate in very dehydrated

children being a major risk factor for cerebral edema (60,61).

Our current recommendation is to add bicarbonate to the rehydration fluid if the serum pH is less than 7.2. The amount to be replaced is calculated to correct the serum bicarbonate to a level of 12 mEq/l, and it is given over 4–6 h without any bolus administration. Bicarbonate therapy is discontinued as soon as the venous bicarbonate level has reached 12 mEq/l, even when the calculated amount has not yet been delivered. To calculate the amount of bicarbonate needed, one subtracts the actual serum bicarbonate level from 12, and multiplies that value by the weight in kilograms and a correction factor of 0.6. The calculated amount of bicarbonate to be given is added to the intravenous fluids as sodium bicarbonate, taking into consideration that the concentration of sodium chloride has to be decreased proportionally to reach an adequate concentration of sodium in the fluid. This bicarbonate is to be delivered to the patient in a slow infusion over 4–8 h and never as a rapid (IV push) bolus.

G. Glucose

As the patient's serum glucose level approaches 250–300 mg/dl, or possibly when the serum glucose level falls at a rate greater than 100 mg/dl/h, glucose is added to the intravenous fluid, usually as 5% dextrose water and half-normal saline. If the serum glucose level continues to fall rapidly, 10% dextrose water is given to provide calories to the patient who has had a major caloric loss over the preceding few weeks. Preventing the drop in blood glucose level below 250 mg/dl is based on studies by Arieff and Kleeman showing that cerebral edema can be induced in rabbits if the blood glucose level drops rapidly below this level from hyperglycemic levels (62). Thus glucose is added to prevent both a blood glucose decrement of more than 100 mg/dl/h from high levels and to allow the development of normoglycemia from 250 mg/dl slowly. Avoidance in a rapid drop of osmolarity is probably more important than the actual serum glucose level, but this has not been studied formally.

H. Other Therapeutic Considerations

If the patient is extremely acidotic and in shock, the administration of oxygen for a short time may improve peripheral oxygen delivery. Catheterization of the bladder is rarely necessary and carries with it the risk of infection. If the patient is unconscious, nasogastric suction is necessary to prevent the aspiration of vomitus. Under all circumstances, the event precipitating the episode of DKA should be sought and treated accordingly. During therapy, continuous clinical and biochemical monitoring is mandatory. Initially, hourly measurements should be made of plasma glucose, electrolyte levels, osmolarity, and blood gas values. Serum calcium and phosphorus concentrations should be measured intermittently. The frequency of elec-

trolyte measurements can be decreased as the patient's condition improves, although blood glucose levels should be obtained every hour. Accurate measurements of fluid intake and output should be made with appropriate changes in the therapeutic regimen. If possible, the patient should be treated in a metabolic ward or intensive care unit, where the staff is fully conversant with the therapy of DKA. Careful watch for the complications of DKA should be maintained throughout the first 12–24 h of therapy.

VIII. COMPLICATIONS OF DKA

A. Persistent Acidosis

Persistent acidosis may or may not be accompanied by continued hyperglycemia and may be related to insulin resistance, requiring a higher insulin dose regimen. However, the usual cause is unrecognized or untreated infection or inadequate fluid replacement.

B. Overhydration

Overhydration results from overestimation of the initial fluid deficit or failure to monitor the patient's fluid balance during the course of therapy. Overhydration may result in peripheral edema or even cardiac failure in the very young child. Peripheral edema (known as insulin edema) may also be caused by hypoalbuminemia, which is frequently seen during the correction of DKA because of shifts of albumin from the intra- to the extravascular space (11).

C. Hypoglycemia

Often hypoglycemia occurs 8–12 h after the initiation of therapy if serum glucose levels are not monitored regularly. This complication is less likely to occur with the use of low-dosage insulin regimens (63). Hypoglycemia is a possible cause of lethargy, disorientation, and recurrence of coma or seizures. It is easily preventable by increasing glucose delivery or reducing the insulin dose as soon as low serum glucose levels are seen during hourly monitoring.

D. Hypokalemia

Low serum potassium levels reflect even lower intracellular concentrations. These intracellular potassium deficits account for some of the symptoms accompanying DKA, such as gastric stasis and ileus. If sufficient potassium supplements are not given, classic ECG changes of hypokalemia are observed. Hypokalemia is potentially lethal, causing cardiac arrhythmia. Serum potassium levels should be monitored carefully even if insulin is given subcutaneously and oral hydration is possible.

E. Cerebral Edema

Cerebral edema is the most feared complication of DKA, occurring in 0.2–1% of children with DKA and more frequently in children than in adults. It has very high mortality and morbidity rates. It most commonly occurs after 3–12 h of therapy, even in patients who did not have significant hyperosmolarity. After initial improvement in clinical, biochemical, and CNS signs, patients experience greater irritability, CNS depression, and, later, seizures and coma. These conditions may occur even without obvious papilledema. The pathogenesis remains an enigma. A number of theories attempt to explain cerebral edema, none of which is entirely satisfactory or proven (43,64). These theories include the following:

1. A rapid drop in the blood glucose levels below 250 mg/dl. However, of the 17 patients reported in the medical literature, only nine had glucose levels that reached this range (43).

2. A rapid drop in serum osmolarity or severe hyponatremia. It is difficult to assess accurate sodium levels because of the associated hyperlipidemia in some of these patients. Despite this difficulty, the serum sodium levels were not lower than 130 mEq/l in seven of the reported cases. Also, rapid changes in serum osmolarity could not be documented (43,65). However, another study reports that progressive hyponatremia was a distinctive factor in children who developed cerebral edema (66). This supports our experience.

3. Overhydration or rapid fluid administration. Again, the theory is difficult to prove because many patients who receive the same amount of intravenous fluids as those who develop cerebral edema do not have any adverse effects. In the patients reported, the amounts and rates of fluid administration were variable. In addition, two patients had received only oral fluids prior to the development of cerebral edema (43).

4. Increased polyol activity in the brain. It is postulated that the accumulation of osmotically active sorbitol in the brain can account for the elevated CNS pressure documented in the majority of patients with DKA who were studied. However, it seems that the osmotic contribution of sorbitol is not sufficient to cause cerebral edema (67,68).

5. Cerebral anoxia associated with decreased 2,3 DPG levels. Rapid bicarbonate infusion or change in pH could precipitate such an event (59). This treatment was not unusual in the patients reported in the medical literature. However, cause and effect have not been proven.

6. An increase in the insulin induced Na^+/H^+ antiporter pump activity, which increases the accumulation of intracellular fluid by increasing sodium movement into the brain cells. An exchange with ketone bodies may also be involved (69).

A number of other mechanisms have also been postulated, but none has been proven (64). However, the fact that the frequency of cerebral edema appears to be de-

creasing suggests that slow, careful therapy with insulin fluid and electrolytes may be important in its prevention.

A patient who shows any signs of cerebral edema should be immediately treated with mannitol with appropriate cerebrospinal fluid pressure monitoring in an intensive care unit. Confirmation with a CT scan is not always possible and may be difficult without a baseline image. However, magnetic resonance imaging (MRI) may be useful to exclude infarction as a cause of the cerebral pathology seen in the pediatric DKA population in our center and elsewhere (64).

IX. PREVENTIVE THERAPY

The development of DKA in the child or adolescent with previously diagnosed diabetes mellitus is caused by a failure of therapy, the responsibility of which must be borne by the patient, the family, the physician, and the entire therapeutic team. DKA certainly should be preventable in the patient with previously diagnosed diabetes. Proper daily blood or urine monitoring, or both, by the patient or family should identify metabolic alterations that may lead to DKA and thus allow initiation of therapeutic intervention, which should prevent the progression of the metabolic problem. Frequent daily monitoring of blood glucose and the initial morning urine specimen for ketones should allow appropriate preventive therapy. The presence of ketones necessitates that each voiding thereafter be checked. The persistence of small amounts of ketones for more than 3 h or the presence of large concentrations is an indication to contact the physician for specific directions.

General principles for preventive management include an increase in oral fluid intake and the administration of additional regular insulin at a dosage of 0.1–0.25 units/kg every 3–4 h or ultra-short-acting insulin every 2–3 h in the presence of persistent ketonuria. The development of nausea and continuous vomiting requires examination by a physician and, frequently, hospitalization. Temperature elevation should also be reason for direct observation by the physician. The usual childhood illnesses, such as flu, laryngitis, tonsillitis, and otitis media, which may be tolerated by the average child with little or no major disability, may rapidly lead to major metabolic disorder in the child with diabetes. The parents must understand that early contact with their physician is essential to prevent DKA. The availability of a 24 h hotline is most important in ensuring that the families of diabetic children receive prompt and accurate direction for the management of impending illnesses.

A particular problem has arisen since the widespread acceptance of home blood glucose monitoring. It is the position of most patients and many physicians that the utilization of blood glucose level observations makes ketone testing superfluous. This is not true. Observation of blood glucose concentration provides no information on

the presence or absence of ketonuria or ketonemia. Although it is true that DKA rarely occurs in the presence of normal or modestly elevated blood glucose values, it is also true that many children and adolescents do not perform accurate measurements of blood glucose concentrations. The child who is performing only one or two blood glucose determinations daily may not record persistent or episodic hyperglycemia. Those patients with previously diagnosed diabetes admitted for treatment of ketoacidosis who were supposedly monitoring blood glucose concentrations carefully almost certainly would have been alerted earlier about a change in metabolic status if ketones had been checked.

Despite the best intentions and careful observation and intervention by the family, a small number of cases of DKA in individuals with known diabetes will almost inevitably continue to occur. Most of these cases will be the result of emotional stress in children and family without a rapid response and early intervention. The use of very-short-acting insulin in insulin pumps is another more recent common factor. The interruption of its delivery can cause rapid ketoacidosis because there is no insulin reservoir. The other major group of patients who may develop acute-onset DKA are those with acute infections, usually viral and associated with gastroenteritis. A preventive approach to DKA is essential if the cost and the mortality associated with IDDM in children are to be reduced. Education about diabetes and its complications is the cornerstone upon which this approach must be constructed. The utilization of a therapeutic team, including physician, diabetes nurse–educator, dietician, and social worker–behaviorist, will enhance the likelihood that adequate education will be delivered and continuing needs met. Prompt attention to recurrent illnesses, even minor ones, is essential. DKA in the child can and should be prevented.

Autoimmune Endocrinopathies

William E. Winter

University of Florida College of Medicine, Gainesville, Florida, U.S.A.

I. AUTOIMMUNITY AND AUTOIMMUNE DISEASES

A. Role of the Immune System

Cells of the immune system, including macrophages, T lymphocytes (e.g., T cells), and B lymphocytes (e.g., B cells), must recognize one another as well as somatic cells of the body to achieve proper intercellular communication (1) (Fig. 1). This recognition is afforded by polymorphic cell surface molecules encoded by genes within the major histocompatibility complex (MHC), as well as by various adhesion and other cell-cell recognition molecules (2). The human MHC, which is termed the human leukocyte antigen (HLA) complex, is located on the short arm of chromosome 6. By differentiating self from nonself (a process sustained by thymic T-lymphocyte education, B-lymphocyte education, and peripheral T-cell tolerance), the immune system is able to recognize and react to foreign antigens, providing protection from microbiological invasion and certain cancers that express “new” antigens.

The immune system must survey or monitor two major spaces of the body: the cytoplasmic space and the extracellular/intravesicular space. Class I MHC molecules (HLA-A, B, and C in humans) monitor the cytoplasm of nucleated cells whereas the extracellular/intravesicular space is surveyed by class II MHC molecules (HLA-DR, DQ, and DP in humans). The intravesicular space is the space that exists within cellular vesicles formed during pinocytosis and phagocytosis of extracellular materials.

B. Communication Between Cells via MHC Molecules: Class I MHC Molecules

Class I MHC heavy chains are each encoded by single loci within the HLA complex. At the cell surface, each HLA-encoded chain is coexpressed with beta-2-micro-

globulin as the class I MHC molecule. The molecules present cytoplasmic peptides, both self and nonself, to CD8 T cells (e.g., lymphocytes). Class I MHC molecules are found on the surfaces of all nucleated cells. If an activated CD8 T cell recognizes a peptide, usually viral in origin, presented by a class I MHC molecule, that CD8 T cell will function as a cytolytic-T lymphocyte (CTL or Tk [killer] cell) and will induce apoptosis in the cell presenting the peptide that was recognized (Fig. 2). Differences in MHC molecules between donor and recipient play a major role in foreign tissue rejection serving as the classically described transplantation antigens.

Apoptosis is programmed cell death. In apoptosis, the apoptotic cell essentially involutes, breaks into fragments contained within plasma membrane, and undergoes an “intracellular” necrosis where intracellular materials are not released to the extracellular space until the cell has fully autodigested. In response to viral infection, apoptosis does not release viable virions: as the cell autodigests, the intracellular virus is also digested, protecting adjacent cells from exposure to potentially infectious virus. Cytolytic-T lymphocytes (e.g., T killer cells) represent the “effector” stage of activated CD8 positive T lymphocytes. T cells, both CD4 and CD8, predominantly use alpha/beta T-cell receptors to recognize MHC-presented peptides (3). Gamma/delta-bearing T cells represent about 5% of circulating T cells and are in high concentration along mucosal surfaces such as in the Peyer’s patches in the gut. The role of such gamma/delta T cells is still poorly understood.

Upon recognizing a “target” cell, the CD8-positive Tk cell juxtaposes its cell membrane against the target cell and inflicts cell membrane damage by the release of perforin, a C9-like protein that forms pores in the target cell membrane. In the target cell, plasma membrane holes are produced by perforin, and granzymes enter the target cell cytoplasm through these holes to induce apoptosis. Apoptosis can also be induced in the target cell via membrane

Figure 1 Initial contact of CD4 T cells with antigen peptide plus microenvironmental influences stimulates and differentiates the Th0 CD4 T cell into a Th1 cell or a Th2 cell CD4 T cell (e.g., IFN- γ from natural killer cells and IL-12 from dendritic cells push CD4 T cells towards a Th1 phenotype, IL-4 from CD4 T NK1.1+ cells pushes CD4 T cells towards a Th2 phenotype).

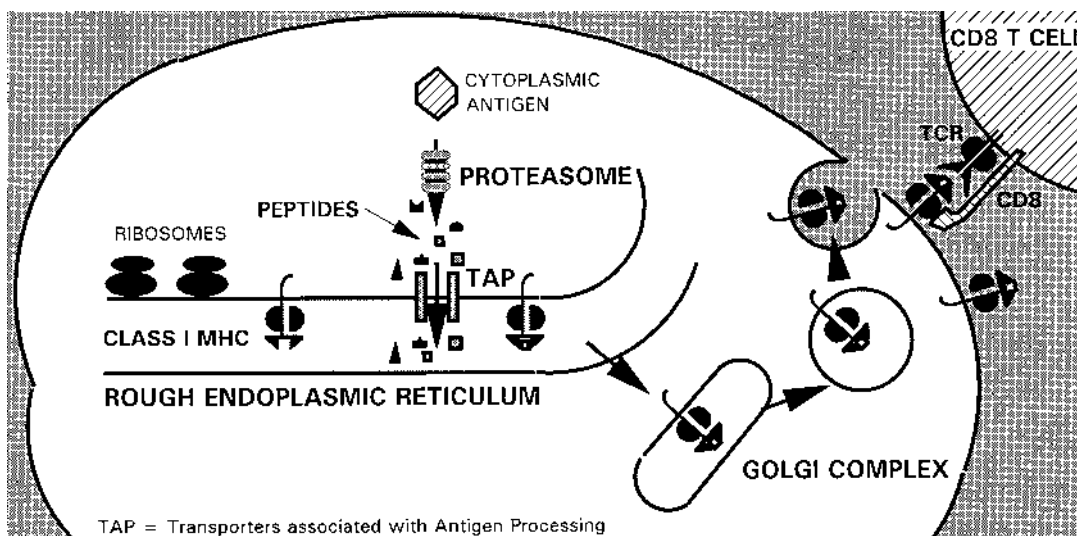

Figure 2 Cytoplasmic antigens, either endogenous or exogenous (e.g., viral infection), are processed by proteasomes to peptides. These peptides are transported into the lumen of the rough endoplasmic reticulum (RER) by transporters associated with antigen processing (TAP). Once the class I MHC molecule is loaded with peptide, a transport vesicle buds from the RER. This vesicle passes through the Golgi complex to fuse eventually with the plasma membrane, where the class I MHC molecules and peptides are oriented to the outside of the cell. In this way, class I MHC molecules display cytoplasmic contents (e.g., peptides) to CD8 T cells. MHC, major histocompatibility complex; TCR, T-cell receptor.

contact between the CD8-Tk-cell-expressed cell-surface molecule FAS ligand and FAS on the target cell surface.

C. Communication Between Cells via MHC Molecules: Class II MHC Molecules

Class II MHC molecules present extracellular peptides to CD4-positive T-helper cells to initiate immune responses that culminate in humoral and/or cell-mediated responses designed to remove the invader from the body (Fig. 3). These heterodimeric molecules (HLA-DR, DP, and DQ in humans) are restricted in their distributions to specialized antigen-presenting cells (APCs): monocyte-derived cells, B lymphocytes, and dendritic cells found in lymph nodes. Monocyte derived-cells include tissue macrophages, Kupffer's cells that line the liver sinusoids, alveolar macrophages, central nervous system microglia, and glomerular mesangial cells. Via class II MHC molecules, such APCs present (e.g., display) extracellular-derived peptides to the alpha/beta T-cell receptors of CD4 T cells. Almost all infectious agents in some stage of their life cycle pass through the extracellular space of the cell and thus these agents (or their toxic products) can be presented to CD4 T cells.

Initial MHC typing (e.g., allele identification and classification) in animals was discovered and accomplished by tissue transplantation. This led to the naming of these molecules as histocompatibility antigens. Serological typing of class I and class II MHC molecules followed. In the 1990s DNA-sequence-based allele typing

became a reality using a variety of molecular techniques including allele-specific polymerase chain reactions (PCR), allele-specific oligonucleotide probes, and direct sequencing of PCR-amplified gene segments. Based on classic cellular immunology, the *in vitro* mixed lymphocyte reaction results primarily from differences in class II MHC molecules.

As a population, humans express a large number of different class I and class II MHC alleles. This ensures that the population as a whole should be able to present peptides from any potential pathogen to T cells and thus react to that pathogen in a protective manner. In a single individual, up to six different class I MHC molecules can be expressed when the individual is heterozygous at each of the HLA-A, HLA-B, and HLA-C loci. Because some class II MHC alpha and beta DP and DQ chains from the maternal and paternal chromosomes can pair (e.g., trans-complementation), theoretically a single individual can express up to 12 different class II MHC molecules. Molecular cloning of the HLA genes and sequence analysis has revealed a tremendous degree of MHC genomic polymorphism in the human population. A recent count of the various MHC alleles is presented in Table 1.

D. Coordination of the Acquired Immune Response: CD4 Th1 and Th2 Cells

The CD4 T cells orchestrate (e.g., direct) the immune response. CD4 T-cell function can be described in two polarized functional modes: Th1 cells and Th2 cells. The

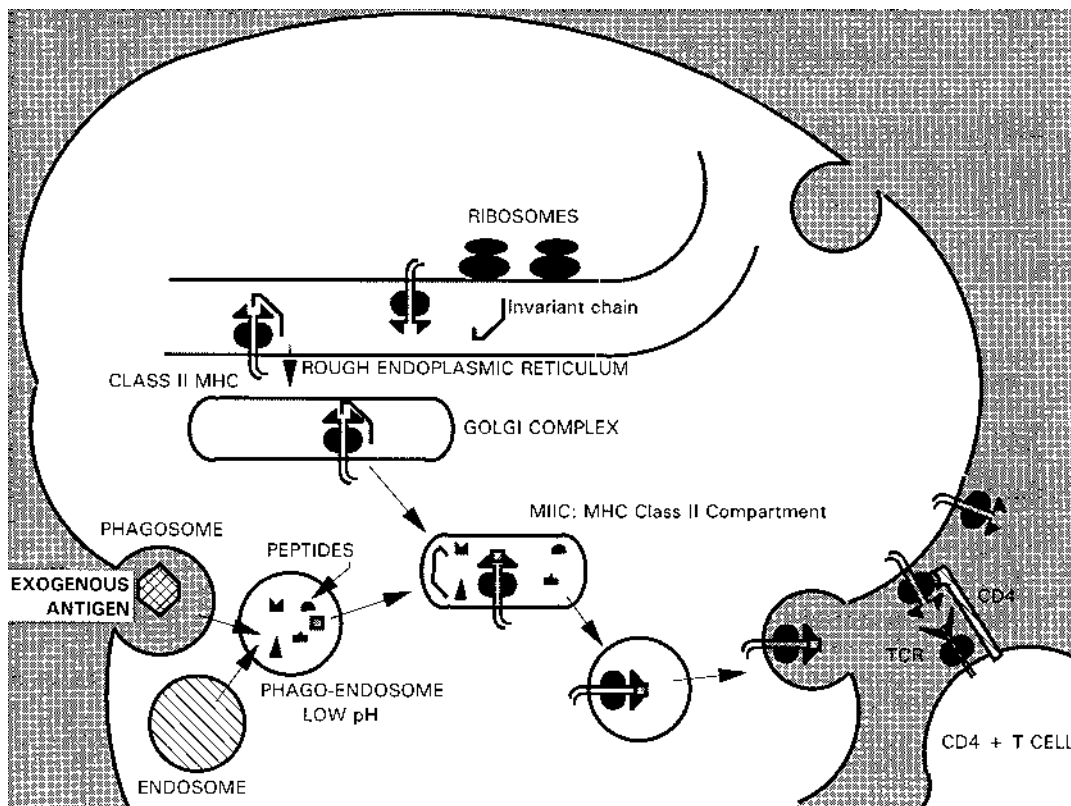

Figure 3 Within the rough endoplasmic reticulum (RER), class II MHC molecules bind the invariant chain that protects the class II MHC molecule from inadvertent loading by cytoplasmic peptides. A transport vesicle containing the class II MHC-invariant chain complex buds from the RER and passes through the Golgi complex. Extracellular antigens are taken up by specific antigen-presenting cells via phagocytosis or pinocytosis. The resulting phagosome then fuses with an endosome. Within the phagoendosome, antigen is degraded and peptides result. Fusion of the phagoendosome with the class II MHC transport vesicle forms the MHC class II compartment (MIIC). The low pH of the phagoendosome degrades the invariant chain, allowing peptide loading into the class II MHC molecule. Fusion of the MIIC with the plasma membrane allows the class II MHC molecules to be placed on the plasma membrane displaying peptides to CD4 T cells.

Table 1 Number of MHC Alleles per locus

MHC Alleles	No.
Class I MHC molecules	
HLA-A	95
HLA-B	20
HLA-C	50
Class II MHC chains	
DPβ	80
DPα	12
DQβ	35
DQα	20
DRβ	239
DRα	1

Th1 cells are responsible for stimulating cell-mediated immunity including activation of CD8 T cells, macrophages, and natural killer (NK) cells (4). Th1 and Th2 cells can both play a role in activating B cells, thereby stimulating humoral (antibody-mediated) immunity. Extracellular invaders such as bacteria and viruses are opsonized by antibody and complement and are then phagocytosed by granulocytes or macrophages to clear these pathogens. Fungi are phagocytosed and destroyed by Th1-activated macrophages. If the pathogen has reached the cell's cytoplasm, the CD8 T cell will activate apoptosis in that host cell to destroy the pathogen and its site of reproduction.

The primary difference between Th1 and Th2 cells is in the cytokines that they secrete: Th1 cells release interleukin-2 (IL-2, T-cell growth factor), gamma interferon (IFN-γ) and IL-12, whereas Th2 cells release IL-4, IL-5, IL-6, and IL-10. Each subset secretes cytokines that also regulate the other subset: IFN-γ from Th1 cells suppresses

Th2 cells and IL-10 and transforming growth factor beta (TGF- β) (5) from Th2 cells suppress Th1 cells. A third subset of CD4 T cells has also been described that is present in mucosa activated by mucosal antigen presentation. These so-called Th3 cells secrete the immunosuppressive cytokine TGF- β as do Th2 cells.

E. Autoimmunity and Central Tolerance: T Cells

Autoimmunity is a disorder of self–nonself recognition whereby self is recognized aberrantly as nonself and an autoreactive process occurs. If sufficient damage is incurred in the target tissues, circulating proteins, or cells, a clinically recognizable autoimmune disease results. Pathological autoreactivity could result in pathogenic autoantibodies and/or an antiseif cell-mediated immune responses that would serve as the effectors of the autoimmune process. Autoreactivity to self-antigens that could induce autoimmune diseases is normally restricted by the phenomenon of immunological tolerance.

Tolerance is the active process by which the immune system does not normally develop an effector response to self-antigens (6). T-cell tolerance is acquired by the time of birth and is necessary to ensure that the body does not mount an immune response to self. Central T-cell tolerance results from self–nonself discrimination that occurs in the thymus during T-cell development (7). In the thymus, T cells must express CD4, CD8, and a TCR during T-cell thymic ontogeny. Developing T cells, called thymocytes, must be able to recognize self-MHC to avoid apoptosis; however, excessive adherence to self-MHC (which might trigger autoimmunity) also leads to apoptosis. This destruction of antiseif T cells in the thymus results in so-called clonal deletion.

In the process of clonal deletion, T cells that have been rescued by their initial interaction with self-MHC will be induced to undergo apoptosis at the thymic corticomedullary junction if their TCR interaction with MHC is excessively strong. Ultimately in the thymus, CD8 T cells survive because of their modest ability to perceive class I MHC molecules; CD4 T cells survive because of their modest ability to perceive class II MHC molecules.

Normally T-cell thymic ontogeny results in T cells exiting the thymus that recognize self-MHC molecules and, presumably, foreign peptides. However, these T cells do not strongly recognize self-peptides. The ability of T cells to recognize MHC is critical to the antigen–peptide-presenting role of MHC molecules. There would be no purpose for TCRs to interact, for example, with self-surface molecules that do not present peptides. The ability of TCRs to perceive peptides presented by one's own MHC molecules is termed MHC restriction. The TCR recognizes the presented peptide plus a portion of the MHC molecule.

F. Autoimmunity and Central Tolerance: B Cells

Tolerance towards self antigens is primarily a function of T cells. However developing B cells can undergo tolerization: IgM-positive, IgD-negative immature, naive B cells upon exposure to antigen will either be anergized or induced to undergo apoptosis. When a B cell is tolerized but does not die, the B cell is said to be anergized. If the tolerized B cell is induced to undergo programmed cell death, the B cell undergoes apoptosis. Anergy results when few antigenic epitopes interact with the B-cell receptors. On the other hand, apoptosis is triggered when multiple antigenic epitopes interact with the B-cell receptors, providing a more powerful tolerization signal. B-cell tolerance is a continuing process because B cells are produced by the bone marrow throughout an individual's life.

G. Autoimmunity and Peripheral Tolerance: T Cells

Peripheral tolerance (or anergy) has evolved, presumably, because not all antigens necessarily enter the thymus during T-cell ontogeny (8) (Fig. 4). Initial T-cell activation, regardless of whether the cell is a CD4 or CD8 T cell, requires two signals. One signal is antigen–peptide-specific via MHC-TCR whereas the second signal is antigen-nonspecific (e.g., CD28 of the T cell interacting with B7 on the cell expressing the MHC molecule). Peripheral tolerance results when the antigen-specific signal is present (e.g., self-MHC do present self-peptides) but the second activation signal is absent. In fact, once exposed to antigen peptide in the absence of the second signal, the T cell can not respond in the future and is thus essentially permanently anergized. This aspect of peripheral tolerance produces so-called clonal anergy. Defects in T-cell signaling are hypothesized to play a role in loss of tolerance in type 1 diabetes (9).

H. Autoimmunity and Peripheral Tolerance: B Cells

Peripheral tolerance in terms of B cells occurs via T-cell tolerance. Like T cells, B cells require two sets of signals to become activated. One set of signals comes from the interaction of the B-cell receptor (surface antibody) and the antigen, and the second set of signals comes from helper CD4 T cells of either the Th1 or Th2 subclasses. If the antigen is bound by B-cell surface antibody but there is no T-cell help, the B cell will not be activated, will not proliferate, will not class switch, and will not undergo affinity maturation. Therefore naive mature B cells without T-cell help (because the T cells are tolerant) should not produce large amounts of high-affinity IgG autoantibodies.

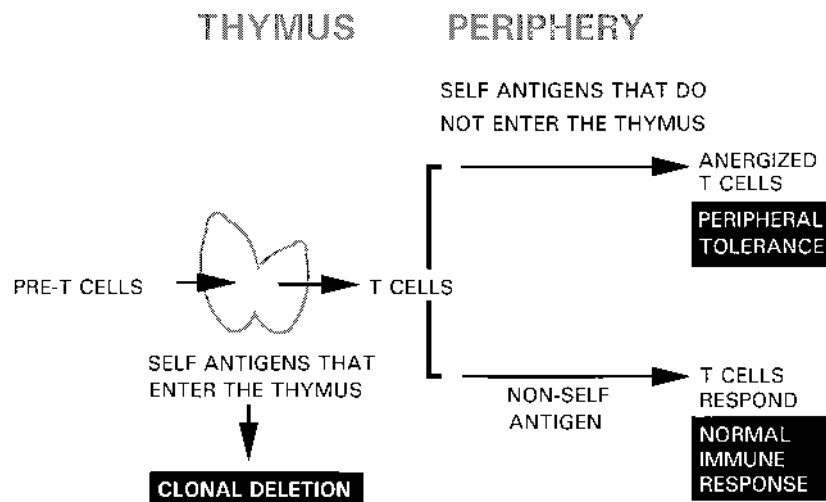

Figure 4 In the thymus, exposure of developing T cells to antigen peptides produces clonal deletion of such potentially autoreactive T cells. This process can be described as central thymic tolerance. T cells that leave the thymus and subsequently encounter novel self-antigen not previously seen in the thymus can be anergized producing peripheral tolerance. The remaining T cells are then available to respond to nonself antigens, elaborating a protective immune response.

I. Autoimmunity and Loss of Tolerance

When a breakdown in tolerance occurs, the immune system recognizes self as foreign and mounts a humoral and/or cell-mediated immune response that can result in an autoimmune disease (10). Only one autoimmune disease has been shown to be monogenic (autoimmune polyglandular syndrome type 1) (11), while all other autoimmune diseases are polygenic (12). Loss of tolerance can occur by many theoretical routes. However, loss of peripheral tolerance is thought to be the most reasonable explanation based upon the highly selective nature of organ-specific autoimmune responses and diseases. As an alternative, tolerance may have never been initially developed (13). Loss of peripheral tolerance most likely results from molecular mimicry (14). Molecular mimicry occurs, theoretically, when an immune response to a foreign antigen cross-reacts with a self antigen leading to clinical disease. Molecular mimicry is likely in the prototypic autoimmune disease rheumatic fever. Examples of molecular mimicry include similarities in the antigenic structure of group A, β -hemolytic *Streptococcus*, and antigens found in the heart (producing carditis), joints (resulting in arthritis), and basal ganglia (eliciting chorea). For example, cardiac myosin shares certain antigenic epitopes with streptococcal M protein. Similarities between HLA antigens and bacterial antigens have been described in reactive arthritides associated with intestinal infection (e.g., *Proteus*). For example *Klebsiella* nitrogenase and HLA-B2 are cross-reactive and implicated in the pathogenesis of ankylosing spondylitis and Reiter's syndrome (arthritis, conjunctivitis, and urethritis). Further cross-reactivities are described among collagen antigens and mycobacteria.

Mycobacterial proteoglycan wall component and cartilage protein cross-reactivity has been described in rheumatoid arthritis. Other theories of how tolerance fails or is broken include failure of thymic clonal deletion (15), failure of peripheral tolerance, sequestered antigen theory, altered self-antigen (16), aberrant class II MHC expression, superantigen theory of autoimmunity, and polyclonal B-cell stimulation.

The factors that lead to a disruption in self-tolerance, resulting in autoimmunities, have not been fully identified (17). To a large degree, this phenomenon is genetically programmed, since autoimmune diseases are frequently associated with specific immune response gene alleles (e.g., specific HLA types). For example, ankylosing spondylitis is increased in frequency in men who especially carry the HLA-B27 allele. Systemic lupus erythematosus (SLE) is more common in HLA-DR2 positive individuals. Environmental influences, including viral infections and diet, are also often implicated in the triggering of autoimmune processes. As noted previously, molecular mimicry between an environmental antigen and an endogenous antigen could lead to autoimmunity. Amino acid sequence homologies have been described between Coxsackievirus and the beta-cell autoantigen, glutamic acid decarboxylase (GAD). Whereas eradication of virally infected cells by T-cell lysis provides an important defense against viral illnesses, this mechanism may expand beyond its immunological defense function and lead to an autoimmune disorder. Th1 cells may play a crucial role in the process (18).

With refinements in laboratory technique, intracellular antigens (i.e., thyroglobulin) can now be found in the

circulation of normal subjects. This discovery discredits much of the so-called sequestered antigen theory of autoimmune disease for at least several endocrinopathies. It is of great interest that many autoantigens are enzymes whose distribution is often limited to specific tissues (19,20). During the aging process, there is a progressive breakdown in self-tolerance and an increased appearance of autoimmune phenomena with self-reactive autoantibodies. However, clinically apparent autoimmune disease may not be obvious in older persons because of the decreased efficiency of the immune system with advancing age, and the limited duration of an autoimmune process that begins in an elderly person. Thus with aging a higher prevalence of various autoantibodies will be recorded; however, fewer of those individuals harboring such autoantibodies will actually express disease. In contrast in younger individuals, autoantibodies will be of lower prevalence yet more of the individuals expressing those autoantibodies will be affected with clinically apparent disease.

II. CLASSIFICATION AND RECOGNITION OF AUTOIMMUNE DISEASES

Autoimmune diseases can be classified as organ-specific (e.g., autoimmune endocrinopathies) (21–23; Table 2) or non-organ-specific or systemic (e.g., collagen vascular diseases) (Table 3). Autoimmune diseases in which an antibody is made to a circulating hormone (e.g., insulin autoantibodies: autoimmune hypoglycemia), thyroid hormone autoantibodies (24), thyroid-stimulating hormone (TSH) autoantibodies (25), adrenocorticotropin (ACTH) autoantibodies (26), and testosterone autoantibodies (27) form a subgroup of the organ-specific autoimmunities.

Four types of findings support an autoimmune cause for a disease: Evidence of humoral (antibody/B cell) and/or cell-mediated (T-cell) autoreactivity; ability to transfer disease with either serum or lymphocytes (this is usually performed in animal models of autoimmune disease); disease recurrence in transplanted tissue in the absence of

Table 2 Organ-Specific Autoimmune Disorders

Antireceptor diseases	Hepatobiliary autoimmunities
Atopic diseases involving B ₂ -adrenergic receptors	Chronic active hepatitis
Atrophic thyroiditis	Cryptogenic cirrhosis
Graves' disease	Primary biliary cirrhosis
Insulin-resistant diabetes/acanthosis nigricans syndrome	Sclerosing cholangitis
Hypoglycemia—insulinomimetic autoantibodies	Dermatological autoimmunity
Myasthenia gravis	Autoimmune alopecia totalis or areata
Autoimmune endocrinopathies	Autoimmune vitiligo
Addison's disease	Bullus pemphigoid (bullus, gestationis, and cicatricial)
Autoimmune diabetes insipidus	Chronic bullous disease of childhood
Autoimmune hypoparathyroidism	Dermatitis herpetiformis
Autoimmune polyglandular syndrome type 1	Epidermolysis bullosa acquisita
Autoimmune polyglandular syndrome type 2	Erythema nodosa
Autoimmune primary gonadal failure	Linear IgA disease
Hashimoto's thyroiditis	Pemphigus (vulgaris, foliaceus, and paraneoplastic)
Hypophysitis	Neuromuscular
Pancreatic alpha-cell autoimmunity	Acute disseminated encephalomyelitis
Pancreatic delta-cell autoimmunity	Chronic inflammatory demyelinating polyradiculoneuropathy
Type 1 diabetes mellitus	Chronic neuropathy with monoclonal gammopathy
Anti-circulating-protein disorders	Eaton-Lambert syndrome
Anti-ACTH autoantibodies	Guillain-Barré syndrome
Anti-TSH autoantibodies	Multifocal motor neuropathy with conduction block
Insulin autoantibodies—hypoglycemia	Multiple sclerosis
Thyroid hormone autoantibodies	Myasthenia gravis
Autoimmune cytopenias	Polymyositis
Immune hemolytic anemia	Stiff-man syndrome
Immune leukopenia	Paraneoplastic syndrome
Immune thrombocytopenic purpura	Cerebellar degeneration
Gastrointestinal autoimmunities	Encephalomyelitis
Celiac disease	Opsoclonus—myoclonus syndrome
Chronic lymphocytic gastritis/pernicious anemia	Retinopathy
Crohn disease	Basement-membrane autoimmunity
Ulcerative colitis	Goodpasture syndrome

Table 3 Non-Organ-Specific Autoimmune Disorders

Connective tissue diseases
Ankylosing spondylitis

Dermatomyositis
Mixed connective tissue disease
Progressive systemic sclerosis (scleroderma)
Psoriasis
Reactive arthritides
Reiter syndrome
Rheumatic fever
Rheumatoid arthritis
Sjögren (sicca) syndrome
Systemic lupus erythematosus
Vasculopathies
Hypersensitivity vasculitis
Kawasaki disease
Polyarteritis nodosa
Takayasu arteritis
Temporal arteritis
Thromboangiitis obliterans
Wegener's granulomatosis
Sarcoidosis
Graft-vs.-host disease

immunosuppression; and ability to prevent or cure disease with immunotherapy through either immunosuppression or induction of tolerance (28).

Autoantibodies, which are the hallmark of B-cell autoimmunity, can be identified by several methods (Table 4). Their participation in an autoimmune disorder can be assessed by complement fixation and lysis of target cells in tissue culture or by promoting cytolysis of target cells by NK cells or macrophages in the process of antibody-dependent cell cytotoxicity. In other diseases, autoantibodies may bind to membrane receptors stimulating target cells, as in Graves' disease or insulinomimetic hypoglycemia; or interfere with receptor functions, as occurs in myasthenia gravis or Eaton-Lambert syndrome. In myasthenia gravis the target autoantigen is the acetylcholine receptor. On the other hand, in Eaton-Lambert syndrome the autoantigen is the presynaptic voltage-gated calcium channel. Autoantibodies to ganglionic acetylcholine receptors in autoimmune autonomic neuropathies have been described (29).

The finding of lymphocytic infiltration of a target organ or tissue is histopathological evidence of cell-mediated autoimmunity. Cell-mediated autoreactivity can also be shown in vivo by positive delayed-type hypersensitivity reactions during skin testing with specific syngeneic, allogenic, or xenogeneic self antigens. Cell-mediated autoimmunity can be assessed in vitro by the production of cytokines such as IL-1, IL-2, tumor necrosis factor, or interferon production, or by proliferation of T cells mea-

Table 4 Identification of Autoantibodies*Methods*

Cytoplasmic autoantibodies

Indirect immunofluorescence, Ig and complement-fixing Ig, using unfixed human tissue sections as substrates.

Immunohistochemical methods.

Immunoprecipitation: sera or Ig against cell extracts.

Hemagglutination of tissue antigen-coated red blood cells.

Other methods: radioimmunoassay, complement-fixation assays, ELISA.

Cell-surface autoantibody determinations

(using isolated xenogeneic or allogeneic target cells) by indirect immunofluorescence; binding of [¹²⁵I] protein A, antigen precipitation by serum from an affected individual; or as measured by flow cytometry with a fluorescein-labeled second antibody.

Determination of autoantibody effects

Cell metabolism/products

Measurement of changes in cell metabolism (i.e., cAMP production) or cell products (hormones) after exposure to sera, or purified or partially purified Ig serum fractions. Target cells are isolated from tissue, tissue culture, or tissue slices.

Cytolysis

Measurement of cytolysis by ⁵¹Cr release or supravital staining after the addition of sera, or purified or partially purified Ig serum fractions.

Transplacental passage

Study of the clinical effects of autoantibodies transplacentally passed from mother to fetus or neonate.

Passage to animals

Purification of Ig (Protein A or NH₄ [SO₄]₂) and passage to animals.

sured by [³H]thymidine incorporation. T-cell cytolysis of target cells in tissue culture can be measured by ⁵¹Cr release or supravital staining of damaged cells. Healthy cells retain ⁵¹Cr once labeled for a specific length of time and exclude supravital stains.

Cytokines and reactive oxygen intermediates (O₂⁻) are also incriminated as mediators or final effectors of autoimmune cell damage (30). IL-1 is often implicated along with IFN-γ and tumor necrosis factor in damaging beta cells. In the case of type 1 diabetes mellitus, in tissue culture IL-1 is toxic to isolated islets. At low dosages, IL-1 inhibits glucose-stimulated insulin release, while at higher dosages IL-1 is directly toxic and leads to islet cell death. Certain lymphokines (i.e. IFN-γ) may induce high levels of class I MHC expression as well as low levels of class II MHC expression that may propagate autoimmune responses once initiated.

Several other lines of evidence can support an autoimmune cause for a particular disease: clinical association with known autoimmune diseases; disease association with particular HLA alleles; the ability to induce a similar

disease in animals after injection of self antigens (often in Freund's adjuvant to exaggerate the response); increased disease frequency in females compared with males; and increased disease frequency with advancing age. A wide variety of autoimmune mechanisms have been proposed as outlined in Table 5.

This chapter will discuss endocrinopathies believed to have an autoimmune cause with particular reference to genetics and HLA relationships; classify endocrinopathies into autoimmune polyglandular syndromes and describe their relationship to other nonendocrine autoimmune diseases; discuss available diagnostic tests (31); and elaborate a clinical approach to the endocrinopathies.

III. AUTOIMMUNITY TO THE PANCREATIC ISLETS, INSULIN RECEPTORS, AND INSULIN

A. Type 1 Diabetes Mellitus

1. Classification

In 1997, the American Diabetes Association (ADA) (32) reclassified diabetes mellitus according to cause. Thus the term type 1 diabetes mellitus replaced the term insulin-dependent diabetes mellitus. Type 1 diabetes is insulinopenic diabetes that results from autoimmune beta-cell destruction (type 1A diabetes) or whose cause is unknown (type 1B diabetes). Likewise noninsulin-dependent dia-

betes mellitus (NIDDM) was reclassified as type 2 diabetes that results from insulin resistance in combination with relative insulinopenic beta-cell failure.

Nonautoimmune forms of insulinopenic diabetes for which a cause has been identified are classified as other specific types of diabetes in the 1997 ADA scheme. These disorders include diabetes secondary to transcription factor mutations (hepatocyte nuclear factor [HNF] 4 β , HNF-1 β , insulin promoter factor-1, and HNF-1 α), glucokinase mutations (33), certain types of mitochondrial mutations (34), drugs and poisons (e.g., the rodenticide Vacor [35], drug toxicity [36]), and viral infections (e.g., Coxsackie B4 [37]; rubella [38]).

2. Clinical Impact of Type 1 Diabetes

Type 1 diabetes is a major clinical problem in both children and adults, and approximately 1 in 500 children are affected (39). It can be argued that diabetes is the most significant endocrine disorder affecting developed populations. Before the introduction of rigorous glycemic control as the standard of care as dictated by the Diabetes Control and Complications Trial results (40), expected life span from the time of diagnosis was reduced by one-third. For example, if the normal life expectancy of a 10 year child was to age 70 with 60 more years of life expected, in type 1 diabetes the expected life span would be reduced to age 50. Microvascular complications (retinopathy and nephropathy) are major causes of morbidity and mortality in type 1 diabetes. Premature macrovascular disease (coronary artery, carotid artery, and peripheral vascular disease) and neuropathy are also major contributors to morbidity and mortality (see Chapter 25). The leading causes of premature death in type 1 diabetes are coronary artery disease and renal failure. With better diabetes management, there is hope that these grim statistics can be avoided and revised.

3. Causes

The majority of cases of type 1 diabetes result from a cell-mediated autoimmune process (41) that selectively destroys the pancreatic beta cells. Both CD8 T cells and macrophages are believed to be responsible for beta-cell necrosis. Islet-cell autoimmunity can develop very early in life (42); it has been reported to develop prenatally (43) and is transferable by bone marrow transplantation (44). Roles for Th1 and Th2 cells have been implicated (45).

Multiple lines of evidence support an autoimmune basis for type 1 diabetes. In patients dying within 6 months of diagnosis of type 1 diabetes, 60–~90% have pancreatic insulinitis (46). Insulinitis is the histological description of lymphocytic infiltration of the pancreatic islets with destruction of the beta cells and a depletion in insulin content. With increasing duration of the disease, there is progressive disappearance of pancreatic beta cells. Non-beta cells (alpha, gamma, and pancreatic polypeptide cells) are not subject to autoimmune targeting or perma-

Table 5 Suggested Pathogenic Mechanisms of Autoimmune Endocrinopathies

Autoantibody hormone-receptor binding
Blocking of receptor-hormone activation (e.g., atrophic thyroiditis)
Stimulation by autoantibodies with receptor activation (e.g., Graves' disease)
Autoantibody-induced target cell destruction/dysfunction
Formation of local immune complexes with subsequent local inflammation
Complement-dependent cytotoxicity
Antibody-dependent cell cytotoxicity by macrophages, natural killer cells, possible role for subsequent IL-1, TNF mediated cytotoxicity
Autoantibody binding to a circulating protein with inappropriate levels of circulating free hormone producing excessive or deficient hormone effects (e.g., autoimmune hypoglycemia)
Immune complex formation with distal localization and destruction (e.g., immune complex nephritis secondary to autoimmune thyroid disease)
Cell-mediated (classic CD8+ killing or delayed-type hypersensitivity) target cell destruction by T cells without participation of autoantibodies
Cytokine and/or free radical destruction of target organ
Combinations of the above

ment damage. Thus, the beta cell most likely carries antigens unique to insulin-producing cells. Of the major antigens so far discovered that are targeted in type 1 diabetes (e.g., glutamic acid decarboxylase, insulinoma-associated antigen 2, and islet sialoglycoconjugate), only insulin appears to be absolutely beta-cell-specific (47).

4. Natural History of Type 1 Diabetes

The natural history of type 1 diabetes can be addressed in five stages. Stage 1 is defined as genetic susceptibility; stage 2: evidence of humoral and/or cell-mediated autoimmunity without detectable metabolic perturbations; stage 3: declining first-phase insulin response to intravenously administered glucose; stage 4: oral glucose intolerance; stage 5: frank clinical type 1 diabetes (48). Issues of genetic susceptibility will be addressed in the next section. Following a discussion of the genetics, environmental triggers will be examined. Next, islet autoantibodies and immune abnormalities in type 1 diabetes will be analyzed. Finally metabolic progression to type 1 diabetes will be reviewed under the heading of prediction and prevention.

5. Genetics of Type 1 Diabetes

Susceptibility to type 1 diabetes can be inherited, although most cases (~85%) of type 1 diabetes are sporadic. Whereas the general population frequency of type 1 diabetes in the United States is ~1:500 (0.2% of the population affected), siblings of type 1 diabetes patients experience a 25-fold higher risk of type 1 diabetes (e.g., 1:20 or 5% affected). Likewise offspring of a type 1 diabetes father or mother are also at increased risk: 1:14 (7%; 35-fold increased risk) and 1:50 (2%; 10-fold increased risk), respectively. Ethnic origin greatly influences risk for type 1 diabetes. Finns experience the highest risk in the world (1:100) while Chinese and Japanese have the lowest risk for type 1 diabetes worldwide (1:10,000) (49). Risks for type 1 diabetes in white North Americans and southern Europeans, and African-Americans are intermediate: 1:500 and 1:1000, respectively. Nevertheless, inheritance of susceptibility to type 1 diabetes is not mendelian but instead is multifactorial and polygenic. Clearly no single gene allele is always associated with type 1 diabetes nor are unique DNA sequences observed in subjects with type 1 diabetes (50). The association of specific HLA-loci and type 1 diabetes was first recognized in the 1970s for HLA-B alleles and then, more powerfully, associated with DR alleles in the late 1970s and early 1980s. In the mid to late 1980s the predominant role of HLA-DQB1 and A1 alleles was discovered in providing proclivity to type 1 diabetes.

In studies from the University of Florida involving more than 1000 individuals with type 1 diabetes, ~95% express at least one HLA-DR3 and/or DR4 allele. Compared with a general population frequency of ~3%, ~40% of type 1 diabetes patients are heterozygous for

HLA-DR3 and DR4. After DR3/DR4 heterozygotes, DR4 homozygosity is the next highest risk genotype followed by DR3 homozygotes and DR4/DRx heterozygotes (X = nonDR3/DR4 allele). Only 5% of type 1 diabetes patients lack both HLA-DR3 and DR4. In individuals with HLA-DR3 or DR4, the second antigen excluding DR3 and DR4 is most commonly DR1. DR2 and DR5 are usually protective of type 1 diabetes (51).

In contrast to the data in whites, in African-Americans with type 1 diabetes only 70% have a HLA-DR3 and/or DR4 allele, suggesting a greater heterogeneity of causes of youth-onset diabetes in African-Americans than in whites (52). In African-Americans, while HLA-DR4 is associated with type 1 diabetes DR3 is not. Thirty percent of African-Americans with youth-onset diabetes lack both DR3 or DR4 alleles. Islet-cell autoantibody (ICA) frequencies at diabetes onset in African-Americans are also considerably lower than in whites (40% vs. ~75%), thus providing further evidence of etiological heterogeneity.

Using recombinant DNA methodologies, the serological DQw3 antigen associated with DR4 has been divided by analysis of DR4-related DQ β genes (DQw3) into type 1 diabetes-susceptible (DQB1*0302) and type 1 diabetes-resistant or neutral (DQB1*0301 and DQB1*0303) type 1 diabetes-risk subtypes (53). The susceptibility to type 1 diabetes is inherited, at least in part, by way of inheritance of DQA1*0501-DQB1*0201 (associated with DR3) and DQA1*0301-DQB1*0302 (associated with DR4) or closely linked alleles (54). Individuals heterozygous for DQA1*0501-DQB1*0201/DQA1*0301-DQB1*0302 can have a 32-fold increased risk for type 1 diabetes. This would be an absolute risk of ~6.4% risk based on a general population frequency of type 1 diabetes of 1:500. HLA-DQB1*0602 is highly protective of type 1 diabetes, with only 1:15,000 persons carrying this allele developing type 1 diabetes (55). HLA-DQB1*0602 is also protective of type 1 diabetes in subjects with autoimmune polyglandular syndrome type 1 (56). The DR4 molecular split DR*0403 is also highly protective of the development of type 1 diabetes.

For the DQB1 alleles associated with type 1 diabetes, at position 57 of the β 1 exon, there are non-aspartic-acid residues (e.g., serine, valine, and alanine) as opposed to type 1 diabetes-resistance alleles where aspartic acid is present (57). This amino acid difference alters the class II MHC antigen-binding cleft and thus influences which antigen peptides are presented (58). Many studies have associated nonaspartic acid alleles with type 1 diabetes susceptibility (59). Arginine at position 52 in the DQ α chain has also been related to type 1 diabetes susceptibility (60). A combination of these DQA1 and DQB1 alleles (particularly in the *trans* configuration) further increases risk for type 1 diabetes (61). The DR2 and DR5 associated DQA1-DQB1 haplotypes are, respectively, DQA1*0102-DQB1*0602 and DQA1*0501-DQB1*0301. As opposed

to whites and DQB1, in Japanese DQA1 alleles are the major MHC susceptibility factors (62). However Korean and white type 1 diabetes subjects display similar HLA susceptibility patterns (63). Dorman et al. have proposed that variations in population frequencies of DQB1 non-aspartic-acid alleles correlate with the population frequency of type 1 diabetes (64). She et al. have recently presented an excellent overview of the genetics of type 1 diabetes with reference to the MHC (65). The influence of various DQ loci is summarized in Table 6.

Studies of multiplex families show that the inheritance of type 1 diabetes is associated with particular parental haplotypes. In sibling pairs with type 1 diabetes, instead of the expected random haplotype distribution (25% HLA identical, 50% haploidentical, 25% nonidentical) a predominance of like haplotypes is found (60% HLA identical, 25% haploidentical, less than 5% non-identical). There is an apparent transmission bias for type 1 diabetes: ~7% of children fathered by type 1 diabetes men develop type 1 diabetes as opposed to 2% of the offspring of type 1 diabetes mothers (66). This is due to the preferential inheritance of a DR4-bearing haplotype from the affected type 1 diabetes father (70% transmission to offspring vs. expected 50% transmission) (67). In both type 1 diabetes fathers and mothers, there is transmission bias of DR3 (60% transmission to offspring vs. expected 50% transmission).

Polygenic inheritance of susceptibility to type 1 diabetes is certain (68). Polymorphisms in at least 14 different genetic loci have been associated with type 1 diabetes in humans (69–73). The loci have been identified by population studies and sib-pair analysis. The loci can be classified according to the certainty with which the data support a genetic association with type 1 diabetes (Table 7). Despite this surfeit of loci, the MHC remains the most important susceptibility factor (Table 8) and provides 40–50% of genetic susceptibility to type 1 diabetes. The next most influential gene may be the insulin gene and its hypervariable region (74).

6. Environmental Triggers in the Pathogenesis of Type 1 Diabetes

Because concordance for type 1 diabetes in identical twins is only 33–50%, environmental factors are thought to play a role in triggering type 1 diabetes (75). Environmental triggers of beta-cell autoimmunity under investigation include diet/breastfeeding (76), toxins, drugs, immunizations (77), viral infections (78–80), and stress. Suspected toxins include alloxan-like or streptozotocin-like agents that induce oxidant beta-cell damage, and smoked or cured mutton. Viral infections hypothesized to trigger type 1 diabetes include coxsackie A, coxsackie B (81), cytomegalovirus, ECHO virus (82), Epstein–Barr virus, rubella, mumps, and retroviruses. There is no unequivocal evidence to suggest that children should avoid cows' milk products to prevent type 1 diabetes (83), although cow's

DR3/DR4 (+)	1:40	12.5

milk (vs. breastfeeding), bovine serum albumin, and beta-lactoglobulin exposure have been found in various studies to act as diabetogenic influences (84).

Because of the inherent plasticity of the genome, especially with respect to T-cell receptor and immunoglobulin gene rearrangements, the supposition that monozygotic twins are immunogenetically identical can be questioned (85). In persons who develop type 1 diabetes, the relative contributions of genetic and interacting environmental factors appear to be highly variable. Genetic factors may predominate early in life whereas environmental exposures may become more important with advancing age. It is assumed that once a person is predisposed to type 1 diabetes by the possession of particular immune response genes (HLA-associated and those outside the MHC) and nonimmune response genes, the proper environmental exposure may trigger or foster the initiation of the autoimmune process. It is unfortunate that the triggers to the development of type 1 diabetes remain largely unknown (86–91).

7. Islet Autoantibodies

Although many types of autoantibodies have been described in the sera of persons with type 1 diabetes (Table 9) (92), investigators have focused their studies on four types of islet autoantibodies: ICA (107), insulin autoantibodies (IAA) (108), glutamic acid decarboxylase autoantibodies (GADA) (109), and insulinoma-associated-2 autoantibodies (IA-2A) (110).

The ICA and ICSA autoantibodies (111,112) have been described in the sera of patients with type 1 diabetes since the mid-1970s. At the time of diagnosis, 70–80% of caucasian children with type 1 diabetes have ICA; how-

ever, the frequency falls thereafter (113). By 5 years' duration of type 1 diabetes, ICA frequency has declined to approximately 25%, and after 10 years ICA persists in sera in less than 5%. First-degree relatives of type 1 diabetes patients have a frequency of type 1 diabetes similar to their ICA frequency: 3–5%. In Pasco County, Florida, in a study of ~10,000 normal school children, ICA were detected in 1:~250 children (114).

In patients with clinically apparent type 2 diabetes, some 5–15% are ICA positive (115–117), and, with time, these patients tend to progress to insulin dependence. These individuals also express higher frequencies of the type 1 diabetes-associated HLA-DR alleles DR3 and DR4. Autoantibodies to GAD have also been described in such patients with apparent type 2 diabetes. Such islet-autoantibody-positive individuals with type 2 diabetes, according to the 1997 ADA scheme, are now classified as having autoimmune diabetes and in reality have type 1 diabetes. Because of the attenuated pace of beta-cell destruction and older-onset of disease, the term latent autoimmune diabetes of adulthood (LADA) has been applied to such clinical circumstances (118–121).

Since ICA react with intracellular antigens of all cells of the pancreatic islets, ICA are not involved in the pathogenesis of type 1 diabetes. However sera containing ICSA have been shown in vitro to be cytotoxic to rodent islet cells (122) and can inhibit glucose-stimulated insulin release by islets (123). ICSA may also react preferentially with beta cells, unlike other islet autoantibodies that react with all cells of the islet (e.g., ICA and GADA).

ICA usually predate the clinical presentation of type 1 diabetes by months or years (124). ICA-positive nondiabetic patients evaluated serially by glucose tolerance testing often show insulinopenia to intravenous glucose injection; later, rises in fasting and stimulated glucose concentrations occur after oral glucose challenges (125). Work by Schatz et al. has shown that ICA are polyclonal including both kappa and lambda light chains and all four IgG subclasses (126). Higher-titer ICA appear to predict an increased risk for the development of type 1 diabetes in nondiabetic individuals. Furthermore, newly diagnosed individuals with type 1 diabetes who have higher ICA titers are at higher risk to lose endogenous C-peptide secretion more rapidly (127). A similar claim has been made for higher-titer GADA (128).

Standardization of ICA testing has been accomplished by workshops held under the aegis of the Juvenile Diabetes Foundation. This led to the establishment of ICA titers being reported as JDF units. To calculate JDF units, the next to last positive titer is multiplied by 10. Thus if a serum level were last positive at a dilution of 1:64 (e.g., negative at 1:128), the next to last positive dilution is 1:32. Multiplying 32 by 10 gives a JDF titer of 320 JDF units.

With greater than 90% beta-cell destruction, significant insulinopenia results with consequent hyperglycemia,

unrestricted ketogenesis, and clinical insulin-dependent diabetes. Data from the Pasco County, Florida, study (114) indicate that ICA in the general population predicts type 1 diabetes as well as ICA in nondiabetic first-degree relatives of patients with type 1 diabetes. The ability to predict type 1 diabetes in the general population is most important because ~85% of type 1 diabetes patients do not have a first-degree relative with type 1 diabetes.

Another type of autoantibody found in ~40% of newly-diagnosed patients with type 1 diabetes is the IAA (129). The enzyme-linked immunosorbent assay (ELISA) method for the detection of IAA does not correlate with the development of type 1 diabetes (130,131). However, IAA detected by a serum-binding assay when present with ICA is highly predictive of insulinopenia and the eventual development of type 1 diabetes.

In 1990, the Mr 64,000 (64 Ka) islet immunoprecipitable autoantigen was shown to be GAD (109). ICA react with GAD as well as a sialoglycoconjugate target antigen (132) and recombinant IA-2 (133). Non-GAD ICA have been noted by Richter et al. (134). GAD normally converts glutamate to γ -aminobutyric acid (GABA). GAD is expressed predominantly in the central and peripheral nervous systems but also in testes, ovary, adrenal, pituitary, thyroid, islets, and kidney (135). GAD comes in two molecular weights coded for by separate genes (GAD65 on chromosome 2 and GAD 6 on chromosome 10). GAD65 and GAD67 exhibit ~70% amino acid homology. GADA are most commonly directed against GAD65 (136–138). Radiobinding immunoprecipitation assays for GADA require that labeled GAD be kept in solution (as opposed to an ELISA format) because GADA recognize conformational determinants. Epitope reactivity for GADA among nondiabetic and diabetic individuals may explain why not all GADA in nondiabetic individuals predicts type 1 diabetes (139).

A primary sequence homology between portions of GAD and the P2-C protein expressed by Coxsackie virus has been described (140). GAD cellular autoimmunity has been shown (141). In addition to GAD, cell-mediated immune responses to other islet antigens have been described such as insulin secretory granule proteins and beta-cell membrane antigens (142). One group of investigators proposed that cellular and humoral GAD reactivity are inversely associated with type 1 diabetes risk (145). Using the older immunoprecipitation assay, Atkinson et al. (146) showed that 64 kDa autoantibodies were highly predictive of type 1 diabetes. Since this initial report, many studies have confirmed that GADA in nondiabetic individuals predicts the later development of type 1 diabetes. GADA in patients with clinical so-called type 2 diabetes correlates with insulin deficiency similar to ICA.

The most recently identified autoantigen of great importance is a member of the plasma membrane protein tyrosine phosphatase family: insulinoma-associated anti-

gen-2 (IA-2) (147–149). Located on lymphocytes, CD45 is another example of a protein tyrosine phosphatase. Recent work has identified a second transmembrane protein tyrosine phosphatase: IA-2 β (150). IA-2 and IA-2 β share several common epitopes while other epitopes are unique to each molecule.

In the prediction of type 1 diabetes in nondiabetic individuals using islet autoantibody testing, it is now clear that the presence of a single autoantibody is not as powerful a predictor of the later development of type 1 diabetes as positive findings of multiple islet autoantibodies. When multiple islet autoantibodies are present, the risk for developing type 1 diabetes rises substantially (151–154). Furthermore in children when multiple autoantibody positivity islet autoimmunity is coupled with depressed first-phase insulin response to intravenously administered glucose, risk for type 1 diabetes can exceed 50% over 5 years follow-up and approaches 100% over 10 years. Although the biochemical autoantibodies GADA and IA-2A provide many methodological advantages over ICA testing, ICA testing should not be abandoned because of its higher specificity than GAD or IA-2A and its ability to detect autoimmunity to several islet autoantigens not detected by the single GADA or IA-2A assays (155).

8. Immune Abnormalities in Type 1 Diabetes

Besides insulinitis and islet autoantibodies (e.g., ICA, IAA, GADA, and IA-2A), a number of other immunological abnormalities have been described in type 1 diabetes: elevated levels of Ia (class II MHC) and TAC- (transferrin receptor) positive T cells (activated T cells), increased K-cell levels, perturbed numbers or ratios of T-helper/inducer (CD4) and T-cytotoxic/suppressor (CD8) cells, lymphocytotoxic autoantibodies, circulating immune complexes, possible decreased IL-2 production by lymphocytes from type 1 diabetes patients, impaired CD4-positive T-lymphocyte function, and potentially decreased class I MHC expression. In vitro, lymphocytes from type 1 diabetes patients have been shown to produce migration inhibition factor when exposed to xenogeneic islets or islet homogenates. Lymphocytes in vitro have produced islet adherence and cytolysis and have inhibited insulin release. Recently Clare-Salzler and colleagues have described variations in antigen-presenting cell function in type 1 diabetes and prostaglandin synthase 2 expression (156).

Further evidence of an autoimmune cause for type 1 diabetes is found in the association of type 1 diabetes with other recognized autoimmune diseases (particularly chronic lymphocytic thyroiditis [157] and atrophic gastritis), and with disturbed frequencies of particular HLA-DR and DQ types (158). In contrast to many other autoimmune disorders, type 1 diabetes is slightly more common in males than females and more commonly presents in childhood than in adult life.

9. Prediction, Immunotherapy, and Prevention of Type 1 Diabetes

In the natural history of type 1 diabetes, autoantibody-positive individuals progress through varying stages of glucose intolerance to clinical diabetes (159). The earliest clinical abnormality is a decline in first-phase insulin response to intravenously administered glucose at time 1 plus 3 min (160,161). Later, intolerance to oral glucose challenges appears. After 1–2 years of glucose intolerance upon oral testing, a typical history of polyuria and polydipsia is found as the patient presents with frank clinical diabetes. Weight loss and diabetic ketoacidosis may occur if the diagnosis of diabetes is delayed.

In studies undertaken largely in the 1980s, immunosuppression of newly diagnosed type 1 diabetes patients with cyclosporin or azathioprine and glucocorticoids produced short-lived remissions (162–164). Because of the limited success of these trials and the intrinsic toxicities of such immunosuppressive agents, researchers have recently attempted to induce immunological tolerance to beta-cell antigens as a method of preventing type 1 diabetes (165). The first beta-cell antigen to be used in such trials is insulin by subcutaneous injection for high-risk individuals and oral insulin in lower-risk individuals (166). This is the basis for the Diabetes Prevention Trial 1 study that started in 1993 (167). However, oral insulin administration begun at disease onset is ineffective in changing the disease course over the first 12 months following diagnosis (168).

Nasal insulin administration is being attempted in Finland in the Diabetes Prediction and Prevention (DIPP) trial (169). In New Zealand (170) and Canada, Texas, and Europe (European Nicotinamide Intervention Trial [ENDIT]) (171), nicotinamide is being studied as a beta-cell-selective antioxidant. However, several papers have disputed the claim that nicotinamide is of any benefit in preventing or treating type 1 diabetes (172,173). Islet beta-cell (174) and stem-cell (175) transplantation is a promising field in beta-cell reconstitution.

Success in such trials may lead to the routine treatment of prediabetic individuals, enabling one to forestall or actually prevent type 1 diabetes (176). Such trials are to be considered strictly experimental at this time (177).

B. Type B Insulin-Resistant Diabetes and Acanthosis Nigricans

In this rare syndrome, insulin resistance occurs as a result of autoantibodies directed towards the insulin receptor that interfere with insulin binding (type B insulin resistance and acanthosis nigricans) (178). Acanthosis nigricans of the skin is recognized as raised, waxy plaques that occur in skin folds especially around the neck and upper trunk, under the arms, breasts, and in the groin where skin abrasion occurs. In severe cases, the elbows, knees, and periumbilical skin can become exceptionally rough.

Type B disease, which has been described in a few adolescents, is more common in females and is associated with other autoimmune disorders. Type B patients may display antinuclear antibodies, anti-DNA antibodies, episodic hypocomplementemia, hypergammaglobulinemia, and leukopenia. A number of type B patients have been reported with systemic lupus erythematosus, scleroderma, Sjögren's syndrome, and ataxia–telangiectasia (179). In one patient, a dramatic remission was induced with steroid therapy (180). Insulin receptor autoantibodies and a type-B-like syndrome have been described in an adult with pheochromocytoma (181). The diagnosis of type B insulin-resistant diabetes should be pursued in patients with type 2 diabetes and acanthosis nigricans who require high dosages of insulin (>100–1000 units/day) for treatment of hyperglycemia. The presence of non-organ-specific autoantibodies or non-organ-specific autoimmune diseases increases the likelihood of type B disease.

In contrast to the type B syndrome, another nonimmunological form of severe insulin resistance and acanthosis nigricans (type A) is associated with hypogonadism and/or the Stein-Leventhal polycystic ovary syndrome phenotype. In this disorder, there is a decrease in receptor number with normal receptor affinity and no antireceptor autoantibodies.

C. Hypoglycemia Secondary to Insulinomimetic Autoantibodies

Antireceptor autoantibodies usually block insulin action. Patients have been described with antireceptor autoantibodies that displayed insulin-like action producing hypoglycemia (182). This disorder has been reported in children (183). Hypoglycemia secondary to insulinomimetic autoantibodies has been identified in adults with Hodgkin's disease (184) and lupus erythematosus (185,186). Insulinomimetic autoantibodies, which are a rare cause of hypoglycemia, can be considered when the biochemical determinations suggest hyperinsulinism (e.g., nonketotic hypoglycemia) yet insulin concentrations are depressed. Tests for insulin receptor autoantibodies are available generally only from research laboratories.

D. Autoimmune Hypoglycemia

In this disorder, an autoantibody is produced against circulating insulin (187,188). Whereas insulin antibodies are common in patients who have received exogenous insulin (including human insulin), patients with autoimmune hypoglycemia spontaneously develop such antibodies (189). Pediatric cases have been identified (190). This condition is most often recognized in Japan (191), but it has been reported in Norway and the Netherlands (192). Some subjects have developed this syndrome following exposure to antithyroid medications used to treat Graves' disease (193). Nevertheless, a recent report noted a decline in insulin autoantibodies despite continuation of methimazole

therapy in a patient with Graves' disease and autoimmune hypoglycemia (194).

The circulating autoantibody–insulin complexes can release insulin inappropriate to metabolic needs, increasing the free insulin concentration (195). At these times, hypoglycemia results from relative hyperinsulinism. The amount of circulating insulin complexed to autoantibodies may also lead to glucose intolerance or a mild diabetic state as well as hyperglycemia during fasting.

Similar to insulin antibodies resulting from exogenous insulin administration, autoimmune hypoglycemia is associated with HLA-DR4 (196). IAA described above in prediabetic individuals do not appear to be associated with hypoglycemia. In so-called prediabetes, IAA serve as markers of beta-cell autoimmunity.

E. Pancreatic Alpha-Cell and Delta-Cell Autoimmunity

Bottazzo and Lendrum in 1976 first described autoantibodies that reacted solely with the cytoplasm of the pancreatic glucagon-producing alpha cells and with the somatostatin-secreting delta cells (197). The Pasco County, Florida, ICA study found that the frequency of alpha-cell autoantibodies (ACA) was similar in controls and relatives of type 1 diabetes patients (0.5% vs. 0.6%, respectively). ACA are apparently very rare in type 1 diabetes patients because they were not found in any of 62 ICA-negative type 1 diabetes patients studied. Eleven ACA-positive patients were also studied using arginine infusion and did not display glucagon deficiency (198). Del Prete et al. had previously shown normal glucagon responses to arginine infusion in two patients with ACA (199). Asymptomatic autoantibodies to the glucagon molecule have been reported (200). ACA is a very interesting autoantibody because as yet there are no disease associations with it. Subjects with ACA do not display disturbed HLA-DR frequencies, in contrast to nondiabetic individuals with ICA who exhibit increased frequencies of HLA-DR3 and DR4.

IV. AUTOIMMUNE THYROID DISEASE

Autoimmune thyroid disease (AITD) can present clinically as goiter and/or thyroid dysfunction: either hyper- or hypothyroidism. AITD includes a spectrum of disorders bridging chronic thyroiditis (201) and Graves' disease (202). Graves' disease is the most common form of primary hyperthyroidism in which thyrotoxicosis results from agonistic TSH receptor autoantibodies. AITD is commonly seen in both children and adults and rarely develops prenatally (203).

Thyroid inflammation (so-called thyroiditis) can be classified as acute (suppurative) resulting from bacterial thyroid gland infection, subacute (deQuervain) resulting from viral thyroid gland infection, or chronic resulting

from an autoimmune lymphocytic infiltration of the gland. There are two clinical forms of chronic thyroiditis: goitrous and atrophic thyroiditis. Hashimoto originally described the association of chronic lymphocytic thyroiditis and goiter in 1912 and it is this form of thyroiditis that bears his name (Hashimoto's thyroiditis). Taken together, all forms of AITD represent the most common causes of autoimmune endocrinopathies in humans. Among all forms of AITD there is a striking female predominance (see Chapter 17).

A. Chronic Lymphocytic Thyroiditis

1. Thyroiditis

Chronic lymphocytic thyroiditis (CLT) is the most common cause of goiter and acquired hypothyroidism in childhood (204). Patients presenting with a goiter may progress to frank hypothyroidism because of continued gland destruction, while other patients may pass through a transient state of hyperthyroidism (hashitoxicosis) with release of thyroid hormone from a period of accelerated thyroid gland destruction, with later development of hypothyroidism. In atrophic thyroiditis, an autoantibody to the TSH receptor may be present that blocks TSH action (e.g., an antagonistic TSH receptor autoantibody) (205,206). About 20–25% of individuals with atrophic thyroiditis exhibit antagonistic TSH receptor autoantibodies compared with 10% of individuals with goitrous thyroiditis. Goiter is not present in the patients with atrophic thyroiditis, unlike patients with CLT. With disappearance of antagonistic TSH receptor autoantibodies, hypothyroidism can spontaneously remit (207).

Atrophic thyroiditis, goitrous thyroiditis, and Graves' disease often coexist in single pedigrees. About 50% of first-degree relatives will be affected with AITD, suggestive of autosomal dominant inheritance. Higher levels of dietary iodine are associated with higher population frequencies of CLT.

Histological examination of the thyroid of patients with CLT reveals lymphocytic infiltration with germinal center formation. In the late stages of disease, fibrosis and atrophy are present. The intrathyroidal plasma cells are a major source of thyroid autoantibody production. T-cell lines derived from the thyroid glands of subjects with AITD demonstrate a predominance of CD4 expression (208) and Th1 cytokine patterns (209). These data are consistent with the destruction of thyroid follicular cells effected through a Th1-cell-mediated autoimmune response. In contrast, Graves' disease may represent a predominantly Th2 disease with pathogenic autoantibody production.

An interesting phenomenon is the finding of class II MHC (e.g., HLA-DR) expression on thyroid follicular cells in both patients with Hashimoto's thyroiditis (~100% of cases) and Graves' disease (~70% of cases). Two competing hypotheses explain the role of such aberrant class II MHC expression. A proautoimmune hy-

pothesis states that T-cell secretion of IFN- γ elicits HLA-DR expression and that the follicular cells then present autoantigens to CD4 T cells to foster the autoimmune response (210). Stimulation of naive CD4 T cells could not occur, however, because thyroid follicular cells fail to express the costimulatory molecule B7. An alternative hypothesis is that aberrant class II MHC expression actually downregulates autoimmunity by inducing anergy in naive T cells, because of the absence of B7 co-expression with class II MHC. Both hypotheses could be true: naive cells could be anergized, yet activated cells that do not require B7 activation could be stimulated. Cytokine secretion such as IL-1, TNF, and IFN- γ can all depress thyroid cell function in vitro (211,212). IL-1 β induces Fas expression on normal thyroid follicular cells in vitro (213). Once Fas is expressed, such thyroid follicular cells could trigger so-called bystander apoptosis by interacting with Fas ligand on adjacent cells. Increased apoptosis has been recognized in glands of patients with Hashimoto's thyroiditis (214).

Autoantibodies to the thyroid microsomes (thyroid microsomal autoantibodies, TMA), to thyroglobulin (thyroglobulin autoantibodies, TGA), and to nonthyroglobulin colloid antigen (CA2) can be found very frequently in affected patients (215). The major microsomal autoantigen is thyroperoxidase (TPO) whose autoantibodies are termed TPOAb (216). A thyroid-growth-promoting autoantibody that does not interact with the TSH receptor has been suggested (217). In clinical practice, the finding of TMA, TPOAb, and/or TGA in the presence of euthyroid goiter or goitrous hypothyroidism is consistent with Hashimoto's thyroiditis. When these autoantibodies are present in cases of nongoitrous hypothyroidism, atrophic thyroiditis is diagnosed.

The TMA autoantigen has been shown to be TPO as noted above (218). Existing in two molecular forms (105 and 110 kDa), thyroperoxidase is a glycosylated hemoprotein located on the apical plasma membrane of thyroid follicular cells. Located on chromosome 2, the thyroperoxidase genes covers >150 kb and contains 17 exons. TPO functions to oxidize iodide and to organify iodine covalently bound to thyroglobulin tyrosine residues, forming monoiodothyronine (MIT) and diiodothyronine (DIT). TPO is next responsible for the coupling reaction forming triiodothyronine and tetraiodothyronine. The catalytic domain of TPO is oriented toward the colloid space where organification of iodide and iodination of thyroglobulin occur. On the immediate extracellular N-terminal portion of TPO, an epidermal growth factor precursor-like domain and complement protein C4b-like domain are recognized. TPO demonstrates extensive homology with myeloperoxidase, an autoantigen in some forms of systemic vasculitis (219).

The TMA autoantibody reacts with TPO in its native conformation (220). Antibodies to TPO (e.g., TPOAb) are more sensitive for the detection of AITD; however, because such TPOAbs are more common in the general pop-

ulation than TMA, TPOAb may be less specific than TMA. This may lead to improvements in the TMA assay but this is still somewhat controversial (221).

Autoantibodies to thyroglobulin (e.g., TGA) are not as common as TMA/TPOAb in all forms of AITD and CLT. Thyroglobulin is a 2748 amino acid, 330 kD homodimeric glycosylated iodoprotein that can represent 75% of the total protein content of the thyroid gland. There are multiple regions of repeated structure within the protein. The coding portion of the thyroglobulin gene covers >250 kb of DNA and 42 exons. The gene is located on chromosome 8q24. Synthesized by thyroid follicular cells, thyroglobulin is secreted into the lumen of the thyroid follicle forming the colloid, where it becomes the substrate for thyroid hormone synthesis.

Two new autoantigens have been recognized in AITD: megalin (GP330) and the thyroid Na⁺/I⁻ symporter. Megalin is a multiligand receptor found on the apical surface of selected epithelial cells including the thyroid gland. Antibodies to megalin were found in 50% of subjects with autoimmune thyroiditis and 10% of Graves' disease subjects (222). Megalin is also referred to as a polyspecific receptor protein. Na⁺/I⁻ symporter is not believed to be a major thyroid autoantigen because autoantibodies to the symporter are found in only 10% of subjects with Hashimoto's thyroiditis and 20% of Graves' disease subjects (223).

In children, TMA correlates best with the presence of CLT; virtually 100% of children with CLT will have TMA, albeit some also have TGA (224,225). About 2% of the general childhood population have at least one antithyroid autoantibody. Thyroid autoimmunity is also highly associated with gastric parietal cell autoimmunity: approximately 25% of TMA-positive patients also have gastric parietal cell autoantibodies (PCA). About 25% of PCA-positive patients likewise also have TMA, indicating an underlying genetic predisposition to both thyroid and gastric (thyrogastric) autoimmunities in such patients (226). The histological correlate of PCA is chronic lymphocytic gastritis that can cause achlorhydria, iron deficiency, and intrinsic factor deficiency. Long-term deficiency of intrinsic factor can cause cobalamin deficiency and pernicious anemia. A major target autoantigen in atrophic gastritis is the H⁺/K⁺ ATPase pump. Both the 95 kDa alpha subunit and 60–90 kDa beta subunits of the gastric H⁺/K⁺ ATPase pump (proton pump) are targeted (227,228).

Thyrogastric autoimmunities appear to be frequently inherited as an autosomal dominant trait with increased expression in female patients. Unlike type 1 diabetes, CLT and thyrogastric autoimmunities are not inherited in association with particular parental HLA haplotypes (229). HLA does appear to modulate (230) the clinical expression of the disease: DR4 and/or DR5 are associated with CLT and pernicious anemia in population studies and DR3 is associated with Graves' disease. A model can be created

in which a non-HLA gene provides the predominant susceptibility to AITD that, in the presence of DR4 or DR5, stimulates a Th1-mediated antithyroid attack presenting as autoimmune thyroiditis, whereas the presence of DR3 stimulates a Th2-mediated antithyroid attack presenting as Graves' disease.

Genetics does play a major role in the pathogenesis of CLT in studies of adults. No data in children have been reported. In a study of 2945 female Danish twin pairs, concordance for autoimmune hypothyroidism was 55% in monozygotic twins and 0% in dizygotic twins (231). Concordance in TPOAb and/or TGA positive results was 80% in monozygotic twins and 40% in dizygotic twins. Besides the genetic influence of HLA, association studies strongly suggest that the cytotoxic T-lymphocyte-associated serine esterase-4 (CTLA-4) gene located on chromosome 2q33, or genes closely linked to CTLA-4, influence the development of AITD including Graves' disease and Hashimoto's thyroiditis (232). CTLA-4 is expressed on the surface of activated T cells. Interaction of CTLA-4 with B7 from antigen-presenting cells provides a suppressive influence to downregulate activated T cells. Therefore failure to turn off activated T cells could theoretically lead to autoimmunity. Kotsa et al. showed that microsatellite-defined CTLA-4 allele 106 was increased in autoimmune hypothyroidism (233). Donner et al. from Germany demonstrated that the alanine CTLA-4 leader sequence polymorphism (threonine/alanine) at amino acid 17 was more frequent in Hashimoto's thyroiditis (22%) than controls (15%) (234). One year later these investigators described that a -318 cytosine/thymine promoter variant associated with AITD (both Graves' and Hashimoto's thyroiditis) was linked to an exon 1 polymorphism (235). However, by itself, Hashimoto's thyroiditis was not significantly associated with a promoter polymorphism. Thymine in the promoter was linked to adenine in exon 1 of the CTLA-4 gene. In contrast to these German data, researchers from the United Kingdom did not find evidence for genetic association of the -318 polymorphism with Graves' disease, autoimmune hypothyroidism, or systemic lupus erythematosus (236). It is controversial whether CTLA-4 plays a role in the association of AITD and type 1 diabetes. Djilali-Saia et al. (237) found no influence for CTLA-4 on the association of type 1 diabetes and AITD. While the CTLA-4 codon 17 A/G polymorphism was associated with autoimmune hypothyroidism, the polymorphism was no more strongly associated with type 1 diabetes plus AITD than Graves' disease or Hashimoto's thyroiditis alone. On the other hand in Japanese type 1 diabetes subjects under age 30 years (238), the G-variant of the Thr17Ala CTLA-4 exon polymorphism was more common in type 1 diabetes subjects than controls (39% vs. 28%) and was more common in type 1 diabetes subjects with AITD (54%) than either of the other groups. The authors point out that while there are no data to suggest that the Thr17Ala polymorphism influences the func-

tion of CTLA-4, this polymorphism may be linked to an AT microsatellite polymorphism that could affect mRNA stability.

A new locus on chromosome 13 termed Hashimoto's thyroiditis locus-1 (HD-1) was detected in linkage studies in 1999 (239). This locus was uniquely linked to Hashimoto's thyroiditis and did not show linkage to Graves' disease. In a subset of the families studied, a locus on chromosome 12 was linked to Hashimoto's thyroiditis. One locus on chromosome 6 (AITD locus-1 [AITD-1]) was linked to both Hashimoto's thyroiditis and Graves' disease. This locus was close to, but distinct from, the HLA complex.

As opposed to the above population association studies, using family-based linkage studies many candidate gene loci have been excluded as affecting AITD including CTLA-4, the T-cell receptor $V\alpha$ and $V\beta$ complexes, the Ig heavy chain locus (240), the estrogen receptor alpha gene, and the aromatase gene (241). The Graves' disease-1 locus (GD-1) on chromosome 14 is also not linked to Hashimoto's thyroiditis (242) nor is the TSH receptor gene associated with AITD (243).

Thus the current state of the genetics of CLT can be summarized as follows. In families, AITD including CLT, atrophic thyroiditis, or Graves' disease appears to be inherited as a dominant trait. HLA DR4 and/or DR5 are associated with an increased risk for CLT. Loci on chromosomes 2 (CTLA-4) and 13 also influence the development of CLT. Non-MHC regions on chromosome 6 and chromosome 12 deserve further study.

2. Effects of AITD on the Fetus and Newborn: Congenital Hypothyroidism and Transient Hyperthyrotropinemia

Women with CLT do not have a significantly increased risk of bearing a infant with congenital hypothyroidism because TMA, TPOAb, and TGA that do cross the placenta are not pathogenic. This has been known for over 20 years (244). However, if the mother has antagonistic TSH receptor autoantibodies, transient congenital hypothyroidism or transient hyperthyrotropinemia can result (245). In one study, 15 of 34 women giving birth to children with congenital hypothyroidism had evidence of TSH receptor antagonist autoantibodies (246). Variable neonatal thyroid function can be observed in babies born to mothers with AITD, ranging from hypothyroidism to hyperthyroidism depending upon the mix and titer of agonist vs. antagonist TSH receptor autoantibodies (247). A report of familial nongoitrous congenital hypothyroidism due to maternal AITD was reported as early as 1960 (248). In a North American study, TSH receptor-blocking autoantibodies accounted for 2% of infants with congenital hypothyroidism identified in a T4 screening program and overall affected 1:180,000 newborns (249).

Thyrotropin-binding inhibitory immunoglobulins have been identified in infant and maternal sera (250).

Finding thyroid-binding inhibitory immunoglobulins in mothers of infants with congenital hypothyroidism suggests that the hypothyroidism will be transient. However, thyroid replacement therapy in such infants should be continued until age 3 or 4 years when a trial without hormone replacement can be carried out to confirm or deny that the hypothyroidism is persistent (251).

3. Postpartum Thyroiditis

With an increasing frequency of adolescent girls becoming mothers (intended or unintended teenage pregnancy), pediatricians and pediatric endocrinologists must be aware of postpartum thyroiditis that occurs in 5–10% of women following delivery (252). Postpartum thyroiditis is a variant of autoimmune thyroiditis: following delivery, mothers can express any one of several possible clinical courses including hypothyroidism (3–6 months following delivery; ~40% of cases of postpartum thyroiditis), hyperthyroidism (~35% of cases), or hyperthyroidism followed by hypothyroidism (~25% of cases) (253,254). In many cases, euthyroidism supervenes by 12 months postpartum yet there is an high risk of hypothyroidism in the long term (255). After 3–5 years, up to 25% of such women can develop hypothyroidism. About one-third of women with postpartum hyperthyroidism appear to have Graves' disease (256). Postpartum thyroiditis recurs very commonly in subsequent pregnancies. An increased rate of miscarriage in women with thyroid autoantibodies has been suggested (257).

Postpartum thyroiditis may represent a rebound of thyroid autoimmunity following delivery with release of the general immunosuppressive state imposed on the immune system by pregnancy (258). Effervescence of autoimmune disease following parturition is also seen in women with other autoimmune diseases such as Graves' disease and systemic lupus erythematosus. Women who are positive for thyroid autoantibodies in the first trimester have a 33–50% risk of experiencing postpartum thyroiditis. Women with type 1 diabetes are at threefold higher risk for postpartum thyroiditis than women in the general population (259).

During episodes of hypothyroidism, thyroid hormone replacement in postpartum thyroiditis is appropriate to restore the euthyroid state. Thyroid hormone can be discontinued at ~9 months to observe whether the euthyroid state has recurred. During a phase of hyperthyroidism, if symptoms are mild, no therapy is indicated because thyrotoxicosis rarely lasts more than 1–2 months. Similar to hashitoxicosis, postpartum thyrotoxicosis is usually the consequence of thyroid gland destruction and release of thyroid hormone; thus antithyroid drugs such as propylthiouracil or methimazole are not indicated. Radioactive iodine uptake in a hyperthyroid stage of postpartum thyroiditis is not elevated unless true Graves' disease is present. If therapy is required for thyrotoxicosis, a beta-blocker such as propranolol can be used but the drug's

dosage should be tapered once the destructive phase of postpartum thyroiditis remits.

B. Graves' Disease

Graves' disease is the result of thyroid-stimulating autoantibodies (TSAb) that mimic the action of TSH by binding to and activating the TSH receptor (260). These immunoglobulins, upon binding to TSH receptors on the surface of thyroid epithelial follicular cells, stimulate cyclic AMP production, and thus lead to excessive thyroid hormone production and clinical hyperthyroidism (261). Some TSAbs may also activate phospholipase A₂ and these autoantibodies may be particularly goitrogenic. The TSH receptor is the major thyroid autoantigen in Graves' disease. As opposed to CLT, in which thyroid gland destruction is mediated by a CD4 Th1-mediated cell-mediated response, Graves' disease results from a CD4 Th2 response against the TSH receptor (262).

Covering 60 kb, the 10 exon TSH receptor gene is located on chromosome 14q31 (263). Smaller mRNA transcripts can be observed, but the major mRNA is 4.3 kb. Prior to glycosylation, the TSH receptor apoprotein core weighs 84.5 kDa and ~100 kDa after glycosylation. The first nine exons encode the N-terminal extracellular domain of 398 amino acids. Six N-glycosylation sites are identified in the extracellular domain. TSH binds to this region of the TSHR. Encoded by a single large exon (exon 10), the 346 amino acid carboxyl half of the receptor contains the seven hydrophobic transmembrane segments that are connected by three extra- and three intracellular loops and the cytoplasmic tail of the TSHR. This portion of the TSHR demonstrates homology with other G protein-coupled receptors and activates the G_s protein complex upon TSH binding to the extracellular domain. The TSH receptor is a member of the superfamily of G-protein-coupled receptors. Other members of this receptor superfamily include the ACTH receptor, α -adrenergic and β -adrenergic catecholamine receptors, luteinizing hormone (LH) receptor, follicle-stimulating hormone (FSH) receptor, human chorionic gonadotropin (hCG) receptor, glucagon receptor, parathyroid hormone (PTH) receptor, and somatostatin receptor. TSH receptor autoantibodies bind to the extracellular domain of the receptor as expected (264).

TSAbs were first described in the McKenzie mouse assay system as long-acting thyroid stimulator (LATS) (265). LATS was observed as delayed, but prolonged, thyroid gland stimulation after the injection of human immunoglobulin into mice. In some patients with low levels of LATS a substance that blocked LATS absorption by thyroid cells was termed LATS protector (LATS-P) (266). LATS-P corresponds more closely to human-specific LATS. In commercial radioimmunoassays to measure TRAbs, either thyrotrophin-binding inhibitory immunoglobulins (TBII) or thyroid-stimulating immunoglobulins (TSI) can be determined (267). TBII detect autoantibodies that can bind to the TSH receptor by the ability of human

serum to compete with radioactively labeled TSH for binding to the TSH receptor. TBII titers are higher when more [¹²⁵I]TSH binding is inhibited. The TBII assay does not differentiate agonistic autoantibodies as seen in Graves' disease from antagonistic autoantibodies as observed in many cases of atrophic thyroiditis and some cases of Hashimoto's thyroiditis. On the other hand, the TSI assay detects antibodies with stimulatory effects on the TSH receptor as seen in Graves' disease. The TSI assay is typically negative in cases of autoimmune thyroiditis. The action of TSIs can be measured as the production and release of cAMP or thyroid hormone from slices of thyroid glands or cultured thyroid cells such as the FRTL-5 thyrocyte line. The titer of TSIs does not correlate with the severity of Graves' disease.

Being IgG autoantibodies, TRAbs can cross the placenta. In about 1% of pregnancies in which the mother presently has Graves' disease or had Graves' disease in the past, TRAbs with agonistic activity against the TSH receptor produce fetal and neonatal hyperthyroidism. In cases of maternal Graves' disease, some experts have suggested that testing for TRAbs should be undertaken in the third trimester of pregnancy to assess the risk of neonatal Graves' disease. If the TRAb titer is high, there is an increased risk of fetal and neonatal hyperthyroidism. Cord blood testing for TRAbs is another approach if maternal testing has not been pursued previously. TRAbs may be persistent even if the mother has had a thyroidectomy for treatment of Graves' disease or is spontaneously euthyroid.

The clinical appearance of neonatal hyperthyroidism may be delayed for 3–10 days if the mother was treated with the antithyroid drugs propylthiouracil or methimazole. Because TRAbs can represent a mixture of agonistic (e.g., TSIs) and antagonistic TSH receptor autoantibodies, the clinical course in the neonate born to a woman with Graves' disease can be variable. If there is sustained fetal tachycardia, treatment of fetal hyperthyroidism with maternal administration of propylthiouracil and concurrent T4 can be considered because of the increased risk of poor fetal outcome (268).

TMA/TPOAb and/or TGA are found in the sera of a large percentage of patients with Graves' disease. These autoantibodies, therefore, do not differentiate CLT from Graves' disease. In patients with sustained hyperthyroidism, and exophthalmos and/or pretibial myxedema, who are positive for TMA/TPOAb and/or TGA, the diagnosis of Graves' disease is appropriate. However with positive TMA/TPOAb and/or TGA, if the patient is predominantly clinically euthyroid with goiter or hypothyroid and an episode of hyperthyroidism lasted only 2 months or less, the appropriate diagnosis is CLT with temporary hashitoxicosis from transient accelerated thyroid gland destruction. The radioactive iodine uptake in Graves' disease is elevated; the radioactive iodine uptake in hashitoxicosis is not elevated.

In terms of genetic susceptibility to Graves' disease, it has already been mentioned that AITD, including Graves' disease, is often inherited in an apparent autosomal dominant mode within affected families (269). First-degree family members of individuals with Graves' disease display a high frequency of thyroid autoantibodies and AITD as well as GPCA, pernicious anemia, islet autoantibodies, and type 1 diabetes (270). Graves' disease is associated with HLA-DR3 (271), but, within families, inheritance of AITD is not linked to the inheritance of specific HLA haplotypes (272). In the HLA-DQ region, Graves' disease is associated with DQA1*0501 (273). Recently the HLA DRB3*020/DQA1*0501 haplotype has been associated with Graves' disease in African-Americans (274).

In the mid-1990s, CTLA-4 polymorphisms on chromosome 2q33 were implicated in influencing genetic susceptibility to Graves' disease (275). Researchers studied a CTLA-4 gene (AT)n microsatellite polymorphism within the 3' untranslated region of exon 3. The relative risk for Graves' disease with the 106-base pair allele was 2.82. Two years later the CTLA-4 exon 1, 49 A/G polymorphism interchanging alanine for threonine was associated with Graves' disease (276). Graves' disease patients show more alanine alleles than controls (73% vs. 58%). The CTLA-4 A/G polymorphism was substantiated in a new data set from the United Kingdom in 1999 (277). These investigators also found preferential transmission of the A allele to offspring with Graves' disease. Researchers from the University of Newcastle-upon-Tyne calculated that 50% of inherited susceptibility to Graves' disease was provided by the CTLA-4 and MHC regions (278).

Loci on chromosomes 14q31 (termed GD-1 [242, 279]), 12q (IFN- γ [280]), 6 (TAP1 and TAP2 [281]), 20q11.2 (termed GD-2 [282,283]) and the X chromosome (termed GD-3 [279]), IL-4 promoter (chromosome 5q31.1 [284]), vitamin D receptor (285) and chromosome 18q21 (286) have subsequently been linked to or associated with Graves' disease. Loci shown not to be associated with Graves include the TSH receptor (287,288), TNF receptor 2 (chromosome 1p36.3-p36.2 [289]), IL-1 α , IL-1 β , IL-1 receptor antagonist, IL-1 receptor, IL-4 receptor, IL-6, IL-10, and TGF- β (284,290). Although the MHC and CTLA-4 loci appear to have the greatest influence on the development of Graves' disease, many other loci are under investigation on multiple chromosomes (291).

Exophthalmos in Graves' disease and other thyroid disorders is also believed to be immunologically mediated (292). The spectrum of such associations is termed thyroid-associated ophthalmopathy (TAO). Clinically euthyroid patients presenting with exophthalmos often have TMA, TGA, and LATS-P (293). Even without frank exophthalmos, 68% of patients with Graves' disease have abnormally increased intraocular pressure on upward gaze (294).

Since part of the thyroid's lymphatic drainage traverses the retro-orbital space, it has been postulated that

thyroid antigens such as thyroglobulin might attach to the eye muscles and cause tissue damage as immune complexes are formed between thyroglobulin and anti-thyroglobulin autoantibodies. An exophthalmos-stimulating autoantibody has been described. Antibody to a soluble eye-muscle antigen has also been demonstrated. A older hypothesis that is again gaining favor proposes that growth of retro-orbital tissues in autoimmune exophthalmos is due to TSH receptors on fat cells and muscle cells that are affected by thyroid-stimulating immunoglobulins. The nature of the orbital antigens is unresolved and controversial, revolving around discussions of the TSH receptor, a 64 kD autoantigen (295), a 72 kD heat shock protein (296), and the G2s gene product (297). Regarding the causes of ophthalmopathy associated with Graves' disease, there is evidence for both CD4 Th1 and CD4 Th2 subset involvement (298). Various therapies for extreme exophthalmos that threaten vision include prednisone, orbital irradiation, surgical decompression, and newer uses of immunomodulatory agents such as nicotinamide (299).

V. AUTOIMMUNE ADDISON'S DISEASE

Addison's disease is manifested as glucocorticoid and mineralocorticoid deficiency. Second only to iatrogenic adrenal cortical suppression from exogenous glucocorticoid administration, autoimmune adrenalitis with lymphocytic infiltration of the adrenal cortex is the most common cause of Addison's disease. In the era before antibiotics were available, tuberculosis was the most common cause of adrenal failure.

Complement-fixation testing using saline extracts of adrenal tissue was the first methodology employed to detect adrenal autoantibodies (300). Shortly thereafter, indirect immunofluorescence using cryostat sections of unfixed human adrenal cortical tissue became the method of choice for the detection of adrenal autoantibodies. Cytoplasmic fluorescence of the adrenal cortical cells demonstrates that adrenal cytoplasmic autoantibodies are present in the serum being tested (301). All layers of the adrenal cortex often fluoresce, whereas the medulla rarely fluoresces (302). The adrenal cortical cytoplasmic autoantigens were localized to the microsomes of the adrenal cortical cells by examination of ultracentrifuged adrenal fractions (303). A peroxidase-labeled protein A technique has been also been developed to detect adrenal autoantibodies (304). However, the results of such autoantibody testing were not identical to those using indirect immunofluorescence. Adrenal cytoplasmic autoantibodies are detected in up to 75–80% of new-onset subjects with Addison's disease (305).

Autoantibodies to the surface of human or murine adrenocortical cells can be detected in some patients by indirect immunofluorescence. In one study, 24 of 28 individuals (86%) with Addison's disease displayed auto-

antibodies to the adrenal cell surface (306). Cytoplasmic and surface autoantibodies are strongly correlated. Because of the difficulty and expense of obtaining isolated viable adrenal cortical cells, such tests for surface autoantibodies are relegated to research laboratories and have been replaced by the enzyme autoantibody immunoassays discussed below.

In the 1990s, with the molecular cloning of the adrenal steroidogenic enzymes, various immunoassays were developed to detect autoantibodies directed against these enzymes. The adrenal enzymes 17-alpha-hydroxylase (307), 21-hydroxylase (308,309), and the side chain cleavage enzyme P450_{sc} have been shown to be autoantigens targeted in individuals with adrenalitis. The P450_{sc} enzyme autoantibody is identified in sera from patients with autoimmune polyglandular syndrome type 1 but not in patients with isolated autoimmune Addison's disease (310). The 21-hydroxylase autoantibodies are believed to be most clearly associated with Addison's disease and adrenal cytoplasmic autoantibodies (311). Germane to 21-hydroxylase as a major autoantigen in Addison's disease is that in-vitro-demonstrated suppression of in-vivo 21-hydroxylase activity does not advance progression to adrenal failure (312). This illustrates that while adrenal autoantibodies are plentiful in autoimmune Addison's disease, these autoantibodies are not pathogenic.

Similarly to the natural history of type 1 diabetes, the development of Addison's disease passes through various sequential, cumulative stages: elevated renin and normal to low aldosterone, deficient cortisol response to ACTH injection, elevated basal ACTH concentrations, and deficient basal aldosterone and cortisol secretion (313). Similarly to the predictive function of islet autoantibodies for the development of type 1 diabetes, autoantibodies directed against the adrenal cortical cytoplasm or steroidogenic enzymes precede the first appearance of the clinical manifestations of Addison's disease (314).

Adrenal cytoplasmic autoantibodies are predictive of the development of Addison's disease in children and, to a lesser degree, in adults (315). Complement-fixing adrenal cytoplasmic autoantibodies may be more strongly associated with progression to adrenal failure than those that do not fix complement (316). This likely reflects the fact that complement-fixing autoantibodies are higher-titer autoantibodies. This certainly appears to be the case for "non-complement-fixing" ICA vs. "complement-fixing" ICA: higher-titer ICA more strongly predict the development of type 1 diabetes in nondiabetic individuals.

Addison's disease occurs in less than 3 years in up to 50% of initially asymptomatic adrenal cytoplasmic autoantibody-positive individuals. In adrenal cytoplasmic autoantibody-positive children, 9 of 10 developed Addison's disease during follow-up of up to 10 years. The nonaddisonian child, nevertheless, still had laboratory evidence of adrenal insufficiency (317).

The relationship between increased titers of adrenal autoantibodies (both cytoplasmic and 21-hydroxylase au-

toantibodies) and more severe degrees of impaired adrenocortical function and increased risk of progression to Addison's disease has been recognized (318). In the natural history of the development of Addison's disease, adrenal autoantibody concentrations were reported to rise until the development of clinical disease, when autoantibody reactivity waned.

Excluding autoimmune polyglandular syndrome 1, isolated autoimmune Addison's disease and autoimmune Addison's disease associated with autoimmune polyglandular syndrome 2 has been associated with HLA-B8 and HLA-DR3. These associations are no stronger than the HLA associations discussed for AITD and are considerably weaker than the HLA associations described for type 1 diabetes. Adrenalitis commonly occurs with other autoimmune diseases (autoimmune polyglandular syndrome types 1 and 2 [319]) and Addison's disease by itself or as part of autoimmune polyglandular syndrome 2 has also been associated with HLA-DR4 in addition to HLA-DR3. Therefore, the genetic basis for type 1 diabetes and Addison's disease is, in part, similarly linked to an HLA-associated gene or genes.

Polymorphisms of the CTLA-4 gene at the 49 A/G site were associated with Addison's disease in subjects with the HLA-DQA1*0501 allele (320). In studies of the (AT)_n microsatellite within exon 3, the 106 base pair allele was more common in English patients with Addison's disease than controls but no difference was observed in Norwegians, Finns, or Estonians (321). In 2000, a study from the United Kingdom demonstrated an association between the G allele of the CTLA-4 A/G polymorphism in isolated Addison's disease as well as Addison's disease that was part of autoimmune polyglandular syndrome type 2 (322).

VI. ACQUIRED PRIMARY GONADAL FAILURE

In patients with hypergonadotropic hypogonadism, the presence of serum steroidal cell autoantibodies (SCA) detected by indirect immunofluorescence supports the diagnosis of an autoimmune cause for primary gonadal failure (323). SCA were described using indirect immunofluorescence as early as 1968 (324). In patients of either gender, such autoantibodies react with steroid hormone-producing cells in the theca interna/granulosa layer of graafian follicles, cells of the corpus luteum, the placental syncytiotrophoblast, Leydig's cells of the testes, and cells of the normal adrenal cortex. If SCA are present, an independent determination about the presence of adrenal cytoplasmic autoantibodies cannot be made.

Premature menopause, male climacteric, or infertility are clinical manifestations of gonaditis (325). Gonaditis is seen more often in female patients and is usually recognized in association with autoimmune polyglandular syndrome type 1 but can occur in autoimmune polyglandular

syndrome type 2. Approximately 1:4 women with autoimmune Addison's disease will exhibit amenorrhea and 10% will develop premature ovarian failure (326). In the absence of associated autoimmune disorders, SCA specifically against the ovary can be rare (327). On the other hand, Fenichel et al. (328) observed gonadal autoantibodies in ~60% of cases of idiopathic premature ovarian failure. SCA frequently predict later ovarian failure. Over 12 years of follow-up, ovarian failure occurred in 100% of SCA-positive women with autoimmune polyglandular syndrome type 1 (329).

Autoantibodies directed against steroidogenic enzymes in cases of gonaditis should not be surprising given the embryological commonality of the adrenal cortex and gonads. However, in the absence of associated adrenal autoimmunity, autoantibodies to P450_{scc} 17-hydroxylase and 21-hydroxylase are uncommon (330,331), while autoantibodies to 3 β -hydroxysteroid dehydrogenase have been reported in at least one study (332). Autoantibodies to 3 β -hydroxysteroid dehydrogenase in women with premature ovarian failure have been associated with DQB1 alleles with aspartic acid at position 57 (333). This might be somewhat surprising since non-aspartic-acid residue 57 DQB1 alleles increase risk for type 1 diabetes.

VII. IDIOPATHIC HYPOPARATHYROIDISM

Idiopathic (presumed autoimmune) hypoparathyroidism in children is often seen in association with mucocutaneous candidiasis or autoimmune Addison's disease as part of autoimmune polyglandular syndrome type 1 (334). Lymphocytic infiltration of the parathyroid glands is observed in cases of idiopathic hypoparathyroidism, especially if associated with autoimmune polyglandular syndrome type 1. This attests to the autoimmune nature of so-called idiopathic hypoparathyroidism in at least some patients.

There is continued controversy about whether parathyroid autoantibodies can be detected by indirect immunofluorescence (335,336). Parathyroid autoantibodies detected by indirect immunofluorescence can be preabsorbed with human mitochondria, indicating that such parathyroid autoantibodies are not tissue-specific (337). Using Western blotting, autoantibodies to the extracellular domain of the calcium receptor in patients with hypoparathyroidism have been reported (338). However this finding has yet to be substantiated by other research laboratories. Autoantibodies cytotoxic for cultured bovine parathyroid cells in subjects with hypoparathyroidism have been described (339). Finally autoantibodies to circulating parathyroid hormone (340,341) and the renal tubular parathyroid hormone receptor (342) have been observed in adults but have not so far been described in children.

In the absence of recognized causes of hypoparathyroidism (eg., postparathyroidectomy or DiGeorge syndrome), and in the absence of candidiasis and Addison's

disease (or adrenal autoantibodies), it is presently not possible to confirm the diagnosis of idiopathic hypoparathyroidism as autoimmune in etiology because of the lack of confirmed autoantibodies to the parathyroid gland that can be easily measured (see Chapter 19).

VIII. HYPOPHYSITIS AND AUTOIMMUNE DISEASE OF THE PITUITARY

In rare cases of hypopituitarism in which mass lesions of the pituitary were suspected, histological examination of surgical specimens has revealed hypophysitis (343). Such idiopathic lymphocytic hypophysitis is believed to be autoimmune in etiology. In some patients with type 1 diabetes, as well as their immediate relatives, autoantibodies reactive with prolactin and growth-hormone-secreting cells have been visualized by indirect immunofluorescence (344). No associations between such autoantibodies and clinical disease were recognized in these individuals. By Western blotting, pituitary autoantigens of 40 kDa and 49 kDa have been identified, although expression of these proteins was not restricted to the pituitary (345). For the 49 kDa autoantibody, positive sera were most common in subjects with lymphocytic hypophysitis (70%) with lower frequencies in subjects with Addison's disease (42%), thyroid autoimmunity (15%), rheumatoid arthritis (13%), and normal subjects (10%). In a group of Swedish patients with hypopituitarism, 28% had 49 kDa autoantibodies (346). Cases of lymphocytic hypophysitis continue to be reported (347) and definitely occur in children (348). However idiopathic hypopituitarism in children is believed generally to be rarely caused by autoimmunity (349).

IX. AUTOIMMUNE DIABETES INSIPIDUS

In some patients with idiopathic diabetes insipidus (DI), autoantibodies to the antidiuretic-hormone-producing cells of the hypothalamus have been recognized (350). Problematic is the need for fresh human hypothalamus as substrate for indirect immunofluorescence. DI-associated hypothalamic (vasopressin-cell) autoantibodies are not removed by preabsorption with vasopressin, oxytocin, neurophysin I, or neurophysin II (351). Up to one-third of children with otherwise idiopathic DI may have an autoimmune process responsible for their condition. An adult has been reported with scleroderma and DI (352). Suspected autoimmune DI has also been observed in cases of autoimmune polyglandular syndrome type 1 (353) and other autoimmune conditions (354–356). Adolescents with autoimmune DI and hypophysitis have been reported (357,358). Most cases of hypophysitis do not involve the posterior pituitary. DI-associated hypothalamic (vasopressin-cell) autoantibodies can precede the development of DI and appear to be predictive of the development of DI in initially unaffected subjects (359,360).

X. ASSOCIATED NONENDOCRINE AUTOIMMUNE DISEASES

A. Chronic Lymphocytic Gastritis Producing Atrophic Change

Gastritis has been classified as type A gastritis with sparing of the antrum, evidence of autoimmunity to the gastric parietal cells, destruction of the parietal cells and hypergastrinemia; or as type B gastritis due to *Helicobacter pylori* infection with involvement of the antrum and hypogastrinemia (361). Autoimmune atrophic gastritis (type A gastritis) due to chronic lymphocytic infiltration of the gastric fundus, as noted previously, is commonly associated with thyroiditis and type 1 diabetes (362–364). In this process the gastric parietal cells in the fundus and body of the stomach are destroyed along with their ability to secrete hydrochloric acid and intrinsic factor. Achlorhydria can be frequently found; however, intrinsic factor secretion is usually preserved except in cases of long-standing gastric autoimmunity. With prolonged deficiency of intrinsic factor, pernicious anemia manifested as a megaloblastic anemia and neuropathy may occur during mid to late life.

Autoantibodies to the cytoplasm of the gastric parietal cell (PCA) and autoantibodies that block vitamin B12 binding to intrinsic factor (IF-blocking autoantibodies), or block the absorption of the IF–vitamin B12 complex, are markers for chronic lymphocytic gastritis. PCA are assayed by indirect immunofluorescence using stomach fundus as substrate. As noted previously, the target autoantigen in chronic lymphocytic gastritis is the H^+/K^+ ATPase pump. An ELISA methodology for the detection of H^+/K^+ ATPase pump autoantibodies has been described (365).

Gastric parietal cell autoantibodies often appear early in the course of the disease, are associated with achlorhydria, and are absent in about half the patients by the time pernicious anemia is clinically apparent. Intrinsic factor autoantibodies can appear late in the course of disease, often close to the onset of pernicious anemia and thereafter.

B. Chronic Hepatitis

In the absence of a previous hepatitis B or hepatitis C infection, chronic hepatitis may result from an autoimmune process. Chronic autoimmune hepatitis is observed frequently in autoimmune polyglandular syndrome type 1. The presence of autoantibodies to smooth muscle (SMA; ~50% prevalence), mitochondria (antimitochondrial antibodies [AMA]; ~15% prevalence) and liver–kidney–mitochondrion-1 [LKM1]) can serve as markers for autoimmune hepatitis (366). Although nonspecific, antinuclear antibodies (ANA) can also be observed in ~80% of cases of autoimmune hepatitis.

Nine different mitochondrial antigens have been described termed M1 through M9. The E2 subunit of the pyruvate dehydrogenase complex (the M2 AMA antigen), the asialoglycoprotein receptor (367), cytochrome P450, UDP-glucuronosyl-transferases (368), and F-actin (the SMA autoantigen) are autoantigens described in chronic hepatitis.

C. Celiac Disease

Celiac disease (also known as celiac sprue or gluten-induced enteropathy) is characterized by gluten intolerance, abnormal small bowel histological changes, and malabsorption. IgA autoantibodies against gliadin, reticulin, and endomysium have been described in subjects with celiac disease, but the major autoantigen appears to be the enzyme transglutaminase (369). Individuals with transglutaminase autoantibodies (370) should undergo periodic small bowel biopsy. If the histological findings of celiac disease are identified, wheat and wheat products should be eliminated from the diet. Transglutaminase autoantibodies have been detected in ~10% of subjects with type 1 diabetes.

XI. AUTOIMMUNE DISEASE ASSOCIATIONS

The concurrence of multiple autoimmune endocrinopathies (with or without other nonendocrine autoimmune diseases) is common. Two consistent associations have been classified into the autoimmune polyglandular syndromes (APS) (371,372) (Table 10). Almost every disease combination (Table 11) has been noted clinically.

A. APS-1

In APS-1, the primary diseases usually present clinically in the order listed in Table 10. If a component disease is skipped, it usually does not present later. Malabsorption, early-onset pernicious anemia, alopecia, vitiligo, primary

Table 10 Autoimmune Polyglandular Syndromes

Type	Diagnostic criteria
1	At least two of the following: Mucocutaneous candidiasis Hypoparathyroidism Addison's disease or adrenal autoantibodies
2	Addison's disease (or adrenal autoantibodies) plus Autoimmune thyroid disease (Schmidt syndrome) Insulin dependent diabetes, or Autoimmune thyroid disease and insulin-dependent diabetes (Carpenter syndrome)

-, unobserved or rare; +, observed; ++, common; +++, pathognomonic.

hypogonadism, and chronic active hepatitis may frequently accompany APS-1. AITD and/or type 1 diabetes are infrequently encountered. Another term used for APS-1 is autoimmune polyendocrinopathy-candidiasis-ectodermal dystrophy (APECED), emphasizing that selective immunoendocrinopathies are associated with candidiasis and ectodermal problems.

APS-1 can be identified in siblings although most cases are sporadic. The greatest recent development in the genetics of autoimmune endocrine disease was the identification of a single gene locus termed the autoimmune regular (AIRE) that is responsible for APS-1 (373) [located on chromosome 21 (374)]. Homozygosity or compound heterozygosity for AIRE mutations produces APS-1 in an autosomal recessive pattern of inheritance (375). The predicted protein sequence of AIRE suggests that AIRE functions as a transcription factor (376).

B. APS-2

APS-2 was first described by Schmidt (Schmidt syndrome: Addison's disease plus chronic lymphocytic thyroiditis) and later as Carpenter syndrome (Schmidt syndrome plus type 1 diabetes). Unlike APS-1, which presents in childhood, APS-2 can occur at any age, but occurs more commonly in midlife and shows a female

Table 12 Autoimmune Endocrinopathy Associations

A. Type 1 diabetes	Autoimmune thyroid disease Chronic lymphocytic thyroiditis Graves' disease Pernicious anemia Addison's disease
B. Genetic syndromes (Down, Turner, Klinefelter)	Type 1 diabetes Autoimmune thyroid disease Chronic lymphocytic thyroiditis Graves' disease Pernicious anemia
C. Congenital infections (rubella)	Type 1 diabetes Chronic lymphocytic thyroiditis

predominance (2:1) in contrast to APS-1 in which the gender ratio is unbiased. APS-2 is strongly associated with HLA-DR3 and DR4 and may share certain common genetic origins with type 1 diabetes (377). However, when subjects with type 1 diabetes are excluded from the APS-2-HLA analysis, the strong HLA association disappears.

C. Other Autoimmune Endocrinopathy Associations

The association of type 1 diabetes with thyrogastric autoimmunity is of great clinical importance (378) (Table 12). Approximately 20% of patients with type 1 diabetes have TMA, and 9% have PCA. These autoantibodies are usually present at the time of diagnosis of type 1 diabetes. Of type 1 diabetes patients with TMA, almost one-half will eventually manifest thyroid dysfunction. Of these, 80% develop primary hypothyroidism, while the remaining 20% will manifest Graves' disease. Hyperthyroidism may precede the clinical onset of type 1 diabetes.

In childhood, frank pernicious anemia is unusual in type 1 diabetes patients with PCA; however, achlorhydria is commonly associated with the PCA autoantibody. Adrenal cytoplasmic autoantibodies are present in 2% of type 1 diabetes patients and are most commonly associated with TMA and PCA (APS-2). Six percent of children and young adults with type 1 diabetes and TMA have adrenal cytoplasmic autoantibodies. Approximately one-half of patients with adrenal cytoplasmic autoantibodies will show evidence of chemical hypoadrenocorticalism (i.e., raised basal renin/ACTH levels) while 20% will have more overt features of adrenocortical insufficiency when

Table 13 Clinically Useful Tests for the Diagnosis of Autoimmune Endocrinopathies and Related Diseases

Disease	Autoantibody	Technique
Type 1 diabetes	ICA: Islet cell cytoplasmic autoantibody IAA: Insulin autoantibody GADA: GAD autoantibody IA-2A: IA-2 autoantibody	IFL (unfixed blood group O pancreas) RBA RBA RBA
Chronic lymphocytic thyroiditis	TMA: Thyroid microsomal autoantibody TPOAb: thyroperoxidase autoantibody TGA: Thyroglobulin autoantibody	HA, IFL, RIA, CF, latex agglutination RIA or immunochemiluminometric assay HA, IFL, RIA, CF, latex agglutination
Graves' disease	TMA, TPOAb, TGA TBII: Thyrotropin-binding inhibitory immunoglobulin	See above Radioreceptor assay
Addison's disease	TSI: Thyroid-stimulating immunoglobulin ACA: Adrenal cytoplasmic autoantibody 21-hydroxylase autoantibody	In vitro bioassay, RIA IFL RBA
Primary gonadal failure	SCA: Steroidal cell autoantibody 3β-hydroxysteroid dehydrogenase autoantibody	IFL RBA
<i>Associated nonendocrine diseases</i>		
Chronic lymphocytic gastritis/ pernicious anemia	PCA: Gastric parietal cell autoantibody IFAb: Intrinsic factor blocking autoantibody	IFL RIA
Chronic active hepatitis	SMA: Smooth muscle autoantibody Mitochondrial autoantibody	IFL IFL
Celiac disease	Transglutaminase autoantibody	ELISA
Vitiligo	Melanocyte or tyrosinase autoantibody	IFL WB

studied (379). At least 1:6 such patients will ultimately develop clinical Addison disease, giving an overall prevalence of Addison disease in type 1 diabetes patients of 0.33% (1:300).

In many genetic syndromes, especially those with chromosomal abnormalities (i.e., Down, Turner, and Klinefelter syndromes), increased frequencies of autoimmune endocrinopathies (especially thyrogastric autoimmunity and type 1 diabetes) are recognized. In patients with congenital infections such as rubella, the frequencies of AITD and type 1 diabetes are increased. Undoubtedly new autoimmune polyendocrinopathies will continue to be described in the future such as the triple H syndrome (dysfunction of the hippocampus [impaired anterograde memory], hair follicle [alopecia areata], and hypothalamic–pituitary–adrenal axis from isolated ACTH deficiency) (380).

Table 13 outlines a variety of tests available for autoantibody detection. Those in bold are often of greatest potential value to the clinician. A positive autoantibody result in an unaffected individual can predict the later development of autoimmune disease. In an affected individual, a positive autoantibody result can demonstrate that

the disease in question has an autoimmune cause. A clinical approach to the testing of clinically unaffected yet autoantibody-positive individuals is presented in Table 14 (see below). Again, prediction and prevention studies concerning type 1 diabetes should only be carried out in a research setting.

XII. CLINICAL APPROACH TO THE AUTOIMMUNE ENDOCRINOPATHIES AND RELATED DISEASES

In general, whenever one autoimmune disease is suspected or diagnosed, a search for other autoimmune diseases should be launched guided by knowledge of the common associations noted previously (381,382).

Any patient with TMA/TPOAb should be studied for PCA and vice versa. Any patient with TMA/TPOAb and/or PCA should be evaluated for adrenocortical cytoplasmic or 21-hydroxylase autoantibodies, especially if type 1 diabetes is present. Because of the high frequency of CLT and atrophic gastritis in patients with type 1 diabetes, all type 1 diabetes patients should be screened

Table 14 Clinical Evaluation of Individuals Positive for Various Autoantibodies

Condition/autoantibody(s)	Yearly clinical evaluation/measurement
ICA, GADA, IA-2A and/or IAA ^a	Frequently sampled intravenous glucose tolerance test: if first-phase insulin response is repeatedly <1% percentile, enter into research trial to prevent type 1 diabetes*; in established type 1 diabetes: measure TMA/TPOAb and/or TGA, and PCA; islet autoantibody positivity usually confirms autoimmune diabetes from beta-cell attack.
TMA, TPOAb, and/or TGA	TSH measurement; if abnormal: measure FT4; treat either hypo- or hyperthyroidism; measure PCA (because of thyrogastric autoimmunity association)
Adrenal cytoplasmic autoantibody (or) 21-hydroxylase autoantibody	Cortrosyn stimulation test; supine renin; treat glucocorticoid and/or mineralocorticoid deficiency (Addison's disease)
Steroidal cell autoantibody (or) 3 β -hydroxysteroid dehydrogenase autoantibody	Estradiol in women or testosterone in men, LH and FSH; treat hypogonadism; also: evaluate adrenal function as per adrenal cytoplasmic autoantibody or 21-hydroxylase autoantibody positive
Gastric parietal cell autoantibody	Vitamin B12 (if >100 and <300 pg/ml: measure plasma or urine methylmalonic acid); ferritin; treat vitamin B12 and/or iron deficiency; measure TMA/TPOAb and TGA (because of thyrogastric autoimmunity association)
Smooth muscle autoantibody (or) mitochondrial autoantibody	Alanine amino transferase; if abnormal: total protein, albumin, total and direct bilirubin, alkaline phosphatase; liver biopsy; if hepatitis is detected, treat autoimmune hepatitis (e.g., glucocorticoid therapy)
Transglutaminase autoantibodies	Small bowel biopsy
Autoimmune polyglandular syndrome type 1 without apparent hypoparathyroidism	Calcium and phosphate; if hypocalcemia and/or hyperphosphatemia detected: measure intact PTH; treat hypoparathyroidism
Autoimmune polyglandular syndrome type 1 without apparent hypoadrenalism	Adrenal cytoplasmic autoantibody (or) 21-hydroxylase autoantibody [and] cortrosyn stimulation test and supine renin; manage as above per adrenal cytoplasmic or 21-hydroxylase autoantibody-positive
Mucocutaneous candidiasis and/or isolated hypoparathyroidism	Test for adrenal cytoplasmic or 21-hydroxylase autoantibodies; if positive, follow up as per adrenal cytoplasmic autoantibody or 21-hydroxylase autoantibody-positive

^aFor research purposes only.

at the time of diagnosis of type 1 diabetes for TMA/TPOAb and PCA (383). Patients with serological evidence of thyroid autoimmunity should have thyroid-stimulating hormone (TSH) measured yearly to detect incipient hypo- or hyperthyroidism in their earliest stages (384). PCA-positive patients should have yearly measurements of serum vitamin B12 and ferritin levels, and be given replacement treatment accordingly.

At present, screening for ICA, IAA, GADA, and IA-2A in the general population and first-degree relatives of type 1 diabetes patients is not recommended outside of the research setting because definitive, safe, and totally efficacious immunotherapy is not currently available. Likewise HLA typing to assess risk for type 1 diabetes is not recommended. On the other hand, individuals with a family history of CLT or atrophic gastritis should be screened for TMA/TPOAb and PCA.

Patients with mucocutaneous candidiasis and/or hypoparathyroidism should be tested for adrenal cytoplasmic or 21-hydroxylase autoantibodies. Patients with such autoantibodies should then undergo yearly assessment of adrenal function consisting of a cortrosyn stimulation test and/or morning cortisol and ACTH measurements and peripheral plasma renin activity after the patient has been supine for at least 30 min. Patients with APS-1 should be tested for steroidal cell autoantibodies and the development of gonadal failure near the time of puberty. This can be accomplished by measuring levels of sex steroids and gonadotropins. Such patients should also be screened for mitochondrial and smooth-muscle autoantibodies as indicators of chronic active hepatitis. At that time, serial studies of liver function (e.g., ALT) would be indicated.

XIII. SUMMARY

Numerically, the majority of endocrine disorders seen in childhood are the result of autoimmune processes. Recognition of the interrelationships among the autoimmune endocrinopathies provides the rationale for autoantibody screening. Identification of autoantibody-positive individuals followed by appropriate endocrine testing allows the clinician to anticipate and treat disease states before their frank clinical presentation. This can lower the morbidity and mortality of autoimmune endocrine disorders in childhood. In the long run, this should lower the costs of caring for patients with these highly prevalent conditions.

Multiple Endocrine Neoplasia Syndromes

Giulia Costi and Noel K. Maclaren

Weill Medical College of Cornell University, New York Presbyterian Hospital, New York, New York, U.S.A.

I. INTRODUCTION

The multiple endocrine neoplasia (MEN) syndromes are inherited diseases characterized by the occurrence of tumors in two or more endocrine glands in a single patient and/or the family member of the patient. Although they are relatively rare, their importance is due to their risk of malignancies, which can be reduced by early diagnosis and treatment, especially among family members. There are two types of MEN syndromes, types 1 and 2, with distinct patterns of tissue involvement (Table 1).

II. MEN-1

Multiple endocrine neoplasia type 1 (Wermer syndrome) is an autosomal dominant disorder defined by a collective predisposition to tumors of the endocrine glands of the parathyroids, anterior pituitary, and pancreatic islets. More rarely, foregut carcinoid tumors may arise, while nonendocrine tumor expressions such as lipomas, facial angiofibromas, and skin collagenomas are relatively frequent. The prevalence of MEN-1 as estimated by autopsy studies approximates 2.5:1000 (1). However 1–18% of patients with primary hyperparathyroidism have been reported to have underlying MEN-1 (the prevalence is age dependent) while among patients with a gastrinoma the prevalence has been reported from 16 to 38%, and to near 3% among patients with pituitary tumors (2). All age groups may be affected, but in 80% of patients, the clinical manifestations will have appeared by the fifth decade of life (3). PTH secreting tumors are very rare in children, but they are increasingly common through late mid-life.

A. Genetics and Pathogenesis

In 1997 the gene responsible for MEN-1 syndrome was identified on chromosome 11q13 (4), consisting of 10 exons with an 1830 base-pair coding region that encodes a

novel protein, named *menin* that is 610 amino acids long. Many different mutations in the MEN1 gene have been discovered, and most (75%) are functionally inactivating, consistent with MEN1 being a tumor-suppressor gene (5). In 5–10% of the cases where the mutations are not in the coding region of the MEN1 gene, they may occur in the promoter or enhancer regions that affect MEN1 transcription rates (6). No correlations have been reported between genotype and phenotype (7). The menin protein has a nuclear location, with two nuclear-binding domains located in the C-terminus (8). All the truncated MEN1 proteins seen in MEN-1 lack at least one of these nuclear localization signals resulting from nonsense and frame-shift mutations. *Menin* binds to junD, a jun/fos transcription factor, and it inhibits tumor-suppressor transcriptions stimulated by junD (9).

B. Clinical Features

The most common clinical problem in this syndrome results from the hypersecretion of the hormones by the glands affected.

1. Primary Hyperparathyroidism

Primary hyperparathyroidism is the most common expression of MEN1, occurring in 95% of patients (10). The disease presents usually as a long preclinical asymptomatic stage characterized by hypercalcemia followed by the onset of polyuria, polydipsia, muscular weakness, constipation, nephrolithiasis, and back pain from demineralized bone/osteitis fibrosa cystica. Older patients may develop characteristic subperiosteal absorptions of the second phalanges and so-called salt and pepper changes resulting from alternating hypo- and hyperdensities in the skull x-rays. Older patients are prone to changes in affect and mental problems that can have them erroneously diagnosed as senility or psychiatric disorders. A hypercalcemic storm or crisis is rare, as is the development of

Table 1 Genetics and Clinical Features of MEN Syndromes

	Locus	Gene	Mutation distribution	Mutation effect	Encoded protein	Inheritance	Age of onset (years)	Clinical features	Age to perform gene analysis in family members (years)
MEN-1	11q13	<i>MEN1</i>	Spread over nine coding exons	Gene inactivation	Nuclear protein, binding junD	Autosomal dominant	15–25	Primary hyperparathyroidism Pituitary tumors Pancreatic tumors	15
MEN-2			Exons 10, 11					Medullary thyroid carcinoma	
MEN-2a					Transmembrane glycoprotein, tyrosine kinase	Autosomal dominant	30–40	Pheochromocytoma Primary hyperparathyroidism	5
MEN-2b	10q11.2	<i>Rat</i>	Exon 16	Gene activation			1–18	Medullary thyroid carcinoma Pheochromocytoma	Neonatal
FMTC			Exons 10, 11, 13, 14				30–40	Medullary thyroid carcinoma	5

parathyroid cancer. Laboratory findings document total (serum) calcium and ionized calcium (plasma) levels plus low serum phosphate levels in the face of elevated and nonsuppressed concentrations of plasma parathyroid hormone (PTH). Measurement of PTH by immunoassays often detects fragments, which have no biological activity. Measurements of more intact molecules or those determining the midportion of the molecule have lower margins of error. Replicate elevations of serum calcium over 10.2 mg/dl are consistent with the diagnosis; levels over 13 mg/dl can be life-threatening and require urgent treatment. Patients have hypercalciuria exceeding 200–300 mg/day on normal diets. In such cases, or with acute symptoms, hydration with saline infusions and diuretics to force natriuresis is helpful in the emergency situation. Oral phosphate can be given with more chronic effects, however, the dosages given should be initially low (1–2 gm daily) to avoid precipitation of calcium phosphate in cardiac tissues. Later, higher dosages (2–4 g daily) can be given. Mithramycin is a cytotoxic antibiotic that can inhibit bone resorption, but is toxic and best reserved for cancer-related hypercalcemias. Bisphosphonate compounds will be increasingly used to control both acute and chronic hypercalcemias.

MEN1 can be differentiated from sporadic parathyroid adenoma by the earlier age of onset of the hypercalcemia (typically 15–25 vs. 50–60 years), and the lack of female bias (the male/female ratio of MEN-1 is 1:1), the autosomal dominant pattern of inheritance in pedigrees, and the presence of pituitary or pancreatic manifestations. MEN-1 should also be differentiated from familial hypocalciuric hypercalcemia that has its onset from birth and is characterized by low levels (<100 mg in adults) of cal-

cium in the urine and normal level of PTH in the serum (11).

Surgical removal of the hyperfunctioning tumors is the treatment of choice, which is best accomplished by a good preoperative work-up involving ultrasound or magnetic resonance imaging (MRI) studies, and sometimes preoperative venous sampling for PTH since 20% of all parathyroid tumors are located in the upper mediastinum. Management of the hyperparathyroidism is controversial; surgery may be put off if the patient has only mildly elevated serum calcium level, no renal or bone problems, no previous hypercalcemic crisis, and is prepared to be closely monitored. Surgical intervention is, however, indicated when the calcium level increases more than 11.0 mg/dl, and/or renal stones or bone density decreases occur.

2. Pituitary Tumors

Pituitary tumors occur in 15–20% of patients with MEN-1 (12). Some 60% of these tumors are prolactinomas, fewer than 25% are growth-hormone-secreting, and about 5% secrete adrenocorticotrophic hormone (ACTH). Non-functioning tumors can also be observed clinically. The clinical characteristics of these tumors are similar to those found in sporadic neoplasias and they depend on the hormone(s) secreted and the size of the tumor. Patients can present with amenorrhea, infertility, and galactorrhea in women; impotence in men; and acromegaly or Cushing disease. Pituitary tumors can also compress the optic chiasm, causing bilateral peripheral hemianopsia. The diagnostic and therapeutic approach to pituitary tumors in the context of MEN-1 is not different from that in sporadic

cases and consists of medical therapy (bromocryptine or the long-acting somatostatin analog Octreotide) or selective hypophysectomy and radiotherapy for residual unresectable tumor.

3. Pancreatic Tumors

The occurrence of *pancreatic tumors* in MEN-1 syndromes is important because of their malignant potential. The incidence of pancreatic islet cell or gastrointestinal tumors in MEN-1 is age dependent but varies from 30 to 80% (13). The most common cause of symptomatic disease is the Zollinger-Ellison syndrome leading to persistent peptic ulcerations and hyperacidity due to the hypersecretion of gastrin, often from a pancreatic islet cell. The hypercalcemia from parathyroid adenoma can exacerbate the symptoms and further elevate serum gastrin concentration. Patients with Zollinger-Ellison syndrome may also present with diarrhea or steatorrhea. The diagnosis is made by demonstrating a raised fasting serum gastrin concentration in association with an increased basal gastric acid secretion. Whereas H₂ receptor histamine antagonists cimetidine or Tagamet, ranitidine (Zantac), or famotidine (Pepcid) usually reduce gastric acidity, they often fail in this condition. However, reduction of basal acid output may be achieved by the substituted benzimidazoles (e.g. Omeprazole), which are potent inhibitors of parietal cell H⁺/K⁺-ATPase (14).

Because of the multifocal nature of the tumors in MEN-1 syndrome, surgical therapy is controversial and often not successful. Only 16% of patients so treated become free from symptoms after surgical intervention (15). In some islet tumors, watery diarrhea hypokalemia and hypochloremia can be seen in the absence of increased gastrin levels, due to vasoactive intestinal peptide (vipoma) and prostaglandins, while hypersecretion of glucagons can induce weight loss, hyperglycemia, venous thromboses, and a characteristic necrotizing migratory erythema.

Insulinoma is the second most common pancreatic islet cell tumor in patients with MEN-1 and occurs more often in patients under 40 years of age (3). The tumors are typically multicentric and may become malignant. Patients present with hypoglycemia especially after fasting. Biochemical investigations reveal inappropriately raised plasma insulin concentrations in association with hypoglycemia. Elevated plasma C-peptide and proinsulin levels are useful to confirm the diagnosis, since proinsulin levels may be disproportionately high. Surgery is the optimal treatment and is usually curative when a discrete tumor is found (16).

Besides alpha and beta islet cell tumors, others may secrete pancreatic polypeptide or, more rarely ACTH, serotonin, or somatostatin. However, surgical removal of the tumor may be difficult when metastases have already occurred by the time of diagnosis. In some patients the administration of Octreotide may be helpful.

Thymic carcinoid tumors develop in about 5% of the patients, especially in men who are heavy smokers. The tumors are usually nonfunctioning and aggressive (17). Other tumors seen on occasion in MEN-1 include adrenal adenomas (sometimes ACTH secreting) and carcinomas, and cell thyroid tumors that are never of the medullary type.

C. Screening of Family Members

Family members of patients with MEN-1 are at risk for carrying the defective gene; and the closer the relationship, the higher the risk. Screening for the MEN-1 gene is of great importance because early diagnosis and treatment of these tumors can reduce morbidity and mortality. Recently DNA testing for the inherited MEN-1 mutation has become available (18), but the proper role of this test still needs to be defined. Individuals found to be carriers of a mutant gene should nevertheless undergo biochemical screening (serum concentration of calcium, gastrointestinal hormones especially gastrin and prolactin) at least once a year. Every 5 years, pituitary and abdominal imaging should be performed from the age of 5 years on.

III. MEN-2

MEN-2 (Sipple syndrome) is a genetic disease, inherited by an autosomal dominant pattern as is MEN-1, and with high grade of penetrance. It is classified into three different forms. MEN-2a is characterized by C-cell (calcitonin-secreting) tumors of the thyroid (medullary thyroid carcinoma) in virtually every patient, with pheochromocytoma, and/or primary parathyroid hyperplasia. Recently, lichen amyloidosis has been recognized to be part of the syndrome (19). In MEN-2b, patients present with medullary thyroid carcinoma and pheochromocytoma, but do not develop hyperparathyroidism. The thyroid carcinoma is more aggressive than in MEN-2a, and occurs at an earlier age. Patients can also present with mucosal neuromas, intestinal ganglioneuromas, and a marfanoid habitus. Familial medullary thyroid cancer is a variant of MEN-2a, in which the tendency to develop thyroid carcinoma is not associated with other clinical manifestations. There are no accurate population studies for the incidence of the MEN-2 syndromes; however, it is generally assumed that 20–25% of medullary thyroid cancers are heritable.

A. Genetics and Pathogenesis

The gene responsible for MEN-2 has been identified as the *ret* gene located on the chromosome 10q11.2 (20,21). The coding sequence of *ret* consists of 21 exons over a total length of 55 kb. It is a proto-oncogene and the gene product is a cell-surface glycoprotein. The protein is a member of the receptor tyrosine-kinase family, which transduces growth and proliferation signals in tissues de-

rived from the neuronal crest, from which all of the tissues involved in the MEN-2 (thyroid C cells, adrenal medulla and autonomic ganglia) are derived (22). Three ligands have been identified: glial cell-line-derived neurotrophic factor (GDNF) (23), neuturin, and persephin (24). They are expressed in the nervous system and promote the survival of neurons during development. A glycosyl-phosphatidylinositol protein (GFR α 1, GFR α 2) binding of the ligand is also necessary for the activation of *ret* (25). MEN-2a and the MEN-2b are caused by different mutations of the *ret* gene. In the MEN-2a and in familial medullary thyroid carcinoma, most of the mutations occur in the cysteine-rich region of the extra-cellular domain encoded by exon 10. These mutations cause the substitution of cysteine by another amino acid. A few mutations have been found in exons 13, 14, and 15 (26). By contrast, 95% of MEN-2b cases are caused by a mutation in exon 16 with the substitution of methionine with threonine, which alters the substrate-recognition pocket in the tyrosine kinase protein (27). All the mutations both in the MEN-2a and MEN-2b lead to activation of the protein. This is different from almost all other inherited predispositions to neoplasia, which are due to mutations that inactivate tumor suppressor protein (Table 1).

B. Clinical Features

1. Medullary Thyroid Carcinoma

Medullary thyroid carcinoma (MTC) is usually preceded by multicentric hyperplasia of the parafollicular C cells. The clinical manifestation of this tumor is no different from that in the sporadic case, in which it presents as a thyroid nodule or cervical lymphadenopathy. Sometimes MTC can cause Cushing syndrome because of ectopic production of ACTH. Serum levels of calcitonin are usually high, especially if the tumor is palpable. In patients with C-cell hyperplasia or small C-cell tumors, the resting serum levels of calcitonin can be normal but will rise after calcium infusion (28). The necessary treatment of MTC in any MEN-2 syndrome is total thyroidectomy. This should be performed as early as possible, especially in MEN-2b syndrome, in which the MTC tends to be more aggressive and undergo malignant transformation. Metastatic disease has been reported as early as in 1-year-old children (29). Radiation therapy can be useful to reduce the tumor dimension and prevent local recurrence.

2. Pheochromocytoma

Some 40% of patients with MEN-2a and MEN-2b develop pheochromocytomas, usually 10 years or so later than MTC (30). Generally the tumors are nonmalignant at least until they are of large size. Symptoms can include anxiety, headache, diaphoresis, and palpitations. Laboratory evaluations reveal raised excretions of epinephrine and norepinephrine or metanephrines (31). In patients with MEN-2a there is an increased risk of bilateral tu-

mors; imaging studies should be performed to detect possible bilateral disease before surgery is undertaken. Unilateral adrenalectomy is the treatment of choice in cases of unilateral tumor. Bilateral adrenalectomy should be limited to patients with bilateral tumors or, more specifically, in those with a family history of aggressive bilateral adrenal medullary disease.

3. Primary Hyperparathyroidism

Involvement of the parathyroid glands in this syndrome is always benign. It has been reported in 10–25% of patients (32). Hyperplasias or benign adenomas can occur and are often clinically silent. Otherwise symptoms of hypercalcemia or renal stones have been reported. The diagnosis can be achieved finding high or normal level of PTH in the presence of hypercalcemia, as discussed above under MEN-1. The indications for surgery are similar to those in patients with sporadic primary hyperparathyroidism.

C. Screening in Family Members

The early detection of affected family members is essential so that thyroidectomy can be performed as soon as possible. Before DNA testing was available, biochemical screening was performed using intravenous pentagastrin or calcium infusion to stimulate the secretion of calcitonin from malignant or hyperplastic C cells. False-positive responses could, however, occur (33). In family members, such tests, if found to be negative, should be performed yearly. Recently DNA analysis became the optimal test in the MEN-2 syndrome. In a MEN-2 family the affected patient should be analyzed to determine the specific mutation responsible for the disease. The number of possible mutations in the *ret* gene are small and a single mutation can be detected in 90% of cases. Once the mutation in the proband has been found, all other family members should be tested before the age of 4–5 years in case of MEN-2a and familial medullary thyroid carcinomas, and in the neonatal period in the case of MEN-2b (Table 1).

IV. ADRENAL ADENOMA

Benign adenomas are the most common cause of an adrenal mass. The majority of cases are clinically silent, being usually found incidentally during a computed tomographic (CT) scan of the abdomen performed for an unrelated reason. The prevalence of so-called incidentalomas gradually increases from 3 years of age, to be as high as 7% in adults over the age of 50 years (34).

A. Genetics

The molecular mechanisms of the adrenal tumorigenesis have been studied extensively. Evidence has accumulated to show that tumorigenesis in the adrenal gland is different

from that in other endocrine tissues. Cyclic AMP is a second messenger involved in the proliferation and hypersecretion of many endocrine tissues. The activation of G-protein-coupled receptors and GTP-binding proteins, and the regulatory proteins of cAMP, have been involved in the pathogenesis of acromegaly and toxic thyroid adenomas. However, the activation of cAMP/protein kinase A pathway seems not to be important in the development of neoplasia in the adrenal gland (35). Cytogenetic studies have shown that adrenal tumorigenesis is characterized by the amplification of chromosomes not commonly affected in other tumors, suggesting the possible presence of adrenal-specific oncogenes. Adrenal adenoma or carcinoma can occur in several hereditary tumor syndromes such as Li-Fraumeni syndrome, Beckwith-Wiedemann syndrome, MEN-1, Carney complex, and familial adenomatous polyposis. The discovery of the genetic defects underlying these disorders increases the potential understanding of adrenal tumorigenesis.

Li-Fraumeni syndrome is a rare family tumor syndrome characterized by breast cancer, leukemias, soft tissue sarcomas, gliomas, and adrenocortical carcinomas. The genetic defect has been identified as germ-line point mutations in the p53 tumor-suppressor gene. The other nonaffected p53 allele is inactivated in tumor tissue by deletion of the short arm of chromosome 17, thus eliminating all wild-type p53 activity (36).

In Beckwith-Wiedemann syndrome (BWS), a rare disease characterized by macroglossia, gigantism, earlobe pits, and increased risk of Wilms' tumor of the kidney, rhabdomyosarcoma, hepatoblastoma, and adrenal carcinoma are caused by the allelic loss of a tumor suppressor gene mapped to chromosome 11p15 (37).

The Carney complex is a disorder characterized by myxomas of the heart, tumors involving the peripheral nervous system, spotty pigmentation of the skin, and endocrine neoplasia (e.g., adrenocortical tumors). The molecular defect has been identified in mutations of the protein kinase A type 1- α regulatory subunit on chromosome 2p16 (38).

In familial adenomatous polyposis, an autosomal dominant disorder in which patients develop more than 100 adenomatous polyps in the large intestine with a strong tendency to undergo malignant degeneration, adrenocortical neoplasms also occur with an abnormally high prevalence (39). The disease is caused by a mutation in the adenomatous polyposis coli (APC) gene located at 5q21.

The discovery of the genetic defects underlying the familial syndrome and the fact that most of the benign and malignant neoplasia of adrenal are monoclonal suggest that genetic changes at a specific locus are necessary for the development of such tumors. Several candidate genes have been investigated. For aldosterone-producing tumors, the aldosterone synthase receptor (the CYP11B2 gene), the corticotropin-regulated promoter (the

CYP11B1), and the angiotensin II type-1 receptor (ATR-1) have been studied but they seem not to be associated with sporadic adrenal adenoma (40). In cortisol-producing tumors, the loss of heterozygosity of the corticotropin receptor (MC2R) has been discovered to occur frequently in adrenocortical carcinomas but not in adenomas (41). Because there is the loss of heterozygosity on chromosome 11q13 in 20% of sporadic adenomas, some authors studied the expression of the MEN1 gene, located on 11q13, in sporadic adenomas and found mutations in less than 10% of the tumors. This suggests that another tumor suppressor gene is important for the predisposition to adrenal tumors encoded by the 11q13 region (42).

B. Clinical Features

Adenomas that can develop in the adrenal gland can be subclassified in glucocorticoid secreting, adrenocorticoid secreting, and nonfunctioning adenomas.

1. Aldosterone-Producing Adenomas

The clinical manifestations of *aldosterone-producing adenoma* derive from the hypernatremia and hypokalemias and metabolic alkalosis. Patients can present with hypertension, urinary frequency, muscular weakness, paraesthesias, cramps, and tetany. Determination of plasma aldosterone (high), plasma renin activity (low), and 24 h urinary aldosterone excretion (high) should be performed in newly diagnosed hypertensive patients with hypokalemia or young age of onset. A ratio of plasma aldosterone to plasma renin activity of 20 or more indicates the presence of a primary hyperaldosteronism. The relationship is best demonstrated by obtaining a renin level with the patient standing up, in which position the release of renin is normally greatly stimulated.

Once primary hyperaldosteronism is diagnosed, the differential diagnosis lies among aldosterone-producing adrenal tumor, idiopathic adrenal hyperplasia, and glucocorticoid-suppressible hyperaldosteronism in which aldosterone biosynthesis is regulated by ACTH rather than by renin. A postural test can differentiate between adenoma and idiopathic hyperaldosteronism (42). If plasma aldosterone and renin activity are measured in the morning after overnight recumbency and 2 h of ambulation, aldosterone levels increase in patients with adenoma, because of the diurnal fall of the ACTH, which is a minor stimulus to aldosterone production. In the case of idiopathic hyperaldosteronism, the level of plasma aldosterone will rise during the test under the stimulus of angiotensin II that increases in the upright position. Moreover, the level of 18-hydroxycorticosterone is elevated in patients with aldosterone-producing adenomas but is lower in patients with idiopathic hyperaldosteronism. The diagnosis of glucocorticoid-suppressible hyperaldosteronism can be obtained by measuring the plasma level of 18-hydroxycortisol and 18-oxocortisol, which are products of the methyloxylation of cortisol by the aldosterone synthase

that is typically elevated in this condition. The enzyme is the product of a chimeric gene that arose from an unequal crossover. The hybrid gene can catalyze the reaction but is regulated by ACTH instead of the renin–angiotensin system. The administration of dexamethasone for 4 days inhibits the secretion of ACTH and suppresses the production of aldosterone. Recently, DNA analysis for the identification of the hybrid gene mutation responsible for the glucocorticoid-suppressible hyperaldosteronism has become available (43).

Computer tomography is the best imaging technique to identify adrenal mass. It can identify masses of 10 mm, and gives information about size, homogeneity, presence of calcifications or areas of necrosis, and eventual local infiltration.

2. Glucocorticoid-Producing Adenomas

Glucocorticoid-producing adenomas are one cause of Cushing's syndrome that is ACTH-independent. Hyperproduction of cortisol determines the severity of symptoms such as hypertension, obesity, and hirsutism in females. To detect hypersecretion by the adrenal gland, the best test is the 24 h urinary free cortisol level, which, in a patient with adrenal adenoma and subclinical Cushing disease, will be more than 551.8 nmol/day. A dexamethasone suppression test can also be performed.

C. Treatment

If the tumor is hormone-secreting, or is clinically silent but larger than 5 cm, the patient should undergo surgery. The treatment of choice for benign adrenal adenoma is laparoscopic adrenalectomy when the retroperitoneal approach is preferred. If the tumor is suspected to be malignant, classic transperitoneal surgery should be performed (44). Patients with aldosterone-producing adenomas must have their blood pressure carefully controlled and their potassium level monitored before surgery. Hypertension can still be present after the intervention, however, because of long-term vascular damage resulting from prolonged hyperaldosteronism (45). In case of aldosteronomas, moreover, the patient can have a period of hyponatremia and hyperkalemia after the surgery due to continued suppression of the renin–angiotensin–aldosterone system. A high-salt diet and mineralocorticoid therapy may have to be given temporarily. Patients with corticoid-secreting adenomas may likewise need hormonal replacement therapy because of atrophy of the hypothalamic corticotropin-releasing hormone-secreting cells.

V. THYROID ADENOMAS

Thyroid adenomas represent 90% of the nodular lesions of the thyroid. Single nodules are more common in women than in men, but the incidence of thyroid nodules increases throughout life in patients of both genders. The

typical thyroid adenoma is a solitary encapsulated lesion demarcated from the surrounding parenchyma. Adenomas derive from follicular epithelia and, microscopically, the cells form uniform follicles that contain colloid. On histological examination the adenomas can be classified into subtypes based on the degree of follicle formation and their colloid content. These are classified as macrofollicular, microfollicular, Hürthle's cell adenoma, atypical adenoma, and adenoma with papillae.

A. Genetics

Most thyroid tumors are sporadic and nonfamilial, suggesting that the underlying genetic abnormality is likely to be a somatic, acquired mutation. Pituitary thyroid-stimulating hormone (TSH) is the main stimulator of growth and function of normal follicular thyroid cells. When TSH binds to its membrane receptor, it activates guanine–nucleotide-binding protein Gs and stimulates the adenylate cyclase cAMP pathway (46). Increases in the intracellular levels of cAMP activate protein kinase, which in turn stimulates thyroid hormone production and induces the proliferation of thyroid epithelial cells. Adenylate cyclase activity decreases when the GTP is hydrolyzed by the intrinsic GTPase activity of Gs- α . Many thyroid adenomas are caused by activating somatic mutations in genes that encode for the TSH receptor, or the α subunit of the guanyl-nucleotide stimulatory protein (Gs) that results in constitutive activation of thyroid epithelial cells in the absence of TSH (47, 48).

Most of the mutations causing adenomas have been found in the third cytoplasmic loop on the sixth transmembrane segment of the TSH receptor, and in the C-terminus of Gs- α that is critical to the receptor interaction (so-called hot spot sequence) (49,50). These mutations do not explain all the tumors, or toxic adenomas that are not secondary to TSH-R mutations. Other genes encoding for proteins involved in the TSH-R pathway could be activated and responsible for the tumorigenesis. Mutations of the Ras oncogenes have been found in both benign and malignant thyroid tumors. There are three ras proteins: K-ras, N-ras, and H-ras. All of them are membrane-anchored and they mediate signaling through many tyrosine kinases, including those of hormone receptors. The hydrolysis of the GTP to GDP that is bound to the ras protein determines the inactivation of the signal. Mutations in the GTP-binding domain (codons 12,13) or the GTP-ase domain (codon 61) cause activation of the ras oncogenes (51). In thyroid tumors, point mutations or amplifications of all three ras oncogenes can occur (52). There is a general agreement on the role of the ras oncogenes in the early phases of the tumorigenesis, but the real prevalence of these mutations still needs to be determined. The angiogenic and the soluble factors that stimulate them have been recently studied in their pathogenesis. Vascular endothelial growth factor (VEGF), the principal cytokine that mediates angiogenesis, has been associated with tu-

morigenic potential of thyroid cancer cell lines (53). Other authors found overexpression of VEGF in follicular adenomas, Hürthle's cell neoplasia, and papillary carcinomas; in follicular carcinoma and anaplastic carcinomas, VEGF was suppressed, suggesting an important role for the cytokine in the early stages of the thyroid carcinogenesis (54).

B. Clinical Features

Thyroid adenomas often present as a mass without any other clinical sign or symptoms, discovered during an examination or radiological procedure. In a minority of cases, adenomas can be hyperfunctional and cause clinical features of hyperthyroidism. Neoplasia must be strongly considered when nodules are "cold" and do not take up ^{131}I on scanning.

VI. PITUITARY ADENOMAS

Pituitary adenomas are common neoplasia derived from adenohypophyseal cells. They can be small, nonfunctioning lesions that are discovered casually, similiarly to radiological incidentalomas or during autopsy. In some cases they produce hormones that can cause severe clinical syndromes such as acromegaly or Cushing disease. They are typically benign lesions with a very small possibility (0.1%) of becoming malignant. However, they can present from the effects of aggressive local growth invading the brain parenchyma, the cavernous and paranasal sinuses, the bony clivus, and cause symptoms of intracranial mass, hypopituitarism, and/or peripheral visual field disturbances from pressure effects on the optic chiasm (55).

Although the true incidence of pituitary adenomas is not known, recent data suggest that pituitary adenomas occur in as many as 20% of the general population (56). At autopsy, careful histological assessment identifies pituitary adenoma in 22.5–27% of patients, with no gender-based differences in incidence (57). The incidence increases with aging: more than 30% of people 60 years of age have clinically silent tumors. Pituitary adenomas are, however, rare in children, with only 3.5–8.5% of these tumors diagnosed during childhood. At such time they manifest clinically especially in girls, and it has been reported that they are less aggressive and invasive than tumors of adults (58). Pituitary adenomas represent approximately 15% of all intracranial tumors (59). Prolactinomas are the most common type of adenoma; GH- and ACTH-producing adenomas each represent 10–15% (often they are mixed), while TSH-secreting tumors are rare (60).

A. Genetics and Pathogenesis

For many years there has been controversy regarding the molecular basis of pituitary tumorigenesis. Several animal studies have suggested a fundamental role for hypo-

thalamic hormones in the development of pituitary tumors. Recently the question was resolved when it became clear that all the pituitary tumors arise from a single cell. This monoclonality implies that intrinsic genetic alterations account for the initiating event. Furthermore, the tissue surrounding the pituitary adenoma is usually normal, suggesting that independent cellular events do not necessarily precede adenoma formation. It is likely that the majority of pituitary adenomas develop from transformed cells that are dependent on hormonal stimulation for tumor progression (61). The dysregulation of cell proliferation and differentiation may occur by the activation of oncogenes or inactivation of tumor-suppressor genes. Oncogene activation may occur as a result of an activating single-point mutation. Because the gain of function is a dominant event, a single altered allele may be sufficient to produce the phenotypic change. By contrast, the tumor-suppressor genes (TSG) are recessive oncogenes that require the inactivation of both alleles (by deletion, rearrangement, or silencing through methylation) to cause proliferation of the cell in a clonal neoplastic fashion. Heterozygous activating somatic point mutations in the α -subunit of the stimulatory Gs proteins (Gs) were the earliest dominant activating mutations described in endocrine tumors (62). Activation results when a missense mutation replaces residue 201 or 227. The resulting oncogene encodes for mutated G protein called *gsps*, which were first described in a subset of somatotroph adenomas, nonfunctioning adenomas, and other functional pituitary neoplasms. The mutation result in a ligand-independent, constitutively elevated cAMP and hormone hypersecretion.

Recently Melmed and colleagues isolated a novel pituitary tumor-transforming gene (PTTG) (63). They showed increased levels of PTTG mRNA in GH-, prolactin-secreting, and nonfunctional pituitary tumors. In vitro and in vivo experiments showed the strong transforming potential of PTTG. Because of its widespread and abundant expression in pituitary tumors, PTTG most likely has a key role in the early induction of pituitary cell transformation. It potently induces the expression of fibroblast growth factor, a known mediator of cell growth and angiogenesis. Another oncogene involved in pituitary tumorigenesis seems to be the cyclin D1 gene (*CCND1*) located on 11q13. Gene amplification leads to overexpression of cyclin D. Habbers et al. found an allelic imbalance of the *CCND1* gene in the pituitary tumors. They studied the expression of cyclin D1 by an immunohistochemical assay and found that 25% of the tumor cells showed expression of cyclin D1. Both nuclear and cytoplasmic staining was found more frequently in nonfunctional tumors than in somatotropinomas (64). The loss of tumor-suppressor gene function has also been implicated. *MEN1* gene, the TSG located on the long arm of the chromosome 11 (11q13) responsible for the MEN-1 syndrome, has been studied, but menin expression is not downregulated in the majority of the sporadic pituitary

tumors (65). However, these tumors present loss of heterozygosity at the same locus 11q13 in 20% of cases, suggesting that an additional TSG at this locus is involved in the pathogenesis of pituitary adenomas.

The retinoblastoma gene (*RB1*) is another TSG implicated in several neoplasms. Adenocarcinomas of intermediate lobe corticotroph differentiation have been found in *RB1* transgenic knockout mice (66) induced in order to study this gene in the humans, but no mutations have been found in the pituitary adenoma (67). However, preliminary data show loss of heterozygosity at sites telomeric and centromeric to the *RB* locus in some aggressive pituitary adenomas. These data suggest the presence of another TSG located at 13q that is closely linked to *RB1* (68). The frequent loss of heterozygosity of 9p21 also has been found in pituitary adenomas (69). The *CDKN2A* gene maps to this locus and its protein product p16 is a cell cycle regulator that is often disrupted in human neoplasias. It prevents the phosphorylation of *RB* and is responsible for inhibiting progress through the G1/S cell cycle checkpoint. Loss of p16 results in *RB* remaining in its hyperphosphorylated form, negating its ability to inhibit the progression of the cell cycle.

Several growth factors have been implicated in the pathway of the tumorigenesis. They are polypeptides that can regulate cell replication and differentiation, altering the expression of specific genes. The pituitary is a site of synthesis and action of growth factors including insulin-like growth factor-I and II (IGF-I, IGF-II), nerve growth factor (NGF) (70), transforming growth factor- α and β , and basic fibroblast growth factor (bFGF). Some studies suggest that peptides derived from human pituitary tumor cells can stimulate rat adeno-hypophysial cells replication in vitro (71). The role of these growth factors in pituitary tumorigenesis remains to be established. The understanding of the exact mechanism involved in pituitary adenoma will have relevance in clinical practice. The identification of specific molecular markers of tumor invasiveness and recurrence will permit the selection of appropriate follow-up protocols and earlier subcellular therapies.

B. Clinical Features

1. Prolactinoma

Prolactin-secreting adenoma (prolactinoma) is the most common hormonally active pituitary adenoma. When the tumor is less than 1 cm in diameter, it is defined as a microadenoma. If it is 1 cm or larger, then it is classified as a macroadenoma.

In women the first clinical manifestations usually are galactorrhea and ovulatory disorders probably due to inhibition of luteinizing hormone (LH) and perhaps follicle-stimulating hormone (FSH) secretion, because of inhibition of the release of gonadotropin-releasing hormone (GnRH). In men, hyperprolactinemia results in decreased libido, infertility, and impotence. Women usually present with symptoms at a younger age and tend to have mi-

croadenoma. Men tend to present at older ages with larger adenoma that cause visual field abnormalities and hypopituitarism owing to pituitary tissue destruction (72). They only rarely develop galactorrhea. Some patients with a lactotroph adenoma are noted to have subtle acromegalic features. Even if the hypersecretion of GH cannot be documented, the tumors contain prolactin and GH. This kind of tumor is known as acidophil stem cell adenoma, which can be differentiated from the usual lactotroph adenomas because of aggressivity and tendency to recur (73).

In children, prolactinomas are rare, but their clinical presentations have been reported in small numbers of studies. However the frequency of such tumors is likely underestimated since symptoms tend to occur later in life. As reported in adults, prolactinomas in children occur mostly in girls, causing menstrual disturbances (74). Delayed puberty can also be associated with prolactinomas because of the effect of hyperprolactinemia on the hypothalamic-gonadotropic activity. The symptoms of hyperprolactinemia correlate with its severity. Serum prolactin concentrations greater than 20 ng/ml are abnormal. The measurement can be performed at any time, since usual daily activities have little effect on prolactin secretion. However, physical stress and high-protein meals can increase the prolactin concentrations; therefore, a slightly high value should be confirmed. In case of persistent slightly elevated serum prolactin values or when levels are clearly pathological, an MRI to search for a mass lesion in the hypothalamic-pituitary region is required.

A dopamine agonist is the first-line treatment for patients with micro- or macro-adenomas because it decreases the size and secretion of the tumors. Bromocriptine is an ergot derivate that has been used for decades for treatment of hyperprolactinemia. Other dopamine agonists such as Pergolide or Cabergoline can be used if the patient does not respond. Bromocriptine must be given twice a day and the principal side effects are nausea, postural hypotension, and mental dulling (75). If the patient cannot tolerate the dopamine agonists, or if the adenoma does not respond to agonist therapy, transphenoidal surgery should be performed. If a significant amount of hormonally secreting tissue remains after surgery, radiation therapy should follow.

2. GH-Secreting Adenoma

GH-secreting adenoma is the most common cause of acromegaly or gigantism. These adenomas account for about one third of all hormone-secreting pituitary adenomas. The hyperproduction of GH by the tumor stimulates the hepatic secretion of IGF-I, which in turn causes most of the clinical features. In adults the typical sign is acromegaly, which is insidious in onset and progresses slowly. The characteristic findings are enlarged jaw and enlarged swollen soft tissues of the hands and feet. The facial features became coarse, with enlargement of the nose and frontal bones (76). Bone density can be increased and cardiovas-

cular disease including hypertension, left ventricular hypertrophy, and cardiomyopathy can occur (77). In children GH excess results in rapid and excessive growth and attainment of adult height beyond the genetic potential. Typical manifestations of acromegaly can also appear. The diagnosis of acromegaly can be confirmed by measurement of both serum GH concentrations that do not suppress after a glucose load and GH-dependent circulating molecules, such as IGF-I and IGFBP-3. IGF-I concentrations during the day are not influenced by food intake, exercise, or sleep. The result must be interpreted, however, with the age, because IGF-I concentrations are highest during puberty and decline gradually thereafter. In contrast, GH concentrations reflect their pulsatile secretion and are stimulated by a variety of factors including short-term fasting, exercise, stress, and sleep. To obviate this problem, it is best not to obtain random measurements of serum GH.

The most specific dynamic test for establishing the diagnosis of acromegaly is an oral glucose tolerance test in which postglucose values remain greater than 2 ng/ml in 85% of patients with GH hypersecretion (78). Additional hyperprolactinemia occurs in 30% of the patients because the cosecretion of prolactin and GH by a somatotroph adenoma. Once GH hypersecretion has been confirmed, the next step is an MRI study of the pituitary. Pituitary tumors as small as 2 mm in diameter can be detected by this technique and the dimension and the exact extension of the tumor can be identified.

Selective transsphenoidal surgical resection is the treatment of choice for patients with somatotroph adenoma that are small enough to be removed surgically (79). Medical therapy is indicated in patients with adenomas that are too large to be completely removed, or when resection has failed. Somatostatin analogs such like Octreotide inhibit GH secretion by binding to specific receptors for somatostatin (80). The long-acting form of Octreotide, which is administered intramuscularly every 2 or 4 weeks, is now available in the United States.

Somatostatin analogs are usually well tolerated but about one-third of patients may experience nausea, fat malabsorption, and decreased gallbladder postprandial contractility (81). Dopamine agonists such as bromocriptine, Pergolide and Cabergoline inhibit GH secretion in patients with somatotroph adenoma. They have a limited efficacy but combined therapy with Octreotide and a dopamine may be successful when either alone is not. If GH hypersecretion cannot be controlled by surgery or medical therapy, external radiation can be used.

3. TSH-Secreting Adenoma

This kind of adenoma accounts for less than 1% of all hormone-secreting pituitary adenomas and less than 1% of all cases of hyperthyroidism. Adenomas secreting TSH are equally common in men and women, whereas tumors secreting both TSH and prolactin are about five times

more common in women. Most patients have the typical symptoms and signs of hyperthyroidism, but a few patients have mild or even no symptoms (82). Other clinical features in addition to hyperthyroidism are visual field defect, menstrual disturbances, and galactorrhea. In childhood, these tumors are very rare. Patients have an enlarged gland and clinical symptoms and signs of thyrotoxicosis but without exophthalmos.

The characteristic biochemical abnormalities in patients with TSH-secreting adenoma are normal or high serum TSH concentrations and high serum total and free thyroxine (T4) and triiodothyronine (T3) concentrations. The autonomous TSH secretion usually does not increase in response to thyrotropin-releasing hormone (TRH) and does not decrease in response to exogenous thyroid hormone administration. Any patients with hyperthyroidism and elevated serum TSH should undergo a CT or MRI study of the pituitary. MRI is the most sensitive test for the detection of pituitary tumors.

The treatment of choice is transsphenoidal resection of the tumor, even if the surgery will result in no change in one-third of patients. Therefore, many patients also require medical therapy. Dopamine agonists (Bromocriptine, Cabergoline) have proven to be effective but the somatostatin analog Octreotide is effective in almost all patients.

4. Gonadotrophin-Secreting Adenoma

Gonadotroph adenomas are the most common clinically nonfunctioning pituitary macroadenoma. They usually inefficiently secrete or secrete noneffective hormones. Thus they are often identified only when they are large enough to produce neurological symptoms. The most common symptom is impaired vision due to compression of the optic chiasm (83). The patient will complain of diminished vision in the temporal field. Headache and diplopia due to the compression of the oculomotor nerves can occur. Sometimes gonadotroph adenomas became clinically manifest because of excess hormone secretion. The hypersecretion of follicle-stimulating hormone (FSH) determines ovarian hyperstimulation in premenopausal women. In men the hypersecretion of LH can cause elevated testosterone concentrations, which in children will lead to premature puberty (84).

5. ACTH-Secreting Adenoma

Pituitary-dependent hypercortisolism is responsible for approximately two-thirds of cases of Cushing syndrome. The majority of these cases are attributable to basophilic microadenomas. In children and adolescents the clinical manifestation are somewhat different from those seen in adults. Younger patients usually present with weight gain that tends to be generalized, growth failure as direct effect of hypercortisolemia, compulsive behavior, and overachievement in school in contrast with the typical adult emotional lability and depression (85). Menstrual irregu-

larity or amenorrhea is a common symptom in adolescent girls.

Confirmation of Cushing disease can be obtained from results of the 24 h urine free cortisol measurement. In children the value should be corrected by reference to the body surface. To establish that Cushing syndrome is due to a pituitary adenoma, stimulation of ACTH and cortisol following injection of CRH and suppression of cortisol by administration of dexamethasone should be shown. All patients should undergo MRI with the administration of gadolinium. If the MRI is negative, CRH-stimulated bilateral inferior petrosal sinus sampling can be used to confirm that the excessive ACTH comes from the pituitary. Surgical excision by transphenoidal adenectomy is the treatment of choice. The remission rate after surgery is 85–95% in both children and adults (86).

VII. PANCREATIC ADENOMAS

The pancreatic islet contains alpha cells (glucagon), beta cells (insulin), and delta cells (somatostatin), as well as enterochromaffin cells (serotonin). These cells are all part of the APUD system, and tumors so derived secrete a wide variety of polypeptides. Gastrinoma and insulinoma are the most common form. According to a Mayo Clinic Study, the incidence of insulinoma is 0.4:100,000 person-years, and the average age of patients at presentation of insulinoma is in the mid-40s with very low incidence during childhood or adolescence (87). The adenomas are usually small and solitary; the lesion is generally well-encapsulated and highly vascular. Malignant insulinomas occur only in the 5% of cases of adenomas, tend to be larger, and metastasize to the liver and regional lymph nodes.

A. Genetics and Pathogenesis

The molecular mechanism leading to pancreatic tumor is still unclear but several tumor-suppressor genes have been implicated. The tumor-suppressor gene *Smad/DPC4* has been found mutated in nonfunctional pancreatic tumors (88). Loss of heterozygosity in on chromosomes 1, 3q, 3p, 11p, 16p, 17p, and 22q has been noted in several studies (89). Guo and colleagues found overexpression of *p27^{Kip1}* in sporadic pancreatic endocrine tumors without differences between benign and malignant tumors (90). *p27^{Kip1}* is a universal cyclin-dependent kinase inhibitor, which acts as a tumor suppressor and a negative regulator of cell cycle. In various types of human cancers, the suppression of *p27^{Kip1}* expression is linked to aggressive behavior. However, the overexpression of *p27^{Kip1}* in the pancreatic endocrine tumor can be secondary to the other primary molecular dysregulations or be a unique molecular pathway leading to endocrine tumorigenesis. Another molecule involved in pancreatic tumorigenesis is the paired-homeodomain transcription factor PAX4. The PAX gene family encodes highly conserved paired-box-containing transcription factors that control the tissue-specific

expression of genes during embryogenesis. Because of this important role in the differentiation and development of pancreatic beta-cells, Miyamoto et al. studied PAX4 expression in the insulinomas. They found an overexpression of PAX4 mRNA in the tumors, but little or none in the normal islets, suggesting a fundamental role in the development of insulinoma (91).

B. Clinical Features

A patient with insulinoma will characteristically present with fasting hypoglycemia with neurological symptoms such as confusion, personality change, or seizures (92). The release of catecholamine due to the hypoglycemia will result in anxiety, palpitations, weakness, tremor, and sweating. Weight gain has been described.

Diagnosis is based on demonstrating Whipple's triad: hypoglycemic symptoms, blood glucose level less than 50 mg/dl, and relief of symptoms after glucose ingestion. Unfortunately, these symptoms are not specific for insulinoma. Because a single overnight fasting blood sugar level combined with a simultaneous plasma insulin level fails to establish the presence of fasting organic hypoglycemia in more than 35% of patients, a 72 h fast is usually done with blood glucose and insulin levels determined at 2–4 h intervals. Recently a study based on 127 patients with insulinoma demonstrated that a 48 h test is as effective as the 72 h one (93).

Measurement of C-peptide at the end of the fast can help to differentiate endogenous from exogenous (factitious) hyperinsulinemia. C-peptide will be proportionally elevated with insulin in patients with insulinoma, and low or normal in patients who abuse insulin or hypoglycemic agents. Nesidioblastosis and familial hyperinsulinemic hypoglycemia simulate the insulinoma's biochemical findings.

The treatment of choice is surgery, but preoperative localization of the tumor is necessary because of the small tumor size. The imaging techniques available are spiral CT, arteriography, and transabdominal and endoscopic ultrasonography. Patients with metastatic insulinoma or those who are not candidates for or refuse surgery, require medical therapy. Diazoxide, verapamil, phenytoin, and Octreotide have all been used to prevent symptomatic hypoglycemia. Diazoxide, which diminishes insulin secretion, is the most effective and should be given in divided doses of up to 1200 mg/day. However, it causes unwanted hair growth and edema.

Endocrine Tumors in Children

Muhammad A. Jabbar

Hurley Medical Center, Michigan State University School of Medicine, Flint, Michigan, U.S.A.

I. INTRODUCTION

Endocrine tumors in children pose a number of fundamental questions: is the tumor a nonfunctioning, functioning, or hyperfunctioning entity? Is it a malignant or a benign process or a hyperplasia responsive to physiological regulations? Apart from clinical presentation, the answers to these questions often depend on specific hormonal–biochemical, radiological, and histopathologic findings. Consequently, the optimal assessment and management of these patients remains a challenging task and must include the efforts of endocrinologists, oncologists, surgeons, and other support personnel.

This chapter reviews the clinical approach to children with adrenal, gonadal, and pancreatic tumors. Pituitary, thyroid and parathyroid tumors are covered in Chapters 2 and 20, respectively.

II. ADRENAL TUMORS

The incidence of adrenal tumors in children is not known (see Chapter 6 for adrenal cortex and Chapter 8 for adrenal medulla). Of 58 patients reported by Bertagna (1), 11 (19%) were between 0.8 and 15 years of age. Adrenal carcinoma represented about 10% of the carcinomas in childhood, according to a registry-based data from England (2). The age of appearance is usually during the first decade of life (3). Girls are more frequently affected than boys, with ratio of 2.5:1 (4). While familial cases are reported (5), occurrence of adrenal carcinoma in patients with Li-Fraumeni syndrome (6), Beckwith syndrome (7) hemihypertrophy (8), and congenital malformations of the genitourinary tract are well known.

Incidence of nonmalignant tumors increases with age. Malignant tumors show a bimodal distribution with the first peak below age 5 years and the second peak in the fourth to fifth decade (9). Industrial pollutants may play a causative role, as reported from Brazil (10).

On a pathological basis, corticotropin-independent cortisol overproduction represents a spectrum ranging from benign nodular hyperplasia to malignant adrenal tumors. In the 1960s, Meador et al. (11) described primary adrenocortical nodular dysplasia, characterized by non-malignant, autonomously secreting lesions. In another recent review (12), a similar condition predominantly affecting children and young adults has been described with bilateral nodular disease, internodular cortical atrophy, and varying degrees of pigmentation. This condition has also been described in association with the Carney complex, which includes myxomas, pigmented skin lesions, peripheral nerve tumors, and various endocrine tumors (13).

The cause of the nodule formation or dysplasia remains to be established. An adrenal-stimulating immunoglobulin has been implicated in the pathogenesis (14). In McCune-Albright syndrome, nodular hyperplasia of the adrenal glands has been reported as the cause of hypercortisolism (Chapter 9) (15). In these patients, somatic mutation of the alpha subunit of the G-protein occurs during fetal development, creating a mosaicism of normal and mutant-bearing cells. In the latter, G-protein activation of adenylate cyclase increases cyclic AMP with formation of multiple nodules and overproduction of cortisol. Inverted diurnal rhythm, subnormal morning cortisol concentration, and low corticotropin in association with gastric inhibitory peptide (GIP) recently were described. Although the causative role of GIP in cortisol overproduction remains undetermined, data support the hypothesis of abnormal expression of receptors in the adrenal (16,17).

A. Clinical Features

Adrenal tumors in children are usually functional, giving rise to a constellation of symptoms or signs (Chapter 6). Depending on the duration of the disease and the action

of the metabolic, androgenic, and salt-retaining hormones, the clinical spectrum may include Cushing syndrome and virilization to hypertension. A majority of the tumors secrete cortisol, while androgen and aldosterone secretion follow in decreasing frequency. Occasionally there is alteration of the clinical course with evidence of initial glucocorticoid predominance being overlapped by the androgenic effects or vice versa, as the disease progresses. An incidental adrenal tumor without any clinical manifestation is a distinct entity in adults; this represents only about 5% of all adrenal tumors in children.

Weight gain, truncal obesity, moon face, and buffalo hump are observed in 40–60% of children with functional adrenal tumors (Table 1). Obesity and short stature are common presenting features (18–20), although the latter may be the only manifestation of hypercortisolemia in children (21).

Normal or accelerated linear growth may be encountered in children with androgen-producing adrenal tumors. In such cases, the presence of acne, hirsutism, hypertrichosis of the face and trunk, deepening of the voice, and clitoromegaly in females, are the distinguishable physical signs. In prepubertal children, excess androgen will lead to virilization with excess body hair, adrenarche, acne, clitoromegaly or abnormal phallic growth, rapid skeletal growth, along with excess weight gain (22,23). The disorder tends to be more severe and the clinical findings more flagrant in infants than when the onset occurs in

older children (24,25). Premature adrenarche, a common problem in clinical practice, may be the initial presentation, although the severity of the signs and symptoms will help to differentiate the adrenal tumor from benign adrenarche. In postmenarcheal girls, rapid weight gain and menstrual irregularity often results from increased androgens (Chapter 12). Estrogen-secreting tumors of the adrenals are rare in childhood. In prepubertal boys, these may lead to gynecomastia along with enhancement of growth and skeletal maturation; in girls, sexual precocity characterized by premature thelarche and advanced growth may occur (26). If there is evidence of virilization or elevation of blood pressure, concomitant secretion of androgens or mineralocorticoids should be suspected.

Hypertension, plethora, and fluid retention are also common in children with adrenal tumor, being present in up to 70% (Chapter 38). In aldosterone-producing tumors, elevated blood pressure is one of the most common manifestations. Both systolic and diastolic blood pressure is abnormally elevated. Muscle weakness, cramping, paresthesia, polydipsia, and polyuria may occur. Despite fluid retention and increase in the intravascular volume, there is no clinical evidence of edema in these patients. Sodium retention is only mild to moderate. Hypokalemia is the most reliable laboratory abnormality, with electrocardiographic signs of prolonged ST segment and inverted T-wave. Alkalosis is also a frequent finding, causing tetany and Trousseau's sign in untreated patients.

A small percentage of patients are known to have psychiatric symptoms, ranging from acute psychosis and depression to manic-depressive behavior. Asymptomatic hypercortisolemia with normal blood pressure has been reported in children. Diffuse osteoporosis, more noticeable in the vertebral column, is also common in these patients. Impaired glucose tolerance is more frequent than overt diabetes, and the incidence of renal stones is higher than in the general population.

Preoperative differentiation of an adenoma from carcinoma is difficult. Although Cushing syndrome is frequently caused by adenoma, while virilization is associated with carcinoma, benign and malignant tumors may be functionally identical and, thus, clinically inseparable. A normal or exaggerated response to exogenous ACTH stimulation is more often encountered in adenoma than carcinoma but lack of dexamethasone suppression is observed in both (1). Size of the tumor has been noted to be a predictor, with tumor size greater than 75 g being more likely to be malignant (19). Histopathological criteria such as mitoses, necrosis, and capsular and vascular invasion were not reliable predictors of a malignant tumor, as demonstrated by the presence of these findings in patients with benign adenomas (27,28).

B. Diagnosis

Because of the anatomical location deep in the abdomen as well as nonfunctioning nature of the tumors, adrenal adenoma or carcinoma often remains undiagnosed for a

Table 1 Clinical Features of Hypercortisolemia in Children and Adults

considerable period of time. The size attained by these tumors is therefore enormous in many instances. During evaluation of nonspecific complaints or routine physical examination, abdominal mass may be detected in such patients.

Hormonal studies are of vital importance in the diagnosis of adrenal tumors. Levels of urinary free cortisol, 17-KS, and 17-OHCS are significantly elevated in patients with a functioning adrenal tumor (29). Plasma cortisol is elevated, along with loss of diurnal rhythm. Complete androgen profile including DHEA, androstenedione, and testosterone levels should be studied in patients with clinical evidence of virilization (Chapter 17). Differentiation from congenital adrenal hyperplasia is an important but difficult task. In the hypercortisolemic state, lack of suppression of plasma cortisol following administration of dexamethasone is characteristic of adrenal tumors. Therefore, performance of a low-dose or high-dose dexamethasone test should be a priority in these patients (Chapter 41).

Differentiation of pituitary disease from adrenal disease is challenging. Apart from providing further understanding about the functional relations between the pituitary and the adrenal, the metyrapone test may be useful in differentiating adrenal adenomas from carcinomas. In about 50% of cases, adrenal adenoma are responsive to metyrapone while carcinomas are usually nonresponsive. Because the tumors do not respond and the normal adrenal cortices are atrophic, ACTH stimulation test has very limited use in the diagnosis of adrenal tumors. Differentiation of central precocious puberty from estrogen-secreting adrenal tumors in girls may be necessary. Urinary estrogens and 17-KS and plasma DHEA, DHEAS, and estrogens are elevated along with absent gonadotropin response following GnRH stimulation in adrenal tumors. Measurement of serum and 24 h urinary aldosterone levels as well as plasma renin activity is useful for initial evaluation of suspected aldosterone-producing tumors. To differentiate secondary hyperaldosteronism and avoid false-positive results, all medications, particularly diuretics, should be discontinued prior to laboratory studies. In patients with elevated serum aldosterone levels, complete suppression of aldosterone secretion by administration of dexamethasone differentiates dexamethasone-suppressible hyperaldosteronism from primary hyperaldosteronism. Elevated aldosterone levels, low renin activity, and high urinary aldosterone with lack of dexamethasone suppression establishes a diagnosis of hyperaldosteronism (Chapter 6). Further diagnostic studies, including the imaging studies, should be performed in these patients (Chapter 38).

Radiological studies are an important component in the diagnosis of adrenal tumors. CT scan and MRI aim to localize the tumor and define the extent of the disease. Intravenous pyelography is useful to delineate the relationship of the kidney to the tumor mass. Ultrasonography shows an adrenal mass in the majority of cases. CT scan is, however, the ideal method since it allows visualization of other abdominal organs. Angiography is often required to provide the surgeon with a map of the tumor's blood supply.

C. Treatment

Complete surgical excision with replacement steroid therapy provides the best choice for treatment of these patients (30). Preoperative, operative, and postoperative management are of critical importance. For primary pigmented nodular adrenocortical disease, bilateral adrenalectomy with steroid replacement is preferred (27). For adrenal adenoma, unilateral adrenalectomy or resection of the tumor followed by replacement steroid therapy is the treatment of choice. Replacement therapy with glucocorticoid is necessary until normal function in the contralateral gland is restored. This is usually for 6–12 months, although suppression from the tumor can persist for up to 2 years.

For adrenal carcinoma, surgical therapy aims to excise the tumor and local metastasis completely to enhance the chance of cure. For inoperable or partially resectable carcinoma, combination chemotherapy may offer an alternative management approach (31,32). However, experience with pediatric patients is largely anecdotal. Mitotane therapy has been successful in patients with intrauterine adrenal carcinoma and metastasis (34). In addition, medical therapy with metyrapone and aminoglutethimide in combination is useful for control of symptoms. Ketoconazole, an inhibitor of steroid biosynthesis, is the preferred drug to decrease cortisol secretion in selected cases. RU 486, a glucocorticoid antagonist, has also been employed to control the symptoms secondary to hypercortisolism.

D. Prognosis and Follow-Up

Early diagnosis and surgery offer the best hope for long-term survival, with adenoma exhibiting an extremely good outcome. Adrenal carcinoma in children, on the other hand, is an extremely progressive disease. Final adult stature is stunted in most of these patients. Replacement therapy with glucocorticoid is required for an indefinite period of time. Careful follow-up at a 3–6 month interval is mandatory. Clinical assessment and serum levels of cortisol, DHEA, androstenedione, testosterone, and plasma renin activity are necessary to detect recurrent or metastatic disease. The 24 h urinary 17-KS, 17-OHCS, and free cortisol, along with the other hormones that were initially abnormal, should be measured. A repeat dexamethasone stimulation test should be done to assess the suppressibility of cortisol production.

III. GONADAL TUMORS

A. Testicular Tumors

1. Causes and Presentation

Constituting about 1% of all cancers in men, testicular tumors occur most commonly during the third and fourth decades of life. Germ cell tumors, accounting for about 90% of all testicular tumors in the pediatric age group, include embryonal carcinoma, endodermal sinus tumor,

and teratoma, representing a spectrum of progressive histological differentiation. In young adults, however, the spectrum includes seminoma, which represent 30–50% of all germ cell tumors (35,36).

The best-documented risk factor for the development of germ cell tumors is cryptorchidism, which is associated with about 10% of germ cell tumors (Chapter 13) (37–39). The degree of lack of descent of the testes correlates with the likelihood of tumor formation, with abdominal tests more at risk than those in the inguinal area. Orchiopexy performed before the age of 6, however, reduces this risk significantly. The pathogenesis of these tumors is not clear. Incidence of tumor in the contralateral normally descended testis is higher than that of controls. Although several factors including higher temperature, higher gonadotropin levels, and congenitally abnormal germ cells have been proposed, none has provided compelling evidence to attain wide acceptance.

Dysgenetic gonads associated with androgen insensitivity, persistent mullerian syndrome, true hermaphroditism and Klinefelter syndrome have a higher incidence of germ cell tumors (38–40). Down syndrome and cutaneous ichthyosis (40–42) with steroid sulfatase deficiency also has been reported to be associated with occurrence of testicular tumors. One of the strongest risk factors for the development of a germ cell tumor is having a history of prior contralateral tumor (43–45), although a specific causative factor remains undetermined. Familial occurrence of tumor has been reported, with sixfold increase for a son whose father had a germ cell tumor (46).

Inadequately treated congenital adrenal hyperplasia has been observed to be associated with testicular tumors (47,48). It is presumed that the development and progression of these tumors is enhanced by the chronic stimulatory effect of elevated corticotropin.

Painless mass is the common mode of presentation; however, pain and tenderness are found in half the cases. Symptoms or signs due to metastasis to the retroperitoneal

lymph nodes or lungs are the initial findings in a small proportion of patients. Tumors of Leydig cell origin may secrete testosterone, producing signs of sexual development. Unilateral or bilateral gynecomastia may occur as a result of secretion of estrogen or of chorionic gonadotropin by the stromal or germ cell tumors (49).

2. Diagnosis

Careful examination is crucial to the diagnosis testicular tumors. An area of hardness, nodularity, or altered consistency should be determined. Localization of the tumor and differentiation of simple hydrocele from reactive hydrocele with testicular tumor can be reliably performed by sonographic study. Patients suspected of having germ cell tumor should undergo radiographic or imaging studies of the chest, abdomen, and skeletal system to detect metastatic disease. The functional and histological behavior of various testicular tumors is detailed in Table 2.

Malignant behavior of Sertoli cell tumors correlates directly with large size (50). Preoperatively as well as during the follow-up, measurement of biomarkers such as serum human chorionic gonadotropin (hCG) and alpha-fetoprotein (AFP) x-fetoprotein (51) are useful, particularly for monitoring these patients.

3. Treatment

Following diagnosis of testicular tumor, immediate surgery is indicated. For teratoma, surgery alone is usually sufficient while localized germ cell tumor requires radical surgery (involving excision of the spermatic cord structures and the testicle). Periodic evaluation of the chest and abdomen and measurement of serum AFP level allows identification of tumor recurrence. For malignant tumors with metastatic or recurrent disease, radical surgery and chemotherapy (cisplatin, vinblastine, bleomycin) offer the best outcome. However, controversy remains about the

Table 2 Classification, Median Age, Frequency, Secretary, and Histological Characteristics of Childhood Testicular Tumors

Classification	Median age (years)	Frequency (%)	Secretary activity	Tumor characteristics

need for retroperitoneal lymph node resection in pediatric patients.

B. Ovarian Tumors

Ovarian tumors, which represent approximately 1% of childhood malignancies (52), are classified into two categories on the basis of their cells of origin: germ cell tumor and non-germ-cell tumor. Germ cell tumors, which are more common than non-germ-cell tumors in all age groups, account for 90% of ovarian tumors in premenarcheal girls (53). The majority of these germ cell tumors are teratoma, having a histologically benign and functionally inactive nature. Non-germ-cell tumors such as granulosa, theca, Sertoli and Leydig cell tumors represent a small proportion of the ovarian tumors; however, these are of additional clinical significance because of their secretory activity. The granulosa and theca cell tumors predominantly produce estrogens while Sertoli's and Leydig's cell tumors secrete androgens.

Classification, median age, distribution, secretory and histological characteristics, and the common presentation of ovarian tumors are provided in Table 3. Dysgerminoma, the most common germ cell tumor of the ovary, presents with painless abdominal mass. Endodermal sinus tumor, the most aggressive type of the germ cell tumors, presents as a painful mass with rapid metastasis to distant sites. Teratomas, the most common and benign tumor of germ cell origin, usually remain hormonally inactive. In contrast, embryonal carcinomas, which are typically found as an admixture of dysgerminoma, endodermal sinus tumor, or teratoma, may undergo differentiation, become

hormonally active, and manifest with effect of hormone production. Gonadoblastomas are uncommon tumors, yet an important ovarian tumor in girls for two reasons. First, these tumors occur more in phenotypic females with abnormal karyotype containing components of Y chromosomes (46,XY; 45,X/46,XY; 45,X/46,X fra). A recent report has shown the occurrence of gonadoblastoma in 7–10% of Y-chromosome-positive Turner's syndrome patients (54). Second, these tumors, which occur in dysgenetic gonads where differentiation into testis or ovary has been absent or incomplete, usually contain both germ cell and stromal cell components and frequently exhibit a tendency to recur. Since all the gonadal tissue is potentially involved and carcinoma in situ is always a possibility, removal of the gonads is recommended at early stage (55).

About 5% of granulosa cell tumors develop in prepubertal girls. In these girls, with a median age of 8 years, presenting symptoms are attributed to the hormones produced by the tumors. Precocious sexual development characterized by premature breast development, pubic and axillary hair, white vaginal discharge, or irregular uterine bleeding may be the mode of presentation (55). Excessive weight gain with or without acceleration of linear growth may also occur with advancement in the skeletal age (Chapter 9). On rare occasions, androgen production may lead to virilization with hirsutism, clitoromegaly, along with acceleration of growth. In postmenarcheal girls, unregulated estrogen production may lead to irregular bleeding or amenorrhea. Although hormonally inactive tumors may remain asymptomatic, acute abdominal symptoms may be the presentation in a small proportion of these patients. This is largely the result of torsion or rupture of

Table 3 Classification, Median Age, Frequency, Secretory, and Histological Characteristics and Presentation of Ovarian Tumors in Childhood

Classification	Median age (Years)	Frequency (%)	Secretory activity	Tumor and presentation
Germ cell tumors				
Dysgerminoma	16	17	HCG	M ^a /mass

the tumor. Adequate clinical evaluation of these girls should include pelvic examination, to be performed under sedation or anesthesia, since palpable mass is almost always diagnostic of tumor.

To complete the endocrine evaluation, the pituitary-ovarian axis and estrogen profile should be studied. Estradiol level is usually elevated while luteinizing hormone (LH) and follicle-stimulating hormone (FSH) levels are suppressed, thereby excluding the differential diagnosis of central precocious puberty. Vaginal cytology reveals maturation of squamous cells, reflecting the effect of estrogen. Sonographic study helps in localizing the mass in the ovary, although it is not a useful method to exclude adrenal disease. Laparoscopy and biopsy are often necessary. Surgical resection of the lesion (i.e., unilateral salpingo-oophorectomy), usually yields good outcome. Recurrence of the disease is unusual. Compared to adult granulosa cell tumors, juvenile granulosa cell tumors have distinct histological features characterized by luteinized cells, irregular follicles, and fibroblast-like cells and the absence of Call-Exner bodies. The tumors may be cystic, solid or both. Theca cell tumors are often hormonally active and manifest by premature breast development, which is similar to that of granulosa cell tumors. They are usually slow-growing and lack the acuteness often encountered in patients with granulosa cell tumor. Diagnostic studies and management approach are, however, identical in both of these conditions.

Classic virilizing ovarian neoplasms often called arrhenoblastoma, Sertoli-Leydig cell tumors occur most commonly during the teenage or early adult years (56). Due to the effect of androgens, the early symptoms and signs consist of weight gain, amenorrhea, hirsutism, acne, deepening of the voice, and clitoromegaly. Abdominal mass and nonspecific gastrointestinal and urinary symptoms may be present concurrently. Although symptoms and signs are more intense and the progression of the course is more rapid compared to congenital adrenal hyperplasia, androgen-producing adrenal tumor, and polycystic ovarian disease, clinical differentiation may be difficult. ACTH-stimulated adrenal study, GnRH-stimulated gonadotropin profile, and estrogen levels are essential to confirm or exclude these differential diagnoses. Sonographic study of the ovary often provides adequate information to detect cystic lesions. However, computed tomographic (CT) scan is often required to assess the adrenal disease in noncystic ovarian lesions. Histologically, these tumors show an intermediate to poor degree of differentiation (57).

Identification of the cellular origin of such tumors is possible; the presence of mRNA for P450c11 and P450c21 and ACTH receptor will indicate adrenal tissue (58). Prediction of prognosis based on the cells of origin is a possibility.

Because of patients' relatively young age, conservative surgical management with preservation of the uterus

and contralateral ovary is the goal of therapy. In advanced or recurrent disease, chemotherapy and irradiation remain the alternative (59,60), although the benefits of such therapy are not proven.

IV. TUMORS OF ENDOCRINE PANCREAS

A. Nesidioblastosis

This is defined, from the pathologist's point of view, as the diffuse proliferation of islet cells budding off from the pancreatic duct, leading to the formation of numerous small clusters of the B-cells (63-65).

Males and females are equally affected and familial occurrence has been reported. Clinically, the condition is encountered in neonates and infants with persistent symptomatic hypoglycemia (Chapters 23 and 24). Almost exclusively, neonatal hypoglycemia is attributed to impaired hepatic glucose output due to hyperinsulinemia. Severe persistent hypoglycemia determines the clinical picture (66-68). Seizures, apnea, respiratory distress, listlessness, and cyanosis are the common manifestations (69). Neonates are usually macrosomic, and infants frequently weigh above than the 97th percentile. Physical examinations are otherwise unremarkable in these patients. Demonstration of hyperinsulinemia in the face of hypoglycemia, normal liver function, as well as other glucoregulatory hormones confirms diagnosis.

While diagnostic imaging studies are performed and the patient awaits surgical treatment, medical therapy should be instituted. This includes diazoxide, corticosteroids, and epinephrine (69-72). However, partial pancreatectomy is recommended in these patients. Surgery should be performed at the earliest opportunity to minimize episodes of hypoglycemia and the risk of consequent neurologic impairment (69).

Such terms as nesidioblastoma, multifocal ductuloinsular proliferation, microadenomatosis, nesidiodyplasia, and islet-cell dysmaturational syndrome have been used to describe the morphological variants of nesidioblastosis (64,73). Clinical and biochemical means are not helpful to characterize the morphological patterns in these patients (Table 4). At the functional level, further controversy exists about the relationship between hypoglycemia and

Table 4 Distribution (%) of Morphological Patterns in Nesidioblastosis

Lesions	Reference 68	Reference 76
Hyperplasia	33	29

Normal pancreas	30	8

*Report was not available in 4% of the patients.

nesidioblastosis: pathological characteristics similar to nesidioblastosis are known to exist in patients with normoglycemia, while normal pancreatic morphology has been described in patients with hypoglycemia (74–76).

B. Insulinoma

Functioning beta-cell tumors have been found in patients from birth to old age, with approximately 10% of all cases occurring in individuals below 20 years of age (78,79). There is slight preponderance to females, with adequate reasons for this observation being unclear (80).

Although insulinomas may belong to a spectrum that includes islet cell tumors, nesidioblastosis, and multiple endocrine neoplasia (MEN) type 1 (81,82), it is important to differentiate this entity from the rest because of therapeutic implications (Chapter 28). If it is part of MEN type 1, long-term follow-up has to focus on the detection of other tumors. Nesidioblastosis requires more radical surgical resection than what is necessary for a discrete tumor.

1. Clinical Features

In patients with insulinoma, the hypoglycemia due to hyperinsulinemia determines the clinical pictures. Combinations of adrenergic and neuroglycopenic symptoms, as shown in Table 5, are present in vast majority of patients (83,84), although the latter tends to predominate in individuals with organic hyperinsulinism. The time of the day that symptoms occur and the relationship of these symptoms to meals are important. If the symptoms are present in the morning during fasting state, hyperinsulinemic hypoglycemia remains a strong possibility; if symptoms are reported during the postmeal period, excessive insulin response due to leucine sensitivity becomes a possibility. Presence or absence of other diseases, such as pituitary, adrenal, hepatic, renal, or autoimmune diseases, should likewise be ascertained. Family history of MEN-type I, possible access to hypoglycemic agents, history of ethanol

Table 5 Symptoms of Hypoglycemia

ingestion, and the nutritional status of the patient should be specifically determined.

Apart from the symptoms being nonspecific, physical examinations are also noncontributory. Thus, clinical diagnosis of insulin producing tumor is an almost impossible task. As shown in Table 6, initial diagnosis in patients with proven insulinoma is extremely variable, with 50% of patients being diagnosed inappropriately. The duration of symptoms in patients with islet-cell tumor is also variable and may be as short as 2 weeks or as long as 20 years. Because they learn to avoid symptoms by eating frequently throughout the day and night, some patients with longstanding disease may present with obesity and increased linear growth, which may also be the direct consequence of the anabolic and growth-promoting effect of insulin.

2. Laboratory Tests

Although normoglycemia and normal serum insulin levels have been documented in a small percentage of patients with insulinoma (85), this condition is usually suspected in nondiabetic individuals with hyperinsulinemic hypoglycemia during the fasting state. Indeed, absolute values of blood glucose and serum insulin as well as their ratio, normally up to 0.3, at the fasting state requires documentation in these patients before one undertakes more definitive and expensive tests (86). Lack of ketonemia, ketonuria, and acidosis in the presence of fasting hypoglycemia is also strongly supportive of a diagnosis of hyperinsulinemic hypoglycemia.

An amended insulin glucose ratio, calculated by multiplying the insulin level by 100 and then dividing by the blood glucose minus 30, is considered a better discriminator between normal and abnormal insulin secretion. This ratio of normally 50 or less measures the degree of suppression of the pancreatic insulin secretion and reduces false-negative results.

Table 6 Initial Diagnosis in 46 of 91 Patients with Proven Insulinoma

Inebriation	2
Heart attack	1

Source: Ref. 88.

Measurement of plasma C-peptide and proinsulin levels are also useful in differentiating factitious hypoglycemia from islet-cell tumor (87). Normally, the pancreatic insulin secretion parallels the plasma level of peptides. In children with suspected hypoglycemia due to insulinoma, a limited fast of variable duration (6–72 h) is often necessary (88). This is especially the case when hypoglycemia is observed in the absence of inappropriate elevation of insulin levels.

Duration of the fast should be determined on the basis of age, concurrent conditions, and severity of symptoms. Infants and young children should fast 4–12 h under close observation in the hospital. In adults, prolonged fast of 72 h has been used. However, with the availability of insulin, proinsulin, and C-peptide assays, the 72 h fast is not necessary (89).

For detection of symptoms of hypoglycemia and measurements of blood glucose, insulin, and urine ketones at the time of the symptoms, hospitalization is necessary. In patients with insulinoma, the time of symptom development during the fast has been variable, ranging from 7 to 60 h. Spontaneous increase in blood glucose levels has also been reported in such patients.

Provocative tests for assessment of insulin secretion are sometimes necessary (90). This is particularly advantageous when the clinical evidence is compelling, yet time limitations do not allow hospitalization for prolonged fasting. Glucagon, leucine, and tolbutamide are beta-cell-stimulatory agents used for this purpose (90–92). Intravenous calcium infusion is also used as a stimulus to insulin secretion (93,94). However, the tolbutamide test should not be used because it may be dangerous.

Depressed glycosylated hemoglobin and fructosamine levels may be present in patients with insulinoma, supporting the presence of hypoglycemia during the preceding 6–8 weeks.

3. Differential Diagnosis

Hypoglycemia due to various systemic diseases is frequently encountered in clinical practice. Hyperinsulinemia is the primary differentiating feature between these patients and those with insulinoma. The most difficult differential diagnosis is nesidioblastosis.

4. Localization of the Lesion

Once clinical and biochemical evidence of hyperinsulinism is established, anatomical localization of the insulin-secreting lesion is indicated. This is accomplished by ultrasonography, CT scan, highly selective arteriography, or percutaneous transhepatic pancreatic venous sampling.

Of all the methods of study, preoperative ultrasonography is the most inexpensive and least invasive technique to localize pancreatic tumors. However, the accuracy is low, with detection of 25% of pancreatic lesions (95). On the other hand, this will avoid the false-negative results of laparotomy that can occur in patients with nesidioblas-

tosis where no identifiable tumor is present. Preoperative endoscopic ultrasonography increases the accuracy of diagnosis and has been the choice for many surgeons (96).

Using intraoperative ultrasonography by applying the probe on the surface of the pancreas, lesions too small to be palpable have been detected. CT scan performed with contrast enhancement can improve the sensitivity of detection up to 40% (97). Detection of the lesion also depends on its size and location: lesions measuring less than 2 cm or located on the head or tail of the pancreas are most likely to be missed. Although ultrasonography and CT scan have low accuracy, these are reasonable first choices for tumor staging and detection of metastasis. Selective arteriography is useful to demonstrate insulinomas, with a success rate ranging from 30 to 90% (98); lesions as small as 0.5 cm in diameter have been detected. Preoperative angiography is utilized to determine the number, size, and location of the tumors. Tumors located in the head or tail of the pancreas are the most likely to be missed.

Transhepatic venous sampling with simultaneous arterial blood sampling has been useful in detecting small tumors that were missed during preoperative imaging studies (99). Apart from obtaining blood samples from different points in the portal, splenic, and mesenteric venous system, it is important to draw simultaneous peripheral blood samples to allow for changing during the course of the procedure. During this study, venous insulin concentration at least 50% higher than the arterial level is considered to be diagnostic of insulinoma. There is a considerable degree of risk of complication, such as peritonitis, hemorrhage, or perforation of the gallbladder. As a consequence, this procedure should be considered if insulinoma is likely based on the hypoglycemia and hyperinsulinemia and yet ultrasound, CT scan, and arteriography have all been negative. Biochemical markers using alpha-hCG, beta-hCG, or immunostaining technique have been found to be helpful in some patients. Differentiation of malignant lesions from benign by the histological criteria has been unreliable, because the morphological characteristics fail to correlate with the metastatic disease (100).

5. Treatment and Prognosis

To avoid irreversible neurological sequelae of persistent profound hypoglycemia, intense preoperative management is mandatory. Dietary management should be judicious, particularly ensuring a snack before the bedtime. However, treatment is particularly difficult in infants and children due to the uncertainty in ensuring food intake at a timely manner and the variability of the pathology. Diffuse islet cell involvement is more frequent than solitary adenomas, thus making complete surgical removal of the tumor difficult for the surgeons.

For preoperative patients as well as those with inoperable or undetectable tumor, pharmacological agents are

indicated. Diazoxide, a benzothiadiazine derivative, reduces insulin secretion and increases the epinephrine release. When administered at a dosage of 100–800 mg daily this maintains normoglycemia. Although side effects such as fluid retention and hypertrichosis are unacceptable, it is tolerated by most patients. Corticosteroid, used in conjunction with other agents, enhances the effectiveness of maintaining normoglycemia. A long-acting somatostatin analog, SMS 201-995, has shown promise in correcting hypoglycemia (101). Surgical removal of the tumor is the mode of therapy in patients with insulinoma (102) and should be performed at the earliest possible time. Almost 90% of the tumors are benign, and carry a favorable diagnosis.

C. Glucagonoma

Clinical and diagnostic features of glucagonoma, in comparison with vipoma and somatostatinoma, are presented in Table 7. Apart from insulin, endocrine tumors of the pancreas can produce glucagon, pancreatic polypeptide, and somatostatin along with peptides that are not normally present therein, such as VIP, peptide histidine methionine, growth hormone-releasing factors, gastrin, and calcitonin. Due to cosecretion of these hormones by various tumors, clinical syndromes may overlap and appear to be nonspecific. It consequently becomes impractical to pursue the diagnosis in all patients who present with these symptoms. However, glucagonoma, vipoma, and somatostatinoma, despite being rare in children, are interesting because of the cause and effect relationship between the increased hormone levels and the distinct clinical syndromes (glucagon and hyperglycemia, vasoactive intestinal peptide and diarrhea, somatostatin and reduced motility of the gastrointestinal–biliary tract). For a practicing physician, the importance of being familiar with these syndromes is, therefore, obvious: distinct clinical expression caused by altered biochemical environment, increased availability of

precise diagnostic tools, and, most of all, specific therapeutic implications.

The true incidence of glucagonoma is not really known. Postmortem studies in adult patients with neither clinical symptoms nor diabetes have disclosed the presence of glucagonoma (103). However, there are no such data available in children. Glucagon, a 29-aminoacid polypeptide, is secreted mostly by the alpha cells of the pancreatic islets. It stimulates the glycogenolytic process, resulting in elevation of blood glucose.

1. Clinical Features

A characteristic skin rash is the major manifestation in patients with glucagon-secreting islet cell tumor (103–105). Commonly starting in the groin area as erythematous blotches, the lesions migrate to the buttocks, thighs, perineum, and distal extremities. The lesions are necrolytic, with raised and vesiculopustular appearance and gradually become confluent. During the acute stage, these lesions are intensely painful and pruritic. After scaling, the lesions heal and become indurated and hyperpigmented. However, remission and relapse are typical of these lesions, which are due to the glycogenolytic action of glucagon. Glossitis, angular stomatitis, venous thrombosis, and occasional blackout spells occur in association with these lesions. The most common gastrointestinal symptoms are diarrhea and constipation, which is attributed to the altered motility of the intestine. Other findings include anemia and weight loss, which is primarily due to the anorexic and catabolic effect of glucagon. Specific biochemical findings include hypoproteinemia, hypoaminoacidemia, and hypocholesterolemia. Mild hyperglycemia, due to the glycogenolytic effect of glucagon, is also observed in some patients (106).

2. Diagnosis and Management

In the presence of suggestive clinical findings, the diagnosis is readily confirmed by the finding of elevated serum

Table 7 Characteristic Features of Glucagonoma, Vipoma, and Somatostatinoma

Character	Glucagonoma	Vipoma	Somatostatinoma
Amino acid	29	28	14
Normal source	α-cells of pancreatic islet	Intestinal mucosa, central and peripheral nervous system	D cells of pancreatic islet, hypothalamus-pituitary, intestinal mucosa
Physiological action	Raise blood glucose	Neurotransmitter; Enhances intestinal secretion	Reduces intestinal secretion and motility
Characteristics	Rash, glossitis, stomatitis	Persistent and profuse diarrhea mimics cholera	Diabetes, cholestasis, steatorrhea; may have hypoglycemia
Clinical features			
Malignancy (%)	75	60	60
Incidence in children	Not known, cases reported	Not known	Not known
Diagnosis	Elevated plasma level glucagons, insulin; CT scan	Elevated plasma level of VIP or PHM; hypokalemia; CT scan; laparotomy	Elevated serum level of somatostatin; CT scan to detect tumor mass

glucagon concentrations. Plasma insulin levels are also elevated, which explains the mildness of diabetes. A paradoxical rise of plasma glucagon during an oral glucose tolerance test or intravenous tolbutamide test provides additional support to the diagnosis of glucagonoma. However, these tests are superfluous in most cases. Preoperatively, CT scan is necessary to localize the primary and metastatic disease. However, the most valuable technique for tumor localization is selective arteriography: glucagonomas are highly vascular and produce prominent tumor blush.

Treatment involves surgical resection, which leads to dramatic improvement of the rash (106,107). Chemotherapy with dacarbazine (108) and streptozotocin (109) have been useful in case of nonresectable tumors. Somatostatin use alleviates the symptoms, because of the reduction of glucagon (110,111). Although zinc levels in the blood do not correlate with the presence or absence of the rash, oral zinc administration has been shown to improve the skin lesions (112). Adequate nutritional support and reversal of negative nitrogen balance stand at the center of the medical and surgical management of these patients. Parenteral infusions of specific amino acids to correct the catabolic hypoaminoacidemia has led to disappearance of the skin lesions (113).

D. Vipoma

Since the first description of this condition in 1957 by Priest and Alexander (114), various investigators have reported its manifold clinical features (115–119). Various synonyms such as Verner-Morrison syndrome, watery diarrhea hypokalemia–achlorhydria (WDHA) syndrome, and pancreatic cholera syndrome have described the same condition (118). In 1973, Bloom and colleagues renamed this condition vipoma syndrome (116).

VIP is a 28-amino-acid peptide, distributed diffusely in the gastrointestinal submucosa as well as the central nervous system (120). It stimulates water and electrolyte secretion, leading to profuse water loss in the small intestine and colon. Sodium and potassium secretion into the lumen of the bowel also features prominently due to VIP's action. Relaxation of the smooth muscles of gastrointestinal and vascular system, reduction of the gastric acid output, and decrease in the motility of the gall bladder are also caused by the vipoma.

1. Clinical Features

Vipoma is an uncommon disorder in children. Mekhjian reported 6 patients (119), out of 29 diagnosed cases of this syndrome, who were below 5 years of age. Mean age of presentation is 47 years (121), and the incidence has been estimated at 1:10 million per year. There is a female preponderance.

Diarrhea, the major manifestation of the vipoma syndrome, is characterized as persistent, secretory, and large in volume, exceeding 700 ml/day. Stool is isotonic with

plasma and mimics the description of cholera. Apart from the massive water loss, large amounts of potassium and bicarbonate are lost in the stool. Thus, dehydration, hypokalemia, and acidosis lead to significant morbidity and mortality.

Due to the inhibitory effect of VIP on pentagastrin-mediated acid secretion, gastric acid secretion is frequently decreased in these patients. Differentiation from Zollinger-Ellison syndrome is therefore based on diminished basal acid output. Although the serum phosphorus level is normal, hypercalcemia and hypomagnesemia occur in patients with vipoma syndrome. Hypercalcemia is explained on the basis of excessive bone resorption mediated by the VIP. Hyperglycemia, due to the glucagonlike effect of the VIP, is also reported.

2. Diagnosis and Management

Correction of volume deficit, electrolyte abnormalities, hypercalcemia, and hypomagnesemia should be the priority before establishing the diagnosis of vipoma and localizing the tumor.

In the presence of characteristic clinical syndrome, the elevated plasma VIP concentration is diagnostic (122). However, normal plasma VIP levels with increased level of peptide histidine-methionine (PHM), another intestinal secretagogue similar in effect to the VIP, have been described in patients with this syndrome. An intestinal perfusion study is useful to document intestinal secretion and confirm the diagnosis of vipoma syndrome. Anatomical localization of the tumor and its metastasis is obtained by ultrasound and CT scan study. However, false-negative studies are reported, making exploratory laparotomy the most definitive diagnostic modality.

Surgical resection offers the best chance of cure and provides relief of symptoms. In patients with nonresectable or metastatic disease, chemotherapy with streptozotocin may produce remission of symptoms and normalize the plasma VIP levels. Other drugs such as corticosteroids and lithium carbonates have been reported to control the symptoms of diarrhea. Treatment with octreotide, a somatostatin analogue, represents a newer method of non-surgical management of these patients.

E. Somatostatinoma

1. Clinical Features

This is also an unusual disorder in children. Most of the reported cases in literature involve adult patients. Somatostatin, a 14-amino-acid cyclic peptide, is present in the anterior pituitary, hypothalamus, thyroid follicle, D-cells of the pancreatic islet, and intestinal mucosa (123–126). As indicated by its name, it inhibits the pituitary, pancreatic, gastric, and biliary secretion. Thus, in patients with somatostatinoma and consequent increased serum somatostatin concentration, provocative GH and TSH response is inhibited, insulin and glucagon levels are di-

minated, and gastrointestinal and biliary secretion is decreased. Motility of the gastrointestinal and biliary tract is also reduced. Clinically, pancreatic somatostatinoma produces a triad of diabetes, cholelithiasis, and steatorrhea (127,128). Diabetes is usually mild, cholelithiasis is associated with gallbladder stasis, and steatorrhea is due to insufficient exocrine function of the pancreas. However, cosecretion of the hormones can alter the picture, contributing to various nonspecific symptoms. For instance, diarrhea may be the prominent feature in case of calcitonin oversecretion. Due to the altered insulin/glucagon balance, hypoglycemia has been reported in some patients with somatostatinoma (129). Extraprostatic somatostatinoma, usually located in the duodenal mucosa, is more likely to present with biliary obstruction than the above-mentioned constellation of the syndrome. Weight loss and anemia are also present in patients with longstanding disease.

2. Diagnosis and Management

In presence of clinical syndrome, the serum somatostatin level is usually elevated in patients with somatostatinoma. Provocative endocrine studies using tolbutamide, arginine, or the glucose tolerance test may be required in doubtful cases to document lack of change in the insulin and glucagon (129,130). Detection of tumor mass and metastasis requires radiological imaging study, usually with CT scan. Although total surgical resection offers the most favorable outcome, advanced or recurrent disease may require chemotherapy with streptozotocin and 5-fluorouracil (129, 131). Prognosis for treatment depends on the extent of the disease at the time of diagnosis.

Nontraditional Inheritance of Endocrine Disorders

Judith G. Hall

University of British Columbia and British Columbia Children's Hospital, Vancouver, British Columbia, Canada

I. INTRODUCTION

Over the last few years many new developments in the area of molecular genetics have uncovered alternative genetic mechanisms leading to human genetic disorders and disease.

Disorders that were previously thought to have a straightforward mendelian inheritance are now being recognized as involving nontraditional forms of inheritance, such as uniparental disomy, mosaicism, cytoplasmic elements, unstable DNA, and genomic imprinting. With the complete analyses of the human genome, many additional mechanisms of disease are likely to be defined. These newly recognized nontraditional forms of inheritance and their importance in endocrine disorders are reviewed in this chapter.

II. UNIPARENTAL DISOMY

Chromosomes are inherited in pairs. Humans usually have 23 chromosome pairs. The usual normal chromosome pair consists of one chromosome contributed from the father and one from the mother. Occasionally, however, both chromosomes of a particular pair come from only one of the parents. This is called uniparental disomy (1), from uni meaning one; parental and disomy meaning normal number of normal paired chromosomes.

Uniparental disomy (UPD) has now been described with many different human chromosomes. Patients with UPD who have been described so far are usually sporadic, but can be expected to be seen rarely in families with translocations. Three types of problems occur with UPD: genomic imprinting is uncovered, autosomal recessive disorders are produced, and vestigial aneuploidy can be seen.

A. Genomic Imprinting

Uniparental disomy may be associated with abnormalities of growth and behavior, placental abnormalities, and in-

trauterine death. This seems to be related to genomic imprinting (see below).

The classic examples of genomic imprinting being uncovered in UPD involve Prader-Willi syndrome (PWS) (2–4) and Angelman syndrome (AS) (5,6). Prader-Willi syndrome is a disorder that may be present to the endocrinologist. Affected individuals have a round face, obesity, mental retardation, and hypogonadism. In the newborn period, they are usually markedly hypotonic. PWS is associated with an absence of the paternal contribution of chromosome 15 because of a deletion or due to maternal UPD for chromosome 15. Angelman syndrome, on the other hand, presents with a very long face, mental retardation, uncontrolled bouts of laughter, and seizures, and is associated with an absence of the maternal contribution of chromosome 15 because of a deletion or due to paternal UPD for chromosome 15.

Maternal UPD for chromosome 7 is associated with intrauterine and postbirth growth retardation (7–10). These individuals present as or in a similar manner to those with Russell–Silver syndrome. It has been estimated that 10% of Russell Silver syndrome patients have maternal UPD 7 as the cause of their growth deficiency.

Paternal UPD of chromosome 6 is associated with transient neonatal diabetes (11). Although it is not seen in all cases of transient neonatal diabetes, it should be screened for since the natural history may be different from non-UPD cases.

B. Autosomal Recessives

Uniparental disomy, as mentioned, occurs when the two chromosomes in a pair have been inherited from only one parent (1). UPD may be uniparental *isodisomy*, in which the two homologs originate from the same parental chromosome and are identical; or uniparental *heterodisomy*, in which the two chromosomes originate from the two different parental chromosomes and are not identical. When

two copies of exactly the same chromosome are inherited from one parent, an abnormal gene may be present, and thereby both copies of the gene are abnormal. This may lead to an autosomal recessive disease. This is a very unusual situation for an autosomal recessive disease because only one parent is a carrier. A long list of autosomal recessive disorders associated with UPD is accumulating (12) (see Table 1). UPD should also be considered whenever a patient has two autosomal recessively inherited disorders.

C. Vestigial Aneuploidy

UPD is likely to arise from trisomy rescue (14). Most trisomies are embryonic or fetal lethal conditions. The only way such a conception is likely to survive is if a so-called normal diploid cell line develops by the loss of one of the trisomy chromosomes. When that happens, one-third of the time UPD will occur. Such a conception may harbor some trisomic cells in some tissues, which can lead to malfunction, cancer, or anomalies. Thus individuals with UPD must be viewed with concern.

UPD for many other chromosomes has not been associated with an abnormal phenotype (14). Several reports have shown that UPD for other chromosomes, for example chromosome 9 (15) and chromosome 1 (16) has no phenotypic abnormalities. The UPDs of concern seem to be maternal 7, 14, 15, 16, and paternal 6, 11, 15.

In summary, it is important to keep in mind that UPD for certain chromosomes or chromosome regions must be considered a possible mechanism producing disease, particularly related to disorders of growth, many different autosomal disorders (particularly the associations of two recessive disorders), and/or patches of chromosomally abnormal tissue.

III. MOSAICISM

Mosaicism describes an individual who has two different cell lines derived from a single zygote. Studies of placental tissues from chorionic villus sampling have shown that at least 2% of all conceptions are mosaic for chromosomal anomalies at or before 10 weeks of pregnancy (13). This suggests that mosaicism may be quite frequent in humans. Among early abortuses, 50% have a chromosomal anomaly, the most common being trisomy and triploidy. Complete trisomies are usually nonviable, and in most cases are aborted. However, the development of a normal cell line may rescue or allow a trisomic conception to come to term and be viable. In trisomies 13 and 18, Kalousek (17) has shown that all pregnancies that survive to birth have some normal cells in the placenta.

Depending upon the point at which the new cell line arises during early embryogenesis, a patient may have a variety of clinical presentations. In some situations, the trisomic cell line may be lost or overgrown. Mosaicism

Table 1 Uniparental Isodisomy and Recessive Disorders

Chromosome	Transmission	Recessive Disorders
1	Maternal	Epidermolysis bullosa
	Paternal	Pyknodysostosis
5	Paternal	Spinal muscular atrophy
6	Paternal	Complement deficiency
	Paternal	Methylmalonic acidemia
7	Maternal	Congenital adrenal hyperplasia
	Maternal	Cystic fibrosis
	Maternal	Osteogenesis imperfecta
	Paternal	Situs inversus and immotile cilia
8	Paternal	Congenital chloride diarrhea
	Paternal	Lipoprotein lipase deficiency
9	Maternal	Cartilage hair hypoplasia
10	Paternal	Multiple endocrine neoplasia
11	Maternal	Beta thalassemia
13	Paternal	Retinoblastoma
14	Maternal	Rod monochromacy
15	Maternal	Bloom syndrome
16	Paternal	Alpha thalassemia
	Maternal	Familial Mediterranean fever

may be present in some tissues, but not in others. Mosaicism may lead to patchy or asymmetrical distribution for abnormal tissue. There are many conditions that are asymmetrical or patchy (such as Ollier syndrome, multiple exostosis, and McCune-Albright syndrome) that are best explained on the basis of mosaicism.

McCune-Albright is a sporadic disorder characterized by polyostotic fibrous dysplasia, café-au-lait pigmentation, sexual precocity, and hyperfunction of multiple endocrine glands (Chap. 9). Because MAS is usually sporadic and has a characteristic lateralized pattern of cutaneous hyperpigmentation, it has been thought for some time to be likely caused by a somatic mutation occurring early in development, with some cells affected but others not affected. The occurrence and severity of the disease in bone, skin, and endocrine abnormalities in a patient depend on the number of cells carrying the mutated gene in the specific tissue.

MAS has been shown to result from a specific mutation in the alpha subunit of the G_s protein of adenylyl cyclase (18,19). This type of mutation leads to constitutive activation of the G_s protein, inducing proliferation and hyperfunction of cells' responsiveness to hormones. The mutation is not the same in all patients, and different patients have different specific mutations and different distributions of tissue involvement. However the mutation is always consistent within an affected individual. It would be a lethal mutation if there were not normal cells present in some tissues. Many other patchy disorders are being found to represent somatic mutations, or so-called second hits to the normal allele leaving no normal gene. This obviously occurs in cancer, but is also seen in patchy disorders.

IV. GERMLINE MOSAICISM

Germline mosaicism refers to mosaicism of the germ cells (eggs and sperm), and occurs when some germ cells are normal and others carry a genetic abnormality, such as a mutation or differences in chromosome number. Because this situation may be exclusive to the germ cells, it does not become apparent until a couple has children (20). In this type of situation, parents can have two or more children with the same new dominant mutation, but the parents appear to be and test as normal. Germline and somatic mosaicism have been documented on a biochemical and DNA level in some cases of osteogenesis imperfecta (21) and pseudoachondroplasia.

V. GENOMIC IMPRINTING

Genomic imprinting refers to the differences in the phenotype of a disorder depending on the parent from whom it is inherited (22–24). Much of the information on imprinting comes from studies done in mice (25) but, more

recently, several specific clinical disorders have been defined in humans.

One of the first indications that male and female genetic contributions were different came from pronuclear transplantation experiments. Pronuclear transplantation allows the pronuclei of the oocyte and the sperm to be manipulated before fertilization. This technique was used in mice to produce zygotes that have two female pronuclei (gynogenetic) or two male (androgenetic) pronuclei. These studies showed that the zygote with two maternal contributions developed embryos, but the embryos were very small. However, when two paternal contributions were present, a placenta developed but no embryo did. These studies clearly showed that both maternal and paternal genetic contributions are different, complementary, and necessary (26,27).

Mouse and human chromosomes have homologous regions. This has prompted the suggestion that several genes known to be imprinted in mice may also be imprinted in homologous chromosomal regions in humans. Several genes known to be imprinted in mice have been associated with disorders of growth in humans (Table 2) (26–28).

Insulin-like growth factor type II and the H19 genes, for example, are located in the mouse chromosome 7 (29). In humans these genes map to 11p15, which is the area associated with Beckwith-Wiedemann syndrome (30–32), a fetal overgrowth disorder characterized by a predisposition to tumors and hyperinsulinism (Chap. 5).

Because disorders that are imprinted in humans show a difference in the phenotype depending on the parent transmitting the gene, endocrine and other disorders

Table 2 Endocrine Disorders at Risk to Be Imprinted

Chromosome	Endocrine Disorder
6	Insulin-dependent diabetes H-Y antigen Prolactin 21-OH Paget's disease of bone Estrogen receptor MEN I
11	Hypoparathyroidism Adrenocortical cancer MODY
19	Insulin receptor Infertility (LH)
20	Chorionic gonadotrophic cluster Diabetes insipidus Albright hereditary osteodystrophy Growth hormone releasing factor
22	Thyroid-stimulating hormone MEN II

MEN, multiple endocrine neoplasia; LH, luteinizing hormone.

should be suspected to be imprinted if varying phenotypes are seen in a pedigree (Figs. 1 and 2) depending on the transmitting parent. Two disorders suspected of being imprinted on the basis of varying phenotype in the pedigrees are Albright's hereditary osteodystrophy and paragangliomas.

Albright's hereditary osteodystrophy (AHO), also known as pseudopseudohypoparathyroidism, is characterized by short stature, mental retardation, round face, obesity, brachydactyly, and subcutaneous calcifications in the presence of hypocalcemia and parathyroid hormone resistance.

A review of reported cases of AHO showed that there is a marked difference in the phenotype of AHO depending on the parent transmitting the disorder. Davies and Hughes (33) collected data on 36 AHO-transmitting parents. They found that in 92% of the affected cases the allele was inherited from the mother, and the phenotype was fully expressed (AHO + hormone resistance + pseudohypoparathyroidism). The remaining 8% were paternally inherited, and the phenotype was only partially expressed (AHO alone).

Subsequently, mutations of the G_s protein have been observed in patients with AHO, but in contrast to MAS patients these mutations cause deficient expression of the various alternatively spliced isoforms of the G_s protein (34). The gene for G_s protein, which has been isolated on 20q13.11, shows alternative splicing. Several of the isoforms are imprinted.

VI. CYTOPLASMIC INHERITANCE

It is well known that mitochondria (and consequently mitochondrial-associated diseases) are maternally inherited. Some of these mitochondrial mutations lead to endocrine disorders such as Pearson syndrome. However, other cytoplasmic structures, such as the cell wall, nuclear membrane, and endoplasmic reticulum, receive their template for protein folding from the oocyte. Thus, there are likely

Figure 1 Pedigree suggestive of paternal imprinting. Phenotypic effects occur only when the gene is transmitted from the mother but not when transmitted from the father. An equal number of males or females are affected or unaffected phenotypically in each generation. A nonmanifesting transmitter gives a clue to the gender of the parent who passes the expressed genetic information; in other words, in paternal imprinting there are "skipped" male nonmanifesting individuals.

MATERNAL

Figure 2 In pedigrees suggestive of maternal imprinting, phenotypic effects occur only when the gene is transmitted from the father, but not when transmitted from the mother. Equal numbers of males or females are affected or unaffected phenotypically in each generation. A nonmanifesting transmitter gives a clue to the gender of the parent who passes the expressed genetic information; in other words, in paternal imprinting there are "skipped" female nonmanifesting individuals.

to be a variety of other diseases that will be influenced by maternal factors.

VII. SUMMARY

It is clear that nontraditional mechanisms of inheritance may be playing a major role in a number of endocrine disorders, and it is important to look for parent of origin effects in all disorders. This will allow better understanding of some of the genetic mechanisms causing disease, which could lead to better diagnosis, therapy, and counseling of patients and their families.

I. INTRODUCTION

Maintenance of the tonicity of extracellular fluids within a very narrow range is crucial for proper cell function (1, 2). Extracellular osmolality regulates cell shape, as well as intracellular concentrations of ions and other osmolytes. Furthermore, proper extracellular ionic concentrations are necessary for the correct function of ion channels, action potentials, and other modes of intercellular communication. Extracellular fluid tonicity is regulated almost exclusively by the amount of water intake and excretion, whereas extracellular volume is regulated by the level of sodium chloride intake and excretion. In children and adults, normal blood tonicity is maintained over a 10-fold variation in water intake by a coordinated interaction among the thirst, vasopressin, and renal systems. Dysfunction in any of these systems can result in abnormal regulation of blood osmolality, which, if not properly recognized and treated, may cause life-threatening dysfunction in neuronal and other cellular activities.

The posterior pituitary, or neurohypophysis, secretes the nonapeptide hormone vasopressin, which controls water homeostasis by its interaction with the renal V2 vasopressin receptor. This receptor regulates the activity of the water channel, aquaporin-2, in the distal nephron, which controls the reabsorption of water from the urine. Disorders of vasopressin secretion and its action in the kidney lead to clinically important derangements in water metabolism.

II. REGULATION OF THIRST AND FLUID BALANCE

A. Osmotic Sensor and Effector Pathways

1. Vasopressin and Oxytocin Biochemistry

The sequence and synthesis of biologically active 9-amino-acid-long vasopressin peptide was performed by du Vigneaud and colleagues during the mid 1950s (3). Vasopressin was found to be closely related to oxytocin, differing by only two amino acids. By replacement of L-arginine with D-arginine at position 8 of the vasopressin molecule, and amino-terminal deamidation, an analog with enhanced, prolonged antidiuretic to pressor activity ratio was found (desamino-D-arginine vasopressin [dDAVP]) (4). dDAVP is now routinely used in clinical practice.

Vasopressin is initially synthesized as part of a larger precursor protein that also contains neurophysin. After biosynthesis, vasopressin and neurophysin are cleaved, but remain associated within the cell prior to their secretion into the bloodstream. The function of neurophysin is not clear, but may include stabilization of vasopressin against degradation during intracellular storage, and its more efficient packaging of posttranslational processing by the proenzyme convertases within secretory granules.

In all mammalian species thus far analyzed the oxytocin and vasopressin genes are adjacent in chromosomal location [chromosome 20 in the human (5)] and linked tail to tail, in opposite transcriptional orientation. In the

human, they are separated by 12 kilobases (5). This likely explains their origin from the ancient duplication of a common ancestral gene (6). Whether this adjacent linkage is of regulatory significance is under investigation.

Expression of the vasopressin and oxytocin genes occurs in the hypothalamic, paraventricular, and supraoptic nuclei (7, 8). The magnocellular components of each of these nuclei are the primary neuronal populations involved in water balance, with vasopressin synthesized in these areas carried via axonal transport to the posterior pituitary, its primary site of storage and release into the systemic circulation. The bilaterally paired hypothalamic paraventricular and supraoptic nuclei are separated from each other by relatively large distances (approximately 1 cm). Their axons course caudally, converge at the infundibulum, and terminate at different levels within the pituitary stalk and posterior pituitary gland. Vasopressin is also synthesized in the parvocellular neurons of the paraventricular nucleus, where it has a role in modulation of hypothalamic–pituitary–adrenal axis activity. In this site, vasopressin is colocalized in cells that synthesize corticotropin-releasing hormone (9, 10), which are both secreted at the median eminence and carried via the portal–hypophyseal capillary system to the anterior pituitary, where together they act as the major regulators of adrenocorticotropin synthesis and release (11). Vasopressin is also present in the hypothalamic supraoptic nucleus, the circadian pacemaker of the body, where its function is unknown.

2. Regulation of Vasopressin Secretion and Thirst

a. Osmotic Regulation. The rate of secretion of vasopressin from the paraventricular and supraoptic nuclei is influenced by several physiological variables, including plasma osmolality and intravascular volume, as well as nausea and a number of pharmacological agents. The major osmotically active constituents of blood are sodium, chloride, and glucose (with insulin deficiency). Normal blood osmolality ranges between 280 and 290 mOsm/kg H₂O.

The work of Verney (12) first demonstrated the relationship of increased vasopressin release in response to increasing plasma osmolality, as altered by infusion of sodium chloride or sucrose. At that time, it was postulated that intracranial sensors are sensitive to changes in plasma osmolality. Multiple researchers have subsequently confirmed that plasma vasopressin concentration rises in response to increasing plasma tonicity, although the exact nature of the osmosensor had not been defined (13, 14). Neurons of the supraoptic nucleus can respond directly to hypertonic stimuli with depolarization and vasopressin secretion (15), but the majority of evidence indicates that osmosensor and vasopressin-secreting neurons are anatomically distinct (16, 17). The osmosensor is likely to reside outside the blood–brain barrier as implicated by

differential vasopressin secretory response to similar changes in plasma osmolality, depending upon whether the change was induced by salt, sucrose, or urea (12, 18). The organ vasculosum of the lamina terminalis (OVLT) and the subfornical organ (SFO), areas of the preoptic hypothalamus outside the blood–brain barrier, are likely sites of osmosensing because lesions of the OVLT result in impaired AVP secretion and hypernatremia (16, 17). Also, the site of action of angiotensin II infused intracerebrally or peripherally to produce vasopressin secretion and antidiuresis resides within the OVLT (19–21).

The pattern of secretion of vasopressin into blood has been characterized extensively in normal individuals and those with abnormalities in water homeostasis. Normally, at a serum osmolality of less than 280 mOsm/kg, plasma vasopressin concentration is at or below 1 pg/ml, which is the lower limit of detection of most radioimmunoassays (13, 14). Above 283 mOsm/kg, the normal threshold for vasopressin release, plasma vasopressin concentration rises in proportion to plasma osmolality, up to a maximum concentration of about 20 pg/ml at a blood osmolality of approximately 320 mOsm/kg (Fig. 1). The osmosensor

Figure 1 Relationship between serum and urine osmolalities during a water deprivation test. With water deprivation, serum osmolality rises above the threshold for vasopressin secretion, causing antidiuresis and concentration of the urine. In normal persons, when serum osmolality exceeds 300 mOsm/kg H₂O, urine osmolality exceeds 600 mOsm/kg H₂O (solid thick and thin lines, mean and 95% confidence intervals for normal children). In patients with diabetes insipidus (dashed line), urine osmolality does not exceed 200–300 mOsm/kg H₂O, even with marked serum hyperosmolality. In patients with primary polydipsia (dotted line), urine osmolality may not exceed 600 mOsm/kg H₂O, due to partial nephrogenic diabetes insipidus caused by dilution of the osmotic gradient in the renal interstitium (see text). Solid arrowheads denote the thresholds for vasopressin (VP) release and thirst sensation.

can detect as little as a 1% change in blood osmolality. Plasma concentrations in excess of 5 pg/ml are also found with nausea, hypotension, hypovolemia, and insulin-induced hypoglycemia, but further increments in urine concentration do not occur since peak antidiuretic effect is achieved at 5 pg/ml. The rate of rise of plasma vasopressin concentration, and thus the sensitivity of the osmosensor, exhibits substantial (as much as 10-fold) interindividual variation as plasma osmolality increases (22). The set point for vasopressin secretion varies in a single individual in relation to changes in volume status and hormonal environment [e.g., pregnancy (23) or glucocorticoid status (24, 25)]. After the seventh week of gestation, osmotic thresholds for both vasopressin release and thirst are reduced by approximately 10 mOsm/kg, such that normal blood osmolality during pregnancy is approximately 273 mOsm/kg (serum sodium 135 mEq/L) (23, 26).

The sensation of thirst, a more integrated cortical activity, is determined by other anatomically distinct hypothalamic neurons, with afferents involving the ventromedial nucleus (27). The activation of the thirst mechanism is also probably mediated by angiotensin II (28). Whether the osmosensor for thirst and vasopressin release is the same is not certain, although this is suggested by lesions in the anteroventral region of the third ventricle that abolish both thirst sensation and vasopressin release (29). It makes physiological sense that the threshold for thirst (~293 mOsm/kg) is approximately 10 mOsm/kg higher than that for vasopressin release (Fig. 1). Otherwise, during the development of hyperosmolality, the initial activation of thirst and water ingestion would result in polyuria without activation of vasopressin release, causing a persistent diuretic state. Immediately following water ingestion, prior to a change in blood osmolality or volume, vasopressin concentration falls and thirst ceases (30). The degree of suppression is directly related to the coldness (31) and volume (32) of the ingested fluid. This effect is probably mediated by chemoreceptors present in the oropharynx, which guard against the rapid overdrinking of fluids after intense thirst during the time before the lowering of blood osmolality.

As noted above, water balance is regulated in two ways: vasopressin secretion stimulates water reabsorption by the kidney, thereby reducing future water loss; and thirst stimulates water ingestion, thereby restoring previous water loss. Ideally, these two systems work in parallel to regulate extracellular fluid tonicity efficiently (Fig. 2). However, each system by itself can maintain plasma osmolality in the near-normal range. For example, in the absence of vasopressin secretion but with free access to water, thirst drives water ingestion up to the 5–10 l/m² urine output seen with vasopressin deficiency. Conversely, an intact vasopressin secretory system can compensate for some degree of disordered thirst regulation. However, when both vasopressin secretion and thirst are compromised, either by disease or iatrogenic means, there is great

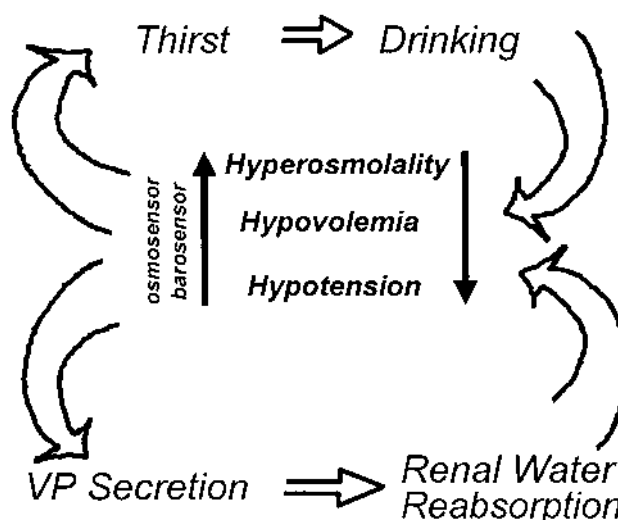

Figure 2 Regulation of vasopressin secretion and serum osmolality. Hyperosmolality, hypovolemia, or hypotension is sensed by osmosensors, volume sensors, or barosensors, respectively. These stimulate both vasopressin (VP) secretion as well as thirst. Vasopressin, acting on the kidney, causes increased reabsorption of water (antidiuresis). Thirst causes increased water ingestion. The results of these dual negative feedback loops cause a reduction in hyperosmolality or hypotension/hypovolemia. (From Muglia L, Majzoub J. Disorders of the posterior pituitary. In: Sperling M, ed. *Pediatric Endocrinology*, 2d ed. Philadelphia: Saunders, 2002:289–322.)

risk for the occurrence of life-threatening abnormalities in plasma osmolality.

b. Nonosmotic Regulation. Separate from osmotic regulation, vasopressin has been shown to be secreted in response to alterations in intravascular volume. Afferent baroreceptor pathways arising from the right and left atria, and the aortic arch (carotid sinus) are stimulated by increasing intravascular volume and stretch of vessel walls, and they send signals via the vagus and glossopharyngeal nerves, respectively, to the brainstem nucleus tractus solitarius (33, 34). Nonadrenergic fibers from the nucleus tractus solitarius synapse upon the hypothalamic paraventricular nucleus and supraoptic nucleus and, on stimulation, inhibit vasopressin secretion (35, 36). Experimental verification of this pathway has included demonstration of increased vasopressin concentration following interruption of baroreceptor output to the brainstem, and decreased plasma vasopressin concentration following mechanical stimulation of baroreceptors, an effect that is diminished by vagotomy (37, 38).

The pattern of vasopressin secretion in response to volume as opposed to osmotic stimuli is markedly different (Fig. 3). Although minor changes in plasma osmolality above 280 mOsm/kg evoke linear increases in plasma va-

Figure 3 Relationships between osmotic and nonosmotic stimuli for vasopressin release. Reaction of plasma vasopressin (AVP) concentration to the percentage increase in blood osmolality (open circles) or decrease in blood volume (closed circles). (Reproduced with permission from Dunn FL, Brennan TJ, Nelson AE, et al. The role of blood osmolality and volume regulating vasopressin secretion in the rat. *J Clin Invest* 1973; 52:3212.

sopressin, substantial alteration in intravascular volume is required for alteration in vasopressin output (39–41). No change in vasopressin secretion is seen until blood volume decreases by approximately 8%. With intravascular volume deficits exceeding 8%, vasopressin concentration rises exponentially. Furthermore, osmotic and hemodynamic stimuli can interact in a mutually synergistic fashion, so that the response to either stimulus may be enhanced by the concomitant presence of the other. When blood volume [or blood pressure (42–44)] decreases by approximately 25%, vasopressin concentrations 20–30-fold above normal and vastly exceeding those required for maximal antidiuresis are evident. It is surprising that the use of vasopressin antagonists has suggested that the high concentration of vasopressin observed with hypotension does not contribute to the maintenance of blood pressure in humans (45).

Nausea, as evoked by apomorphine (46), motion sickness (47), and vasovagal reactions, is a very potent stim-

ulus for vasopressin secretion. This effect is likely mediated by afferents from the area postrema of the brainstem, and may result in vasopressin concentrations two to three orders of magnitude above basal levels. Nicotine is also a strong stimulus for vasopressin release (48). These pathways probably do not involve osmotic or hemodynamic sensor systems, since blockade of the emetic stimulus with dopamine or opioid antagonists does not alter the vasopressin response to hypernatremia or hypovolemia.

Vasopressin secretion is inhibited by glucocorticoids; because of this, the loss of negative regulation of vasopressin secretion occurs in the setting of primary or secondary glucocorticoid insufficiency (49, 50). The effects of cortisol loss both enhancing hypothalamic vasopressin production and directly impairing free water excretion (51) are important considerations in the evaluation of the patient with hyponatremia, as is subsequently discussed.

3. Vasopressin Metabolism

Once in the circulation, vasopressin has a half-life of only 5–10 min, due to its rapid degradation by a cysteine amino terminal peptidase, called vasopressinase. A synthetic analog of vasopressin, dDAVP (desmopressin), is insensitive to amino terminal degradation, and thus has a much longer half-life: 8–24 h. During pregnancy, the placenta secretes increased amounts of this vasopressinase (52), resulting in a fourfold increase in the metabolic clearance rate of vasopressin (53). Normal women compensate with an increase in vasopressin secretion, but women with pre-existing deficits in vasopressin secretion or action (54), or those with increased concentrations of placental vasopressinase associated with liver dysfunction (55) or multiple gestations (56), may develop diabetes insipidus in the last trimester, which resolves in the immediate postpartum period (57). As expected, this form of diabetes insipidus responds to treatment with dDAVP but not with vasopressin (58, 59).

4. Sites of Vasopressin Action

a. Vasopressin Receptors. Vasopressin released from the posterior pituitary and median eminence affects the function of several tissue types by binding to members of a family of G protein-coupled cell surface receptors, which subsequently transduce ligand binding into alterations of intracellular second-messenger pathways (60). Biochemical and cell biological studies have defined at least three receptor types, designated V1, V2, and V3 (or V1b). The major sites of V1 receptor expression are on vascular smooth muscle (61) and hepatocytes (62–65), where receptor activation results in vasoconstriction (66, 67) and glycogenolysis (68), respectively. The latter activity may be augmented by stimulation of glucagon secretion from the pancreas (68). The V1 receptor on platelets also stimulates platelet aggregation (69). V1 receptor activation mobilizes intracellular calcium stores through phosphatidylinositol hydrolysis (66, 70). Despite its initial charac-

terization as a powerful pressor agent, the concentration of vasopressin needed to increase blood pressure significantly is several times higher than that required for maximal antidiuresis (71), although substantial vasoconstriction in renal and splanchnic vasculature can occur at physiological concentrations (72). The recent cloning of the V1 receptor (61–63) has greatly elucidated the relationship of the vasopressin [and oxytocin (73, 74)] receptors and, through sensitive *in situ* hybridization analysis, has further localized V1 expression to the liver and vasculature of the renal medulla, as well as to many sites within the brain, including the hippocampus, amygdala, hypothalamus, and brainstem (64, 65). The V3 (or V1b) receptor is present on corticotrophs in the anterior pituitary (75), and acts through the phosphatidylinositol pathway (76) to increase ACTH secretion. Its binding profile for vasopressin analogs resembles more closely that of the V1 than the V2 receptor. The structure of this receptor has recently been determined in human via cloning of its complementary DNA (76, 77). Its structure is similar to that of the V1 and oxytocin receptors and is expressed in the kidney as well as in the pituitary.

Modulation of water balance occurs through the action of vasopressin upon V2 receptors located primarily in the renal collecting tubule, along with other sites in the kidney including the thick ascending limb of Henle's loop and periglomerular tubules (64, 65, 78). It is also present on vascular endothelial cells in some systemic vascular beds, where vasopressin stimulates vasodilation (79), possibly via activation of nitric oxide synthase (80). Vasopressin also stimulates von Willebrand's factor, factor VIIIa, and tissue plasminogen activator via V2-mediated actions. Because of this, dDAVP is used to improve the prolonged bleeding times characteristic of uremia, type I von Willebrand's disease, and hemophilia (81). The V2 receptor consists of 370 amino acids encoding seven transmembrane domains characteristic of the G protein-coupled receptors (78, 82). These transmembrane domains share approximately 60% sequence identity with the V1 receptor, but substantially less with other members of this family. Unlike the V1 and V3 receptors, the V2 receptor acts through adenylate cyclase to increase intracellular cAMP concentration. The human V2 receptor gene is located on the long arm of the X chromosome (Xq28) (83, 84), at the locus associated with congenital, X-linked vasopressin-resistant diabetes insipidus.

b. Renal Cascade of Vasopressin Function. Vasopressin-induced increases in intracellular cAMP as mediated by the V2 receptor trigger a complex pathway of events, resulting in increased permeability of the collecting duct to water and efficient water transit across an otherwise minimally permeable epithelium (85) (Fig. 4). Activation of a cAMP-dependent protein kinase imparts remodeling of cytoskeletal microtubules and microfilaments that culminate in the insertion of aggregates of water channels into the apical membrane (86). Insertion of

Figure 4 Action of vasopressin in the collecting duct cell. Vasopressin (AVP) binds to the V2 receptor (V2R), causing the binding of GTP to the stimulatory alpha G protein subunit (α). This activates adenylate cyclase (AC), resulting in an increase in cAMP and activation of protein kinase A (PKA). The catalytic subunit of PKA, via phosphorylation of serine 256 of the water channel, aquaporin-2 (AQP2), causes aggregation of AQP2 homotetramers in membrane vesicles and their fusion with the collecting duct luminal membrane, resulting in an increase in water flow from the urine into the renal medullary interstitium. Demeclocycline, lithium, high calcium, and low potassium interfere with these processes, possibly at the level of cAMP generation and AQP2 synthesis or action. (From Majzoub, J. Primary disturbances of water homeostasis. In: Rudolf CD et al., ed. *Rudolf's Pediatrics*, 21st ed. New York: McGraw-Hill, 2002:2025–2028.)

the water channels causes an up to 100-fold increase in water permeability of the apical membrane, allowing water movement along its osmotic gradient into the hypertonic inner medullary interstitium from the tubule lumen and excretion of a concentrated urine (Fig. 4). Molecular analysis of water channels has revealed a family of related proteins, designated aquaporins, which differ in their sites of expression and pattern of regulation (87). Each protein consists of a single polypeptide chain with six membrane-spanning domains. Although functional as monomers, they are believed to form homotetramers in the plasma membrane (85). Aquaporin-2 is expressed mostly within the kidney (88), primarily within the collecting duct (89). It is also expressed in the vas deferens, at least in the rat, although it is not regulated by vasopressin in this location (90). Studies with immunoelectron microscopy have demonstrated large amounts of aquaporin-2 in the apical plasma membrane and subapical vesicles of the collecting duct, consistent with the so-called membrane-shuttling model of water channel aggregate insertion into the apical membrane after vasopressin stimulation (91). In response to water restriction or dDAVP infusion in humans, the content of urinary aquaporin-2 in both soluble and membrane-bound forms has been found to increase (92). In

addition to aquaporin-2, different aquaporins appear to be involved in other aspects of renal water handling. In contrast to the apical localization of aquaporin-2, aquaporins 3 and 4 are expressed on the basolateral membrane of the collecting duct epithelium. They appear to be involved in the flow of water and urea from the inside of the collecting duct cell into the extracellular renal medullary space.

B. Volume Sensor and Effector Pathways

1. Renin–Angiotensin–Aldosterone System

In contrast to the vasopressin system, the classic, or peripheral, renin–angiotensin system primarily affects maintenance of intravascular volume as opposed to plasma tonicity. In addition to the well-established endocrine regulatory system, several local renin–angiotensin systems have emerged, with both autocrine and paracrine effects in their tissue of synthesis, whose regulation is independent of the classic system. Finally, brain and pituitary angiotensin systems involved in blood pressure, autonomic function, and fluid balance have recently been characterized with extensive interaction with the vasopressin system.

a. Endocrine Anatomy and Biochemistry. Renin, which is synthesized by the renal juxtaglomerular apparatus, is a proteolytic enzyme that catalyzes the cleavage of angiotensinogen, synthesized by hepatocytes, into the decapeptide angiotensin (93, 94). Angiotensin I possesses no intrinsic vasoreactive or mineralocorticoid secretagogue activity, but is efficiently cleaved by angiotensin-converting enzyme in the lungs, as well as other peripheral sites, to generate the octapeptide angiotensin II. Angiotensin II is further metabolized to the heptapeptide angiotensin III by removal of one amino-terminal amino acid. Angiotensin II possesses greater vasopressor activity, and is present in approximately fourfold greater amount than angiotensin III. Angiotensins II and III possess equivalent mineralocorticoid secretory activity on the adrenal glomerulosa cells.

Aldosterone, which is the primary and most potent endogenous mineralocorticoid released by the zona glomerulosa, acts on target tissues expressing the nuclear mineralocorticoid (or type I glucocorticoid) receptor to promote sodium absorption and potassium excretion. For control of intravascular volume, the primary target of action of aldosterone is the distal nephron. Here, aldosterone increases synthesis of apical membrane sodium channels, mitochondrial enzymes involved in ATP production, and components of the Na^+ - K^+ ATPase to cause increased sodium reabsorption and potassium excretion (95).

b. Regulation of Secretion. Decreased intravascular volume as sensed by the renal juxtaglomerular apparatus results in release of renin (93, 96). Increased plasma renin activity then allows increased conversion of angiotensinogen to angiotensin I, which in turn is converted peripherally to angiotensins II and III. Increased angio-

tensin II activity causes vasoconstriction and blood pressure elevation, whereas both angiotensins II and III stimulate aldosterone release from the zona glomerulosa and subsequent salt and water retention and potassium, excretion by the distal tubule of the kidney. Expanded intravascular volume, on the other hand, causes decreased renin output and less sodium and water resorption in the kidney, serving to decrease intravascular volume and restore homeostasis.

Changes in vascular volume are not the only regulators of the renin–angiotensin–aldosterone system. Serum potassium concentration directly modulates aldosterone release by the adrenal glomerulosa by its effects on plasma membrane potential and activation of voltage-gated calcium channels (94, 97). By membrane depolarization, increased serum potassium leads to increased aldosterone synthesis, which promotes renal potassium excretion, whereas low serum potassium reduces aldosterone synthesis and decreases urinary potassium losses. Pituitary adrenocorticotropin hormone and vasopressin act via their respective receptors on the glomerulosa cells to increase acute aldosterone secretion. These effects are of short duration because long-term chronic infusions do not chronically elevate aldosterone concentrations. Direct inhibitors of aldosterone secretion, and thus promoters of natriuresis, include atrial natriuretic peptide (98, 99), somatostatin (100–102), and dopamine (103, 104).

2. The Natriuretic Peptide System

In addition to the classic vasopressin and renin–angiotensin–aldosterone systems, the recently defined natriuretic peptide families of ligands and their receptors add further potential for modulation of salt and water balance. The interaction of the natriuretic peptide system occurs both in the central nervous system via effects on vasopressin secretion and peripherally, through its ability both to promote natriuresis directly in the kidney, and inhibit adrenal aldosterone production indirectly.

a. Anatomy and Biochemistry. Atrial natriuretic peptide (ANP) was initially discovered as a component of cardiac atrial muscle that was able to induce natriuresis, a decrease in blood pressure, and rise in hematocrit when injected into rats (105, 106).

The biologically active form of ANP consists of a 28 amino acid peptide that includes a 17 amino acid ring structure (107). The primary sequence of the peptide has been conserved among mammalian species, and in addition to synthesis in cardiac atrial tissue (108) it has been detected in brain, spinal cord, pituitary, and adrenal gland (109–112).

Subsequent investigation defined a second peptide from porcine brain with structural homology to ANP (113). This peptide, designated brain natriuretic peptide (BNP), was later found to be secreted by the heart as well, in this case from both ventricular and atrial tissue (114–116).

A third member of this family, C-type natriuretic peptide (CNP), was also isolated from porcine brain (117). Little CNP can be detected in plasma, and in marked contrast to ANP and BNP, CNP does not increase in plasma in the setting of cardiac failure (118, 119).

b. Regulation of Secretion and Action. Secretion of ANP by cardiac tissue occurs in response to increasing atrial transmural pressure, from both left and right atria (118, 120). Also, increased heart rate, especially increased atrial contractile frequency, results in increased ANP secretion. Ventricular production of ANP has also been demonstrated; it is increased in states of left sided overload associated with ventricular hypertrophy (116).

The physiological ramifications of increased ANP production are several. Infusion of ANP in the setting of normovolemia causes natriuresis, diuresis, and a small increase in divalent cation excretion (118, 119, 121). ANP, through the NPR-A receptor, primarily inhibits sodium reabsorption within the renal inner medullary collecting duct, but also opposes the salt-retaining effects of angiotensin II at the level of the proximal tubule (121). ANP similarly inhibits the actions of vasopressin and aldosterone in the renal tubules (122–124).

ANP modulates mineralocorticoid production in a manner that results in the reduction of intravascular volume of pressure. Although direct reduction in plasma renin activity has been described with ANP infusion (125, 126), the most dramatic response to ANP occurs at the level of the adrenal glomerulosa cell. ANP inhibits aldosterone production by inhibiting action of most aldosterone secretagogues, with the most pronounced reduction being angiotensin II activity (119–121).

BNP synthesis and secretion from cardiac ventricular tissue are augmented in congestive heart failure, and, as for ANP, with hypertension, chronic renal, and chronic liver failure (115, 118).

III. CENTRAL DIABETES INSIPIDUS

A. Causes

Central (hypothalamic, neurogenic, or vasopressin-sensitive) diabetes insipidus can be caused by disorders of vasopressin gene structure; accidental or surgical trauma to vasopressin neurons; congenital anatomical hypothalamic or pituitary defects; neoplasms; infiltrative, autoimmune, and infectious diseases affecting vasopressin neurons or fiber tracts; and increased metabolism of vasopressin. In approximately 10% of children with central diabetes insipidus, the cause is not apparent (127, 128).

1. Genetics

Familial autosomal dominant central diabetes insipidus is manifest within the first half of the first decade of life (129). Vasopressin secretion, initially normal, gradually declines until diabetes insipidus of variable severity en-

sues. Patients respond well to vasopressin replacement therapy. The disease has a high degree of penetrance, but may be of variable severity within a family (130) and may spontaneously improve in middle age (130, 131). Vasopressin-containing neurons are absent from the magnocellular paraventricular neurons (132) but are present in parvocellular regions (133). Several different oligonucleotide mutations in the vasopressin structural gene have been found to cause the disease (www.medcon.mcgill.ca/nephros/avp_npII.html). To date, there have been mutations detected in 22 amino acids of the vasopressin gene, including 15 missense, 5 nonsense, 1 deletion, and 1 frameshift mutations. Vasopressin deficiency is also found in the syndrome consisting of diabetes insipidus, diabetes mellitus, optic atrophy, and deafness (DIDMOAD) (134, 135). One (136), but not another (137), study has suggested that a mitochondrial defect is responsible for the disease. The gene for this syndrome complex, also known as Wolfram syndrome, was localized to human chromosome 4p16 by polymorphic linkage analysis (138), and has recently been isolated (139).

2. Trauma

The axons of vasopressin-containing magnocellular neurons extend uninterrupted to the posterior pituitary over a distance of approximately 10 mm. Trauma to the base of the brain can cause swelling around or severance of these axons, resulting in either transient or permanent diabetes insipidus (140). Permanent diabetes insipidus can occur after seemingly minor trauma. Approximately one-half of patients with fractures of the sella turcica will develop permanent diabetes insipidus (141), which may be delayed as long as 1 month following the trauma, during which time neurons of severed axons may undergo retrograde degeneration (142).

Septic shock (143) and postpartum hemorrhage associated with pituitary infarction (Sheehan syndrome) (144, 145) may involve the posterior pituitary with varying degrees of diabetes insipidus. Diabetes insipidus is never associated with cranial irradiation of the hypothalamic–pituitary region, although this treatment can cause deficits in all of the hypothalamic releasing hormones carried by the portal–hypophyseal system to the anterior pituitary (see Chapter 36). Because vasopressin is carried directly to the posterior pituitary via magnocellular axonal transport, radiation may affect hypothalamic releasing hormone function by interruption of the portal–hypophyseal circulation.

3. Neurosurgical Intervention

One of the most common causes of central diabetes insipidus is the neurosurgical destruction of vasopressin neurons following pituitary–hypothalamic surgery. It is important to differentiate polyuria associated with the onset of acute postsurgical central diabetes insipidus from polyuria due to the normal diuresis of fluids given during

surgery. In both cases, the urine may be very dilute and of high volume, exceeding 200 ml/m²/h. In the former case, serum osmolality will be high; in the latter case it will be normal. A careful examination of the intraoperative record should also help to differentiate between these two possibilities. Vasopressin axons traveling from the hypothalamus to the posterior pituitary terminate at various levels within the stalk and gland (Fig. 5). Since surgical interruption of these axons can result in retrograde degeneration of hypothalamic neurons, lesions closer to the hypothalamus will affect more neurons and cause greater permanent loss of hormone secretion. Of special interest is the triphasic pattern of vasopressin secretion, often, but not always, seen following neurosurgical procedures interfering with the supraoptic–hypophyseal tract (146). Following surgery, an initial phase of transient diabetes insipidus is observed lasting $\frac{1}{2}$ –2 days, and possibly due to edema in the area interfering with normal vasopressin secretion (Fig. 5). If significant vasopressin cell destruction has occurred, this is often followed by a second phase of SIADH, which may last up to 10 days, secondary to release of prestored vasopressin from damaged neurons. A third phase of permanent neurogenic diabetes insipidus may follow if more than 90% of vasopressin cells are destroyed. Usually a marked degree of SIADH in the second phase portends significant permanent diabetes insipidus in the final phase of this response. In patients with coexisting vasopressin and cortisol deficits (e.g., in combined anterior and posterior hypopituitarism following neurosurgical treatment of craniopharyngioma), symptoms of diabetes insipidus may be masked because cortisol deficiency impairs renal free water clearance, as discussed below. In such cases, institution of glucocorticoid therapy

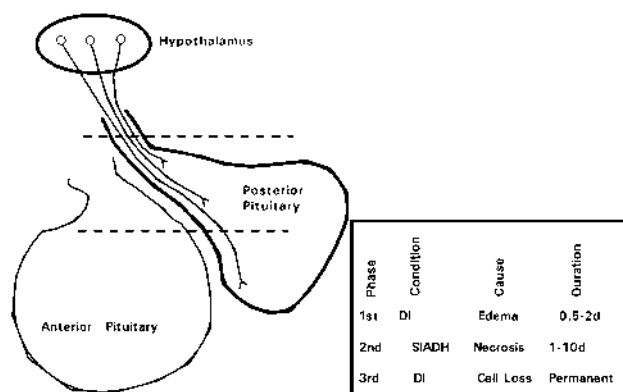

Figure 5 Diabetes insipidus following neurosurgery. Vasopressin neurons terminate at different levels of the posterior pituitary. Depending on the level of neurosurgical damage (dashed lines), different numbers of vasopressin neurons will be permanently damaged. The three phases of the triple phase response to neural damage, along with their causes and duration, are noted in the box.

alone may precipitate polyuria, leading to the diagnosis of diabetes insipidus.

4. Congenital Anatomical Defects

Midline brain anatomical abnormalities such as septo-optic dysplasia with agenesis of the corpus callosum (147), the Kabuki syndrome (148), holoprosencephaly (149), and familial pituitary hypoplasia with absent stalk (150) may be associated with central diabetes insipidus. These patients need not have external evidence of craniofacial abnormalities (149). Central diabetes insipidus due to midline brain abnormalities is often accompanied by defects in thirst perception (147), suggesting that a common osmosensor may control both vasopressin release and thirst perception. Some patients with suspected defects in osmosensor function but with intact vasopressin neurons may have recumbent diabetes insipidus, with baroreceptor-mediated release of vasopressin while upright and vasopressin-deficient polyuria while supine (151).

5. Neoplasms

Several important clinical implications follow from knowledge of the anatomy of the vasopressin system. Because hypothalamic vasopressin neurons are distributed over a large area within the hypothalamus, tumors that cause diabetes insipidus must be very large, or infiltrative, or be strategically located at the point of convergence of the hypothalamoneurohypophyseal axonal tract in the infundibulum. Germinomas and pinealomas typically arise near the base of the hypothalamus where vasopressin axons converge before their entry into the posterior pituitary. For this reason they are among the most common primary brain tumors associated with diabetes insipidus. Germinomas causing the disease can be very small (152, 153) and undetectable by magnetic resonance imaging (MRI) for several years following the onset of polyuria (154). For this reason, quantitative measurement of the β subunit of human chorionic gonadotropin, often secreted by germinomas and pinealomas, and regularly repeated MRI scans should be performed in children with idiopathic or unexplained diabetes insipidus. Empty sella syndrome, possibly due to unrecognized pituitary infarction, can be associated with diabetes insipidus in children (155). Craniopharyngiomas and optic gliomas can also cause central diabetes insipidus when very large, although this is more often a postoperative complication of the treatment for these tumors. Hematological malignancies can cause diabetes insipidus. In some cases, such as with acute myelocytic leukemia, the cause is infiltration of the pituitary stalk and sell (156–158). However, more than 30 patients with monosomy or deletion of chromosome 7 associated with acute blast transformation of myelodysplastic syndrome presented with central diabetes insipidus (159–162), without evidence of infiltration of the posterior pituitary by neoplastic cells, leaving the cause of the diabetes insipidus unresolved.

6. Infiltrative, Autoimmune, and Infectious Diseases

Langerhans cell histiocytosis and lymphocytic hypophysitis are the most common types of infiltrative disorders causing central diabetes insipidus. Approximately 10% of patients with histiocytosis will have diabetes insipidus. These patients tend to have more serious, multisystem disease for longer periods of time than those without diabetes insipidus (163, 164), and anterior pituitary deficits often accompany posterior pituitary deficiency (165). MRI characteristically shows thickening of the pituitary stalk (166). One report suggests that in patients with Langerhans cell histiocytosis, radiation treatment to the pituitary region within 14 days of onset of symptoms of diabetes insipidus may result in return of vasopressin function in more than one-third of affected patients (167).

Lymphocytic infundibuloneurohypophysitis may account for over one-half of patients with so-called idiopathic central diabetes insipidus (168). This entity may be associated with other autoimmune diseases (169). Image analysis discloses an enlarged pituitary and thickened stalk (168, 170), and biopsy of the posterior pituitary reveals lymphocytic infiltration of the gland, stalk, and magnocellular hypothalamic nuclei (171). A necrotizing form of this entity has been described that also causes anterior pituitary failure and responds to steroid treatment (172). Diabetes insipidus can also be associated with pulmonary granulomatous diseases (173) including sarcoidosis (174). Whether antibody-mediated destruction of vasopressin cells occurs is controversial. Over one-half of patients with central diabetes insipidus of a nontraumatic cause have antibodies directed against vasopressin-containing cells (175), and patients with other autoimmune diseases have such antibodies without evidence of diabetes insipidus (176). Many patients with central diabetes insipidus also have antivasopressin peptide antibodies, although their appearance usually follows institution of vasopressin treatment (177). It is very possible that antibodies directed against vasopressin-containing cells or vasopressin are not pathogenetic, but instead are markers of prior neuronal cell destruction.

Infections involving the base of the brain, such as meningococcal (178), cryptococcal, *Listeria* (179), and toxoplasmosis (180) meningitis, congenital cytomegalovirus infection (181), and nonspecific inflammatory disease of the brain (182), can cause central diabetes insipidus. The disease is often transient, suggesting that it is due to inflammation rather than destruction of vasopressin-containing neurons.

7. Brain Death

Central diabetes insipidus can appear in the setting of hypoxic brain death (183). Although its presence has been suggested as a marker for brain death in children (184), in some studies only a minority of patients with brain death manifest the disorder (185), and up to 15% of

patients with cerebral insults and diabetes insipidus ultimately recover brain function (186). Polyuria in the setting of brain death can be accompanied by high concentrations of plasma vasopressin (187), suggesting that some cases mistaken for diabetes insipidus are actually due to other causes, such as cerebral salt wasting with polyuria, as discussed subsequently.

8. Increased Metabolism of Vasopressin

The metabolic clearance rate of vasopressin increases fourfold during pregnancy due to the elaboration of a vasopressinase by the placenta (53). If the mother cannot respond with a concomitant increase in vasopressin action because of pre-existing subclinical central or nephrogenic diabetes insipidus (54), overt, transient disease will appear, usually early in the third trimester and resolve within 1 week of delivery (57, 188). Even without prior defects in vasopressin function, an extreme elevation in vasopressinase concentrations in primigravidas with preeclampsia, liver dysfunction, or multiple gestation (55, 56, 189–191) may result in development of the syndrome.

9. Drugs

The most common agent associated with inhibition of vasopressin release and impaired urine concentrating ability is ethanol (192). Since inhibition of vasopressin release by ethanol can be overcome in the setting of concurrent hypovolemia, clinically important diabetes insipidus due to ethanol ingestion is uncommon (193). Phenytoin, opiate antagonists, halothane, and α -adrenergic agents have also been associated with impaired vasopressin release (194, 195).

B. Diagnostic Approach and Differential Diagnosis

The salient features of neurogenic diabetes insipidus are polyuria and polydipsia. In children, it must first be determined whether pathological polyuria or polydipsia (exceeding 2 l/m²/day) is present, by asking the following questions: Is there a psychosocial reason for either polyuria or polydipsia? Can either be quantitated? Has either polyuria or polydipsia interfered with normal activities? Is nocturia or enuresis present? If so, does the patient also drink following nocturnal awakening? Does the history (including longitudinal growth data) or physical examination suggest other deficient or excessive endocrine secretion or an intracranial neoplasm? If pathological polyuria or polydipsia is present, the following should be obtained in the outpatient setting: serum osmolality; serum concentrations of sodium, potassium, glucose, calcium, and blood urea nitrogen (BUN); and urinalysis, including measurement of urine osmolality, specific gravity, and glucose concentration. A serum osmolality greater than 300 mOsm/kg, with urine osmolality less than 300 mOsm/kg, establishes the diagnosis of diabetes insipidus.

If serum osmolality is less than 270 mOsm/kg, or urine osmolality is greater than 600 mOsm/kg, the diagnosis of diabetes insipidus is unlikely. If, on initial screening, the patient has a serum osmolality less than 300 mOsm/kg, but the intake/output record at home suggests significant polyuria and polydipsia that cannot be attributed to primary polydipsia (i.e., the serum osmolality is greater than 270 mOsm/kg), the patient should undergo a water deprivation test to establish a diagnosis of diabetes insipidus and to differentiate central from nephrogenic causes.

After a maximally tolerated overnight fast (based on the outpatient history), the child is admitted to the outpatient testing center in the early morning of a day when an 8–10 h test can be carried out and is deprived of water (196, 197). The physical signs and biochemical parameters shown in Figure 6 are measured. If, at any time during the test, the urine osmolality exceeds 1000 mOsm/kg, or 600 mOsm/kg and is stable over 1 h, the patient does not have diabetes insipidus. If, at any time, the serum osmolality exceeds 300 mOsm/kg and the urine osmolality is less than 600 mOsm/kg, the patient has diabetes insipidus. If the serum osmolality is less than 300 mOsm/kg and the urine osmolality is less than 600 mOsm/kg, the test should be continued unless vital signs disclose hypovolemia. A common error is to stop a test too soon, based on the amount of body weight lost, before either urine osmolality has plateaued above 600 mOsm/kg or a serum osmolality above 300 mOsm/kg has been achieved. Unless the serum osmolality rises above the threshold for vasopressin release, a lack of vasopressin action (as inferred by a nonconcentrated urine) cannot be deemed pathological. If the diagnosis of diabetes insipidus is made, aqueous vasopressin (Pitressin, 1 U/m²), should be given subcutaneously. If the patient has central diabetes insipidus, urine volume should fall and osmolality should at least double during the next hour, compared with the value prior to vasopressin therapy. If there is less than a twofold rise in urine osmolality following vasopressin administration, the patient probably has nephrogenic diabetes insipidus. dDAVP should not be used for this test, since it has been associated with water intoxication in small children in this setting (198). Patients with longstanding primary polydipsia may have mild nephrogenic diabetes insipidus because of dilution of their renal medullary interstitium. This should not be confused with primary nephrogenic diabetes insipidus, since patients with primary polydipsia should have a tendency towards hyponatremia, rather than hypernatremia, in the basal state. Patients with a family history of X-linked nephrogenic diabetes insipidus can be evaluated for the disorder in the prenatal or perinatal period by DNA sequence analysis, as will be discussed, allowing therapy to be initiated without delay (199).

The water deprivation test should be sufficient in most patients to establish the diagnosis of diabetes insipidus, and to differentiate central from nephrogenic

causes. Plasma vasopressin concentration may be obtained during the procedure (Fig. 6), although it is rarely needed for diagnostic purposes in children (200). It is particularly helpful in differentiating between partial central and nephrogenic diabetes insipidus, in that it is low in the former and high in the latter situation (201). If urine osmolality concentrates normally, but only after serum osmolality is well above 300 mOsm/kg, the patient may have an altered threshold for vasopressin release, also termed a reset osmostat. This may occur following head trauma, neurosurgery, or with brain tumors (202). Magnetic resonance imaging is not very helpful in differentiating central from nephrogenic diabetes insipidus (203). Normally, the posterior pituitary is seen as an area of enhanced brightness in T1-weighted images following administration of gadolinium (204). The posterior pituitary bright spot is diminished or absent in both forms of diabetes insipidus, presumably because of decreased vasopressin synthesis in central, and increased vasopressin release in nephrogenic, disease (204–206). In primary polydipsia, the bright spot is normal, probably because vasopressin accumulates in the posterior pituitary during chronic water ingestion (204), whereas it is decreased in the syndrome of inappropriate antidiuretic hormone (SIADH), presumably because of increased vasopressin secretion (203). Dynamic, fast-frame, magnetic resonance image analysis has recently allowed estimation of blood flow to the posterior pituitary (207). With this technique, both central and nephrogenic diabetes insipidus are associated with delayed enhancement in the area of the neurohypophysis (208).

In the inpatient, postneurosurgical setting, central diabetes insipidus is likely if hyperosmolality (serum osmolality >300 mOsm/kg) is associated with urine osmolality less than serum osmolality. One must beware of intraoperative fluid expansion with subsequent hypo-osmolar polyuria masquerading as diabetes insipidus.

C. Treatment

1. Fluid Therapy

Patients with otherwise untreated diabetes insipidus crave cold fluids, especially water. With complete central diabetes insipidus, maximum urine concentrating ability is approximately 100 mOsm/kg. Since 5 l urine would be required to excrete an average daily solute load of 500 mOsm/m², fluid intake must match this to maintain normal plasma tonicity. With an intact thirst mechanism and free access to oral fluids, a person with complete diabetes insipidus can maintain plasma osmolality and sodium in the high normal range, although at great inconvenience. Furthermore, longstanding intake of these volumes of fluid in children can lead to hydronephrosis (209) and even hyperfluorosis in communities that provide fluoridated water (210).

There are two situations in which central diabetes insipidus is sometimes best treated solely with high levels

Water Deprivation Test

Figure 6 Protocol for evaluation of diabetes insipidus using water deprivation. IV, intravenous; OSM, osmolality; S.G., urinary specific gravity; SQ, subcutaneous. (From Muglia L, Majzoub J. Disorders of the posterior pituitary. In: Sperling, ed. Pediatric Endocrinology, 2d ed. Philadelphia: Saunders, 2002:289–322.)

of fluid intake, without vasopressin. Vasopressin therapy coupled with excessive fluid intake (usually greater than $1 \text{ l/m}^2/\text{day}$ as discussed subsequently) can result in unwanted hyponatremia. Because neonates and young infants receive all of their nutrition in liquid form, the obligatory high oral fluid requirements for this age ($3 \text{ l/m}^2/\text{day}$) combined with vasopressin treatment are likely to lead to this dangerous complication (211). Such neonates are better managed with fluid therapy alone. Although children managed with such a regimen may be chronically thirsty, parents may have difficulty keeping up with the voluminous fluid intake and urine output, and poor growth may occur if adequate calories are not provided along with water (212). These problems are more easily addressed than is life-threatening hyponatremia. In difficult cases, thiazide and/or amiloride diuretics may be added to facilitate renal proximal tubular sodium and water reabsorption (213) and thereby decrease oral fluid requirements. In older children, the use of short-acting agents such as arginine vasopressin (Pitressin) or lysine vasopressin (Diapid) will decrease fluid needs while minimizing the possible occurrence of hyponatremia (see section below on vasopressin and vasopressin analogs).

In the acute postoperative management of central diabetes insipidus occurring after neurosurgery in young children, vasopressin therapy may be successfully employed (214, 215), but extreme caution must be exerted with its use. While under the full antidiuretic effect of vasopressin, a patient will have a urine osmolality of approximately 1000 mOsm/kg and become hyponatremic if she or he receives an excessive amount of fluids, depending on the solute load and nonrenal water losses. With a solute excretion of $500 \text{ mOsm/m}^2/\text{day}$, normal renal function, and nonrenal fluid losses of $500 \text{ ml/m}^2/\text{day}$, fluid intake greater than $1 \text{ l/m}^2/\text{day}$ will result in hyponatremia. In addition, vasopressin therapy will mask the emergence of the SIADH phase of the triple-phase neurohypophyseal response to neurosurgical injury (as discussed above). For these reasons, it is often best to manage acute postoperative diabetes insipidus in young children with fluids alone, avoiding the use of vasopressin (216). This method consists of matching input and output hourly using between 1 and $3 \text{ l/m}^2/\text{day}$ (40 – $120 \text{ ml/m}^2/\text{h}$). If intravenous therapy is used, a basal $40 \text{ ml/m}^2/\text{h}$ should be given as 5% dextrose (D5) in one-fourth normal saline (normal saline = 0.9% sodium chloride) and the remainder, depending on the urine output, as 5% dextrose in water. Potassium chloride (40 mEq/l) may be added if oral intake is to be delayed for several days. No additional fluid should be administered for hourly urine volumes under $40 \text{ ml/m}^2/\text{h}$. For hourly urine volumes above $40 \text{ ml/m}^2/\text{h}$, the additional volume should be replaced with 5% dextrose up to a total maximum of $120 \text{ ml/m}^2/\text{h}$. For example, in a child with a surface area of 1 m^2 (approximately 30 kg), the basal infusion rate would be 40 ml/h of 5% dextrose in one-fourth normal saline. For an hourly urine output of

60 ml , an additional 20 ml/h 5% dextrose would be given, for a total infusion rate of 60 ml/h . For urine outputs above 120 ml/h , the total infusion rate would be 120 ml/h . In the presence of diabetes insipidus, this will result in a serum sodium level in the 150 mEq/l range and a mildly volume contracted state, which will allow one to assess both thirst sensation and the return of normal vasopressin function or the emergence of SIADH. Patients may become mildly hyperglycemic with this regimen, particularly if they are also receiving postoperative glucocorticoids. However, because it does not use vasopressin this fluid management protocol prevents any chance of hyponatremia.

2. Vasopressin and Vasopressin Analogs

Intravenous therapy with synthetic aqueous vasopressin (Pitressin) is useful in the management of central diabetes insipidus of acute onset (214, 215). If continuous vasopressin is administered, fluid intake must be limited to $1 \text{ l/m}^2/\text{day}$ (assuming normal solute intake and nonrenal water losses as described). The potency of synthetic vasopressin is still measured using a bioassay and is expressed in bioactive units, with 1 milliunit (mU) equivalent to approximately 2.5 ng vasopressin. For intravenous vasopressin therapy, 1.5 mU/kg/h results in a blood vasopressin concentration of approximately 10 pg/ml (217), twice that needed for full antidiuretic activity (218). Vasopressin's effect is maximal within 2 h of the start of infusion (218), and one must beware of it sticking to intravenous bottles and tubing. Occasionally following hypothalamic (but not transsphenoidal) surgery, higher initial concentrations of vasopressin are required to treat acute diabetes insipidus, which may be attributable to the release of a substance related to vasopressin from the damaged hypothalamoneurohypophyseal system, which acts as an antagonist to normal vasopressin activity (219).

Much higher rates of vasopressin infusion, resulting in plasma concentrations above 100 pg/ml , should be avoided, as they may cause cutaneous necrosis (220), rhabdomyolysis (220, 221), and cardiac rhythm disturbances (222). Patients treated with vasopressin for post-neurosurgical diabetes insipidus should be switched from intravenous to oral fluid intake at the earliest opportunity, because thirst sensation, if intact, will help regulate blood osmolality, as discussed. Intravenous dDAVP should not be used in the acute management of postoperative central diabetes insipidus, because it offers no advantage over vasopressin, and its long half-life (8–12 h) compared with that of vasopressin (5–10 min) is a distinct disadvantage, because it may increase the chance of causing water intoxication (198). In fact, the use of intravenous dDAVP ($0.3 \text{ } \mu\text{g/kg}$) to shorten the bleeding time in a variety of bleeding disorders (as has been discussed) has been associated with water intoxication (223), particularly in young children who have high obligate oral fluid needs.

A special problem arises when a patient with established central diabetes insipidus must receive a high volume of fluid for therapeutic reasons (e.g., accompanying cancer chemotherapy). Such patients can be managed either by discontinuing antidiuretic therapy and increasing fluid intake to 3–5 l/m²/day (rendering the patient moderately hypernatremic), or by using a low dosage of intravenous vasopressin (0.1 mU/kg/h, approximately one-eighth the full antidiuretic dosage). The partial antidiuretic effect allows the administration of higher amounts of fluid without causing hyponatremia (224).

In the outpatient setting, treatment of central diabetes insipidus in older children should begin with oral dDAVP in dosages of 25–300 µg every 8–12 h. Oral dDAVP tablets have recently come into widespread use. Although when given orally dDAVP is at least 20-fold less potent than when given via the intranasal route, it is reported to be highly effective and safe in children (225–227). Intranasal dDAVP (10 µg/0.1 ml), 0.025 ml (2.5 µg) is given by rhinal tube at bedtime and the dosage is increased to the lowest amount that gives an antidiuretic effect. If the dosage is effective, but has too short a duration, it should be increased further or a second, morning dose should be added. Patients should escape from the antidiuretic effect for at least 1 h before the next dose, to ensure that any excessive water will be excreted. Otherwise, water intoxication may occur. dDAVP is also available as a nasal spray in the same concentration, with each spray delivering 10 µg (0.1 ml). This is the standard preparation used for treatment of primary enuresis. Lysine vasopressin (Diapid) nasal spray (50 units/ml) may be used if a duration less than that of dDAVP is desired. One spray delivers 2 units (0.04 ml), with a duration of action between 2 and 8 h.

In addition to polyuria and polydipsia, decreased bone mineral density has been reported in patients with central diabetes insipidus (228). The decreased bone density was not corrected by vasopressin analog treatment alone, suggesting that institution of bisphosphonate or other therapies designed to prevent bone loss may be of long-term benefit in the treatment of diabetes insipidus.

3. Children with Primary Enuresis

Although normal children have a nocturnal rise in plasma vasopressin associated with an increase in urine osmolality and a decrease in urine volume, those with primary enuresis have a blunted or absent rise in vasopressin, and excrete a higher urine volume of lower tonicity (229, 230). This has suggested that enuretic children have a primary deficiency in vasopressin secretion, although the same outcome could be caused solely by excessive water intake in these children. The use of the V₂ agonist dDAVP is highly effective in abolishing bed-wetting episodes, although relapse is high once therapy is stopped (231–233). Fluid intake must be limited while a child is exposed to

the antidiuretic action of dDAVP to guard against water intoxication.

IV. NEPHROGENIC DIABETES INSIPIDUS

A. Causes

Nephrogenic (vasopressin-resistant) diabetes insipidus can be due to genetic or acquired causes. Genetic causes are less common but more severe than acquired forms of the disease, although genetic causes are more common in children than in adults.

1. Genetic Causes

a. Congenital X-Linked Diabetes Insipidus: V₂ Receptor Mutations. Congenital X-linked nephrogenic diabetes insipidus is caused by inactivating mutations of the vasopressin V₂ receptor. Due to its mode of transmission, it is a disease of males, although rarely females may be affected, presumably due to extreme Lyonization during X-chromosome inactivation (234). In keeping with a germline, as opposed to somatic, mutation in the V₂ receptor, these patients are deficient in all systemic V₂ receptor-mediated actions (235, 236) and have intact V₁-receptor-mediated responses (237, 238). As expected, the V₂ receptor defect is proximal to the activation of renal adenylate cyclase (239, 240). Unlike the function of other G protein-coupled seven transmembrane receptors such as the parathyroid hormone (PTH) and thyroid-stimulating hormone (TSH) receptors, that of the V₂ receptor is unaffected in patients with pseudohypoparathyroidism, who have inactivating mutations in the alpha subunit of G_s (241).

Because of vasopressin resistance in congenital nephrogenic diabetes insipidus, the kidney elaborates large volumes of hypotonic urine with osmolality ranging between 50 and 100 mOsm/kg. Manifestations of the disease are usually present within the first several weeks of life (242), but may only become apparent after weaning from the breast. The predominant symptoms are polyuria and polydipsia. Thirst may be more difficult to satisfy than in central diabetes insipidus. Many infants initially present with fever, vomiting, and dehydration, often leading to an evaluation for infection. Growth failure in the untreated child may be secondary to the ingestion of large amounts of water, which the child may prefer over milk and other higher-caloric substances (243). Mental retardation of variable severity as a result of repeated episodes of dehydration was described frequently in early reports (244). However, the majority of patients reported in recent studies have a normal intelligence, very likely due to an early diagnosis and appropriate treatment (245).

Intracerebral calcification of the frontal lobes and basal ganglia is not uncommon in children with X-linked nephrogenic diabetes insipidus (246–249). Because this appears early and is not seen in children with central di-

abetes insipidus of equivalent severity, cerebral calcification is probably unrelated to the level of dehydration or therapeutic intervention. It is possible that elevated vasopressin concentrations, acting via intact V1 or V3 receptors, contribute to some of the unique manifestations of X-linked nephrogenic diabetes insipidus, such as cerebral calcification, intense thirst, vomiting, and growth failure. Older children may present with enuresis or nocturia. They may learn to reduce food intake (and therefore solute load) to decrease polyuria, which may contribute to growth failure. After longstanding ingestion and excretion of large volumes of water, patients may develop non-obstructive hydronephrosis, hydroureter, and megabladder (209).

Although one founder (arriving in North America from Scotland in 1761 on the ship *Hopewell*) was initially postulated to be the ancestor of most North American subjects with congenital, X-linked nephrogenic diabetes insipidus (250), more than 180 mutations in the V2 receptor have been found, with some appearing to have arisen independently more than once (251–264). These are mostly single base mutations that result in amino acid substitutions, translational frame shifts, or termination of peptide synthesis, and are distributed fairly evenly throughout the receptor protein (www.medcon.mcgill.ca/nephros/avpr2.html). Mutations may affect vasopressin binding, cyclic AMP generation, or possibly transcriptional regulation (265–269). Patients with different mutations will likely be found to exhibit phenotypic heterogeneity, including severity of disease and response to treatment. Genetic heterogeneity may underlie the variable response of patients with X-linked diabetes insipidus to dDAVP treatment. In a family with a known mutation, prenatal or early postnatal DNA screening can unambiguously identify affected males, allowing the institution of appropriate therapy (199).

b. Congenital, Autosomal, Nephrogenic Diabetes Insipidus: Aquaporin-2 Mutations. After the initial description of X-linked nephrogenic diabetes insipidus (270), several patients were reported with similar clinical findings except for autosomal recessive transmission of the disease (271) or normal V2 receptor function outside of the kidney (272). With cloning of the complementary DNA for the renal water channel, aquaporin-2, many patients with autosomal recessive nephrogenic diabetes insipidus have been reported who have a total of 21 mutations different in this gene (Oksche, 1998 #3453) (www.medcon.mcgill.ca/nephros/aqp2.html). Most are missense mutations, although four are nonsense or frameshift mutations. They are scattered throughout the molecule, including within four of the five transmembrane domains, two of three extracellular domains, and two of four intracellular domains. Recently, an autosomal dominant mode of inheritance for nephrogenic diabetes insipidus has been described, associated with mutations in aquaporin-2. One of these dominant mutations results in mixed tetramers of the wild type and mutant alleles being retained in the

Golgi apparatus (273). Aquaporin-2 mutations impair the ability of the luminal membrane to undergo an increase in water permeability following signaling through the V2 receptor. They could include patients previously described who had a normal rise in urinary cyclic AMP in response to vasopressin, without a concomitant increase in urine osmolality (239). Aquaporin-2 protein has recently been shown to be excreted in the urine in both soluble and membrane-bound forms. Aquaporin-2 excretion is low in untreated central and nephrogenic diabetes insipidus, but following dDAVP administration increases markedly in the former, but not latter, disease (92). For this reason, its measurement in urine has been suggested as an aid in the differential diagnosis of diabetes insipidus (92).

2. Acquired Causes

Acquired causes of nephrogenic diabetes insipidus are more common and less severe than genetic causes. Nephrogenic diabetes insipidus may be caused by drugs such as lithium and demeclocycline, both of which are thought to interfere with vasopressin-stimulated cyclic AMP generation or action. Approximately 50% of patients receiving lithium have impaired urinary concentrating ability, although only 10–20% of them develop symptomatic nephrogenic diabetes insipidus, which is almost always accompanied by a reduction in the glomerular filtration rate (274, 275). The risk increases with duration of therapy. Lithium impairs the ability of vasopressin to stimulate adenylate cyclase (276), resulting in a 90% fall in aquaporin-2 messenger RNA expression in renal collecting ducts (277) and may be the basis for its causing nephrogenic diabetes insipidus.

Demeclocycline treatment causes nephrogenic diabetes insipidus by inhibiting transepithelial water transport (278). For this reason, it is useful in the treatment of dilutional hyponatremia associated with inappropriate secretion of vasopressin, as will be discussed. Other agents that cause nephrogenic diabetes insipidus include hypercalcemia, hypokalemia, and therapy with foscarnet (used in treatment of cytomegalovirus infection in immunosuppressed patients) (279, 280), clozapine (280), amphotericin (281), methicillin (282), or rifampin (283). Whether any of these agents causes nephrogenic diabetes insipidus by interfering with the expression or insertion into apical collecting duct membranes of aquaporin-2 water channels is not yet known. Ureteral obstruction (284), chronic renal failure, polycystic kidney disease, medullary cystic disease, Sjögren syndrome (285), and sickle cell disease can also impair renal-concentrating ability. Osmotic diuresis due to glycosuria in diabetes mellitus, or to sodium excretion with diuretic therapy, will interfere with renal water conservation. Primary polydipsia can result in secondary nephrogenic diabetes insipidus because the chronic excretion of a dilute urine lowers the osmolality of the hypertonic renal interstitium, thus decreasing renal-concentrating ability. Finally, decreased protein or sodium up-

take also can lead to diminished tonicity of the renal medullary interstitium and nephrogenic diabetes insipidus.

B. Treatment of Nephrogenic Diabetes Insipidus

The treatment of acquired nephrogenic diabetes insipidus focuses on elimination, if possible, of the underlying disorder, such as offending drugs, hypercalcemia, hypokalemia, or ureteral obstruction. Congenital nephrogenic diabetes insipidus is often difficult to treat. The main goals should be to ensure the intake of adequate calories for growth and to avoid severe dehydration. Foods with the highest ratio of caloric content to osmotic load should be ingested, to maximize growth and minimize the urine volume required to excrete urine solute. However, even with the early institution of therapy, growth and mental retardation are not uncommon (286).

Thiazide diuretics in combination with amiloride or indomethacin are the most useful pharmacological agents in the treatment of nephrogenic diabetes insipidus. Thiazides promote sodium excretion by interfering with sodium reabsorption in the distal tubule of the nephron and altering inner medullary osmolality; the former promotes increased proximal tubule reabsorption of sodium and the latter leads to increased free water reabsorption from the collecting duct (213, 287). Indomethacin, 2 mg/kg/day, further enhances proximal tubular sodium and water reabsorption (213, 288, 289), although this effect is not mediated by inhibition of cyclo-oxygenase (290). The combination of thiazide and amiloride diuretics is the most commonly used regimen for the treatment of congenital, X-linked nephrogenic diabetes insipidus, because amiloride counteracts thiazide-induced hypokalemia (242), avoids the nephrotoxicity associated with indomethacin therapy, and is well tolerated, even in infants (291). In addition, amiloride decreases the uptake of lithium by renal epithelial cells, and for this additional reason has been proposed in combination with thiazide as treatment for lithium-induced nephrogenic diabetes insipidus (292). High-dosage dDAVP therapy, in combination with indomethacin, has been reported to be helpful in treating some subjects with nephrogenic diabetes insipidus (293). This treatment may prove to be useful in patients with genetic defects in the V2 receptor that reduce the binding affinity for vasopressin.

V. HYPONATREMIA AND THE SYNDROME OF INAPPROPRIATE SECRETION OF VASOPRESSIN

The evaluation of hyponatremia requires the exclusion of states of hyperproteinemia, hyperlipidemia, and hyperglycemia that may falsely lower the measurement of serum sodium by flame-emission spectrophotometry.

Hyponatremia (serum sodium <130 mEq/l) in children is usually associated with severe systemic disorders. It is most often due to intravascular volume depletion or excessive salt loss, as will be discussed, and is also encountered with hypotonic fluid overload, especially in infants. Inappropriate excess secretion of vasopressin is one of the least common causes of hyponatremia in children, except following vasopressin administration for treatment of diabetes insipidus.

In evaluating the cause of hyponatremia, one should first determine whether the patient is dehydrated and hypovolemic. This is usually evident from the physical examination (decreased weight, skin turgor, central venous pressure) and laboratory data (high blood urea nitrogen, renin, aldosterone, uric acid). With a decrease in the glomerular filtration rate, proximal tubular reabsorption of sodium and water will be high, leading to a urinary sodium less than 10 mEq/l. Patients with decreased effective intravascular volume due to congestive heart failure, cirrhosis, nephrotic syndrome, or lung disease will present with similar laboratory data, but will also have obvious signs of their underlying disease, which often includes peripheral edema. Patients with primary salt loss will also appear volume depleted. If the salt loss is from the kidney (e.g., diuretic therapy or polycystic kidney disease), urinary sodium will be elevated, as may be urine volume. Salt loss from other regions (e.g., the gut in gastroenteritis or the skin in cystic fibrosis) will cause urine sodium to be low, as in other forms of systemic dehydration. Cerebral salt washing is encountered with central nervous system insults, and results in high serum atrial natriuretic peptide concentrations, leading to high urine sodium and urine excretion.

The syndrome of inappropriate antidiuretic hormone (vasopressin) secretion (SIADH) exists when a primary elevation in vasopressin secretion is the cause of hyponatremia. It is characterized by hyponatremia, an inappropriately increased urinary osmolality (>100 mOsm/kg), normal or slightly elevated plasma volume, and a normal to high urine sodium level (because of volume-induced suppression of aldosterone and elevation of atrial natriuretic peptide). Serum uric acid is low in patients with SIADH, whereas it is high in those with hyponatremia due to systemic dehydration or other causes of decreased intravascular volume (294). Measurement of plasma vasopressin is not very useful because it is elevated in all causes of hyponatremia except for primary hypersecretion of atrial natriuretic peptide (295). Because cortisol and thyroid deficiency cause hyponatremia by several mechanisms discussed subsequently, they should be considered in all hyponatremic patients. Drug-induced hyponatremia should be considered in patients taking potentially contributory medications, as discussed below. In children with SIADH who do not have an obvious cause, a careful search for a tumor (thymoma, glioma, bronchial carcinoma) causing the disease should be considered. Patients

present clinically with nonspecific symptoms of hyponatremia: anorexia, lethargy, weakness, and in severe cases obtundity and convulsions. Signs of diminished intravascular volume, edema, hypothyroidism, adrenal insufficiency, and renal disease are absent by definition.

A. Hyponatremia with Normal Regulation of Vasopressin

1. Hyponatremia with Appropriate Decreased Secretion of Vasopressin

a. Increased Water Ingestion (Primary Polydipsia).

In a hypo-osmolar state with vasopressin secretion normally suppressed, the kidney can excrete urine with an osmolality as low as 50 mOsm/kg. Under these conditions, a daily solute load of 500 mOsm/m² could be excreted in 10 l/m² urine/day. Neonates cannot dilute their urine to this degree, and are prone to develop water intoxication at levels of water ingestion above 4 l/m²/day (approximately 60 ml/h in a newborn). This may happen when concentrated infant formula is diluted with excess water, either by accident or in a misguided attempt to make it last longer (296). A primary increase in thirst, without apparent cause, leading to hyponatremia has been reported in infants as young as 5 weeks of age (212). In older children, with a normal kidney and the ability to suppress vasopressin secretion, hyponatremia does not occur unless water intake exceeds 10 l/m²/day, a feat that is almost impossible to accomplish. Longstanding ingestion of large volumes of water will decrease the hypertonicity within the renal medullary interstitium, which will impair water reabsorption and guard against water intoxication (297). However, hyponatremia will occur at lower rates of water ingestion when renal water clearance is impaired, either because of inappropriately elevated vasopressin secretion (as has been discussed) or for other reasons (see below).

The rare patient in whom the osmotic thresholds for thirst and vasopressin release are reversed illustrates the importance of the normal relationship between these two responses to osmotic stimulation (298). If thirst is activated below the threshold for vasopressin release, water intake and hypo-osmolality will occur and suppress vasopressin secretion, leading to persistent polydipsia and polyuria. As long as daily fluid intake is less than 10 l/m², hyponatremia will not occur. Despite the presence of polyuria and polydipsia, this entity should not be confused with diabetes insipidus because of the presence of hypernatremia. However, dDAVP treatment of such a patient may lower serum osmolality below the threshold for thirst, suppressing water ingestion and the consequent polyuria.

b. Decreased Renal Free Water Clearance. Adrenal insufficiency, either primary or secondary, has long been known to result in compromised free water excretion (25, 51). The mechanisms by which glucocorti-

coids and mineralocorticoids modulate water diuresis have been the subject of substantial investigation. Some studies have demonstrated increased plasma vasopressin activity in the context of glucocorticoid insufficiency (299, 300), consistent with more recent molecular biological evidence that glucocorticoids inhibit transcription of the vasopressin gene (301). However, other investigators have failed to detect vasopressin in plasma of patients with adrenal insufficiency and abnormal water clearance (302). Consistent with vasopressin-independent actions of adrenal steroids on water metabolism, Brattleboro rats with hypothalamic diabetes insipidus manifest impaired excretion of a water load after adrenalectomy (51). In adrenalectomized Brattleboro rats, glucocorticoid administration restored urine flow rate but did not restore maximal urinary diluting capacity. In converse fashion, mineralocorticoid administration restored maximal urinary diluting capacity but not flow rate. Thus, both mineralocorticoids and glucocorticoids are required for normal free water clearance.

In part, these vasopressin-independent actions of mineralocorticoids and glucocorticoids have been attributed to the increased glomerular filtration rate arising from re-expansion of extracellular fluid volume (reduced due to salt-wasting) and improved cardiovascular tone, respectively (24, 303, 304). By restoring the glomerular filtration rate, more free water is delivered to the distal tubule for excretion. In addition, volume repletion reduces the non-osmotic stimuli for vasopressin release of volume depletion and hypotension. Nitric oxide has recently been found to stimulate cyclic GMP-dependent membrane insertion of aquaporin 2 into renal epithelial cells (305). Since glucocorticoid has been shown to inhibit endothelial nitric oxide, it is possible that under conditions (306) of glucocorticoid deficiency, high levels of nitric oxide synthase result in elevated levels of endothelial nitric oxide in the renal vasculature, which in the distal renal tubule stimulate increased, vasopressin-independent aquaporin 2 activity and decreased free water clearance.

Direct effects of glucocorticoid or mineralocorticoid insufficiency on aquaporin expression and function have not been reported. In addition to impairing maximal renal diluting capacity, adrenal insufficiency compromises maximal urine-concentrating capacity (307). This effect has been shown to result from reduced tubular response to vasopressin.

Thyroid hormone is also required for normal free water clearance, and its deficiency likewise results in decreased renal water clearance and hyponatremia. Some studies suggest that vasopressin mediates the hyponatremia of hypothyroidism because ethanol increases free water excretion in hypothyroid patients, but this effect has not been found in other reports (308). In severe hypothyroidism, hypovolemia is not present, and hyponatremia is accompanied by appropriate suppression of vasopressin (309). Similar to the consequences of isolated glucocorticoid deficiency described above, hypothyroidism impairs

free water clearance more than maximal urine-diluting capacity (310). This decrease in free water clearance may result from diminished glomerular filtration rate (GFR) and delivery of free water to the diluting segment of distal nephron, as suggested by both animal (311) and human studies (312).

Given the often subtle clinical findings associated with adrenal and thyroid deficiency, all patients with hyponatremia should be suspected of these disease states and undergo appropriate diagnostic tests if indicated. Moreover, patients with coexisting adrenal failure and diabetes insipidus may have no symptoms of the latter until glucocorticoid therapy unmasks the need for vasopressin replacement (313, 314). Resolution of diabetes insipidus in chronically polyuric and polydipsic patients may likewise suggest inadequate glucocorticoid supplementation or noncompliance with glucocorticoid replacement.

Some drugs may cause hyponatremia by inhibiting renal water excretion without stimulating secretion of vasopressin (Table 1), an action that could be called *nephrogenic SIADH*. In addition to augmenting vasopressin release, both carbamazepine (315, 316) and chlorpropamide (317, 318) increase the cellular response to vasopressin. Acetaminophen also increases the response of the kidney to vasopressin (317); however, this has not been found to cause hyponatremia. High-dosage cyclophosphamide treatment (15–20 mg/kg intravenous bolus) is often associated with hyponatremia, particularly when it is followed by a forced water diuresis to prevent hemorrhagic cystitis (319–321). Plasma vasopressin concentrations are normal, suggesting a direct effect of the drug on increasing water resorption (322). Vinblastine, inde-

pendent of augmentation of plasma vasopressin concentration or vasopressin action (323), and cis-platinum (324, 325) likewise cause hyponatremia. These drugs may damage the collecting duct tubular cells, which are normally highly impermeable to water, or may enhance aquaporin-2 water channel activity and thereby increase water reabsorption down its osmotic gradient into the hypertonic renal interstitium.

B. Treatment

Hyponatremia due to cortisol or thyroid hormone deficiency reverses promptly following institution of hormone replacement. Because the hyponatremia is often chronic, too rapid a rise in serum sodium should be avoided if possible. When drugs that impair free water excretion must be used, water intake should be limited, as if the patient has SIADH to 1 l/m²/24 h, using the regimen proposed.

1. Hyponatremia with Appropriate Increased Secretion of Vasopressin

Increased vasopressin secretion causing hyponatremia may either be an appropriate response or an inappropriate response to a pathological state. Inappropriate secretion of vasopressin, also called SIADH, is the much less common of the two entities (326, 327). Whatever the cause, hyponatremia is a worrisome sign often associated with increased morbidity and mortality (328).

a. Systemic Dehydration. Systemic dehydration (water in excess of salt depletion) initially results in hyponatremia, hyperosmolality, and activation of vasopres-

Table 1 Drugs Impairing Free Water Clearance

Class	Drug	Increases vasopressin secretion
Angiotensin-converting enzyme inhibitors	Lisinopril	
Anticonvulsants	Carbamazepine/oxabarbazepine	Yes
	Valproic acid	
Antineoplastics	Cis-platinum	
	Cyclophosphamide	No
	Vinblastine	Yes
	Vincristine	Yes
Antiparkinsonian	Amantadine	Yes
	Trihexyphenidyl	
Antipsychotics	Haloperidol, thioridazine	
Antipyretics	Acetaminophen	
Hypolipidemics	Clofibrate	Yes
Oral hypoglycemics	Chlorpropamide	Yes
	Tolbutamide	
Selective serotonin uptake inhibitors	Fluoxetine, sertraline, others	Likely
Tricyclic antidepressants	Imipramine, amitriptyline	Yes

sin secretion as reviewed above. In addition, the associated fall in the renal glomerular filtration rate results in an increase in proximal tubular sodium and water reabsorption, with a concomitant decrease in distal tubular water excretion. This limits the ability to form a dilute urine and, along with the associated stimulation of the renin–angiotensin–aldosterone system and suppression of atrial natriuretic peptide secretion, results in the excretion of urine that is very low in sodium. As dehydration progresses hypovolemia and/or hypotension become major stimuli for vasopressin release that are much more potent than hyperosmolality (see above). This effect, by attempting to preserve volume, decreases free water clearance further and may lead to water retention and hyponatremia, especially if water replacement in excess of salt is given. In many cases, hyponatremia due to intravascular volume depletion is evident from physical and laboratory signs such as decreased skin turgor, low central venous pressure, hemoconcentration, and elevated blood urea nitrogen. However, the diagnosis may be subtle. For example, patients with meningitis may present with hyponatremia, for which water restriction has been advocated in the belief that it is due to SIADH. However, several studies have found that volume depletion, rather than SIADH, is often the cause of the hyponatremia (329, 330), and that it resolves more readily when supplemental, rather than restricted, fluid and solute are administered (331). In patients with hyponatremia following head trauma, volume depletion rather than SIADH is the cause in approximately one-half (332).

b. Primary Loss of Sodium Chloride. Salt can be lost from the kidney, such as in patients with congenital polycystic kidney disease, acute interstitial nephritis, and chronic renal failure. Mineralocorticoid deficiency, pseudohypoaldosteronism (sometimes seen in children with urinary tract obstruction or infection), diuretic use, and gastrointestinal disease (usually gastroenteritis with diarrhea and/or vomiting) can also result in excess loss of sodium chloride. Hyponatremia can also result from salt loss in sweat in cystic fibrosis, although obstructive lung disease with elevation of plasma vasopressin probably plays a more prominent role, as reviewed above. With the onset of salt loss, any tendency toward hyponatremia will initially be countered by suppression of vasopressin and increased water excretion. However, with continuing salt loss, hypovolemia and/or hypotension ensue causing non-osmotic stimulation of vasopressin. This plus increased thirst, which leads to ingestion of hypotonic fluids with low solute content, result in hyponatremia. Weight loss is usually evident, as is the source of sodium wasting. If it is the kidney, it is accompanied by a rate of urine output and a urine sodium content greater than those associated with most other causes of hyponatremia except a primary increase in atrial natriuretic peptide secretion.

c. Decreased Effective Plasma Volume. Congestive heart failure, cirrhosis, nephrotic syndrome, positive

pressure mechanical ventilation (333), severe burns (334), and lung disease (bronchopulmonary dysplasia (335–337) [in neonates], cystic fibrosis with obstruction (338, 339), and severe asthma (340, 341)) are all characterized by a decrease in so-called effective intravascular volume (308, 342). This occurs because of impaired cardiac output, an inability to keep fluid within the vascular space, or impaired blood flow into the heart, respectively. As with systemic dehydration, in an attempt to preserve intravascular volume, water and salt excretion by the kidney are reduced, and decreased barosensor stimulation results in a compensatory, appropriate increase in vasopressin secretion, leading to an antidiuretic state and hyponatremia (343). Because of the associated stimulation of the renin–angiotensin–aldosterone system, these patients also have an increase in the total body content of sodium chloride and may have peripheral edema, which differentiates them from those with systemic dehydration. In patients with impaired cardiac output and elevated atrial volume (e.g., congestive heart failure or lung disease), atrial natriuretic peptide concentrations are elevated, which contributes to hyponatremia by promoting natriuresis (see below).

d. Treatment. Patients with systemic dehydration and hypovolemia should be rehydrated with salt-containing fluids such as normal saline or lactated Ringer's solution. Because of activation of the renin–angiotensin–aldosterone system, the administered sodium will be avidly conserved, and a water diuresis will quickly ensue as volume is restored and vasopressin concentrations fall (344). Under these conditions, caution must be taken to prevent too rapid a correction of hyponatremia, which may itself result in brain damage (see below).

Hyponatremia due to a decrease in effective plasma volume caused by cardiac, hepatic, renal, or pulmonary dysfunction is more difficult to reverse. The most effective therapy is the least easily achieved: treatment of the underlying systemic disorder. Patients weaned from positive pressure ventilation undergo a prompt water diuresis and resolution of hyponatremia as cardiac output is restored and vasopressin concentrations fall. The only other effective route is to limit water intake to that required for the renal excretion of the obligate daily solute load of approximately 500 mOsm/m² and to replenish insensible losses. In a partial antidiuretic state with a urine osmolality of 750 mOsm/kg and insensible losses of 500 ml/m², oral intake would have to be limited to approximately 1200 ml/m²/day.

Because of concomitant hyperaldosteronism, the dietary restriction of sodium chloride needed to control peripheral edema in patients with heart failure may reduce the daily solute load and further limit the amount of water that can be ingested without exacerbating hyponatremia. However, hyponatremia in these settings is often slow to develop, rarely causes symptoms, and usually does not need treatment. If the serum sodium levels fall below 125 mEq/l, water restriction to 1 l/m²/day is usually effective

in preventing a further decline. Since water retention in patients with these disorders is a compensatory response to decreased intravascular volume, an attempt to reverse it with drugs such as demeclocycline or specific V2-receptor antagonists (which induce nephrogenic diabetes insipidus, as discussed above) could result in worsening hypovolemia, with potentially dire consequences (345).

In general, patients with hyponatremia due to salt loss (including those with cerebral salt-wasting syndrome) require continued supplementation with sodium chloride and fluids. Initially, intravenous replacement of urine volume with fluid containing sodium chloride, 150–450 mEq/l depending on the degree of salt loss, may be necessary; oral salt supplementation may be required subsequently (295). This treatment contrasts with that of SIADH, for which water restriction without sodium supplementation is the mainstay.

e. Precautions in Emergency Treatment. Severe hyponatremia requires rapid treatment but not rapid correction. Most children with hyponatremia develop the disorder gradually, are asymptomatic, and should be treated with water restriction alone. However, the development of acute hyponatremia, or a serum sodium concentration below 120 mEq/l, may be associated with lethargy, psychosis, coma, or generalized seizures, especially in younger children. Acute hyponatremia causes cell swelling due to the entry of water into cells which can lead to neuronal dysfunction from alterations in the ionic environment, or to cerebral herniation because of the encasement of the brain in the cranium. If present for more than 24 h, cell swelling triggers a compensatory decrease in intracellular organic osmolytes, resulting in the partial restoration of normal cell volume in chronic hyponatremia (346).

The proper emergency treatment of cerebral dysfunction depends on whether the hyponatremia is acute or chronic (1, 347). In all cases, water restriction should be instituted. If hyponatremia is acute, and therefore probably not associated with a decrease in intracellular organic osmolyte concentration, rapid correction with hypertonic 3% sodium chloride administered intravenously may be indicated. As a general guide, this solution, given in the amount of 12 ml/kg body weight, will result in a rise in serum sodium of approximately 10 mEq/l. If hyponatremia is chronic, hypertonic saline treatment must be undertaken with caution, because it may result in both cell shrinkage (Fig. 7) and the associated syndrome of central pontine myelinolysis (348). This syndrome, affecting the central portion of the basal pons as well as other brain regions, is characterized by axonal demyelination, with sparing of neurons. It becomes evident within 24–48 h following too rapid correction of hyponatremia, has a characteristic appearance by computed tomographic and MRI, and often causes irreversible brain damage (348–350). If hypertonic saline treatment is undertaken, the serum sodium level should be raised only high enough to cause an improvement in mental status, and in no case

faster than 0.5 mEq/l/h or 12 mEq/1/day (347–350). In the case of systemic dehydration, the rise in serum sodium levels may occur very rapidly using this regimen. The associated hyperaldosteronism will cause avid retention of the administered sodium, leading to rapid restoration of volume and suppression of vasopressin secretion, and resulting in a brisk water diuresis and a rise in serum sodium (344).

Acute treatment of hyponatremia is more difficult in patients with decreased effective plasma volume. This is both because the underlying disorder makes it difficult to maintain the administered fluid within the intravascular space, and because an associated increase in atrial natriuretic peptide promotes natriuresis and loss of the administered salt. Furthermore, patients with cardiac disease who are given hypertonic saline may require concomitant treatment with a diuretic such as furosemide to prevent worsening of heart failure, which will also increase natriuresis.

C. Hyponatremia with Abnormal Regulation of Vasopressin

1. Hyponatremia with Inappropriate Increased Secretion of Vasopressin (SIADH)

a. Causes. SIADH is uncommon in children (326, 327, 351). It can occur with encephalitis, brain tumor (352), head trauma (332, 353), or psychiatric disease (354), after generalized seizures (355), after prolonged nausea (356, 357), pneumonia (358, 359), or acquired immunodeficiency syndrome (AIDS) (360). Many drugs have been associated with impaired free water clearance as indicated in Table 1. Impaired free water clearance can result from alteration in vasopressin release, increased vasopressin effect at the same plasma vasopressin concentration, or vasopressin-independent changes in distal collecting tubule water permeability. Common drugs shown to increase ADH secretion and result in hyponatremia include carbamazepine (316), chlorpropamide (361), vinblastine (323), vincristine (362), and tricyclic antidepressants (363, 364). Newer sulfonylurea agents, including glyburide, are not associated with SIADH (365). Although it has been believed to be the cause of hyponatremia associated with viral meningitis, volume depletion is more commonly the cause (329, 331).

In contrast, the majority of children with tuberculous meningitis have hyponatremia and SIADH, which predict more severe disease and poor outcome (366–368). SIADH is the cause of the hyponatremic second phase of a triple-phase response seen after hypothalamic–pituitary surgery, as reviewed previously. Hyponatremia with elevated vasopressin secretion is found in up to 35% of patients 1 week after transsphenoidal pituitary surgery (369, 370). The mechanism is most likely retrograde neuronal degeneration with cell death and vasopressin release. Secondary adrenal insufficiency causing stimulation of va-

Figure 7 Changes in organic osmolytes with hyponatremia and after its correction. Under normal conditions, osmotic balance exists between extracellular and intracellular compartments. With acute hyponatremia, water enters cells, causing cell swelling. After approximately 24 h continued hyponatremia, intracellular organic osmolytes decrease, restoring cell volume towards normal. Hypertonic saline treatment of acute hyponatremia results in restoration of normal cell volume, whereas the same treatment of chronic hyponatremia results in cell shrinkage. Large circle, water; closed smaller circle, solute; arrow, direction of water flow. (From Muglia L, Majzoub J. Disorders of the posterior pituitary. In: Sperling M, ed. *Pediatric Endocrinology*, 2d ed. Philadelphia: Saunders, 2002:289–322.)

sopressin release (49) may also play a role, since hyponatremia most commonly follows the removal of adrenocorticotropin hormone-secreting corticotroph adenomas (370). In the vast majority of children with SIADH, the cause is the excessive administration of vasopressin, whether to treat central diabetes insipidus (198, 211) or, less commonly, bleeding disorders (223) (see above), or, most uncommonly, following dDAVP therapy for enuresis.

b. Treatment. Chronic SIADH is best treated by chronic oral fluid restriction. Under full vasopressin antidiuretic effect (urine osmolality of 1000 mOsm/kg), a normal daily obligate renal solute load of 500 mOsm/m² would be excreted in 500 ml/m² water. This, plus a daily nonrenal water loss of 500 ml/m², would require that oral fluid intake be limited to 1000 ml/m²/day to avoid hypo-

natremia. In young children, this degree of fluid restriction may not provide adequate calories for growth. In this situation, the creation of nephrogenic diabetes insipidus using demeclocycline therapy may be indicated to allow sufficient fluid intake for normal growth (371). Demeclocycline is superior to lithium for this purpose (372). However, its use is not recommended in children under 8 years of age and pregnant women, since tetracyclines are extensively incorporated into bones and tooth enamel. Specific V2 receptor antagonists are also being developed for this purpose (373). Acute treatment of hyponatremia due to SIADH is only indicated if cerebral dysfunction is present. In that case, treatment is dictated by the duration of hyponatremia and the extent of cerebral dysfunction, as has been discussed. Because patients with SIADH have volume expansion, salt administration is not very effective

in raising the serum sodium level: it is rapidly excreted in the urine due to suppressed aldosterone and elevated atrial natriuretic peptide concentrations.

2. Hyponatremia with Inappropriate Decreased Secretion of Vasopressin, Due to Increased Secretion of Atrial Natriuretic Peptide (Cerebral Salt-Wasting Syndrome)

Although atrial natriuretic peptide does not usually play a primary role in the pathogenesis of disorders of water metabolism, it may have an important secondary role (335, 374–376). Patients with SIADH have elevated atrial natriuretic peptide concentrations, probably due to hypovolemia, which may contribute to the elevated natriuresis of SIADH and which decrease as water intake is restricted (374). Likewise, the suppressed atrial natriuretic peptide concentrations found in patients with central diabetes insipidus, probably due to the associated hypovolemia, rise after dDAVP therapy (374). However, hyponatremia in some patients, primarily those with central nervous system disorders including brain tumor, head trauma, hydrocephalus, neurosurgery, cerebral vascular accidents, and brain death, may be due to the primary hypersecretion of atrial natriuretic peptide (295, 377–379). This syndrome, called cerebral salt-wasting, is defined by hyponatremia accompanied by elevated urinary sodium excretion (often more than 150 mEq/l), excessive urine output, hypovolemia, suppressed vasopressin, and elevated atrial natriuretic peptide concentrations (>20 pmol/L). Thus, it is differentiated from SIADH, in which normal or decreased urine output, euolemia, only modestly elevated urine sodium concentration, and elevated vasopressin concentration occur. Direct measurement of intravascular volume status with a central venous line is often helpful. The distinction is important because the therapies of the two disorders are markedly different. Treatment of patients with cerebral salt wasting consists of restoring intravascular volume with sodium chloride and water, as with the treatment of other causes of systemic dehydration. The underlying cause of the disorder, which is usually due to acute brain injury, should also be treated if possible.

D. Other Causes of True and Factitious Hyponatremia

True hyponatremia is associated with hyperglycemia, which causes the influx of water into the intravascular space. Serum sodium will decrease by 1.6 mEq/l for every 100 mg/dl increment in blood glucose above 100 mg/dl. Glucose is not ordinarily an osmotically active agent, and does not stimulate vasopressin release, probably because it is able to equilibrate freely across plasma membranes. However, in the presence of insulin deficiency and hyperglycemia, glucose acts as an osmotic agent presumably because its normal intracellular access to osmosensor sites is prevented (380). Under these circumstances, an osmotic

gradient exists, and this stimulates vasopressin release. In diabetic ketoacidosis, this, together with the hypovolemia caused by the osmotic diuresis secondary to glycosuria, results in marked stimulation of vasopressin secretion (381–384). Rapid correction of hyponatremia may follow soon after the institution of fluid and insulin therapy. Whether this contributes to the pathogenesis of cerebral edema occasionally seen following treatment of diabetic ketoacidosis is not known. Elevated concentrations of triglycerides may cause factitious hyponatremia, as can obtaining a blood sample downstream from an intravenous infusion of hypotonic fluid.

VI. CONCLUDING REMARKS

Precise regulation of water balance is necessary for the proper function of multiple cellular pathways. Vasopressin released from the posterior pituitary, stimulated by both hyperosmolar and nonosmotic factors, acts via the kidney V2 vasopressin receptor to stimulate both an increase in aquaporin-2 expression and its insertion into collecting duct luminal membrane, thereby enhancing renal water reabsorption to minimize subsequent water loss. Thirst controls the second major physiological response to hyperosmolality and results in increased water intake to make up for past water loss. The renin–angiotensin–aldosterone and atrial natriuretic peptide systems also make important contributions to water and volume regulation by modulating sodium intake and output.

The proper diagnosis of disorders caused by deficient and excessive action of vasopressin requires a thorough understanding of the physiological regulation of this hormone. Recent advances in molecular medicine have revealed mutations in the vasopressin gene, and the V2 receptor or aquaporin-2 genes, responsible for familial central and nephrogenic diabetes insipidus, respectively. Molecular methods allow the diagnosis of these disorders in the prenatal or early postnatal periods. Nevertheless, the most frequent cause of central diabetes insipidus remains a destructive lesion of the central nervous system caused by tumor or neurosurgical insult, and pharmacological toxicity remains the most common cause of nephrogenic diabetes insipidus.

Hyponatremia is a common occurrence in childhood, but is rarely due to a primary increase in vasopressin secretion (SIADH). It is more commonly caused by hypovolemia (either primary or secondary to decreased effective vascular volume), salt loss, excessive ingestion of hypotonic fluids, or cortisol deficiency. Hyponatremia due to increased vasopressin action is most commonly caused by excessive vasopressin administration during the treatment of central diabetes insipidus or coagulopathies.

Central diabetes insipidus is best treated in infants with fluid therapy, which avoids the administration of vasopressin or its V2 receptor analog, dDAVP. In older children, dDAVP is the drug of choice. Nephrogenic di-

abetes insipidus remains a therapeutic challenge. Hyponatremia due to SIADH is best managed by restricting water intake, whereas salt and water replacement are indicated when hyponatremia is due to hypovolemia or excessive secretion of atrial natriuretic peptide, as occurs in cerebral salt wasting. Hyponatremia causing central nervous system dysfunction is a medical emergency. Blood sodium must be raised promptly, but at a rate not greater than 0.5 mEq/l to avoid the occurrence of central pontine myelinolysis.

Emergencies of Inborn Metabolic Diseases

Jose E. Abdenur

*Foundation for the Study of Neurometabolic Diseases and University of Buenos Aires School of Dentistry,
Buenos Aires, Argentina*

I. INTRODUCTION

Baby JO was born full term, after an uneventful pregnancy and delivery. He had a normal physical examination and was discharged home at 36 h of age. Twelve hours later, the mother noted poor sucking and a weak cry. He was brought to the hospital and found to be lethargic. A sepsis work-up was performed and, as a blood gas revealed respiratory alkalosis, an ammonium level was obtained. The value was 1600 μM (normal up to 80). Blood was sent for analysis of plasma amino acids and he was treated with sodium benzoate, sodium phenylacetate, arginine, and a high glucose infusion rate (GIR). Citrulline levels were 2300 μM and the arginine dosage was adjusted for the treatment of argininosuccinic acid synthetase deficiency. The patient improved and was discharged after 2 weeks on a special diet. His family history revealed that a brother had died at 5 days of age. He had also presented with poor suck and lethargy early in life, was admitted to a hospital, had seizures and lapsed into coma. The diagnosis was sepsis.

This story shows two dramatically different outcomes for two siblings who, undoubtedly, had the same disease. Inborn metabolic diseases (IMD) are a group of genetic disorders in which there is a block in a metabolic pathway. They are usually the product of a single gene defect that affects the activity of an enzyme either directly or through abnormalities in its cofactors or activating proteins. IMD comprise a variety of disorders affecting the metabolism of small (i.e., aminoacids) or large molecules (i.e., sphingolipids). Many patients present with a catastrophic collapse in the neonatal period. However, the age and clinical presentation of patients with IMD are highly variable. Therefore a disease-free period of months or years, or a subacute presentation does not rule out the possibility of an IMD (1). A variable phenotype can be seen in patients with the same enzyme deficiency and clinical heteroge-

neity has even been observed between siblings carrying the same mutations. Nevertheless, when possible, the molecular defect of the patient should be identified. This information is useful for prenatal diagnosis and, in some cases, may allow one to predict the clinical course of the disease (genotype–phenotype correlation), helping one to find the best therapeutic option for each individual.

A complete description of the different IMD can be found in excellent textbooks (2–4). In this chapter, we will describe the most common IMD that can present with acute, life-threatening illness, focusing on the diagnosis and treatment of these emergencies.

II. UREA CYCLE DEFECTS

A. Pathophysiology: The Urea Cycle

High ammonium levels can be found in a variety of diseases, but the most severe causes of hyperammonemia are the urea cycle defects (UCD) (Table 1). The urea cycle prevents the toxic accumulation of ammonium and other nitrogen compounds by incorporating nitrogen not used for protein synthesis into urea. Each molecule of urea contains two atoms of waste nitrogen: one derived from ammonia and the other from aspartate (5,6) (Fig. 1). The urea cycle is also responsible for the biosynthesis of arginine. Abnormalities in the urea cycle produce hyperammonemia and elevation of glutamine. The former may have a deleterious effect on the central nervous system (CNS) through different mechanisms, including alteration in trafficking of amino acids and monoamines between neurons and astrocytes, as well as deficit in cerebral energy metabolism due to inhibition of 2-ketoglutarate-dehydrogenase (5,7). High levels of glutamine produce an intracellular osmotic effect with secondary swelling of astrocytes and increased intracranial pressure, which is clinically expressed by acute encephalopathy (5,7,8,9).

Table 1 Causes of Hyperammonemia**Inborn errors of metabolism**

Urea cycle defects

- N-acetylglutamate synthetase deficiency
- Carbamylphosphate synthetase deficiency
- Ornithine transcarbamylase deficiency
- Argininosuccinic acid synthetase deficiency
- Argininosuccinic acid lyase deficiency
- Arginase deficiency

Organic acidemias: Propionic acidemia, methylmalonic acidemia, isovaleric acidemia, and others

Fatty acid oxidation defects

- Medium-chain acyl-CoA-dehydrogenase deficiency, long-chain 3-hydroxyacyl-CoA-dehydrogenase, and others

Transport defects of urea cycle intermediates

- Lysinuric protein intolerance
- Hyperammonemia–hyperornithinemia–homocitrullinuria syndrome

Glutamato dehydrogenase deficiency (hyperammonemia and hyperinsulinism)

Mitochondrial diseases: Mitochondrial DNA depletion, and others

Pyruvate carboxylase deficiency (neonatal form)

Acquired causes

Transient hyperammonemia of the newborn

Muscular hyperactivity (seizures, respiratory distress syndrome)

Infections with urease positive bacteria (skin, intestine, urinary tract)

Asparaginase treatment

Deficient arginine supply in diet

Treatment with valproate and other anticonvulsants

Hepatocellular carcinoma

Liver insufficiency: Reye syndrome, infections, intoxication, and others

Portocava shunt (liver bypass): Vascular malformations, cirrhosis

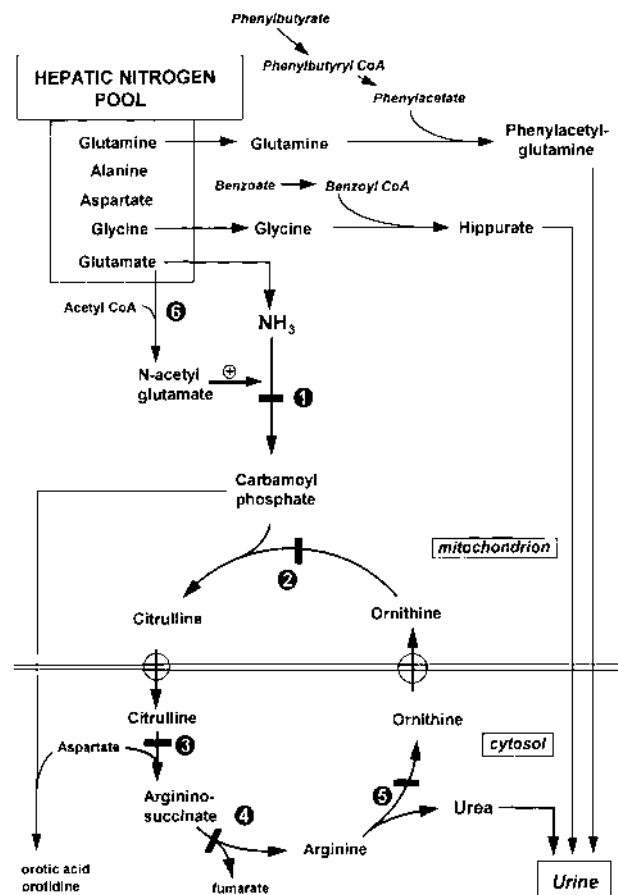

Figure 1 The urea cycle and alternative pathways of nitrogen excretion. Enzymes: 1, carbamyl phosphate synthetase; 2, ornithine transcarbamylase; 3, argininosuccinate synthetase; 4, argininosuccinate lyase; 5, arginase; 6, N-acetylglutamate synthetase. Enzyme defects are shown by solid bars across the arrows. (From Ref. 6.)

There are five enzymes involved in the urea cycle (Fig. 1): carbamylphosphate synthetase (CPS), ornithine transcarbamylase (OTC), argininosuccinic acid synthetase (AS), argininosuccinic acid lyase (AL), and arginase. Because N-acetylglutamate (NAG) is required for the activity of CPS, the enzyme responsible for NAG biosynthesis (NAG synthetase) is also considered to be a part of the pathway (5,6). Defects for each of these enzymes have been described. Except for OTC deficiency, which is X-linked, inheritance in all UCD is autosomal recessive.

B. Clinical Presentation

1. Neonatal Form

Patients with UCD can present with symptoms from birth to adulthood. Neonatal presentation is the most common and is due to a complete deficiency of CPS, OTC, AS, or

AL, all of which have almost identical clinical expression (5,6). These patients are usually born at full term and have a normal physical exam at birth. Between the first 24 and 72 h, depending on protein intake, the neonate presents with poor suck, vomiting, and hypotonia followed by lethargy, seizures, vasomotor instability, hypothermia, and coma. Slight liver enlargement and hyperventilation are also constant findings. AS-deficient patients may present with hypertonicity and trismus; pulmonary hemorrhage has been described as a complication of OTC deficiency (6). If hyperammonemia is not detected, the patient might die with a suspected diagnosis of sepsis, respiratory distress, and/or intracranial bleeding (5,6).

Although infrequent, NAG synthetase deficiency can also have a similar severe neonatal course, but its clinical presentation appears to be variable (5,10).

2. Late-Onset Form

Beyond the neonatal period, the clinical expression of UCD is highly variable, depending on the degree of the enzyme defect, nitrogen intake, and endogenous catabolism. Common presentations are intermittent episodes of vomiting associated with headaches, irritability, agitation, ataxia, and/or lethargy, sometimes progressing to coma. Recovery from these episodes may be complete, or with different degrees of neurological sequelae. These episodes can be triggered by an exogenous protein load or increased endogenous catabolism (i.e., fever, fasting, steroid treatment, surgery, etc.). Strokelike episodes and central pontine myelinolysis have been reported in patients with OTC deficiency (11,12). Hepatomegaly is common in AS deficiency and severe liver involvement, mimicking a Reye's syndrome has been described in several urea cycle defects (1,5,6). Brittle hair (trichorrhexis nodosa) is characteristic of AS- and AL-deficient patients.

A history of anorexia, poor weight gain and a self-imposed protein restriction is frequently overlooked in these patients.

Female carriers for OTC deficiency can have a similar variability in clinical presentation, ranging from completely asymptomatic to severe neonatal hyperammonemia, due to the different degree of lyonization in the hepatocytes (5,13). Some of these women have presented with severe hyperammonemia in the postpartum period (14).

Common misdiagnoses of the late presentation of UCD include migraine, cyclic vomiting, esophageal reflux, food allergies, behavioral problems, or hepatitis (5,6).

Clinical presentation of arginase deficiency differs from the other urea cycle defects. The disease is characterized by chronic encephalopathy progressing to spastic tetraplegia, seizures, and microcephaly. Episodic vomiting and hyperammonemia are less common (5,15).

C. Diagnosis

In the severe neonatal presentation, or during the acute decompensation in the late-onset forms, the most important biochemical finding in patients with NAGS, CPS, OTC, AS, or AL deficiency is severe hyperammonemia (usually greater than 300 μM), with low blood urea nitrogen (BUN) and slight or moderate elevation in liver transaminase levels. It is important to note that in common diseases of the neonatal period such as sepsis, seizures, or asphyxia, ammonia levels rarely exceed the 200 μM level. Also ammonia levels can be falsely elevated if specimens are not collected and processed properly. Respiratory alkalosis, due to the toxic effect of the ammonia to the respiratory center, is another key to the diagnosis (5), but this sign is frequently overlooked. More rarely, patients with UCD can present with metabolic acidosis, probably secondary to dehydration. When severe hyperammonemia

in a sick neonate is found, quantitative measurements of plasma and urine amino acids (AA), acylcarnitines (AC), urine organic acids analysis (UOA) and orotic acid should be performed as soon as possible. Diagnosis of the specific block in the urea cycle is determined by the AA and orotic acid results. Low or undetected citrulline levels are present in NAGS, CPS, and OTC deficiencies (5,6) (Fig. 1). In OTC deficiency, the accumulated carbamyl phosphate will be diverted to the pyrimidine synthetic pathway, producing an increased excretion of orotic acid (and orotidine), which is the basis for the differential diagnosis between OTC and NAGS or CPS deficiencies (5,6,16). Orotic acid can also be increased in AS, AL, and arginase deficiencies but in lesser amounts. Uracil, another pyrimidine, may be found in the UOA of these enzyme deficiencies. Differentiation between NAGS and CPS requires assessment of CPS enzyme activity in hepatocytes and/or an oral load with N-carbamyl glutamate, an analog of N-acetyl glutamate (6).

Patients with AS deficiency have markedly increased citrulline levels (usually more than 1000 μM) and patients with AL deficiency have milder elevations of citrulline (100–300 μM) and increased levels of argininosuccinic acid (5). The latter is detected more easily in urine than in serum amino acids. Other abnormalities in the amino acid profile, common to all of the above-mentioned enzyme deficiencies, are increased glutamine and alanine, due to nonspecific nitrogen accumulation; and decreased arginine and ornithine, due to the impaired arginine biosynthesis (5,6).

In arginase deficiency, in contrast, hyperammonemia is uncommon and the characteristic serum AA profile shows a marked elevation of arginine. Urine amino acids also show a marked elevation of arginine with milder increase in lysine, cystine, and ornithine (15). A liver biopsy, for measurement of enzyme activity, is seldom necessary for diagnostic purposes, except for the differential diagnosis between NAGS and CPS as mentioned above. The most common differential diagnoses of UCD are transient hyperammonemia of the newborn (THAN), organic acidemias (OA), and fatty acid oxidation (FAO) defects. Patients with THAN are usually preterm babies who present in the first 24 h of life with respiratory distress and severe hyperammonemia (even higher than in UCD) (17). Neonates with OA (mainly propionic and methylmalonic) classically present with metabolic acidosis with high anion gap, ketonuria and hyperammonemia. The latter can be as severe as in the UCD. In exceptional cases, metabolic acidosis and ketonuria may be absent but AC and/or UOA are diagnostic (see review organic acidemias, below).

Children with FAO defects can present as neonates but, in general, hyperammonemia is not severe and hypoketotic hypoglycemia and severe liver or cardiac involvement are common in these patients. Acylcarnitines are the main tool for their diagnosis (see review of fatty acid oxidation defects, below).

Other causes of hyperammonemia are outlined in Table 1 (5,6,18,18a).

Diagnosis of UCD in patients out of crisis is more difficult, specially for the female heterozygous for OTC deficiency. Amino acid levels in these female patients are slightly different from normal controls (14,19), but might still fall within the normal range, even during a mild crisis. Enzyme activity measured in liver biopsy samples is unreliable (5). The allopurinol test is useful for diagnosis and carrier detection, but it might not be completely specific (5,19,20). When possible, mutation analysis of the OTC gene should be done. Even though the majority of mutations are private, recent information allows for the establishment of some degree of genotype to phenotype correlations (21,22). This information is also essential for prenatal diagnosis.

D. Treatment: The Acute Episode

For teaching purposes we classify treatment of this emergency into three areas: supportive therapy, anabolism, and detoxification.

1. Supportive Therapy

A hyperammonemic episode is a life-threatening condition with risk for severe brain damage. Nitrogen intake should be discontinued. A central venous line should be placed for intravenous (IV) infusion and an arterial line should be available for blood drawing and blood pressure monitoring. The hemodialysis team should be alerted. Blood samples for measurement of ammonia, blood gas, electrolytes, BUN, glucose, and calcium should be obtained prior to the beginning of the treatment and every 4–6 h thereafter. If intracranial pressure is elevated, therapy with mannitol can be started. Corticosteroids should be avoided, as they will produce a negative nitrogen balance (5). Many patients are dehydrated due to the previous history of vomiting and poor feeding. However, IV fluids should be given cautiously, since cerebral edema is frequently present in severely ill patients. Infections should be searched for and treated accordingly.

2. Anabolism

In order to decrease endogenous protein catabolism, calories to cover at least the basal energy expenditure should be provided (60 Cal/kg/day in newborns) (23) but, when possible, a higher caloric intake (100–120 Cal/kg/day) is desirable. This requires the use of a high glucose infusion rate (GIR), for which a central line is required. The different GIR and calories delivered using different concentrations of dextrose are listed in Tables 2 and 3. In less severely ill patients who can tolerate oral or nasogastric feedings, IV calories can be supplemented by using glucose polymers (10% solution) or one of the protein-free powders available: Pro-Phree (Ross Laboratories, Columbus, OH), Mead-Johnson 80056 (Mead Johnson Labora-

Table 2 GIR Calculated from Different Glucose Concentrations (D%) and Fluid Infusion Rates (ml/kg)^a

cc/kg	D5%	D7.5%	D10%	D12.5%	D15%	D20%

^aConcentrations of dextrose greater than 12.5% should not be used through a peripheral vein.

tories, Evansville, IN). If the gastrointestinal (GI) tract cannot be used, IV lipids (0.5–2 g/kg/day) can be given as long as sepsis is not present and liver enzyme and triglyceride levels are within normal limits.

3. Detoxification

Hemodialysis is the treatment of choice for severe hyperammonemia and can usually normalize ammonium levels in less than 24 h (5,24). If that is not possible, continuous hemodiafiltration, hemofiltration, peritoneal dialysis, or exchange transfusion, in that order, are the alternatives (25,26). Pharmacological treatment with sodium benzoate and sodium phenylacetate should be carried on until dialysis procedures are available. These drugs activate alternative pathways for nitrogen excretion. After being

^aThe 3.4 Cal provided by 1 g intravenous glucose was used for the calculations.

esterified to their CoA-esters, sodium benzoate and phenylacetate will produce hippurate and phenylacetylglutamine, respectively. The latter two compounds are excreted through the urine, diverting nitrogen from the urea cycle (5,27) (Fig. 1). Intravenous preparations are recommended for the acutely ill patient by giving a priming infusion of 250 mg/kg in 25–35 ml/kg of 10% dextrose solution over 90 min, followed by a sustaining infusion of 250 mg/kg given over 24 h in maintenance fluids (5). Lower dosages (5.5 g/m^2 in $400\text{--}600 \text{ ml/m}^2$) are used in older patients. When D10% is used to prepare the priming infusion, the resulting GIR infusion is very high (28–39 mg/kg/min), and we have observed hypoglycemia with hyperinsulinism as a result of the sudden change in IV glucose infusion when the priming dose finishes. To avoid this problem we dilute the drugs in D5%.

Repeat priming doses are not recommended due to the potential toxic effect of these drugs. It is also important that dosages of the IV medications be carefully calculated as cases of overdose with toxic effects have been reported (28). Because drug levels in blood are not routinely measured, we have evaluated levels of benzoylcarnitine by tandem mass spectrometry as a rapid and simple means of estimating the benzoate levels.

Sodium benzoate and sodium phenylacetate provide 6.9 and 6.4 mEq sodium/g, respectively. Therefore, the amount of sodium given to the patient with both drugs in 24 h will be approximately 6.7 mEq/kg. The use of these salts can produce potassium loss (5), which, in association with the increased potassium uptake secondary to the high GIR, may result in hypokalemia. Therefore, serum electrolyte levels must be followed closely, and IV fluids adjusted accordingly. Nausea and vomiting are frequent side effects of the treatment and could be avoided by using antiemetics (5). As an alternative to the IV medications, sodium benzoate or sodium phenylbutyrate can be given via NG tube. Sodium phenylbutyrate is converted into phenylacetate in the body and is twice as effective as sodium benzoate on a molar basis. Recommended dosages are up to 500 mg/kg/day for sodium benzoate and up to 600 mg/kg/day for sodium phenylbutyrate (5,6,27).

Arginine, which becomes an essential amino acid in UCD, should also be provided. The recommended dosage is 210 mg/kg/day for CPS, OTC, and AS deficiencies and 660 mg/kg/day for AL deficiency (4.0 and 12.0 g/m^2 respectively, for older patients). It is also recommended to give a priming infusion over 90 min followed by a sustaining infusion, of a similar dosage, given over 24 h (5). An IV preparation of arginine HCl (10% solution) is available. As an alternative, oral arginine can be given diluted in water via NG tube. A side effect of the treatment with arginine HCl is the development of hyperchloremic metabolic acidosis, which may require treatment with sodium bicarbonate (5). The use of potassium acetate, rather than KCl, is useful to decrease the hyperchloremia resulting from the arginine administration.

E. Long-Term Management

When ammonia levels are close to normal, protein can be added to the parenteral nutrition at an initial dosage of 0.5 g/kg/day. Nasogastric (NG) or oral (PO) feeds can be started as soon as the clinical condition is stable. Protein can be then provided by administration of an infant formula, increasing the intake gradually according to ammonium levels. In general 1.5–2 g/kg/day can be given to newborns and young infants, but protein tolerance decreases after 6 months of age. The use of special formulas with essential amino acids mixtures, to provide about 50% of the total protein intake, is recommended for OTC and CPS and could also be used in AS and AL deficiencies. This approach is used to meet the requirements for essential amino acids and to reutilize waste nitrogen for the synthesis of the nonessential ones (6). To achieve the desired caloric intake (120–140 Cal/kg for a newborn), the formula should be supplemented with one of the protein-free powders available (see above). As an alternative, glucose polymers and oil can be added to the infant formula as a source of calories. Minerals, vitamin, and trace element requirements should be met and enough water must be added to meet the patient's needs and maintain the caloric density at 20–24 Cal/oz. Hyperosmolar preparations may cause diarrhea. The diet should be adjusted frequently to ensure weight gain and growth. Protein and calorie requirements per kg body weight will decrease with age and vary from patient to patient according to the disease, growth rate, and residual enzyme activity. Fasting plasma ammonium, branched-chain AA, arginine, and serum plasma protein levels should be maintained within normal limits; plasma glutamine should be below 1000 μM (5).

Because carnitine deficiency may develop in patients with UCD (27), carnitine should be given to these patients (50–100 mg/kg/day, divided in three doses). The dosage should be adjusted according to free carnitine levels.

When PO intake is satisfactory, the appropriate medicines for long-term treatment (sodium phenylbutyrate, arginine, and/or citrulline) can be given orally, mixed with the formula. Recommended dosages of sodium phenylbutyrate are 0.45–0.60 g/kg/day for newborns and young children, and 9.9–13.0 g/m^2 /day for older patients. When phenylbutyrate is not available, sodium benzoate 0.25–0.5 g/kg/day can be prescribed as alternative. These detoxifying agents might not be needed in patients with AL deficiency (5,6).

Arginine (free base) is given at a dosage of 0.40–0.70 g/kg/day for young children and 0.8–15.4 g/m^2 /day for older patients. The dosage can be adjusted to maintain normal arginine levels for age. Patients with AS and AL deficiencies require the higher dosages. In patients with severe CPS or OTC deficiencies, arginine can be substituted by citrulline, 0.17 g/kg/day or 3.8 g/m^2 /day, according to age. Citrate has been also used to provide a sub-

strate for Krebs-cycle intermediates and might be useful in the treatment of AL deficiency (6).

NAGS deficiency might only require treatment with oral *N*-carbamyl glutamate (100–300 mg/kg/day). (6).

If anticonvulsant agents are needed, valproic acid should be avoided (29).

The outcome for patients with UCD remains very guarded. In general it depends on the disease, age at diagnosis, residual enzyme activity, and compliance with treatment (5,6,30,31). Neurological damage may be directly related to the duration and degree of the initial hyperammonemic episode; therefore, neurological impairment is common in almost all forms with neonatal presentation. Patients with AS deficiency seem to have a better prognosis than OTC- or CPS-deficient patients (5). It is surprising that AL patients appear to have poor outcome in spite of infrequent decompensations (31). Prospective treatment of children with confirmed prenatal diagnosis or at risk of having UCD has been more effective in patients with AS and AL than in OTC and CPS deficiencies (32). Liver transplantation has been performed in several patients. Correction of the hyperammonemia can be obtained but neurological outcome is mainly related to the condition prior to transplantation (31,33). Further studies are still needed to confirm long-term benefits of this therapeutic approach. Efforts to develop gene therapy for UCD are underway (34,35).

III. ORGANIC ACIDEMIAS

A. Pathophysiology

Organic acidemias (OA) are a group of IMDs characterized by an abnormal accumulation of one or more organic acids in body fluids. The majority of the OA are due to defects in the catabolic pathways of AA. However, because the site of the enzymatic block is far from the step where the amino group is lost, AA do not accumulate. The fatty acid oxidation defects and the primary lactic acidemias, which also produce abnormal amounts of organic acids, are described in other sections of this chapter.

For teaching purposes we can classify the OA into three groups (Table 4). The first one includes defects in the metabolism of branched-chain aminoacids. In general, they present with acute “intoxication-like” episodes dominated by metabolic acidosis and increased anion gap (1, 36,37).

In the second group, the clinical picture is characterized by a progressive neurological deterioration (38,39, 40). These patients appear to be normal in infancy or early childhood. Thereafter, mental retardation, movement disorders, ataxia, and/or seizures become apparent. Some of these OA have characteristic neuroradiological findings (38,41,42,43). The most common of these conditions, and one of the most common organic acidemias, is glutaric aciduria type 1 (glutaryl-CoA dehydrogenase deficiency)

(38,41,44). Clinical presentation of these OA highlights the importance of requesting organic acid analysis in every patient with mental retardation, movement disorder, dystonia, and/or macrocephaly of unknown origin, even if episodes of acute metabolic decompensation are absent (45).

In the third group we have listed miscellaneous disorders that are usually diagnosed based on the UOA but have a clinical presentation that differs from the other two groups. In the same group we have included OA with a still unknown enzymatic defect.

For the purpose of this chapter we will focus on the organic acidemias due to defects in branched-chain AA metabolism. They are inherited as autosomal recessive conditions and have a variable phenotype (Fig. 2; Table 4). The most common are isovaleric acidemia (IVA), propionic acidemia (PA), and methylmalonic acidemia (MMA).

Isovaleric acidemia, a defect of leucine metabolism, results from a deficiency of isovaleryl-CoA dehydrogenase. Patients with IVA accumulate isovaleric acid and isovaleryl-CoA. The former is a volatile compound and is responsible for the characteristic sweaty feet odor found in the urine and skin of affected patients (36,37,46).

PA results from a defect in propionyl-CoA carboxylase, a biotin-dependent enzyme (37,60); and MMA from a deficiency of methylmalonyl-CoA mutase. Activity of the latter could be impaired due to defects in the mutase itself (*mut*⁺ or *mut*⁻) or due to defects in the synthesis of its cofactor, adenosylcobalamin (37,61–65). Both PA and MMA accumulate propionyl-CoA, which derives from the catabolism of valine, isoleucine, threonine, methionine, odd-chain fatty acids, and cholesterol side-chain and is also produced by the anaerobic gut flora (87, 88). In general, patients with OA accumulate acyl-CoA esters and organic acids in the mitochondria. These abnormal metabolites inhibit several mitochondrial enzymes, leading to a series of secondary biochemical abnormalities (61). Inhibition of *N*-acetyl-glutamate-synthetase and carbamyl phosphate synthetase are responsible for the hyperammonemia, which usually correlates with the level of organic acid accumulation (89,90). Impairment of pyruvate carboxylase and the shunt of malate explain the hypoglycemia and ketosis found in these patients, and inhibition of the glycine cleavage system may be responsible for the hyperglycinemia (61). Decreased ATP synthesis and hyperlactacidemia may result from inhibition of citrate synthase and pyruvic dehydrogenase (37).

B. Clinical and Common Laboratory Manifestations

The clinical presentation of patients with OA can be organized schematically into a severe neonatal form with metabolic distress, a chronic intermittent late-onset form, and a chronic progressive form (37). Asymptomatic patients have been found as a result of screening programs

and studies performed in relatives of affected individuals (36,37).

1. Neonatal Form

This is the most common and severe. The usual presentation is a neonate with a history of normal pregnancy, delivery, and a short disease-free period, who presents with poor sucking, vomiting, respiratory distress, hypotonia or dystonia, lethargy, and coma. These symptoms are usually attributed to sepsis or, in less severe cases, pyloric stenosis (1,37). Mild dehydration is frequent in MMA and PA (due to vomiting and osmotic diuresis) and a strong sweaty feet odor in urine and skin is present in patients with IVA. Seizures and a Reye's-like syndrome can be present in severely ill patients (1,37). Neutropenia, thrombocytopenia, or pancytopenia is frequent and acute pancreatitis has been diagnosed in decompensated patients with OA (91–93). Other complications include infections, generalized staphylococcal epidermolysis, and alopecia (37,94–96). Acute basal ganglion dysfunction should be suspected in any patient with sudden onset of dystonia and/or movement disorder. The globus pallidum is more frequently affected in MMA and PA (37,97–99), while abnormalities in the caudate and putamen are the most frequent basal ganglia involved in patients with glutaric aciduria type I (38,41,44,67).

The most characteristic biochemical abnormalities are metabolic acidosis, with elevated anion gap and ketosis. Mild hyperammonemia (200–500 μM) is usually present but levels could be as high as those in patients with urea cycle defect (>1000 μM) (89,90). Mild hyperlactacidemia and hypocalcemia, probably due to parathyroid hormone (PTH) resistance, are common (37,96). Amylase and lipase are increased if pancreatitis is present (91–93). Blood glucose levels are usually low, but in some patients they may be high, even before IV fluids have been started (100,101). This is particularly frequent in patients with ketolysis defects (i.e., 2-methyl-acetoacetyl-CoA thiolase, succinyl-acetoacetate-CoA-transferase deficiencies), who can present with hyperglycemia and ketosis resembling an episode of diabetic ketoacidosis (52). In contrast, patients with 3-OH 3-methyl glutaryl-CoA lyase deficiency, a defect affecting leucine catabolism and ketone bodies synthesis, present with metabolic acidosis (characteristic of OA) and hypoketotic hypoglycemia (characteristic of fatty acid oxidation defects) (51–52).

2. Late-Onset Form

In the intermittent, late-onset form, patients present with recurrent attacks of coma or lethargy with ataxia or dystonia. Acute hemiplegia, hemianopsia, and cerebellar hemorrhage have also been described (36–37). Increased protein intake or endogenous catabolism, due to an intercurrent illness, may trigger these crisis. The first attack may present at several months or years of age, or even in adolescence or adulthood, and has frequently been pre-

ceded by episodes of dehydration, anorexia, vomiting, failure to thrive, hypotonia, developmental delay, and/or other symptoms (37,102,103). Between attacks, clinical and laboratory evaluations may appear normal. However, the laboratory profile obtained during the attacks is similar to that described for the severe neonatal form, with the exception of hyperammonemia, which is less frequent (37).

3. Chronic Form

The chronic progressive form is characterized by persistent anorexia, failure to thrive, and vomiting. These symptoms are frequently attributed to gastrointestinal problems. Renal Fanconi syndrome or osteoporosis may develop. Hypotonia and muscle weakness can be present, mimicking congenital or metabolic myopathies. Developmental delay, progressive mental retardation, self-mutilation, and seizures sometimes accompany the above-mentioned symptoms (1,36,37,104).

C. Diagnosis

The most important test is the analysis of UOA performed by gas chromatography and mass spectrometry (GC/MS). Diagnostic possibilities of this test greatly increase if the urine is collected during the acute episode, when the characteristic profile for each OA is most likely to be found (45,105). In an acutely sick patient, the laboratory performing the test must be alerted so that the result can be available as soon as possible. Typical UOA profiles show elevated excretion of 3-OH-isovaleric acid and isovalerylglycine in IVA; and 3-OH-propionic acid, 3-hydroxyvaleric acid, methylcitrate, tiglylglycine and propionylglycine in PA. In MMA, there is a large increase of methylmalonic acid, with or without mild elevation of some of the propionate metabolites (37,45). Ketone bodies (3-OH-butyrate and acetoacetate) may be increased in decompensated patients with any of the above-mentioned OA. Another reliable and fast methodology for the diagnosis of several OA is the analysis of AC by tandem mass spectrometry (TMS). This methodology is highly sensitive and can be performed in blood spots on filter paper (Guthrie card), plasma, urine, or cerebrospinal fluid (CSF) (106–107). AC analysis allows the diagnosis of more than 20 different diseases (OA, fatty acid oxidation defects, and aminoacidopathies) and is being used not only for the diagnosis of symptomatic patients but also for mass newborn screening (108–110). Abnormal profiles can even be obtained from cord blood in asymptomatic newborns (111–112).

A typical AC profile shows a large increase of isovalerylcarnitine in IVA. However, other AC species, such as pivaloylcarnitine and 2-methylbutyrylcarnitine, have the same molecular weight and should be considered when the profile is being interpreted (53,113). In PA and MMA there is a large increase of propionylcarnitine. A slight increase of methylmalonylcarnitine is also usually

Table 4 Organic Acidemias

Common name	Enzyme deficiency	Pathway involved	Comments	References
Organic acidemias due to defects in branched-chain aminoacids				
Isovaleric aciduria	Isovaleryl-CoA dehydrogenase	Leu		36,37,46

present in the latter. It is important to consider that the increase in diagnostic AC species is limited in patients with severe carnitine deficiencies.

Acylglycines by GC/MS stable isotope dilution or TMS may also be used for diagnosis (53,105,113a).

Quantitative AA usually show a nonspecific elevation of glycine. Glutamine is also elevated, reflecting the hyperammonemia usually seen in these patients, with the exception of PA (113b,113c). Total and free carnitine levels are low, with elevation of the acylcarnitine/free carnitine ratio (37).

D. Treatment: The Acute Episode

Rapid recognition and treatment of the acute metabolic decompensation in patients with OA can be life-saving. Treatment should provide supportive therapy, promote anabolism, and remove the offending toxins and should be carried out in specialized centers (37,114).

1. Supportive Therapy

The treatment will depend on the patient’s clinical condition. A central line to ensure IV access and an arterial line for blood pressure monitoring and frequent blood drawing should be placed. Assisted ventilation, inotropics, albumin, and/or blood products are frequently needed.

Acutely ill patients with OA are usually dehydrated due to poor intake, vomiting, hyperventilation, and increased urinary losses. After fluid resuscitation is provided, IV hydration should be aimed at correcting dehydration over a period of 48 h. Rapid rehydration should be avoided due to the risk of cerebral edema. If pH is less than 7.20, metabolic acidosis should be only partially corrected with sodium bicarbonate at an initial dosage of 1–3 mEq/kg, repeated as needed. Overcorrection of the metabolic acidosis should be avoided, since this can increase cerebral edema. In severely acidotic patients sodium overload can be prevented by giving 30–50% of the sodium requirements as sodium bicarbonate instead of sodium chloride.

Blood gases, electrolytes, BUN, glucose, calcium, ammonium, and urine ketones should be monitored every 2–4 h. Initial potassium levels are usually normal or high in acutely ill patients, but these levels might be artificially increased due to the acidosis. In fact, potassium requirements are elevated due to the usual history of vomiting that precedes the admission and to the treatment with a high GIR and insulin (see below). Liver function tests, creatinine, amylase, and lipase levels should be checked initially and repeated as needed. Acute pancreatitis should be treated when present (91–93). Cultures should be obtained and antibiotics started. Staphylococcal and *Candida* infections should be considered in the differential diagnosis, and complete blood count (CBC) and platelet count should be evaluated daily.

2. Anabolism

It has been shown that endogenous production is an important source of abnormal metabolites in nonacutely ill patients with OA. This production is probably due to protein turnover (115,116) and is increased by fatty acid breakdown and intestinal production of propionate in patients with PA and MMA (87,88). These endogenous sources of toxic metabolites become even more important in severely ill patients and treatment should be aggressive to decrease their production (37). Oral intake is usually not possible and IV nutrition should be used to promote anabolism. Initially, this goal can be partially achieved by giving a high GIR to provide at least 8–10 mg/kg/min (Table 2). It is important to note that even with such a GIR, caloric intake is not sufficient to cover the patient's needs (Table 3), which are increased during the decompensation (117). Patients with OA can develop hyperglycemia and glycosuria, even with low GIR. We have documented an inadequate insulin response to hyperglycemia during the acute decompensation (118), which may or not be associated with pancreatitis (91). If hyperglycemia develops, insulin should be used (37,119). The requirements vary depending on the severity of the patient's condition and the GIR. In our experience, in a severely ill patient receiving a GIR of 8–10 mg/kg/min, a dosage of 0.10–0.15 U/kg/h is enough to control hyperglycemia, but it is advisable to start with a lower dosage (0.05 U/kg/h) and to adjust it according to blood sugar levels. Insulin requirements decrease when acidosis improves.

Plasma ammonia levels decrease in parallel with those of the organic acids (90). Once acidosis has been corrected and ammonia and transaminase levels are close to normal, fats can be added to the treatment. If amylase and lipase levels are high or oral intake is not possible, IV lipids (Intralipid) should be used, starting at 0.5 g/kg/day and increasing gradually to 2 g/kg/day. When the oral route can not be used for more than 48 h, total parenteral nutrition (TPN) should be considered. TPN has been successfully used in chronic and acutely ill patients with OA and allows an effective anabolism that cannot be achieved with glucose and lipids alone (119,120). An ideal IV amino acid mixture should contain lower concentration of those AAs that are precursors of the increased organic acid (i.e., leucine in IVA). Such preparations are not available in the majority of the medical centers. As an alternative, any available amino acid solution can be used cautiously. We start with an amount that provides 30–50% of the recommended intake of the AA involved in the metabolic block. This amount can be increased gradually depending on the results of blood gases, ammonium, and serum AA. Levels of the abnormal metabolites in urine (UOA) or blood (acylcarnitines) should also be evaluated to monitor the response to treatment. With a high caloric supply from carbohydrates and fat, an IV amino acid dosage of 1–1.5 g/kg/day can be achieved, but special mixtures, deprived of the offending amino acids, might be required to supply

more protein. As patient improves, the oral/NG tube route can be restarted (see section on long-term treatment).

3. Detoxification

In IVA and MMA, the organic acids are effectively excreted through the urine. Therefore, detoxification procedures should be indicated only in those severely ill patients who do not respond rapidly to treatment in spite of maintaining a good urinary output (37,114). In contrast, urinary excretion of propionic acid is poor, therefore detoxifying procedures should be considered early in the treatment in patients with PA (37,121). The most effective detoxification method is hemodialysis, which allows a high clearance of organic acids, amino acids and ammonium. Hemofiltration, peritoneal dialysis, or blood exchange transfusions can be used when the former is not available. Continuous venovenous hemofiltration is well tolerated by newborns or infants and allows rapid toxin removal (114). Peritoneal dialysis is available in most centers and is more effective in newborns than children. The dialysate should be warmed and buffered with bicarbonate. Hypertonic solutions can be used when overhydration is present. In those circumstances, hyperglycemia can develop and insulin might be needed.

To treat the hyperammonemia, sodium benzoate (250 mg/kg/day) can be used alone, or in conjunction with any of the above-mentioned detoxification procedures (37,122). The amount of sodium provided through this source should be accounted for when the daily sodium requirements are calculated (see section on treatment of urea cycle defects). Intravenous carnitine is another resource for toxin removal. This therapy will correct the decreased levels of free carnitine, provide enough substrate for the synthesis of nontoxic acylcarnitine compounds (i.e., isovalerylcarnitine, propionylcarnitine, etc.) that are excreted through the urine, and restore the intramitochondrial levels of CoA (36,37). After obtaining a sample for basal levels, a dosage of 100–400 mg/kg/day (divided every 4–6 h) should be given. The highest dosage should be used in newly diagnosed patients who may have severe carnitine depletion.

In patients with IVA, treatment with L-glycine increases the conversion of isovaleryl-CoA to the nontoxic compound isovalerylglycine, which is excreted through the urine (36,123). Oral or nasogastric-tube supplementation of L-glycine (250–600 mg/kg/day, divided in four to eight doses) prepared in a 100 mg/ml water solution should be given during the acute episode (36,37). Another potential resource for toxin removal is the administration of cofactors: biotin (10–20 mg/day) in PA and hydroxycobalamin (1–2 mg/day IM) in MMA (37). However, patients with severe neonatal presentation rarely respond to vitamin treatment. Clinical improvement correlates with correction of the metabolic acidosis, hyperammonemia, and ketonuria. Patients with MMA may develop persistent lactic acidemia due to chronic glutathione deficiency,

which can be corrected with high dosages of vitamin C (2 g/day) (124). Lactic acidosis secondary to thiamine deficiency has been described in PA patients (125).

E. Long-Term Management

When the patient's condition allows for it, PO or NG feedings can be started. Natural protein is restricted to meet the recommended amounts of the AAs involved in the metabolic block, and can be initially provided with an infant formula. Total protein requirements for age and gender are achieved by adding special formulas devoid of the offending amino acids (36,37).

Recent studies suggest that energy requirements might be normal or even low in OA patients out of crisis (126). However, energy intake should be adequate to meet the patient's needs for normal growth, to maintain anabolism when poor appetite is present, and also should cover the increased requirements during intercurrent illnesses (37). Caloric requirements can be met with the use of protein-free powders (i.e., Prophree, Ross Laboratories; 80056, Mead Johnson; Duocal, SHS). As an alternative, carbohydrate supplements or oil (except for olive oil in PA and MMA patients) can be added to the formula when these products are not available. Osmolarity of the final preparation should be considered to prevent diarrhea.

Long fasting periods should be avoided (115) and dietary treatment should meet all the requirements for micronutrients and minerals. Iron and calcium supplements are frequently needed. Oral carnitine (in IVA, PA, and MMA) and/or glycine (for IVA) supplementation should be maintained, and vitamin therapy should only continue if a positive response has been documented. Metronidazole has been shown to be effective in decreasing the production of propionate by the gut flora (37,88,127). Recommended dosage is 10–20 mg/kg/day. Due to the possible side effects of metronidazole (leukopenia, peripheral neuropathy, and pseudomembranous colitis), it has been recommended to restrict its use to 10 consecutive days every month (37). We have not seen adverse effects after using the drug at 10 mg/kg/day daily for prolonged periods of time.

The long-term prognosis varies depending upon the particular OA, age at onset, response to vitamin therapy, and residual enzyme activity. Several mutations have been found (128–130), and clear genotype/phenotype has been described for a particular group of MMA patients (131).

Family compliance, psychological adjustment, and education are important for successful treatment. Nasogastric or gastrostomy feedings are usually needed and frequent hospitalizations are common in the most severe cases. Guidelines should be given to parents and primary physicians for special situations such as intercurrent illnesses, immunizations, anesthesia, or surgery (37,132, 133).

Reported long-term outcome has varied from a normal development to different degrees of neurological in-

volvement, including mental retardation and movement disorders (134–140). Other long-term complications, including poor growth, malnutrition, cutaneous lesions (141), deficiency of trace elements (142), and osteoporosis can be prevented if good metabolic control and proper nutritional treatment can be achieved. Cardiomyopathy has been reported in some patients with OA (37,56,143). Tubular dysfunction and progressive renal insufficiency are common in MMA patients (37,144–148). It is not clear if these long-term manifestations can be prevented with optimum metabolic control. Kidney transplantation or combined kidney and liver transplantation have been performed in several patients with MMA. In general, better metabolic control and higher protein tolerance were obtained, but decompensations, mental deterioration, or acute basal ganglia lesions could not be prevented with these treatments (149,151). Similar experience has been reported for PA patients undergoing liver transplant (140,152).

Early diagnosis and intensive treatment are key factors in improving long-term prognosis (36,37). Therefore, the availability of newborn screening with tandem mass spectrometry opens a new chapter for the outcome of these diseases (108–111).

IV. FATTY ACID OXIDATION DEFECTS

A. Pathophysiology: Mitochondrial Fatty Acid Oxidation

Mitochondrial fatty acid oxidation (FAO) disorders are a relatively new group of IMD of increasing relevance. Understanding the FAO process is essential to interpret the pathophysiology of these diseases and to develop adequate strategies for treatment. FAO is the major source of energy for skeletal muscle and the heart, while liver oxidizes fatty acids (FA) primarily during fasting (153,154). The FAO process begins when triglycerides, stored in adipose tissue, are broken down to glycerol and fatty acids, mainly long-chain. The latter are transported in blood bound to albumin and enter liver cells through a specific transport system (155). Carnitine, an important metabolite in fatty acid oxidation, is transported into the tissues by a plasma membrane carnitine transporter (CT) specific for kidney, muscle, and heart (153,154). Once inside the cell, FFA of carbon length 18 or shorter are oxidized in the mitochondria, while longer-chain fats are metabolized in the peroxisomes (156). Fatty acids are activated to their corresponding acyl-CoA by specific acyl-CoA synthetases. The resulting acyl-CoAs enter the mitochondria in different ways, depending on their chain length. Short- (4–6 carbons) and medium-chain (6–10 carbons) acyl-CoAs directly enter the mitochondrial matrix. In contrast, long-chain acyl-CoAs (12–18 carbons) enter the mitochondria through a complex active transport system (Fig. 3). Initially, long chain acyl-CoAs are conjugated to carnitine

by carnitine palmitoyl transferase I (CPT-I), located in the outer mitochondrial membrane. There are two tissue-specific isoforms of CPT-I, hepatic and muscular, but only patients with the hepatic form have been described so far (154). Long-chain acylcarnitines are carried through the intermembranous space by a carnitine–acylcarnitine translocase (translocase). Finally, another enzyme, carnitine palmitoyl-transferase II (CPT II), bound to the inner mitochondrial membrane, releases carnitine and long-chain acyl-CoAs into the mitochondrial matrix (153,154). Carnitine is recycled and acyl-CoAs of all chain lengths undergo a series of cyclic enzymatic reactions (Fig. 3).

The first step in the mitochondrial FAO of saturated straight-chain fats is a dehydrogenation of the acyl-CoA to enoyl-CoA. This reaction is catalyzed by four related enzymes, the acyl-CoA dehydrogenases (ACDs): very

long-, long-, medium-, and short-chain acyl-CoA dehydrogenases (VLCAD, LCAD, MCAD, and SCAD, respectively), which differ in their chain-length specificity (153,156). Nevertheless, there is some degree of overlap in their activity. Recent data suggest that the main enzyme involved with long straight-chain fatty acid metabolism is VLCAD and that LCAD may play a role in the metabolism of branched-chain fatty acids (157). All dehydrogenases have flavin adenine dinucleotide (FAD) bound at the active site. Electrons released during these reactions are channeled by the electron transfer flavoprotein (ETF), a mitochondrial matrix enzyme with α - and β -subunits, and the ETF-ubiquinone oxidoreductase (ETF-QO), a component of the inner mitochondrial membrane that feeds the electrons into the respiratory chain via ubiquinone (156,158). ETF and ETF-QO defects impair not only

the dehydrogenases involved in fatty acid oxidation but also those involved in the metabolism of branched-chain amino acids (valine, isoleucine, and leucine), lysine, hydroxylysine, tryptophan, and sarcosine.

In the second step of FAO, the enoyl-CoAs produced by the ACDs are hydrated to hydroxyacyl-CoAs by an enoyl-CoA-hydratase. Then, the hydroxyacyl-CoAs undergo dehydrogenation to ketoacyl-CoAs by a hydroxyacyl-CoA dehydrogenase and finally there is a cleavage of the thioester bond by an acyl-CoA ketothiolase (Fig. 3). This process completes one turn of the FAO cycle and results in the release of acetyl-CoA and a new acyl-CoA molecule that is two carbons shorter (153,156). The exact mechanism of the last three steps varies for substrates of different chain length. For long-chain acyl-CoA substrates the reactions are carried by a mitochondrial trifunctional protein (MTP) with enoyl-CoA-hydratase, hydroxyacyl-CoA dehydrogenase, and ketoacyl-CoA thiolase activities (159,160). This protein is an octamer composed of four α - and four β -subunits. The α -subunits contain the long-chain 3-enoyl-CoA hydratase activity and the long-chain 3-hydroxy-acyl-CoA dehydrogenase (LCHAD) activities; the β subunit has the long-chain 3-ketoacyl-CoA thiolase activity (161).

Biochemical studies have identified two groups of LCHAD-deficient patients. The first, and most common, has an isolated LCHAD deficiency due to mutations in the LCHAD coding region of the α -subunit gene. Activities of the other two enzymes of the trifunctional protein are preserved in these patients. In the second group all three enzyme activities are deficient (162). For shorter-chain fatty acids, individual enzymes, each one with a single activity, have been identified: short-chain-enoyl-CoA-hydratase (crotonase), short-chain 3-hydroxyacyl-CoA dehydrogenase (SCHAD), and medium-chain 3-ketoacyl-CoA thiolase (153,156).

The acetyl-CoA moieties produced during the FAO are used as a source of energy through the tricarboxylic acid cycle. Under fasting conditions, acetyl-CoA moieties produced in the liver become the substrate for the synthesis of ketone bodies that are used as fuel by several tissues, including the brain. Two enzymes are involved in ketone bodies synthesis: hydroxymethylglutaryl-CoA-synthase and hydroxymethylglutaryl-CoA lyase (Fig. 3) (52,163). The latter is also the final enzyme of leucine catabolic pathway.

B. Clinical Presentation

Several enzymatic defects in FAO and ketogenesis have been found in humans, all inherited as autosomic recessive diseases. These defects have become one of the most important group of IMD, due to the number of patients and the severe outcome. In a series of 107 patients, Saudubray et al. found that 50 patients and 47 siblings died, 30% within the first week and 60% before age 1 year (164).

1. Main Clinical Features

The most common diseases are MCAD, LCHAD, and MAD deficiencies, but it is possible that many patients with long-chain fatty acid oxidation defects still die without recognition of their underlying disease. Table 5 summarizes the known defects in saturated straight-chain fatty acid metabolism found in humans and their most distinctive features. Clinical presentation in patients with FAO defects ranges from completely asymptomatic to severe malformations or unexplained sudden death in infancy or adulthood. As expected by the important role of FAO in liver, heart, and muscle the main clinical presentation of FAO defects is dominated by symptoms related to these organs. Neurological symptoms are also common during the acute crisis and they might be in part related to hypoglycemia and impaired ketogenesis.

Neonatal presentations, including malformations, lethargy, hypotonia, heart-beat abnormalities, liver involvement, or sudden death, were thought to be limited to CPT-II, translocase, and MAD deficiencies (158, 164,182) but neonatal cases of MCAD, LCHAD, and VLCAD deficiencies have also been reported (164, 183,184). In classic cases, patients with FAO defects appear normal until the first episode of metabolic decompensation occurs in infancy or early childhood. A history of a dead sibling is common (164). The metabolic crisis is characterized by vomiting, followed by lethargy, hypotonia, and slight liver enlargement. Respiratory distress due to cardiac insufficiency and/or metabolic acidosis can be present. A prolonged period of fasting, and/or hypercatabolism can trigger the episode. Symptoms are usually erroneously attributed to an intercurrent illness or cyclic vomiting syndrome (153,164). Patients can recover from the initial crisis, and repeat another episode, remaining asymptomatic in between. Liver insufficiency can be severe, leading to a Reye-like syndrome, complicated by hypothermia and gastrointestinal bleeding (185). Cholestasis has also been reported in patients with LCHAD deficiency (164,175,186).

Cardiac involvement is characterized by hypertrophic or, less commonly, dilated cardiomyopathy. Severe arrhythmia (ventricular and supraventricular tachycardia, ventricular fibrillation), conduction defects (bundle branch block, atrioventricular (AV) block, sinus node dysfunction), and cardiac insufficiency can be found in neonates, especially in those with CPT-II, translocase, and LCHAD deficiencies (154,164,170,182), which are diseases in which there is an accumulation of long-chain-acyl-CoAs and long-chain acylcarnitines. Heart-beat disorders have not been observed in CT, CPT-I, or MCAD deficiencies. Pericardial effusion and endocardial fibroelastosis have been described (187).

Symptoms of skeletal muscle involvement have been described for the majority of the FAO defects, and they are especially common in patients with CPT II-adult type-, LCHAD and mild MAD deficiencies. Usual mani-

Table 5 Defects in Mitochondrial Oxidation of Saturated Straight-Chain Fatty Acids

Known enzyme deficiencies in humans	Main organ involved			Distinctive features
	Liver	Muscle	Heart	
Defects in plasmatic membrane transport				
Carnitine transporter (CT)	Yes	Yes	Yes	Very low plasma carnitine levels (165).
Fatty acid transport protein (FATP)	Yes	No	No	Severe episodic liver failure. Two patients reported (155).
Defects in mitochondrial transport				
Carnitine palmitoyltransferase I (CPT-I)	Yes	No	No	Plasma carnitine elevated or normal. Renal tubular acidosis reported (166).
Carnitine-acylcarnitine translocase (translocase)	Yes	Yes	Yes	Neonatal presentation. Heart beat abnormalities. Hyperammonemia (167).
Carnitine palmitoyltransferase II (CPT-II)	Yes	Yes	Yes	Severe neonatal presentation. Renal and brain abnormalities reported (168,169).
Neonatal	Yes	No	Yes	Less frequent (169,170).
Infantile	No	Yes	No	Most common cause of rhabdomyolysis and myoglobinuria (169).
Late onset (most frequent)	Yes	Yes	Yes	
Mitochondrial beta oxidation				
Very long-chain acyl-CoA-dehydrogenase (VLCAD)	Yes	Yes	Yes	Neonatal and infantile presentation. Arrhythmias (171).
Medium-chain acyl-CoA-dehydrogenase (MCAD)	Yes	No	No	Most frequent FAO defect. Reye-like episodes. Sudden death (172).
Short-chain acyl-CoA-dehydrogenase (SCAD)	Yes	Yes	No	Variable phenotype. Ophthalmoplegia, myopathy, metabolic acidosis (173,174).
Long-chain 3-hydroxy-acyl-CoA-dehydrogenase (LCHAD)	Yes	Yes	Yes	Retinitis pigmentosa, peripheral neuropathy (175,176).
Mitochondrial trifunctional protein (MTP)	Yes	Yes	Yes	Few cases reported. More severe than LCHAD deficiency (177).
Short-chain 3-hydroxy-acyl-CoA-dehydrogenase (SCHAD)	Yes	Yes	Yes	Few cases reported. Variable phenotype. Ketonuria, muscle and liver isoforms (?) (178).
Medium-chain 3-ketoacyl-CoA thiolase deficiency (MCKAT)	Yes	Yes	Yes	Few patients known. Typical organic acid profile (179,180).
Electron transfer				
Multiple acyl-CoA-dehydrogenase (MAD)				
Electron transfer flavoprotein (ETF)	Yes	Yes	Yes	Great phenotypic variation from severe neonatal form with malformations to progressive muscle weakness with lipidic myopathy (158).
ETF-ubiquinone-oxidoreductase (ETF-QO)	Yes	Yes	Yes	
Ketone body synthesis				
Hydroxymethylglutaryl-CoA-synthetase (HMG-S)	Yes	No	No	Few patients reported (163,181).
Hydroxymethylglutaryl-CoA-lyase ^a (HMG-L)	Yes	No	No	Hypoketotic hypoglycemia and severe metabolic acidosis. (51,52,163).

Abnormalities related to liver, muscle, and heart involvement are described in the text.

^aEnzyme involved in ketogenesis and leucine catabolism.

festations are hypotonia and/or progressive proximal weakness. Acute episodes of muscle pain or cramps, fatigue, and/or exercise intolerance with rhabdomyolysis can appear in response to stress, prolonged exercise, or cold, and can produce acute renal failure. Muscle involvement has not been associated to CPT-I deficiency (154,164,188). Malformations are mainly associated with MAD deficiency, but have also been described in CPT-II deficiency. Most common dysmorphic features are a high forehead, wide-spaced eyes, and low-set ears, resembling a Zellweger syndrome. Renal dysplasia (polycystic kidneys) and brain malformations have also been reported (153,158,164).

Retinitis pigmentosa and peripheral neuropathy have been found in patients with LCHAD deficiency. The former seems to be related to deficiency of docosahexaenoic acid (DHA). Endogenous synthesis of DHA may be impaired in LCHAD-deficient patients and a preliminary study treating these children with oral DHA has shown promising results (189). Mental retardation and/or other neurological sequelae are observed mostly in patients who had severe encephalopathy associated to Reye's-like syndrome (164,185).

Other manifestations, specific for a given defect, are outlined in Table 1.

2. Maternal Complications During Pregnancy of Affected Fetuses

The association between LCHAD deficiency in the fetus and maternal pre-eclampsia, the syndrome of hemolysis, elevated liver enzymes, and low platelets (HELLP syndrome) or acute fatty liver of pregnancy (AFLP) has been well documented (162,190–192). These complications have been reported in up to 79% of pregnancies with fetuses affected with LCHAD, while there were no complications if the fetus was heterozygous or normal. Ibdah et al. reported that the complications were related to the presence of the prevalent E474Q mutation on one or both alleles (homozygous or compound heterozygous) of the LCHAD-affected fetus (162,191). However, a recent report describes three families with trifunctional enzyme deficiency and maternal hepatic dysfunction in pregnancy not associated with the common E474Q mutation (193).

Affected LCHAD patients show a higher incidence of prematurity, asphyxia, intrauterine growth retardation, and intrauterine death than their unaffected siblings (190). These findings highlight the importance of obtaining molecular diagnoses for patients and parents, and to provide adequate genetic counseling and molecular prenatal diagnosis when indicated (194). More recently, AFLP has also been reported in pregnancies with fetal CPT-1, MCAD, and SCAD deficiencies, raising the possibility of a common mechanism producing liver disease in mothers carrying fetuses affected with FAO defects (195–197).

3. Sudden Infant Death

Many FAO defects have been associated with episodes of sudden, unexpected, infant death. Different studies analyzing postmortem specimens of liver, bile, cultured fibroblasts, or blood spots in filter paper have estimated that 2–5% of sudden infant death syndrome (SIDS) can be attributed to FAO defects (198–200). They include deficiencies of the carnitine transporter, translocase, VLCAD, LCHAD, MCAD, SCHAD, and MAD (171,198–204). The mechanism of sudden death in these patients is not clear, but acute arrhythmia may account for the unexpected deaths in children with abnormalities in long-chain fatty acid metabolism (182). Acylcarnitine analysis by tandem mass spectrometry in postmortem bile or in the newborn screening samples (Guthrie card) stored by state programs have significantly expanded the retrospective diagnosis of fatty acid oxidation disorders (200,204,205). With the availability of newborn screening by tandem mass spectrometry and early treatment, it is reasonable to expect that the number of patients who experience sudden death due to FAO defects will decrease significantly.

Other metabolic diseases, not involving fatty acid metabolism, have also been found in children who experience sudden or unexpected death in infancy. Among others they include glutaric aciduria type I, myophosphorilase deficiency, lysinuric protein intolerance, and defects of the respiratory chain (1,200,206–209).

C. Laboratory Abnormalities

The most common laboratory abnormality found during an acute episode is hypoglycemia. Ketone bodies can be detected in urine, but in smaller amounts than expected for the degree of hypoglycemia (hypoketotic hypoglycemia). Total nonesterified fatty acids (NEFA) are increased, and the NEFA to ketone body ratio is abnormally high (>3) when the sample is obtained before IV glucose is started (210). As an exception to the rule, patients with SCHAD deficiency may present with large amounts of ketones in urine (178).

Elevated liver enzymes, mild hyperammonemia, and slight metabolic acidosis are common. Abnormal clotting factors are seldom observed. Very high levels of CK (several thousands) and aldolase reveal muscle involvement. Hyperuricemia appears to be a common finding in MCAD deficiency and mild elevation of lactic acid is present in LCHAD deficiency (175,211). Myoglobinuria can be present in any FAO defect affecting skeletal muscle, and is a common presentation in the adult form of CPT II deficiency (153,154,164).

During the acute episode, a liver biopsy under light microscopy shows micro- and macrovesicular steatosis. These abnormalities usually lead to the diagnosis of Reye syndrome. However, the electron microscopy will lack the characteristic mitochondrial changes of Reye syndrome (188,212). Fibrosis and cirrhosis has been described in

liver biopsies of VLCAD and LCHAD deficiencies. Pathology of skeletal and cardiac muscle shows fatty infiltration (lipidic myopathy) (153,158,188).

D. Diagnosis

Once the diagnosis of a FAO defect is suspected, samples should be immediately obtained for specialized metabolic studies. They must include blood spots in filter paper (Guthrie card), serum, and urine. Analysis of acylcarnitines (AC) by TMS in plasma or blood spots in filter paper have become the most important tool for diagnosis of FAO defects. This methodology is highly sensitive and abnormal profiles can be obtained even when samples are collected out of crisis. In rare cases an AC profile can be misread as normal when free carnitine levels are very low or when the sample is obtained out of crisis in nonfasting conditions. Typical AC profiles can be identified for CPT-II/translocase, LCAD/VLCAD, MCAD, SCAD, LCHAD, and MAD as well as for HMG-CoA-lyase deficiencies (106,107,213–215). In the transport defects of long-chain fatty acids and the carnitine uptake deficiency AC are uninformative; in CPT-I deficiency, low levels of all AC species (including acetylcarnitine), combined with high levels of free carnitine, are suggestive of the defect (216). AC have been reported as normal in children with SCHAD (203) and HMG-CoA-synthase deficiencies (217). AC analysis performed in the newborn screening card have allowed retrospective diagnosis in patients who died of MCAD, CPT II, VLCAD, translocase, and MAD deficiencies (111,169,185,202,204,218). Tandem mass spectrometry is also being employed by many screening programs around the world for the neonatal detection of FAO defects as well as other IMD (109–111,219,220). It is likely that early diagnosis and treatment will change the natural history of the disease for many patients (221).

Urine OA profile is the second choice for the diagnosis of FAO defects. It is important that analysis and interpretation be performed in an experienced center. Several defects can be diagnosed if samples are obtained during the acute episode; they include HMG-CoA-lyase, MCAD, LCHAD, SCAD, MCKAT, SCHAD, and MAD. However, frequently the results may be suggestive of, but nonspecific for, an FAO defect or give a false-negative result when samples are collected after the patient has been started on supportive therapy (105,188,222). Therefore, patients with FAO defects can be misdiagnosed if only standard OA analysis is performed.

Quantitative analysis of acylglycines by GC/MS stable isotope dilution or tandem mass spectrometry is an alternative method for diagnosis when acylcarnitines are not available and/or when UOA analysis gives a negative result (105,223).

Carnitine levels are informative. Total and free carnitine levels are normal or high in CPT-I deficiency and extremely low in the CT defect. In all other FAO diseases, total and free carnitine are usually decreased, and the per-

centage of acylcarnitines is increased (164,188). Another method for the diagnosis of FAO defects is to measure the levels of individual free fatty acids in plasma by GC/MS (224). This method is sensitive but time consuming. We have shown that in MCAD and MAD deficiencies, levels of individual fatty acids correlate well with those of the acylcarnitine of the same carbon length (221,225). However, short-chain-3-hydroxy fatty acids are not esterified with carnitine and therefore their measurement might be important for the diagnosis of SCHAD, when the acylcarnitine profile is noncontributory (226).

In vitro flux studies with labeled fatty acids in lymphocytes of fibroblasts are another useful tool for diagnosis (227,228). Fasting or loading tests are less frequently needed and should only be performed in experienced centers if the above-mentioned specialized tests are not informative (164). Enzyme activity can be measured in the majority of these conditions in cultured fibroblasts, liver, and/or muscle. Tissue specificity is known for CT, and CPT-I, and has also been postulated for SCHAD, while HMG-CoA-synthase is only expressed in liver.

Molecular studies are available for most of the FAO defects (229). Common mutations have been described in MCAD and LCHAD deficiencies. Several studies have shown that a missense mutation 985 A>G, accounts for the majority of the mutant alleles in MCAD deficiency, being more prevalent in northern Europeans (219,229–231). In LCHAD deficiency, a common 1528 G>C mutation has been identified (175,229).

E. Treatment: The Acute Episode

Acutely ill patients with suspected FAO defect should be treated in an experienced pediatric intensive care unit. Delay in proper treatment may result in death or permanent brain damage (164,188).

1. Supportive Therapy

Intravenous hydration should be given cautiously because patients with hyperammonemia may have cerebral edema and patients with heart involvement may develop cardiac insufficiency. Intracranial pressure monitoring should be considered if brain swelling is suspected and mannitol can be used if needed. Clotting factors may be required in patients with severe liver dysfunction and H₂ blockers should be given to prevent gastrointestinal bleeding.

Salicylates and valproic acid are contraindicated due to their potential mitochondrial toxicity and should be investigated as a potential cause of the metabolic crisis (232). Epinephrine and glucagon have a lipolytic effect and therefore should be avoided.

2. Anabolism

In order to suppress lipolysis, intravenous fluids should provide a glucose infusion rate of 10 mg/kg/min or more,

regardless of the blood sugar levels found on admission (164,188). If patients develop hyperglycemia, IV insulin can be given. Due to the required high glucose concentration in the IV fluids, a central line is needed. As an alternative, glucose (10% glucose polymers solution) can be provided via NG tube. In patients known to have long-chain fatty acid defects, medium-chain triglycerides (1–3 grams/kg/day) can be added via NG tube as soon as the GI tract allows for it.

3. Detoxification

Treatment with intravenous carnitine (100–200 mg/kg/day) is life saving for the carnitine transport defect (CTD). There is general agreement to the use of carnitine (50–100 mg/kg/day) in patients with short- and medium-chain defects (153,156,164). However, use of carnitine for defects involving long-chain fatty acids is still controversial, due to the possible role of long-chain acylcarnitines in the development of heart beat abnormalities (164). A recent study also shows that medium- and long-chain acylcarnitines suppress mitochondrial fatty acid transport through inhibition of translocase (233). A conservative approach is to start treatment with 50% of the usual dosage and adjust it to maintain free carnitine levels within normal limits.

Riboflavin (100–200 mg/day) should be tried in patients with MAD and SCAD deficiencies, even though only a few patients with mild variants have been reported to respond to it (188).

F. Long-Term Management

Carnitine is the only treatment needed for the CT deficiency. For all other FAO defects, the key to chronic treatment is to avoid prolonged fasting and to use a fat-restricted diet. Guidelines for treatment of the different conditions are outlined in Table 6. The formula to be used depends on the enzymatic defect. There is a rationale for the use of medium-chain triglycerides (MCT) in patients with impaired metabolism of long-chain fatty acids (FATP,

CPT-I, translocase, CPT-II, VLCAD, LCHAD, MTP). In contrast, the use of MCT is contraindicated for patients with short- or medium-chain FAO defects as well as for MAD and defects in ketogenesis. Enough essential fatty acids (linoleic and α -linolenic) acids should be provided to avoid deficiencies. Dietary supplementation with DHA appears to be beneficial in LCHAD-deficient patients to prevent retinal damage (189). In addition to the low-fat diet, patients with MAD should also have a mild protein restriction. Patients HMG-CoA-lyase may likewise benefit from leucine restriction.

Blood glucose, liver enzymes, uric acid, ammonia, and CK are late markers of a metabolic crisis (188) and cannot be used to monitor fasting tolerance or response to dietary changes. In contrast, acylcarnitines have been shown to be a sensitive marker. AC levels tend to increase rapidly during short fasting periods and reflect the accumulation of toxic metabolites (221,225). Treatment of infants and young children with severe enzyme deficiencies needs to be aggressive and may require frequent feedings during the day and overnight NG or G-tube feedings (164). In children over 2 years of age, the diet can be supplemented with uncooked cornstarch. In children with poor appetite who have severe enzyme deficiencies, cornstarch can be given at regular intervals throughout the 24 h, as used for patients with glycogen storage diseases. In less severely affected patients uncooked cornstarch (1–2 g/kg) can be used at bedtime only. We have documented the beneficial effect of uncooked cornstarch in decreasing abnormal metabolites in children with MCAD, MAD (221,225), and LCHAD deficiencies. As an alternative for young children whose amylase activity is deficient, we have successfully used cornstarch with exogenous amylase (221).

Education and family compliance are essential to avoid life-threatening decompensations, which can occur very rapidly in young patients. Long-term prognosis varies according to the disease, residual enzyme activity, age at diagnosis, and long-term treatment. The mortality rate has been estimated at 25% for MCAD deficiency; the ma-

Table 6 Guidelines for the Nutritional Treatment of Fatty Acid Oxidation Defects

	Metabolic abnormality		
	Long-chain FAO	Medium- and short-chain FAO, HMG-CoA-synthase	Electron transfer (MAD), HMG-CoA-lyase
Calories	>20% RDA	>20% RDA	>20% RDA
Protein	RDA	RDA	7%
Fat	25–30%	15–25%	15–20%
MCT	15–20% (1–3 g/kg/d)	Contraindicated	Contraindicated
LCFA	±10%	—	—
EFA	4%	4%	4%
CHO	60–65%	60–75%	73–78%

MCT, medium-chain triglycerides; LCFA, long-chain fatty acids; EFA, essential fatty acids; CHO, carbohydrates. Fat and CHO are expressed as % or total calories.

majority of these patients die in the initial episode (185,234). Long-term complications in MCAD deficiency include developmental delay, muscle weakness, failure to thrive, and cerebral palsy (172,185,234). To prevent the mortality and severe morbidity of MCAD, it would be mandatory to implement newborn screening programs (108,172,185, 219).

Limited information is still available for the long-term prognosis of patients with other FAO defects, but it is likely that, as shown for MCAD deficiency, newborn screening may change the natural history of these diseases (221).

V. PRIMARY LACTIC ACIDEMIAS

The primary lactic acidemias (PLA) are a group of IMD with variable clinical presentation, including life-threatening episodes of metabolic acidosis, and complex biochemical, enzymatic, and molecular diagnosis. They represent abnormalities in pyruvate metabolism that are recognized biochemically by its primary consequence, hyperlactacidemia, and clinically by symptoms reflecting energy deficiency (1,235). Pyruvic acid produced by the glycolytic pathway can follow different metabolic fates. To produce energy, pyruvate enters the mitochondria and undergoes aerobic catabolism via acetyl-CoA, the tricarboxylic acid cycle (TCA) and the respiratory chain (Fig. 4). During fasting periods, pyruvic acid can also be an intermediary substrate for gluconeogenesis, via oxaloacetic acid. A block in any of the many enzymatic steps involved in those pathways can increase pyruvic acid levels, with simultaneous elevation of lactic acid and alanine, and limit the production of energy or glucose synthesis. In general, the PLA can be classified into four groups:

- Defects in pyruvate dehydrogenase complex
- Defects in the TCA cycle
- Defects in gluconeogenesis
- Defects in oxidative phosphorylation (respiratory chain)

A. Pathophysiology and Clinical Presentation

Correlation between symptoms and enzymatic block is difficult: one enzymatic defect can present with different phenotypes and different enzyme deficiencies can give a similar clinical presentation. A detailed description of each enzymatic defect is beyond the scope of this chapter, so we will mainly address those conditions that can present with severe hyperlactacidemia, requiring emergency treatment.

1. Pyruvate Dehydrogenase Complex

Deficiency of pyruvate dehydrogenase complex (PDHC) is one of the most frequent causes of PLA. This thiamine-dependent enzymatic complex is responsible for the decarboxylation of pyruvate to acetyl-CoA (Fig. 4) and is

made of four different components: $E_1-\alpha$, $E_1-\beta$, E_2 , and E_3 . Two regulatory components at the E_1 level are known: pyruvate dehydrogenase kinase and pyruvate dehydrogenase phosphatase, which inactivate and activate, respectively, the enzyme activity. An E_3 -binding protein (formerly called X-lipoate protein) is also part of the complex (235,236). Deficiencies in different components of the PDHC have been reported, but the most common is the deficiency of the $E_1-\alpha$ subunit.

Three different clinical presentations have been outlined. The most severe is neonatal, characterized by overwhelming lactic acidosis at birth. These children present soon after birth with poor feeding, hypotonia, lethargy, and respiratory distress. Mild dysmorphism (frontal bossing, low nasal bridge, upturned nose, long philtrum) has been described, and death occurs within the first weeks of life (236,237). A less severe picture appears in infants and young children with hypotonia, developmental delay, and seizures. The third form presents with acute, intermittent episodes of ataxia, which can be triggered by a high-carbohydrate intake (235–237). The $E_1-\alpha$ subunit is encoded by an X-linked gene. However, due to the important role of the PDHC in energy metabolism, males as well as females can be affected. Most defects of $E_1-\alpha$ gene are de novo, with point mutations being more common in males and deletions or insertions in females (236,238). This information is extremely important for genetic counseling.

Defects in the E_2 component, the E_3 -binding protein, and the pyruvate dehydrogenase phosphatase, while rare, have been reported (236,239,240). Described phenotypes have ranged from severe mental retardation to Leigh syndrome and refractory lactic acidosis.

The E_3 component (dihydrolipoamide dehydrogenase) is common to three other enzymatic complexes: the α -ketoglutarate dehydrogenase (α -KGD) (involved in TCA cycle), the branched-chain 2-ketoacid dehydrogenase (BCKD), which is the enzyme deficient in maple syrup urine disease (MSUD), and the glycine cleavage system (involved in glycine catabolism). Few patients with deficiency of the E_3 component (lipoamide dehydrogenase) are known. Their clinical and biochemical presentation is variable, with a combination of the different manifestations of the PDHC, α -KGD, and BCKD deficiencies. Recurrent episodes of liver failure, cardiomyopathy and myoglobinuria have also been reported (235,236, 241–243).

Progressive involvement of the basal ganglia and brainstem is frequent in PDHC-deficient patients, and can lead to nystagmus, dystonia, apnea, or sudden, unexpected death. Magnetic resonance imaging (MRI) findings in these patients are suggestive of subacute necrotizing encephalopathy (Leigh syndrome). However, it is important to note that Leigh syndrome has also been described in patients with pyruvate carboxylase, the TCA cycle, and respiratory chain deficiencies (see below) as well as in other inborn metabolic diseases (IMD) (1,244,245). Other

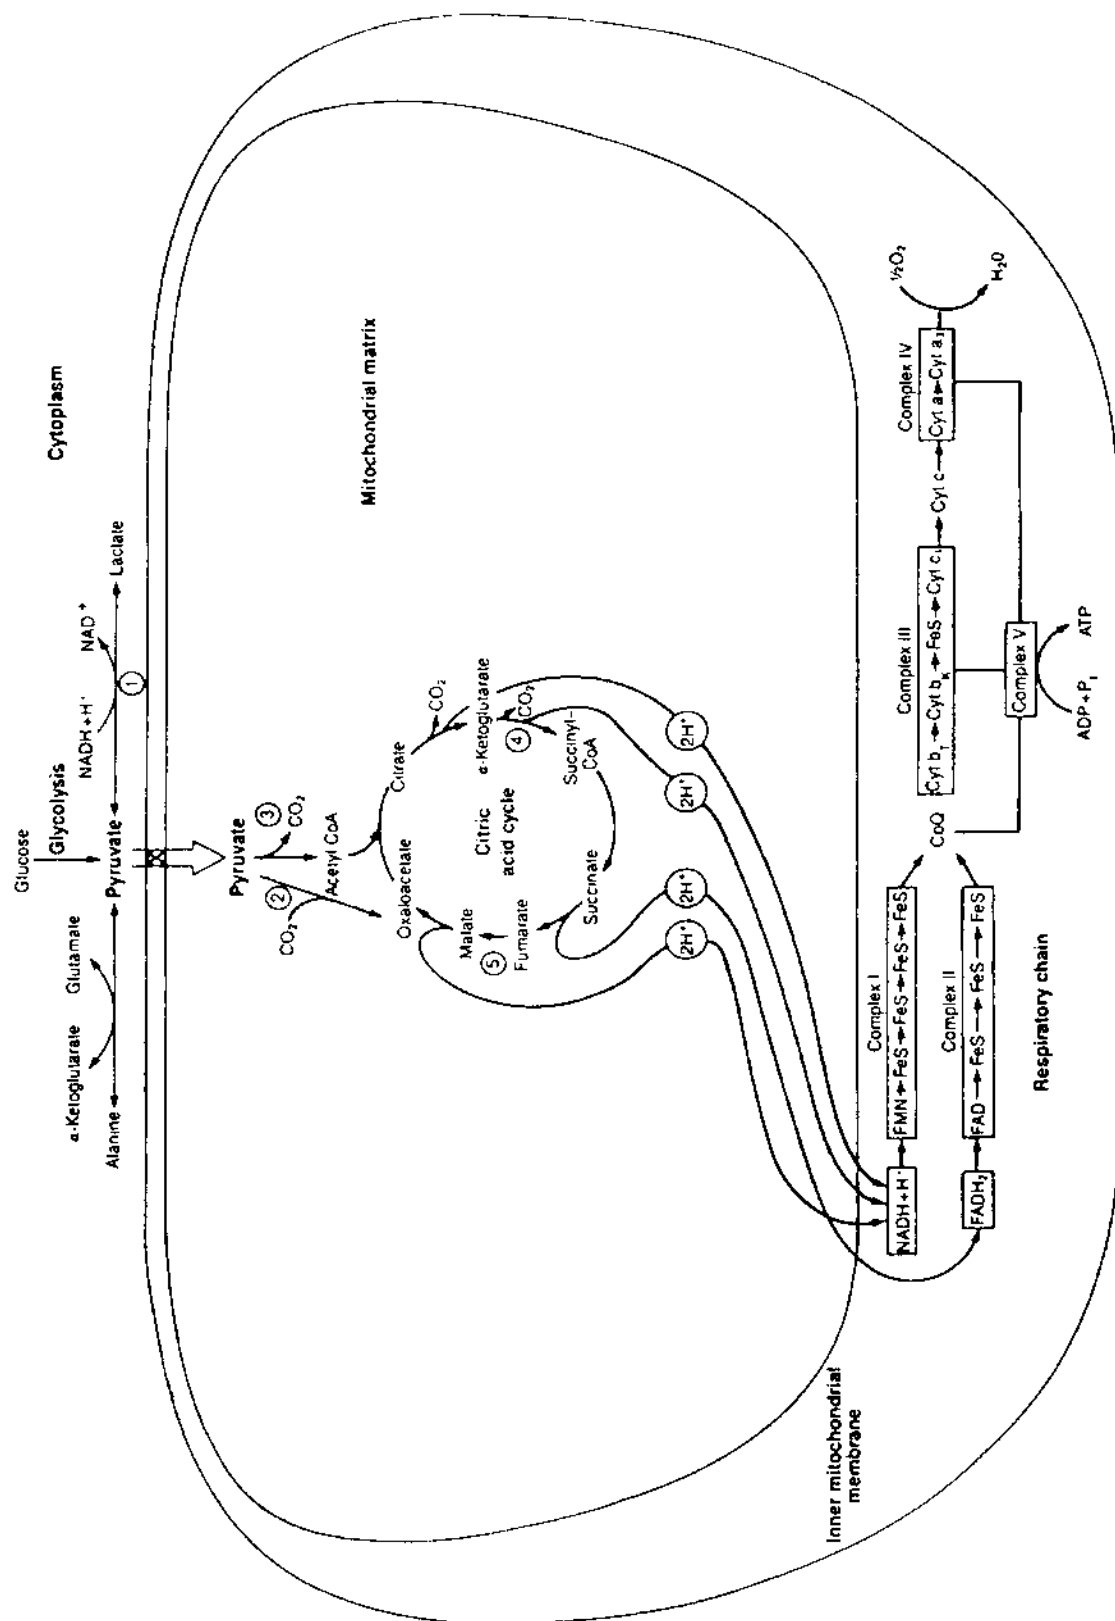

Figure 4 Pyruvate metabolism, the TCA cycle, and the respiratory chain. See explanation in the text. Enzymes: 1, lactate dehydrogenase; 2, pyruvate carboxylase; 3, pyruvate dehydrogenase complex; 4, α -ketoglutarate dehydrogenase; 5, fumarase. (From: D.C. De Vivo and S. Di Mauro. Disorders of pyruvate metabolism, the citric acid cycle and the respiratory chain. In: *Inborn Metabolic Diseases. Diagnosis and management*. J. Fernandes, JM Saudubray and Tada. Eds. Springer Verlag-1st Ed., 1990, pp. 127-160.)

frequent abnormalities of the CNS in PDHC deficiency are congenital malformations of the brain, including agenesis or hypoplasia of the corpus callosum (235–237).

2. Defects in the TCA Cycle

The TCA cycle is responsible for the oxidative decarboxylation of citrate to oxaloacetate (Fig. 4). Several enzymes are involved, and defects in α -ketoglutarate dehydrogenase (α -KGD), fumarase, and succinate dehydrogenase (SDH) have been characterized. Structure of α -KGD is similar to the PDHC and the BCKD, sharing with them the E_3 component. Therefore the three enzymes can be affected in E_3 deficiency (see section on PDHC deficiency above). A few patients with isolated α -KGD have also been reported. They present in infancy or early childhood with severe neurological involvement, including developmental delay, hypo- or hypertonia, and ataxia (235,246–248). Structural brain abnormalities can be present.

Fumarase deficiency appears to be more common. Clinical presentation ranges from severe neurological involvement, seizures, and death in childhood to mild mental retardation and survival into adulthood (235,248–250). Dysmorphic facial features and neonatal polycythemia have been recently reported (251). Structural brain malformations such as diffuse polymicrogyria, hypomyelination, agenesis of the corpus callosum, Leigh syndrome, decreased white matter, and cortical atrophy are common (250,251). A few patients with SDH are known. This TCA cycle enzyme is also part of complex II of the respiratory chain (succinate–ubiquinone oxidoreductase) and these patients' clinical presentation resembles more a respiratory chain defect (see below) (235). A combined deficiency of SDH, aconitase, complex I and III has been reported (252). This defect is apparently caused by abnormalities in the iron–sulfur clusters common to these enzymes.

3. Defects in Gluconeogenesis

Gluconeogenic defects involve deficiencies in the four regulatory enzymes of this pathway: pyruvate carboxylase, phosphoenolpyruvate carboxykinase, fructose-1,6-diphosphatase, and glucose-6-phosphatase. Deficiency of the latter affects gluconeogenesis as well as glycogen degradation and is responsible for the glycogen storage disease type I. In general, patients with gluconeogenic defects present not only lactic acidosis but also hypoglycemia and hepatomegaly. Pyruvate carboxylase (PC), a biotin-dependent enzyme responsible for the carboxylation of pyruvate to oxaloacetate (Fig. 4), plays an important role in gluconeogenesis, lipogenesis, and energy production. Decreased availability of oxaloacetate also impairs the synthesis of aspartate and glutamate with secondary abnormalities in the urea cycle and the synthesis of glutamine-derived neurotransmitters. Deficiency of the PC can be isolated or as a part of the biotinidase or ho-

locarboxylase synthetase deficiencies (see organic acidemias). Isolated PC deficiency has been described in about 40 patients. Three clinical presentations are differentiated. The most severe form presents in neonates with lactic acidosis, hypotonia, and seizures, progressing to coma and death in the first few months of life (235,236). A less severe phenotype, mainly described in North American Indians, presents in infancy with developmental delay, failure to thrive, and seizures, progressing to severe mental retardation. Mild hepatomegaly is present in both clinical presentations. Macrocephaly and brain abnormalities, including decreased myelination, ischemia-like lesions, cyst, periventricular leukomalacia, Leigh syndrome, subdural hematomas, and brain atrophy have been described (235,236,253,254). These abnormalities are thought to be related to the important role of PC in astrocyte metabolism. The third, less common, phenotype is characterized by episodic attacks of lactic acidosis with slight neurological involvement (235,236).

Phosphoenolpyruvate carboxykinase (PEPCK) deficiency is very rare. Symptoms appear in the newborn period or early infancy and include failure to thrive, hypotonia, lethargy, and hepatomegaly. Renal tubular acidosis as well as skeletal and cardiac muscular involvement have been reported (235).

Fructose-1,6-diphosphatase (FDP) deficient patients present in the newborn period with symptoms of hypoglycemia, hypotonia, and liver enlargement. Neurological involvement in these patients is only related to the hypoglycemic episodes (255).

4. Defects in Oxidative Phosphorylation

The oxidative phosphorylation (OXPHOS) is a complex system that carries electrons through a series of reactions to generate ATP. Our understanding of this system has greatly increased in the last few years with significant advances in molecular genetics. The OXPHOS is composed of five different complexes (I, II, III, IV, and V), located in the inner mitochondrial membrane. Each complex has several protein components, some of them encoded by nuclear DNA (nDNA) and others by mitochondrial DNA (mtDNA) (256,257). The only exception is complex II, which has only nDNA-encoded proteins. Differentiation between abnormalities in the OXPHOS caused by defects in nDNA or mtDNA is important for prenatal diagnosis and genetic counseling: nDNA defects follow a mendelian inheritance, while mtDNA is maternally transmitted.

The nuclear DNA is responsible for the synthesis of about 70 OXPHOS subunits, their transport into the mitochondria, and their proper processing and assembly (256). A great number of the nuclear genes, the majority of them still unidentified, are responsible for these processes.

The mtDNA is a small circular molecule (16.5 kb) that encodes for 13 OXPHOS subunits together with ribosomal RNAs and the 22 mitochondrial transfer RNAs

necessary for mRNA expression (256,257). Each cell contains hundreds of mitochondria and thousands of mtDNA. In patients with mtDNA abnormalities, normal and abnormal mtDNA coexist in the same cells (heteroplasmy). During cell division, mitochondria are randomly distributed to the new cells (replicative segregation) and, as the cells divide, the relative proportions of normal and abnormal mtDNA change (256). These characteristics of the mtDNA have clinical implications. In the same patient some tissues/organs may or may not be affected depending on their proportion of normal and abnormal mtDNA. Furthermore, tissues that are not affected at one point may become affected when the number of abnormal mitochondria reaches a threshold for phenotypic expression. These facts explain why the same molecular defect can present with different phenotypes, which can also change over time (256–258).

Clinical presentation of patients with OXPHOS diseases is extremely variable. Neonatal decompensation, with severe metabolic acidosis, is not frequent but has been described in fatal and benign infantile myopathy due to complex IV (COX deficiency) as well as in deficiencies of other complexes (257–260). These children present in the neonatal period with severe hypotonia, abnormal movements, poor sucking, lethargy, respiratory distress, and severe lactic acidosis. Ketosis is usually present. A picture resembling neonatal-onset diabetes mellitus, with hyperglycemia, ketosis, and hyperlactacidemia has been reported in patients with OXPHOS defects (261). Another severe neonatal presentation is seen in one of the variants of the mitochondrial DNA depletion syndrome (see below). These children develop severe liver failure, with hypoglycemia, lactic acidosis, and elevated liver enzymes within the first day of life. Liver histopathological examination reveals micronodular cirrhosis, cholestasis, microvesicular steatosis, and accumulation of iron. Electron microscopy shows abnormal proliferation of mitochondria. Less severe infantile forms of this syndrome have been reported in children with failure to thrive, vomiting, hypotonia, hypoglycemia, and progressive liver dysfunction (258,262–264).

Because OXPHOS is present in all cells, patients with a subacute or chronic course can have different combinations of symptoms and signs. In general, an OXPHOS defect must be considered when there is an unexplained association of symptoms, with early onset and a rapidly progressive course involving seemingly unrelated organs (257,258). A list of the most frequent signs and symptoms is presented in Table 7. Patients with OXPHOS diseases are prone to multiorgan involvement; therefore abnormalities in tissues with high energy needs including muscle, liver, kidney, pancreas, bone marrow, heart, brain, retina, auditory nerve, and endocrine system should be searched for. In patients with CNS involvement MRI of the brain will provide useful information (Table 7) (265). Different combinations of symptoms and signs are possible, and classification of OXPHOS diseases has been difficult.

Table 7 Most Frequent Findings Associated with OXPHOS Diseases

Hypotonia
Developmental delay
Progressive encephalopathy, regression
Seizures, myoclonus
Strokelike episodes
Recurrent ataxia
Cortical blindness
Brain abnormalities
Absence of corpus callosum
Porencephalic cysts
Abnormal signaling of the basal ganglia
Leukodystrophy
Cortical atrophy/poliodystrophy
Leigh's disease
Sudden infant death
Muscle weakness, myopathy
Myalgia, exercise intolerance, myoglobinuria
Palpebral ptosis, progressive external ophthalmoplegia
Cataracts, corneal opacities
Retinitis pigmentosa
Sensorineural hearing loss
Cardiomyopathy (mainly hypertrophic)
Heart block (A-V, and others)
Failure to thrive, intrauterine growth retardation
Renal Fanconi's syndrome
Tubulointerstitial nephritis, renal failure
Episodic vomiting
Chronic diarrhea, villous atrophy
Exocrine pancreatic dysfunction
Liver failure
Anemia (sideroblastic), myelodysplasia
Diabetes mellitus
Growth hormone deficiency
Hypothyroidism, hypoparathyroidism
Recurrent hypoglycemia
Craniofacial dysmorphic features
Hair abnormalities (dry, thick, brittle hair)
Skin abnormalities (mottled pigmentation in exposed areas)

Source: Refs. 256–258.

They have been categorized based on their molecular defect in mtDNA or nDNA. Known mtDNA abnormalities include point mutations, deletions, and duplications. In general, point mutations follow a pattern of maternal inheritance while deletions tend to be sporadic. Many of them correlate with well-defined syndromes, but significant overlapping and variation exist (Table 8).

In the last few years, an increasing number of mutations in nuclear OXPHOS genes are being recognized. The most frequent inheritance in this group is autosomal recessive, but any mendelian pattern is possible. Some clinical entities are defined but their genes are still unidentified. They include, among others, the mtDNA depletion syndrome, hereditary spastic paraplegia, and the

Table 8 Most Common Clinical Syndromes Associated with mtDNA Defects**Mainly associated with mtDNA mutations**

Mitochondrial encephalomyopathy, lactic acidosis, and stroke-like episodes (MELAS) (266)
 Myoclonic epilepsy and ragged-red fibers (HERRF) (267)
 Neuropathy, ataxia, and retinitis pigmentosa (NARP) (268)
 Leber's hereditary optic neuropathy (LHON) (269)
 Diabetes mellitus and deafness (270)

Mainly associated with mtDNA deletions/duplications

Pearson syndrome: Anemia (sideroblastic)/pancytopenia, exocrine pancreatic insufficiency, failure to thrive, liver dysfunction, myopathy, lactic acidosis (271,272)
 Kearns Sayre syndrome: Age before 20 years, progressive external ophthalmoplegia, retinitis pigmentosa, cerebellar ataxia, increased CSF protein, complete heart block, diabetes mellitus (273)
 Wolfram syndrome: Diabetes insipidus, diabetes mellitus, optic atrophy, and deafness (274)
 Progressive external ophthalmoplegia (275)

myoneurogastrointestinal encephalopathy (MNGIE) (256, 258,264). Nuclear genes responsible for specific deficiencies of subunits in complex I (producing Leigh disease) and complex IV (cytochrome oxidase deficiency) have been identified (256,259). More important, nuclear genes affecting the OXPHOS have been found to be the cause of Friedreich's ataxia (276) and the Barth syndrome (277). It is likely that in the next few years more chronic diseases associated with nDNA defects affecting OXPHOS will be described.

B. Diagnosis

Initial laboratory work-up for a patient with suspected PLA with an acute or chronic presentation is similar. In patients with intermittent symptoms, diagnostic possibilities increase when samples are obtained during the acute decompensation. Fasting blood levels for lactate (L), pyruvate (P), ammonia, and AAs and urine for organic acids should be obtained.

Additional information can be obtained by measuring blood levels of 3-OH-butyrate (3OHB), acetoacetate (AcAc), total and free carnitine, and urine amino acids. Accurate measurement of L and P requires rapid and proper handling of the specimens. Arterial samples are preferred, and the use of a tourniquet should be avoided if venous samples are to be obtained.

In patients with acute decompensations, laboratory tests disclose severe metabolic acidosis, high anion gap, and markedly elevated lactic acid. The lactic/pyruvate (L/P) molar ratio should be calculated (normally 10–20). A low to normal value suggests PDHC deficiency. By contrast, PC and respiratory chain defects (complex I, III, and IV) show elevated L/P ratios (278). Reduced 3OHB/AcAc ratio is seen in PC deficiency (235,278). Lactic acidosis due to poor perfusion, hypoxia, liver insufficiency, sepsis, or sedation with propofol (2,6-di-isopropylphenol) (Diprivan, Zeneca Pharma, Mississauga, ON, Canada) should be ruled-out (278,279). In general they do not present with ketosis.

In patients with chronic disease, even slight elevations of lactate provide a clue for diagnosis. More severe biochemical abnormalities might only be present during attacks, which are usually triggered by intercurrent illnesses. In some patients increased lactic acid levels are only detected when they are measured 1–2 h after a regular or a high-carbohydrate meal. Elevated fasting levels of lactic acid that decrease after a high-CHO meal, with simultaneous increase in ketone bodies, are suggestive of PC deficiency (235). In patients with CNS involvement and normal lactic acid in blood, L and P levels have to be measured in cerebral spinal fluid.

Hypoglycemia is associated with lactic acidemia during fasting in patients with gluconeogenic defects, while hyperglycemia can be found in OXPHOS and PDHC deficiencies (261,278). Mild hyperammonemia is present in neonates with PC and fumarase deficiencies and increased uric acid and hypophosphatemia are found in those with FDP deficiency. In the latter, provocative tests with fructose and glycerol, performed under close supervision, are useful for diagnosis. Glucose tolerance tests should be avoided because they can trigger an acute decompensation in PDHC-deficient patients.

Urine organic acids analysis provides useful information in PLA patients, but, with the exception of the TCA cycle defects, cannot determine the site of the metabolic block. Usual findings are elevated lactic, pyruvic, and 2-hydroxybutyric acids. Elevation of TCA cycle intermediates (succinic, fumaric, malic, and α -ketoglutaric acids) might be present in patients with OXPHOS defects. Ketonuria suggests PC deficiency. However, increased ketones can also be found in patients with other PLA defects. Glycerol and glycerol-3-phosphate can be found in the urine of patients with FDP deficiency. A recent report suggests that glycerol intolerance syndrome might be indeed a partial FDP defect (280). α -Ketoglutaric and lactic acids are increased in α -keto glutarate dehydrogenase. However, abnormal excretion of the former could be intermittent (247). Increased α -ketoglutaric is also found in patients with glycogen storage disease type I. In patients with lipoamide dehydrogenase (E_3 deficiency), the increased levels of lactic and α -keto glutaric acids are accompanied by metabolites of 2-hydroxy- and 2-ketoacids. Fumarase deficiency is characterized by increased fumaric

acid with different degrees of lactic, succinic, and α -ketoglutaric acids (235). Methylglutaconic acid has been reported in several patients with OXPHOS defects, as well as in other diseases (see section on organic acidemias) (278).

Isolated elevations of lactic acid in urine can be found in patients with urinary infections due to *E. cloacae* (281) and in patients with short gut or blind loop syndrome, who excrete high amounts of D-lactic acid, which is undistinguishable from the L-isomer (282). Quantitative plasma AAs have similar limitations to UOA. A common finding for all PLA is an elevation of alanine, while elevated glutamate and glutamine may be present in patients with PDHC, α -KGD, and OXPHOS deficiencies (235, 278). Serum amino acids are characteristic in the neonatal form of PC deficiency, with increased elevation of alanine, proline, citrulline, and lysine and decreased levels of aspartate and glutamine (235,236,253,254). In the E₃ subunit deficiency, mild elevations of branched-chain AAs and alanine are characteristic.

A muscle biopsy is another important tool for the diagnosis of PLA, especially for OXPHOS diseases. Specimens should be obtained for light and electron microscopy and tissue should be immediately frozen for enzymatic studies. The specimens should be referred to an experienced laboratory. The presence of ragged red fibers (modified Gomori trichrome stain) are suggestive of an OXPHOS defect. Important information is also obtained from succinate dehydrogenase and cytochrome oxidase reactions, immunohistochemistry, mtDNA quantification, and electron microscopy (245,258,283).

Enzymatic diagnosis for defects in pyruvate oxidation, the TCA cycle, and gluconeogenesis can be done in blood, fibroblasts, or other tissues (235,236). The reference laboratory should be contacted for the best specimen to be obtained for each particular enzyme. Enzyme activity for the respiratory chain is best measured in muscle. However, the assessment is complicated due to several factors, including different percentages of abnormal mtDNA and different isoforms of the same enzyme in different tissues (245,257,258). Point mutations in a tRNA of the mtDNA, or mtDNA depletion can affect the enzyme activity of several respiratory chain complexes. Secondary deficiencies of the respiratory chain due to defects in mitochondrial β -oxidation and other enzyme deficiencies are possible (257). In patients who die unexpectedly, enzymatic studies can be done on frozen samples (skeletal muscle, heart, liver, and brain) if they are obtained no more than 4 h postmortem.

Molecular diagnosis for the majority of the enzymes described is available. Regarding the OXPHOS defects, the mutations or deletions should be searched for, according to the clinical presentation (245,256,258).

C. Treatment: The Acute Episode

Treatment of acute neonatal lactic acidemia requires an intensive care unit. Sodium bicarbonate in large amounts

is usually required to control the metabolic acidosis. If hypernatremic metabolic acidosis develops, it should be treated with peritoneal or hemodialysis. Special solutions with sodium bicarbonate (instead of sodium chloride) and devoid of acetate or lactate should be used in those procedures. A high GIR can severely worsen the lactic acidemia in patients with PDHC deficiency. Therefore, initial intravenous fluids should provide a low GIR that can be increased according to clinical and biochemical response. A high GIR is indicated in patients with PC deficiency.

After the appropriate samples for diagnosis have been obtained, treatment with one or several drugs can be started in patients with life-threatening lactic acidemia (Table 9). A wide range of dosages have been used. Assessment of the response to vitamin therapy is difficult and well-documented data are rare. The most commonly used are biotin, thiamine, riboflavin, and coenzyme-Q₁₀. These compounds are cofactors involved in the different metabolic pathways. Vitamins C and K have been used as artificial electron acceptors (235,256,284). Dichloroacetate (DCA) stimulates the activity of the PDHC and is used, in dosages of 15–200 mg/kg/day in the treatment of PLA of unknown origin as well as in PDHC and complex I deficiencies (235,256,284). In patients with low carnitine levels, carnitine supplementation (50–100 mg/kg/day) should be used to maintain normal free carnitine levels. A recent report documents a marked improvement of a cardiomyopathy following treatment with idebenone, a synthetic analog of coenzyme Q₁₀ (285). Treatment with succinate, nicotinamide, corticosteroids, chloranphenicol, vitamin-E, methylene blue, and acetylcarnitine have been advocated for some conditions (256,284). When final diagnosis becomes available, an attempt to withdraw those vitamins not involved in the metabolic block should be done, one at a time, with careful monitoring of the clinical and biochemical response.

Table 9 Pharmacological Treatment for PLA

Agent	Dosage (range)	Deficiency
Thiamine	500–2000 mg/day	PDHC
	200–300 mg/day	OXPHOS
Lipoic acid	10–50 mg/kg/day	PDHC
Dichloroacetate	15–200 mg/kg/day	PDHC, OXPHOS
Biotin	10–50 mg/day	PC
Riboflavin	50–300 mg/day	OXPHOS
Coenzyme-Q ₁₀	60–360 mg/day	OXPHOS
Idebenone	30–90 mg/day	OXPHOS
Vitamin C	500–4000 mg/day	OXPHOS
Vitamin K ₃ , menadione or K ₁ , phyloquinone	50–100 mg/day	OXPHOS

D. Long-Term Management

In patients with chronic disease it is advisable to add one drug or vitamin at a time, according to the suspected diagnosis, and maintain careful monitoring of the patient's response. However well-documented long-term studies are difficult and, in general, prognosis is poor. In patients with PDHC deficiencies, thiamine (500–2000 mg/day), lipoic acid (which is bound to the E₂ component), carnitine, and DCA have been tried with variable results (235,242). A high-fat (75–80%), low-CHO (5%) diet has been useful in some patients. The rationale is to provide alternative sources of Acetyl-CoA, not derived from pyruvate (235,284). However, a detailed study showed mild improvement in development but not change in long-term survival of these patients (286). In PDHC deficiency due to abnormalities in the E₃ component, dietary treatment is more difficult because the affected enzymes impair protein, carbohydrate, and fat metabolism. Restriction of branched-chain amino acids (as in MSUD) is helpful to reduce blood levels of branched-chain AAs and their metabolites in urine (235).

In patients with PC deficiency, treatment with biotin (10–50 mg/day) is indicated. Citrate and aspartate have also been tried in the treatment of this condition, with improvement in blood chemistry but poor long-term neurological outcome (254). A low-fat–high-CHO diet with frequent feeds is also indicated in patients with PC deficiency as well as in all the other gluconeogenic defects (235,284). Restriction of protein intake to reduce production of gluconeogenic substrates has also been proposed in PC deficiency.

In patients with FDP deficiency, mild restriction of sucrose and fructose is indicated. Controlled exercise has been helpful in some patient with OXPHOS defects to enhance the aerobic capacity and decrease lactic acid levels (256). Liver transplantation has been performed in patients with hepatic respiratory chain disorders, but extrahepatic manifestations may appear later despite successful transplantation (287). Treatment with valproic acid and phenobarbital should be avoided because they inhibit the respiratory chain (257). Supportive treatment for the different manifestations of OXPHOS diseases (exocrine pancreatic deficiency, anemia, diabetes, renal Fanconi's syndrome, etc.), as well as psychological support for patients and family should be provided.

VI. MAPLE SYRUP URINE DISEASE

A. Pathophysiology

Maple syrup urine disease (MSUD) is an autosomal recessive disease affecting the metabolism of the branched-chain amino acids (BCAA) leucine, isoleucine, and valine. BCAA play an important role in intermediate metabolism. They are substrates for gluconeogenesis and ketogenesis, and their end-catabolic product, acetyl-CoA, is a precursor for fatty acid and cholesterol synthesis. The defect in

MSUD is located in the branched-chain 2-ketoacid dehydrogenase complex (BCKD), which is made of four different components: E₁- α , E₁- β , E₂, and E₃ (288). The E₁ component is thiamine dependent. BCKD deficiency results in the elevation of BCAA and their corresponding branched-chain 2-ketoacids (BCKA) 2-ketoisocaproic, 2-keto-3-methylvaleric, and 2-ketoisovaleric. Accumulation of these compounds is responsible for the characteristic odor as well as the clinical course of the disease.

B. Clinical and Laboratory Manifestations

Five phenotypes have been described, based on the clinical presentation and response to thiamine therapy: classic, intermediate, intermittent, thiamine-responsive, and E₃- (dihydrolipoamide dehydrogenase) deficient (288). The classic form is the most common. Children appear normal at birth, but between the first and the second week of life present with poor feedings, lethargy, dystonic posturing, seizures, and apneas. The characteristic maple syrup odor can easily be detected in urine. This intoxication-like encephalopathy resembles that of the organic acidemias. Biochemical abnormalities include ketoacidosis and hypoglycemia; hyperammonemia may be mild or absent (37,288). Diagnosis can be made by measurement of either plasma AAs or UOA. Typical findings in the former are elevated levels of BCAA, mainly leucine (1000–5000 μ M/l), and the presence of L-alloisoleucine, which is a transamination product of the 2-keto-3-methylvaleric acid (105). Routine UOA analysis shows an elevation of branched-chain 2-OH-acids and BCKA. The latter are better detected when the sample is previously oximated. Ketone bodies are also usually present.

The intermediate form of MSUD presents in infancy to young adulthood with neurological impairment, seizures, failure to thrive, and ataxia. Ketoacidosis is less severe and acute crisis may be absent. In these patients BCAA are always abnormal, with leucine levels ranging between 400 and 2000 μ M/l (289).

The intermittent form presents in children or adults with episodes of acute decompensation (ataxia, seizures, coma, and ketoacidosis) triggered by infections or high protein ingestion. Plasma leucine values are mildly elevated during the crisis, but they can be normal while compensated (288).

The thiamine-responsive patients are a heterogeneous group. Their clinical presentation resembles that of patients with the intermediate form of the disease. Treatment with thiamine tends to normalize the BCAA levels, and some patients can be completely off diet. Thiamine dosages have ranged from 10 to 1000 mg/day and response was achieved days or weeks after starting the treatment (37,288,290).

The E₃ component of the BCKD is common to other three enzymatic complexes: pyruvate dehydrogenase complex (PDHC), α -ketoglutarate dehydrogenase (α -KGD), and the glycine cleavage system (involved in glycine catabolism). Clinical presentation in these patients is varia-

ble, combining features of BCKD and primary lactic acidemias (see section on PDHC deficiency above).

MSUD is transmitted as an autosomal recessive condition and has been diagnosed in all ethnic groups. The general incidence of the disease is estimated at 1:185,000, but the incidence is much higher for some inbred communities, such as the Mennonites (288). Mutations in the genes encoding for the different components of the BCKD have been identified. Different genotypes correlate with the severity of clinical presentation (288,289).

C. Treatment: The Acute Episode

Acute management of MSUD patients follows the same principles outlined for the treatment of organic acidemias (see section on organic acidemias above). Patients with MSUD usually require less bicarbonate than OA to correct the metabolic acidosis. High-energy nutrition alone is not sufficient to lower leucine levels rapidly (37). Therefore dialysis should be considered early in the treatment, especially in patients with acute and severe encephalopathy and/or with leucine levels above 1500 μMol . Hemodialysis, hemofiltration, and continuous blood exchange transfusion, in this order, are the preferred methods for toxin removal (24,114,291). As in OA, pancreatitis and brain edema have been reported in acutely ill MSUD patients (37,292–294). The latter has been documented in CT and MR studies, which also showed dysmyelination of several areas of the brain in patients under poor metabolic control (295). Unlike in OA, secondary carnitine deficiency is not common in MSUD patients.

D. Long-Term Management

Long-term treatment of UCD patients is also based on the same principles as the organic acidemias (see section on organic acidemias above). Because leucine is considered the most toxic of the BCAA, leucine requirements are followed to prescribe the diet. Occasionally, small amounts of valine and isoleucine need to be added to the diet because the tolerance for leucine is lower than of the other two BCAA. Administration of thiamine is indicated for thiamine-responsive patients. Prognosis of MSUD patients has dramatically improved due to the early diagnosis achieved through newborn screening programs (NBS), intensive treatment, and availability of special formulas. NBS programs are being performed using the traditional bacterial inhibition assay or new techniques such as TMS. The later is being used in many centers to detect not only MSUD but also many other IEM (109,110,296). We have detected abnormal levels of leucine + isoleucine and valine before 24 h of age in a patient with MSUD whose sibling had a classic form of the disease (111). These results suggest that TMS will lower the impact of early discharge on newborn screening.

For children treated in specialized centers, survival is 100% (37,288). However, some degree of psychomotor impairment seems to be present, even in patients with early diagnosis and strict dietary treatment (294,297,298). Successful pregnancies have been reported in patients with intermediate MSUD who were evaluated with close monitoring (288).
