About the Series

“Clinical Pediatrics” is a series of books designed to continually update the knowledge of the practicing pediatrician in diverse areas of the specialty. Each volume in the series addresses rapidly developing topics that are changing the attitudes and treatment approaches of the clinician. The chapters comprising the volumes represent the state of the art on the various subjects from the vantage point of recognized experts in the field.

The books already published in this series are *Common Pediatric Disorders*, *Congenital Metabolic Diseases*, *Antimicrobial Therapy in Infants and Children*, *Food Allergy*, *Metabolic Bone Disease*, and *Pediatric Endocrinology*. The first edition of the last book was published in 1985, the second edition in 1990, and the third edition in 1996. This book has become the most sought-after reference book in the field, making necessary an updated fourth edition. This fourth edition of *Pediatric Endocrinology* is the ninth book in the Clinical Pediatrics series. It is an updated, improved, and greatly expanded version, which covers the field in a comprehensive manner to update clinicians on the numerous recent advances in pediatric endocrinology. The most frequent encounters by pediatricians are covered and reviewed in a practical, patient-oriented, yet scientific style, making it an invaluable resource for pediatricians and specialists alike.

These books serve as the foundation for the volumes that will follow, each complementing the others. Together, they will constitute a comprehensive review of the most recent developments in pediatrics.

Fima Lifshitz

Foreword

The fourth edition of *Pediatric Endocrinology* is designed according to the same concept as that of the first three, but it far exceeds the very significant accomplishments of the previous editions. The first three editions, each of which was more complete and broadly informative than the last, were written for a diversified audience of general pediatricians, pediatric endocrinologists, geneticists, and others. Each of these texts became the most used and sought-after in the field in the United States and throughout the world. *Pediatric Endocrinology* became established as the most respected book on the subject, dating back to the publication of the first edition in 1985. A review of the content of this, the fourth edition, reveals an even more improved text. Each chapter is written by highly respected clinicians who are also investigators in the topics covered. The book has a very practical clinical approach, yet it provides comprehensive coverage of all the major endocrine glands and diseases. The content of each of the various chapters is fully inclusive, which augments the value of the presentation of each subject. The balance between the clinical material and the physiology, pathophysiology, and treatment information is ideal. The review of each topic is as updated as is feasible in constructing a book of this magnitude.

Readers and users of this text will be pleased and appreciative of the effort and successful accomplishment of Dr. Lifshitz and his colleagues who edited and authored this fourth edition. Dr. Lifshitz has again demonstrated his insight and capability as an accomplished educator for students at all levels. Congratulations on this contribution, a legacy to pediatric endocrinology!

Robert M. Blizzard, M.D.

*Professor and Chairman Emeritus
The University of Virginia School of Medicine
Charlottesville, Virginia, U.S.A.*

As the number of pediatric endocrinologists continues to grow worldwide, so does the scope of the field. The spectrum of pediatric endocrinology has expanded to encompass genetics, nutrition, immunology, biochemistry, and psychology. In addition, the explosive increase in numbers of patients seen in today's pediatric endocrine clinics reflects the heightened awareness of the role of hormones in health and disease in children. Molecular genetic studies completed since the last edition of the book have further elucidated the etiology of many endocrine and metabolic disorders. These new studies have been incorporated into the chapters of the fourth edition, edited by our friend and colleague, Dr. Fima Lifshitz. New chapters have been added to this edition, while existing chapters have been updated, creating a thorough yet succinct book.

I would like to congratulate Dr. Lifshitz who, again, has assembled the foremost specialists in all areas of pediatric endocrinology to create this book, which has become indispensable to pediatric clinicians and researchers alike.

Preface

The more you practice what you know, the more you know what to practice.

W. Jenkins

The fourth edition of *Pediatric Endocrinology* is a comprehensive book in the field designed to meet the needs of the practicing physician, yet it is written at a level suitable for the subspecialist. The 43 chapters of this book are completely updated and the information contained provides state-of-the-art knowledge in all areas of the specialty. There have been multiple changes in the field since 1985 when the first edition was published. The most important advances were incorporated into the previous editions and were brought to the clinicians in didactic, practical chapters. Each contained comprehensive discussions addressing all clinical situations encountered in the practice of this subspecialty. The fourth edition of *Pediatric Endocrinology* constitutes the culmination of the experience and accomplishments reflected in previous editions. It is a mature, seasoned book that reflects the continuous growth and accumulated wisdom of the 63 contributors. Their knowledge is eloquently transmitted in each chapter.

As in previous editions, the book is divided into seven parts, each dealing with a major area of childhood endocrinology: "Growth and Growth Disorders," "Adrenal Disorders and Sexual Development Abnormalities," "Thyroid Disorders," "Disorders of Calcium and Phosphorus Metabolism," "Hypoglycemia and Diabetes Mellitus" and "Miscellaneous Disorders." The final part includes an updated chapter on dynamic tests used by pediatric endocrinologists, as well as one with a more complete collection of newer and updated reference charts and tables utilized to assess patients with growth disorders and endocrine alterations. Additionally, there are two new chapters of current interest; one on reimbursement issues with a coding supplement, and another on using the Web to obtain information on genetic and hormone disorders. These should make it easier for the busy practitioner to care for children with pediatric endocrine disorders. Also included are new conceptual chapters on major topics in the field not covered in previous editions, i.e., worrisome growth, multiple endocrine neoplasia syndromes, hyperlipoproteinemias, hypertension, and supplements to enhance athletic performance.

Each of the 43 chapters of this book contains sufficient material to cover the topic in its entirety and impart new information to enhance the knowledge of the practitioner and the subspecialist. It provides the reader with the most updated and pertinent information to address questions asked in the care of patients with endocrine and endocrine-related disorders. From pathophysiology to treatment, there is a succinct and clear description of the subject in each chapter. The book fully encompasses the daily problems seen in pediatric endocrine practices.

The field of pediatric endocrinology has rapidly advanced and changed very significantly in many aspects, not only in medical knowledge and the scientific basis of endocrinology. The practice of the specialty has also evolved and changed radically, together with changes brought about by "managed health care." It has changed the way we care for our patients and the way we practice our specialty, as well as many other aspects of our practice. Not all of these changes have been positive. One of the most significant casualties has been the transmission of the knowledge accumulated by prominent academic pediatric endocrinologists. As the editor of this book I experienced first-hand this sad state of affairs. Since the last edition was published in 1996, the support for teaching endeavors in many institutions has virtually vanished, and the academic pediatric endocrinologist is now an endangered species. Many of our colleagues have moved to other areas and away from clinical academic practices, and those who stayed work on a battlefield and have no time to invest in teaching endeavors. Those who contributed to this book did so on their own time, often against the implicit wishes and mandates of administration. The current constraints of the health care system have also taken a toll in academic programs. It praises productivity in other areas, not in teaching, nor in writing and transmitting knowledge through a chapter in a book. Even secretarial support was often not available to some contributors for this activity.

Thus, I am particularly and evermore grateful to my colleagues who revised and updated their chapters, and to those who provided new sections for this book. They all made very significant contributions, which continue to make this book a most valuable and necessary tool for pediatricians and pediatric endocrinologists alike. I believe this edition was brought forth with much more effort

and commitment than previous ones, and I profusely thank all the contributors; without their dedication and talent there would not be a fourth edition. Hopefully the cycle of healthcare will continue to evolve and to move forward positively. I wish that in the future the academic pediatric endocrinologist will be given the recognition and support that are deserved. This will allow us to devote energy to enhancing our knowledge and passing it on to practicing physicians for the health of our children.

Fima Lifshitz, M.D.

Diego Botero

Children's Hospital and Harvard Medical School, Boston, Massachusetts, U.S.A.

I. THE GENERAL PROBLEM

One of the primary concerns of pediatricians is the appropriate growth of their patients. Parents and children also worry about "growth" as evidence of good health. Several conditions, as discussed later, may alter the height, weight, and growth progression of a patient; these must be diagnosed and treated. However, there are other problems in being short, even when the body size is only mildly affected. Indeed, any person who is below average height (in the United States 5 feet 9 inches for men and 5 feet 5 inches for women) may also experience a number of psychosocial difficulties. Dwarfs have these problems to a greater degree, with various amounts of tolerance and rejection according to the different customs and beliefs of the locality in which they live. Recent medical research on the subject questioned whether short stature is a handicap (1) or whether this is a problem that requires growth hormone therapy (2). Also there are issues concerning the quality of life and the potential benefits that may be attained by increasing adult height (3). There are additional questions about the reasons for internalizing behavior problems and/or poor social skills of short stature individuals. All these concerns challenge the justification for extraordinary means of treating a short-stature child. It has been postulated that growth hormone treatment in short children is an issue beyond medicine, involving many aspects best resolved at present by a research approach (4, 5).

However, there is ample evidence of prejudice in our society towards the short person. The psychosocial prejudice toward the short person transcends age, gender, race, creed, and financial status: all short people may be victims of discrimination. This seldom mentioned form of

prejudice, like sexism or racism, is well established in this country and may be prevalent throughout the world. It has been called heightism. (The reader is referred to the book *The Height of Your Life*, by Ralph Keyes, for a very comprehensive and interesting review of this problem.) This book approaches heightism in a wry and humorous fashion. It highlights facts regarding height so basic to our relationships with others that we have ceased to think about them. It is from this book that the following comments have been extracted.

So pervasive is the bias against short people that no one notices it—no one, that is, except the short person. The English language illustrates this bias clearly. Feisty is the classic example, a word normally used in tandem with "little." Distinguished, by contrast, may not be synonymous with "tall" but rarely is used to refer to short persons. Other very important phrases remind us regularly of the importance of height: compare "looks up to" and "looks down upon." The question is always; how tall are you, instead of the neutral, what is your height? The song "Short People" by Randy Newman describes those below-average in height who have "grubby little fingers" and "dirty little minds" with "no reason to live." This song is a spoof of bigotry with a catchy tune, yet it made the hit parade. The composer meant it as a joke; of course, he is 5 feet 11 inches!

Height is one of the most important traits both parties try to match when it comes to selecting a personal relationship. In romantic matters, little men are "cut down to size." An ideal lover is never short, and at present both genders seem to feel that in relationships the male should be taller than the female. Even Sandy Allen, who at 7 feet 7 1/2 inches is certified by *The Guinness Book of World Records* as the tallest woman in the world, was quoted as

saying, "I've got this old-fashioned idea, I will never marry anyone smaller than I am." She never married. Thus, the tall man seems to have all of womankind to choose from, whereas the short man appears to be limited to short women. Indeed, there may be more interreligious and interracial marriages than there are couples in which the man is shorter than the woman. The former Secretary of State Henry Kissinger was acknowledged as a truly unusual phenomenon because he married a taller woman. Rewards for being tall in our society include money. Business, it seems, is interested in short men mostly as customers for elevator shoes. The president of the Mutual Life Insurance Company surveyed its policyholders and found a nearly perfect correlation between body height and policy value. Several studies have pointed out that taller persons earn higher salaries. Corporate recruiters also tend to choose the taller of two equally qualified applicants. Even when he succeeds, despite the odds against him, the short person is often accused of being a "Little Napoleon."

Height is more than a mere statistic: for men it is a measure of manhood. Height brings acknowledgment, deference, and power. Big and strong are, from childhood, considered nearly the same word. The dominant figures in advertisements and legendary figures in the movies are usually represented by tall people. Height is equated with power to such a degree that it plays a very important role in politics. Most US presidents have not been short; the shortest was James Madison at 5 feet 4 inches. Only six other presidents were slightly below the present average height. Americans have usually favored the taller political candidate. As a matter of fact, the taller of the two major presidential candidates is usually sent to the White House. There have been only four exceptions. In 1924, Calvin Coolidge (5 feet 10 inches) defeated John Davis (5 feet 11 inches); in 1972, Richard Nixon (6 feet) defeated George McGovern (6 feet 1 inch), in 1976 Jimmy Carter (5 feet 6 inches) defeated Gerald Ford (6 feet 1 inch). In the 2000 election, both candidates were over 6 feet tall, but George W. Bush, who is slightly shorter than Al Gore, won the election only by a Supreme Court decision, while the popular vote went to the taller Mr. Gore by a substantial margin. In this, as in most presidential elections, the American public voted by the inch. However, this form of prejudice may also transcend the United States. For the first time in the history of Mexico, the very tall opposition candidate Mr. Vicente Fox defeated the official shorter presidential candidate of the PRI Party in the 2000 election. This was a very unusual accomplishment since the PRI party had held power consecutively for over 75 years.

Although human esthetics and social tastes clearly favor tallness, nature shows no such preference. Anthropologists estimate that, for most of history, natural selection kept adult male heights within a range below our current averages. Supporting the natural selection process, infants' skeletons, which are abundant in old graveyards, are

rather tall; in fact their length is comparable to our present norms. Some experts think that these two phenomena are related. It seems that environmental problems were more detrimental to youngsters destined to be large, and only those destined to be small survived the rigors of malnutrition and disease. Ashley Montagu, in *Human Evolution*, wrote: "At least in part the recent increase in overall size visible in the modern adult population is due to the fact that improved standards of food and medical care have allowed genetic combinations to survive which would have been selected against in ages past."

II. THE MEDICAL PROBLEM

Pediatricians are often consulted by parents worried about short stature in their children. This term needs definition. "Short stature" has been defined as height below the third percentile; therefore, 3% of normal children would be classified as being short. "Dwarfism," the severe form of short stature, is defined as height below 3 standard deviations (SD) from the mean. The population selected for reference is important when judgments are made about the shortness of an individual. A number of different reference charts have been used in this country in recent decades, each varying somewhat from others because of the representative population from whom the data were derived (e.g., predominantly rural children from Iowa vs. Boston city children). A revision of the 1977 National Child Health Survey growth percentile was recently completed and was published in May 2000 by the Center for Disease Control and Prevention (CDC) (www.cdc.gov/growthcharts). These growth charts are included in the chapter of Reference Charts in this book (Chapter 43). These new charts are recommended for use as an enhanced instrument to evaluate the size and growth of children (6).

These charts are based on more up-to-date improved data gathered from the National Health Examination Surveys (NHANES I, II, and III) with five supplementary data sources. They feature several noteworthy items including the inclusion of 3rd and 97th percentiles. In addition, these charts contain data extending to 20 years of age, and they better represent the current growth patterns of the population. One other important contribution is that there is better continuity between 2–3 years and the >2 years growth in the charts. The new 2000 CDC percentiles have been adjusted slightly to account for the fact that recumbent length should be greater than the stated differences of 0.8 cm in the national surveys. Another significant consequence of updating the data is that the new percentiles of the CDC tend to be a bit higher for weight from 0 to 2 years. The 2000 growth charts also include body mass index (BMI) values of years 2 and older.

Although these growth charts constitute an important advancement over the previous charts used (1977 NCHS percentiles), they are not ideal for use in all infants and children. In particular they may misdiagnose the normalcy

of growth in some young children as discussed below, including constitutional short stature or breastfed babies. These growth charts show average growth patterns of height and weight gain during specific periods in life (i.e., adolescent growth spurt). These percentile charts were based on cross-sectional data that effectively average growth across different periods. In individual patients the developmental stage of puberty will therefore make the pattern of growth vary in accordance with it, and that is not shown in the charts. In theory, useful supplementary growth charts for the pubertal periods are available, but these data were derived from nonrepresentative samples recorded a long time ago. Another concern with the CDC 2000 graphs is that it is hard to visualize the metric numbers in the axis, and the grids are not easy to follow. Therefore in this book we have published an improved version of those graphs. (See Chapter 43 for Reference Charts).

A program for monitoring the growth of children has been prepared by the Eurogrowth Study Group (www.eurogrowth.org). This is excellent for individually tracking the physical growth of children from birth to 36 months of age (7). It allows the monitoring and the plotting of individual growth data, calculates growth velocity, provides body mass index centiles, measures influences of breastfeeding on growth, modifies growth by midparental height, corrects growth for gestational age of premature infants, calculates Z scores, and offers multilingual access (8–11). It is a highly recommended tool to assess growth in children up to 36 months of age.

Pediatricians know that most children with mild short stature eventually become average-sized adults; however, some children have serious growth disturbances that may prevent them from reaching normal adult size. The Newcastle study in England (12) supported the need for an explanation of the cause of short stature in all children whose height falls below the third percentile. Almost half of the 5000 infants born in Newcastle in 1960 were measured for height at age 10. The height of 111 children fell below the third percentile: 16 were found to have a previously unsuspected organic disease as a cause of short stature. These findings demonstrate that it is unusual for a “normal” child to have a height below the third percentile, although most of these children may be healthy. However, it may also be inferred that in 10–15% of children who are short, a pathological condition may be found to account for the short stature. Therefore, the cause of short stature should always be investigated in all children whose height is below the 3rd percentile and more importantly in those who fail to grow at appropriate growth rates.

Growth-related disorders are also the most frequent problems encountered by pediatric endocrinologists. Pediatricians often seek consultation to help in the diagnosis and management of children with growth disturbances and these children are referred to pediatric endocrinologists. Even in a pediatric endocrine referral center, a large pro-

portion of patients with short stature are usually healthy children. At times children are referred for short stature although they are of normal height. This may be because of either poor, inaccurate measurements, or because of the need of a pediatric endocrinologist to reassure a patient or family when a child is growing in the lower end of the normal range. A pathological condition accounted for poor growth and/or short stature in about one-third of the short-stature patients seen in a tertiary referral center (13).

III. DIAGNOSIS OF SHORT STATURE

In most instances of short stature a diagnosis is usually made, although in some patients the cause of short stature may defy the differential diagnosis of numerous experts. The different causes of short stature in children are listed in Table 1. This classification differentiates most forms of short stature into two main categories: short patients who are normal and short patients who have an abnormality that produces the short stature and poor growth. These basic concepts should be considered in the diagnosis of all short patients. That is, one must differentiate between the short child who is healthy and growing normally from those who are sick and not growing well. This is most important, since a clinician must determine if a short child is subject to a pathological cause, which must be diagnosed to provide adequate treatment, from one who may only need reassurance without a major work-up. Each of these two possible categories of short stature denotes not only the cause but also the pathophysiological process involved and the prognosis for final adult height. The specific applicable situation should be recognized by the physician before subjecting the patient to expensive and complicated investigations.

Other classifications to determine the different categories of short patients have been used by pediatric endocrinologists. For example, familial or genetic short stature was referred to as “intrinsic shortness.” Constitutional growth delay was called “delayed growth,” and all other disorders resulting in poor growth were called “attenuated growth” and/or “normal variance short stature” (14). Other authors have used the term “idiopathic short stature” to describe short individuals who are growing poorly, who have no demonstrable functional abnormality in growth hormone secretion, and whose parents are normal in height (15). Idiopathic short stature often implies a continuum of growth hormone insufficiency, not clearly demonstrable by the classic biochemical criteria (Chapters 2, 3 and 41). However, these terms to classify short patients are unnecessary because the two categories proposed above are inclusive and sufficient to understand and clarify growth problems.

A specific diagnosis can usually be made to define the patient’s condition by appropriate observations. These include accurate measurements over time and specific comprehensive testing when the usual laboratory data do not define the diagnosis.

Table 1 Causes of Short Stature

Normal
Constitutional growth delay
Genetic-familial short stature
Constitutional growth delay and familial short stature
Pathological
Nutritional
Hypocaloric
Chronic inflammatory bowel disease
Malabsorption
Celiac disease
Zinc deficiency
Endocrine
Hypothyroidism
Isolated growth hormone deficiency
Hypopituitarism
Excess cortisol
Precocious puberty
Chromosome defects
Turner syndrome
Down syndrome
Low birth weight short stature (intrauterine growth retardation)
Sporadic
Characteristic appearance
Russell-Silver syndrome
De Lange syndrome
Seckel bird-headed dwarfism
Dubowitz syndrome
Bloom syndrome
Johanson-Blizzard syndrome
Bone development disorders
Achondroplasia
Chondrodystrophies
Other skeletal disorders
Metabolic
Mucopolysaccharidosis
Other storage disorders
Chronic disease
Chronic renal disease
Chronic liver disease
Congenital heart disease
Pulmonary (cystic fibrosis, bronchial asthma)
Poorly controlled diabetes mellitus
Chronic infections (including human immunodeficiency virus infection)
Associated with birth defects or mental retardation
Specific syndromes
Nonspecific defects
Psychosocial
Chronic drug intake
Glucocorticoids
High-dosage estrogens
High-dosage androgens
Methyphenidate
Dextroamphetamine

Pediatric endocrinologists believe that short stature by itself may not be of concern for the individual, if he or she is healthy. However, there is ample evidence that height may play a role in the risk for adult-onset disease. For example, in large population studies it was found that short stature raises the risk for coronary heart disease. The Physician Health Study (16), the Framingham Study (17), and the Royal Canadian Health Force Study (18) showed that the size of the individual was important as a risk factor for myocardial infarction in adults. Although the mechanisms for the increased risk were not elucidated, they may be related to the size of the coronary arteries, which would be expected to be smaller in shorter individuals. Thus, they would be more prone to be blocked by atherosclerotic plaque than in taller adults who would have larger arteries.

IV. GROWTH PATTERNS

A. Growth Progression

The most important tool to assess growth problems in a short child is to evaluate the pattern of growth. Growth is a continuous process that starts at conception and ends with fusion of the epiphysis after pubertal development is completed. At any time during this process there may be variations or alterations in growth progression. These can only be identified with accurate measurements over time. Unfortunately, the most frequent method of measuring height, using a flip-up horizontal bar on a weighing scale, is subject to great errors caused by the child's slumping posture and considerable variation in the angle of the horizontal bar. Children should be measured standing upright and fully extended against a wall or firm vertical structure to which a properly mounted, accurate measuring device is attached. A steel tape measure, properly affixed to the wall, serves this purpose well and economically. The child stands shoeless, heels down, as erect as possible, and with the head directly forward. The back of the head, chest, gluteal area, and heels should touch the vertical surface. A firm object (e.g., a carpenter's angle) is then placed at a right angle over the top of the head and against the wall above the head. A Harpenden stadiometer (Holtain Limited, Crymych, Dyfed, UK), which determines height accurately (within 0.25 cm) is the most sophisticated instrument (19). However other devices are less expensive and/or are comparable in accuracy to the more expensive Harpenden stadiometer (20).

Thus previous height and weight data are useful and very important in the assessment, if these measurements are accurate. The data must be plotted on standard growth charts to evaluate the pattern of growth. A normal pattern of growth may be defined as a pattern of progression of height and weight compatible with established standards for age, and that is appropriate for the genetic potential of the individual. It should also be appropriate for the

various growth patterns of specific patients, stages of development, racial groups and population types (19–28) (Chapter 43).

On the other hand, pathological growth should always be considered in children who do not grow well regardless of height (Fig. 1). Any child who falls behind in growth across major percentiles in the chart should be evaluated, even when the height is not below the 3rd percentile (29). It must be kept in mind that growth is not continuously linear, but instead occurs in steps between saltation and stasis (30). Therefore, growth progression over a long period of time is more informative than extrapolations based on shorter periods of time. The growth rate varies according to the seasons, generally being fastest in the spring and summer. The growth rate in the fastest 3-month period is two to three times higher, but could be up to seven times the height increment during the slowest growth period in the other months (31, 32). Therefore, growth progression should be evaluated over a period of at least 6 months to 1 year (15). In addition, there is a great variation in the growth at different stages of life. In the first year of life, linear growth is very fast: a total of approximately 25 cm is gained. However, the rate of growth declines rapidly over the first year, from 38 cm/year in

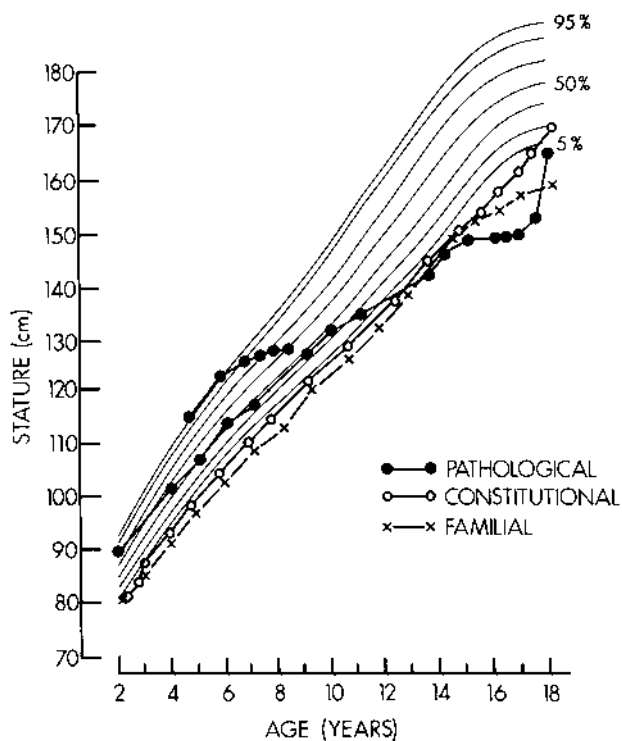

Figure 1 The growth patterns of three patients with short stature and one patient with pathological growth disorder who nevertheless was of normal height. The patient with pathological short stature received treatment at age 17 and attained catch-up growth. (From Ref. 13.)

the first 2 months to 28 cm/year at 4 months of age and 12 cm/year at 1 year of age (33). In the second year of life it is 10 cm/year, in the third through fourth years 7 cm/year, and in the fifth through sixth years 6 cm/year. From then on to puberty it is 5 cm/year (31, 32). Guidelines for abnormal growth rates adjusted for chronological age are as follows: fewer than 7 cm/year under age 4 years, fewer than 6 cm before age 6, and fewer than 4.5 cm from 6 years until puberty. At this stage growth acceleration ensues. Pubertal growth spurt occurs during early puberty and before menarche in girls (Tanner stages II–III), during which time they grow at a mean velocity of 10.3 cm per year. The pubertal growth period is longer in boys than in girls. The growth data of each patient must be plotted on the appropriate chart for that particular child. As mentioned above, new standards for the general population have been established and the recent CDC growth charts are recommended for use (5). In addition, growth velocity charts may be helpful because these take into account different stages of growth such as pubertal growth spurt. As mentioned above, the Eurogrowth Program is an excellent tool for use in infants up to 36 months of age, as it considers most variables that may influence growth progression at this stage in life (7–11).

However, monitoring weight gain in short-stature patients is as important as following the height progression. Changes in weight progression may precede alterations in height increments in certain conditions such as nutritional dwarfing and obesity (34–37). Therefore, monitoring height alone does not provide sufficient information to assess a growth pattern, as discussed in the section of nutritional growth retardation. Accurate weight measurements should be made on a regular hospital weighing scale. An infant should be stripped of clothes and diapers, and older children should wear a hospital gown or light clothing. These measures minimize inaccuracies resulting from variability in clothing weight, which varies with season. Adherence to these rules is important if we are to take note of changes in weight over time.

B. Genetic Potential

The genetic potential of the child should be considered in the evaluation of the present growth pattern. Any deviation from the expected height for the family should be worrisome (38). For this purpose, formulas and standards for target height for the family and predicted adult height have been developed. The following formulas provide an easy way of estimating the target height:

For males: (mother's height + 13 cm
+ father's height) divided by 2

For females: (father's height – 13 cm
+ mother's height) divided by 2

This formula provides the midparental height ± 2 SD (1 SD would be equivalent of about 5 cm). However, It

is important to remember that the parents' heights should be measured and not guessed.

The target height obtained by this method is then applied to the 20-year line of the gender-appropriate growth chart. The projected height is determined by extrapolating the child's growth along his or her own channel. If the projected final height is within 5 cm of target or midparental height, the child's height is appropriate for the family. On the other hand, if the difference between the target and the projected height is more than 5 cm, a pathological cause should be considered.

A simple way of evaluating whether a child is within the normal limits of height for the family is to compare the stature of the patient with the midparental height in charts developed specially to assess the correlation coefficient of these variables (38) (Fig. 2). This correlation coefficient changes little between ages 2 and 9 years. For this norm, a simple chart plotting the age in relation to parents' heights can be constructed with the usual percentile for the family stature. Figure 2 depicts charts of three patients with different diagnoses. Patient A's height falls on the third percentile, and his parents' heights midpar-

ental have an average of 157 cm. The position of this patient's stature in the chart is between the 10th and 25th percentiles. Thus, for the population at large, this patient would be small, but he would be appropriate for his immediate family. Therefore, this patient may have familial short stature. In contrast, patient B, who has the same height as patient A, has parents of average height (midparental height 167 cm). This means that patient B is actually very short for the family and requires further work-up. Patient C is a more extreme case: his parents are actually tall. Although this patient's height is equal to that of the other two patients, his stature falls more than 3 SD from the family norm.

In addition to the projected target height, the predicted adult height should also be considered in the evaluation of the short child. There are three popular methods of calculating a child's predicted adult height. These are based on the fact that in a normal individual, there is a direct correlation between the degree of skeletal maturation and the time of epiphyseal closure, which is the event that ends skeletal growth. Predictions of ultimate height consider the fact that the more delayed the bone age is for the chronological age, the longer the time before epiphyseal fusion ends further growth. However, predictions of ultimate adult height are not totally accurate and are of limited value in children with growth disorders, since the predictions vary if children do not grow at normal rates. The data also may not be accurate for short patients from very short parents' (39). It has been shown that children from very short parents may end up taller in adult stature, and their target height and their predicted height may be underestimated.

The Bayley-Pinneau method is the most commonly used method to assess the predicted height (40). This method is based on the postulate that skeletal age at the time of the radiograph study correlates well with the proportion of adult height that the child will achieve. This correlation is more accurate after 9 years of age. The Tanner-Whitehouse (TW) method utilizes TW standards for the assessment of the bone age (41). In addition to bone age, this method takes into consideration actual height, chronological age, parental heights, and, in girls, the occurrence of menarche. The third method used in predicting adult height is the Roche-Wainer-Thissen (RWT) method. This method gives attention to the weight or nutritional status of the child (42). Additionally, recumbent length is used instead of standing height. The five predictor variables in this method are recumbent length, weight, bone age, chronological age, and parental heights.

One of the main sources of inaccuracy of adult height prediction is the inaccuracy of the bone age estimation. A small difference in bone age determination can lead to a great difference in height prediction, especially during the pubertal growth spurt (43). Comparability studies of the various methods of adult height prediction suggest that the RWT method is the most accurate, but it involves the

Figure 2 The Tanner standards for height of girls and boys from 2 to 9 years in relation to parents' height. (From Ref. 48.)

greatest amount of calculation. Its inaccuracy increases with age, and it therefore should not be used when more than half of the bones are adult (42, 43). In general, height prediction methods differ with respect to their accuracy and their tendency to overestimate or underestimate adult height (43). However, height prediction, as such, is useful only in children with normal growth rates and has limited usefulness in children who are not growing at normal rates. The calculation of target height for the family and the predicted adult height (by all three methods) can be done by computer programs developed for this purpose (ARC Software). Currently several manufacturers of growth hormone provide software at no cost to the clinician with which to follow patients with growth problems and the means to assess the information needed for a precise diagnosis.

C. Bone Maturation

In order to assess properly the predicted adult height, accurate bone maturation patterns are necessary. The two most commonly used methods of assessing the maturation or skeletal age are the Greulich and Pyle (G-P) (44) and the Tanner-Whitehouse (TW2) methods (41). The former method utilizes standards derived from US children living in Cleveland; the latter was derived from British children (45). The G-P method of assessing bone age is usually done by comparing an x-ray film of the frontal view of the left hand and wrist with given standards of the G-P atlas. The TW2 method is always done by assigning scores to each of the 20 hand bones, including the radius, ulna, carpals, metacarpals, and phalanges, depending on their stage of maturation. The total score determines the bone age. The advantage of the TW2 method over the G-P method is that it appears to be more objective. Moreover, it can differentiate bone age up to one-tenth of a year, whereas the G-P method gives only a rough approximation, with intervals of 6–12 months between the standards. Thus, the TW2 method is more sensitive in following small changes in bone age, but it is more time-consuming and few clinicians used it.

Studies comparing the two methods of bone age determination in the same ethnic population among children aged 2–24 years suggest that the median G-P skeletal ages were markedly greater than the corresponding chronological ages, particularly from 6 to 9 years in boys, and from 4 to 8 years in girls (45). The differences between these scales could be a result of real differences in the rates of skeletal maturation in the different populations. Studies were also done to determine whether there are significant differences among methods of evaluating skeletal age in relation to the group of bones studied. The results showed that when bone age is assessed by examining all the bones, but excluding the carpals, there is a high correlation with the bone age detected by measuring the maturation of all bones, including the carpals (45).

The bone maturation pattern is also helpful in differentiating the type of short stature. The bone growth in children with constitutionally delayed growth is slightly retarded (2, or at the most, 3 years), and it is usually proportional to height. When adolescence begins and the growth spurt occurs, the bone age increases proportionally to height. The bone age in patients with familial or genetic short stature is seldom retarded more than 1 year compared with chronological age, and it usually follows a normal maturation pattern. In contrast, there may be a marked bone age delay in children with pathological short stature, such as hypothyroidism, growth hormone deficiency, or chronic disease. The bone age may be even further behind than that expected for height. A short adolescent with sexual infantilism and a bone age maturation delay greater than 3 years is more likely to have pathological short stature, such as that caused by hypopituitarism or hypothyroidism. The degree of the delay may also reflect the length of time the patient has had the disease.

D. Body Proportions

Aside from body weight, height, and bone progression, attention must be given to the changes in body proportions during growth (46). The skeleton does not grow in a completely proportional manner. At birth, the upper to lower body ratio is 1.7. As the legs grow, the ratio becomes 1.0 by 10 years of age. If growth plates close early, as in precocious puberty, the proportions are those of a child, with short limbs compared with the trunk. On the other hand, if growth is prolonged as in hypogonadism, the limbs are longer compared with the trunk (47). Various types of tubular bone alterations are often found among short patients (48). These categorize patients into specific diagnostic groups and potential treatments. Thus, aside from accurate measurement of height, weight, and target and predicted height, every child who presents with a growth problem should be evaluated for disproportionate limb or trunk shortening. This information helps to narrow the differential diagnosis, including ruling out skeletal dysplasia. A detailed anthropometric evaluation of a child's body segments is indispensable.

The arm span should be measured with the patient standing against a flat wall, the arms stretched out as far as possible to create a 90 degree angle with the torso. The distance between the distal ends of both middle phalanges is measured to determine the arm span. Normally, the arm span is shorter than the height in boys under the age of 10–11 years and in girls under 11–14 years, after which the arm span becomes longer than the height. The average adult male has an arm span about 5.3 cm greater than his height, and the adult female has an arm span 1.2 cm greater than her height (Chapter 43). Conditions that adversely affect the vertebrae may result in growth retardation and disproportionately long arms. Children with arm spans that are disproportionately longer than their heights should also be evaluated for scoliosis.

Determination of the upper and lower body segment is also essential because skeletal dysplasias that result in growth problems are usually characterized by disproportionate shortening of the lower limbs or spine (Chapter 4). This can be done by measuring the distance between the upper border of the symphysis pubis and the floor in a patient who is standing against a flat wall in the proper position for height measurement. This measurement is difficult to obtain accurately, because the superior border of the symphysis pubis is not easy to locate and palpate, particularly in some obese patients. Preferably, the sitting height can be measured to represent the upper segment, using a Harpenden sitting table (Holtain Ltd.). The patient is asked to sit on the table with the back of the knees touching the table edge. The vertical unit is then moved close to the patient's back and the patient positioned so that the entire back, including the back of the head, touches the vertical surface. The sitting height is indicated by a counter, and the sitting height to standing height ratio, or relative sitting height, is calculated and multiplied by 100. The normal absolute and relative sitting heights of the different ages and sexes are listed in chapter on Reference Charts (Chapter 43). Conditions that cause disproportionate limb shortening include achondroplasia, hypochondroplasia, and Turner syndrome. On the other hand, the trunk height may be disproportionately shorter than the limbs in scoliosis or in spondyloepiphyseal dysplasia (Chapter 4).

The determination of rhizomelia should be made by accurate measurements of the proximal and distal segments of the limbs. This is important to assess for skeletal dysplasias, some of which may present clinically as short stature, without any other associated feature, such as mild

hypochondroplasia or short-limbed short stature of genetic or familial nature (48). Disproportion between the upper arm and forearm length may be determined by measuring the shoulder-to-elbow (SE) length and the elbow-to-metacarpal length (EMC; Fig. 3) using an anthropometer. For SE length, the blades of the anthropometer are positioned from the midshoulder to the distal end of the humerus, with the elbow at a 90 degree angle and the upper arm next to the lateral side of the chest. To obtain the EMC length, the blades are positioned from the tip of the elbow to the distal end of the third metacarpal of the closed hand. Normally, the SE/EMC ratio is about unity. Rhizomelia is present if this ratio is lower than 0.98 (48). The presence of shortening of specific bones may likewise lead to the diagnosis of certain syndromes, such as type E brachydactyly (49), Turner syndrome (50), or pseudopseudohypoparathyroidism (51). These patients may be seen by the physician because of short stature and must be differentiated from those with familial genetic and short stature in whom metacarpal bone shortening and other tubular bone shortenings are very prevalent (48, 52).

To detect metacarpal shortening, a ruler is placed in front of the patient's fist. In most of the normal population the three knuckles of the third, fourth, and fifth fingers touch the ruler simultaneously. In brachymetacarpia V, however, there is a gap of 2 mm or more between the fifth knuckle and the edge of the ruler, as shown in Figure 4. This clinical observation has been confirmed radiologically (52). In patients with Turner syndrome and pseudopseudohypoparathyroidism, fourth metacarpal shortening is frequent. This can be detected radiologically and clinically in a manner similar to that used to detect fifth metacarpal bone shortening (50, 51). There is a gap be-

Figure 3 Measurement of shoulder-to-elbow length (SE) and elbow-to-end-of-third metacarpal length (EMC) is shown using an anthropometer. SE is the distance between the shoulder and the tip of the elbow, whereas EMC is the distance between the tip of the elbow and the distal end of the third metacarpal on a closed fist. (From Ref. 48.)

Figure 4 A straight ruler is applied against the distal ends of the third, fourth, and fifth metacarpals of a tightly closed fist. The clinical observation of brachymetacarpia V was confirmed radiologically when the fifth metacarpal bone failed to intercept a straight line connecting the distal ends of the third and fourth metacarpal bones by more than 2 mm. (From Ref. 52.)

tween the fourth knuckle and the edge of the ruler, which touches the third and fifth knuckles simultaneously. Standards at various ages for all body parts have been established (46), and the handbook of auxological measurements should be a part of every physician's reference library to help in the evaluation of growth problems and other syndromes.

Recently the so-called SHOX gene was located in the short arm of the sex chromosome. This acronym stands for short stature homebox and defines a deficiency of one copy of the SHOX gene (53). It is believed to be the cause of some forms of short stature, including Turner syndrome (54) and Leri Weill syndrome (55). It is believed to play a significant role in growth problems with disproportionate short limbs and tubular bones alterations, particularly in patients with Madelung deformity (i.e., shortening and bowing of the radius with dorsal subluxation of the distal ulna, and partial foreleg anomalies) (53). It remains to be established whether SHOX plays a role in other more common forms of short stature, such as children with brachymetacarpia or milder forms of rhi-

zomelia. This test is now available for clinicians (www.esoterix.com).

E. Physical and Dental Examinations

Aside from obtaining accurate anthropometric measurements, a detailed physical examination may help to elucidate the cause of short stature or growth failure. Specific stigmata are present in common dysmorphology syndromes, such as Russell–Silver syndrome, Williams syndrome, Turner syndrome, and Prader-Willi syndrome (49). Signs of chronic illness should be looked for, such as pallor, dry skin, abnormal hair texture, splenomegaly, enamel hypoplasia, or dental caries. An important part of the physical examination that may provide insight into a child's maturational development is evaluation of dental age. Tables 2 and 3 list the ages at which primary and secondary teeth are expected to erupt (56). Remember that there are wide variations in the time of eruption, which may be affected by local and environmental factors, such as the size of the jaw, position of the unerupted teeth, and premature loss of deciduous teeth (57).

Table 2 Average Age at Eruption of Primary Teeth

Tooth	Age (months)
Central incisor	6–9
Lateral incisor	7–10
Canine	16–20
First molar	12–16
Second molar	20–30

Children with growth hormone deficiency or untreated hypothyroidism usually have a significantly delayed dentition or abnormal teeth (i.e., hypodontia, usually of the upper incisors), potentially associated with the epidermal growth factor gene on chromosome 4 (58–59). Mild delays in dental progress may occur in constitutional delay of growth and development.

V. CONSTITUTIONAL GROWTH DELAY

The most common cause of short stature and sexual infantilism in the adolescent is constitutionally delayed growth and sexual development. This diagnosis constitutes a large proportion of the growth disorders seen by pediatric endocrinologists. The total incidence in the population may even be higher, because pediatricians usually do not refer these patients to an endocrinologist. This entity is characterized by short stature as a variant of normal growth. These patients are the typical “slow growers” and

“late bloomers,” with a familial prevalence. Often it is recognized long before adolescence, when sexual development is not yet a concern. The child with constitutional delay of growth and development typically is characterized by a deceleration of growth occurring during the first 2 years of life, followed by normal growth progression paralleling a lower percentile curve throughout the rest of the prepubertal years, until a late catch-up growth or growth spurt occurs in adolescence (Fig. 5). Fathers usually report a similar pattern of growth and delayed puberty. Patients with constitutional growth delay usually follow a familial pattern of growth; growth delay is itself inherited from multiple genes from both sides of the family. There may be no short stature in the family, but there may be similar growth patterns. Usually it occurs in boys, only occasionally in girls. The diagnosis of constitutional growth delay in girls should be made only after eliminating other possibilities of pathological growth patterns (60).

In a longitudinal study it was clearly shown that growth progression in patients with constitutional growth delay slows within the first 3–6 months of life (61). Both height and weight gain decelerate, and infants destined to have constitutional growth delay downcross percentiles until age 2–3 years (62). Thereafter, they grow at a normal rate until adolescence. This type of recanalization of growth is also seen in infants with familial short stature (see below). However, body weight progression differs between the two types of infants. In patients with constitutional growth delay, body weight gain slows, whereas in those with familial short stature it does not. Thus, patients with constitutional growth delay appear to fail to thrive with body weight deficits for length, whereas infants with familial short stature maintain a normal, or even an excess, body weight for length. These growth patterns are maintained throughout childhood, but before puberty patients with constitutional growth delay patients exhibit body weight gain and recover the body weight deficits for height before exhibiting sexual development (62). These data suggest that in constitutional growth delay there may be an association with suboptimal nutrition at the time that weight progression decreases in infancy.

Of interest is that in developing countries suboptimal nutrition was shown to produce a growth pattern similar to that of constitutional growth delay (63). In children with growth failure due to primary malnutrition, when the nutritional intake improved, growth resumed at a lower percentile, as in patients with constitutional growth delay. Once there was downregulation of the growth, the patients canalized their growth at a lower level than that before the nutritional insult. A similar pattern of growth retardation may be induced in experiments with rats subjected to suboptimal nutrition. When given a low-protein diet they ceased growing. When a normal dietary intake was provided they resumed growth at an appropriate rate, but in a lower percentile (64). In these rats there were long-

Figure 5 Constitutional growth retardation. Left: Note the readjustment of the growth channel and weight percentile in early infancy. Right: Note the progression of height and weight below, but parallel to, the lower percentile. Body weight deficits for height are evident. There is delayed pubertal growth spurt eventually leading to normal predicted adult stature, which is in range for the target height. (From Lifshitz F, Tarim O, Worrisome growth patterns in children. *Int Pediatr* 1994; 9:181–188.)

term alternations in growth hormone and insulin secretion after the temporary dietary protein restriction in early life. These alterations in the neurosecretory axis, together with subnormal insulin secretion, likely correlated to the lack of catch-up growth. These data suggest that the down-regulation of growth in the early life of patients with constitutional growth delay may also be nutritionally related, although it is not clear why these infants would ingest insufficient nutrients for growth at this stage of life. These patients appear to have failure to thrive, and the differential diagnosis may be difficult while the recanalization of growth is taking place.

Patients with constitutional growth delay may also show an apparent deviation from the normal curve sometime between 10 and 14 years. However, this may represent merely the difference between the prepubertal child with constitutional delay of growth and development and the average child already having a pubertal growth spurt. There is also a 2–4 year delay in skeletal maturation, retarded sexual development, and a 60–90% incidence of a familial history of delayed growth and pubertal development (65). The mechanism of this phenomenon is still unclear. Some investigators consider it the result of a tran-

sient or partial growth hormone deficiency (66–68). Other groups believe that it is the result of permanently diminished growth hormone secretion during sleep (69) or modifications in the region of the IGF-I gene (70). Some investigators think that the growth hormone alterations in these patients are caused by a deficiency of testosterone or estrogen, which are known to stimulate the production and secretion of growth hormone (71). In most patients with constitutional growth delay, however, there are no abnormalities in growth hormone secretion, nor are there any other detectable endocrine alterations (72). However, some authors believe that there may be a partial growth hormone insensitivity (73).

Although children with constitutional delay attain a normal height during adulthood, they generally end up along the lower end of the normal height for their family (74, 75). Studies have shown that in boys with untreated constitutional delay in growth and puberty, there was no significant difference between final and predicted adult height, but there was a significant difference between final height and measured midparental height. Thus, although these boys reach their predicted height, they were short for their families (74, 76). This is probably the result of

the lower peak height velocity attained by later maturers than normal or early maturers (77). Other factors may play a role: for example, the selection for presentation to the clinic probably accounts for the finding that children with constitutional growth delay do not, on the average, attain the average percentile of their parents as expected (74). This may indicate that only the smallest of the sibships come to the attention of the physician (65). Also, this could be due to the possible effects of suboptimal nutrition (62) on the ultimate height and bone development. Based on various data available, it can be concluded that a child with constitutional delay of growth and puberty with a target or predicted height of 3 SD below the population mean is unlikely to reach the normal adult range of height (75, 78).

Most patients with constitutional growth delay are also short for genetic reasons. Children who have this type of short stature and who come to the attention of the pediatric endocrinologist have both constitutional growth delay and familial short stature. If a child is destined to be an average-sized adult (50th percentile) but has a 2 year delay as a child, at age 10 he or she is at the population fifth percentile. At 14 years, he is 5 cm below the general population's fifth percentile. Such patients may not come to the attention of the pediatric endocrinologist, especially because one or both of the parents may remember that he or she was a late bloomer and realize what is happening. On the other hand, if a patient is destined to reach only the 10th percentile as an adult and is 2 years late as a child, then at age 14 he would be about 2–3 cm below the third percentile, that is, more than 2 SD below the mean, and therefore likely to be referred for an endocrinological work-up. The typical boy with this syndrome is otherwise healthy, 10 years of age, and with the height and bone age of an average 8 year old. At the age of 12 (2 years later), height age and bone age are appropriate for age 10 years. Linear and skeletal growth remain consistent, but delayed, until his adolescent growth spurt takes place and secondary sexual characteristics appear. This condition is often difficult to diagnose when the patient is first seen unless measurements at various earlier ages are available, and follow-up height increments are assessed. The main concern with these patients is the psychological aspect of both the short stature and the lack of secondary sexual characteristics. In severe cases there may be a defective self-image and social withdrawal.

Treatment of patients with constitutional growth delay with or without familial short stature is controversial. The practicing physician is now under mounting pressure to prescribe human growth hormone (hGH) for short children who are not deficient in this hormone. The medical literature contains reports of improved growth with this treatment in "normal short children" who are experiencing a variety of combinations of constitutional delay and familial short stature (14, 79). To date, there is no definite evidence that even when such children transiently respond with improved growth rates with growth hormone treat-

ment, or any growth-promoting agent for that matter, there will be a permanent beneficial effect on ultimate stature. Papers published in recent literature on this subject demonstrate that there may be a mild improvement of the adult height of these patients (80, 81).

A randomized trial of growth hormone in short-normal girls clearly showed that those treated with growth hormone for up to 10 years attained an ultimate height of 5–10 cm above that of those who did not receive this medication (82). These data are important as the clinician now has information to base a clinical decision regarding the potential benefits of treatment. The potential gain of a few centimeters in height has to be considered with regard to the long-term treatment necessary to induce the extra height, potential side effects, and cost. For a complete review of the subject of growth hormone treatment of short children, the reader is referred to Chapter 3 on growth hormone treatment.

Although puberty eventually occurs spontaneously, treatment with testosterone in boys for a limited duration is recommended primarily for amelioration of the psychological problems associated with delayed puberty (83). However, treatment is recommended only if the bone age is greater than 12 years. Before this age, there may be a risk of inappropriately advancing the bone age and thus compromising the eventual adult height (84). The recommended dosage is 50 mg intramuscular testosterone enanthate or 170 mg of the cypionate form every month for 4–6 months. The 6 month course can be repeated if puberty does not progress spontaneously. Methyltestosterone may be used, but it may have potential toxicity to the liver. The use of anabolic steroids has been utilized to stimulate growth as well as to promote sexual development (85–89). Ideally, this should promote both these objectives with minimal side effects and without danger of damage to the gonads or a decrease in the patient's final adult height. In addition, there seems to be a psychological advantage to inducing puberty in patients who might otherwise have very delayed maturation.

Treatment with these medications should be reserved for patients who have attained the psychological development appropriate for puberty. Therapy may not be indicated in any patient with a chronological age of under 12 years or a bone age under 10 years. One should always keep in mind that anabolic steroids given for short periods may accelerate growth and bone maturation, but will not increase ultimate height. In fact, they may even prevent attainment of maximum height potential. Fluoroxymesterone is an anabolic compound that seems to be the best growth-promoting agent available. Long-term studies have shown that this drug causes accelerated growth without adversely causing rapid bone maturation or compromising adult height. For a comprehensive review of the effects of oxandrolone on growth, the reader is referred to an excellent article published elsewhere (89).

Aside from androgens and anabolic steroids, other pharmacological agents that have been used in the treat-

ment of these children who are not growth hormone deficient include propranolol, clonidine, and dopaminergic drugs, such as L-dopa (levo-dopa) and bromocriptine (90–93). Clonidine treatment of constitutional short stature improved the growth of some, but not all patients treated, nor in placebo-controlled studies (91–93). Other drugs used include luteinizing hormone-releasing hormone administration at physiological intervals to stimulate testosterone production by means of pituitary gonadotropin secretion (68). However, these regimens are expensive and cumbersome. Although these drugs have been shown to increase growth hormone secretion, the growth-promoting effects are debatable. Also, long-term studies on their effect on the final height of children treated by such drugs are not promising (89, 93).

The decision to use pharmacological intervention must necessarily be based on the patient's emotional outlook and the severity of delay. Most children with constitutional delay of growth and development are able to cope with this condition, if they are properly reassured about their ultimate height and development. This diagnosis, by definition, presages eventual normal maturity and height without medical intervention. A good deal of

caution is warranted when treating such a benign alteration, although the induction of more rapid maturation with medications is an immediate reward. A careful assessment of the nutritional intake is recommended, with particular attention to deficits in micronutrients, iron, and calcium, since these patients may have decreased bone density as adults (94). If deficits are uncovered, nutritional therapy is recommended.

VI. FAMILIAL SHORT STATURE

Familial short stature has also been defined as genetic short stature. These patients are short throughout life and are short as adults, but characteristically they grow at normal rates in their own percentile (see Fig. 1); however, their height is within normal limits when allowance is made for parental heights (95). The growth of these patients in infancy reveals that growth channels were reduced some time between 6 and 18 months of age (62) (Fig. 6). After 2–3 years of age growth assumes a steady channel below the fifth percentile. This is because a child's size at birth is mostly determined by maternal fac-

Figure 6 Familial short stature. Left: During infancy, the height progression is readjusted to growth channel, which is more appropriate for the genetic potential. Right: The new height percentile is maintained without further fall-off from the lower percentile, and the weight is appropriate for height. Note that short stature is life-long and there is no catch-up growth in puberty. The predicted height of the patient is in range for the target. (From Lifshitz F, Tarim O, Worrisome growth patterns in children. *Int Pediatr* 1994; 9:181–188.)

tors. After 6 months, the genetic influence predominates, and therefore a child who was born of average size may now shift to lower channels because his or her parents are of short stature. In contrast to patients with constitutional growth delay, these infants gain weight at a steady rate, do not exhibit weight deficits for height, and have no bone age delay (62).

The bone age of patients with familial short stature is consistent with their chronological age, although usually there is a component of constitutional delay in growth and development. The diagnosis of familial short stature is made when the child's height is normal, when allowance is made for parental heights, or the predicted adult height falls within the target range for the family. Tubular bone alterations were described as significantly more prevalent in children with familial short stature children and adults than in the normal height population (48). These tubular bone alterations include fifth metacarpal bone shortening (brachymetacarpia V, Figs. 3 and 4), rhizomelia, and disproportionate shortening of the arms and lower limbs. Most children and adults with familial short stature had two to four types of tubular bone alterations, whereas most individuals with normal stature had either none or only one type of tubular bone defect. A direct linear relationship was observed between the degree of shortening of the fifth and first metacarpal bones, but not of the other metacarpal bones (48).

These findings suggest that in some patients with familial short stature there may be an inherited defect in endochondrial ossification, which is the major process involved in tubular bone elongation and increase in stature. This defect may result not only in overall decrease in stature but also in disproportionate limb shortening. Patients with familial short stature may show a heterogeneous group of conditions, which manifest as short stature, with or without minor tubular bone alterations, and with or without disproportionate limb shortening, and/or present short stature with no other stigmata. For example, patients with type E brachydactyly have no other skeletal abnormalities except short stature and metacarpal and metatarsal shortening (49). Hypochondroplasia, particularly when mild, may only manifest as short stature with a slight, disproportionate limb shortening and brachydactyly (96). Unless careful observations and measurements of the different body segments are made, these patients can be underdiagnosed as having only plain and simple familial short stature. In these cases, a detailed radiological study and segregation analysis of the family members must be done. The availability of SHOX-DNA studies for diagnostic purposes remains to be established as a valid indicator for clinical assessment of these types of patients (53–55).

Although it is important to consider the parents' heights in evaluating a child's short stature, it should be remembered that a parent's stature is not necessarily familial or genetic (39). Stature also depends on a multitude

of environmental factors that may have affected a parent's growth, including nutrition, drugs, and illness (97). Thus, considering the heights of the parents' siblings and parents, as well as obtaining a medical history of the parents, are also important before making a diagnosis of simple familial short stature (95). In these patients as in children with constitutional growth delay, there is pressure to consider treatment to increase growth and attain an increased ultimate height. As mentioned above, evidence is now available demonstrating a small potential gain in height with prolonged growth hormone therapy (80–82). In normal girls with genetic short stature given this medication for up to 10 years, there was a mean gain of 5–10 cm in ultimate adult height compared with the group not treated (82). However, the cost of such prolonged therapy to gain a very modest height increment should always be kept in mind, as well as other potential side effects.

VII. PATHOLOGICAL SHORT STATURE

Pathological short stature is the least frequently occurring but most serious cause of short stature. Pathological short stature should be suspected in children who do not grow normally, those with a growth velocity of less than 4.5 cm/year after 6 years of age, and in those with marked short stature. Bone maturation is usually quite delayed, often behind that expected for height. These patients usually fail to develop sexually, and the prognosis for ultimate height is dependent on the specific diagnosis (see Table 1). Pathological short stature has accounted for over one-third of the short patients referred to a pediatric endocrinology center (13). This incidence is high compared with the general population (12), but appropriate for a referral center.

It is essential to recognize these patients. A precise diagnosis must be established for early treatment. Often the only evidence of disease is the growth abnormality. The disturbances found to account for the short stature in these children may vary depending on the interest of the pediatric endocrine center to which the patient is referred. The causes are most often endocrine, metabolic, or nutritional disturbances. Undoubtedly, other alterations known to interfere with growth in children, such as renal or cardiac, predominate in patients referred to these types of subspecialty centers. The specific pathological causes of short stature due to hypopituitarism, as well as Turner syndrome are reviewed in detail in Chapters 2 and 9. Individuals with Turner syndrome have sex chromosome abnormalities and often present because of short stature. The karyotype could be either pure 45,XO or a variety of mosaicism. In the latter case, the girl may present only with short stature with or without delayed puberty, with none of the dysmorphic features of Turner syndrome (Chapter 10). The pathogenesis of the short stature is unclear, but recent studies suggest a functional abnormality of the hypothalamic–pituitary axis. During an overnight study of

their nocturnal growth hormone secretion patterns, children with Turner syndrome had a significantly decreased number and frequency of peaks compared with normal children. Moreover, their responses to acute growth-hormone-releasing hormone (GHRH) stimulation are lower. This abnormal growth hormone neuroregulation is thought to be caused by the absence of gonadal steroids (98). Human growth hormone, anabolic steroids, and low-dose estrogen therapy, alone or in combination, have been recommended for increasing these patients' heights (Chapters 3 and 10) (99–101).

Other chromosomal defects can lead to short stature, the most common autosomal abnormality being Down syndrome. This anomaly is also the most common malformation in humans; it occurs with an incidence of 1:600. These children follow a typical growth pattern (see Chapter 43: Growth Charts) and have obvious dysmorphic features. The average adult female height is about 57 inches, and the average adult male is about 61 inches. Patients have a tendency to be overweight beginning in late infancy and throughout the remainder of the growing years (25). Growth and weight gain may also be affected by a concomitant congenital heart defect. The underlying cause of short stature remains unexplained; however, low circulating levels of insulin-like growth factor I (IGF-I) and diminished provoked and spontaneous growth hormone secretion have been reported in some patients (102, 103). However, most of the studies performed on Down syndrome patients in regard to hGH secretion were done without consideration of body composition, excess fat being a known cause of decreased growth hormone secretion (104). Thus, caution is encouraged in interpreting the results of growth hormone testing in these patients or using them in justifying treatment with growth hormone. Growth hormone treatment of a small number of patients with Down syndrome has resulted in an accelerated short-term linear growth and an increase in head circumference. However, careful and cautious evaluation of the safety, efficacy, and ethical ramifications of growth hormone treatment of children with Down syndrome is recommended before embarking on this form of intervention (105).

Short stature associated with congenital anomalies is also seen with bone diseases classified as skeletal development disorders, which result in disproportionate short stature are discussed in Chapter 4. The primary error leading to the disease may affect either the cartilaginous or the bone-forming stage of bone development. More than 250 different types of bone dysplasia are known, but the cause of most of these is unknown. The classification is therefore based largely on morphological criteria rather than metabolic or molecular ones (106, 107). This disproportion seen in many skeletal dysplasias may have therapeutic implications because some bones grow better than others. Therefore, growth-promoting agents may accentuate the disparity among the various bones.

One group of conditions characterized by severe short stature and typical dysmorphic features is occasionally referred to as primordial dwarfism because no specific cause for the short stature is defined, and no skeletal dysplasia is identifiable. Short stature is prenatal in onset, these children are born small for gestational age, and skeletal age is retarded (58). The most notable among the causes of primordial dwarfism is Russell–Silver syndrome, described independently by Silver in 1953 and Russell in 1954. Skeletal asymmetry is a distinct feature of this disorder, as is clinodactyly of the fifth finger and small triangular face with downturning of the corners of the mouth. Café-au-lait spots are usually present. De Lange syndrome typically is characterized by mental retardation, microbrachycephaly, bushy eyebrows and synophrys, and long, curly eyelashes. Patients have a small nose, anteverted nostrils, high arched palate, micrognathia, hirsutism, delayed dentition, micromelia, phocomelia and/or oligodactyly, hypospadias, undescended testes, and hypoplastic external genitals. There may or may not be associated endocrinopathies (108).

Bloom syndrome is characterized by mild microcephaly with dolichocephaly, malar hypoplasia, and facial telangiectaticerythema. There may be a mild mental deficiency and immunoglobulin deficiency. Death is usually caused by a lymphoreticular malignancy (58). Johanson-Blizzard syndrome is characterized by varying degrees of intellectual impairment. Clinical characteristics include hypoplastic or aplastic alae nasi, hypoplastic deciduous teeth, and absent permanent teeth. They may have cryptorchidism, micropenis, imperforate anus, hydro-nephrosis, septate or double vagina, primary hypothyroidism, and/or pancreatic insufficiency (58). Seckel syndrome is characterized by microcephaly, mental deficiency, premature synostosis, receding forehead, prominent nose, micrognathia, low-set and malformed ears, relatively large eyes with downslanting palpebral fissures, clinodactyly of the fifth finger, and dislocation of the radial head and/or hips. These patients are referred to as bird-headed dwarfs because of the disproportionately large nose size in comparison with the mandible and face (58). Finally, Williams syndrome is characterized by varying degrees of mental retardation, medial eyebrow flare, short palpebral fissures, depressed nasal bridge, epicanthal folds, periorbital fullness of subcutaneous tissues, blue eyes, anteverted nares, long philtrum, and prominent lips with open mouth. Nails are hypoplastic, and there may be cardiovascular anomalies, including supra-alveolar aortic stenosis, pulmonary artery stenosis, ventricular or atrial septal defects. There may also be renal artery stenosis, hypertension, and hypoplasia of the aorta (58).

VIII. INTRAUTERINE GROWTH RETARDATION

Intrauterine growth retardation (IUGR) refers to a pathological condition found in infants who have low birth

weight (LBW) for their gestational age as a result of different genetic and/or environmental influences during gestation. The Third National Health and Nutrition Examination Survey showed an overall 8.6% prevalence of U.S. newborns who are small for gestational age (SGA) of all live births (109). Elsewhere the prevalence of this condition is approximately 3% (110).

IUGR is especially important because of the higher incidence of morbidity and mortality in such children and the potential long-term complications of IUGR in adults. Infants with LBW are 5–10 times more likely to die in the first year of life than are normal birth weight infants (111, 112). Those who survive may present neurological and developmental disabilities, and have an increased risk of reduced rate of postnatal growth with ultimate short stature. Although some IUGR babies may grow and develop normally and attain normal stature as adults, about 10–15% do not exhibit catch-up growth and remain short throughout life (109). The association of IUGR with several adult-onset disorders has also been described and is currently the aim of broad research. An increased incidence of hypertension, cardiovascular and cerebrovascular disease, noninsulin-dependent diabetes mellitus (NIDDM), and lipid disorders have been reported in adults with clinical antecedent of LBW (113–120).

IUGR has been defined most commonly as a birth weight of under the 10th percentile for the gestational age (121–123). This weight cutoff has been criticized for allowing an overestimation of the real incidence of this disorder, since this implies that 10% of normal infants will have a birth weight below the 10th percentile. However, there is a significant increased risk for fetal death in those with birth weights between the 10th and the 15th percentiles (124), but up to 70% of all SGA infants may be constitutionally small fetuses expressing their genetic potential, and may not be at risk for perinatal morbidity or mortality. The remaining 30% are growth-restricted infants because of various pathological conditions, and are at risk for an adverse outcome (125–128). The standards for fetal growth developed by Brenner et al. (129), which included 30,772 deliveries made at 21–44 weeks gestation, are very useful to evaluate the presence or absence of IUGR.

A. Etiology

Normal uterine growth depends on the genetic potential of the fetus modulated by environmental, hormonal, and other biological factors, including maternal health and nutrition (130). Infants of small parents tend to be small, with maternal size having the greatest influence (131). Several factors play an important role in the etiopathogenesis of IUGR. Fetal growth failure may be due to extrinsic factors, mainly maternal, or to intrinsic fetal growth retardation. The extrinsic factors occur later in pregnancy as a result of placental disorders or maternal disease, which compromise the delivery of oxygen and nutrients

to the fetus. Of special importance is the nutritional status of the mother, as this has major implications on fetal growth. Chronic undernutrition, more prevalent in developing countries, is responsible for a large population of infants with IUGR worldwide. Different outcomes are observed according to the stage of fetal development at which maternal malnutrition takes place (132, 133). Early fetal malnutrition may affect growth permanently by reducing cell proliferation and size. A decrease of the cell size with preservation of cell population is the pathological consequence of later malnutrition, which might also result in growth deficit. Infants exposed to early fetal malnutrition have LBW and are symmetrically small (proportionate IUGR). Undernutrition in late pregnancy results in an asymmetrically growth-retarded infant whose head circumference is preserved as a result of a physiological adaptation (brain-sparing phenomenon), by which a major selective blood flow is directed to the brain (130).

There is undoubtedly an association between maternal weight status and infant birth weight (134). Adequate prenatal care and improved maternal nutrition, through balanced calorie or protein supplementation, leads to an overall increase in infant birth weight and to a decreased rate of LBW deliveries in at-risk populations (135). These guidelines have been endorsed by the American College of Obstetricians and Gynecologists (136) and used by the supplement food programs for Women, Infants, and Children (137). Previous nutritional guidelines recommended a gain of 22–27 pounds for women of all weight categories. Currently, the Institute of Medicine recommends for underweight women (body mass index < 19.8 kg/m²) a weight gain of 29–40 pounds; for average women (body mass index between 19.8 and 26 kg/m²) 25–35 pounds; and for overweight women (body mass index between 26 and 29 kg/m²) 15–25 pounds (134). These recommendations for weight gain during pregnancy have been associated with a decreased incidence of LBW (133–137).

Other maternal risk factors associated with IUGR include maternal short stature, early menarche, short interpregnancy interval, and high maternal parity. Maternal constraints of fetal growth that result in IUGR may be multigestational, an effect that may take several generations to correct (131). Often several other conditions overlap, such as chronic malnutrition and substance abuse, tobacco smoking, and alcohol ingestion (139). Mothers who live at high altitudes (>3000 m) may have systemic hypoxemia that could account for the LBW. Other maternal illnesses can impair the fetal growth because of systemic hypoxemia, including cardiac disease (mainly cyanotic type), sickle cell disease, or severe asthma. Proteinuric hypertension during pregnancy also is often complicated by growth retardation.

Intrinsic fetal factors that tend to reduce the size of the baby for gestational age include various infectious agents. These are usually responsible for early onset of IUGR, and have more severe consequences, such as

agents associated with the TORCH syndrome (toxoplasmosis, other infections, rubella, cytomegalovirus, herpes simplex). Of these, rubella and cytomegalovirus are the most important identifiable agents associated with marked fetal growth retardation. These viral agents reduce cell number and subsequent birth weight by simultaneously inhibiting cell division and producing cell death (140).

Chromosomal abnormalities, including Down syndrome, trisomy 13, trisomy 18, Turner syndrome, and other major congenital malformations are other intrinsic factors that compromise the growth and development of the fetus (141). Chromosomal aberrations and single-gene defects often result in fetal growth failure by interfering with cell division. Several syndromes cause multiple congenital malformations and are associated with IUGR (141). As mentioned above, this group of conditions is characterized by IUGR and typical dysmorphic features, which at times are identified at birth (58). Included are patients with Russell–Silver, De Lange, Bloom, Johnson–Blizzard, and Williams syndromes.

The role of imprinting genes on fetal growth is another area of interest in the causation of IUGR. Kohler et al. (142), reported the first imprinting gene (*grf1*) to be implicated only in postnatal growth control. It codes for a protein (Grf-1) found exclusively in the hypothalamus and acts as an important regulator of synthesis and release of growth hormone (GH). The Grf-1 protein is not detected in the fetus and is only slightly detectable at birth, but is clearly present on the second postnatal day. Analysis of heterozygous mutant mice for this gene confirmed that *grf1* is an important imprinted gene whose deletion leads to a significant postnatal growth deficiency that persisted in adult mice. In contrast to other imprinting genes implicated in fetal growth, *grf1* is the first to be related exclusively to postnatal growth control.

B. Hormonal Influences

Neither growth hormone nor thyroid hormones are important regulators of fetal growth. Insulin has a major effect on growth and size at birth, mostly during the third trimester when it stimulates fetal lipogenic activity, including a rapid accumulation of adipose tissue. Insulin induces protein synthesis and hepatic glycogen deposition, increases nutrient uptake and utilization, and has a direct anabolic effect. In general, growth-restricted infants are characterized by fetal hypoglycemia, which limits insulin secretion and fetal glucose production with increased protein breakdown. This reduces protein accretion, which results in slow growth. In addition, insulin plays a permissive role in the release of different growth factors from placental tissues (143). The placental lactogen, a structural related placental peptide that has many GH-like actions, also seems to play an important role in fetal growth. Maternal serum concentrations of placental lactogen rise significantly in the third trimester, parallel with a rise in serum IGF-I (144, 145).

IGF-I and IGF-II, which in the fetus function independently of pituitary GH, also have important effects on the growth and differentiation of various tissues. There is a positive correlation between the serum levels of IGF-I and birth weight (146, 147). Insulin-like growth factor levels are regulated in a reciprocal direction by maternal nutritional status. Alterations in the GH–IGF axis have been reported in infants with IUGR (147, 148). Evidence exists that GH, IGF-I, and insulin-like growth factor-binding protein 3 (IGFBP-3) are regulated in a different way in SGA infants than in infants whose birth weight is appropriate for gestational age (147). There is an inverse relation between the levels of IGF-I, its major transporter, IGFBP-3, and birth weight. The cord levels of IGF-I and IGF-II are lower in SGA infants than in neonates whose weight is appropriate for gestational age (145). Also, higher basal levels of serum GH and a higher GH response to the growth-hormone-releasing hormone have been reported in SGA infants, which might be indicative of GH resistance or insensitivity (148). In IUGR infants who achieve catch-up growth, levels of IGF-I and IGFBP-3 normalize. By midchildhood, higher serum concentrations of IGF-I have been found in this group of children than in normal control subjects. This may reflect a stage of GH resistance that could be the result of a different reprogramming of the IGF-I axis than that occurring in utero (149).

Other potential factors may play a role in fetal growth. Weber et al. (150) found clear evidence of a relationship between birth month and body size at 18 years of age, with maximal height obtained in children born in spring and minimal height obtained in children born in autumn. The underlying physiological mechanism for this effect might involve the light-dependent activity of the pineal gland. Melatonin is active during the prenatal period via transplacental passage, and its cyclic production in the newborn is already established by 9–15 weeks after birth.

Recent studies (151, 152) have shown that leptin, the product of the *ob* gene, a hormone produced in adipose tissue, may play a role in the nutritional homeostasis of the fetus and in fetal growth. The hormone has been detected in fetal blood as early as the 18th week of gestation. No relationship has been found between maternal and fetal serum leptin levels. The birth weight and the body mass index correlate strongly with the serum concentration of leptin in infants (152). Infants who are SGA have a serum leptin concentration equivalent to half of the values found in infants whose weight is appropriate for gestational age. In infants who are large for gestational age, the concentration of leptin is likewise three times higher than in infants who are SGA. Although not universally reported, there seems to be a gender correlation for leptin levels, with higher serum concentrations in female infants (151). Leptin levels are influenced significantly by fatty mass and are highly related to nutritional status during the

fetal and neonatal periods. The role of this hormone in the postnatal growth of infants with IUGR remains to be elucidated.

C. Assessment of Growth in Fetuses and Infants

The detection in utero of fetuses with IUGR may maximize the chance of survival and reduce their chance of morbidity and mortality. Ultrasound can detect up to 80% of fetuses with IUGR with great precision. However, there may be an incidence of 20% false-positive results (153). Several measurements have been implemented via ultrasound to make a diagnosis of IUGR: fetal abdominal circumference, biparietal diameter, head circumference, and skeletal length. In order to detect abnormalities in fetal growth, at least two serial ultrasound measurements should ideally be taken before the 26th week of gestation. Doppler ultrasound measurement of fetal cardiac output, systemic blood flow, and organ supply (particularly with respect to placental circulation) is a powerful tool in identifying IUGR fetuses at risk of acidemia. Cordocentesis to measure lactate concentration in fetal blood is one of the earliest markers of fetal distress. A significant correlation exists between elevated and midtrimester β -core fragment levels of human chorionic gonadotropin and IUGR, comparable to third-trimester ultrasound and superior to maternal serum analytes (154). This could be a promising new tool for the early prediction of IUGR in at-risk populations.

At birth, the ponderal index (PI) ($\text{birth weight (g)} \times 100/\text{length (cm)}^3$) is a measurement of proportionality that is simple and easily available. It has been used to determine the symmetry of infants with IUGR. Infants with low PIs have been exposed to short periods of malnutrition that compromises mostly the weight but not the length or the head circumference (disproportionate IUGR). On the other hand, infants with "normal" PIs are proportionate at birth and may have been exposed to a more chronic injury in utero. The ratio of midarm to head circumference, which reflects somatic muscle and fat stores, has been proposed as a better predictor of morbidity than PI (155).

D. Postnatal Growth and Outcome

It is important to recognize that infants with IUGR even without any major disability may fail to catch up, and their IUGR may be a cause of short stature (156). It has been shown that 15–20% of infants with IUGR will have short stature by the age of 4 years and 7.9% will have short stature at 18 years of age. Infants with IUGR usually experience catch-up growth during the first 2 years of life, with most infants achieving this growth in the first 6 months of life (109). Of those children who do not show

catch-up growth, 50% will remain short as adults (125). However the most important determinants of the final height of infants with IUGR are unknown. Leger et al. (157) reported in a longitudinal study involving 213 SGA infants that the most important factors determining final height were parental height (especially the mother's stature) and birth length, rather than variables such as gender, birth weight, or PI.

Strauss et al. (158) evaluated a cohort of infants born with IUGR and found no differences in terms of risk factors (birth weight, birth length, head circumference, PI, maternal weight gain, maternal size, placental size, smoking, toxemia, or hypertension) between the infants who showed catch-up growth and those who did not, suggesting that genetic factors rather than environmental events account for the persistent effects of IUGR on growth. The importance of a genetic contribution is supported by the increased prevalence of IUGR within some families and the discovery of single-gene mutations in IGF-1 in some infants with IUGR (159). The Third National Health and Nutrition Examination Survey (109) showed a tendency of infants who were SGA at birth to be shorter and to have smaller head circumferences despite catch-up growth. In general, after an initial period of rapid growth, infants who were SGA at birth can be expected to attain growth around the 25th percentile in early childhood. Unlike term infants who are SGA, LBW infants who are born preterm usually show poorer progress. Infants with IUGR attain 80% of catch-up growth in the first 6–8 months of life (111). In those in whom catch-up growth does not take place, final stature may be compromised.

However, the postnatal growth of IUGR infants often is compromised by failure to thrive (FTT). The incidence of FTT in IUGR infants appears to be high, and it is often difficult to determine if such infants are growing normally after birth without experiencing catch-up growth or if they have FTT. Kelleher et al. (160) reported an incidence of 19.7% of FTT in a cohort of 914 preterm infants with LBW who were evaluated for 3 years. Infants who experienced FTT remained smaller on all growth parameters (weight, length, and head circumference) at 36 months of age compared to their matched controls. On the other hand, IUGR infants who are labeled as experiencing FTT may be growing appropriately and may be subjected to unnecessary diagnostic and therapeutic studies (13). One example of normal growth in IUGR misdiagnosed as FTT is shown in Figure 7. The weight and length of this patient were plotted on a growth chart for normal children, not on the specific IUGR growth charts available for these infants. However, a simple examination of the anthropometric measurements of this patient ruled out the diagnosis of FTT. The patient tripled his weight by 1 year of age and quadrupled it by 2 years. His length likewise progressed well and remained proportional to weight throughout. A careful evaluation of the growth pattern and weight gain elucidated the differential diagnosis.

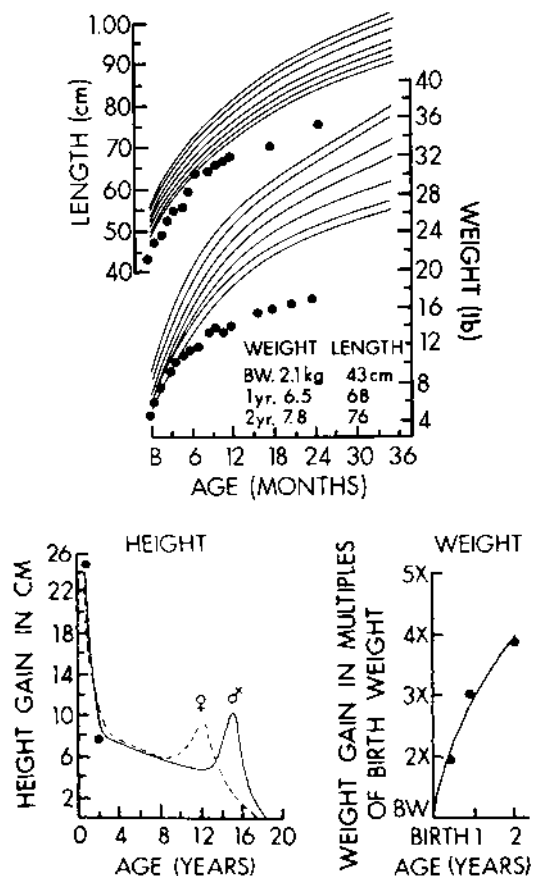

Figure 7 Top. Growth patterns of a patient with intrauterine growth retardation. Bottom. The growth velocity is plotted against normal standards. Note that this patient did not have failure to thrive nor was it suspected because he was growing at a normal velocity. (From Ref. 13.)

The diagnosis of FTT cannot be sustained when the birth weight is tripled within the first year of life. This rate of growth is the one that occurs in normal children. However, this infant did not exhibit catch-up growth. Infants with IUGR who start with a tremendous size deficit and who do not exhibit catch-up growth may be expected to remain proportionally small thereafter. Aside from the absence of catch-up growth, these children with IUGR may undergo early puberty and be unusually short as adults (161). Often these children may be forced to increase calorie intake in order to grow more in length to no avail.

However if weight gain progression does not occur at a normal rate, FTT must be considered. Because infants with IUGR often have other associated abnormalities such as neurological, cardiac, or pulmonary disorders, these may contribute and compromise growth and/or lead to

FTT. Frequently these patients also present oral motor dysfunction (162) resulting in "poor feeding." Nutrient intake in LBW infants is difficult at best, and most often does not meet the recommended dietary intakes (163). There is an accumulated nutrient deficit during the first few weeks of life of energy, protein, and other nutrient alterations that has an impact on infants' growth. The long-term consequences of this accumulated nutrient deficit may be important: as much as 45% of the growth variation was related to this. Thus, IUGR infants must be carefully monitored to ensure an adequate intake, which should allow for their maximum growth after birth. This is particularly important because growth hormone was recently approved for treatment of such infants, and this should not be undertaken without appropriate nutrient intake.

Growth failure in IUGR children is a new Food and Drug Administration (FDA)-approved indication for HGH therapy (Chapter 3). With the availability of unlimited amounts of biosynthesized HGH, the possibility of improving the final adult stature of children with IUGR by giving daily injections of HGH has been assessed in several studies (164–173). Although long-term results of HGH therapy in children with IUGR are not yet available, some studies have shown a short-term growth benefit after 2–4 years of HGH therapy (164–173). A clear dose–response effect to HGH was also shown (169–171). Dosages from 0.4–1.2 U/kg have been implemented, with a better growth response occurring with the highest dosages of HGH. However, some studies have shown that by using high dosages of HGH (>1.2 U/kg) accelerated skeletal maturation occurs. This could minimize the long-term benefits of the initial growth response (161) and the final height of IUGR subjects may not differ with and without growth hormone treatment (174).

High dosages of HGH have been used in infants with IUGR based on the hypothesis of a state of HGH insensitivities in this group of patients, which might be overcome by administering elevated dosages of the hormone. The use of high dosages of HGH in infants with IUGR is only recent and although HGH seems to be well-tolerated, long-term side effects have not been ruled out. Taking into consideration some data showing a potential risk for hyperinsulinism in infants and children with IUGR (115, 117–119), and since one of the potential side effects of GH therapy is the induction of insulin resistance, the use of high dosages of HGH in these patients must be viewed with caution.

Although some of these studies have shown promising results with HGH therapy, this form of treatment has only been implemented for a relatively short period of time, and no long-term data on the beneficial effects on final adult height are yet available (169). In most of these studies administration of HGH was started in patients over 2 years of age (171). To date, it is not known if there may

be a better chance to induce a higher level of recanalization of growth with an earlier onset of HGH therapy.

E. Long-Term Effects

IUGR may have important long-term consequences, resulting in increased morbidity and mortality in adulthood. Experiments using animals (175, 176) indicate that transient events in fetal and early life might lead to permanent and significant changes in physiology and metabolism later in life. These studies have shown that undernutrition during critical period of rapid growth in fetal and early life may permanently modify the structure and physiology of different organs, including that of the endocrine pancreas, liver, and blood vessels, changing their structure and physiology permanently. In this way, hormonal physiology and tissue sensitivity could be definitely compromised, leading to disease in adult life, a phenomenon called "programming" (177). Hales and Barker (178), in their "thrifty phenotype" hypothesis, have pointed out how prenatal nutrition has an effect on fetal development that becomes evident in adulthood. This hypothesis has been supported by animal experiments. Pregnant rats fed with isocaloric, protein-restricted diet have offspring with lower birth weights, decreased β -cell mass, decreased islet vascularization, and impaired insulin response (176). This damage might be irreversible if a normal diet after birth does not restore a proper insulin response by adulthood. Thus, permanent endocrine dysfunction is one consequence of initial in utero nutritional insult.

Epidemiological and long-term follow-up studies have shown an inverse relation between birth weight and several adult-onset diseases (178, 179). A higher percentage of essential hypertension, impaired glucose tolerance, NIDDM, ischemic heart disease, high serum triglycerides, and low serum high-density lipoprotein concentration (syndrome X) has been reported in adults with a clinical history of LBW (180). These studies have shown a reduction in insulin response in prepubertal children and adults with a history of IUGR. The lower sensitivity to insulin seen in infants with IUGR might indicate that insulin resistance is present during childhood even without clinical manifestations. Low birth weight secondary to malnutrition during fetal development might be associated with abnormalities in muscle structure and function, which could interfere with glucose uptake, normally induced by insulin. Thus the β -cells must produce larger amounts of insulin to keep serum glucose levels within the physiological range, which in the course of time could lead to their exhaustion. Previous studies (177–180) have shown an association of several cardiovascular risk factors with insulin resistance. Thus, the presence of insulin resistance in children with IUGR could be a risk factor for the development not only of adult-onset NIDDM (117–119) but also of cardiovascular disease. A higher prevalence of arterial hypertension, high serum triglyceride concentrations, and low concentrations of high-density

lipoprotein cholesterol is found in adults with antecedent of LBW (177).

A threefold increased risk of NIDDM in men over 60 years of age with the clinical antecedent of IUGR was reported in a Swedish study (118). A recent study of a cohort of 70,000 women from the Nurses' Health Study (117) likewise found a strong inverse correlation between birth weight and NIDDM among more than 2000 confirmed cases of NIDDM. Women who weighed less than 5 pounds at birth had a relative risk for NIDDM of 1.83, compared with a risk of 0.83 in women who weighed more than 10 pounds at birth.

It is evident that growth restricted newborns are not all created equally (181). In recent years HGH trials have demonstrated an apparent beneficial effect on patients with noncomplicated IUGR treated after 2 years of age for 2–4 years. Most of these studies (171) have shown recanalization and improvement of height, although long-term data demonstrating gain in adult height are lacking. Whether an improved height attained with HGH treatment could ameliorate some of the long-term sequelae of IUGR in adult life is not known at present. However, in very stunted IUGR patients, it can be expected that psychological adjustment could improve with treatment that results in increased height.

IX. FAILURE TO THRIVE

The term, "failure to thrive" (FTT) is used to describe infants and young children whose body weight and weight gain are substantially less than those of their peers. It is defined as growth deceleration to a point below the third percentile in weight; a child who has fallen across two or more percentiles; or a child whose weight is less than 80% of the ideal weight for age.

FTT accounts for 1–5% of tertiary hospital admissions for patients less than 1 year of age (182). Many more children, perhaps 10%, are managed as outpatients by physicians throughout the United States (183). Despite its established status in medical terminology, the concept of FTT lacks a clear definition and should be considered a sign or symptom, not a diagnosis or a disease (184).

Children with FTT are typically diagnosed in the first few months of life and their illness may persist for years. All FTT infants have physiological alterations due to malnutrition, but the causes can be categorized as organic or nonorganic (185). Organic FTT (OFTT) involves infants who have specific diagnosable disorders. It is only identified in 20% to 40% of children hospitalized with FTT and even less frequently in outpatient clinics.

Non-organic failure to thrive (NOFTT) is a subtype of FTT that accounts for the majority of infants with FTT, although the percentage varies from institution to institution. NOFTT does not imply a specific cause, but merely suggests that the cause is primarily external to the infant (186). In addition, there may be an overlap between OFTT

and NOFTT owing to the presence of minor infections, vomiting, and diarrhea together with behavioral problems and altered eating behavior. Therefore, several authors have questioned the adequacy of this dichotomous view, suggesting the need for a third category: so-called mixed cause (187, 188). NOFTT is more than a growth problem. Children with NOFTT present a low rate of weight or length gain, delayed development, abnormal behavior, and distorted caretaker–infant interaction.

Failure to thrive can be due to a variety of disorders that may have little in common except for poor body weight. Each one of them must be recognized and treated accordingly (189–191). However, the goals of nutritional rehabilitation are similar regardless of the cause. On the other hand, pediatricians should always be aware of different patterns of growth in the first years of life that can present as factitious failure to thrive (192). These patterns include patients with constitutional growth delay and/or familial short stature. Because the size of an infant at birth is more related to maternal size and intrauterine influences than to genetic factors, in some children an adjustment in growth velocity greater than 25% (across two percentile lines) takes place as a recanalization of normal growth. A significant decrease in growth rate in these conditions may represent a physiological event in the first years of life and does not necessarily indicate FTT. Also, patients with IUGR may mimic the symptoms of FTT as described above.

A. The Breastfed Baby

Caution must also be taken in labeling an infant who is exclusively breastfed as having FTT. Because growth charts for breastfed infants are not usually used, a normal growth pattern of a breastfed baby may seem to be lower on the growth channel of the most frequently used growth charts, which are based on studies of infants who were mostly formulafed (193, 194). To date, no clear data would warrant discouraging breastfeeding of an infant whose growth seems to deviate across channels in such growth charts. Human milk is the ideal and most readily available nutrient, and should therefore be continued and encouraged as much as possible. However, breastfeeding alone may not be adequate for a particular child who indeed may be failing to gain weight appropriately (195–197). Breast feeding must be closely monitored to ensure that adequate lactation is present and that the infant thrives at an appropriate rate as plotted on growth charts specific for breastfed babies (11).

The effect of prolonged breastfeeding on growth is controversial. One study (194) demonstrated that exclusively breastfed infants had slower length velocity after 3 months of age than infants who were weaned early and given formula plus solids. This trend was more obvious at 9 months of age. In this study, relative weight for length had no deficit. The growth of breastfed and formulafed infants from 0 to 18 months of age was investigated in

the so-called DARLING study (198). The mean weight of breastfed infants was shown to drop below the median of the formulafed group between 6 and 18 months of age. In contrast, length and circumference values were similar between the two groups. The results of the study showed that breastfed infants gain weight more slowly than formulafed infants from similar socioeconomic and ethnic backgrounds during the first 9 months of life.

A comprehensive assessment of the effects of prolonged breastfeeding on children's growth was performed by Grummer-Strawn (199). In this retrospective analysis of 13 studies, eight reported negative relationships between breastfeeding and growth, two found a positive effect, and three showed mixed results. Even if prolonged breastfeeding is found to impair weight gain, the protection that breast milk offers against infection and other health benefits would argue in favor of preserving the policy of encouraging human milk feedings as the main food, (sole feeding for the first 4–6 months of life), particularly where sanitary conditions are poor. Prolonged breastfeedings also provide beneficial impact on birth spacing, mother–child interactions, infections, allergies, other morbidities, and infant mortality.

B. Clinical Findings

In the NOFTT syndrome, both inadequate nutrition (i.e., nature) and distorted social stimulation (i.e., nurture) contribute to poor weight gain, delayed development, and abnormal behavior. The clinical characteristics of infants with this type of FTT include small for age, thin for length, wide-eyed expression or gaze aversion, thin chests, wasted buttocks, prominent abdomen, hanging folds under the arms, expressionless face, decreased vocalization, gross motor activity, and response to social stimuli; lack of cuddling, and clenched fists.

There is evidence that NOFTT infants may present a combination of biological vulnerability, environmental difficulties, and be the products of parents with poor marital relationships (200, 201). Infants with this type of FTT are more passive, more likely to sleep through meals or take longer to finish their meals, and more likely to be diagnosed as hypotonic. There is also evidence that NOFTT infants receive less appropriate developmental stimulation at home and have developmental delays.

Developmental delays have also been linked to oral–motor dysfunction (OMD), which is frequently found in FTT children. When children with FTT were compared with children of the same developmental age with cerebral palsy, the oral–motor profiles were remarkably similar. It has been hypothesized that children with OMD might have subtle neurodevelopmental disorders (202). At 20 months of age, FTT infants were twice as likely to show mental developmental quotients less than 80 (200). The infants also showed less sociability. The clinician evaluating a child with FTT must also consider that prenatal factors may play a role in causing the problem. The pos-

sibility of prenatal exposure to psychoactive substances needs to be ascertained, including exposure to alcohol, tobacco, and other drugs (203). There may also be signs of neglect, abuse, or illness in infants with FTT. It should be kept in mind that confirmation of the diagnosis of NOFTT is always based on a positive growth and behavioral response to treatment.

C. Nourishing and Nurturing

Every child who fails to thrive has either not taken, has not been offered, or has not retained adequate energy to meet his or her nutritional needs. However, FTT infants prove that nourishment involves much more than ingestion of food. In most instances NOFTT results from a disruption in nurturing practices that ultimately affects the child's ability to obtain proper nourishment. These nurturing factors include parental beliefs and their concept of nutrition. Also the infant's behavior or adverse social or psychological environments may contribute to an inadequate nurturing environment, leading to NOFTT. Therefore, direct observation of mother–infant feeding and their social interaction is a necessary part of the evaluation. A careful nutritional evaluation must also be performed, which should include collecting dietary intake from a 24 h dietary recall or, more accurately, a food diary for 3–7 days. It should also address meal frequency, feeding patterns, and an assessment of all fluids given. It is also valuable to determine whether any particular food was restricted or promoted i.e., “no junk food,” increased fruit juice consumption (204–208), or if there are vegetarian practices (209–211).

Often the diet record suggests that the child is receiving adequate calories for weight and length, but not for age. This level of intake allows the infant to maintain current weight but does not provide sufficient nutrients for growth. Sometimes the dietary intake is adequate in calories and protein, but is deficient in specific nutrients, such as iron, zinc, and/or other micronutrients, resulting in growth faltering (212–215). Supplementation studies have demonstrated that improvements in nutrient intake result in improved growth, including bone mineralization and maturation (216–218).

Particular attention should be paid to the presence of nonspecific symptoms, such as intermittent vomiting, spitting up, diarrhea, and frequent upper respiratory tract infections. These may be present in infants with NOFTT and in other organic conditions (i.e., gastroesophageal reflux) (219). So-called feeding difficulties may also lead to decreased nutrient intake in NOFTT infants (220). These infants exhibit unusual behaviors, such as wide-eyed staring, gaze avoidance, fist clenching, and apathy toward their caregivers. Although apathy and decreased motor activity are recognized behaviors in malnourished infants (221, 222), many of the abnormal behaviors of patients with NOFTT are not attributable to malnutrition alone.

Some nutritional alterations may influence the in-

fant's behavior. Iron deficiency during infancy has been associated with anorexia, irritability, and lack of interest in their surroundings (223, 224). Zinc deficiency may likewise compound the course of FTT and excess lead ingestion may complicate the clinical picture even before the lead blood levels reach a toxic concentration. NOFTT infants were shown to have lead blood levels in a range formerly thought to be safe (i.e., 15–20 mg/dl) (225). These elements should be monitored in all FTT patients and treatment should be given when alterations are demonstrated.

If decreased nutrient intake is found to be the cause of inappropriate weight gain, the question becomes: Why are insufficient amounts of food consumed by infants with NOFTT? Are these infants simply not offered enough? Do the infants fail to signal hunger or satiety? Do they have a poor appetite or refuse food?

D. Neglect and Deprivation

In frequent cases, parental stress affects the way infants interact with their mothers (190–192). The quantity and quality of social and emotional stimulation between mother and child may be decreased even before clinical evidence of FTT is apparent. Many mothers of NOFTT infants are depressed, come from lower socioeconomic groups, lack a support group, and/or are themselves under multiple stresses. Mothers from higher socioeconomic groups may also lack the emotional strength or motivation to interpret or respond to the needs of their infant. As more mothers become engaged in work outside of the home or involved in activities that are independent of their family responsibilities, their children may not be getting the appropriate attention to meet their needs for nurturing (226).

Psychosocial deprivation may also lead to FTT in infants (227–229). It has long been known that neglect and deprivation may lead to FTT. King Frederick in Sicily was interested in learning the innate language of humans. Consequently he isolated infants to learn what language they would speak spontaneously. These children did not thrive and thereafter died due to lack of communication and attention (230, 231). Also, it has long been known that infants often died and did not thrive in foundling homes (232–236) or hospitals (237, 238). A classic example of the role of nurturing influencing somatic growth was described by Waddissom (236). She described the experience of two German orphanages run by women of different personalities. The children under the care of the unpleasant, aggressive woman who did not render nurturing care did not thrive, whereas those under the care of the woman with opposite personality traits grew well. Both groups had similar dietary intakes. These patients usually have no hormonal disturbances such as growth hormone deficiency to account for poor growth, and they usually recover when sufficient nourishment and nurturing is given.

E. Infantile Anorexia

An infant behavior that typically leads to FTT is infantile anorexia nervosa, which is characterized by food refusal, extreme food selectivity, and undereating despite parental efforts to increase the infant's food intake. The onset of this disorder usually is between 6 months and 3 years of age, with peak prevalence around 9 months of age (239). The feeding difficulties stem from the infant's thrust for autonomy; a striking observation in these infants is their willfulness. Mother and infant become embroiled in conflicts over autonomy and control, which manifest primarily during feeding time. This conflict leads to a battle of wills over the infant's food intake. Characteristically, parents mention that they have tried "everything" to get the infant to eat. Chatoor and colleagues (240) hypothesized that this separation-related conflict interferes with the infant development of somatopsychological differentiation. The process of differentiating somatic sensations, such as hunger or satiety, from emotional feelings, such as affection, anger, or frustration, is clouded by noncontingent responses by the parents to cues coming from the infant. As a result of this confusion, the infant's eating becomes controlled by emotional experiences instead of by physiological needs. The focus of the treatment is on improving communication between the parents and the infant to facilitate the process of separation and individuality. In a cognitive-behavioral approach, the therapist explains to the parents the infant's behavior and suggests ways to positively modify and structure mealtimes to facilitate growth.

F. Laboratory Findings

Poor nutrition and psychosocial factors are by far the most frequent factors leading to NOFTT. Therefore, laboratory tests offer limited value in determining the causes of growth deficiency and should only be used when the findings from the history and physical examination indicate something organic or possible nutritional alterations. In some cases, the child's bone age should be determined to facilitate the process of ruling out systemic chronic diseases or a hormonal abnormality. This measurement may also be of help as a baseline for future growth and bone development progression.

Unless organic disease is suspected, detailed testing should be reserved for patients in whom management of nutritional and psychosocial problems does not result in the expected improvement in the rate of growth. It has long been known that fewer than 1% of laboratory tests showed an abnormality that helped identify the cause (241). However, laboratory evaluation of the nutritional status should be comprehensive to assess for deficiencies that are not clinically apparent (242). Such an evaluation should include iron deficiency, which may be responsible for anemia and some of the long-term complications of FTT even when there is no anemia (212–221).

If weight gain does not occur soon after advice is given to the parent(s) about feedings, the child needs to be evaluated more intensely. Usually these patients are admitted to the hospital to have possible organic alterations ruled out, and most importantly simultaneously to receive appropriate nutritional intake to induce weight gain and thus to verify that the patient has the capacity to grow well (243).

G. Management

In the past, hospital care was routinely recommended as part of the initial management of FTT patients. The goals were to ensure an adequate dietary intake, to observe the child's behavior, and watch the family-child interactions. Despite today's economic constraints, hospital care is justified when the patient has not responded to appropriate outpatient management; the severity of the malnutrition warrants it; or abuse, neglect, or both are suspected. A meta-analysis of NOFTT found that hospitalization significantly improved growth recovery and sustained catch-up growth (244). However, an aggressive outpatient management program may also be appropriate (245). The use of a multidisciplinary team usually offers special advantages in the rapid correction of undernutrition and developmental progress in children with NOFTT (246).

Nutritional therapy of FTT children has several goals: (a) achieving ideal weight for height; (b) correcting nutrient deficits; (c) allowing catch-up growth; (d) restoring optimal body composition; and (e) educating parents in the nutritional requirements and feeding of the child. Regardless of why a child fails to thrive, effective nutritional management consists primarily of providing enough calories to achieve a positive energy balance and growth. The World Health Organization Expert Consultation on Energy and Protein Requirements recommended that "whenever possible, energy requirements should be based on measurement of expenditure rather than intake" (247). The standard energy expenditure prediction equations were all derived from data accumulated from healthy children. Thus they may underestimate about one-quarter of the true energy requirement for infants with FTT (248).

Because nutritional intervention is usually the focus in treating children with FTT, high-calorie, adequate protein feeding has been advocated for many years. With this treatment the child recovers more rapidly, the stay in the hospital is shorter, and more children can be treated in a given period of time at less cost. Nurses or trained therapists should feed the infant initially to allow identification of a feeding problem and to ensure that intake will be adequate. Proper feeding of the FTT child can be achieved most often with infant formula that is given in sufficient quantities to meet the child's specific nutrient needs. Protein and other types of supplementation are usually not needed, but some products can be used when indicated.

Tube feedings are indicated only in cases of severe malnutrition or failure to induce weight gain in the hos-

pital. They may be necessary if the child is severely debilitated, metabolically unstable, or requires immediate restoration of fluid and electrolyte balance. Tube feedings may be useful for children with NOFTT as a temporary behavior modification modality, or in patients who fail to respond to other methods of nutritional rehabilitation (249).

Many clinical trials have indicated that supplementation with micronutrients improves weight gain in growth-faltering patients. Single-nutrient deficiencies are cumbersome to document and micronutrient deficiencies commonly coexist. For example, iron deficiency may be present without iron deficiency anemia, and zinc deficiency may be difficult to document by the lack of a good indicator. Yet clinical trials of iron supplementation have positive effects on weight gain, linear growth, and psychosocial behavior (212, 221, 250). Similar studies have revealed positive effects with zinc supplementation on growth as well as on morbidity and severity of infections in children. (251–256). Vitamin and mineral deficiencies sometimes become evident only after the infant starts growing and gaining weight. Therefore a multivitamin–mineral preparation that includes iron and zinc is recommended for all undernourished children.

Nutritional rehabilitation for these children must accomplish catch-up growth, which is defined as the acceleration in growth that occurs when a period of growth retardation ends and favorable conditions are restored. Catch-up growth in FTT depends on the provision of calories, protein, and other nutrients in excess of normal requirements. Children need 25–30% more energy and nearly double the amount of protein for catch-up growth (257). The extent to which nutritional rehabilitation can restore normal body size and composition is a critical subject. Returning to one's previous growth curve does not indicate achievement of a normal body composition (258).

H. Recovery

During the recovery period, parental nutrition education programs are extremely important. When families with psychosocial maladaptations are revealed to be major contributors to FTT, the physician must discuss these behaviors in a nonjudgmental way, so that guilt is not increased or compliance endangered. Parents should be reassured, and support should be provided for correction of the problems as much as possible.

To improve their infant's eating habits, parents should be introduced to inpatient treatment programs for food-refusing infants (259). Parents and infant may have to be separated at meal times. The nurse must feed the child with structured, time-limited meals. Parents are to be given individual therapy and afterwards be reintroduced to the feeding situation. Parents must be educated regarding the catch-up growth process and long-term growth goals for their child. The baseline appearance of a cachectic child may bias the family's perception of recovery.

The misperception that the recovering child is too plump may result in an abrupt diet change and abandonment of high-calorie feedings.

In all instances and at all stages of the evaluation and treatment of FTT, a "working alliance" between key family members and professionals must be established (260). Developing such relationships can be a challenge and it requires the availability and commitment of multidisciplinary teams to assist the family in the treatment of NOFTT.

Continued treatment after discharge from the hospital is necessary and the infant should be evaluated at regular intervals for a long time. Growth, development, and social behavior must be carefully and continually monitored. Temporary placement in a more favorable setting within the family or in a foster care environment may be necessary if the immediate family is judged as incapable of following through on the recommended management.

I. Long-Term Outcome

A few systematic long-term studies of growth and development in NOFTT infants have been carried out. The longest follow-up study on growth found a difference between former FTT children and control children when the relationship between the height and weight ages of the children were compared with their chronological ages (261). Of the children with FTT, 6 of 14 were 1 or more years below their chronological age for height and weight. In the comparison group it was 1 child out of 14. Studies of catch-up growth show that NOFTT children continue to do poorly developmentally despite increased weight. A study by Singer showed that even after extended hospitalization, NOFTT infants manifested persistent intellectual delays at a 3 year follow-up examination, despite maintenance of weight gains achieved during early hospitalization (262).

These children remained significantly behind their control group in language development, reading age, and verbal intelligence. They also scored lower than the control group on a social maturity rating.

J. Special Considerations

The physician faces specific additional problems when dealing with a NOFTT patient in the managed health care environment. The diagnostic coding of such children is fraught with so-called Catch-22 dilemmas (263). Medical, nutritional, developmental, and/or psychiatric diagnosis may be utilized, but no optimal classification and coding scheme exists for use in these patients. The rapid growth of managed care also has significant implications for access to care, quality of services, reimbursement, and payment for health care. The special needs of these patients amplify the issues and challenges in ensuring that managed care is an effective component of community resources that foster healthy growth and development (264). These patients are at risk for concurrent illness and ad-

verse development outcomes. A healthier child ultimately requires fewer services and indirect benefits may also occur with fewer health care expenditures and lifelong productivity.

X. NUTRITIONAL GROWTH RETARDATION

The single most important cause of growth retardation worldwide is poverty-related malnutrition (265). When suboptimal nutrition is continued for prolonged periods of time, stunting of growth occurs as the main clinical picture (266, 267). However, nutritional growth retardation (NGR), as found in pediatric endocrine practices in the United States, is usually not the result of poverty-related malnutrition. NGR and delayed sexual development among suburban upper middle class adolescents is most often a result of self-restrictive nutrient intake (35, 268). Also, poor growth and inadequate nutrition have been found in such systemic problems as chronic inflammatory bowel disease (CIBD) and celiac disease (CD) (269, 270). Children with NGR are generally referred to the pediatric

endocrinologist because of short stature or delayed puberty. Therefore, pediatricians and pediatric endocrinologists need to recognize NGR and become familiar with its causes and treatment.

A. Diagnosis

Pediatric endocrinologists usually evaluate linear growth accurately in the assessment of patients with short stature, but often little consideration is given to body weight progression. Although the importance of evaluating the pattern of stature increments throughout life in the differential diagnosis of short stature cannot be overemphasized, the assessment of the progression of body weight is equally relevant to be able to recognize NGR. Figure 8 illustrates this point.

This 15-year-old boy was referred to the endocrine clinic with short stature of unknown cause. He was healthy in all other respects, and the only presenting symptom was deteriorating linear growth. On examination, both his height of 146.9 cm and weight of 37.6 kg were below the fifth percentile. No body weight deficit for height was evident, and sexual development was de-

Figure 8 a. The patient was referred because of short stature. Initially, the heights and weights depicted were the only available data. Signs of sexual development were absent. b. Complete growth data for the patient, who began dieting at 12 years of age. (From Ref. 272.)

layed (Tanner stage 1). The initial measurements provided by the referring pediatrician indicated a decreasing growth rate with appropriate weight gain that was progressing just below the fifth percentile (Fig. 8a). However, after additional growth data were obtained and all height and weight records were compiled, a typical picture of nutritionally related growth retardation emerged (Fig. 8b). At 12 years of age, his weight gain ceased, which subsequently resulted in deceleration of linear growth and pubertal delay. Review of his nutritional intake showed that he was consuming only approximately 60% of his estimated energy needs based on age and gender. He was an athletic boy who described a desire to remain slim and avoid obesity, a syndrome that was discovered in 1983 (34).

The Wellcome Trust classification differentiates NGR from other types of malnutrition characterized by wasting and stunting (271). The anthropometric criteria for ND stipulate low weight for age with minimal deficit in weight for height. By these criteria, it may be difficult to differentiate NGR children from those who have familial short stature or constitutional growth delay. Cross-sectional data in these normal children may also demonstrate weights below the mean for age. Only the longitudinal progression of body weight and height can more clearly reveal NGR (272), which may occur even when there is weight-for-height excess (273). In NGR there is a deteriorating linear growth and/or delayed sexual development associated with inadequate weight gain (Fig. 9a,b) (34, 268, 272). This pattern of growth is seen in organic forms of NGR, as in chronic inflammatory bowel disease (274), as well as in nonorganic forms, that is, ingestion of restrictive diets (207). Furthermore, although concern is heightened when weight or height measurements fall below the fifth percentile, deterioration across percentiles of weight and height may also indicate NGR, even when height and weight are above the fifth percentile. With nutritional rehabilitation, catch-up growth is usually achieved.

The analysis of body weight progression may be the most important clue to diagnosis of NGR in patients with short stature (Fig. 9a,b). The calculation of theoretical weights and heights based on previous growth percentiles may be used to compare current anthropometric indices quantitatively with previously established patterns of weight and height progression (Fig. 9a). Theoretical weight is defined as the weight the patient should have had at the time of the examination, if the patient had continued to gain weight along the previously established percentile during the premorbid growth period (272). Body weight for height deficits are not common in NGR, but there is often a body weight deficit for theoretical weight (Fig. 9a,b). In contrast, short patients without NGR, such as those with constitutional growth delay, continue to gain weight along established percentiles and the body weight at the time of assessment is equal to the theoretical body weight (Fig. 9c).

The growth patterns of NGR must also be differentiated from normal variations in growth that may occur as a result of variations in frame size, feeding practices, or constitutional factors that may resemble NGR. Most normal children exhibit minimal deficits or excesses in body weight in proportion to height and grow along established percentiles (275). These constitutional variations in body weight are usually within one or two major percentiles of the height; they represent variations in frame size and do not necessarily reflect over- or undernutrition. The body weight and height increments of a child with constitutional thinness are depicted in Figure 10. Although his body weight was two major percentile lines below the height percentile, representing more than 20% body weight deficit for height, the adolescent grew and developed normally. A body weight deficit for height that remains constant and permits normal growth to proceed along a set percentile cannot be construed as abnormal. In contrast, a fall in growth associated with a poor rate of weight gain may indicate NGR, even without an appreciable body weight deficit for height (Figs. 8b,9a).

The pattern of growth and weight gain in NGR differs from that of children with constitutional growth delay or familial short stature. The latter type of patients grow at constant rates, and their weight progression is also maintained in their respective percentiles after 3 years of age, as described above. In infancy, the pattern of growth and weight gain among constitutional growth delay and NGR may be indistinguishable. However, the children with constitutional growth delay usually recanalize their growth and gain weight and height over time at appropriate levels, and do not exhibit any nutritional intake alterations. There may likewise be confusion at this stage in life between NGR and the breastfed infants. The latter gain at appropriate rates when their length and weight are plotted in specific growth charts for this type of infant as described above.

Patients with nutritional growth retardation do not appear to be wasted, and the biochemical parameters of nutritional status, including serum levels of retinol-binding protein, prealbumin, albumin, transferrin, and triiodothyronine (T3) levels, do not differentiate NGR patients from those with familial or constitutional short stature (276). Other indices of malnutrition, such as the urinary creatinine–height index or urinary nitrogen/creatinine ratio, do not usually reflect abnormalities. The reason is that NGR patients have adapted to their suboptimal nutritional intake and they maintain homeostasis by decreasing growth, thereby reaching an equilibrium with preservation of all nutritional markers. We also showed that IGF-1 levels could not differentiate NGR patients from those with familial constitutional short-stature (276). This is in contrast to other studies, which measured IGF levels and their binding proteins (IGFBP) in fasting and in varying levels of nutritional intake, both in rodents and in humans (277–286).

These studies showed that IGF-I is reduced in children with protein-calorie malnutrition and in rats chronically deprived of nutrients. Reductions in IGF-I concentrations were observed in fasted volunteers (281). However, the degree of nutritional insufficiency in NGR is not as severe as that observed in protein-calorie malnutrition or fasting. The amount of nutrient restriction in NGR may impair growth by altering other cellular mechanisms without affecting the serum IGF-I levels. Because the energy restriction is mild, and NGR children consume sufficient dietary protein, IGF-I concentrations may be preserved within a range appropriate for bone age development. Likewise, studies in rats showed IGF-I concentrations to be maintained within normal ranges or to improve rapidly when diets containing 15% protein and 90% of the total energy requirements were consumed (287, 288). Serum IGF BP-3 concentrations are likewise de-

creased in prolonged fasting and/or protein deficiency states (284). However, alterations in IGFBP-3 levels in more subtle forms of suboptimal nutrition like that observed in NGR have not yet been studied.

On the other hand, we reported that NGR patients show decreased activity of erythrocyte Na^+ , K^+ -ATPase compared with familial short-stature children (276). This enzyme is involved with the active transport of sugars and amino acids and with cellular thermogenesis. It normally accounts for approximately one-third of the basal energy requirements (289). A diminished energy intake lowers the basal metabolic rate (290) and decreases Na , K -ATPase activity (291). Thus, it may be a good marker of NGR. Because anthropometric parameters may be lacking or inaccurate and biochemical markers may not be sufficient to detect NGR, a more sensitive test is required for diagnosis. Erythrocyte Na^+ , K^+ -ATPase activity may offer

Figure 9 Growth pattern of nutritional dwarfing (a,b) compared with constitutional growth delay (c). a. Body weight gain and height progression decreased after 10 years of age. Extrapolated weight after age 14 years revealed a body weight deficit based on previous growth percentile. However, there was no body weight deficit for height; with nutritional rehabilitation, there was recovery in weight gain and catch-up growth. b. In another patient there is a body weight deficit for height, but the deficit for theoretical weight is more marked. (From Ref. 272.)

Figure 9 Continued. c. Patient who does not have nutritional dwarfing. This patient, with constitutional growth delay, shows a body weight gain consistently along the lower percentile, with no deviation in growth. Note that there was no body weight deficit for height or for theoretical weight based on previous growth. (From Ref. 272.)

Figure 10 Constitutional underweight for height. Note the constant progression of both height and weight in the same percentiles for at least 4 years. Even though there is body weight deficit for height, there cannot be malnutrition because there must be a positive balance for growth to occur. (From Ref. 272.)

such a diagnostic tool. To date, however, this assay has not been widely available for clinical purposes, it is cumbersome, and can be applied only on a research basis.

B. Pathophysiology

Patients with nutritional growth retardation have reached an equilibrium between their genetic growth potential and their nutritional intake because growth deceleration is the adaptive response to suboptimal nutrition (292, 293). Diminished growth brings the nutrient demands into balance with the nutritional intake without adversely affecting biochemical or functional homeostatic measures. Of course, there are limits to these adaptive possibilities. If nutritional deprivation becomes more severe, acute malnutrition may be superimposed on the chronic state, leading to NGR. In such patients, malnutrition would be reflected by

altered anthropometric measurements, such as weight and skinfold thickness or biochemical indices.

It has been known for many years that diminished energy intake leads to a reduced metabolic rate even before there is a loss of body weight. The rate of protein synthesis may decrease in response to a reduction in energy intake, because this process is energy expensive and accounts for 10–15% of the basal metabolic rate (294, 295). Protein catabolism is also sensitive to energy deprivation. Reduction in dietary energy sources may lead to an increased nitrogen flux in which protein breakdown is accelerated to provide energy (296). Nitrogen retention markedly increases during nutritional rehabilitation of malnourished children (295, 297). In addition, nutritional recovery normalizes the excretion of amino acids (296) and increases the rate of protein synthesis (298). In NGR, the result of the altered rates of protein turnover and ni-

trogen retention may be the cessation of normal growth as an adaptive response to the decreased intake. In addition to suboptimal energy intake, various mineral and vitamin deficiencies have been implicated in the causes of NGR, as discussed below.

However, it remains controversial whether decreased body size is an advantageous adaptation to a limited food supply or whether adverse health and functional impairments result (292, 293). It has been demonstrated that physical activity is decreased with a 20% decrease in energy consumption (299), but other functional impairments are more difficult to assess. The decreased growth velocity nevertheless constitutes a functional compromise per se, which should be detected and treated as early as possible.

C. Endocrine Adaptation

The changes in the endocrine system in response to undernutrition are adaptive in nature and largely revert to the "normal" state after nutritional status is improved (300). Undernutrition may involve single or multiple micronutrient deficiencies, and thus any one or a combination of deficits could be the primary problem leading to the endocrine alterations. A detailed description of the hormonal alterations in malnutrition has been published elsewhere (272, 300). However, it must be remembered that most studies have been conducted in severely malnourished patients, which may not accurately reflect more subtle forms of suboptimal nutrition leading to NGR. For example, although circulating growth hormone (GH) levels are increased in severe malnutrition, we have shown that pubertal NGR children show decreased overnight growth hormone secretion and prepubertal subjects have an increased growth hormone response to growth-hormone-releasing hormone (GHRH) stimulation (72). An interesting finding is that body composition is a significant determinant of spontaneous growth hormone secretion. In normal children with short stature, the degree of adiposity modifies spontaneous growth hormone secretion and alters the amplitude of growth hormone pulses in puberty and the number of pulses in prepubertal children (72). Indeed, NGR may be easily confused with growth hormone deficiency or neurosecretory dysfunction if the deterioration in weight progression is overlooked (Fig. 11). These patients respond to nutritional rehabilitation and do not require HGH treatment.

D. Causes

1. Organic Causes

Various pathological conditions that lead to decreased nutritional intake or malabsorption may cause NGR (301). Crohn's disease, celiac disease, and cystic fibrosis are some of the relatively more common pathological conditions. However, any alteration that reduces energy intake or excess energy expenditures may lead to decreased growth. Also included are cardiac or renal diseases. When

Figure 11 Nutritional dwarfing or growth hormone deficiency? The patient was diagnosed to have GH deficiency at age 10 years because of poor growth. However, because of inadequate weight gain associated with decreased growth increments, therapeutic trial with an adequate diet was tried in lieu of growth hormone. Note the catch-up growth after the initiation of nutritional rehabilitation. (From Ref. 272.)

the dietary intake is disturbed, as in patients with cleft palate or other developmental disabilities, there may also be NGR. The acquired immunodeficiency syndrome and human immunodeficiency virus (HIV) infection were also shown to be associated with short stature and poor growth, that preceded any other manifestation of disease (Chapter 37) (302). However, the growth data in HIV-infected patients clearly indicate NGR because body weight progression failed to proceed at appropriate rates even before any other symptom of the disease was apparent (303). It is very likely that anorexia and decreased intake of nutrients lead to suboptimal nutrition in HIV-infected patients and cause NGR, even before other signs and symptoms of the disease become apparent.

Chronic inflammatory bowel disease (CIBD) is usually associated with impaired linear growth, retarded skeletal maturation, and delayed sexual development. This problem is estimated to occur in 5–10% of pediatric patients with ulcerative colitis and 25% of patients with Crohn's disease (304, 305). Growth failure may be the first indication of CIBD and may precede disease-related

symptoms (306). Therefore, the diagnosis of CIBD should always be considered in children who cease to grow adequately, even in the absence of gastrointestinal complaints. Although the pathogenesis is influenced by age at onset, duration of disease, disease activity, and medication intake, suboptimal nutrition is now recognized as the primary factor in growth failure in Crohn's disease (274). Multifactorial nutritional alterations include a decreased nutrient intake, impaired absorption of nutrients, specific nutrient deficiencies, and enhanced protein losses through the gastrointestinal tract. Decreased energy intake in children with CIBD has been associated with anorexia and the early satiety and discomfort that accompany eating.

The total daily calorie intake of CIBD patients usually is not above the recommended dietary allowance (RDA) for height age (306). Multiple studies have documented catch-up growth when adequate energy is provided (304, 305). Various forms of nutritional support (parenteral, elemental, or complex diet) have been employed, often resulting in decreased disease activity and improved growth (307–309). In addition to energy and protein deficits, other nutritional alterations may affect growth in patients with CIBD. Iron deficiency, particularly when there is blood loss through the stools, may compound anorexia and poor growth (310). These patients also may have magnesium deficiency (311) and zinc deficiency (312). It has been shown that large enteric losses of zinc occur in CIBD patients who have diarrhea and small bowel disease. In addition, zinc absorption may be reduced. Therefore, nutritional rehabilitation is essential for the treatment of CIBD patients. This may reverse the growth retardation and even improve the disease itself (313–314).

Growth failure in association with gastrointestinal symptoms is common in children with active CD. It has been shown that up to 55% of patients with CD were below the third percentile for height and up to 60% were below the same percentile for weight. Failure to thrive was present in 25% of children with celiac disease at the time of diagnosis (315, 316). However, several investigators have reported short stature as the sole manifestation of CD (270, 315–317). These asymptomatic patients were considered to have so-called occult celiac disease. The prevalence of asymptomatic CD is highly variable. It was reported to be present in up to 8% in some studies (270, 316), whereas in others it was higher: 24 and 48% (315, 317). This may be the result of geographic differences in the prevalence of the disease and/or the level of suspicion in recognizing these patients. The incidence of CD in the western New York area, estimated by serum IgA–endomysial antibody, has been reported to be 1:3752 (318).

The recognition of occult CD is dependent on the alertness of the clinician to consider this entity as a cause of short stature. Many asymptomatic CD patients have a history of diarrhea at an early age or have iron deficiency. They may also have other alterations when studied (e.g.,

increased stool fat, antigliadin, and antiendomysial antibodies, low serum folate and ferritin levels) that point to the possibility of CD (319–321) as the cause of short stature. Although various methods may be used for screening purposes, these are not diagnostic of CD (315, 317, 318). Therefore, a small bowel biopsy is the “gold standard” for the diagnosis of this disease, and should be performed in every short child showing NGR from unidentified causes. A history of diarrhea during the first year of life and/or the presence of iron deficiency in a short patient should also warrant consideration of CD and therefore of a small bowel biopsy. The diagnosis of CD should be confirmed by documentation of catch-up growth with weight and height gain after institution of a gluten-free diet, which is the only treatment available for the disease. Long-term studies of children with CD suggest that those who do not comply with the diet have significantly lower mean heights and weights and a greater abnormality of the intestinal mucosa than those who are compliant.

2. Nonorganic Causes

The prevalence of nonorganic NGR leading to malnutrition and poor growth in affluent communities is unknown. Only those patients whose height is markedly impaired have been recognized thus far. However, suboptimal nutritional intake may result in a fall in height within the normal percentiles that may elude medical attention. In a survey of 1017 high school students from a middle-class parochial school, a high incidence of low-weight students was reported. More than 25% of these students weighed less than 90% of their ideal body weight for height, but only 1.8% of them had growth patterns suggestive of NGR (275). In a pediatric endocrine clinic in a referral center in the same geographic area, we detected more than 300 patients with NGR.

The most common causes (73%) of nutritional alterations that resulted in NGR and delayed sexual development among adolescents referred to us were nonorganic. There were patients in whom a specific fear or health belief was identified as the cause of the poor nutritional intake leading to short stature (207, 226, 268, 272). A fear of obesity or a fear of hypercholesterolemia was specifically verbalized by some. However, most patients with nonorganic NGR expressed preoccupations that involved similar issues of body weight and cholesterol and concern with a so-called healthy dietary intake. They avoided excess dietary fat and cholesterol and what they termed junk food (272). Regardless of the reason for the inadequate nutritional intake, the result in these children was NGR.

These patients with inadequate dietary intake appeared to be free of severe psychopathology. They did not meet the inclusion criteria for severe eating disorders, such as anorexia nervosa or bulimia nervosa. Moreover, in a controlled, double-blind, prospective study, it was demonstrated that these children did not have behavioral or psychosocial deviations and did not differ from a group

of normal or short-stature children (322). Thus, we concluded that the dietary habits that led to NGR were a result of the prevalence of current health beliefs and preoccupation with slimness, weight control, and the search for longevity through the intake of idealized diets (35, 205, 207).

A recent national survey found that 31% of fifth grade girls have dieted (323). Abramovitz and Birch explored 5-year-old girls' ideas, concepts, and beliefs about dieting (324). They found that 34–64% of the girls had ideas about dieting and weight loss and understood the link with body shape. Girls' knowledge about how people diet is inappropriate. These included descriptions of modified eating behaviors, such as drinking diet shakes, sodas, eating more fruits and vegetables, special foods, and restrictive eating behaviors. Mothers seem to be modeling both health-promoting and health-compromising eating behaviors to their daughters. Girls whose mothers reported current or recent food restrictions were more than twice as likely to have ideas about dieting (324). Another factor found to influence girls' ideas, concepts, and beliefs about dieting is family history of overweight. The media was also mentioned by 55% of the children as a source of dieting ideas (325).

Neumark recently published results from a national survey examining weight-related behaviors among 6728 American adolescents in grades 5–12 (323). Almost half of the female population (45%) and 20% of male adolescents reported dieting. Older female adolescents were significantly more likely to diet than younger ones. Dieting was reported by 31% of 5th graders and increased consistently to 62% among 12th graders. The largest increase was among female adolescents between the 8th (40%) and 9th (53%) grades. Thirteen percent of the girls and 7% of the boys reported disordered eating behaviors. In another study, Neumark found that in 3832 adults and 459 adolescents from four regions of the United States, a high percentage of them reported weight control behaviors. Based on gender, weight control behaviors were found in 56.7% of adult women, 50.3% of adult men, 44.0% of adolescent girls, and 36.8% of adolescent boys (326).

Moses et al. showed that high school adolescents in an affluent suburban location were dieting at a very high rate (327). Forty-one percent of the adolescents were dieting on the day of the survey. Sixty-seven percent of all the adolescents had made on their own important dietary efforts during the past 4–8 weeks. Dieting occurred in normal-weight and underweight students. About 30% of dieters were among the underweight and normal weight for height. However, the proportion of the overweight students who were dieting was relatively low: 50–60%.

Children not only diet but also worry about their body appearance and distorted proportions about weight. More and more children are concerned and dissatisfied with their body image. Studies have shown that 55% of girls and 35% of boys in grades 3–6 want to be thinner (328).

The Children's Version of the Eating Attitude Test showed a negative correlation with children's BMI. It was found that 4.8% of them had scores suggestive of anorexia nervosa. Stice et al. found that eating disturbances that emerged during childhood led to inhibited and secretive eating, overeating, and vomiting. Maternal body dissatisfaction, internalization of the thin ideal, dieting, bulimic symptoms, and maternal and paternal body mass prospectively predicted the emergence of childhood eating disturbances. Infant feeding behavior and body mass during the first month of life also predicted the emergence of eating disturbances (329).

Parents who worry about their children becoming overweight may set the stage for a vicious cycle. Johnson and Birch found those parents who control what and how much their children eat may impede energy self-regulation and put these children at a higher risk for being overweight (330). Furthermore, the Framingham Children's Study showed that children whose parents had high degrees of dietary control had greater increases in body fatness than did children whose parents had the lowest levels of dietary restraint and noninhibition (331).

A distorted perception of ideal body weight, manifested as below appropriate body weight for height, is very prevalent among high school students. Adolescents often know what their ideal weight should be, but some prefer to be 10% less than their ideal weight for their height (327). Health-compromising behaviors and the fear of obesity may have detrimental consequences in children. Inappropriate nutrient intake may lead to NGR, failure to thrive, and various other nutritional problems (326).

There is also a high prevalence of extreme measures taken by high school students to avoid obesity throughout the country (327, 332, 333). In addition to dieting, they may have inappropriate eating habits and purging behaviors. These data indicate just how powerful and important it is for adolescents to achieve an ideal slim and trim figure. Young persons, even when they are not overweight, diet to avoid obesity at a time when they are still growing and developing (35, 327, 332, 333). Regardless of their physical needs, they strive to reach a thin ideal, consequently developing nutritional short stature (35, 327). In addition to growth retardation, other potential medical complications may be associated with excessive dieting, bingeing, and purging: electrolyte disturbances, dental enamel erosion, acute gastric dilation, esophagitis, enlargement of the parotid gland, aspiration pneumonitis, and pancreatitis.

However, it must be kept in mind that the population at large is also quite concerned about cholesterol and preoccupied with diets to lower cholesterol levels (334). These concerns are also prevalent among children (335). The medical profession and the American Academy of Pediatrics have also recommended a low-fat–low-cholesterol diet for the population at large in an effort to prevent adult-onset diseases. However, there are potential harmful

consequences of feeding children with adult diets (334). A low-fat–low-cholesterol intake may lead to nutritional short stature (35, 335) and nutrient deficits (272). A recent study confirmed our observations demonstrating that children on low-fat, low-cholesterol diets can easily ingest inadequate nutrient intake (336).

Careful assessment of weight and height progression will clearly identify children who are not gaining weight and growing appropriately (204, 268, 301, 327). An awareness by health care providers and pediatric endocrinologists of the prevailing eating attitudes and behaviors among adolescents in the population of their practice's area may help detect the adolescent at risk for more serious problems. Simple tests and questionnaires may help to identify the patient with eating disorders (337). The 24 h dietary recall may identify short-stature patients who have inappropriate dietary intake. Patients with obesity constitute another group of children who often diet. Although these children usually do not present to the pediatric endocrinologist because of poor growth, when obesity occurs in association with short stature there may be concerns about their health. A variety of endocrine disorders may affect obese children who do not grow well (Chapter 28). Diet-related growth failure may be uncovered by a careful history, thereby eliminating other concerns. Weight loss is associated with a negative balance that does not allow growth in height even if the child is obese (338). Therefore, during the treatment of obesity in children, allowances must always be made to maintain a balance between the need of a patient to lose weight and the nutritional requirements that allow growth in height.

Nutritional rehabilitation for NGR of nonorganic origin requires providing the patient with adequate caloric and nutrient intake for the restoration of previous growth patterns. Initially, estimation of energy requirements should be based on the age- and gender-specific RDA using the patient's theoretical weight. Adequate intake of protein usually accompanies sufficient caloric intake, but care should be taken that micronutrient intakes meet the RDA. If results of biochemical tests reveal specific deficiencies, such as iron or zinc, these nutrients should be supplemented. Some patients may not be willing or able to consume a completely balanced diet and may require a multivitamin and mineral supplement. A careful diet history can elucidate food preferences and eating patterns that can be used to devise an appropriate dietary plan. Our experience has been to offer general dietary suggestions rather than to prescribe a specific diet. Frequent follow-up visits provide an opportunity to revise and update dietary recommendations and to obtain weight and height measurements.

Although the appropriate diet can be easily determined, successful intervention requires a change in dietary patterns and possibly health beliefs as well. Increasing the caloric density of the child's diet often involves raising the dietary fat content to at least 30–35% of calories. The

increase in fat consumption may concern both the child and the parent, especially in patients who fail to grow because of dieting. The assurance that an appropriate nutritional intake will result in normal growth, without producing obesity, is necessary supportive therapy. This is of particular concern in the initial stages of the treatment, when weight increases rapidly, whereas no noticeable effect on height is observed.

3. Vitamin and Mineral Deficiencies

Regardless of NGR's cause, patients may present with multiple vitamin and mineral deficiencies that contribute to growth failure (272, 335). There may be generalized malnutrition with multiple macro- and micronutrient deficits, or there may be more specific nutritional alterations, as discussed below.

Vitamin A is an important nutrient for gene expression of growth hormone. Studies have shown an improvement in linear growth in some subsets of supplemented children (339). A study in Java found that children who consumed small frequent amounts of vitamin A in fortified monosodium glutamate experienced greater height gain but similar weight gain to control children (340). In the Sudan, dietary vitamin A intake, but not vitamin A supplements given once every 6 months, was positively associated with greater weight gain and with linear growth of children (341, 342). This suggests that small daily supplements of vitamin A may be beneficial over and above the benefits imparted by periodic doses of vitamin A. However, in other intervention studies, vitamin A supplements had no effect on either linear growth or weight gain even when other vitamins and nutrients in addition to vitamin A were supplemented. In a large placebo-controlled study in Tamil Nadu, India, children were visited every week and given a small dose of vitamin A or a placebo. In spite of a large protective effect against mortality, the supplements had no effect on growth (343).

Multiple postulated mechanisms link other vitamin deficiencies with poor growth. These include iron, folate, and/or B₁₂ deficiency, which lead to poor oxygen delivery to tissues, and to multiple metabolic pathways that alter protein synthesis leading to impaired growth. Furthermore, there may be anorexia and inappropriate intake in iron deficiency. Iron supplementation in school children demonstrated beneficial effects on appetite, growth, and anemia (344, 345). Vitamin-D-deficiency rickets can, of course, present with growth failure and osteomalacia.

In several prospective cohort studies in developing countries, the onset of stunting coincided with dietary deficiencies of several micronutrients, including iron, zinc and iodine (346). Height deficits were associated with chronic deficits in energy and protein, as well as suboptimal zinc levels. Multiple micronutrient deficiencies may explain why supplementary feeding programs that aimed at only increasing energy and protein intake resulted in limited physical growth (347).

Growth retardation caused by zinc deficiency in humans was first reported by Prasaad et al. in 1963. The patients had remarkably short stature and hypogonadism. They were shown to have zinc deficiency documented by decreased zinc concentrations in plasma, erythrocytes, and hair. Studies with ^{65}Zn revealed that plasma zinc turnover was greater, the 24 h exchangeable pool was smaller, and the excretion of ^{65}Zn in stool and urine was less in the growth-retarded subjects than in the controls (348). Further studies showed that the rate of growth was greater in patients who received supplemental zinc than in those receiving only an adequate animal protein diet (349). Since then, many cases of marginal or moderate growth impairment in children with zinc deficiency as a consequence of inadequate zinc intake have been reported from various parts of the world (350, 351). It appears that zinc deficiency is prevalent throughout the world in both developed and developing countries. Favier indicated that, depending on the country, 5–30% of children had moderate zinc deficiency, responsible for small-for-age height (352). Those reports showed positive effects of oral zinc supplementation on growth velocity in children with zinc deficiency (349–352).

It is also well known that zinc deficiency in pregnant women causes fetal growth retardation. Kirksey et al. revealed a significant correlation between maternal plasma zinc concentrations measured at midpregnancy and birth weight (353). Neggers et al. reported that the prevalence of low birth weight (LBW) infants was significantly higher (eight times) among women with serum zinc concentrations in the lowest quartile in early pregnancy, independent of other risk factors (354). However, the effects of zinc supplementation in pregnancy are not clear. It is now speculated that zinc supplementation during pregnancy might be beneficial only in populations that are zinc deficient and at high risk of poor fetal growth (355).

Marginal zinc deficiency seems to be prevalent in infancy. Michaelsen et al. examined zinc intake and status in healthy term infants from birth to 12 months of age in Denmark, and found suboptimal zinc status in many subjects during late infancy. They also reported that serum zinc level at 9 months was positively associated with growth velocity during the period from 6 to 9 months (356).

The zinc status in short-stature patients with normal GH secretion was tested by body zinc clearance studies to detect the marginal zinc nutriture, and to evaluate the effects of oral zinc supplementation (357). This Japanese study indicated that about 60% of short children had marginal zinc deficiency. Oral zinc supplementation was effective on height gain in short boys with marginal zinc deficiency, but not in girls. There was also a significant correlation between the body zinc clearance values and percentage increases in the growth velocity after oral zinc supplementation, indicating that oral zinc supplementation was most effective on height gain (357). The reason for

such a high incidence of marginal zinc deficiency in Japanese short children may be mainly the recent prevalence of precooked food, snacks, and convenience foods in their diets. In 1993 Nakamura et al. conducted an age-matched control study showing that oral zinc supplementation was effective in improving the growth rate in short children with marginal zinc deficiency. They reported that oral zinc supplementation induced increases of serum IGF-1, osetocalcin, and alkaline phosphatase activity (358).

There have been a few reports on the relationship between zinc deficiency and GH secretory insufficiency. Nishi et al. described a 13-year-old Japanese boy with growth disturbance who had partial GH deficiency due to chronic mild zinc deficiency. His diet was low in animal protein and consisted primarily of rice and vegetables, because he disliked meats, fish, eggs, and dairy products that were rich sources of zinc. His plasma zinc level and GH responses to the pharmacological stimulation tests were low. After 3 months of oral zinc supplementation, however, his growth velocity improved without GH replacement therapy, and his plasma zinc levels and GH responses to those tests increased to the normal range (359).

The mechanism by which zinc deficiency causes growth disturbance has been controversial. Zinc is required for activities of more than 300 enzymes (zinc metalloenzymes), in which zinc is located at the active site, including DNA polymerase, RNA polymerase, and thymidine kinase. Because these enzymes are important for nucleic acid and protein synthesis and cell division, zinc may be essential for growth. Furthermore, several hundred zinc-containing nucleoproteins are probably involved in gene expression of various proteins (349, 360).

Zinc deficiency may adversely affect GH production and/or secretion (359). Since zinc has an important role in protein synthesis, IGF-1 synthesis can be impaired by zinc deficiency. Ninh et al. reported that low IGF-1 levels in zinc-deprived rats were closely associated with decreased hepatic IGF-1 gene expression and with a diminution of liver GH receptors and circulating GH-binding protein (GHBP). They also suggested that decreased hepatic GH receptors and/or GHBP concentrations might be responsible for the decline of circulating IGF-1 in zinc-deficient animals (361).

The presence of a large amount of zinc in bone tissue suggests that zinc plays an important role in the development of skeletal systems (362). Retardation of bone growth is a common finding in various conditions associated with zinc deficiency. Zinc has a stimulatory effect on bone formation and mineralization (363). Zinc is required for alkaline phosphatase activity and the enzyme is mainly produced by osteoblasts whose major function is to provide calcium deposition in bone diaphysis. The administration of vitamin D3 or zinc produced a significant increase in bone alkaline phosphatase activity and DNA content was synergistically enhanced by the simul-

taneous treatment with zinc (363). The receptors for 1,25-dihydroxyvitamin D₃ were shown to have two zinc fingers at the site of interaction with DNA (364). One possible function of zinc is to potentiate the interaction of the 1,25-dihydroxyvitamin D₃ receptor complex with DNA at that site. Zinc also directly activates aminoacyl-tRNA synthetase in osteoblasts, and it stimulates cellular protein synthesis. Moreover, zinc has an inhibitory effect on osteoclastic bone resorption by suppressing osteoclast-like cell formation from marrow cells (362).

Zinc deficiency should be considered as a causative factor in some children with unexplained short stature. Oral zinc supplementation should be considered as the growth-promoting therapy for children with short stature once the status of their zinc nutrition is established. Not all zinc intervention studies have found improved growth patterns in subjects receiving supplements. Rosado et al. performed a randomized clinical trial among young Mexican children, comparing daily doses of iron, zinc, both, or placebo (365). Others have also reported no effect of zinc supplementation on growth rates (366, 367), and some have hypothesized that the presence of multiple micronutrient deficiencies may be at least in part to blame (368, 369). Prentice reported that zinc supplementation failed to show beneficial effects on height gain in Guatemalan children, although the relatively short supplementation period of 25 weeks might have been insufficient to detect subtle changes in growth velocity (370). A systematic review of 25 clinical trials that evaluated the impact of zinc supplementation on growth found a significant pooled effect of an increment of 0.22 standard deviations (SD) on height and 0.26 SD on weight (371). The greatest impact of zinc supplementation was found in stunted children (in whom an increase of 0.49 SD was found in height), and in those with low initial zinc concentrations.

XI. LABORATORY AIDS IN DIFFERENTIATING SHORT STATURE

Any patient who falls below the third percentile in height and/or has decreased growth rates (falling across the major percentiles) should receive a complete diagnostic evaluation. Because there are multiple causes of short stature and growth retardation, laboratory investigation should be geared toward confirming or ruling out the differential diagnoses based on information obtained from history and physical examination. It is important to assess, in addition to the growth rates: history of chronic illness and medications, midparental and target height, birth size, growth pattern, nutritional state, pubertal stage, body segment proportions, bone age, and predicted adult height. The following simple laboratory screening tests may be performed: urinalysis, urine metabolic screening, hemoglobin, hematocrit and ferritin levels, measurement of sedimentation rate and creatine phosphokinase (CPK), ve-

nous blood gases with simultaneous urine pH, liver and kidney function tests, and antigliadin and antiendomycil antibodies.

A karyotype is imperative in every girl with short stature, even in the absence of the stigmata of Turner syndrome. Children who demonstrate skeletal abnormalities on physical examination deserve evaluation for metabolic bone disease, such as mucopolysaccharidosis, mucopolipidosis, and gangliosidosis (Chapter 4). In addition, skeletal abnormalities should be looked for in accordance with body proportion alterations detected on physical examination (i.e., hypochondroplasia) (46, 58, 95).

Endocrine causes of short stature and/or poor growth may be determined by evaluating thyroid function and assessing the hypothalamic-pituitary axis (Chapters 2, 3, and 38). Examination of the eye grounds and visual fields should be done, but a magnetic resonance imaging (MRI) scan may be necessary if hypopituitarism is considered. A thorough nutritional assessment should be made if there is a growth pattern of NGR. If zinc deficiency is suspected, serum zinc levels may be obtained, but they are usually not sufficient to establish the diagnosis. Other tests may be necessary before treatment is instituted as described above.

A number of tests to assess growth hormone status have been devised using various provocative tests: insulin, L-dopa, arginine, clonidine, and other agents (372). Growth hormone is secreted at intervals and random growth hormone measurements are useless. Estrogen and/or androgen priming before provocative testing is also useful in Tanner I or Tanner II children to differentiate between GH deficiency and constitutional growth delay (373, 374). A frequent test is to measure GH after exercise (375). Pituitary function may also be evaluated comprehensively using a combined hormonal stimulation test (376). This utilizes sequentially administered insulin or arginine or L-dopa, thyrotropin-releasing hormone, and gonadotropin-releasing hormone. In addition, deficiency of GHRH may be ruled out by giving human pituitary GHRH and evaluating the patient's growth hormone response. So-called neurosecretory growth hormone dysfunction can be determined by performing an overnight growth hormone study and assessing growth hormone pulsatile secretions under physiological conditions, such as sleep.

The indications for this test are for those patients who may demonstrate a normal growth hormone response to pharmacological stimuli, but may not be able to secrete growth hormone under physiological conditions (377-379). However, there is no completely reliable test for diagnosing or excluding growth hormone deficiency in short children (Chapters 2, 3). IGF-I and IGF-BP levels are decreased in growth hormone deficiency and may help in differentiating short children with growth hormone deficiency (380-383). However, these tests are not useful in NGR or younger patients. Measuring levels of GHBP or

IGFBP may also help differentiate the different conditions, as well as IGF levels and their response to exogenous growth hormone administration. Details of the foregoing tests and procedures are described in Chapter 41. However, it should be kept in mind that growth measurements over time are better guidelines than many of the tests mentioned above. Indeed without the clinical growth data, the results of the tests are hard to interpret.

XII. FINAL CONSIDERATIONS

Short children and their parents face a number of specific psychosocial problems. These problems are frequently associated with the developmental stage of (384) the child's life. The parents frequently have difficulty in accepting the child's height and in treating the child according to age level. By 7 or 8 years of age the child usually has become acutely aware of his or her short stature. The teenage years are much more difficult for the short-stature child than for the child of normal or mildly abnormal height. The problems of short stature are often compounded by lack of sexual development and withdrawal from heterosexual social activities or by other transition periods, such as moving to a new school or community. Despite these developmental problems, the short individual frequently makes an adequate adjustment to life as an adult (384).

Other issues transcend the purely developmental aspects of short stature, such as the general personality mechanisms of the small child and his or her parents. Of importance are the school achievements of such children and the specific techniques they develop in coping more effectively with their environment. One of the most important problems of short people is being treated in an infantile manner, appropriate for their size, but not for their age. Some short people respond to being treated as a younger child by behaving immaturely (Peter Pan reaction). Others rebel against being pampered and sometimes develop various neurotic and psychosomatic symptoms, including denial, withdrawal, phobias, and compensatory fantasies. Still others find a more satisfactory solution in the reaction of "mascotism."

Frankness (diplomatic rather than brutal) is desirable in counseling short and dwarfed people about their situation in life. They are then able to plan the future realistically, to discuss the taboos that beset them, and to perfect techniques in dealing with silly comments about their size and age. Emotional deprivation and neglect may cause a certain type of dwarfism (385). This may be the primary problem and, when resolved, growth occurs. Short stature is not typically associated with intellectual defect (386). Dwarfed people may expect to be employed and, under some circumstances, graduate from college. Short people can meet one another by joining such organizations as Little People of America, P.O. Box 622, San Bruno, CA 94006; the Human Growth Foundation, Inc., 4607 David-

son Drive, Cherry Lane, MD 20815; or Magic, 1327 North Harlem Drive, Oak Park, IL 60302. They may legitimately hope for romance, marriage, and a successful sex life and should consider help regarding their height through the use of footwear that may increase their size without other major procedures or therapies (Elevators, Richlee Shoe Co., P.O. Box 3566, Frederick, MD 21705, Tel 1-800-290TALL).

University of Wisconsin, Madison, Wisconsin, U.S.A.

I. INTRODUCTION

Disorders involving the growth hormone (GH) pathway result in insulin like growth factor-I (IGF-I) deficiency or ineffectiveness and may be congenital or acquired. Congenital GH deficiency is associated with structural malformations of the central nervous system, hypothalamus, or pituitary. IGF-I deficiency/resistance may result from genetic defects involving critical factors in the embryological development of the pituitary or in the cascade from hypothalamic stimulation of GH release to completion of IGF effects on growth. Acquired abnormalities affecting the GH/IGF axis range from damage to the hypothalamic-pituitary region from tumors, infection, autoimmune disease, or radiation to a broad spectrum of chronic conditions characterized by catabolism.

The frequency of GH deficiency (GHD) has been estimated in various studies to range from 1:4000 to 1:10,000 (1). Estimates based on clinic referral populations are inherently biased. An excellent population-based study of 80,000 schoolchildren in Salt Lake City documented growth rates over 1 year; of the 555 children who were below the third percentile in height and had growth rates <5 cm/year, 16 had previously undiagnosed GHD. Combined with known instances in the population (i.e., children being treated for GHD), this gave a prevalence estimate of 1:3500 in the school-age population (2). An estimate of relative contributions of organic and idiopathic or genetic causes can be gleaned from the large post marketing databases of manufacturers of recombinant human (rh) GH. Among >20,000 children being treated with rhGH registered in the National Cooperative Growth Study, ~25% of those with proven GHD had an organic

cause. Nearly half of these (47%) were central nervous system (CNS) tumors, including craniopharyngioma, 15% were CNS malformations, 14% septo-optic dysplasia, 9% leukemia, 9% CNS radiation, 3% trauma, 2% histiocytosis, and 1% CNS infection (3). Comparable findings were obtained in the European postmarketing surveillance study (Kabi International Growth Study; KIGS). Some 22% of approximately 15,500 children with GHD had an organic cause, congenital in 24% of this subgroup. The most common central malformation was empty sella, accounting for 37%, followed by septo-optic dysplasia in 24% of those with congenital organic GHD. Among the 76% of patients with organic GHD considered acquired, craniopharyngioma accounted for 24% and other CNS tumors for 30%, leukemia 16%, histiocytosis 3.5%, trauma 3%, and CNS infection 1% (4).

II. PITUITARY GLAND, GROWTH HORMONE, AND IGF-I

A. Embryology of the Pituitary Gland

The pituitary, traditionally considered the “master gland,” appears early in embryonic life. At 3 weeks’ gestation, the ectodermal stomodeum of the embryo develops an outpouching anterior to the buccopharyngeal membrane. This outpocketing is Rathke’s pouch, which usually separates from the oral cavity and will give rise to the adenohypophysis of the pituitary gland. An evagination of the diencephalon then gives rise to the neurohypophysis of the pituitary gland. In rare cases, the primitive oral cavity origin of the pituitary results in a functional pharyngeal adenohypophysis (5). The fetal pituitary gland consists of the

pars distalis (anterior lobe), pars nervosa (posterior lobe), and the pars intermedia (6). Secretion of pituitary hormones can be detected as early as week 12 in the fetus, and some of these hormones are found within the pituitary by 8 weeks' gestation (7). Average newborn pituitary weight is 100 mg.

Differentiation of the primordial pituitary gland requires a cascade of factors to be expressed in critical temporal and spatial relationships. These include extracellular signaling factors from the adjacent diencephalon that initiate anterior pituitary gland development from the oral ectoderm, and transcription factors that control pituitary cell differentiation and specification. Several homeodomain transcription factors directing embryological development of the anterior pituitary have been found to have mutations that result in congenital defects affecting the synthesis of GH and one or more additional pituitary hormones (9, 10).

The homeobox gene expressed in embryonic stem cells (HESX1) is important in development of the optic nerve, as well as of the anterior pituitary. HESX1 has also been referred to as the Rathke's pouch homeobox gene (Rpx). The three mutations that have been described account for a small minority of instances of septo-optic dysplasia with variable GH and other pituitary deficiencies (11).

LIM-type homeodomain proteins (named for the 3 homeodomain proteins *lin-11*, *Islet-1*, and *mec-3*), known as LHX3 accumulate in the Rathke pouch and the primordium of the pituitary and are thought to be involved in the establishment and maintenance of the differentiated cell types (12). Only four patients in two families have been described with mutations of this transcription factor, which results in deficiencies of all pituitary hormones except adrenocorticotropin, and cervical spine rigidity indicating extrapituitary function for this factor (13).

Prophet of Pit1 (PROP1) represses HESX1 expression at the appropriate time and is required for initial determination of pituitary cell lineages, including gonadotropes and those of Pit1 (GH, thyroid-stimulating hormone [TSH], prolactin [PRL]). Nine recessive mutations have been described in PROP1 that result in GH, PRL, TSH, gonadotropin, and variable adrenocorticotropin (ACTH) deficiency. Eleven recessive and four dominant mutations have been reported affecting the Pit1 gene, with resultant GH, PRL, and TSH deficiency (10, 14).

Somatotroph development is also dependent on hypothalamic GH-releasing hormone (GHRH). Mutation in the gene encoding the GHRH receptor results in severe GH deficiency (15, 16).

B. Functional Anatomy of the Pituitary Gland

The adult pituitary weighs 0.5 g and has average dimensions of 10 × 13 × 6 mm (Fig. 1). The pars intermedia is vestigial in the adult, except in pregnancy. The adeno-

hypophysis receives hormonal modulating signals from the hypothalamus, transmitted from ventromedial and infundibular nuclei axons that terminate in the hypophyseal portal system. These signals result in production of specialized cells of the pars distalis of ACTH by 8 weeks gestation, TSH by 15 weeks gestation, somatotropin (GH) by 10–11 weeks gestation, prolactin by 12 weeks, and the gonadotropes, luteinizing hormone (LH) and follicle-stimulating hormone (FSH) by 11 weeks. The pars distalis has at least three distinct hormone-producing cell populations classified by staining characteristics (8). Fifty percent of the cells are chromophobes, 40% are characterized as acidophils, and the remainder as basophils. Acidophils secrete GH or prolactin. Basophils secrete TSH, LH, FSH, or ACTH. Some basophils have a positive periodic acid–Schiff (PAS) base reaction: these are the cells that secrete the glycoproteins LH, FSH, or TSH. Although chromophobe cells are known to produce ACTH in the rat pituitary, the role of these cells in the human pituitary remains unclear.

Anterior pituitary hormones enter the portal venous system to drain into the cavernous sinus, enter the general circulation, and ultimately exert long-distance influence over their respective target organs. PRL has an effect on lactation through direct effects on breast ductal tissue. ACTH stimulates the adrenal cortical production of cortisol and affects renal reabsorption of water. TSH promotes growth of the thyroid and production of thyroxine. LH and FSH stimulate gonadal maturation and hormonal cycling. GH exerts indirect growth effects through the elaboration of IGF-I in the liver, direct growth effects on bone, and direct metabolic effects, primarily in adipose tissue. Although the pars intermedia had been identified as a site of possible melanocyte-stimulating hormone (MSH) production, more recent studies suggest that MSH is actually being produced in the pars distalis and enters the portal venous system to exert a distant effect on skin pigmentation (17).

The pars nervosa, or infundibular process, and the infundibulum, or neural stalk, comprise the neurohypophysis. The infundibulum consists of the pituitary stalk and median eminence and is the direct connection to the hypothalamus. The neurohypophysis receives, stores, and releases two important hormones produced in the hypothalamus. These hormones, oxytocin and arginine vasopressin, originate in the supraoptic and paraventricular nuclei of the hypothalamus. The 100,000 axons of these nuclei are unmyelinated and form the supraopticohypophyseal tract that transports oxytocin and vasopressin to be stored in the posterior lobe of the pituitary (7, 18).

The rich blood supply of the pituitary gland is subject to interruption during periods of severe hypotensive stress and hypoxia, resulting in the Sheehan syndrome of hypopituitarism. This is classically described after intrapartum hypotension, but is possible in any hypovolemic crisis or increased intracranial pressure episode, as in hypopi-

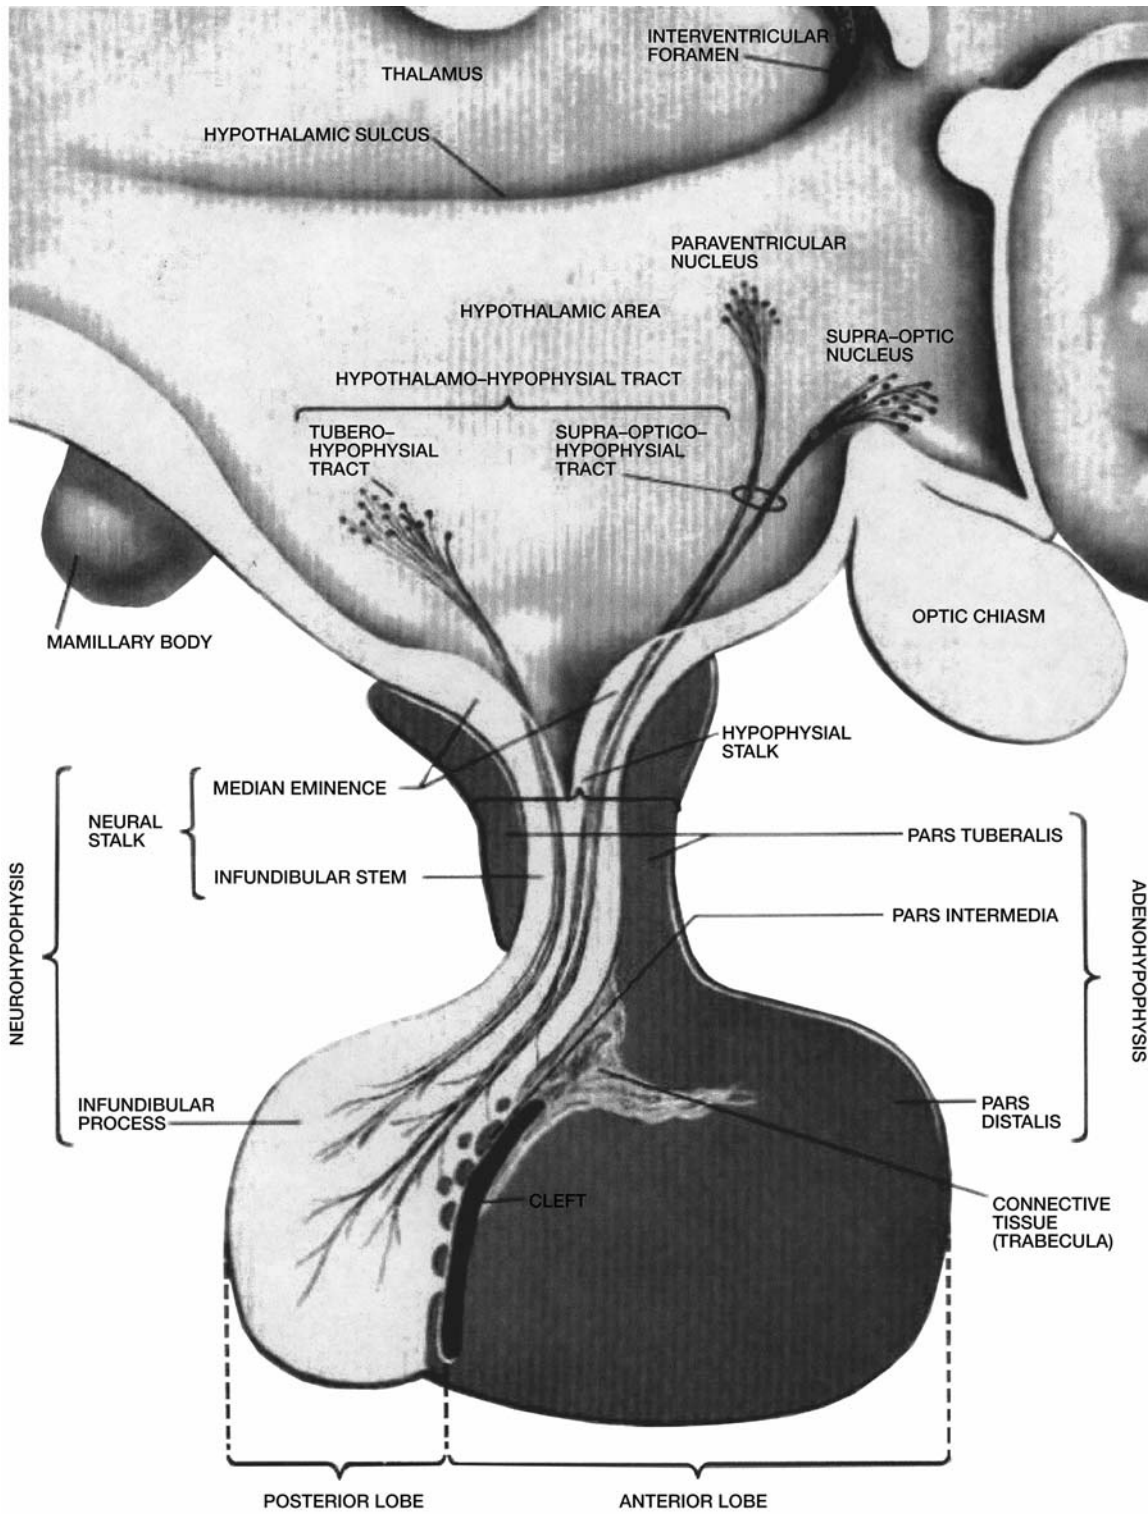

Figure 1 Diagrammatic illustration of the pituitary gland, showing anatomical divisions. (From Ref. 20.)

tuitarism following recovery from cerebral edema (19). The internal carotid arteries supply the vascular branches that bathe the pituitary. The right and left superior hypophyseal arteries, which branch into anterior and posterior divisions, supply the median eminence and infundib-

ulum. The neurohypophysis and stalk are supplied by the right and left inferior hypophyseal arteries. The hypophyseal portal vessels, which originate from capillary beds in the median eminence and infundibular stem, supply the pars distalis (Fig. 2) (18, 20).

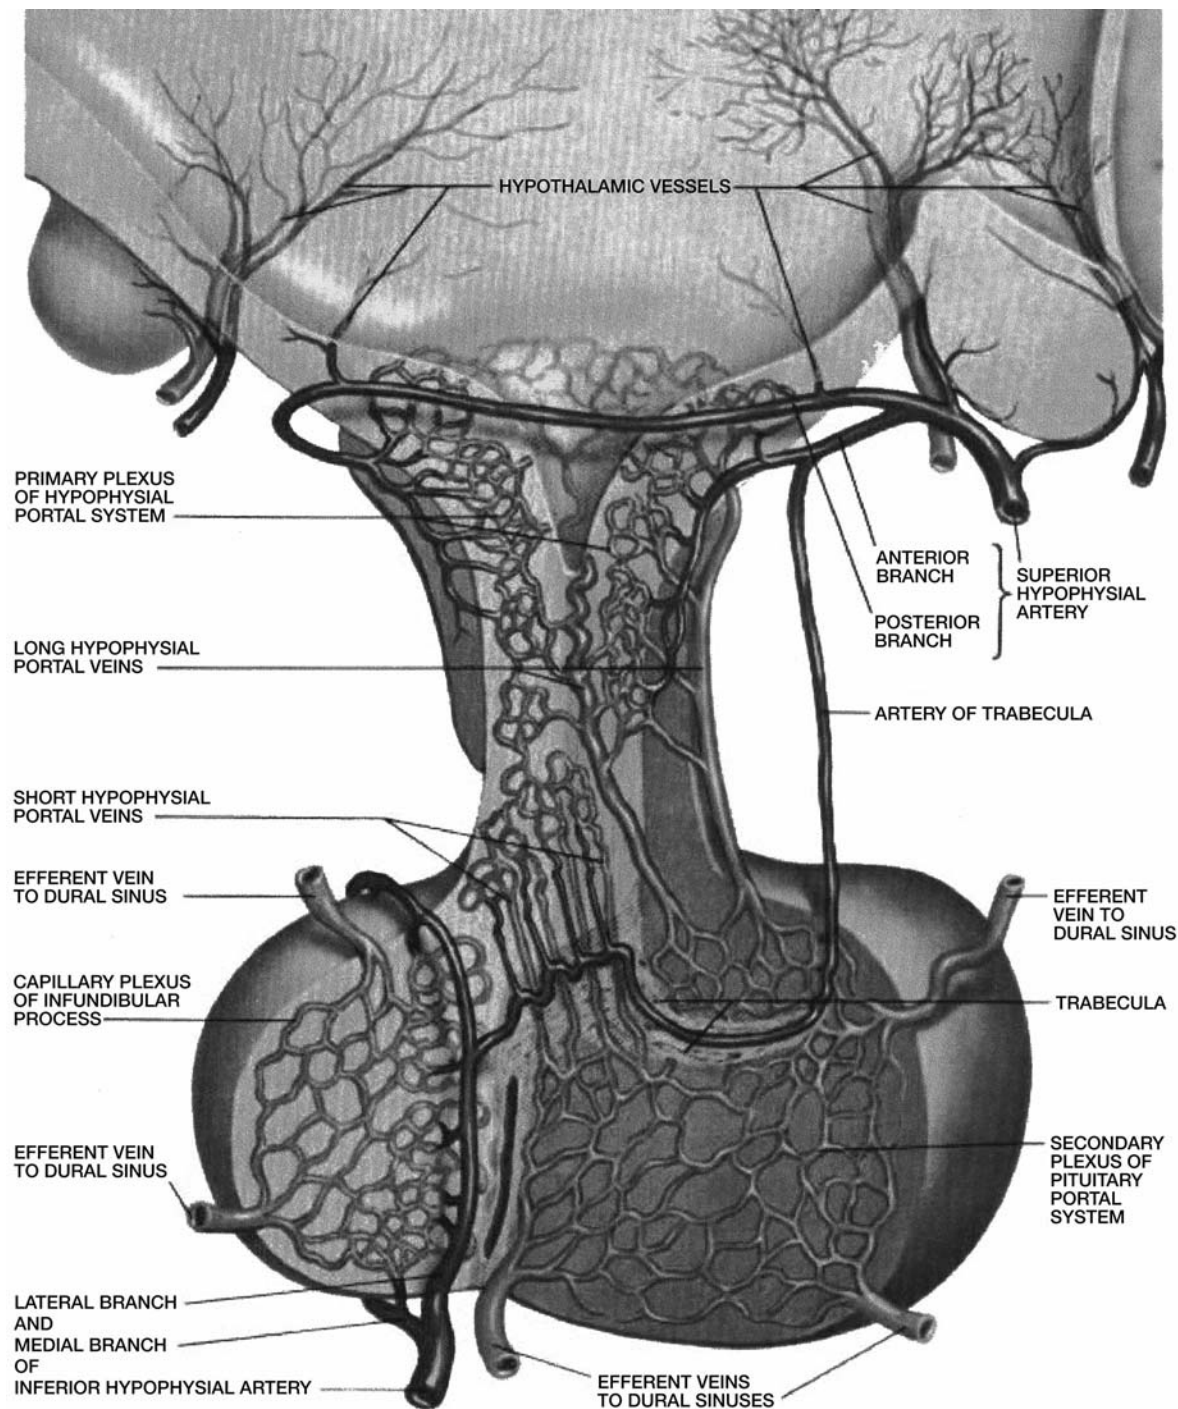

Figure 2 Diagrammatic illustration of pituitary blood supply. (From Ref. 20.)

Figure 3 Simplified diagram of the GH-IGF-I axis involving hypophysiotropic hormones controlling pituitary GH release, circulating GH binding protein and its GH receptor source, IGF-I and its largely GH-dependent binding proteins, and cellular responsiveness to GH and IGF-I interacting with their specific receptors. C. Biochemistry and Physiology of the GH/IGF-I/IGF-Binding Protein Axis

1. GH

Human GH is a single-chain, 191 amino acid, 22 kD protein, containing two intramolecular disulfide bonds (21). Release of GH from the anterior pituitary somatotrophs is controlled by the balance between stimulatory GHRH and inhibitory somatostatin (SS) from the hypothalamus (Fig. 3). This balance is regulated by a variety of neurological, metabolic, and hormonal influences; numerous neurotransmitters and neuropeptides are involved. These include vasopressin, corticotropin-releasing hormone, thyrotropin-releasing hormone, neuropeptide Y, dopamine, serotonin, histamine, norepinephrine, and acetylcholine, which respond to various circumstances that affect GH secretion such as sleep, fed–fasting state, stress, and exercise. Other hormones including glucocorticoids, sex steroids, and thyroid hormone also influence secretion of GH. These various influences are important in the evaluation of GH secretion, which may give abnormal results despite normal somatotroph function.

Stimulation of GH release by GHRH is via specific GHRH receptors. A number of synthetic hexapeptides, referred to as GH-releasing peptides (GHRPs), have been developed that act on other receptors to stimulate GH release (22, 23). The naturally occurring ligand for the GHRP receptor, ghrelin, has been isolated and cloned (24). Ghrelin is unique among mammalian peptides in its requirement of a posttranslational modification for activation. This involves addition of a straight chain octanyl group conferring a hydrophobic property on the N terminus that may permit entry of the molecule into the brain. Similarly to synthetic GHRPs, ghrelin binds with high affinity and specificity to a distinct G protein-coupled receptor (25). Unlike GHRH, ghrelin is synthesized primarily in the fundus of the stomach (24), as well as in the hypothalamus (26) and its receptor is more widely distributed than that of GHRH. Ghrelin may have widespread metabolic effects in addition to being synergistic with GHRH in the stimulation of GH release.

Some 75% of circulating GH is in the 22 kD form. Alternative splicing of codon 2 results in a deletion of 11 amino acids and formation of a 20 kD fragment account-

ing for 5–10% of secreted GH. Other circulating forms include deamidated, N-acetylated, and oligomeric GH. About 50% of GH circulates in the free state, the rest bound principally to GH binding protein (GHBP). Because the binding sites for the radioimmunoassay of GH are not affected by the GHBP, both bound and unbound GH are measured (27).

2. GHBP

A high-affinity GHBP was identified in rabbit and human serum in the mid-1980s (28), and separate reports in 1987 found this binding protein to be absent in the sera of patients with GH resistance (29, 30), who were identified by high circulating GH concentration with a clinical picture of severe GH deficiency. The recognition that circulating GHBP in rabbit serum corresponded to liver cytosolic GHBP was followed by the purification, cloning, and sequencing of human GHBP (31). The human GHBP was found to be structurally identical to the extracellular hormone-binding domain of the membrane bound GH receptor (GHR). The entire human GHR gene, localized to the proximal short arm of chromosome 5, was subsequently characterized (32). The GHR was the first to be cloned of a family of receptors that includes the receptor for prolactin and numerous cytokine receptors. Members of this family share ligand and receptor structure similarities, in particular the requirement that the ligand bind to two or more receptors or receptor subunits and interact with signal transducer proteins to activate tyrosine kinases (33).

In humans, GHBP is the proteolytic product of the extracellular domain of the GHR. This characteristic permits the assaying of circulating GHBP as a measure of cellular-bound GHR, which usually correlates with GHR function. The GH molecule binds to cell surface GHR, which dimerizes with another GHR so that a single GH molecule is enveloped by two GHR molecules (34). The intact receptor lacks tyrosine kinase activity, but is closely associated with JAK2, a member of the Janus kinase family. JAK2 is activated by binding of GH with the GHR dimer, which results in self-phosphorylation of the JAK2 and a cascade of phosphorylation of cellular proteins. Included in this cascade are signal transducers and activators of transcription (STATs), which couple ligand binding to the activation of gene expression, and mitogen-activated protein kinases (MAPK). Other effector proteins have also been examined in various systems. This is a mechanism typical of the growth hormone/prolactin/cytokine receptor family (27, 35).

The GH receptor in humans is also synthesized in a truncated form (GHRtr) lacking most of the intracellular domain. Although the quantity of this GHRtr is small relative to the full-length GHR, release of GHBP from this isoform is increased (36). Some of the changes in body composition that occur with GH treatment in GH deficiency may be related to changes in the relative expression of GHR and GHRtr (37).

3. IGF-I

Most of the growth effect that gives GH its name is indirect, via stimulation of IGF-I production, primarily in the liver (38). IGF-I is a 70 residue single-chain basic peptide, and IGF-II a slightly acidic 67 residue peptide. Their structure is similar to that of proinsulin: A and B chains connected by disulfide bonds and a connecting C-peptide, but unlike the posttranslational processing of insulin, there is no cleavage of the C-peptide. The two IGFs share approximately two-thirds of their possible amino acid positions and are 50% homologous to insulin (39, 40). The connecting C-peptide is 12 amino acids long in the IGF-I molecule and 8 amino acids long in IGF-II, and has no homology with the comparable region in the proinsulin molecule. The IGFs also differ from proinsulin in having carboxy terminal extensions. These similarities and differences from insulin explain the ability of IGFs to bind to the insulin receptor and insulin's ability to bind to the type 1 IGF receptor, as well as the specificity of IGF binding to the IGF-BPs.

4. IGF-BPs

Hepatic IGF-I circulates almost entirely bound to IGF-binding proteins (IGFBPs), with <1% being free. The IGFBPs are a family of 6 structurally related proteins with a high affinity for binding IGF. At least 4 other related proteins with lower affinity for IGF peptides have been identified and are referred to as IGFBP-related proteins (41). The principal BP, IGFBP-3, binds 75–90% of circulating IGF-I in a large (150–200 kD) complex consisting of IGFBP-3, an acid-labile subunit (ALS), and the IGF molecule. ALS and IGFBP-3 are produced in the liver as a direct effect of GH. The remainder of bound IGF is in a 50 kD complex with mostly IGFBP-1 and IGFBP-2. IGFBP-1 concentrations are controlled by nutritional status as reflected in insulin levels, with the highest IGFBP-1 concentrations found in the fasting, hypoinsulinemic state. The circulating concentration of IGFBP-2 is less fluctuant and partly under the control of IGF-I; levels are increased in IGF-I deficiency due to GH insensitivity, but increase further with IGF-I therapy (42).

The actions of IGFBPs are under intense investigation (38, 43, 44). The IGFBPs modulate IGF action by controlling storage and release of IGF-I in the circulation and influencing its binding to its receptor, facilitate storage of IGFs in extracellular matrices, and exert independent actions. IGFBPs 1, 2, 4, and 6 inhibit IGF action by preventing binding of IGF-I with its specific receptor. The binding of IGFBP-3 to cell surfaces is thought to decrease its affinity, effectively delivering the IGF-I to the type 1 IGF receptor. IGFBP-5 potentiates the effects of IGF-I in a variety of cells. Its binding to extracellular matrix proteins allows fixation of IGFs and enhances binding to hydroxyapatite. IGFs stored in such a manner in soft tissue may enhance wound healing. IGF-independent mechanisms for IGFBP-1 and IGFBP-3 proliferative effects have

been demonstrated in vitro and nuclear localization of IGFBP-3 has been reported. In addition to IGFBP phosphorylation and cell surface association determining the influence of IGFBPs, specific protease activity, particularly affecting IGFBP-3, is also important in the modulation of IGF action in target tissues. The proteolytic activity may alter the affinity of the binding protein for IGF-I, resulting in release of free IGF-I for binding to the IGF-I receptor (38, 43, 44).

5. IGF Receptors

IGF binding involves three types of receptors: the structurally homologous insulin receptor and type 1 IGF receptor and the distinctive type 2 IGF-II/mannose-6-phosphate receptor (Fig. 4). Splice variants and atypical forms occur but have not been found to have physiological significance, Insulin/IGF-I hybrid receptors, however, are ubiquitous and may be the most important receptors for IGF-I in some tissues (44).

The type 1 IGF-I receptor and insulin receptor are heterotetramers consisting of two alpha subunits that contain the binding sites and two beta subunits containing a transmembrane domain, an ATP-binding site, and a tyro-

sine kinase domain comprising the signal transduction system (44). The IGF-I receptor is able to bind IGF-I and IGF-II with high affinity but the affinity for insulin is approximately 100-fold less. Although the insulin receptor has a low affinity for IGF-I, IGF-I is present in the circulation at molar concentrations 1000 times those of insulin. Thus, even a small insulin-like effect of IGF-I could be more important than that of insulin itself, were it not for the IGFBPs that control the availability and activity of IGF-I. In fact, intravenous infusion of rhIGF-I can induce hypoglycemia, especially in the IGFBP-3-deficient state (45). It is not known why IGF-II and M6P share a receptor. This receptor differs from the type 1 receptor in binding only IGF-II with high affinity, IGF-I with low affinity, and insulin not all (44).

D. Role of IGF-I in Growth

The importance of IGF-I in normal intrauterine growth in humans has been demonstrated in a single patient with a homozygous partial deletion of the IGF-I gene (46), and in a second patient with inactivating mutations of the IGF-I receptor (47), both having severe intrauterine growth

Figure 4 Components of the IGF-IGFBP-IGF/IGFBP receptor axis. (Reprinted from Collett-Solberg PF, Cohen P. Genetics, chemistry, and function of the IGF/IGFBP system. *Endocrine* 2000; 12:121–136, with permission from Humana Press.)

retardation. Cord serum IGF-I and IGF-II concentrations correlate with birth weight and are significantly increased in large for gestational age infants compared with appropriate for gestational age newborns (48). Intrauterine IGF-I synthesis, however, does not appear to be GH dependent, because most patients with genetically determined severe IGF-I deficiency (GHRD), or GH gene mutations, have normal or only minimally reduced intrauterine growth. Standard deviation score (SDS) for length declines rapidly after birth, however, in these conditions, demonstrating the immediate need for GH-stimulated IGF-I synthesis for postnatal growth (49). Growth velocity in the absence of GH is approximately half normal (49).

The metabolic and growth effects of GH and IGF-I are compared in Table 1. In addition to direct protein-sparing effects and synthesis and release of IGF-I from the liver, GH stimulates autocrine and paracrine production of IGF-I in other tissues, primarily bone and muscle (Fig. 3). GH has a direct effect on differentiation of prechondrocytes into early chondrocytes, which in turn secrete IGF-I. This local IGF-I stimulates clonal expansion and maturation of the chondrocytes, resulting in growth (50). It is estimated that 20% of GH-influenced growth is the result of the direct effect of GH on maturing bone and the autocrine/paracrine production of IGF-I in this tissue (51). Treatment studies of children with GHRD given IGF-I compared to GH-deficient patients treated with GH support this hypothesis (52, 53). IGF-II is considered an important growth factor in utero, but its role in extrauterine life is unclear; concentrations of IGF-II in serum parallel those of IGF-I.

III. CLASSIFICATION OF DISORDERS INVOLVING THE GH/IGF-I AXIS

The classification in Table 2 is based on the fundamental role of IGF-I, with *primary IGF-I deficiency* referring to

Table 1 Metabolic Effects of GH and IGF-I

	GH	IGF-I
GH secretion	—	Decreased
IGF-I production	Increased	—
IGFBP-1	Decreased	Decreased
IGFBP-2	Decreased	Increased
IGFBP-3	Increased	No effect
Insulin: secretion	Increased	Decreased
sensitivity	Decreased	Increased
Hepatic glucose output	Increased	Decreased
Muscle glucose uptake	Decreased	Increased
Lipolysis	Increased	No effect ^a
Nitrogen balance	Increased	Increased
Protein synthesis	Increased	Increased

^aDecreased with very high dosages.

genetic and acquired defects in IGF-I synthesis, *secondary IGF-I deficiency* including congenital and acquired GH insensitivity, *tertiary IGF-I deficiency* including congenital and acquired forms of GH deficiency, and *IGF-I insensitivity*.

IV. CONGENITAL GH DEFICIENCY

A. Hypothalamic–Pituitary Malformations

Anterior and posterior pituitary deficiencies associated with various congenital syndromes affecting the hypothalamus, the pituitary, or both may be discovered through magnetic resonance imaging (MRI) of the hypothalamus and pituitary gland. These abnormalities may result in apparent deficiencies in infancy or not until later in childhood.

Anencephaly has long been recognized as a cause of an ectopic, hypoplastic, or malformed pituitary gland (54, 55). Slightly less severe in the clinical spectrum of major cranial malformations, holoprosencephaly is commonly associated with hypothalamic defects resulting in pituitary hormone deficiency. Associated defects can range from cyclopia to hypertelorism, with varying coexistent defects, including palatal or lip clefts, nasal septal aplasia, or, in surviving older children, a single central incisor (56, 57). Schizencephaly, sometimes identified by MRI during evaluation of gait disturbance, can also be associated with hypothalamic–pituitary malformation. Lastly, even isolated cleft lip or palate may be associated with hypothalamic or pituitary defects (58, 59).

Septo-optic dysplasia (SOD) is another malformation syndrome closely associated with hypopituitarism (60). At least 50% of children with SOD have hypopituitarism (54, 61). A child identified as having SOD should be referred to a pediatric endocrinologist for monitoring or testing. In its most severe form, SOD is associated with hypoplasia or absence of the optic nerves or chiasm, agenesis or hypoplasia of the septum pellucidum, and hypothalamic defects, and is known as deMorsier syndrome (59, 62–64). Typically, growth failure due to GH deficiency becomes apparent between 6 and 18 months of age.

Other specific, rare genetic syndromes can be associated with hypopituitarism. Rieger's syndrome, the result of a transcription factor gene mutation, results in hypopituitarism associated with coloboma of the iris, glaucoma, and dental hypoplasia (65, 66). Pallister Hall syndrome is associated with hypothalamic hamartoma-blastoma, micropenis, cryptorchidism, and postaxial polydactyly (67). Because MRI is used increasingly in the evaluation of children with unexplained neurological findings, additional genetic syndromes affecting the structural integrity of the hypothalamic–pituitary axis may be recognized. The use of MRI has led to the recognition that many children thought to have idiopathic GH deficiency actually have abnormal posterior pituitary or stalk regions (68).

Table 2 Classification of IGF-I Deficiency and IGF-I Resistance with Clinical and Biochemical Features

Condition	GHD ^a	Ht SDS	Biochemistry			
			GH	GHBP	IGF-I	IGFBP-3
Primary IGF-I Deficiency						
Congenital						
Defect in IGF-I synthesis	No	−6.9 (IUGR)	High	Normal	Very low	Normal
Acquired						
Alagille syndrome (12)	No	Varies	High	High	Low	Normal
Secondary IGF-I Deficiency						
Congenital						
GH receptor deficiency	Yes	−4 to −12	High	Low/nml/high	Very low	Low
GH–GHR signal transduction defect	Yes (Arab) No (Pakistani)	−3.4 to −6	High	Normal	Very low	nml/low
Acquired						
Catabolic states/chronic illness	No	Normal–low	High	Low/nml	Low	nml/low
Tertiary IGF-I Deficiency						
Congenital						
GHRH receptor deficiency	No	−4.3 to −8.9	Low	Normal	Low	Low
GHD	Yes	≤3	Low	Normal	Low	Low
Acquired						
GH inhibiting antibodies	Yes	−3 to −8.5	Low	Normal	Low	Low
GHD	Yes	Varies	Low	Normal	Low	Low
IGF-I Insensitivity						
Congenital						
IGF receptor deficiency	No	Severe/IUGR	High	Normal	High	High
IGF–IGFR signal transduction defects	No	−2 to −4.6	Normal	?	High	?

^aPhenotype.

Ht SDS, standard deviation score for height.

Some children found to have hypopituitarism have MRI findings of an interrupted pituitary stalk. The lesion may be congenital and accompanied by varying degrees of diabetes insipidus or anterior pituitary deficiencies. Other instances are probably acquired during trauma and may show some recovery of function later.

Hypothalamic dysfunction may explain the not infrequent finding of the short child with abnormal growth velocity and delayed bone age who, to the surprise of the endocrinologist, has a normal response to provocative GH testing. Some investigators have surmised that these children, while able to produce GH in response to pharmacological stimuli, fail to have adequate daily secretion of GHRH and thus, GH (69). This may be particularly true for a subset of children: those who have had prophylactic intracranial irradiation for leukemia (70). Children with GH deficiency following cranial radiation were found to respond to GHRH administration with augmented levels of GH (71).

Spontaneous GH secretion testing for this neurosecretory disorder can be cumbersome, requiring an indwelling catheter and the obtaining of frequent spontaneous growth hormone samples over a 24 h period or a

nocturnal 12 h period. For this reason and because GHRH is not a commercially available therapeutic option, common practice is to pursue a trial of GH therapy, usually for 6 months, in the short child with poor growth velocity and normal provocative GH testing results.

Another example in which the phenotype of GH deficiency may be hypothalamic in origin is the child with Prader–Labhart–Willi syndrome (PLWS), resulting from partial deletion of chromosome 15 or maternal uniparental disomy (i.e., the loss of paternally derived genetic material on chromosome 15). PLWS results in a phenotype of variable short stature, hypothalamic obesity, hypotonia, and hypogonadism (72). GH therapy results in an increase in lean body mass and growth velocity sustained over the 2 years of reported trials of therapy (73).

The empty sella syndrome is frequently found by MRI during the evaluation of children with isolated growth hormone deficiency or panhypopituitarism, but is only a finding in 2% of healthy children (74). Mild elevation of serum prolactin may be observed. The empty sella is the enlarged pituitary fossa, the size of which has been altered by herniated arachnoid contents. An empty sella may be a primary or secondary finding (75). Sec-

ondary causes include surgery, irradiation, and tumor. The actual pituitary tissue is flattened against the fossa wall, leading to varying degrees of hypopituitarism.

Prenatal and postnatal injuries are known to result in the birth of some infants with hypopituitarism (76). Breech delivery is also associated with hypopituitarism, but may be the result rather than the cause of hypopituitarism (77). Support for this hypothesis includes the finding of microphallus in some newborn boys with perinatal asphyxia (78, 79), suggesting inadequate prenatal gonadotropin, GH, or both. In some instances, however, perinatal asphyxia may compromise pituitary blood flow with subsequent ischemic pituitary damage.

B. Hereditary Forms of GH Deficiency

Although studies of GH response with GHRH and GH-releasing peptides indicate a hypothalamic basis for many instances of GHD, no defects have been described that affect GHRH synthesis (80). Numerous mutations have been described, however, affecting homeodomain transcription factors for pituitary development, the GHRH receptor, and GH genes.

1. Pituitary Differentiation Factors

As noted in the section on pituitary differentiation, *HESX1* and *LHX3* are factors involved in differentiation of the Rathke pouch into distinctive pituitary cell types. A missense mutation of *HESX1* has been described in a single family with septo-optic dysplasia, agenesis of the corpus callosum, and anterior hypopituitarism. Heterozygous members of the family were unaffected. Three siblings having deficiency of all pituitary hormones but adrenocorticotropin were found to be homozygous for a missense mutation in the *LHX3* gene. A single patient with the same hormonal status in another family had an intragenic deletion that predicted a severely truncated protein lacking the entire homeodomain (13). One of these patients had an enlarged anterior pituitary, whereas the others had pituitary hypoplasia. All four had rigidity of the cervical spine resulting in limited rotational ability of the head.

Some instances of multiple pituitary hormone deficiency (MPHD) have been attributed to dominant and recessive mutations of the gene for pituitary transcription factor, POU1F1 (formerly referred to as Pit-1), which is critical for the differentiation of somatotrophs, thyrotrophs, and lactotrophs. Recessive mutations, of which seven have been reported, result in varying degrees of loss of DNA binding or transcriptional activation functions (10). Mechanisms for the effects of the four dominant mutations are less readily explained, one involving enhanced binding of the mutant to GH and PRL promoter sites, another impairing distal enhancer activation; mechanisms for the other two mutations remain unexplained. Affected patients have intact ACTH, LH, and FSH function (81). Such occurrences have also been characterized by a small or normal sella turcica (82, 83). Since the orig-

inal description of a Pit1 mutation in 1992 (84), only a few cases have been reported.

A similar phenotype to that found in POU1F1 mutation is caused by mutation of the PROP1 gene in the Ames dwarf mouse. This gene encodes a paired-like homeodomain protein expressed briefly in embryonic pituitary and necessary for POU1F1 expression (85). Thus, it was anticipated that mutation of the PROP1 gene in humans would result in a clinical picture similar to that with POU1F1 mutations. It was demonstrated in several families, as well as in sporadic cases, however, that mutation of the PROP1 gene can cause gonadotropin deficiency in addition to somatotropin, thyrotropin, and prolactin deficiency (86–88). In the families described by Nader et al. (89) in 1975, and by Parks et al. (90) in 1978, now recognized to be families with PROP1 deficiency, MPHD was associated with sellar enlargement. In a few instances in which this mass has led to surgical intervention, histological examination indicates proliferation of undifferentiated connective tissue (91). This phenomenon does not appear to be genotype specific and varies within the families of the same genotype (Fig. 5); the clinical importance is the need to differentiate this pituitary enlargement from adenoma, craniopharyngioma, or other tumor. Adrenocorticotropin deficiency may result from progressive deterioration of the pituitary or be specific to certain mutations, suggesting a role for PROP1 in the differentiation or maintenance of corticotroph cells (92).

Homozygosity for a GA or an AG deletion in the sequence 296GAGAGAG in exon 2 of PROP1, originally noted in one of the first four families with PROP1 deficiency reported by Wu et al. (86), is the most common of the eight recessive mutations that have been described, reported in patients from Russia (87, 93), Turkey (93), Jamaica (91), the United States (93), Brazil (91, 93), and Dominican Republic (94). The series of three dinucleotide repeats appears to be a mutational hot spot, with susceptibility to misalignment of DNA, generating slippage and deletion independently in different populations. Another mutational hot spot also results in a 2 bp deletion in exon 2 (149delGA) that leads to the same serine to stop codon change at codon 109. It is present as a compound heterozygote with the 296delGA mutation in children with MPHD from four Russian families (10). The 296GAdel mutation represents a severe loss of function mutation. The altered sequence predicts a protein of 108 amino acids with a frameshift and truncation in the second α -helix of the DNA-binding domain. When expressed in a mouse PROP1 context, the recombinant protein lacks detectable DNA-binding and transcriptional activation activities (86). The severity of the hormone deficiency phenotype is compatible with the complete loss of PROP1 activity.

PROP1 mutations are an important cause of MPHD, in contrast to the situation with POU1F1 mutations. Of 52 Polish patients with MPHD, 33 had mutations in

Figure 5 Lateral skull films for sellar area in patients with familial anterior hypopituitarism due to PROP1 deficiency, from left to right and top to bottom: ages 17, 21, 23, 27, 29, 33, 38, 40 years, and normal sister age 22 years (third row, right). The first, fourth, and fifth subjects have sellar enlargement for height and bone age. (Reprinted from Rosenbloom AL, Selman-Almonte A, Brown MR, Fisher DA, Baumbach L, Parks JS: Clinical and biochemical phenotype of familial anterior hypopituitarism from mutation of PROP-1 gene. *J Clin Endocrinol Metab* 1999; 84:50–57; © The Endocrine Society.)

PROP1, and none in POU1F1; all 11 multiplex families had mutations, while 17 of 27 isolated cases did (10). Of 73 subjects with MPHD in Switzerland, 35 had PROP1 mutations, including all who were affected in 17 multiplex families (95).

2. GHRH Receptor Defects

Reports of mutations of the GHRH receptor gene come from inbred populations in India, Pakistan, and Brazil (15, 96–99). The first two families reported consisted of two children each from Indian Muslim families not known to be related, one of which was consanguineous (96, 97). These patients were homozygous for a G to T transversion at position 265 of the GHRH-R gene, which introduces a premature stop codon at residue 72, a mutation that was also found in 18 Pakistani patients who were part of a multiply consanguineous pedigree (15). The largest group of patients described thus far, 105 white patients of Por-

tuguese descent from an inbred population in northeastern Brazil, exhibit homozygosity for a different splice site mutation (98, 99).

As expected, individuals with GHRH receptor mutations have severe short stature and high-pitched voices. There is mild delay in sexual maturation but fertility has been demonstrated for both males and females (who require delivery by cesarean-section). One affected couple had an obligatorily affected but otherwise normal child. A number of clinical features differentiate subjects with GHRH receptor mutation from individuals with related conditions of severe isolated GH deficiency or GH insensitivity. GHRH-receptor-deficient patients have a normal penis size before puberty, whereas micropallus is typical of patients with GH deficiency and insensitivity. Unlike congenital GHD and GHRD, history of hypoglycemia has not been elicited in any of the populations with GHRH receptor deficiency and there is minimal or no facial hy-

poplasia or prominence of the forehead (Figs. 6, 7). The Pakistani patients had asymptomatic low blood pressure and relatively small head sizes, but this has not been noted in the other reports. In further contrast to GHD and GHRD, central adiposity is uncommon and body proportions are normal in those with GHRH receptor mutation. A further interesting difference from GHRD is that there is no difference in the markedly low levels of IGF-I, IGF-II, and IGFBP-3, or the elevated levels of IGFBP-2 between prepubertal and adult individuals (15). In GHRD, IGF-I, IGF-II, and IGFBP-3 levels are significantly greater and IGFBP-2 concentrations significantly lower in adults than in children (100, 101).

3. Isolated (I) GHD

Four autosomal recessive disorders, an autosomal dominant mutation, and an X-linked form of IGHD have been identified (102).

1. IGHD IA is a recessive condition caused by heterogeneous defects of the gene for GH (GH-1), and is the most severe form of GHD. Defects of the GH-1 have included gene deletions, and frameshift and nonsense mutations (1, 103–107). Because these individuals have complete GHD with no exposure to endogenous GH, the administration of rhGH results in formation of anti-GH antibodies and cessation of growth response after a few months in most, but not all patients (1, 108–110). In an Italian family with three affected children, two showed high-titer antibodies and ceased responding to exogenous GH, while the third sibling continued to respond and had low-titer antibodies (111).

2. IGHD IB is also an autosomal recessive condition differing from IGHD IA by the presence of detectable levels of endogenous GH and, consequently, continued response to rhGH administration without the development of anti-GH antibodies. This form of IGHD results from mutations affecting splicing of the GH-1 gene. These rare mutations have been described in Middle Eastern consanguineous families. The result of some of these mutations can be complete absence of measurable circulating GH, thought to be due to loss of anti-GH antibody-binding sites necessary for the radioimmunoassay reaction. The presence of some GH-related protein has been supported by the absence of development of anti-GH antibodies when these patients are treated with rhGH (97). In an Arab Bedouin family from Israel with IGHD IB, carriers of the mutant GH-1 allele were significantly shorter than those who were homozygous normal; one-third of 33 heterozygotes, but only 1 of 17 normal homozygotes had stature >2 standard deviations (SD) below the mean (112).

3. IGHD II is differentiated from IGHD I because it is inherited in an autosomal dominant mode, the result of dominant negative mutations of the GH1 gene. Affected individuals typically have an affected parent and respond well to rhGH administration. Most of the mutations that have been described associated with this form

of IGHD are in intron 3 of the GH gene and alter splicing of GH mRNA with skipping or deletion of exon 3. It is not clear why these mutations prevent expression of normal GH from the unaffected allele (the dominant negative phenomenon) (113–115). With one of the splice mutations, resulting in del32-71-GH, transfection studies in neuroendocrine cell lines demonstrated suppression of wild-type GH by the mutant as a posttranslational effect caused by decreased stability rather than decreased synthesis of the wild-type GH (116).

4. IGHD III is inherited in an X-linked manner. It is associated with agammaglobulinemia in some but not all families, suggesting contiguous gene defects on the long arm of the X chromosome as a cause of some instances of IGHD III (117).

5. Bioinactive GH. The presence of immunologically detectable but biologically ineffective GH has been proposed for a number of reported patients with the appearance of GHD, normal levels of radioimmunoassayable GH in the circulation, and low concentrations of IGF-I (118). Radioreceptor assay for GH in these cases has indicated lower concentrations than in the radioimmunoassay, and therapeutic response to rhGH is comparable to that in IGHD (118, 119). A mutation resulting in a heterozygous single amino acid substitution in the GH1 gene has been described in a patient thought to have bioinactive GH. Although there was an abnormal GH peak on isoelectric focusing, there was also a normal one and the patient shared this mutation with his normal father, suggesting that it was not pathological (120). In quest of a molecular defect in such patients, 200 children with short stature found to have GH sufficiency were reviewed. Three were identified who had short stature and growth velocities consistent with GHD, but elevated basal and stimulated levels of immunoassayable GH, and low concentrations of IGF-I and IGFBP-3 in the serum. A rat lymphoma cell proliferation assay and an immunofunctional assay for GH gave abnormally low responses compared to results on the radioimmunoassay (RIA). High-resolution sequencing of both strands of the coding region and display sites of genomic DNA and sequencing of the CD did not reveal GH-1 gene mutation in any of the patients. It was postulated that the reduced biological activity of abnormal translation product could be due to posttranslational processing in these patients (121).

V. ACQUIRED GH DEFICIENCY

A. Tumors

By far the most common cause of acquired GH deficiency in children is tumor. Craniopharyngiomas account for the greatest number of tumors causing GH deficiency, but several other benign or malignant tumors can also be responsible for the deficient state (122–124). Benign lesions that damage the hypothalamic–pituitary axis include pi-

Figure 6 Comparison of patients with GHRD and GHRH receptor deficiency. Upper left: 30-year-old man with GHRD (Laron syndrome), height 106 cm (-10.8 SDS), with 17-year-old brother, height 162 cm (-2.1 SDS). Upper right: 21-year-old twins with GHRH receptor deficiency, heights 119 and 118 cm (-8.8 , 8.9 SDS) and normal adult from region (height 168 cm). Lower: 27-year-old woman with GHRD, height 106 cm (-9.4 SDS), 24-year-old unaffected sister, height 155 cm (-1.4 SDS), and 25-year-old affected sister, height 112 cm (-8.4 SDS). Note in patients with GHRD family resemblance but with marked foreshortening of the face, prominence of the forehead, obesity, in men, frontotemporal baldness, and relatively short upper extremities. In contrast, the men with GHRH receptor deficiency have normal facies and body proportions, without obesity. (Upper right photo reprinted from Maheshwari HG, Silverman BL, Dupuis J, Baumann G. Phenotypic and genetic analysis of a syndrome caused by an inactivating mutation in the GH-releasing hormone receptor: dwarfism of Sindh. *J Clin Endocrinol Metab* 1998; 1983:4065–4074; © The Endocrine Society.)

tuitary adenoma, Rathke's cleft cyst, and arachnoid cyst (125). Primary malignant tumors that can affect this region include dysgerminomas, germinomas, meningiomas, and gliomas (126). Although metastatic tumor is a more common cause of GH deficiency in adults than in children, childhood Hodgkin's disease or nasopharyngeal carcinoma can metastasize to the pituitary or hypothalamus (126). Signs and symptoms of primary or metastatic malignancies and benign intracranial lesions can be visual loss (particularly bitemporal hemianopsia, for optic chiasm lesions), papilledema, headache with sleep or on awakening, emesis, and behavioral changes (126). Lesions

in the hypothalamus may additionally cause hypersomnolence, appetite changes, or diabetes insipidus (127). Weight loss may result from appetite loss or excess fluid losses from diabetes insipidus. Symptoms of prolactin excess, including amenorrhea or galactorrhea, may occur, because of the loss of dopamine inhibition from the hypothalamus.

1. Craniopharyngioma

Two-thirds of craniopharyngiomas are found in a suprasellar location. The tumor most likely arises from rem-

Figure 7 Top: 7-year-old boy with GHRH receptor deficiency, height 95 cm (-5.2 SDS) and weight 12 kg (5th percentile for height) with bone age 3 years, spontaneous and stimulated GH concentrations <1.5 $\mu\text{g/L}$, and serum IGF-I concentration below the level of measurability. Note absence of frontal bossing, facial hypoplasia, or truncal obesity. Bottom: 8-year-old boy with GHRD, height 78.9 cm (-9.1 SDS) and weight 9.2 kg (5th to 10th percentile for height) with a bone age of 3.3 years, spontaneous serum GH concentration 31 $\mu\text{g/L}$ (immunoradiometric assay), IGF-I 8 ng/ml (2 SD range for age 52–222, for bone age 20–79), IGFBP-3 141 ng/ml (2 SD range for age 2400–5800, for bone age 1180–3280), and IGFBP-2 500% of normal. Note small facies, frontal bossing, depressed nasal bridge and truncal obesity, despite low weight percentile. Ptosis (left) has been seen in $\sim 15\%$ of Ecuadorian patients with GHRD.

nants of the invagination of the embryonic stomodeum that gives rise to the adenohypophysis in the fetus. However, some neuropathologists believe the tumor could instead arise from metaplastic squamous epithelial cells in the adenohypophysis (125). The tumor accounts for 6–10% of all pediatric brain tumors and is most common from ages 5 to 15 years, but a second peak in incidence is seen in adults ages 50–70 years (123). MRI imaging often shows a calcified lesion, and histopathological examination reveals an encapsulated, oil-containing cystic tumor of squamous epithelial cells that show keratinization. The high cholesterol content of the tumor aids in identification on MRI. In one series, 95% of patients with craniopharyngioma had at least one anterior pituitary hormone deficiency at diagnosis, and 38% had hyperprolactinemia (122). Diabetes insipidus does not usually occur preoperatively (128). In the Jenkins series, nearly two-

thirds of patients had tumor recurrence, which correlated with cyst size. The best long-term prognosis is seen in patients with purely cystic lesions, and patients with tumor symptoms before the age of 5 years may have a worse prognosis than older patients (124). After initial surgical resection, virtually all patients with craniopharyngioma have hypopituitarism. Sleep and appetite centers in the hypothalamus may be damaged by the tumor or by the attempted resection. Hyperphagia and resultant obesity tend to correlate with damage to the ventromedial and/or paraventricular nuclei (125), and this excess nutrition may result in normal or supranormal growth velocity despite profound GH deficiency.

In a series of 20 patients with craniopharyngioma reported by Jenkins, 19 of 20 had GH and gonadotropin deficiencies at diagnosis (122). Thirteen patients had secondary or tertiary hypothyroidism, and 10 had ACTH de-

ficiency. None of the patients had diabetes insipidus before surgical resection.

With surgical resection, nearly all patients with craniopharyngioma will have at least temporary vasopressin deficiency. The development of further pituitary deficiency depends upon degree of tumor resection (129), which will also influence long-term survival. With attempted complete removal of the tumor (without subsequent radiation), 42% of patients have tumor recurrence (124). Gross total resection of the tumor gave a 90% cure rate in another series, but about one-third of patients experienced behavioral problems, appetite or sleep dysfunction, and memory deficits postoperatively (126). Near-total excision followed by fractionated radiotherapy may provide the best prognosis (130, 131).

2. Rathke Cleft Cyst

A Rathke cleft cyst (RCC) is a benign lesion believed to arise from Rathke's pouch remnants, neuroepithelium, or metaplastic anterior pituitary cells (132). The lesion is generally intrasellar and may result in hypopituitarism, neurological findings, or visual deficits (125). The lesion is often mucoid and may contain cuboidal, columnar, or ciliated epithelium. It may be difficult to differentiate from a craniopharyngioma or arachnoid cyst. In one series, 81% of patients with RCC had preoperative hypopituitarism, 60% had neurological dysfunction, and 38% had visual losses (132). As in craniopharyngioma, hyperprolactinemia may result from loss of dopamine inhibition of prolactin secretion.

3. Arachnoid Cleft Cyst

The arachnoid cleft cyst (ACC) usually occurs in an intrasellar location and may be difficult to identify preoperatively. ACC occurs typically in older patients than does craniopharyngioma or RCC. The cyst is lined by arachnoid cells and contains cerebrospinal fluid. It is either a congenital lesion or an acquired lesion that occurs when the diaphragma sella permits herniation of the arachnoid membrane. The endocrine prognosis is worse for ACC than RCC or craniopharyngioma, most likely due to more chronic, high-pressure damage to the adenohypophysis by the cyst (132).

4. Pituitary Adenoma

Although more common in adults than in children, the pituitary adenoma may cause hypopituitarism in children by pressure damage to surrounding normal pituitary tissue. Five to 6% of childhood pituitary tumors are adenomas and may occur in isolation or as part of multiple endocrine neoplasia type I (133). More than half of these adenomas are prolactinomas; the remainder may secrete ACTH or GH, or may be nonfunctioning (134). Histopathological evaluation often reveals areas of hemorrhage within the adenoma; hemorrhage may cause pituitary ap-

oplexy, and, if longstanding, the hemorrhagic areas may become cystic. (133).

B. Other Causes of Acquired GH Deficiency

A variety of other causes of acquired GH deficiency have been identified. Among the mechanical causes of GH deficiency are trauma with or without skull fracture, irradiation for therapy of malignancy, and surgery. Hemorrhage into the pituitary or hypothalamus may cause hypopituitarism and has been reported in patients receiving chronic anticoagulant therapy as well as in those with pituitary apoplexy. Inflammatory processes resulting in hypopituitarism include autoimmune hypophysitis, infectious diseases resulting in meningitis or encephalitis, and infiltrative processes such as sarcoidosis, histiocytosis X, and hemochromatosis. Cerebral edema occurring with diabetic ketoacidosis has also been reported to result in hypopituitarism (19, 135).

1. Head Trauma

Following significant head trauma, 40% of patients may have transient or permanent vasopressin deficiency (127). On occasion, apparently permanent anterior hypopituitarism has spontaneously resolved months after the head injury (136). Varying degrees of other pituitary hormonal deficiencies may be seen. Hypopituitarism may result from direct structural damage to the hypothalamus or pituitary or because of hypovolemia with severe blood loss or increased intracranial pressure. Hypopituitarism may occur after seemingly minor head trauma (137) and should always be a diagnostic consideration in the evaluation of the child abuse victim with head trauma.

2. Radiation Therapy

Current CNS oncological radiation includes conventional radiation, as well as proton-beam, gamma knife, and yttrium-90 or gold-198 radiotherapy. All of these therapies may cause pituitary insufficiency (127, 138). With conventional radiation of 50 Gy for 4 weeks for pituitary adenoma, 11 of 22 patients developed hypopituitarism within 4.2 years (139). Head and neck irradiation, or "mantle" radiation for lymphoma, may lead to pituitary deficiencies as well (140). It is prudent to evaluate growth velocity, weight gain, and, in pubertal age patients, pubertal progression, at frequent intervals in the first 5 years following radiation to the head.

3. Pituitary Apoplexy

Pituitary apoplexy has been described in patients with pituitary adenomas and in women in the immediate postpartum period (141). It may also occur in severely dehydrated patients with diabetes mellitus, trauma, or intracranial pressure changes, or in patients undergoing chronic anticoagulation or radiation therapy (127, 142). Postpartum apoplexy is known as Sheehan's syndrome.

Apoplexy is due to hemorrhage or infarct into an adenoma or into normal pituitary tissue, with subsequent hypopituitarism. Failure to recognize the signs of ACTH deficiency resulting from apoplexy can have fatal consequences. Patients may have severe headache ("the worst of my life"); diplopia or visual loss; deficits of cranial nerves III, IV, or VI; sensorium changes; or hypotension. Diagnosis is confirmed by findings on computed tomographic (CT) scan or MRI.

4. Inflammatory Disease

Autoimmune or lymphocytic hypophysitis has been described in patients with autoimmune polyglandular syndrome, in postpartum women, and as an isolated finding (143, 144). Diagnosis can be difficult to confirm but may be based on the finding of pituitary antibodies (not commercially available) or of lymphocytic infiltration on pituitary biopsy (145). Patients with meningitis or encephalitis may also develop hypopituitarism with bacterial, viral, or fungal infections (146). Infiltrative diseases uncommonly cause hypopituitarism in children, but may result from histiocytosis X, sarcoidosis, or hemochromatosis due to chronic blood transfusions for thalassemia (147). A thickened pituitary stalk may suggest the diagnosis on MRI. Children with histiocytosis X initially have diabetes insipidus (DI) without other hormonal deficiencies and with a thickened pituitary stalk (148). The child with histiocytosis and DI often has unusual, desperate, water-seeking behaviors, such as drinking from flower vases or pets' water dishes. Subsequently, GH deficiency, alone, or with other pituitary deficiencies, may occur.

5. Deprivation Syndrome

Failure to thrive thought to result from lack of nurturing in infants raised in institutions was described as anaclitic depression (149). Talbot et al. (150) initially suggested that growth failure can occur beyond infancy associated with emotional deprivation and characterized by subtle nutritional inadequacy. The spectrum of pathology associated with growth failure in dysfunctional settings has been referred to as deprivation, maternal deprivation, emotional deprivation, or environmental deprivation dwarfism, psychosocial dwarfism, and hyperphagic short stature. Fifteen years after the report of Talbot et al., Patton and Gardner (151, 152) stressed the importance of historical information in defining some instances of growth failure as a truly psychosomatic disorder. They speculated that the problem could be attributed to hypothalamic influences on the pituitary secretion of GH, undernutrition as a result of neglect, diminished appetite resulting from depression and lethargy, or decreased intestinal motility and absorption due to nutritional and emotional factors.

Deprivation dwarfism was later described as a triad of extreme short stature, voracious appetite, and markedly delayed sexual maturation in nine patients who had had

feeding difficulties in infancy, persistent sleep problems, and whose parents had serious psychological disturbances; growth improved markedly with foster placement (153). The clinical syndrome was further described in 13 children initially thought to have idiopathic hypopituitarism to include, in addition to high degrees of social disruption and pathology in the family and severe growth failure, bizarre eating and drinking behavior by history, sleep disturbances, malabsorption with foul-smelling stools, delayed speech, and abdominal protuberance. The children ate out of garbage cans, "stole" food, gorged, and ate from the pets' dishes. They drank from toilet bowls, glasses filled with dishwater, rain pools, and old beer cans holding stagnant water. Removal from the home was associated with growth acceleration and behavioral improvement. Emotional factors, malabsorption, inadequate nutrition, and hypopituitarism were all considered as possible contributors (154). Endocrinological evaluation indicated frequent deficiency in adrenocorticotropin and GH with return of GH responses to normal; occasional patients had normal GH values, but it was not recognized at that time that recovery of GH secretion might occur very early after removal from the home (155). Others confirmed deficient GH and ACTH responses to hypoglycemia in children, but not infants, with the deprivation syndrome and noted that some children had normal or elevated serum GH concentrations at the time of admission, reminiscent of the range of possibilities with malnutrition (156).

Two important investigations published in 1969 addressed the question of whether environmental or maternal deprivation, in the presence of adequate nutrition, could result in growth failure. Rhesus monkeys, shown to be extremely dependent on maternal attention and physical play for normal behavioral development, were provided an ad libitum diet, but deprived of all social contact and environmental stimulation from birth, including direct human contact except that required for maintenance and experimental measures. Despite developing persistent behavioral abnormalities including autistic posturing, fear, inability to engage in social play and, after maturity, to engage in social and sexual activity, their growth was completely normal (157).

A remarkable prospective study was carried out by Whitten et al. of 16 human infants aged 3–24 months referred for growth failure, who were of normal weight at birth (158). During a 2-week period of initial hospitalization with minimal mothering and plentiful calories, and a period of high-intensity mothering, comparable weight recovery occurred. In the home setting, provision of adequate calories supervised by a home visitor, described to the family as a study protocol rather than supervision, also resulted in adequate gain. Some of the mothers admitted that the amount of food consumed was considerably greater than they had been providing. Other mothers have likewise admitted to intentional starvation as a form of

Figure 8 Three children with deprivation syndrome. Left: 7-year old daughter (on right) of psychotic parents, with hepatomegaly and lack of normal social behavior, standing with a normal-sized age mate. Right upper: daughter of alcoholic single mother, this 5-year-old was thought to have gluten-induced enteropathy to explain her short stature (height SDS -4.1 , height age 2 years 4 months). In the care of her grandmother, she gained 20 lbs in 10 months, nearly doubling her weight, and grew 7-1/4 inches (height SDS -1.2 , height age, 4 years 8 months). Right lower: 5-year-old thought to have GHD to explain severe short stature (height SDS -5); when she returned 6 months later to start pituitary GH injections, she had grown 4 inches and it was learned that her social situation had changed dramatically after the initial hospitalization.

abuse, or to avoid having the child get sick, bloated, throw up, or have loose stools (159). Extensive studies of mothers of affected infants and children have demonstrated a range of pathology affecting mothering skills and character (160, 161).

In a review of 185 patients hospitalized for evaluation of failure to thrive, 50% could be attributed to environmental deprivation, corresponding precisely to the percentage noted 20 years earlier by Talbot et al. (150). Or-

ganic causes were suggested by history and physical examination; only 1.4% of laboratory studies performed were of diagnostic value and only if there was a specific indication for the test from the clinical evaluation (162).

The frequent observation of disturbed sleep patterns in these children suggests that their growth failure might be related in part to a failure of nocturnal GH secretion, dependent on the attainment of deep sleep (163). Polygraphic sleep recordings soon after hospital admission in

children with psychosocial dwarfism demonstrated a gross deficit of stage IV sleep and a decrease in the overall slow-wave sleep episodes, both stage III and IV. After 3–15 weeks in the new environment and with growth recovery, stage IV sleep returned (164). More recent studies have demonstrated progressive improvement in GH pulse amplitude, with maintenance of the individual's characteristic pulsatility (165, 166).

The deprivation syndrome can now be recognized as a social pathology resulting in chronic undernutrition and secondary endocrine deficiencies, primarily GH and ACTH, which are readily reversible with provision of adequate food intake (Fig. 8). Removal from the home temporarily or permanently is usually necessary, particularly for older children. Infants with failure to thrive often have mothers who mean well, but are immature, dependent, and insensitive to their infants' needs; counseling and support may make it possible for the child to thrive in the home (161). In the few recognized instances in which exogenous GH has been administered to children with deprivation syndrome, responses have been nil to much less than typical of GH deficiency, as one might expect in the context of noncompliance and undernutrition (167, 168).

VI. CONGENITAL GH INSENSITIVITY

A. GH Receptor Deficiency (GHRD)

Following the initial report (169) of three Yemeni Jewish siblings "with hypoglycemia and other clinical and laboratory signs of GH deficiency, but with abnormally high concentrations of immunoreactive serum growth hormone," 22 patients were reported from Israel, all Oriental Jews, with an apparent autosomal recessive mode of transmission in consanguineous families (170). These reports preceded the recognition of the critical role of cell surface receptors in hormone action and it was postulated that the defect was in the GH molecule these patients were producing. This impression was substantiated by the observation of free fatty acid mobilization, nitrogen retention, and growth in patients being administered exogenous GH (170). These effects may have been due to other pituitary hormones in the crude extracts administered or to nutritional changes in the investigative setting. In the first patient reported outside of Israel, in 1968, there was no response to exogenous GH, leading to the hypothesis that the defect was in the GH receptor (171). This hypothesis was substantiated by the failure to demonstrate sulfation factor activation with exogenous GH administration, reported in 1969 (172) and reports in 1973 and 1976 that the patients' GH was normal on fractionation, in its binding to antibodies, and in its binding to hepatic cell membranes from normal individuals (173–176). *In vitro* demonstration of cellular unresponsiveness to GH was demonstrated by the failure of erythroid progenitor cells from the peripheral blood of two patients to respond to

exogenous GH (177). The failure of radioiodine-labeled GH to bind to liver cell microsomes obtained from biopsy of two patients with Laron syndrome confirmed that the defect was in the GHR (178). The two reports of absent GHBP in sera of patients with Laron syndrome (29, 30) appeared just before the publication of the finding that GHBP was the extracellular domain of the cell surface GHR (31).

Mutations of the GHR have provided insight into its physiology. Thirty-six distinct mutations in the extracellular and transmembrane domains produce a clinical picture of severe GH/IGF-I deficiency in the homozygous state or as compound heterozygotes, whereas two dominant negative mutations of the intracellular domain result in a milder clinical syndrome. Some individuals described with features of GH resistance appear to have defective signal transduction by the GH–GHR complex. Knowledge of the biology and signaling of the GHR has attracted extensive research interest because GH is a powerful regulator of somatic growth, mitogenesis, and metabolism, with a wide variety of effects on target cells, all mediated by the GHR, which is expressed in 40 different tissues.

The structure of the human GHR gene is depicted in Figure 9. There are eight variants (V1–V8) contributing to the 5' untranslated region (UTR), followed by nine coding exons (exons 2–10). Exon 2 encodes the last 11 base pairs of the 5'-UTR sequence, an 18 amino acid signal sequence, and the initial five amino acids of the extracellular hormone binding domain. Exons 3–7 encode the extracellular hormone-binding domain, except for the terminal 3 amino acids of this domain, which are encoded by exon 8. Exon 8 further encodes the 24 amino acid hydrophobic transmembrane domain and the initial four amino acids of the intracellular domain. Exons 9 and 10 encode the large intracellular domain. Exon 10 also encodes the 2 kb 3'-UTR. Four of the alternative 5'-UTRs of the human gene have been cloned from genomic DNA, indicating that each was encoded by a separate exon. It has been suggested that this variability serves to regulate translational efficiency of the mRNAs (179). The human GHR is unique in existing in an alternative splice isoform that excludes exon 3; this deletion has no demonstrable effect on GHR function (180).

The report of the characterization of the GHR gene included the first description of a genetic defect of the GHR, a deletion of exons 3, 5, and 6 (32); recognition that the exon 3 deletion represented an alternatively spliced variant without functional significance resolved the dilemma of explaining deletion of nonconsecutive exons. No other exon deletions have been described in patients with GHI, but the additional defects of the GHR gene that have been described in association with GH insensitivity (GHI) include eight nonsense mutations, 14 missense mutations, five frame shift mutations, 10 splice mutations, and a unique intronic mutation resulting in in-

Catholicism during the Spanish Inquisition. The latter make up the largest cohort ($n = 70$) and the only genetically homogeneous group. All but one subject have the E180 splice site mutation that is shared with at least one Israeli patient of Moroccan heritage. Most of the other defects appear to be highly family-specific, with the R43X mutation that is seen in a single Ecuadorian patient, two other nonsense mutations (C38X, R217X), and the intron 4 splice mutation being the only ones thus far described that appear in disparate populations, on different genetic backgrounds, indicating mutational hotspots (190). Because the molecular defect in the GHR has been identified in about one-third of the patients with GHRD outside of Ecuador, it is likely that the list of mutations will continue to grow and provide further insight into the function of the GHR.

B. Partial GHI

GH resistance might be expected to occur in an incomplete form, analogous to insulin resistance, androgen insensitivity, or thyroid hormone resistance. Affected children might have growth failure with normal or slightly increased GH secretion, variable but usually decreased GHBP levels, decreased IGF-I concentrations, but not as severely reduced as in GHD or GHRD, and might respond to supraphysiological dosages of GH. It might also be expected, given the need for dimerization of the GHR for signal transduction, that certain mutations could have a dominant negative effect in the heterozygous state.

Credibility for a heterozygous defect as a cause of short stature requires the demonstration of functional significance, not only by transfection of the mutant allele but also by cotransfection with wild-type GHR gene, to approximate the circumstance *in vivo*. Goddard et al. (191) have identified six mutations in eight children with short stature (SDS for height -5.1 – -2.0) and normal or increased stimulated GH levels. One patient had compound heterozygosity involving a novel mutation in exon 4 (E44K) and a mutation in exon 6 previously associated with GHRD in the homozygous state (R161C). Two other patients were heterozygous for this mutation. The other five patients included two who were heterozygous for the same novel mutation in exon 7 (R211H), and one each with novel mutations of exon 5 (C122X), exons 7 (E224D), and exon 10 (A478T). Expression *in vitro* of these four novel mutations involving the extracellular domain has shown functional effects, although cotransfection studies have not yet been reported. The defect involving exon 10 has not been expressed *in vitro*. Other defects without demonstrable significance have been described involving exon 10 (192–194). None of these putative partial GHI patients had the clinical phenotype of GHD. Five of the eight patients were treated with GH and had variable improvement in growth velocity, from slight to dramatic, in the first year (191). This variable response

could be due to GH resistance or to the fact that the patients were not GH/IGF-I deficient.

The subjects studied by Goddard et al. were selected from the large Genentech National Cooperative Growth Study database in pursuit of the question raised by the observation that GHBP concentrations are low in children with idiopathic short stature (ISS; i.e., short children without a recognizable syndrome or GHD). Using a ligand-mediated immunofunction assay Carlsson et al. (196) studied a large number of short children with known causes of growth failure such as GHD and Turner's syndrome, or ISS, and compared their GHBP concentrations in serum to those of normal controls. Ninety percent of the children with ISS had GHBP concentrations below the control mean and nearly 20% had concentrations that were 2 standard deviations or more below the normal mean for age and gender. Whether the distribution of GHBP concentrations in children with unexplained short stature indicates that partial GH resistance is a common cause of short stature remains to be demonstrated.

If heterozygous mutations of the GHR ultimately prove to be one cause of partial GH resistance, this would explain only a very small proportion of cases of idiopathic short stature. This impression is supported by a review of 37 patients who had relatively high GH responses to insulin and failure to increase IGF-I concentrations in the serum after several days of GH administration. GHBP concentrations were normal. Only one patient in this group failed to demonstrate a growth response to exogenous GH. The authors concluded that partial GH insensitivity was likely to be a rare cause of unexplained short stature (196).

The possibility of an effect of heterozygosity for a mutation known to cause GHRD in the homozygous state was explored in the unique Ecuadorian cohort with GHRD, which comprises a large population with a single mutation, permitting genotyping of numerous first-degree relatives. There were no significant differences in stature between carrier and homozygous normal relatives, indicating a lack of influence of heterozygosity for the E180 splice mutation of the GHR (197). A more general indication of the lack of influence of heterozygosity for GHR mutations involving the extracellular domain on growth comes from studies of the large multicenter European-based GHI study. In both the European and Ecuadorian populations the stature of parents and of unaffected siblings does not correlate with statural deviation of affected individuals (197, 198), while an expected high correlation exists between parents and unaffected offspring (197). If the mutations that cause growth failure in the homozygous state also affected growth in heterozygotes, heterozygous parents and predominantly heterozygous siblings would have height SDS values that correlated with those of affected family members. In the Ecuadorian families, there was no difference in height correlations with parents between carriers and homozygous normal offspring (197).

C. Growth Hormone–GH Receptor Signal Transduction Failure

Evidence of a post-GHR defect in three siblings of Palestinian Arab origin has been presented by Laron et al. (199). The children had typical features of severe GHD, but normal GHBP and IGFBP-3 levels with severe IGF-I deficiency. The molecular defect has yet to be identified. In contrast to these patients, four GHBP-positive children from two unrelated Pakistani families, who had high GH, low IGF-I, and low IGFBP-3 serum concentrations, had no phenotypic features of Laron syndrome except for short stature, which was less severe than in typical GHRD (200). Fibroblasts from the children in one of the families demonstrated failure to activate part of the GH-signaling pathway (201).

VII. ACQUIRED GH INSENSITIVITY

Acquired resistance to GH is a ubiquitous adaptation in a number of protein catabolic states such as malnutrition, poorly controlled diabetes mellitus, and chronic renal disease. Growth failure is a variable result. GHBP is diminished for reasons that remain unexplained in these conditions, with elevated GH concentrations, decreased IGF-I, and normal to decreased IGFBP-3 concentrations. IGFBP-1 concentrations are elevated and reflect the catabolic state, and in those with diabetes, relative insulin deficiency (202). Children with end-stage renal disease, in addition to having decreased GHBP, normal or elevated GH, and low normal IGF-I concentrations, have high concentrations of IGFBP-3, IGFBP-1, and IGFBP-2, thereby decreasing IGF-I bioavailability (203). These catabolic or chronic disease conditions may affect the GH–IGF-I axis in a manner comparable to the sick euthyroid syndrome. In the case of renal disease, the excess binding of IGF-I is not sufficient reason for invoking a GH-resistant explanation.

VIII. PRIMARY IGF-I DEFICIENCY AND IGF-I RESISTANCE

A. Congenital IGF-I Synthetic Defect

A single case of defective IGF-I synthesis due to a gene deletion has been described in a patient with a homozygous partial deletion of the IGF-I gene. His profound intrauterine growth retardation (IUGR) persisted into adolescence and he had sensorineural deafness with mental retardation (46). The absence of the craniofacial phenotype of severe GHD and the presence of normal IGFBP-3 in this patient, despite unmeasurable levels of IGF-I, indicates that the craniofacial features and low IGFBP-3 of GHD and GHR deficiency are related to an absence of the direct effects of GH that do not act through the me-

dium of IGF-I synthesis. It is also noteworthy that profound IUGR and mental retardation are not characteristic of GHD or GHRD (204, 205), but IGF-I knockout mice have defective neurological development as well as growth failure (206). Thus, IGF-I production in utero does not appear to be GH-GHR dependent. Elevated GH levels would be expected in this circumstance as a result of the absence of IGF-I suppression of somatostatin; diurnal levels of GH were high, with an overnight GH peak of 171 ng/ml (46).

B. Acquired IGF-I Synthetic Defect

Alagille syndrome (chronic intrahepatic cholestasis) is associated with moderate growth failure in 50% of instances along with elevated GH and GHBP levels, and normal IGFBP-3 levels. Thus, this does not appear to be a GH-resistant state but one involving failure of IGF-I generation due to hepatic dysfunction (207).

C. Congenital IGF-I Receptor Defect

Defects in the IGF type I receptor or in the IGF receptor signal transduction pathway have been hypothesized in several patients. IGF-I resistance has been invoked as a cause of short stature in the Pygmy people, demonstrated by failure of response of T cells from such patients to IGF-I in vitro; the absence of IGF-I elevation that should accompany such resistance, however, requires explanation (208).

Loss of a single allele for the IGF receptor caused by distal long arm deletion of chromosome 15 fails to abolish in vitro effects of IGF-I and, therefore, would not appear to explain short stature in affected patients (209). Homozygous IGF-I receptor deletion is probably lethal (210).

Three patients have been reported with normal or high GH levels and elevated IGF-I levels. In two of these patients, normal bioactivity was demonstrated for the circulating IGF-I and fibroblasts from skin biopsies of these patients responded normally to recombinant IGF-I (211–213). It was hypothesized that these patients might have a tissue-specific (i.e., skeletal) IGF-I unresponsiveness. Such an explanation could also be invoked to explain the findings of normal IGF-I levels, lack of response to exogenous GH, and normal fibroblast response to IGF-I in those patients with heterozygous deletion of the IGF-I receptor gene (209).

A systematic examination for mutations in the IGF-I receptor was pursued in 38 children with IUGR who remained <2 SD for length after 18 months of age. This group was selected for study because IGF-I receptor knockout mice have more severe IUGR than do IGF-I knockout mice. A single patient was identified with compound heterozygosity for mutations resulting in amino acid substitutions. He had severe IUGR (birthweight 1420 g at 38 weeks), poor postnatal growth, and elevated con-

centrations of IGF-I and integrated GH concentration when prepubertal, consistent with IGF-I resistance. The location of the mutations was within a putative ligand-binding domain (47).

IX. DIAGNOSTIC EVALUATION

A. Clinical Assessment

Children should be evaluated for growth problems based on the following criteria:

- Height velocity <25th percentile for >6 months
- Downward crossing of percentiles on growth chart after age 18 months
- Height below -2 SD for age
- Height below genetic potential (-2 SD below midparental height)
- Bone age delay comparable to height age

Evaluation should begin with a complete history, including consideration of the mother's pregnancy (illness, toxins, alcohol/drugs used, gestation), perinatal events, birth weight and length, signs of chronic disease or abnormality in psychosocial status, and growth history. Family history of growth and pubertal timing are important, and parental heights should be measured, if possible. Calculation of midparental and target heights provides a context for determining the child's growth potential, based on current bone age and height, and whether, in fact, there is an abnormality.

Midparental height is calculated as:

$$\text{Girls: } \frac{(\text{father's height} - 13 \text{ cm}) + \text{mother's height}}{2}$$

$$\text{Boys: } \frac{(\text{mother's height} + 13 \text{ cm}) + \text{father's height}}{2}$$

Target height = midparental height ± 2 SD (1 SD = 5 cm)

Height needs to be measured against the wall, using a fixed scale and a right-angle device against the head, with the back of the head, spine, and heels against the wall or device without flexion of the legs. Head circumference should also be measured and compared to standard curves for age and size. Body proportions can be determined by measuring span from middle fingertip to middle fingertip of the outstretched arms, and upper to lower segment calculated by measuring the distance from the top of the symphysis pubis to the floor with the legs slightly apart and straight. This distance is subtracted from total height to obtain the upper segment. Major and minor anomalies should also be looked for as clues to syndromes associated with small stature; the presence of a dysmorphic syndrome, however, does not obviate the possibility of concomitant GHD.

Accurate weight is important because the endocrine causes of growth failure result in height deviation that is greater than that of weight, so that such individuals often have greater than normal weight for height. The physical examination should also assess pubertal status and look for any signs of chronic illness, typically associated with low weight for height.

The typical somatic features of severe secondary and tertiary IGF-I deficiency, listed in Table 3, are not cause specific (Fig. 10). Many, if not most, such patients, including those with GHRH receptor deficiency, GH gene deletion, and GHRD, have normal intrauterine growth. SDS for length declines rapidly after birth in severe GHD or GHRD (Fig. 11) indicating the GH dependency of extrauterine growth. It was formerly thought that the first 6 months of infantile growth was not GH dependent, but this was based on inadequate data in severe GHD. Growth velocity with severe GHD or GHRD is approximately half normal (Fig. 12). Occasional periods of normal growth velocity, as noted in Figure 12, may be related to improved nutrition (214).

Despite normal sexual maturation in isolated secondary or tertiary IGF-I deficiency, the pubertal growth spurt is minimal or absent, as documented in some of the most extensive available data, in subjects with GHRD from Israel and Ecuador (49, 215). The adolescent growth spurt is GH-dependent, reflected in significantly elevated circulating levels of GH and IGF-I compared to preadolescence and adulthood (216). Among 24 Israeli patients with GHRD followed from infancy to adulthood, persistent growth beyond the normal time of adolescence was seen only in boys. In the Ecuadorian population girls also showed this phenomenon (Fig. 11). Adult stature in GHRD varies from -12 to -5.3 SD in Ecuadorian patients and -9 to -3.8 SDS in others in the literature, using the US standards (49). This is a height range of 95–124 cm for women and 106–141 cm for men in the Ecuadorian population. This wide variation in the effect of GHRD on stature was seen not only within the affected population but also between affected siblings. This intrafamilial variability has also been described with severe GHD due to GH gene deletion (108) and between those having the same mutations in the GHRH receptor (15). With multiple pituitary hormone deficiency, resulting in failure of adolescence, growth may continue into the 30s and 40s (Fig. 13).

Children with familial causes of IGF-I deficiency may be recognized by knowledgeable family members at birth because of craniofacial characteristics of frontal prominence, depressed nasal bridge, and sparse hair, as well as small hands or feet, and hypoplastic fingernails. Decreased vertical dimension of the face is typical of severe GHD or GHI and has been demonstrated in GHRD by computer analysis of the relationships between facial landmarks in all patients, including those with normal appearing facies. This foreshortening is particularly apparent

Table 3 Clinical Features of Severe IGF-I Deficiency Due to GH Deficiency or GH Receptor Deficiency

Growth
Birth weight: normal; birth length; usually normal
Growth failure, from birth, with velocity 1/2 normal
Height deviation correlates with (low) serum levels of IGF-I, -II, and IGFBP-3
Delayed bone age, but advanced for height age
Small hands or feet
Craniofacial characteristics
Sparse hair before age 7; frontotemporal hairline recession all ages
Prominent forehead (bossing)
Head size more normal than stature, with impression of large head
“Setting sun sign” (sclera visible above iris at rest) in 25% <10 years of age
Hypoplastic nasal bridge, shallow orbits
Decreased vertical dimension of face
Blue scleras
Prolonged retention of primary dentition with decay; normal permanent teeth, may be crowded; absent third molars
Sculpted chin
Unilateral ptosis, facial asymmetry (15%); only reported in GHRD
Musculoskeletal/body composition
Hypomuscularity with delay in walking
Avascular necrosis of femoral head (25% of GHRD)
High-pitched voices in all children, most adults
Thin, prematurely aged skin
Limited elbow extensibility after 5 years of age
Children underweight to normal for height, most adults overweight for height; marked decrease of ratio of lean mass to fat mass, compared to normal, at all ages
Osteopenia indicated by dual energy x-ray absorptiometry
Metabolic
Hypoglycemia (fasting)
Increased cholesterol and LDL-C
Decreased sweating
Sexual development
Small penis in childhood; normal growth with adolescence
Delayed puberty
Normal fertility

when patients are compared with their unaffected relatives (Figs. 6, 7) (217). Blue scleras, the result of decreased thickness of the scleral connective tissue, permitting visualization of the underlying choroid, were originally described in Ecuadorian patients with GHRD, and subsequently recognized in other populations with GHRD, as well as in GHD (94, 204, 218, 219).

Hypomuscularity is apparent in radiographs of infants with GHRD, and is thought to be responsible for delayed walking, despite normal intelligence and timing of speech onset (100). Radiographs of children who are GH-deficient or insensitive also suggest osteopenia; dual-photon absorptiometry and dual energy x-ray absorptiometry in children and adults confirm this. Limited elbow extensibility is an unexplained phenomenon seen in most patients over 5 years of age with GHRD or severe GHD. It is an acquired characteristic, absent in younger children and increasing in severity with age (94, 100). Although children may appear overweight, those with GHRD, and some with

GHD, are underweight to normal weight for height, while most adults, especially females, are overweight with markedly decreased lean to fat ratios (Figs. 6, 7, 10) (100).

Symptoms of hypoglycemia, including convulsions, particularly in infancy, are common in children with isolated GHD, MPH, and GHI, indicating the critical importance of direct metabolic effects of GH in the fasting state: increasing hepatic glucose output, decreasing glucose uptake, and increasing lipolysis (Table 1, Fig. 3). Persistent physiological jaundice of infancy has also been noted with GHD. Decreased sweating has been described in GHD and documented by pilocarpine electrophoresis in patients with GHRD. The subjects had significantly reduced sweat secretion rates and elevated sweat electrolyte concentrations, indicating that sweat gland function is under the influence of the GH-IGF-I axis (220).

Severe GHD is associated with small penis size with normal penile growth at adolescence or with testosterone treatment in childhood. This is also true of GHRD but,

Figure 10 Similar phenotype for GH gene deletion, left; GH receptor deficiency, center; and idiopathic combined pituitary hormone deficiency (GH, thyroid), right. Left: Argentinian brothers with type I-A familial GHD, aged 2 yrs 11 months (left) and 5 years (right), demonstrating marked heterogeneity of the growth effect despite common genetic cause; the height SDS for the younger boy was -7.1 and for the older boy -8.6 . (Reprinted from Rivarola MA, Phillips JA III, Migeon CJ, Heinrich JJ, Hjelte BJ: Phenotypic heterogeneity in familial isolated growth hormone deficiency type I-A. *J Clin Endocrinol Metab* 1984; 59:34–40; © The Endocrine Society.) Center: Subject at 9.4 years of age, with a bone age of 3.5 years, has a height SDS -9.1 ; despite the appearance of obesity, his weight for height is just under the third percentile. Right: Boy at 8-1/2 years, with a bone age of 2 years, has a height SDS -8.5 and weight for height well below the third percentile, approximately 4 SD below the mean. These patients are clinically indistinguishable despite their distinctive diagnoses; all show prominent foreheads, immature facies with foreshortening, the appearance of obesity, particularly truncal, despite reduced weight for height, and small phallus.

for as yet unexplained reasons, not in severe GH–IGF-I deficiency resulting from functional mutations of the GHRH-R (15). Although puberty may be delayed 3–7 years in some 50% of individuals with isolated GHD or GHRD, there is normal adult sexual function with documented reproduction by males and females (100).

There is no evidence that GHD per se results in intellectual impairment. Studies that do not account for the ascertainment bias related to the cause of the GHD, or the effects of other deficiencies in multiple pituitary hormone deficiency, can be misleading. Intellectual impairment was originally considered a feature of the Laron syndrome (221). Among 18 affected children and adolescents with Laron syndrome administered the Wechsler Intelligence Scale for Children, only 3 had IQs within the average range (90–110); of the remaining 15 subjects, three were in the low–average range (80–89), three in the borderline

range (70–79), and nine in the intellectually disabled range (<70). These studies were done without family controls, so that the possibility of other factors related to consanguinity that might affect intellectual development could not be addressed. In a follow-up study 25 years later, the investigators re-examined eight of the original 18 patients and four new patients with GHRD, excluding five patients with mental disabilities who were in the original study (222). This group had mean verbal and performance IQs of 86 and 92 on the Wechsler scale without evidence of visual motor integration difficulties noted in the earlier group, but there was a suggestion of deficient short-term memory and attention. The investigators hypothesized that early and prolonged IGF deficiency might impair normal development of the central nervous system, or that hypoglycemia common in younger patients may have had a deleterious effect.

Figure 11 Length SD scores of nine girls from Ecuador (open circles, solid lines) and two brothers from southern Russia (solid circles, dashed lines) with known birth lengths, evaluated over the first 2–3 years of life. Figure 13 Adult Ecuadorian siblings with multiple pituitary hormone deficiency demonstrate persistence of responsiveness to growth promotion effects of exogenous GH. Left: 33.4-year-old woman with SDS for height -5.9 and bone age 11 years, and 31.7-year-old man with height SDS -5.6 and bone age 13.5 years, with investigator at time of diagnosis. Right: The woman at 37.1 years of age with a bone age of 13.5 years; she has received thyroid and cortisol replacement for 3.7 years, rhGH for 2.6 years (until 14 months previously), and low dosages of estradiol for the past 2.6 years; her height SDS is now -2.5 , an increase of 3.4 SDs. The man at age 35.4 years with SDS for height SDS -3.0 , an increase of 2.6 SDs, and bone age 15.8 years; he has also received thyroid and cortisol replacement since diagnosis, rhGH until 6 months previously and incremental testosterone since 1 year after diagnosis.

The recent description of intellectual impairment with severe IGF-I deficiency due to partial deletion of the IGF-I gene added concern about potential effects of severe IGF-I deficiency in utero (46). Nonetheless, patients with severe IGF-I deficiency due to GH gene deletion or GHRH receptor deficiency have not been intellectually impaired (15, 108). Sporadic anecdotal reports of patients with GHRD suggested a normal range of intelligence. The collective data from the European IGF-I treatment study group, which includes a wider range of clinical abnormality than either the Ecuadorian or Israeli populations, note a mental retardation rate of 13.5% among 82 patients, but formal testing was not carried out (198). Here again, the high rate of consanguinity was proposed as an explanation; hypoglycemia could not be correlated with these findings.

In the Ecuadorian GHRD cohort, exceptional school performance was reported among 51 affected individuals of school age or older who had attended school, with 44 typically in the top three places in their classes and most thought to be as bright or brighter than the smartest of their unaffected siblings (223). The first controlled documentation of intellectual function in a population with GHRD was in the Ecuadorian patients, a study of school-age individuals compared to their close relatives and to

community controls. No significant differences in intellectual ability could be detected among these groups, using nonverbal tests with minimal cultural limitations. It was hypothesized that the exceptional school performance in this population might have been related to the lack of social opportunities due to extreme short stature, permitting greater devotion to studies and superior achievement in school for IQ level (205).

The clinical findings of intellectual impairment with IGF-I gene deletion (46) and intellectual normality with GHRD is consistent with gene disruption studies in mice. The IGF-I-deleted mouse is neurologically impaired, while the GHRD mouse is behaviorally normal (224). Thus, while GH-independent IGF-I synthesis appears necessary for normal brain development in utero, GH-dependent IGF-I production is not necessary for normal brain development and function.

B. Laboratory Evaluation

The methods for GH testing include provocative stimulation with arginine, insulin, clonidine, L-DOPA, and glucagon, frequently with propranolol priming, and physiological testing with exercise or serial sampling. Priming with sex steroids is often done, especially in late prepub-

Source: Adapted from the Meet-the-Professor session handouts for the Endocrine Society 81st Annual Meeting, June 12–15, 1999, Clinical Utility of IGF and IGFBP Measurements by Ron G. Rosenfeld, M.D.

ertal children. GH secretion is pulsatile throughout the day, with the usual concentration being low, typically below the limits of sensitivity of most assays. Thus, random GH samples are not helpful unless they are elevated, which might occur as a result of the stress of venipuncture. These various stimuli provoke GHRH release, suppress somatostatin, or work in combination. Serial sampling studies have not been helpful in diagnosis (225). Exercise must be standardized in terms of VO_2 max, which is difficult to accomplish.

The problems with GH testing are:

Response only correlates with successful GH treatment when there is unequivocal deficiency (226).

Deficient GH response to stimulation is seen without endocrine disease, for example, in malnutrition, and during the slow growth phase of preadolescence.

There is great variability in the assay from laboratory to laboratory. The monoclonal immunoradiometric assay results in values that are approximately two-thirds those of the polyclonal assay (227).

There is great intraindividual variability in response from day to day, including nocturnal profiles (228).

Responses vary with age and body mass (229).

The definition of a normal response is arbitrary.

In view of these difficulties with GH testing, the measurement of GH-dependent IGF-I and IGFBP-3 for the diagnosis of GHD has been proposed as a functional bioassay. These substances have low or no circadian variation. They are present in sufficient concentration to minimize difficulties with assay sensitivity. They vary with nutritional status and in disease states, however, and there is wide age variation (Table 4). They may also be normal in children with GHD resulting from brain tumors.

Two studies have looked at the usefulness of IGF-I and IGFBP-3 measurements. Based on results of peak stimulated GH and mean nocturnal GH concentrations, Nunez et al. (230) organized 104 short-statured patients into three groups: GHD ($<7 \mu\text{g/L}$), borderline ($7\text{--}10 \mu\text{g/L}$, or nocturnal GH below -2 SD of mean for age and pubertal stage), and idiopathic short stature (ISS, $>10 \mu\text{g/L}$). Confirmed was the earlier finding that nocturnal GH monitoring had little diagnostic value (225). IGF-I and IGFBP-3 concentrations, expressed as SD scores, correlated with peak stimulated GH but with wide scatter and primarily as a result of the strong correlations in the GHD group. Although means differed, there was not a significant difference between IGFBP-3 concentrations among patients in the three diagnostic groups, and only the GHD group differed in IGF-I mean concentration from the other two. The practical application of these findings was to use IGF-I for initial testing, with a criterion of -1.0 SD to identify a subgroup that would include 88% of those

with GH deficiency, 71% of borderline GHD, and 46% of ISS. With IGF-I and IGFBP-3 above -1.0 SD, 68% of ISS would be identified as not requiring GH testing. Evaluation of growth velocity over the next 3–6 months will identify those children requiring further testing.

In a study that classified 203 children into one of two groups, GHD and normal on the basis of response to provocative testing, IGF-I and IGFBP-3 concentrations were found to correlate with peak GH response. In children <10 years of age with GHD, however, IGF-I concentrations were below the cutoff of -2 SD in only half, for a sensitivity of 53.3%. IGFBP-3 gave a comparable sensitivity of 60% and the combination was even less sensitive (46.6%). Specificity, however, was nearly 100% for both IGF-I and IGFBP-3. In 10–20-year-olds specificity and predictive value of these measures were generally lower (231).

C. GHD

GHD may be considered with the following findings or circumstances:

- Other systemic causes of growth failure ruled out
- Subnormal growth rate
- Progressive decline in height percentile
- Delayed bone age
- Low IGF-I, IGFBP-3
- Poor GH response to stimulation
- Predisposing condition (e.g., brain irradiation, optic atrophy)
- Other evidence of pituitary dysfunction (e.g., neonatal hypoglycemia, microphallus, midfacial hypoplasia, central adiposity, single central incisor)

Consensus guidelines for the diagnosis and treatment of GHD in childhood and adolescence were developed by the GH Research Society in October 1999 (232). The process of evaluation of the GH-IGF axis was summarized as follows:

In a child with slow growth, whose history and auxology suggest GHD, testing for GH/IGF-I deficiency requires IGF-I/IGFBP-3 levels and GH provocation tests after hypothyroidism has been excluded. In suspected isolated GHD, two GH provocation tests (sequential or on separate days) are required. In those with defined CNS pathology, history of irradiation, MPHD or a genetic defect, one GH test will suffice. In addition, an evaluation of other pituitary function is required. In patients who have had cranial irradiation or malformations of the hypothalamic–pituitary unit, GHD may evolve over years and its diagnosis may require repeat testing of the GH–IGF axis.

It is recognized, however, that some patients with auxology suggestive of GHD may have IGF-I and

or IGFBP-3 levels below the normal range on repeated tests, but GH responses in provocation tests above the cut-off level. These children are not classically GH deficient but may have an abnormality of the GH-IGF axis and, after the exclusion of systemic disorders affecting the synthesis or action of IGF-I, could be considered for GH treatment.

An MRI (or CT scan) of the brain with particular attention to the hypothalamic-pituitary region should be carried out in any child diagnosed as having GHD.

Conclusion

The diagnosis of severe GHD is usually straightforward, as there are well-defined clinical, auxological, biochemical, and radiological abnormalities. However, the diagnosis of moderate GHD can be associated with normal values within the IGF axis and a normal MRI. It is very important that the response to GH treatment be carefully reviewed, particularly in those patients with moderate GHD.

D. GHRD

GHRD is readily diagnosed in its typical and complete form because of severe growth failure; the somatic phenotype of severe GHD; elevated serum GH levels; and marked reduction in IGF-I, IGF-II, and IGFBP-3 concentrations, with increased concentrations of IGFBP-1 and IGFBP-2. Most such individuals will also have absent to very low concentrations of GHBP, although the less common GHBP-positive forms make absence of GHBP an important but not essential criterion. As noted in Table 2, some of the biochemical features of GHRD may be shared by conditions associated with acquired GH insensitivity, such as malnutrition and liver disease. In a large multinational study designed to identify patients for replacement therapy with recombinant human IGF-I (rhIGF-I), a scoring system was developed that assigned one point for each of the following:

- Height >3 SD below mean height for age
- Basal GH >2.5 $\mu\text{g/L}$
- Basal IGF-I <50 $\mu\text{g/L}$
- Basal IGFBP-3 <-2 SD
- IGF-I rise with GH (0.05 mg/kg/day \times 4 days) <15 $\mu\text{g/L}$
- IGFBP-3 rise with GH stimulation <0.4 mg/L
- GH binding <10% (based on binding of ^{125}I -hGH)

A score of 5 out of the possible 7 was considered diagnostic for GHRD. This standard resulted in identification of 82 patients from 22 countries who reflect a wide variability for each criterion. Particularly noteworthy was that height SDS range was up to -2.2 (233). These criteria recognize the age and gender (after age 7 years) variation of IGFBP 3 by using a standard of ≤ 2 SD but,

oddly, designate a fixed standard for IGF-I that falls within the range of normal for children under age 7 (Table 4).

As noted above, the presence of a homozygous mutation or a compound heterozygous mutation affecting the GHR usually provides definitive diagnosis. Thirty-one of the 82 patients reported by Woods et al. (198) underwent a genetic study of the GHR, of whom 27 had abnormalities affecting both alleles of the GHR gene, in association with clinically and biochemically unequivocal GHRD. Identification of heterozygous mutations, however, is not necessarily helpful because, as noted earlier, polymorphisms have been described that appear to have no phenotypic consequences.

X. TREATMENT

A. GHD

1. History

The history of GH therapy for the treatment of GHD now spans more than 40 years. In 1958, Raben reported the first use of human pituitary-derived GH for replacement therapy in a child with hypopituitarism (234). Until the advent of recombinant GH products for general use in 1985, GH therapy was in very limited supply and subject to many interruptions, because of the limited supply of human pituitary gland and the absence of effects of GH extracted from the pituitary glands of other mammalian species. As a result, only a very select group of patients could be treated. These children had unmistakable GHD, having failed to respond to at least two GH stimulation tests using extremely stringent criteria. Treatment with as little as 2.5 units once weekly was effective in improving growth velocity (235, 236); however, overall, children were suboptimally treated because of relatively low dosage and intermittent therapy due to limited supplies. At best, they achieved an adult height -2 to -2.5 standard deviations below the normal means (237, 238).

Use of pituitary-derived GH came to a rapid halt in 1985 with the recognition of Creutzfeldt-Jakob disease (CJD) in recipients of pituitary-derived GH (239, 240). CJD is a rare prion disease with a long latency period, transmitted by the pituitary-derived product to at least 70 former patients. Affected individuals develop neurological degeneration and dementia. Diagnosis is difficult, requiring brain biopsy. There is no therapy (241, 242).

Fortunately for patients with GHD, rhGH (a 192 amino acid product) entered formal testing in 1981 and was approved for use by the Food and Drug Administration in 1985. With the advent of recombinant product, a continuous, unlimited supply of GH became available for the more optimal treatment of children with GHD. Such a large and reliable supply has allowed physicians to seek the best dosages and treatment intervals and to verify the safety of therapy.

2. Guidelines of GH Therapy

In patients with GHD, GH therapy provides the best growth velocity response in the first 12 months of therapy (three to five times pretreatment velocity), and improved velocity (above pretreatment levels) is maintained throughout the duration of therapy. Continuous therapy in a dosage range of 0.15–0.30 mg/kg/week, divided into six or seven daily doses per week, optimizes response, and the long-term result is further improved by early initiation of therapy (before the age of 6 years) (243–248). Some investigators recommend that therapy be given at bedtime, because GH secretion in normal children is maximal during sleep (232). Standard of care dictates that children being treated currently are evaluated every 3–6 months by endocrinologists familiar with monitoring for efficacy and safety. The ultimate objective of therapy, of course, is to normalize adult height, but considerable debate remains surrounding the definition of “normal.”

3. Adult GH Therapy

Although his or her epiphyses are fused, the adult with GHD nevertheless may benefit from continuation of GH replacement therapy, at a much smaller dose than that used to stimulate growth. Long-term monitoring of adults with GHD has revealed a striking physical profile in the absence of continued therapy, an increased risk for obesity, for lipid disorders, and for significant cardiovascular morbidity and mortality (249, 250). Recognition of the role of GH in lipolysis, muscle strength, and generalized well-being in adults has led to acceptance of the use of rhGH in management of adults with hypopituitarism (251). The observation that the recently appreciated cardiovascular risk factor of elevated serum homocysteine is improved in men with GHD treated with GH suggests a mechanism for the increased risk with GHD (252, 253). Current guidelines include cessation of growth-promoting GH therapy in the patient who has reached adult height. Because spontaneous resolution of GH deficiency has been documented in 50–80% of patients, particularly those with isolated GHD, any adult being considered for adult GH replacement therapy should undergo provocative GH stimulus testing within 6 months of cessation of GH therapy (251). An adult patient diagnosed with any pituitary deficiency should likewise undergo GH stimulation testing, because of the recognized benefits of identification and treatment of adult-onset GHD.

4. Safety Issues

Long-term, worldwide use of rhGH has allowed endocrinologists to monitor and document the relative safety and rarity of side effects associated with the recombinant product. Unlike pituitary-derived GH, recombinant GH does not carry a risk of human infectious contamination. Large-scale collaborative efforts, such as the National Cooperative Growth Study (NCGS) sponsored by Genentech and the KIGS (Kabi International Growth Study) spon-

sored by Pharmacia and Upjohn are permitting endocrinologists to share and analyze data regarding safety and efficacy of rhGH, in therapy of hypopituitarism and other growth-deficient states.

In 1998, Root et al. (244) summarized the North American NCGS experience in the use of recombinant human GH in more than 20,000 children, of whom 44% had idiopathic GH deficiency and 13.8% had organic GH deficiency. This evaluation, like the others that preceded and followed it, confirmed the general safety of GH in patients who do not have other underlying risk factors (particularly malignancy or genetic syndromes in which malignancy is a frequent feature).

Side effects that have been reported in patients receiving recombinant human GH are listed in Table 5. Salt retention with peripheral edema is sometimes noted with initiation of GH therapy. Pseudotumor cerebri has been noted to occur in some patients in the first 5 years of therapy (254). It is more common in patients with renal insufficiency or Chiari malformation. Typically, symptoms resolve with temporary cessation of therapy and generally do not recur when therapy is reintroduced a week or more later. Some investigators advocate resumption of GH therapy at lower doses with gradual increases to the pre-symptomatic level.

Prepubertal gynecomastia has been reported in some children treated with GH (255). Twenty-five percent of patients with GHD may have falling T4 levels after starting GH replacement therapy, necessitating regular assessment of serum thyroxine levels during GH therapy (256). GH antibodies develop in some patients, but diminution of growth response beyond that normally expected with continued therapy does not occur, except in the rare patient with type IA GHD. Scoliosis is sometimes seen, particularly during the period of peak growth velocity, and can compromise final height in some patients. Slipped capital femoral epiphysis (SCFE) may occur with therapy, possibly reflecting a growth effect rather than an adverse effect of GH (257); children with long-standing IGF-I deficiency may be at greater risk of this complication.

Table 5 Reported Side Effects of Growth Hormone Treatment

Growth of nevi
Peripheral edema
Pseudotumor cerebri
Gynecomastia
Pancreatitis
Slipped capital femoral epiphysis
Scoliosis
GH antibody formation
Hypothyroidism
Hyperinsulinism
Glucose intolerance/type 2 diabetes

Among GHRD patients from Ecuador, 25% had radiological evidence of Legg-Perthes disease (100). Therefore, careful monitoring for knee pain, hip pain, or limp should be a part of each clinic visit, and patients' families should be instructed to report any joint symptoms or gait changes. Pancreatitis is a rare side effect of GH therapy, but should be suspected in the patient with recurrent abdominal pain and emesis (258).

Although hyperinsulinemia may occur in response to GH therapy, glucose intolerance or diabetes has been considered rare. A retrospective analysis of the KIGS database found 85 of 23,333 children reported as having abnormal glucose metabolism, 43 of which were confirmed using American Diabetes Association (ADA) criteria. Eleven of the 43 had type 1 diabetes, consistent with expected frequency for the population, whereas 18 had type 2 diabetes and 14 impaired glucose tolerance, giving an incidence of type 2 diabetes of 34.4:100,000 years of GH treatment. The type 2 diabetes was not associated with obesity and did not clear up with discontinuation of GH (259). The authors' rejection of half of the patients diagnosed by their physicians as having glucose intolerance or diabetes reflects the more stringent criteria of the ADA than those of the WHO that these European investigators were more likely to be using. Even without this consideration, this is an approximately 20-fold greater incidence than expected in a largely white population (260). Similar observations have not been reported from the NCGS database.

The mitogenic potential of GH has led to careful monitoring and considerable concern about whether GH therapy might increase a patient's risk of malignancy or of tumor recurrence if a patient has had a primary malignancy. Studies to date have not revealed an increase in cancer risk for patients receiving GH replacement therapy. Although an increase in size of nevi can be seen, there has been no increase in melanoma formation. Careful analysis of a cluster of cases of leukemia in Japanese patients receiving GH therapy and similar extensive evaluation of nine cases in the United States and Canada revealed that the number of cases was not different from that expected for the general population (261–263). In the US/Canadian cohort, six of the patients had risk factors for leukemia (262). Specific examination of risk for patients with treated malignancies has not demonstrated that GH increases tumor recurrence risk (264). Patients with malignancy should not receive GH therapy during the acute phase of the malignancy and should be disease-free for at least 1 year after successful surgery, radiotherapy, or chemotherapy before starting GH therapy (265). Patients who have had malignancies or who have syndromes in which malignancy is a known component should have close monitoring by an endocrinologist, oncologist, neurosurgeon, or geneticist at frequent intervals.

The development of a purified, relatively safe rhGH product has allowed many patients with hypopituitarism to attain normal height and health. The availability of

rhGH has also permitted many non-GH-deficient short children, including those with a variety of genetic syndromes, to receive GH therapy in hopes of improving their final height. For those children, therapy has had varying degrees of success.

B. GHI/GHRD

Soon after the cloning of the human IGF-I cDNA, human IGF-I was synthesized by recombinant DNA techniques (rhIGF-I) (266, 267). Subcutaneous preparations of rhIGF-I became available in 1990. Results have been reported for 67 patients with GHI treated with rhIGF-I for 12 months or longer. Five of these patients had GH gene deletion with acquired GHI due to GH inhibiting antibodies (53). The rest had primary GHI, including Pakistani and Arab patients thought to have postreceptor defects.

1. Dose–Response

In the European multicenter study (268), responses to twice-daily doses varied, but average dosage was similar to that used in the North Carolina (53, 269, 270) and Ecuadorian (52, 271) study populations. As predicted from short-term studies, IGFBP-3 levels did not increase during long-term treatment with rhIGF-I. In the only direct comparison of dosages, there was no difference in growth response between 80 $\mu\text{g}/\text{kg}$ body weight and 120 $\mu\text{g}/\text{kg}$ twice daily, apparently defining a plateau effect (52). Improvement in mean height SDS over 2 years was 1.2 in the European study, 1.5 for the higher dosage and 1.3 for the lower dosage in Ecuador, and 1.3 in the North Carolina study. The European multicenter study and Ecuadorian study patients achieved two-thirds of their improvement in the initial year (Table 6). In the Israeli patients treated with single daily injections of rhIGF-I (120 $\mu\text{g}/\text{kg}$), there was an improvement of only 0.4 SDS during the first year of treatment, with no further improvement for the 6 patients completing 2 years of therapy (272). This supports the rationale for twice-daily administration, which was based on kinetic studies in normal controls.

Comparison of growth response of 22 rhIGF-I treated GHRD patients and 11 GH-treated GHD patients in the same setting demonstrated mean growth velocity increment in those with GHRD to be 63% of that achieved with GH treatment of GHD in the first year and less than 50% in the second and third years (52). The North Carolina group has reported IGF-I treatment responses after 6.5–7.5 years in five children with GHRD and three with GHI from antibody formation (53). The inadequate growth response compared to GH treatment of GHD persisted over this longer term treatment period, with a mean improvement in height SDS of only 1.4 (from -5.6 to -4.2), thus only sustaining the improvement of the first 2 years of treatment, as noted in Table 6. The most recent report from the European study described 17 patients treated for 48 months or longer. Overall increase in height SDS was 1.67 ± 1.16 , suggesting modest continued im-

provement over time in this group, but still markedly less than expected with GH replacement therapy (273). Studies in Ecuador noted correlation of growth acceleration with trough levels of serum IGF-I, obtained before the 12 hourly injection (52). Also noted was an increase in body weight for height; in the European study, the gain in BMI correlated with improvement in SDS for height. In the

North Carolina patients, fat mass increased with treatment and was thought to reflect high-dosage IGF-I insulin-like effects during peak times following IGF-I injection (53).

The lesser rate of response to IGF-I in GHI/GHRD than to GH in GHD could be attributable to failure to increase IGFBP-3 and ALS levels, a direct GH effect. However, three children who had defective IGF-I synthe-

Figure 14 Face and hair changes in 17.7 year old patient (bone age, 13 years) with GHRD during 6 months treatment with IGF-I, 120 $\mu\text{g}/\text{k}$ twice daily and depot GnRH agonist begun at age 16.5 years. (Reprinted from Rosenbloom AL. IGF-I treatment of growth hormone insensitivity. In: Rosenfeld RG, Roberts CT (eds.). *The IGF System: Molecular Biology, Physiology, and Clinical Applications*. Copyright 1999, with permission from Humana Press, Totowa, NJ; pp. 739–769.)

sis attributed to a postreceptor defect did not grow better while receiving IGF-I than did subjects with GHRD, despite their normal IGFBP-3 levels (199, 272). Furthermore, acromegaloïd facial changes in some patients (Fig. 14) indicate that the amount of IGF-I reaching tissues is supraphysiological (53, 271, 273). The more likely explanation for the relatively modest growth response is the absence of the direct GH effects at the growth plate. These effects include epiphyseal prechondrocyte differentiation, increased responsiveness to IGF-I, and enhancement of local production of IGF-I that stimulates clonal expansion of the differentiating chondrocytes (50, 51). Of great interest would be studies of the administration of recombinant IGFBP-3 with rhIGF-I. The pursuit of further treatment studies with rhIGF-I, however, is limited by the decision of manufacturers to no longer produce IGF-I.

2. Adverse Events

Hypoglycemia is frequent in children with GHRD, and was a concern with rhIGF-I treatment because of the very low IGFBP-3 levels resulting in greater amounts of free IGF-I. Severe hypoglycemic episodes have been reported in the European treatment study (268). During a 6-month placebo controlled trial of rhIGF-I treatment in children with GHRD, however, there was no difference in the frequency of hypoglycemia between placebo and treatment groups (274). Headache is a frequent complaint among treated patients, but also did not vary in frequency between placebo-treated and rhIGF-I-treated patients (268). Pain at the injection site is common and injection into lumps may result in cessation of response. Tachycardia, reflecting the inotropic effect of IGF-I (276), is uniformly present early in treatment, but clears after several months (277). Less frequent side effects include parotid swelling, facial nerve palsy, lymphoid hyperplasia that may require tonsillectomy or adenoïdectomy, papilledema, and pseudotumor cerebri. Coarsening of the facial features with mandibular hyperplasia and excessive weight gain are also seen in some patients (278, 279). Hyperandrogenism, with oligomenorrhea or amenorrhea, acne, and elevated serum androgens, has been described in prepubertal and young adult patients given single daily injections of rhIGF-I (280).

Growth Hormone Treatment

David B. Allen

University of Wisconsin Medical School, Madison, Wisconsin, U.S.A.

I. INTRODUCTION

Human growth hormone (GH) was first used more than 30 years ago to stimulate growth in a child with hypopituitarism (1). Subsequently, a limited supply of pituitary glands from which GH could be extracted and purified required that GH therapy be restricted to children with the most severe and unequivocal GH deficiency. Strict, arbitrary laboratory criteria were established to identify patients likely to derive the greatest benefit from scarce GH. Delays in diagnosis and treatment, interruptions in therapy, and dosage restrictions were common during this time. Consequently, while GH accelerated growth of these individuals, adult statures were usually less than average (2–4).

In 1985, the first case of Creutzfeld-Jakob disease (CJD) in patients who had received GH was recognized; investigation disclosed that pituitary glands from which the GH was derived were contaminated with subviral particles. Distribution of pituitary-derived GH was stopped. Subsequently, in the United States, CJD was diagnosed in seven recipients of GH distributed by the National Hormone and Pituitary Program (5, 6). It was fortunate that 192 amino-acid biosynthetic GH, first tested in the United States in 1981, was approved by the Food and Drug Administration (FDA) in 1985 (7) and a second 191 amino-acid biosynthetic GH was approved in 1987. The production of GH by biological systems (*Escherichia coli* and, more recently, mammalian cells [8]) transplanted with the GH gene yields a virtually unlimited supply of GH.

Biosynthetic GH therapy eliminated the risk of CJD and offered children with severe GH deficiency an opportunity for optimal treatment. Children with milder forms of inadequate GH secretion, previously excluded from receiving GH, could be treated. Increased availability of recombinant DNA-derived GH has also allowed investigation of its growth-promoting effects in poorly growing children who do not fit traditional definitions of

growth hormone deficiency (GHD), many of whom were previously believed to be unresponsive to GH treatment. In addition, metabolic effects of GH apart from linear growth promotion are now being studied extensively, leading to new indications for GH therapy.

Abundance of GH has added complexity to decisions about treatment of stature disorders. Human growth hormone *augmentation* therapy has now been added to GH *replacement* therapy, thus expanding the traditional boundaries of endocrinology endeavors, in which missing hormones are replaced and excessive hormones production suppressed. Advantages conferred by increased height in social, economic, professional, and political realms of Western society are well documented. Concern about social and psychological harm of short stature, and hope for effective therapy, have resulted in increased referrals for growth-promoting therapy. However, data confirming that stature per se is a primary determinant of psychological health are limited, although some have reported a higher frequency of underachievement, behavior problems, and reduced social competency in short-statured children (9). Neuroendocrine dysfunction (e.g., classic growth hormone deficiency), rather than stature itself, may correlate most closely with psychological and scholastic impairment (10). Although the physiological benefits of GH supplementation to children with severe GH deficiency *appear* obvious, data confirming the efficacy of GH therapy in improving the quality of life of non-GH-deficient recipients are scarce (11).

For many children, GH treatment will be appropriate therapy after the cause, concerns of patients and parents, and likelihood of success have been assessed. For most short children, however, efforts to build self-esteem through parental support, judicious selection of activities, and counseling will be more effective than injected GH therapy. The decision to institute long-term GH therapy should include both careful physical and psychological evaluation, to determine whether the degree of disability

and likelihood of therapeutic benefit justify investment of the required emotional and monetary resources. Although experience has shown that side effects appear minimal, other possible effects remain unknown. Unexpected benefits may also be found.

The spectrum of disorders for which GH has been prescribed and the number of children receiving treatment (Table 1) continue to increase. In this chapter, we review aspects of GH treatment for severe, "classic" GH deficiency, including recent information on nongrowth metabolic effects of GH for adult GH-deficient individuals. Treatment of various short-stature conditions and catabolic disorders with GH is also considered, reflecting the recent proliferation of investigations of the metabolic and growth-promoting effects of GH in non-GH-deficient individuals. Possible risks and ethical issues related to GH therapy are also addressed.

II. GROWTH HORMONE PHYSIOLOGY

Human growth hormone is secreted by the anterior pituitary gland throughout life under the primary influence of stimulatory growth hormone-releasing hormone (GHRH) and inhibitory somatostatin (SRIH). Both of these regulatory peptides are synthesized in and released from the hypothalamus. The cyclical pulsatile secretion of GH is a response to a coincident decline in SRIH release and abrupt increase in GHRH secretion, modified by the input of neurotransmitters and the metabolic status upon the hypothalamus and somatotroph (12). Both GH and insulin-like growth factor-1 (IGF-1) exert positive feedback on SRIH secretion, and GH exerts negative feedback on

GHRH secretion. Growth hormone is released in response to sleep, exercise, and relative hypoglycemia. Sleep-associated pulses of GH release usually occur in the first 30–60 min of sleep, and can occur at any time of day when individuals reach stages 3 and 4 of slow-wave sleep. Vigorous exercise for 15–20 min provokes a significant GH surge in 90% of normal children. Since surges in GH are more prolonged in physically unfit than in fit individuals performing comparable work, exercise-induced GH release appears more related to physical stress than to exercise *per se*. Psychological stress, such as venipuncture or general alarm, also produces GH elevations. Rises in GH occur with the postprandial decline of blood glucose concentration, and GH secretory surges occur more often in the hours preceding meals than those following meals (13).

Human growth hormone is synthesized and stored in acidophils of the pituitary gland and accounts for as much as 8% of pituitary weight. About 80% of secreted GH has a 191-amino acid sequence and molecular weight of 22 kD; the other 20% is approximately 20 kD and is produced by alternate gene splicing, which deletes amino acids 32–46 from the RNA. Human growth hormone is found in pituitary gland and plasma as monomers, dimers, and oligomers. Many other variants of GH, including proteolytically cleaved, N-acetylated, and deamidated forms, may also be found either as physiological variants or products of the extraction process. Because GH is species-specific, animal GH other than that from primates is ineffective in humans. Circulating GH-binding protein (GHBP) complexes about 50% of GH and probably acts as a modulator of release and distribution to tissues (14).

Table 1 Growth Disorders, Illnesses, and Metabolic Conditions for which hGH Treatment has been Investigated.

Familial short stature	Catabolic states
Constitutional delayed growth	Postoperative wound healing
^a Intrauterine growth retardation:	Burns
Russell-Silver syndrome	Regenerative or reparative states
^a Turner syndrome	Fractures
Skeletal dysplasia	Peripheral nerve damage
Hypochondroplasia	Neural tube defects
Achondroplasia	Spina bifida
Spondyloepiphyseal dysplasia	Myelomeningocele
Multiple epiphyseal dysplasia	Chronic illness
Hypophosphatemic	Glucocorticoid-dependent disorders (renal transplantation, juvenile rheumatoid arthritis, asthma)
Miscellaneous syndromes	Chronic renal failure
Noonan syndrome	Cystic fibrosis
^a Prader-Willi syndrome	AIDS wasting
Down syndrome	Inflammatory bowel disease
^a Growth hormone deficiency in adults	Aging

^aFDA-approved indication for GH therapy.

GHBP shows immunological identity with the extracellular domain of the GH receptor, and concentrations of GHBP are low in patients with GH receptor deficiency (15). The regulation of GHBP remains uncertain; gonadal steroids such as estrogen increase GHBP activity, while GH secretory status appears to play a minor role (16).

Serum GH concentrations are high in full-term and premature infants during the first 24 h of life, averaging 50–60 ng/ml and resulting from both enhanced frequency and amplitude of pulses (17). In full-term, but not in premature infants, GH levels fall after 48 h. Thereafter, growth hormone concentrations reflect pulsatile secretion, which occurs more often and with higher peaks during infancy, diminishes during childhood, and is lowest in late prepubertal childhood and in adults. Spontaneous puberty in boys or androgen treatment of prepubertal boys results in significant increases in GH release (18). This sex-hormone-induced augmentation of growth hormone secretion is primarily an amplitude-modulated phenomenon, although more frequent GH peaks do occur (19). It is interesting, however, that testosterone's effect on pubertal growth may be largely independent of changes in circulating GH (20). Stimulation of the somatotrophic axis by testosterone is partly dependent upon its aromatization to estradiol; GH levels in adult women are higher than in men and rise in men when they are given estrogens (21).

The very short half-life (less than 20 min) of circulating GH requires that blood sampling be carried out at frequent intervals to identify peaks. Studies of children indicate that normal and short stature are both associated with a broad range of GH secretion patterns (22). Whereas it was previously thought that a bimodal distribution of GH secretion discretely separated normal from abnormal, it is now clear that (with the rare exception of *complete* GH deficiency secondary to GH gene deletion or abnormalities of expression) a continuum of "inadequate" GH secretion likely spans classic and partially GH-deficient children, children with delayed growth and puberty, and other poorly growing children who pass provocative tests but still secrete less GH than their peers. An asymptotic relationship between growth velocity and spontaneous GH secretion has been postulated for short children (23). This spectrum of GH insufficiency, in which there are varying degrees of abnormal GH secretion, creates enormous difficulty in interpreting tests of GH secretion.

III. GROWTH HORMONE EFFECTS

The objective of GH therapy traditionally has been to increase the growth rate and adult height of short-statured GH-deficient children. The effectiveness of this therapy has been assessed through achievement of normal growth velocity and height. Although linear growth promotion remains the focus of GH therapy, additional metabolic effects of GH are being actively investigated for their po-

tential clinical application. The major indirect actions of GH are anabolic and growth-promoting, mediated by insulinlike growth factors (principally IGF-1), and include cell proliferation and protein synthesis in both skeletal and nonskeletal tissues. The IGFs are a family of peptides with molecular weight similar to insulin that have insulinlike activity. Circulating IGFs are produced primarily by the liver in response to GH stimulation, and circulate bound to larger carrier proteins (IGFBPs) with molecular weight of 28–150 kDa. Since most organs synthesize IGFs, their action may occur within their cells of synthesis (autocrine), on cells in the immediate area (paracrine), and at distant sites (endocrine). A complex interplay of IGF production rates, clearance, and degree of binding to various IGFBPs modulates the levels and systemic activity of free IGFs (24).

The most apparent metabolic effect of GH is stimulation of linear growth in children prior to epiphyseal fusion. The relative roles of GH and IGF-1 in stimulating bone growth may be most accurately described by a so-called dual effect model of GH action, in which GH stimulates cartilage precursor cells first to differentiate and subsequently to produce, and become responsive to, autocrine and paracrine mitogenic effects of IGF-1 (25). The wide distribution of receptors for IGF-1, and the fact that blood levels of IGFs are higher than in any tissue, suggest that the endocrine function may also be important. However, administration of IGF-1 to hypophysectomized rats does not promote growth equivalent to that of GH (26). IGF-1 also participates in negative feedback regulation of GH secretion by stimulating hypothalamic somatostatin secretion (27) and by inhibiting the action of GHRH (28).

IGF-1 levels correlate with the clinical state of GH deficiency, sufficiency, or excess. Serum IGF-1 levels are low in utero and in infancy, increase with age in both boys and girls, reach maximum values during puberty (earlier and higher in girls than boys), and decline to adult values as adolescence is completed. Although often used as part of the assessment of hypopituitarism, IGF-1 levels do not exclusively reflect GH production and are age-dependent. Concentrations of IGF-1 correlate more closely with bone age and puberty (29) than with chronological age. Hypothyroidism, malnutrition, poorly controlled diabetes, and chronic disease diminish secretion of IGF-1. Thus, a low serum IGF-1 level is consistent with, but not diagnostic of, GH deficiency. The normally low levels of IGF-1 in infants and young children preclude its diagnostic utility for classic GH deficiency in this age group. Given these limitations, the use of IGF-1 alone as a screening test for GH status is of little diagnostic value. However, the Growth Hormone Research Society recently recommended measurement of IGF-1 and IGFBP3 in addition to provocative GH testing as a means of identifying children with abnormalities in the GH/IGF axis not detected by standard tests.

Other metabolic effects of GH can be described as anabolic, lipolytic, and diabetogenic (Fig. 1). Growth-hormone-induced growth acceleration is facilitated by concomitant enhancement of protein synthesis in bone, cartilage, skeletal muscles, the erythropoietic system, and other major organs. Administration of GH produces positive nitrogen balance, increased amino acid transport into cells, increased intracellular RNA, and decreased urea production and blood urea nitrogen (BUN) levels. The metabolic efficacy of total parenteral nutrition is also enhanced by GH (30). A high-normal or mildly elevated BUN level and low serum phosphorus and alkaline phosphatase level are usually observed in GH deficiency and reverse with GH treatment. Effects on mineral metabolism include increased intestinal calcium absorption and urinary calcium excretion and reduced urinary phosphate excretion (31). Bone density and levels of osteocalcin, procollagen type 1, and 1,25-dihydroxyvitamin D are reduced in GH-deficient children and increase with long-term GH therapy (32).

Growth hormone receptors and expression of GH receptor mRNA have been demonstrated in both preadipocyte cultures and mature adipocytes. Some actions of GH in adipose tissue are mediated directly through interaction with the GH receptor, while others are mediated indirectly through IGF1. These actions include inhibition of differentiation of immature adipocytes to mature adipocytes; enhancement of lipolysis and site-specific free fatty acid release from adipose tissue; and inhibition of lipoprotein lipase and stimulation of hormone sensitive lipase (33). Consequently, GH-deficient children tend to demonstrate increased, predominantly abdominal, subcutaneous fat that lessens and becomes more peripheral during therapy with exogenous GH. Non-GH-deficient children also display reduction in overall body fat during GH therapy. The mechanism by which GH reduces adipocyte size *in vivo* remains unclear, but *in vitro* studies suggests that GH increases the basal rate of lipolysis and depresses reesterification of free fatty acids (34).

The effects of GH on carbohydrate metabolism are complex. Intravenous administration of GH causes an acute fall in blood glucose, most likely reflecting enhanced transport of glucose into adipose and skeletal muscle cells. GH is pivotal for the maintenance of normal glucose homeostasis in infants, but this critical role is markedly diminished in older children and adults. In a child with GH deficiency, insulin secretion is diminished, related in part to pancreatic islet cell hypoplasia. Glucose tolerance tests may reveal impaired ability to dispose of a carbohydrate load. However, fasting hypoglycemia can also occur in such patients because of heightened sensitivity to insulin. Administration of GH reduces sensitivity to insulin, thereby correcting hypoglycemia, and increases insulin secretion. Chronic administration of GH results in compensatory hyperinsulinemia and is associated with the development of insulin resistance. In summary, the com-

bined effects of GH on both the release of and response to insulin create states of altered carbohydrate intolerance in situations of either GH deficiency or excess.

IV. GROWTH HORMONE DEFICIENCY

The classic presentation of severe growth hormone deficiency is characterized by marked growth retardation, diminished growth velocity, delayed skeletal maturation, absence of other explanations for growth retardation, and subnormal secretion of GH, both physiological and in response to provocative stimuli. Genetic (e.g., altered GH or GHRH gene), anatomical or congenital (e.g., midline cranial defects, septo-optic dysplasia, vascular malformations), and acquired abnormalities of the hypothalamus and pituitary (e.g., craniopharyngioma, glioma, histiocytosis) are identifiable in many affected children. Evaluation of pituitary gland anatomy using magnetic resonance imaging has revealed a spectrum of more subtle morphological abnormalities associated with the diagnosis of GH deficiency (35). Irradiation or chemotherapy for malignancies and traumatic brain injury also cause organic hypopituitarism, and accounts for an increasing incidence of GH deficiency as survival of these patients improves. In spite of this growing list of causes, most children with GH deficiency still are designated as *idiopathic*, often due to apparently defective hypothalamic regulation of GH release, rather than inability to synthesize GH. It is likely that further improvement in imaging techniques will reveal additional organic lesions contributing to this dysfunction.

Idiopathic GH deficiency usually occurs sporadically but may be familial (36). Its frequency has been reported to be from 1:4000 children to 1:60,000 (37, 38). Although the latter figure is similar to the treated population in the United States before 1985, the true incidence of classic GH deficiency is probably in the range of 1:10,000. These estimates are complicated by the fact that, with the exceptions of GH gene deletion and severe pituitary or hypothalamic dysfunction, GH deficiency is partial, rather than complete. The incidence of GH deficiency is likely to continue to rise due to improved prolonged survival of children who have received radiation therapy for malignancies.

Arbitrary laboratory criteria currently provide a technical distinction between GH deficiency and GH sufficiency, even though it is generally accepted that there is no meaningful physiological distinction between children whose provoked GH levels fall slightly above or below laboratory threshold values. Evidence is accumulating to support the notion that GH deficiency is not a distinct entity, but rather a spectrum of disorders of GH pulsatility. A continuum of GH secretion may span essential absence of GH, partial GH deficiency, and a spectrum of so-called normal GH secretion. Some investigators have found significant correlations between spontaneous GH secretion

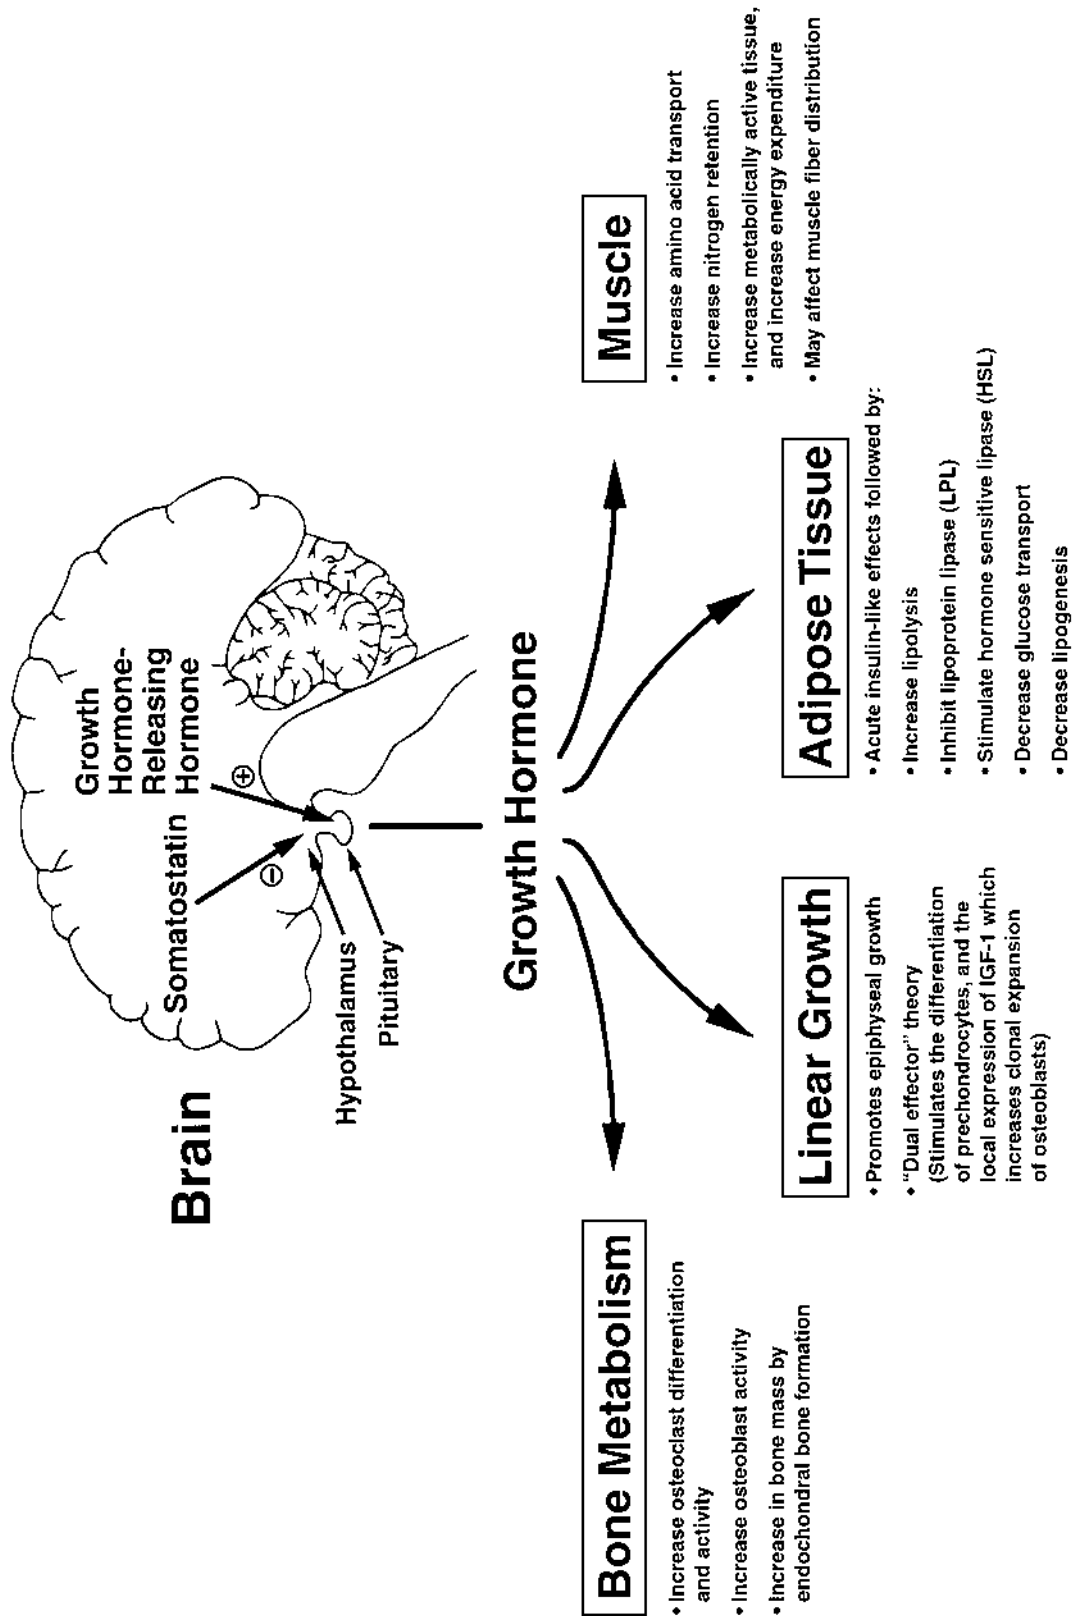

Figure 1 Multiple sites of growth hormone action.

and statural growth rates (39) while others have not (40). The blurring of what was once thought to be a clear distinction between GH deficiency and sufficiency has combined with the luxury of available, expensive GH to create new opportunities, uncertainties, and controversies in GH therapy.

Profoundly GH-deficient infants and young children may present initially with hypoglycemia. This is more commonly associated with adrenocorticotropin (ACTH) deficiency and hypocortisolism, but hypoglycemia may persist in spite of glucocorticoid replacement. Prompt administration of GH is necessary to prevent the neurological sequelae of persistent or recurrent hypoglycemia. Microphallus occurring in the newborn with GH deficiency most often, but not invariably, is associated with gonadotropin deficiency. Since GH is largely responsible for phallic growth after the first few months of life, (untreated) isolated GH deficient males may display poor phallic growth during early childhood. This problem can be effectively treated with GH and very small doses of androgen. Growth velocity may be mildly or severely impaired, depending on the degree of GH deficiency and/or presence of accompanying hormonal deficiencies. Bone age is usually delayed in patients with GH deficiency, but is often less delayed than height age (age for which the child's height is average). Bone age is less delayed in isolated GH deficiency than with multiple pituitary hormone deficiencies. So-called catch-up growth, a period of supranormal growth velocity often observed particularly during early GH treatment, is accompanied by skeletal maturation proportion to growth achieved, leading to the *appearance* of accelerated bone age advancement.

At least half the children with GH deficiency were described in 1968 as having an isolated hormonal defect (41). This proportion has steadily risen as more children with partial or neurosecretory GH deficiency have been recognized and diagnosed. A rise in GH secretion and increase in growth velocity observed following pulsatile GHRH administration in many of these patients indicates that deficient hypothalamic regulation of pituitary GH secretion is the cause of GH deficiency in many patients with isolated GH deficiency (42). However, GH deficiency is often accompanied by deficiencies of other anterior pituitary hormones: adrenocorticotrophic hormone (ACTH), thyroid stimulating hormone (TSH), luteinizing hormone (LH), follicle-stimulating hormone (FSH) and posterior pituitary antidiuretic hormone (ADH, synthesized in hypothalamic nuclei). Hypopituitarism, defined as the deficient production or release of one or more hormones from the pituitary, may be primary or secondary to hypothalamic dysfunction. When deficiencies other than GH occur, they are, in decreasing order of frequency, LH and FSH, TSH, and ACTH (43).

Deficiency in ADH, manifested as diabetes insipidus, usually occurs in acquired GH deficiency (e.g. craniopharyngioma, surgical trauma) or congenitally as part of

the septo-optic dysplasia (SOD) syndrome. In contrast to anterior pituitary hormones, ADH is synthesized in the hypothalamus and transported to and stored for release in the posterior pituitary, which is embryologically distinct from the anterior pituitary. Consequently, with the exception of SOD, deficiency of ADH is rarely seen with idiopathic hypopituitarism. On the other hand, extensive surgery for pituitary tumors will usually result in ADH deficiency (if it was not present before) and variable but usually progressive loss of other pituitary hormonal secretion (44). A combination of less extensive surgery and irradiation, or irradiation alone, has been recommended as a more moderate approach to treatment of such patients. However, the gradual development of impaired GH secretion is also observed in many children who undergo cranial irradiation for neoplasms of the central nervous system (45). With radiation of the hypothalamic-pituitary axis, GH is the first hormone to be affected and the degree of hormonal deficit is related to the radiation dosage (46). In one study, 5 years following 3.75–42.5 Gy radiation therapy, all patients were GH deficient; gonadotropin, ACTH, and TSH were deficient in 91%, 77%, and 42% of patients, respectively (47).

Timing of the onset of puberty normally is related most closely to a child's reaching a state of maturation (rather than chronological age) corresponding to a bone age of 10–11 for girls, and 11.5–12.5 for boys. Late recognition and treatment of GH deficiency often result in delayed bone age and pubertal development. In addition, late diagnosis of GH deficiency may not allow sufficient treatment time for height age to catch up to bone age prior to puberty; these children may experience rapid pubertal development without an adequate pubertal increment in height, resulting in reduced adult stature. LH-releasing hormone agonist therapy, which can slow or stop pubertal advancement, or aromatase inhibitor therapy, which may reduce estrogen-mediated epiphyseal plate closure, may offer effective means of "reclaiming" the time required for sufficient growth, but further controlled studies are needed to evaluate the efficacy of these treatments. A preferable option includes prompt recognition of GH deficiency and optimization of GH dosage and schedule, which facilitate both the achievement of normal prepubertal height and entrance into puberty at a more appropriate chronological age.

A. Treatment

For over 30 years, the diagnosis of GH deficiency was based on the analysis of serum GH levels following at least two provocative stimuli. The limited amount of available pituitary-extracted GH dictated that few short children could be treated. Criteria were established by national committees of the National Pituitary Agency (which later became the National Hormone and Pituitary Program [NHPP]) to ensure that the most severely affected GH-deficient children would receive GH treatment. Thus, only

very short, very slowly growing children who had very low GH levels on stimulation tests qualified for GH therapy, and these children were treated only until a height within -2 to -2.5 standard deviations (SD) of normal adult height was reached. This meticulous rationing of scarce GH to the most severely affected children maximized the overall benefit that could be derived from this therapy.

Improved pituitary collection and extraction strategies increased availability of GH during the 1970s and, as a result, criteria for treatment were relaxed. Whereas stimulated levels of GH less than 3–5 ng/dl were originally considered to be sufficiently subnormal to indicate GH deficiency, the threshold GH level required for this diagnosis gradually rose to 7 ng/dl, then 10 ng/dl, and, in some clinics, to 12 ng/dl. Currently, children with levels in the higher subnormal range and children with normal stimulated GH levels but low spontaneous GH secretion are now designated as having “partial” GH deficiency.

Interpretation of tests for GH is also complicated by laboratory variation. Whereas the NHPP originally provided uniform material, standards, and methodology for GH testing, later commercialization of GH assays methods created significant variation in laboratory values for GH in a single blood sample. Today, expanding definitions of so-called partial GH deficiency variations in GH assays, and unlimited GH availability have transformed the historically clearly defined and tightly regulated practice of diagnosing and treating GH deficiency into a rapidly evolving and controversial endeavor.

Growth failure caused by severe GH deficiency is a universally accepted therapeutic indication for GH treatment. Treatment of growth failure due to partial GH deficiency, defined by subnormal stimulated GH levels, has also become accepted practice. However, it is now widely recognized that children with partial or subtle defects in the secretion of GH are difficult to identify, and no individual assessment of GH secretion or GH-associated biochemical finding unerringly detects such subjects (48). A single provocative test for GH (a necessary but not sufficient criterion for these diagnoses) appears to lack both specificity and sensitivity in identifying GH insufficiency. In children of normal stature, stimulated GH levels may be <7 ng/ml in as many as 20% (49). Specificity may be increased by performance of a second provocative test. On the other hand, a normal GH response to provocative stimuli does not guarantee sufficient spontaneous GH to maintain normal growth.

Attempts to define milder forms of GH through frequent blood sampling and analysis of spontaneous GH secretion pattern have led to the development of elaborate mathematical techniques for their interpretation. Children with subnormal GH secretion following cranial irradiation, who may pass provocative GH testing, may be identified solely by this frequent sampling method. (Over time, classic GH deficiency occurs in many of these patients

[50].) However, determination of spontaneous GH secretion requires considerable time, expense, and technical help, and is complicated by technical difficulties, disturbed daily and nighttime routines of the patients, and lack of reproducibility (51). Current methods have been criticized for their inability to differentiate normal children from short, GH-responsive children, and even from classic GH-deficient children. In summary, measurement and analysis of spontaneous GH secretion are sometimes helpful in identifying GH-sufficient subjects, but adds little in most instances to provocative tests in the identification of the GH-deficient child. With either test, the notion of a discrete cutoff level of GH secretion that reliably differentiates GH deficiency from normal is historical, and has limited relevance to current practice of pediatric endocrinology. The diagnosis of mild forms of GH insufficiency depends primarily upon clinical perception; laboratory tests of GH secretion provide ancillary information that help to confirm or disprove that clinical diagnosis.

Whom to treat for isolated idiopathic GHD and for how long is further complicated by the fact that most children who are treated with GH do not have permanent or complete GHD, but have insufficient secretion of GH to support normal childhood growth. When children with isolated GHD are retested after GH replacement therapy has been interrupted, 30–70% will have a normal GH response. Children with a previous diagnosis of partial GHD (i.e., peak stimulated GH levels of 5–10 $\mu\text{g/L}$ or low 24-h integrated GH secretion) are particularly likely to have normal results on posttreatment testing (52).

Various studies of time of initiation, dosage, and frequencies of GH administration have advanced progress toward optimal treatment of GH deficiency during childhood. Subcutaneous daily GH administration is currently preferred, with the average GHD child in the United States receiving initial treatment with 0.3 mg/kg/week divided into six or seven doses. GH preparations are essentially equivalent, but vary in preparation and delivery. They include lyophilized GH that is mixed with a sterile diluent, pre-mixed GH solutions in a multiple dose vial, GH pen/needle delivery system, a nonneedle delivery system, and a depot preparation given every 2–4 weeks. Intranasal preparations are being developed (53). Since growth before puberty is a major determinant of final adult height, early initiation of GH treatment allows more complete normalization of height prior to puberty and an improved final height prognosis (54). There can be a temptation to defer injection therapy in young children in order to minimize discomfort and inconvenience, but the available evidence strongly supports early recognition, referral, diagnosis, and treatment of severely GH-deficient patients as an important step to optimizing their growth potential.

Increasing the dosage of GH improves growth rate; a dose–response equation derived from treatment of children of all ages with various degrees of GH deficiency reveals a logarithmic relationship between GH dosage and

growth rate for thrice weekly dosages ranging from 0.015 to 0.1 mg/kg (55). The variation around the mean of each of these growth rate points is great, attesting to the poorly understood contribution of factors other than GH levels to the normal linear growth process. Other studies of daily GH injections confirmed the relationship between growth rate and so-called conventional doses of GH (56). A recent study using 0.025, 0.05, and 0.1 mg/kg *daily* in prepubertal severely GHD children showed significantly greater growth velocities and gains in cumulative height SDS in the 0.05 and 0.1 mg/kg/day groups compared with the 0.025 mg/kg/day group after 2 years of treatment. There were no significant differences between the 0.05 and 0.1 mg/kg/day groups (57). The serum IGF1 response to GH is also dose-dependent, continuing to rise as GH is administered in doses above currently prescribed levels (58). Results of epidemiological studies that suggest an association between high serum IGF1 levels and the incidence of malignancy have prompted a recommendation that IGF1 and IGFBP3 levels be monitored on a regular basis. A younger age, greater delay in height age and bone age, and greater severity of GH deficiency based upon provocative testing each correlate with improved *initial response* to GH therapy. Using multiple regression analysis, variables that have positive effects on *adult height* of GH-treated patients include taller parents, more frequent GH injections, longer duration of GH treatment, taller height at start of GH treatment, and greater severity of GH deficiency.

Increased frequency of GH administration improves growth rate, suggesting the so-called pulsing message of GH to its target cells, in addition to adequacy of GH levels, enhances linear growth. When the same weekly dosage is given in daily injections, rather than three times per week, an improvement in first-year growth rate of about 1.5 cm/year is observed (59). On the other hand, subcutaneous administration of depot preparations of GH at every-other-week intervals, has also been shown to increase growth rates effectively nearly to the same degree (60). Nocturnal administration, which more closely mimics physiological GH secretion, may also add to efficacy (61), although this is not consistently observed. Regardless of the regimen chosen, the effect of GH wanes with time, and the first year of treatment usually produces the greatest growth increment. Following this early phase of rapid growth, short-term increased replacement doses of GH renews catch-up growth without adverse metabolic effects (62). Seasonal variation in growth rate during GH therapy, with peaks in the summer and nadirs in the winter (North American population), has also been described (63).

Children who have undergone removal of craniopharyngioma frequently experience growth acceleration in the absence of measurable GH. This phenomenon may be attributable to postoperative nutritional excess and hyperinsulinemia (64), although other mechanisms (e.g., GH

variants, IGFs) are also postulated (65). Polyphagia and significant weight gain are usually also observed. Although supplementation with GH is not required to sustain linear growth, body composition analysis reveals increased fat mass and decreased lean mass typical for the GHD state. Avoidance of excessive cortisol replacement therapy is extremely important in these individuals. This growth pattern may persist, allowing attainment of normal adult stature without GH therapy, but GH may nevertheless be indicated to improve body composition and other metabolic consequences of GHD.

The distinct augmentation of GH pulsations and increased production rates that occur during normal puberty raise the question of whether GH replacement dosages also should be increased during puberty. Insufficient dosage and frequency of GH administration has been shown to permit epiphyseal closure in GH-deficient adolescents prior to adequate catch-up growth, thereby reducing expected adult height (66). In one study, doubling the dosage of GH during puberty did not significantly change growth rate, but did tend to advance pubertal maturation (67). On the other hand, a larger and more recent randomized trial showed that an increase in dosage to 0.7 mg/kg/week (in contrast to conventional dosage recommendations of 0.18–0.35 mg/kg/week) improved growth rates, near-adult height, and height SDS in GHD adolescents without evident adverse effects (68). Since the cost of such treatment must be balanced with the possible added benefit achieved, the most effective frequency and dosage of GH therapy during puberty is yet to be determined.

Children treated with GH may experience transient or persistent declines in serum thyroxine (T4) levels; in approximately 25%, T4 levels become abnormally low and may impair response to GH. Thyroid function tests should be monitored periodically (especially early) during GH therapy to ensure detection of secondary T4 deficiency and prevent this treatable cause of a poor response to GH. Cortisol supplementation may also impair the growth response to GH; as little as 7.5–10 mg/day of hydrocortisone may be growth-suppressive in a school-aged child. Thus, when ACTH deficiency has been documented, the dosage of daily cortisol replacement therapy should be reduced to a level sufficient to prevent symptoms of fatigue and lack of energy. In prepubertal children, these replacement levels are quite low, and some children with idiopathic hypopituitarism, even with evidence for ACTH deficiency, will not need cortisone replacement in the absence of illness or stress.

Testosterone or other anabolic agents will enhance the growth velocity of a prepubertal GH-deficient child taking GH, but (except for boys with micropallus) should not be given if the bone age is less than 9 years, and then in very low dosages initially. Treatment for the purpose of virilization in a boy who is gonadotropin-deficient should be initiated after bone age approximates 11–12 years with low-dosage (e.g., 50 mg) testosterone enanthate intra-

muscularly per month to prevent accelerated epiphyseal maturation. Dosages can be gradually increased to adult replacement levels (e.g., 200–300 mg testosterone enanthate every 3–4 weeks) over the next several years. It has recently become clear that estrogens have a potent effect on bone age acceleration in patients with Turner syndrome, and may have an accelerating effect on the growth resulting from GH therapy. The androgen oxandrolone, which cannot be aromatized to estrogen, in low dosages has also been useful in accelerating growth rate in both boys and girls. Future management of short stature during puberty may include other measures (e.g., aromatase inhibitors) designed to reduce epiphyseal-maturing estrogen effects while preserving growth-accelerating effects of GH and androgens.

B. Effects of Treatment

With early diagnosis, careful attention to accompanying hormonal deficiencies, and progressive dosage adjustments, children with GH deficiency reach normal adult height (Fig. 2) (69). Bone age will advance with GH treatment, but usually not more than height age. Linear growth often accelerates faster than bone age following initiation of GH therapy, leading to increases in predicted final height. Even with successful long-term GH therapy, however, correction of disabling short stature does not consistently normalize the psychosocial outcome for adults with GH deficiency (70). Psychosocial counseling, which increases both therapeutic compliance during childhood and social outcome during adulthood (71), should be a consistent adjunct to parenteral GH administration.

The consequences of severe GH deficiency (GHD) in adult life and the beneficial effect of replacement therapy are increasingly well established. Accurate selection of appropriate candidates for adult GH treatment, and the transition of their care from pediatrics to adult medicine, require careful consideration of several issues. Since the

majority of children who are diagnosed as GHD and treated with GH do not have permanent GHD, anticipatory counseling regarding possible lifelong treatment should be focused on children with panhypopituitarism and those with severe isolated GHD associated with central nervous system abnormalities. Appropriate timing for termination of so-called growth-promoting GH therapy should be guided by efforts to balance the high cost of late-adolescent treatment with the attainment of reasonable statural goals. Confirmation of GHD following provocation with appropriate stimuli (i.e., not clonidine) is appropriate for all candidates for adult GH therapy. Testing of the GH axis can be performed within weeks of GH cessation, but confirmation of an emerging adult GHD state with body composition, blood lipid, and quality of life assessments may require 1 or more years of pretreatment observation. Although it remains unclear whether such a period of observation is needed or even advisable for late adolescents with unequivocal panhypopituitarism, it is likely that a transition from growth-promoting to adult replacement dosages of GH therapy without interruption will be recommended. Selection of patients for lifelong adult GH replacement therapy will present diagnostic, therapeutic, and ethical dilemmas similar to those arising from treatment of childhood GHD. The experience and expertise of pediatric endocrinologists in diagnosing and treating GHD should be offered and utilized in the identification and transitioning of appropriate patients to adult GH therapy (72).

V. IDIOPATHIC SHORT STATURE AND CONSTITUTIONAL GROWTH DELAY

For every short child who has impaired GH secretion, many more are short for other reasons. Parental concerns about the disadvantages of their child's short stature are legitimized by a "heightist" premise in modern America:

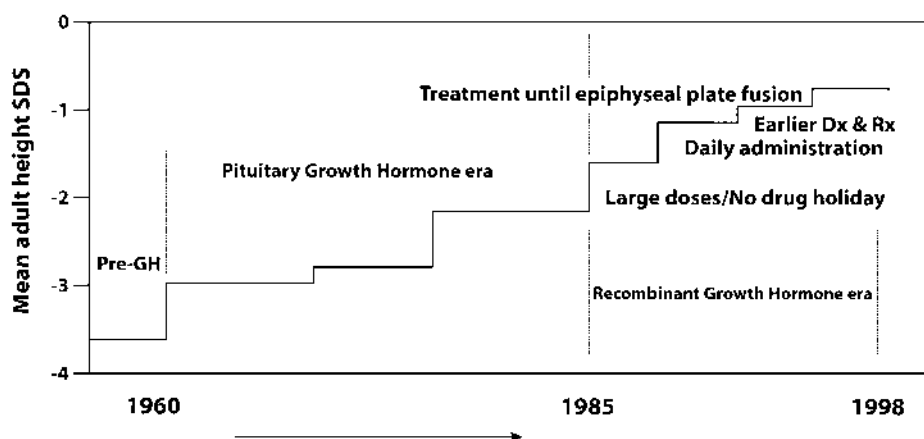

Figure 2 Progress in efficacy of childhood GH treatment. (Adapted from Ref. 69.)

to be tall is good and to be short is to be stigmatized (73). The preponderance of white males in the GH-treated population suggests that these social pressures give rise to ascertainment of short-statured patients biased by gender, race, and socioeconomic status (74). Stigmatization based upon height begins in childhood. Feelings of incompetence and low self-esteem may arise from the short child's struggle with stature, although these problems may depend as much on the projection of parental perceptions of their child's vulnerability and immaturity as on short stature per se (75). Future studies investigating improvement in *quality of life*, as well as improved stature growth, of non-GH-deficient children treated with GH will be of paramount importance.

Since the previous edition of this text, the medical literature has been replete with reports of non-GH-deficient children treated with GH, and numerous studies continue to investigate new indications for GH (Table 1). Many extraordinarily short children have overlapping diagnostic conditions (e.g., familial short stature and constitutional growth delay), which complicate interpreting the response of a specific condition to GH therapy. Specific disorders that have undergone investigational trials to date, some of which are currently approved indications for GH therapy, are discussed in the following sections.

The prospect that GH therapy may accelerate growth and increase adult height of markedly short but otherwise healthy children has generated great interest and debate. Serum GH concentrations are usually normal in these children; however, children with severe constitutional growth delay (CGD) may demonstrate temporary failure to secrete GH in response to stimuli, which normalizes with pubertal progression or induction (76). The finding that 30–70% of adults diagnosed as GH deficient during childhood have normal GH levels later suggests that this phenomenon is more common than generally recognized. Thus, repeat provocative testing for GH following short-term sex hormone treatment is advisable before considering a commitment to GH therapy for most near-pubertal patients who fit clinical criteria for CGD.

Administration of GH at dosages used to treat GH deficiency increases growth velocity in the majority of these children throughout at least 3 years of treatment. A controlled study reported that mean growth velocity increased during the first year from 5.3 to 7.4 cm/year and height SD score increased by 0.63 in GH-treated children compared with no change in velocity or SD score for untreated children (77). Growth rates declined during each successive year of therapy and, in one study, approximated pretreatment growth velocity by the fourth year (78). In a more recent study, however, daily GH therapy during years 2 and 3 sustained growth rates of 7.6 and 7.2 cm/year respectively, compared with baseline growth rate of 4.6 cm/year (79). Short, non-GH-deficient children who demonstrate sustained acceleration of growth rate when given GH therapy tend to attain prepubertal heights

that are closer to, but do not exceed, their genetic height potential (80).

Information regarding the efficacy of GH in improving the final height of children with idiopathic short stature (ISS) or CGD is now accumulating. Since height at onset of puberty is a more important determinant of adult height than pubertal growth (because prepubertal growth normally contributes 85% of final height), the most effective GH therapy will require substantial growth acceleration prior to puberty. Increases in standardized Bayley–Pinneau predictions of adult height have been consistently reported during prepubertal GH therapy, but these gains do not improve substantially during treatment of pubertal subjects. Puberty generally appears to occur at expected time in GH-treated children with ISS or CGD, but an accelerated tempo of puberty has been noted in boys (81) and an earlier age of onset in girls (82). This possible decrement in height acquired during puberty probably accounts for reports of *actual* final heights of GH-treated children that fall short of earlier more optimistic height predictions (83). Alternative strategies include administration of a higher dosage of GH for 2 years prior to puberty to achieve normalization of adolescent height, precluding the need for GH therapy during puberty (84). Long-term GH therapy in non-GHD adolescents may increase insulin resistance, but not impaired glucose tolerance or hyperlipidemia (85).

How effective is GH therapy at increasing adult height of non-GHD individuals? Of several studies published in the mid-1990s, only two reported final heights greater than pretreatment predicted heights and only one reported an improved proportion of subjects with final height greater than the midparental target height (86). On the other hand, a more recent study of 80 non-GHD children treated with GH (highly variable duration of treatment) showed a mean increase in SD score for height from -2.7 to -1.4 . The mean (\pm SD) difference between predicted adult height (using Bayley–Pinneau method) before treatment and achieved adult height among boys was 5.0 ± 5.1 cm and 5.9 ± 5.2 cm for girls; still, only a few subjects achieved their midparental target height (87). Thus, it appears that long-term GH treatment of non-GHD short children at currently recommended dosages can lead to statistically significant increases in final height in *some* children. Unfortunately, in this and other studies, no clinical (e.g., pretreatment growth rate) or biochemical (e.g., overnight endogenous GH secretion) determinants reliably predicted the individual response to GH therapy. Consequently, whether improvements in final height due to GH therapy alone are *sufficiently likely or clinically significant* to justify cost and commitment to several years of therapy is still debatable.

Novel approaches to the treatment of idiopathic short stature include concomitant suppression of pubertal hormones using GnRH agonist therapy and reduction of estrogen production using aromatase inhibitors. A recent

study reported that combined gonadotropin releasing hormone agonist/growth hormone (GnRH/GH) therapy for 3 years resulted in gains in predicted height of 8–10 cm without demonstrable side effects (88). Final height data on these patients are not yet available, and current expense of such treatment is formidable. Anecdotal evidence regarding effectiveness of aromatase inhibitor therapy exists (89), but long-term studies in pubertal boys are just beginning.

VI. TURNER SYNDROME AND NOONAN SYNDROME

Between 95 and 100% of girls with Turner syndrome (TS) experience growth failure, and the untreated mean final height of these patients is 143 cm (90), approximately 20 cm below the female average of the corresponding ethnic group. Growth curves for TS have been developed by European investigators, and results in North American patients closely match these data (91). Individual's height percentiles on this TS curve do not change from childhood to adulthood if patients remain untreated. During childhood, average growth velocity is 4.44 cm for each year of bone age advancement. The lower final height results from the combined effects of mild intra-uterine growth retardation, a lack of a pubertal growth spurt (due to ovarian failure to produce estrogens), and growth failure during childhood due to abnormalities in growth plate cartilage (92) and a possible resistance to the

action of GH. Studies clearly show that TS patients do not have classic GH deficiency, although endogenous GH levels (93, 94) and urinary GH levels (95) are below normal after the age of 8 years.

With the exception of GH-deficient children, girls with TS have received the longest trials of GH therapy (up to 10 years). Numerous studies have demonstrated that GH, with or without anabolic steroids, can accelerate growth in girls with TS (96–98). During subsequent years of treatment, growth rates declined but remained higher than those of untreated girls. In one cohort, 14 of 17 girls receiving GH alone equaled or exceeded their original projected adult heights, while 41 of 45 girls receiving combined oxandrolone–GH therapy did so. The mean height of girls who completed a mean of 7.6 years of GH therapy (n = 17) was 150.4 cm, a gain of 8.4 cm over the expected average height, while those treated with GH plus oxandrolone (n = 43) achieved a mean final height of 152.1 cm, representing an average gain of 10.3 cm over predicted height without treatment (Fig. 3) (99). These results suggest that an adult height above the lower limit of normal for American women (150 cm) is now an attainable goal for many girls with this syndrome. Somewhat more modest effects on total height gain (e.g., mean 0.7 SD increase) are also reported, particularly when estrogen treatment was initiated prior to 14 years of age (100). These data have led to regulatory approval for the use of GH to treat the short stature of TS in many countries worldwide (including the United States). Critical fac-

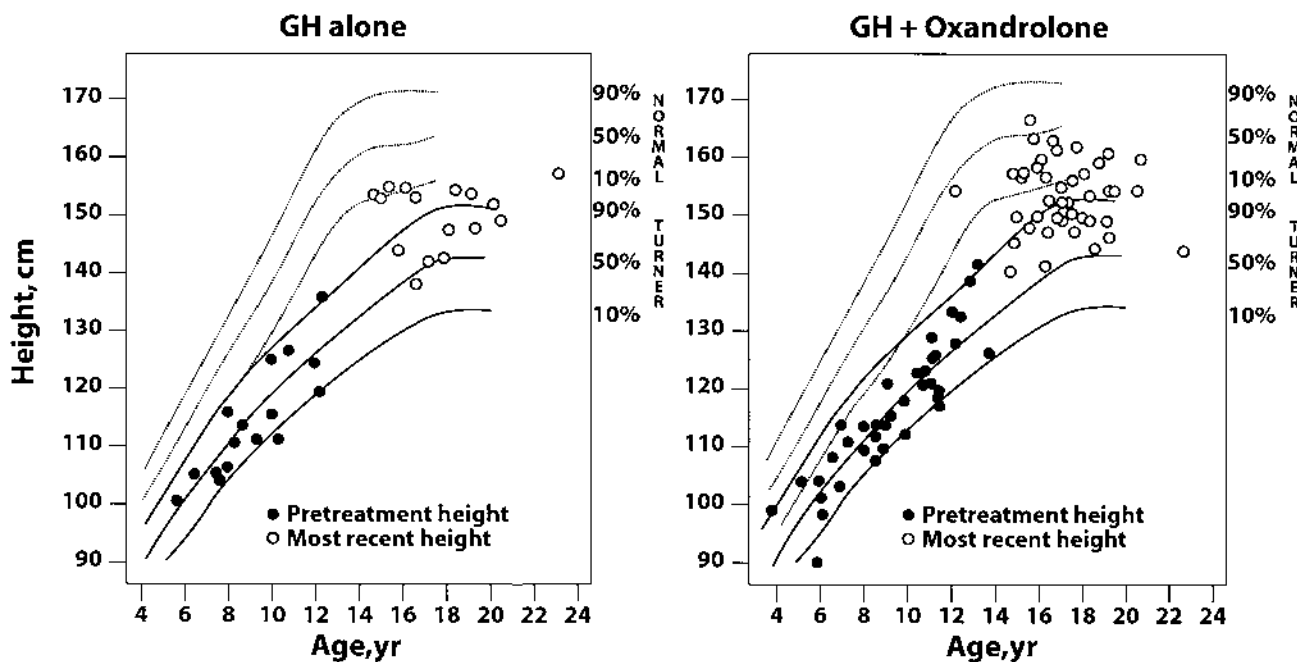

Figure 3 Effect of GH therapy alone and with oxandrolone on last available height in girls with Turner syndrome. (From Ref. 99.)

tors for a successful outcome appear to be GH dosage and the number of years of GH treatment before estrogenization (101).

As a result, initiation of GH therapy is currently recommended as soon as a patient with TS has dropped below the 5th percentile of the normal female growth curve. This may be as early as 2 years of age. For girls below 9–12 years of age, the recommended starting dosage is 0.05 mg/kg/day, although individualization of dosing is appropriate based upon response. In older girls or in girls >8 years of age in whom therapy is started when short stature is extreme, concomitant administration of a steroid that cannot be aromatized to estrogen, such as oxandrolone (0.05 mg/kg/day), should be considered. Girls given oxandrolone should be monitored for potential side effects including clitoral enlargement and glucose intolerance. GH + oxandrolone therapy is continued until a satisfactory height is achieved or until bone age is >14 and annual growth rate is <2 cm. Estrogen is not recommended as a growth-promoting agent, and the initiation of estrogen therapy should be timed to minimize negative effects on growth and adult height (102).

Adverse effects of GH therapy in TS patients have been minimal. Although osteopenia is more prevalent in patients with TS, bone mineral status is not impaired (and may be improved) in GH-treated adolescents with TS (103). Autoantibodies to endocrine organs also occur in TS with increased frequency; GH therapy does not alter immune function in TS (104). Glucose tolerance is of particular interest given the increased incidence of diabetes mellitus in adults with TS and the diabetogenic action of GH. Frequency of impaired glucose tolerance is increased over normal in children with TS. Investigations to date have revealed no significant change in glucose tolerance tests or levels of glycosylated hemoglobin during GH therapy (105). However, obese patients or patients with high insulin concentrations before start of GH therapy may be at greater risk for deterioration (106). Elevations in plasma insulin concentrations are more frequent when GH therapy is combined with oxandrolone, which may also impair glucose tolerance by induction of insulin resistance.

Noonan syndrome (NS) is an autosomal dominant disorder that shares clinical features with TS, including growth retardation usually in the absence of GH deficiency. A recent 3 year controlled trial showed a mean increase in growth rate from a baseline of 4.4 cm/year to 8.4, 6.2, and 5.8 cm/year during years 1, 2, and 3 of GH therapy respectively. Mean height SD score increased from -2.7 to -1.9 in GH-treated NS patients compared with a change from -2.7 to -2.4 in nontreated NS children. However, height acceleration was not significant during the second or third years when pubertal subjects were excluded (107). Others report that initial GH-induced growth acceleration is followed by a waning of effect with long-term therapy; in a small group of 10 pa-

tients, a mean increment in final height of only 3.1 cm was observed (108). In both studies, no deleterious effects on myocardial thickness were observed

VII. INTRAUTERINE GROWTH RETARDATION

For approximately 10% of children with intrauterine growth retardation (IUGR), the pattern of growth continues to be abnormal from intrauterine life to full maturity (109). Included in this group are children with dysmorphic features compatible with Russell-Silver syndrome. Even though bone age is often delayed early in childhood, the adolescent growth spurt usually occurs early and is reduced in magnitude (110). Although a minority of children with IUGR display subnormal spontaneous or provoked GH concentrations, results of these tests do not predict their responsiveness to GH.

In a study reported more than 30 years ago, approximately 50% of prepubertal children with IUGR responded to twice- or three times weekly GH injections with significant growth acceleration (111). Studies of daily administration of GH reveal consistent increases in short-term growth velocity (e.g., from 6.7 to 10.4 cm/year) (112); greater increments in growth velocity have been achieved with higher GH dosages (113). Prolonged (3 years) GH treatment of children with IUGR sustains an accelerated growth rate but does not increase height for bone age score, pointing to an unaltered final height outcome (114). Nevertheless a recent report of 5 years of treatment (115) and a separate epianalysis of four randomized studies of 6 years duration (116) both indicate that administration of GH (0.033–0.067 $\mu\text{g}/\text{kg}/\text{day}$ with both continuous and discontinuous regimens employed) can normalize stature of short, non-GHD IUGR children, at least during childhood and early puberty (Fig. 4).

Growth failure in IUGR children has recently been approved by the FDA as an indication for GH therapy. Furthermore, the successful and novel use of intermittent high-dosage GH therapy in this group of patients is an important observation that could potentially be applied to other GH treatment indications. Whether IUGR children derive substantial psychological benefits from a more rapid tempo of growth during childhood (even without enhanced final stature) remains uncertain. It is noted that difficulty of accurately assessing bone age maturation in dysmorphic syndromes such as Russell-Silver syndrome may reduce validity of predicted heights. Higher-dose GH therapy has also led to hyperinsulinemia in some of these children. Therefore, continuation of these clinical trials until final height will be required to determine the safety and efficacy of GH for IUGR. Given the accelerated tempo of puberty in these patients, concomitant administration of GnRH analog or aromatase inhibitors to permit a longer period of growth may be indicated for severely height-disabled individuals with IUGR.

Figure 4 Effect of varying dosages of long-term GH therapy on heights in children with intrauterine growth retardation. (From Ref. 115.)

VIII. CHRONIC RENAL FAILURE AND HYPOPHOSPHATEMIC RICKETS

Poor nutrition, anemia, and chronic metabolic acidosis contribute to the growth failure characteristic of chronic renal failure (CRF). In addition, elevated fasting GH levels, exaggerated responses to provocative stimuli, depressed serum IGF-1 levels, and increased levels of IGF-1 binding protein (in particular IGFBP-1) suggest resistance to the action of GH (117). Pharmacological dosages of GH are able to overcome these growth-retarding influences in some patients with CRF through metabolic effects of GH (e.g., enhanced renal acid excretion [118]), increases in IGFs and ternary complexes that overcome inhibitory effects of excess IGFBPs (119), and direct growth-promoting effects. A randomized, double-blind, placebo-controlled study of 125 prepubertal growth-retarded children with CRF revealed first-year (10.7 ± 3.1 cm/yr) and second-year (7.8 ± 2.1 cm/yr) growth rates in the GH-treated group that were significantly greater than those seen in the placebo group. The beneficial effect on final height potential predicted by this study (Fig. 5) (120) was recently confirmed in one study of 38 GH-treated children with CRF who reached a final height 1.4 SD *above* standardized height at baseline compared with mean final height of 50 nontreated matched control children with CRF that was 0.6 SD *below* standardized height at baseline (121). In general, responsiveness to GH appears to be inversely related to the degree of renal function impairment and metabolic compromise. Growth failure due to CRF is an approved indication for GH therapy.

Growth hormone excess produces hyperfiltration and increases glomerular sclerosis in the setting of uremia, (122), raising a theoretical concern that GH treatment of children with CRF could accelerate deterioration in renal function. However, current information suggests no adverse effect of GH therapy on glomerular filtration rate (GFR); loss of GFR is unchanged during the first year of

GH treatment compared to the year before treatment (123). Reports of accelerated rises in serum creatinine may reflect increased body size and creatinine production without a commensurate increase in GFR (124). Thus, growth itself, rather than GH, may place additional metabolic demands upon compromised, but stable, renal function. Hyperinsulinemia, often present before GH therapy due to uremic insulin resistance, may remain stable or worsen during GH therapy. However, glucose homeostasis, assessed by oral glucose tolerance testing and glycosylated hemoglobin levels, has remained stable (125). Transient intracranial hypertension may occur during GH treatment of children with CRF, but is relatively rare and is reversible with temporary cessation of drug or reduction in dosage.

In normal kidneys, GH increases renal phosphate retention. Consequently, GH has been administered to poorly growing children with X-linked hypophosphatemic rickets (XHR). In a recent study reporting final height outcome, GH therapy combined with conventional treatment resulted in a change in height SD score in six children with XHR (mean baseline -3.4 , mean post-treatment, -2.4) whereas no change in height SD score was observed in six XHR patients not treated with GH. Phosphate retention, bone markers, and radial bone mineral density increased only in the GH-treated group (126). Additional long-term studies are needed to verify the value of long-term GH therapy for patients with this disorder.

IX. SKELETAL DYSPLASIAS

Numerous forms of skeletal dysplasia may cause significant growth retardation. Detailed descriptions of clinical and radiological features and inheritance patterns belie a lack of understanding of the basic pathophysiology for many of these disorders, although associated genetic mu-

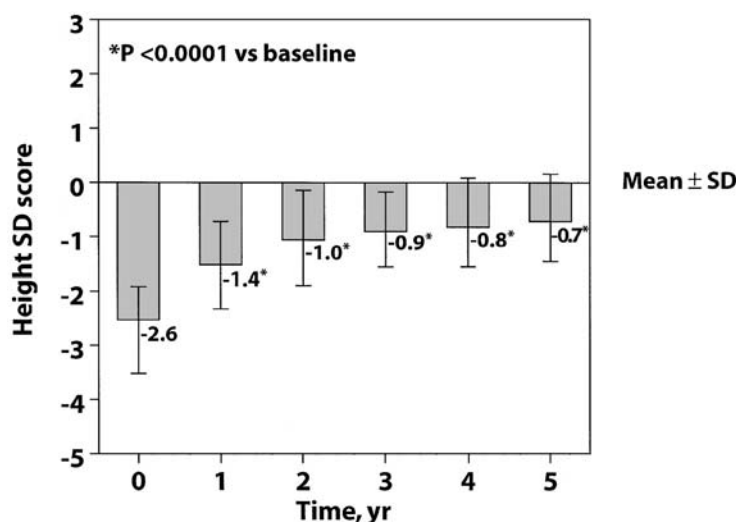

Figure 5 Beneficial effects of GH therapy on long-term growth in children with chronic renal insufficiency. (From Ref. 120.)

tations (e.g., fibroblast growth factor receptor-3 in achondroplasia) are steadily being recognized.

A short-term study of GH therapy in children with hypochondroplasia showed an increase in first year growth rate that was proportionally distributed between limb and spine growth (127). Variation in response to GH with regard to rate and proportionality of growth has also been reported, and may be related to defects in the IGF-1 gene in some patients (128). Growth response to GH is generally less than that observed in children treated for classic GH deficiency and declines after initial acceleration. Thus, modest improvement in adult height might be expected from currently used regimens of GH therapy. Higher GH dosage, concomitant GnRH analog treatment, and use of aromatase inhibitors could conceivably alter this prognosis. Patients with achondroplasia demonstrate normal secretion of GH, IGF-1 levels, and IGF-1 receptor activity (129). Reports of response to GH are variable. Some data indicate little change in growth rate, even when higher than conventional dosages are used (130). More recent studies suggest that GH therapy can increase growth rate and height z-score in a dose-dependent manner without significant side effects (131). Effects on ultimate height remain unknown. Preliminary trials of GH therapy for spondyloepiphyseal dysplasia and multiple epiphyseal dysplasia are in progress.

X. GLUCOCORTICOID-TREATED CHILDREN

Treatment of many chronic disorders (e.g., juvenile rheumatoid arthritis, asthma, renal transplantation, inflammatory bowel disease), which themselves may lead to growth failure, includes glucocorticoid therapy. Glucocorticoids (GC) impede linear growth through several mechanisms,

including promoting protein catabolism, inhibiting collagen synthesis, impairing the action of IGF-1, and suppressing endogenous GH secretion through augmentation of hypothalamic somatostatin tone (132). Thus, these patients could be considered logical candidates to benefit from both the growth-promoting and anabolic effects of GH therapy.

Early studies, implementing relatively low dosage and infrequent administration of GH, demonstrated marginal and inconsistent beneficial effects (133). Subsequent investigations of daily GH therapy for children with stable GC-treated illness (134) or who had undergone renal transplantation (135) show more consistent resumption of normal growth velocity during 1–3 years of treatment. Biochemical markers of growth (e.g., type 1 procollagen levels) are also normalized by GH administration. Responsiveness to GH appears greatest in those on moderate-dosage GC regimens with stable, nonarthritic underlying disease. Persistence of disease activity and higher GC dosage (e.g., prednisone dosage >0.35 mg/kg/day) (136) interfere with GH responsiveness.

Recent analysis of larger numbers of GC-dependent children ($n = 83$) evaluated over a 12 month period reveal a mean response to GH therapy (mean dosage = 0.3 mg/kg/week) of doubling of baseline growth rate (e.g., 3.0 ± 1.2 cm/year to 6.3 ± 2.6 cm/yr) (Fig. 6) (137). Responsiveness to GH is negatively correlated with the dosage of GC. In 14 severely growth-impaired children with rheumatoid arthritis (mean height SDS = -4.0), GH administered at a dosage of 0.5 mg/kg/week resulted in an increase in mean growth velocity from 1.9 to 4.5 cm/year (138). While difficult to prove, *preservation of height SDS* most likely represents a beneficial therapeutic outcome for these children. Long-term GH-responsiveness and effects of GH therapy on final height in GC-treated children nev-

Figure 6 Effect of GH therapy on growth in children treated with glucocorticoids. (From Ref. 137.)

ertheless remain unknown, and GH treatment of GC-dependent children remains experimental.

Salutary effects of GH therapy (0.05 mg/kg/day administered daily) on the growth of children following renal transplantation are also reported. Growth rates of pre-pubertal children after renal transplantation have generally increased two- to threefold during the first 1–2 years of GH therapy, decline subsequently but remain above baseline growth velocity (139). Gains in height SD scores approximate 1 SD following 2–4 years of therapy, and approximately one-half of the children achieve “normal” heights (i.e., within 2 SD of the mean). Growth stimulation in pubertal children with renal allografts, while less consistent than that observed in younger patients, is still significant (140).

In addition to restoring linear growth, GH therapy may counter some of the catabolic effects of GC. Studies using isotope tracer infusions suggest that GH, directly or through IGF-1, counteracts GC-induced protein catabolism through independent stimulation of protein synthesis without altering protein breakdown (141). Alternatively, accompanying hyperinsulinemia might contribute substantially to the observed protein anabolic effect by decreasing proteolysis. GH may also counteract the antianabolic effects of GC on bone. In a group of adults receiving chronic GC treatment, in whom GHRH-stimulated GH levels were suppressed, levels of osteocalcin and carboxy-terminal propeptide of type I procollagen rose with short-term GH therapy (142). Detailed studies of the metabolic effects of GH administration in children receiving long-term GC therapy have not yet been done.

Potential adverse effects of combined GH/GC therapy in children with GC-dependent disorders include altered

carbohydrate metabolism, stimulation of autoimmune disease activity, increased cancer risk, and, in transplant recipients, graft dysfunction or rejection. Elevated fasting and stimulated insulin levels have been observed in renal allograft patients receiving GH; however, these changes frequently predate institution of GH therapy, correlate with prednisone dosage, and are not affected by the addition of GH. Among all GH-treated GC-dependent children, detectable elevations in blood glucose concentrations have been rare. GH-induced exacerbations of chronic disease activity also appear to be very unusual, but the number of patient-years available for study of this question remains small. With regard to renal allograft function and survival, actions of GH on glomerular hemodynamics, glomerular morphology, and immune stimulation are theoretical reasons for concern. Nevertheless, most investigators report no difference between GH-treated and control renal allograft patients with regard to changes in GFR, effective plasma flow, other measures of renal function, and rates of allograft rejection. Although preliminary analysis of one randomized prospective study suggested that GH might slightly increase allograft rejection rates, final analysis indicated that biopsy-proven acute rejection episodes were not significantly more frequent in the group receiving GH (143). Long-term and careful follow-up of children with renal transplants receiving GH therapy is still needed to resolve this important issue.

XI. PRADER-WILLI SYNDROME

Growth of children with Prader-Willi syndrome (PWS) is characterized by moderate intrauterine and postnatal

growth retardation, followed by near-normal growth rates as caloric intake increases and obesity typically develops. Substantial evidence now supports a true GH deficient state in PWS: lack of nutrition-induced growth acceleration, relatively low IGF1 levels, diminished GH responses to GH provocation, and body composition abnormalities (i.e., reduced muscle mass, increased fat mass) resembling states of GH deficiency. Administration of GH to children with PWS results in growth rate increases equivalent to those observed in severely GH-deficient children (Fig. 7). In addition, GH therapy increases lean body mass, decreases fat mass, and increases bone mineral density (144, 145). Reductions in fat mass result from increases in total body energy expenditure and preference for fat oxidation as an energy source (confirmed reductions in respiratory quotient). In addition to cognitive and behavioral disabilities, profound hypotonia severely limits the physical function of individuals with PWS. Treatment with growth hormone improves measures of strength and agility in children with PWS, substantiating claims of so-called real-life benefits of GH for these children. These changes in body composition and physical function are dose-dependent and attenuate, but do not regress, during prolonged GH therapy (146). Growth failure related to PWS is a recent approved indication for GH treatment.

XII. OTHER SYNDROMES AND DEFECTS ASSOCIATED WITH SHORT STATURE

Short stature is a component of more than 100 syndromes. Subnormal secretion of GH has been reported in some children with Down syndrome (147). Preliminary treatment trials of these children show short-term responses to GH similar to those of Russell-Silver syndrome and Turner syndrome. Short stature is also a common problem in children with neural tube defects such as spina bifida or myelomeningocele, who may have spinal and/or lower skeletal abnormalities. Secretion of GH is normal unless accompanying hydrocephalus impairs hypothalamic-pituitary function. In a small group of patients with neural tube defects and subnormal GH secretion, GH treatment over 36 months significantly improved growth rates of body length and arm span. However, the increase in length SD score was not significant (148).

The expansion of GH therapy into populations affected by mental disability or with limited ambulatory capability raises complex ethical questions by focusing attention on the expectation that successful GH therapy ought to improve the quality of life, rather than merely the height, of treated individuals (149). For each of these groups of patients, analysis of larger, longer prospective trials, conducted within a GH investigational protocol, are needed before recommendations about efficacy can be made. When this information is available, treatment decisions can be made for individual patients (rather than

Figure 7 Growth rates of children with Prader-Willi syndrome treated with GH compared to untreated control subjects with PWS. (from Ref. 144.)

diagnostic groups) based upon degree of disability and likelihood of long-term enhancement in quality of life.

XIII. ADULTS WITH GH DEFICIENCY AND THE ELDERLY

The availability of unlimited supplies of human GH has been accompanied by a wealth of new information regarding the consequences of GH deficiency in adults and the benefits of replacement treatment. Lack of GH in adulthood can lead to contraction of lean body mass and water, expansion of fat mass (particularly central abdominal fat), diminution of bone mineral content, increased concentrations of total and low-density lipoprotein (LDL) cholesterol, increased atherothrombotic propensity, impaired cardiac function, impaired psychological well-being, and decreased life expectancy (150). Placebo-controlled studies of GH therapy in adults with *complete* GH deficiency have revealed a marked increase in muscle mass, decrease in fat mass (151, 152), and improvements in exercise performance (153). Subjective improvements in quality of life indicators such as vigor, ambition, and sense of well-being are also reported (154). Consequently, adult GHD is now an FDA-approved indication for GH therapy.

Adverse effects due to fluid retention (e.g., edema, carpal tunnel syndrome) are fairly common, but reverse

with dosage reduction or continuation of the same dosage. Dosages used are markedly lower than those used per kilogram during childhood: the Growth Hormone Research Society recommends that dosage not be weight-based. Patients are to be commenced on a low-dosage (0.15–0.3 mg/day) regimen, which is then gradually increased in accordance with clinical and biochemical responses. Maintenance dosages varies considerably, and is influenced by gender and age, but rarely exceed 1 mg/day. Women usually require higher dosages than men, while the elderly require lower dosages (155).

The normal decline in the activity of the GH-IGF-1 axis that occurs with advancing age appears to contribute to the decrease in lean body mass, increase in adipose tissue mass, and possible loss of energy. Administration of GH to non-GH-deficient men over 60 years old caused significant increases in lean body mass, bone density, and skin thickness, with concomitant reductions in fat mass (156). Following GH therapy, deterioration of these parameters resume in age-appropriate fashion. Although the implications of such therapy are enticing, the risk–benefit ratio and cost-effectiveness of GH therapy in the general aging but healthy population have not been established. Administration of GH has also been used by younger adults in conjunction with heavy resistance exercise training in an effort to maximize skeletal muscle protein anabolism and strength. However, in a placebo-controlled study of young normal men, resistance training supplemented with GH did not further enhance muscle anabolism and function (157). These results suggest that increased fat-free mass seen with GH supplementation was probably due to an increase in lean tissue other than skeletal muscle.

XIV. CATABOLIC STATES

Well-documented salutary effects of GH on nitrogen retention and protein synthesis rates have prompted investigation of GH therapy in various catabolic, regenerative, or reparative states. Nitrogen balance is improved by GH in postoperative patients under hypocaloric conditions (158) and GH partially reverses nitrogen wasting in obese humans made catabolic by dietary restriction (159). Growth hormone also improves the efficiency of parenteral nutrient utilization in patients requiring total parenteral nutrition. Improvements in weight and lean tissue mass have also been documented in pediatric burn patients (160). However, results of controlled trials of GH treatment in acute-care settings have not all been favorable. One placebo-controlled trial in normal adults showed that full-thickness wound healing was significantly *delayed* by GH therapy (161). A large randomized controlled trial of high-dosage GH treatment of adult patients during a severe catabolic illness in the intensive care setting showed higher mortality in GH-treated patients (162). Although perhaps influenced substantially by the high dosages of

GH administered, these data have nevertheless created substantial concern about use of GH in the critical care setting. Most physicians currently discontinue GH in acutely ill patients in the hospital who are taking GH chronically. Whether GH treatment of overwhelmingly ill patients induces the release or potentiates the action of harmful cytokines is currently under investigation.

Anabolic effects of GH therapy have also created interest in its use as ancillary therapy for several chronic illnesses. GH has been shown to improve the body composition of patients with acquired immunodeficiency syndrome's (AIDS) wasting syndrome (another FDA-approved use of GH). Improved lean tissue mass, height and weight gain, and decreased protein catabolism have been reported in children with Crohn's disease and chronic ulcerative colitis (163). In children with cystic fibrosis, a randomized controlled trial showed significant improvements in height and weight gain, lean tissue mass, and pulmonary function, accompanied by decreased hospitalization time (164). During the next decade, we can look forward to considerable new knowledge about the anabolic effects of GH in these and related settings.

XV. ADVERSE EFFECTS OF GH TREATMENT

Recombinant biosynthetic GH preparations are highly purified and free of contaminants. The possibility of viral transmission through GH has been virtually eliminated. However, surveillance of patients who received pituitary-derived GH for development of Creutzfeld-Jakob remains important. Antigenicity of GH preparations is also low (165), although GH antibodies can be detected in 10–30% of treated children. With rare exceptions (less than 0.1%), these antibodies do not impede effects of GH.

GH administration to healthy subjects acutely increases serum T3 and reciprocally decreases free T4. Laboratory indications of hypothyroidism may likewise be seen in as many as 25% of GH-deficient children treated with GH, with declines in serum T4 levels reflecting increased peripheral conversion of T4 to T3 (166). GHD patients who display subnormal nocturnal TSH surges, signifying a pre-existing central hypothyroidism, are more likely to display subnormal T4 and free T4 levels during GH therapy, and to benefit from thyroid replacement (167). Most studies, however, indicate that children with normal thyroid function before treatment do not develop significant perturbations in thyroid hormone metabolism during GH therapy.

GH deficiency is associated with reductions in lean body mass and total body water, with accompanying reductions in renal plasma flow and glomerular filtration rates. Edema and sodium retention rarely occurs early in the course of GH therapy (particularly in older, heavier children and adolescents), attributable to an antinatriuretic effect on the renal tubule of GH and/or IGF-1. Minor elevations in plasma renin activity and aldosterone ob-

served in the first 3 days of treatment resolve within a week or 2 (168). Occasionally, fluid shifts within the central nervous system are sufficient to cause benign intracranial hypertension (pseudotumor cerebri) and its symptoms of headache, visual loss, vomiting, and papilledema. It is speculated that direct fluid-retaining properties of GH and/or action of locally produced IGF-1 on cerebrospinal fluid (CSF) production are causative. Most instances have occurred during early (although not invariably) treatment of patients with severe GHD or other risk factors for this condition (e.g., chronic renal insufficiency, Prader-Willi syndrome). Cessation of GH therapy has reversed the symptoms in reported cases, and some patients experience spontaneous resolution of symptoms in spite of continued GH treatment (169). Resumption of GH treatment has been successfully accomplished with reinitiation at a lower dosage and gradual return to the initial dosage. It is recommended that fundoscopic examination be performed on all patients before initiation of GH therapy and periodically thereafter (170).

Until recently, GH had been used primarily as replacement therapy for GH deficiency. Adverse effects of GH therapy become more likely as higher dosages are used for pharmacological GH *augmentation* therapy. Recommendations for GH dosage, derived largely from growth response data, are in excess of calculated estimates of normal GH production in a prepubertal child, and dosing guidelines for adolescents are increasing further. IGF-1 levels in some GH-treated girls with Turner's syndrome approach those found in acromegaly (171), and anecdotal reports of development of acromegaloid features (e.g., large hands and feet) during higher than conventional dosage GH therapy have appeared. GH excess reduces insulin sensitivity, and given the trend toward higher dosages, it is important to assess a GH dosage's effect on carbohydrate metabolism. Nearly all studies of GH therapy in children and adults show an increase in fasting and postprandial insulin levels. However, glucose homeostasis is generally not impaired (172). Furthermore, normal levels of blood glucose and glycosylated hemoglobin may be preserved by hyperinsulinemia, which when persistent can be associated with atherosclerosis and hypertension. One study of long-term high-dosage GH therapy found normal glucose metabolism and higher levels of insulin (which did not correlate closely with dosage) that returned to normal when GH therapy was discontinued (173). Given these reassuring data, a recent report of an increased frequency of type 2 diabetes in childhood GH recipients was surprising. Fewer than half of affected subjects were obese or had other risk factors for diabetes, two-thirds were in puberty, and diabetes persisted in all patients after GH discontinuation (174). Other pharmacoepidemiological databases have not reported an increase in diabetes incidence. Careful prospective follow-up of individuals during and after GH therapy is needed to resolve this issue.

Perhaps the greatest concern regarding GH therapy is the theoretical possibility that GH could facilitate the de-

velopment of cancers. Growth hormone is mitogenic, and there is evidence in animals of a cause and effect relation between supraphysiological doses of GH and development of leukemia (175). Three clinical settings have raised concern: GH-treatment-induced new malignancy; GH-treatment-induced recurrent malignancy; GH-treatment-induced second malignancy in those already treated for one tumor. In 1988, reports from Japan describing leukemia in GH-treated children raised concern about new malignancy (176). An extended follow-up study of 6284 recipients of pituitary-derived GH revealed a relative risk of leukemia in recipients of GH of 2.6 (90% confidence interval, 1.2–5.2). Five of six subjects had antecedent cranial tumors as the cause of GH deficiency, and four had received radiotherapy (177). Subsequent analyses, based on much larger total patient-years of GH treatment, indicate that the rates of new leukemia in (non-Japanese) patients without pre-existing risk factors who are treated with GH is no greater than expected for the general population (178). This lack of increased risk in children without pre-existing risk factors was recently confirmed in the Japanese population (179). Any possible increased incidence of leukemia appears limited to those patients with known risk factors, and due to the small numbers of events in such patients, it remains impossible to determine any contribution of GH therapy. With regard to nonleukemia cancers, a retrospective analysis of large postmarketing database found no evidence of an increased risk of developing an extracranial, nonleukemia neoplasm in GH-treated patients (180).

With regard to recurrent malignancy, no report has associated GH therapy with an increased incidence of tumor recurrence. A lack of reliable knowledge about the natural history of recurrence of these tumors, however, supports a cautious interpretation of such data. Most recurrences occur within the first 2 years of treatment, and most endocrinologists defer institution of treatment until a year of stable remission has passed. While this may result in some lost growth for the child, it also avoids the inevitable association of GH therapy and tumor recurrence during this high-risk period. With regard to second malignancy, no study to date has directly compared the incidence of new second tumors in those receiving GH and those not.

In humans, GH and IGF-1 have been shown to affect numerous immune functions, but these effects do not appear to translate into clinically relevant problems in GH-treated children. The possibility that GH might influence the growth rate of melanocytic nevi has been raised. However, a recent study failed to show any relationship between melanocytic nevi count and duration of GH therapy in girls with TS, and the melanocyte count in children with GHD was not different from controls and was not influenced by GH therapy (181). GH treatment causes an increase in both the proliferative and hypertrophied zones of the growth plate that may reduce the force needed to

shear it. An increased frequency of slipped capital femoral epiphysis has been reported during treatment with GH (182). This rare complication is more common in children with organic causes of severe GHD, who require close monitoring for limp and hip or knee pain (183). Progression of scoliosis may be more rapid during GH therapy, but available data do not suggest an increased frequency of scoliosis as a result of GH exposure. Nevertheless, some children more likely to receive GH therapy (e.g., those with Turner syndrome, Prader-Willi syndrome) already have an increased frequency of scoliosis, and require close monitoring. Concerns raised regarding other potential adverse effects of GH therapy (e.g., reduced testicular volume, gynecomastia, deterioration of renal function in patients with CRF, cardiac ventricular hypertrophy in those with Turner and Noonan syndromes) have, to date, either not been realized or considered not to be of sufficient clinical significance to alter prescribing (184).

In summary, nearly two decades of experience with recombinant GH has proven this therapy to be remarkably safe when used in conventional substitution dosages for GH deficiency. Higher-dosage therapy for other causes of growth retardation also appear to be safe, but continued surveillance of its metabolic effects is indicated. There appear to be very few medical contraindications to GH therapy. Nevertheless, the experience of transmission of Creutzfeldt-Jakob syndrome via pituitary GH is a poignant reminder that a farsighted view must be taken of the potential ramifications of long-term hormonal therapy.

XVI. ETHICAL ISSUES IN GH TREATMENT

Limited availability of GH once provided a barrier to expanding its use beyond children who were unequivocally GH deficient. Today, increased supply of GH has been matched by increased demand. Ten years ago in the United States, there was one approved indication for GH, two GH manufacturers, and approximately 10,000 children receiving treatment at a cost ranging between \$5000 and \$40,000 per year. Today, there are six FDA-approved indications for GH (Table 1), multiple US and international manufacturers, and well over 30,000 patients treated. Nevertheless, GH therapy remains expensive. Relaxed diagnostic criteria have obliterated any clear boundary between GH deficiency and sufficiency, allowing many partially affected children access to treatment. Future goals of GH therapy appear likely to shift further toward supplementing and enhancing individuals' well being rather than merely returning them to some physiological baseline. Careful longitudinal studies, many of which are already in progress, will be required to determine the efficacy of GH in accomplishing these goals.

But what *can* be done with GH is not necessarily what *should* be done. Ethical justification for these goals, not merely the efficacy of GH therapy in accomplishing them, also deserves careful scrutiny. New uses of GH raise

complex philosophical, psychological, and economic, as well as medical questions that physician–scientists alone cannot answer (185). Even if GH is shown to increase effectively the growth of non-GH-deficient children and even if treatment can be accomplished without toxicity, additional considerations are needed to assess responsibly the long-term *value* of the added height increment, and to balance expected benefit with issues of resource allocation and fairness.

Widespread distribution of GH has been partially deterred by high drug costs. It is a paradox that although the source of GH is no longer limited, the resources with which to pay for it are becoming increasingly so. Prescribing GH requires a difficult and often uncomfortable balancing of responsible use of medical resources with an obligation to do the best for each individual patient. But is taller really better for each patient (186)? Concern about psychological harm is invoked as a primary rationale for treating short stature, yet data confirming the efficacy of GH therapy in alleviating the psychosocial consequences of short stature are scarce. If the ultimate goal of GH therapy is not tall stature but, rather, an improved quality of life, documentation of psychosocial impairment due to stature prior to therapy and improvement following GH therapy ought to play an important role in the initiation of GH therapy and evaluation of its efficacy (187). To date, however, growth rate and final adult height remain the measures by which therapeutic success is judged.

Responsiveness to GH, described above in many groups of short-statured individuals, is a necessary but not sufficient indication for treatment. Because of enormous expense and concerns that such widespread access would not ameliorate disadvantages of short stature, it seems appropriate to restrict access within this group based upon the presence of significant functional or psychological disability related to stature and the likelihood of improvement with treatment. Most short children will not satisfy these additional criteria. Children with severe GH deficiency are likely to be both more disabled and more responsive than non-GH-deficient children, justifying the former's preferential treatment. Is it justified to restrict access of others to GH based on the laboratory diagnosis of GH deficiency? Some have argued that equally short children share a similar disability, regardless of whether stimulated GH levels fall just above or just below an arbitrary threshold. If both are GH responsive and truly disabled by height, there appears to be little ethical justification for treating only the child with lower GH test results (188).

Alleviating the disability of short stature, rather than normalization of GH levels, has traditionally been the primary goal of GH therapy. Determining an appropriate end-point for GH therapy remains controversial. Attainment of genetic potential for height, which is a realistic possibility with optimal diagnosis and treatment, remains a goal for many (189). Consistent adherence to the goal

of alleviating disabling short stature, on the other hand, implies that GH therapy be discontinued when *each* treated child reaches an adult height no longer considered a disability. No policy regarding GH therapy will ever eliminate the first percentile on the growth curve, but the second strategy has as its goal bringing children into the *normal opportunity range for height* without further enhancing those who have achieved a height within the normal adult distribution. By adhering to the *treatment* of disabling short stature, and resisting the *enhancement* of normal stature, physicians treating children with GH would minimize their contribution to society's heightist perception that to be taller is to be better (190).

Skeletal Dysplasias

Mordechai Shohat

Rabin Medical Center–Beilinson Campus, Petah Tikva, Israel

David L. Rimoin

Cedars–Sinai Medical Center and UCLA School of Medicine, Los Angeles, California, U.S.A.

I. INTRODUCTION

The human skeletal dysplasias are a heterogeneous group of disorders that result in disproportionate short stature. Although most are rare, these developmental defects of the skeleton cause a significant proportion of the cases of moderate to severe short stature (1).

Before 1970, the diagnosis for most patients with disproportionate shortening of the limbs was achondroplasia, and those with short trunks were thought to have Morquio syndrome. The understanding and appreciation of the heterogeneity within the skeletal dysplasias led to a systematic description of over 100 different forms, which have been primarily classified on the basis of clinical and radiographic changes. With the recent explosion of knowledge in the biochemistry and molecular biology of connective tissue, rapid progress has occurred in the delineation of the basic defect in these disorders. It is important to make a specific diagnosis in each case so that an accurate prognosis can be given and proper genetic counseling provided. Furthermore, each of these disorders is associated with a variety of skeletal or nonskeletal complications, which an accurate diagnosis allows one to anticipate, treat promptly, or prevent.

II. DIFFERENTIATION

The current nomenclature for these disorders is confusing. The specific name for a given condition usually describes the skeletal segment involved (e.g., the epiphyseal dysplasias and the metaphyseal dysplasias), or uses a descriptive Greek term (e.g., thanatophoric [death-bringing] dysplasia, metatropic [changing] dysplasia, and diastrophic [twisted] dysplasia). Some disorders are eponyms (e.g.,

Kniest dysplasia and Ellis–van Creveld syndrome). Occasionally, the name was derived to describe the pathogenesis (osteogenesis imperfecta), but usually inaccurately (e.g., achondroplasia and achondrogenesis).

The extent of the heterogeneity in these disorders and the variety of methods used for their classification have resulted in further confusion. Clinical classifications have organized the skeletal dysplasias into those with short-limbed dwarfism and those with short-trunk dwarfism. Age of onset of the disease and associated clinical abnormalities have also been used in subclassifying these disorders. Still other disorders have been classified on the basis of their apparent mode of inheritance, for example the dominant and X-linked varieties of spondyloepiphyseal dysplasia.

The most widely used method for differentiating the skeletal dysplasias has been the detection of skeletal radiographic abnormalities. Radiographic classifications are based on the different parts of the long bones that are abnormal (epiphyses, metaphyses, or diaphyses; Figs. 1, 2). Thus, there are epiphyseal and metaphyseal dysplasias, which can be further classified depending on whether the spine is also involved (spondyloepiphyseal dysplasias and spondylometaphyseal dysplasias). Furthermore, each of these classes can be subclassified into several distinct disorders based on a variety of other clinical and radiographic differences.

As the morphology, pathogenesis, and especially the basic biochemical and molecular defect in each of these disorders are unraveled, this nomenclature is being changed to refer to the specific pathogenetic or metabolic defect. The etiological or pathogenetic nomenclature is now being used for certain skeletal dysplasias, such as the mucopolysaccharidoses, mucopolipidoses (e.g., β -glucuron-

Figure 1 Classification of chondrodysplasias based on radiological involvement of long bones (A–C) and vertebrae (D and E).

Involvement	Disease category
A + D	Normal
B + D	Epiphyseal dysplasia
C + D	Metaphyseal dysplasia
B + E	Spondyloepiphyseal dysplasia
B + C + E	Spondyloepimetaphyseal dysplasia

idase deficiency, fucosidosis), type II collagenopathies, and disorders of mineralization (hypophosphatasia).

III. INTERNATIONAL CLASSIFICATION AND NOMENCLATURE

In an attempt to develop a uniform nomenclature for these syndromes, an international nomenclature and classification for the skeletal dysplasias were proposed in 1969 and updated in 1977, 1983, 1991, and 1997 (6). The most recently updated classification can be found on the World Wide Web at www.csmc.edu/genetics/skeldys.

The term “dwarfism” is no longer used and the disorders have been referred to as “dysplasias” or “dysostoses.” The international classification, originally organized the skeletal dysplasias into five major groups:

1. Osteochondrodysplasias: abnormalities of cartilage or bone growth and development
2. Dysostoses: malformation of individual bones, singly or in combination (does not reflect a generalized disorder of the skeleton)
3. Idiopathic osteolyses: a group of disorders associated with multifocal resorption of bone
4. Skeletal disorders associated with chromosomal aberrations
5. Skeletal disorders associated with primary metabolic disorders

In the differential diagnosis of short stature, osteochondrodysplasias are of major importance. These are a complex group of diseases caused by primary abnormalities of cartilage or of bone growth or development. This group was organized following classifications:

1. Defects of growth of tubular bones or spine, or both (further referred to as chondrodysplasias)
2. Abnormalities in the amount, density, and remodeling of bone (includes disorders with a decrease or increase in bone and disorders of mineralization and mineral metabolism)
3. Disorders involving disorganized development of cartilage and fibrous connective tissue

Recent advances in molecular genetics have made possible the identification of the basic defects in many common skeletal disorders. The Fifth International Nomenclature committee, which met in Los Angeles in 1997, not only updated the nomenclature with the addition of a number of newly described syndromes but also completely revised the organization of these disorders into a clinically and pathogenetically based classification (Table 1). Thus, disorders that share clinical, radiographic, morphological, or biochemical features, suggesting that they share common pathogenetic mechanisms, were grouped together. This classification will certainly undergo constant revision as the basic defect in each of these disorders is discovered.

IV. DIAGNOSIS AND ASSESSMENT

The diagnosis of skeletal dysplasias is based on the clinical, radiographic, pathological, and, increasingly, biochemical and molecular studies. Table 1 summarizes the clinical, genetic, and radiographic features of the common chondrodysplasias and those with abnormalities in the amount, density, and remodeling of bone.

A. History

An accurate medical and family history may be of major importance in arriving at a diagnosis. A complete family history, details of stillborn children, and parental consanguinity should be obtained. Parents should always be closely examined, looking for evidence of a dysplasia in a partially expressed form. Because each of the skeletal dysplasias most frequently appears as a sporadic case in the family, an isolated instance of a skeletal dysplasia in a family cannot provide information on the mode of inheritance of the particular disorder. However, the type of familial aggregation, when it occurs, can be helpful. For example, if two dwarfed siblings are born to normal parents, then achondroplasia, which is an autosomal dominant trait, is unlikely, and one should suspect an autosomal recessive disorder. If two achondroplastic parents produce a severely affected offspring, it is most likely

homozygous achondroplasia, rather than thanatophoric dysplasia. However, different modes of inheritance have been observed in disorders that resemble each other clinically, such as the X-linked and certain autosomal forms of spondyloepiphyseal dysplasia. On the other hand, in some dominant disorders, a high incidence of gonadal mosaicism has been shown to account for recurrent cases in the same family. For example, in osteogenesis imperfecta

type II, gonadal mosaicism may result in a recurrence risk of 6%.

Because the skeletal dysplasias become apparent at various ages, it is helpful to obtain accurate measurements from infancy onward and, especially, to know whether the shortening was evident at birth. Although in certain disorders marked variability in expression is seen with both prenatal and postnatal onset of the disease in the same

Figure 2 Radiographs of knee (a–c) and spine (d) from patients with a variety of chondrodysplasias. a. Epiphyseal dysplasia: note the small irregular epiphyses and normal metaphyses from a patient with spondyloepiphyseal dysplasia congenita. b. Metaphyseal dysplasia: note the irregular and widened metaphyses with normal epiphyses from a patient with metaphyseal dysplasia, Schmid type.

Figure 2 Continued. c. Epimetaphyseal dysplasia: note the abnormal epiphyses and metaphyses from a patient with spondyloepimetaphyseal dysplasia, Strudwick type. d. Platyspondyly: note the flat and irregular vertebrae from a patient with spondylometaphyseal dysplasia, Kozlowski type.

family (e.g., osteogenesis imperfecta type I), this information may help limit the diagnosis to a small number of disorders. Thus, a child who was normal until 2 years of age and then developed disproportionate short-limbed dwarfism is more likely to have pseudoachondroplasia or multiple epiphyseal dysplasia than achondroplasia or spondyloepiphyseal dysplasia congenita. In some disorders, growth may be normal for several years. For instance, in the X-linked form of spondyloepiphyseal dysplasia tarda, growth retardation is not apparent until

between 5 and 10 years of age. Relative body proportions may change with age in some disorders, such as metatropic dysplasia, in which only the limbs are short at birth; because of progressive kyphoscoliosis, such patients become short-trunked during childhood.

B. Physical Examination

A detailed physical examination may disclose the correct diagnosis or point to the likely diagnostic category. It is

Table 1 Clinical, Genetic, and Radiographic Features in the Chondrodysplasias

Dysplasias	Clinical features	Radiographic features
<p>Achondroplasia group (the disorders in this group have similar radiographic changes but range from severe neonatally lethal thanatophoric dysplasia through achondroplasia to mild hypochondroplasia).</p> <p>Achondroplasia</p>	<p>AD; 80% represent new mutation; the most common skeletal dysplasia (1:25,000 births); rhizomelic shortening of limbs (recognizable at birth); final height averages 135 cm in men and 125 cm in women, with wide variability; hands are short and broad, wedge-shaped gap between third and fourth fingers (trident); lumbar gibbus in infancy usually replaced by prominent lumbar lordosis; limbs with skin folds in children; the mean head circumference follows a curve above the 97th percentile for normal individuals; achondroplasia specific curves are valuable to recognize hydrocephalus; prominent frontal bossing, hypoplasia of maxilla, mandibular prognathism; hypotonia is frequent during infancy; mental development is normal; except for patients with severe complications or sudden infant death, life span is normal; recurrent otitis media and chronic serous otitis are common and lead to conductive hearing loss in adults; overgrowth of fibula and joint laxity cause progressive genu varum; nerve root compression and spinal claudication are common complications in adults; (FGFR3 mutation)</p>	<p>Large calvaria, short base of skull, small foramen magnum (computed tomographic scan norms are available); ribs are short, cupped anteriorly; decreased lumbosacral interpedicular distance, squared off ilia, small sacroscliotic notches; limbs are short and broad; oval radiolucency in proximal femur and humerus in infancy; overgrowth of fibula</p>
Hypochondroplasia	<p>AD; recognized from 2 to 3 years of age; short-limbed (rhizomelic) short stature; there is wide variability in severity and much overlap in appearance with achondroplasia; this type of skeletal dysplasia is probably very common and easily undiagnosed in mildly short individuals; head is normal; patients are stocky and muscular; hands and feet are short and broad; mild genu varum and mild lumbar lordosis; mild mental retardation has been reported in some cases</p>	<p>Mild achondroplastic changes: skull normal or mildly enlarged; ribs are normal or slightly flared; distal lumbosacral interpedicular narrowing; long bones: rhizomelia; short wide bones; elongated fibula; prominent deltoid tubercles</p>
Thanatophoric dysplasia	<p>AD; the most common lethal type; markedly short limbs; large bulging forehead \pm cloverleaf skull; prominent eyes; small, narrowed, pear-shaped thorax; \pm congenital heart and CNS defects (FGFR3 mutation)</p>	<p>The long bones are short and bowed; metaphyseal flaring with medial spikes; severe platyspondyly; the vertebrae are hypoplastic, U-shaped on AP view; cupped and short ribs; large calvaria</p>

Table 1 Continued

Dysplasias	Clinical features	Radiographic features
Spondylodysplastic and other perinatally lethal conditions group (distinct lethal types of skeletal dysplasia)		
Achondrogenesis type IA	AR; lethal; very short limbs; short and barrel-shaped chest; extremely soft skull; round or oval face	Characterized by poor ossification of the spine, more extreme shortening of femora and other long bones; long bones have concave ends and spurs in the middle shaft; type IA (Houston-Harris) is differentiated from Achondrogenesis IB (Fraccaro) by the lack of rib fractures, appearance of the long bone, and cartilage histology
Metatropic dysplasia group		
Metatropic dysplasia	AD; normal to long in length at birth, short-limbed in infancy, becoming short trunked later with progressive kyphoscoliosis; prominent joints; tail-like sacral appendage, large head with ventriculomegaly may be present; C1/C2 subluxation is frequent and requires surgical fusion; severe cases die in infancy of RDS	Extreme platyspondyly with flattening of vertebrae and relatively large intervertebral spaces; long bones: irregularly expanded metaphyses giving barbell-like appearance; flattened and irregular epiphyses; short and broad tubular bones in hands; marked flaring of iliac crests (halberd appearance)
Short rib dysplasia (SRD) group with or without polydactyly		
Short-rib polydactyly syndrome (I, II, III)	AR; lethal, hydropic appearance, narrow thorax, severe RDS, polydactyly; in type I (Saldino Noonan) high frequency of cloacal abnormalities and postaxial polydactyly; type III is probably the mild end of type I disease; type II (Majewski) has high frequency of cleft lip and palate, multiple internal anomalies, and pre- and postaxial polydactyly	Extremely short horizontal ribs; the pelvis is small and hypoplastic in type I, whereas in II the pelvis is normal; in type I the long bones are very short with metaphyseal spurs; in type II the long bones have a more rounded appearance, especially the middle segment
Asphyxiating thoracic dysplasia (ATD) (Jeune)	AR; long narrow thorax and RDS with variable severity; \pm postaxial polydactyly; progressive nephropathy; cystic changes in kidney, liver and pancreas	Ribs are short, cupped anteriorly; square short ilia; flat acetabulum with spurs at ends (trident appearance)
Chondroectodermal dysplasia (Ellis van Creveld)	AR; narrowed thorax, short limbs, and polydactyly; often with congenital cardiac anomalies (ASD, single atrium, PDA) and ectodermal abnormalities; hypoplastic nails, natal teeth, multiple frenula, cleft lip and palate, epispadias	Ribs and pelvis are similar to ATD; acromesomelic shortening of limbs; hamate-capitate fusion
Atelosteogenesis and omdysplasia group (characterized by hypoplastic humeri or femora, absence of ossification of several bones, or ossification of what should remain cartilage)		

Table 1 Continued

Dysplasias	Clinical features	Radiographic features
Otopalatodigital syndrome type II	X-linked; characterized by distinct facies, short and broad distal segments of thumbs and toes; proportional short stature and sometimes mental retardation; facies have prominent forehead, flat nasal root, flattening of the midface and small jaw; \pm hearing defect (conductive); dislocation of radial heads and/or hips may be present	Small ilia; hypoplastic distal radius results in dislocations; wide lumbar interpedicular distance; small mandible; radiographic changes may not become apparent until later in infancy
Diastrophic dysplasia group		
Diastrophic dysplasia	AR; acute swelling of pinnae of ears in infancy; cauliflower ears; laryngomalacia; short limbed (rhizomelic), severe clubfeet, joint contractures, proximally placed abducted thumb; progressive scoliosis; there is wide variability in expression even within the same family; sulfate transporter defect (DTDST). More severe DTDST deficiency in atelosteogenesis 2 and achondrogenesis IB	Hypoplasia of epiphyses and flaring metaphyses in long bones; extracarpal bones; short and wide metacarpals and phalanges; lumbar interpedicular narrowing; C2/C3 dislocation; peritracheal, ear pinnae, and precocious costal cartilage ossification
Type II collagenopathies group (all the disorders in this group share defects in type II collagen secondary to mutations in the COL2A1 gene)		
Kniest dysplasia	AD; short trunk, progressive kyphoscoliosis; joint limitation; face is flat and round; myopia and cleft palate are common; Swiss cheese cartilage	Coronal clefts in flattened vertebrae, small ilia, increased acetabular angles; barbell-like femora as a result of broad metaphyses, delayed ossification of femoral heads, cloud effect in epiphyseal region; squared-off metacarpals and phalanges
Stickler syndrome	AD; marfanoid habitus, myopia, retinal detachment, conductive hearing loss, hyperextension of joints, may lead to joint pains and morning stiffness; cleft palate and mandibular hypoplasia. In some families, a type XI collagen defect has been found, and in a few, the disorders does not segregate with either COL2 or COL11	Mild epiphyseal dysplasia (especially proximal femur and distal tibia), degenerative arthrosis (hips), wedging of thoracic vertebrae, and Schmorl's disease of spine
Spondyloepiphyseal dysplasia (SED) congenita (Spranger-Wiedeman)	AD; evident at birth; variable severity; rhizomelic shortening of limbs, but these appear long relative to trunk; hands and feet are normal in size; clubfeet; neck is extremely short; it is important to rule out C1/C2 subluxation, which may lead to dislocation; broad barrel chest, lordosis; severe myopia, joint laxity, cleft palate, genu valgum or varum, waddling gait	Platyspondyly and epiphyseal dysplasia; delayed ossification of epiphyseal centers and the epiphyses appear irregular, fragmented, and flattened (especially femoral); coxa vara; vertebrae are ovoid in childhood but later become flat, irregular, with narrowed disk space; odontoid hypoplasia with C1/C2 subluxation

Table 1 Continued

Dysplasias	Clinical features	Radiographic features
Achondrogenesis II (Langer-Saldino) and hypochondrogenesis	AD; lethal; very short limbs; short and barrel-shaped chest; extremely soft skull; round or oval face; deficient type II and the presence of type I collagen in cartilage	In contrast to achondrogenesis type I, the long bones are straighter, relatively longer with cupping of their ends, with milder cases known as hypochondrogenesis
Spondyloepimetaphyseal dysplasias (SEMD; Strudwick type)	AD; resembles SED congenita at birth; SEMD is differentiated from SED by radiologic evidence of metaphyseal changes; Strudwick type is characterized by specific radiological changes such as peripheral “popcornlike” ossification of the femoral epiphyses, pectus carinatum, and genu valgum; type II collagen abnormalities have been documented	Delayed epiphyseal ossification, club shaped femora (first year), metaphyseal changes (>3 years), multiple epiphyseal centers in femoral heads, greater involvement of fibular and ulna than tibia and radius; platyspondyly; pear-shaped vertebrae; C1/C2 subluxation
Other spondyloepiphyseal (meta) physeal dysplasias group		
SED tarda	X-linked recessive; short stature develops in midchildhood; short limbs and short trunk; mild to severe kyphoscoliosis; large chest capacity; hands and feet are normal in size; early onset osteoarthritis in back and hips mutations in sedlin	Flat vertebrae with hump-shaped center; hypoplastic iliac wings; epiphyseal hypoplasia of large bones; premature osteoarthritis of hips
Dyggve-Melchior-Clausen dysplasia	AR; short trunk, short stature with barrel chest, lumbar lordosis, restricted joint mobility, and waddling gait; mental retardation in most cases	Changes similar to those in SED; anterior beaking of vertebral bodies; a fine lacelike ossification above the iliac crest and irregular small carpal and metacarpal bones
Multiple epiphyseal dysplasia and pseudoachondroplasia group		
Pseudoachondroplastic dysplasia	AD; short limbs, short stature usually not apparent until 2–3 years; in some patients the limb shortening is predominantly rhizomelic, in others mesomelic; hyperlaxity of joints is associated with severe varus or valgus or as a combined (“wind-swept”) deformity; the facies are characteristically attractive; all cases have been found to have mutations in COMP	Epiphyses and metaphyses of the tubular bones are involved, with platyspondyly and anterior tonguing of the vertebral bodies; acetabular irregularity, hypoplastic ischium and pubis; striking hand involvement with shortening of tubular bones, irregular metaphyses, and small round epiphyses
Multiple epiphyseal dysplasias (Fairbanks and Ribbing types)	AD; mild short stature; pain and stiffness in knees, hips, and ankles; waddling gait is common in severe Fairbanks type; osteoarthropathy of hips in mild Ribbing type—Mutations in COMP, COL9A2, and COL9A3 have been described to date	Characterized by flattened, fragmented, or irregular epiphyses (all areas, including hands and feet in Fairbanks; primarily the hips in Ribbing); earliest features may be delay in epiphyseal ossification; no metaphyseal or vertebral changes are seen; Schmorl’s nodes are common

Table 1 Continued

Dysplasias	Clinical features	Radiographic features
Chondrodysplasia punctata group (stippled epiphyses)		
Chondrodysplasia punctata (punctate epiphyseal dysplasia)	Several dysplasias (AR, rhizomelic type; XLD, Conradi-Hunerman; and XLR forms); laryngomalacia and upper airway obstruction; limbs are proximally shortened in the rhizomelic type and asymmetrically shortened in the XLD types; cataract, ichthyosis, and contractures are common; rhizomelic type is caused by a peroxisomal defect, whereas the Conradi-Hunerman form is due to a sterol metabolic defect	Stippled calcification of epiphyses, periarticular tissues, and growth plate zones; stippling of laryngeal cartilage; coronal clefts of vertebrae
Metaphyseal dysplasia group		
Metaphyseal dysplasias		
Jansen	AD; severe short stature; recognizable in early infancy; rhizomelic shortening; severe leg bowing, mandibular hypoplasia; joints are large with contractures; arms less affected than legs. Mutations in PTHRP receptor	All types are characterized by metaphyseal involvement; all metaphyses including hands and feet are severely affected but improve with age
Schmid	AD; mild to moderate short stature (130–160 cm) and bowing of legs; enlarged wrists and flaring of rib cage; coxa vara; mutations in type X collagen	Most prominent changes are in hips, shoulders, knees, ankles, and wrists
McKusick type (cartilage–hair hypoplasia)	AR; severe to moderate postnatal growth deficiency, short broad hands and loose joints; genu varum; fine, light, sparse hair and light complexion; increased susceptibility to severe varicella infection	Knees especially are involved, in contrast to Schmid; proximal femoral metaphyses are normal to mildly involved; fibula is long relative to tibia; ribs are short with anterior cupping
Others	Combination of metaphyseal abnormalities and immune deficiency can also be found in Schwachman syndrome (AR), associated with pancreatic insufficiency and chronic neutropenia; metaphyseal chondrodysplasia—thymic lymphopenia syndrome (AR); and in adenosine deaminase deficiency (AR)	
Spondylometaphyseal dysplasia group (association of vertebral changes along with metaphyseal abnormalities in the long bones)		
Spondylometaphyseal dysplasia (SMD) Kozlowski type	AD; growth retardation is usually apparent after 1–2 years; short trunk, short stature, and waddling gait develop; pectus carinatum, kyphoscoliosis, and precocious osteoarthritis; numerous other less well defined types of SMD have been described	Platyspondyly and general metaphyseal irregularities in the tubular bones; “open staircase” appearance to vertebrae on AP films; marked retardation of carpal ossification

Table 1 Continued

Dysplasias	Clinical features	Radiographic features
Mesomelic dysplasia group	Heterogeneous group characterized predominantly by shortening of the middle segments of the limbs	In all types, the bones of the forearms and shins are disproportionately shortened
Dyschondrosteosis	AD, the common type; mesomelic short stature (mild to moderate); Madelung deformity of the wrist; heterozygous mutations in SHOX gene	Hypoplasia of the distal ulna; \pm radial head dislocation (Madelung deformity)
Langer type	AR, rare, represents the homozygous form of dyschondrosteosis; severe short stature, mandibular hypoplasia; homozygous for SHOX mutation	Limb bones are short and thick; hypoplastic fibula and distal ulna
Robinow	AD; flat facial profile, mesomelic shortening, and genital hypoplasia; hypoplastic mandible and hypertelorism, flat nose, and hypoplastic nails	Madelung deformity; posterior osseous fusion of vertebrae; hemivertebrae
Nievergelt type	AD; brachydactyly and clubfeet	Rhomboid-shaped radius, ulna, tibia, fibula; radioulnar and tarsal synostosis
Rheinhardt	AD; radial bowing of hands and lateral bowing of legs	Short radius and ulna; hypoplasia of distal ulna and proximal fibula
Acromelic and acromesomelic dysplasia group (shortening of the limbs, primarily affecting the hands and feet)		
Acromesomelic dysplasia	AR; several distinct skeletal dysplasias characterized by disproportionate shortening, predominantly affecting forearms, hands, feet, and legs; recognizable at birth; trunk slightly shortened	Mild epiphyseal ossification delay; brachydactyly with cone epiphyses; hypoplasia of iliac base and irregular acetabulum; wedging of vertebrae in adults
Trichorhinophalangeal 1 (TRP) dysplasia	AD; mild disproportionate short stature, sparse hair, pear-shaped nose, medial accentuation of the eyebrows; short stubby hands; multiple joint contractures; severe genu valgum or varum; a small chromosomal deletion in 8q24.12 was shown to be the cause for all types; TRP type 1 involves a smaller deletion than in the Langer-Giedion syndrome	Numerous phalangeal cone-shaped epiphyses of the hands; Legg-Perthes-like changes occasionally occur in the hips
Pseudohypoparathyroidism (type E brachydactyly)	AD, mild short stature, marked short IV metacarpal in hand (\pm feet); \pm hypocalcemia; \pm parathyroid hormone unresponsiveness	Short IV metacarpals and metatarsals
Dysplasia with significant membranous bone involvement group		
Cleidocranial dysplasia	AD; variable expressivity; large prominent forehead, wide persistent open fontanelles, drooping shoulders, narrow chest, abnormal dentition, coxa vara and joint laxity, short and squared fingers; proportionate short stature may occur. Transcription factor defect (CFBAI)	Varying degree of hypoplasia of membranous bones; absent or hypoplastic clavicles; narrowed and high pelvis; delayed closure of the anterior fontanelle with wormian bones are characteristic

Table 1 Continued

Dysplasias	Clinical features	Radiographic features	
Bent-bone dysplasia group			
Campomelic dysplasia	AR; bending of long bones; cutaneous dimples at the site of bend; large head, 46 XY sex reversal in phenotypic females is common; some with severe RDS because of small thorax, hypoplastic tracheal rings, and other anomalies; Sox 9 mutations. Various types of short-limb bent bone dysplasias have been described (kyphomelic dysplasia) that must be differentiated	Slender bent femur and tibia; enlarged dolichocephalic skull with shallow orbits; pelvis is tall and narrow; hypoplastic ischiopubic rami, hypoplastic scapulae	
Multiple dislocations with dysplasia group			
Larsen syndrome	AD (AR?); marked hyperlaxity and multiple dislocations (especially hips, knees, elbows) are characteristic; prominent forehead, low nasal bridge, hypertelorism, and cleft uvula are common features; disproportionate short stature; the associated skeletal abnormalities and craniofacial features help to differentiate Larsen syndrome from Ehlers-Danlos syndrome	Multiple joint dislocations with secondary epiphyseal deformities; supernumerary carpal and tarsal ossification centers develop; premature fusion of the epiphyses and shaft of the first distal phalanges	
Dysplasias	Clinical features	Radiographic features	Inheritance
Dysplasias with decreased bone density group			
Osteogenesis imperfecta (defects in type I collagen as a result of mutations in either COL2A1 gene or COL1A2 gene)			
Type 1	Excessive bone fragility, blue sclerae, conductive hearing loss in adolescence, hyperlaxity of ligaments, nonprogressive aortic root dilatation (12%), most have late-onset short stature, some families with opalescent teeth	General osteopenia (especially vertebral bodies), angulation at site of previous fractures, wormian bones in skull	AD
Type 2	Lethal, low birth weight and short birth length, soft skull, beaking of the nose, hypotelorism, short and deformed limbs, thin and fragile skin; prenatal diagnosis by ultrasound, biochemical and molecular genetic studies	Extreme beading of ribs, crumpled appearance of long bones (femora), diffuse osteopenia of skull	Almost all are AD; gonadal mosaicism
Type 3	Nonlethal severe bone fragility leading to progressive deformity and marked short stature, sclerae may be blue at birth but become less blue with age, most with opalescent dentin, cardiorespiratory complications may lead to death	General osteopenia and marked deformity of bones; fractures may be present at birth, bowed long bones, progressive platyspondyly (codfish vertebrae) and kyphoscoliosis, wormian bones in skull	AD

Table 1 Continued

Dysplasias	Clinical features	Radiographic features	Inheritance
Type 4	As type 1 but with white sclerae (may be blue at birth), some families with opalescent teeth	Osteopenia, variability in severity and age of onset of fractures, multiple wormian bones of skull	AD
Disorders with defective mineralization			
Hyperphosphatasemia with osteoectasia	Onset 2–3 years, progressive painful skeletal deformity, fractures, short stature, large skull; elevation of alkaline phosphatase	Dense areas interspersed with lucent areas, generalized demineralization (juvenile Paget's disease)	AR
Hypophosphatasia congenital lethal	Disproportionate short stature at birth, bowing deformity, thin skull vault, death from respiratory distress; low serum alkaline phosphatase	Generalized poor ossification, thin ribs, hypoplastic vertebrae, splayed and frayed metaphyses	AR
Tarda	Milder, onset in childhood, bowing of legs, premature loss of teeth; reduced serum alkaline phosphatase, elevated phosphoethanolamine in the urine	As in congenital type but milder changes	AD
Hypophosphatemic rickets	X-linked hypophosphatemic rickets; bowing of legs and short stature, late dentition; low serum phosphate	Radiographic changes are those of rickets	X-linked dominant
Pseudo vitamin D deficiency rickets (VDD)			
Type 1	Defective 1 α -hydroxylation of 25-hydroxyvitamin D	As in rickets	AR
Type 2	Impaired target organ responsiveness to vitamin D	As in rickets	AR
Increased bone volume or density			
Osteopetrosis			
Precocious form	Onset in early infancy, failure to thrive, malignant hypocalcemia, anemia, thrombocytopenia, hepatosplenomegaly, optic atrophy leading to blindness, impaired bone resorption as a result of defect in maturation of osteoclasts; early bone marrow transplantation may be successful	Generalized hyperostosis at birth, "bone in bone" appearance (vertebrae), crowded marrow cavity, dense base of skull	AR
Tarda	Onset in childhood; may go undetected until adulthood; excessive fractures, mild craniofacial disproportion, mild anemia, osteonecrosis of bones (especially mandible) may develop; a distinct form with renal tubular acidosis and mental retardation has been found to be caused by a deficiency of carbonic anhydrase type 2; chromosome location: 8q22	Generalized increased density, defective metaphyseal modeling, dense base of skull	AD or AR

Table 1 Continued

Dysplasias	Clinical features	Radiographic features	Inheritance
Pycnodysostosis	Short limbs, short stature from infancy; wide anterior fontanelle, large cranium with open fontanelle, small chin, short hands and feet, increased fractures, sclerae may be blue, mutation in cathepsin K	General hyperostosis, hypoplasia of distal phalanges in hands, wide sutures, and wormian bones	AR
Dysosteosclerosis	Postnatal onset of short stature, severe hypodontia and early loss of teeth, fractures, visual and hearing loss	General hyperostosis, platyspondyly	AR
Osteopoikilosis	Commonly asymptomatic, joint pains	Numerous small osteodense foci in epiphyses and carpal centers or tubular bones	AD
Craniotubular dysplasias			
Cranio metaphyseal dysplasia	Broad osseous prominence of nasal root, bony encroachment on cranial foramina and nasal passages	Hyperostosis of skull, mandible, nasal and maxillary bones; lack of modeling of metaphyses of long bones (Ehrleinmeyer flask appearance)	AD and AR
Diaphyseal dysplasia (Camurati Engelmann)	Failure to thrive and fatigability, onset at age 4–10 years, progressive increased pain in the legs, encroachment on cranial nerves; syndactyly, enamel hypoplasia	Symmetrical fusiform enlargement of the diaphyses, normal metaphyses and epiphyses, sclerosis of anterior base of skull	AD
Craniodiaphyseal dysplasia	Flattening of nasal root in early infancy, with increasing hypertelorism, marked encroachment of cranial nerves in foramina, normal stature	Massive hyperostosis and sclerosis of the skull and face with widened shafts of tubular bones	AR
Endosteal hyperostosis and sclerosteosis	Progressive mandibular enlargement from childhood; in adults sclerotic encroachment of optic and acoustic nerves	Marked accretion of osseous tissue at the endosteal surface, fusion between carpal bones	AR and AD
Tubular stenosis (medullary stenosis)	Hypocalcemia, delayed closure of fontanelle, and early-onset myopia	Narrowing of medullary cavity caused by widening diaphyseal cortex	AD
Pachydermoperiostosis	Progressive thickening of the skin, clubbing of fingers, easy fatigability, joint pain, blepharitis, sensory hearing loss	Subperiosteal thickening of tubular bones	AD
Frontometaphyseal dysplasia	Pronounced supraorbital ridge	Prominent frontum, \pm large frontal sinuses; no hyperostosis of rest of skull; mild metaphyseal changes in long bones	X-linked dominant
Osteodysplasty (Melnick-Needles)	Abnormal gait and bowing of extremities, dislocation of hip, delayed closure of fontanelle, usually normal stature, exophthalmos, protruding cheeks, micrognathia, incurving of the distal segment of the thumbs	Uneven thickening of cortex bones, metaphyseal modeling defect, wavy ribs, narrowed iliac wings	AD (AR rare)

AR, autosomal recessive; AD, autosomal dominant; XLR, X-linked recessive; XLD, X-linked dominant; ASD, atrial septal defect; PDA, patent ductus arteriosus; CNS, central nervous system; AP, anteroposterior. RDS, respiratory distress syndrome.

For a complete listing of Skeletal Dysplasias, see The International Nomenclature of Constitutional Disorders of Bone, 1998; www.csmc.edu/genetics/skeldys/nomenclature.

essential to determine whether the shortening is proportional. In general, patients with disproportionate short stature have skeletal dysplasias, whereas those with relatively normal body proportions have endocrine, nutritional, prenatal, or other nonskeletal defects. There are exceptions to these rules: cretinism can lead to disproportionate short stature, and a variety of skeletal dysplasias, such as osteogenesis imperfecta and hypophosphatasia, may result in normal body proportions.

A disproportionate body habitus may not be readily apparent on casual physical examination. Measurements that are essential for determining whether an abnormally short individual is disproportionate include the following:

1. Upper/lower segment ratio (U/L ratio): Although sitting height is a more accurate measure of the head and trunk length, it requires special equipment for consistent accuracy. U/L segment ratio, on the other hand, provides a fairly accurate measure of body proportions and can be easily obtained. The lower segment measure is taken from the symphysis pubis to the floor at the inside of the heel, and the upper segment is obtained by subtracting the lower segment value from the total height. McKusick has published standard U/L curves for both white and black Americans that are quite useful for rapid assessment of proportion (1). For example, a normal white infant has an upper/lower segment ratio of approximately 1.7; it decreases to 1.0 at 7–10 years and then falls to an average U/L of 0.95 as an adult. Blacks, on the other hand, have relatively long limbs and have an U/L of approximately 0.85 as adults.
2. Arm span: Another index of limb versus trunk length, this measurement usually falls within a few centimeters of total height.

These measurements must be obtained before the possibility of a mild skeletal dysplasia, such as hypochondroplasia or multiple epiphyseal dysplasia, can be excluded. Short-limbed dwarfs have an abnormally high U/L ratio and an arm span that is considerably shorter than their height.

If a child has short-limbed dwarfism, it is important to determine whether all segments of the limb are equally shortened or whether the shortening primarily affects the proximal (rhizomelic), middle (mesomelic), or distal (acromelic) segment (Fig. 3).

The presence or absence of extraskeletal manifestations may be helpful in making a diagnosis. During the examination, attention should be given to the head size, facial appearance, and specific physical findings, such as myopia, cleft palate, clubfoot, hearing, joint laxity, and bone deformity. In the older child or adult, the complications associated with specific disorders may provide ad-

ditional information for making the diagnosis. For example, spinal stenosis with spinal cord claudication is characteristic of achondroplasia; odontoid hypoplasia and C1/C2 subluxation are frequently found in Morquio syndrome, spondyloepiphyseal dysplasia, and metatropic dysplasia; fibular overgrowth (and genu varum) is seen in achondroplasia and cartilage hair hypoplasia.

C. Skeletal Radiographs

A full series of skeletal views is usually required (2). These views include anteroposterior (AP), lateral, and Towne views of the skull, AP and lateral views of the spine, and AP views of the pelvis and extremities, with separate AP views of hands and feet. Lateral views of the foot are particularly helpful in identifying punctate calcifications of the calcaneus, which may be a clue to the diagnosis of the milder forms of chondrodysplasia punctata, confirming the delayed ossification of the calcaneus and talus in newborns with spondyloepiphyseal dysplasia congenita, and in delineating the double ossification centers of the calcaneus in Larsen syndrome.

Attention should be paid to the specific parts of the skeleton involved (spine, limbs, pelvis, and skull) and, within each, where the abnormality is located (epiphysis, metaphysis, diaphysis, or combination). Because the skeletal radiographic features in many of these disorders change with age, reviewing radiographs taken at different ages is helpful. Moreover, epiphyseal closure, which occurs after puberty, frequently obliterates the specific abnormalities that would have permitted a specific diagnosis to be made had the films been taken before puberty. Nevertheless, skeletal radiographs alone are often sufficient to make the diagnosis because the classification of these disorders has been based primarily on their radiographic features.

Apart from the changes in the epiphyses, diaphyses, and metaphyses, some radiographic features characterize certain disorders:

- So-called Dumbbell-shaped femur in the newborn period: metatropic dysplasia and Kniest dysplasia
- Bending of long bones (campomelia): common in campomelic dysplasia, kyphomelic dysplasias, osteogenesis imperfecta, congenital hypophosphatasia, and thanatophoric dysplasia.
- Calcified projections or spikes on lateral borders of the metaphyses of the femur: thanatophoric dysplasia, achondrogenesis, and short-rib polydactyly syndrome type I/III
- Fractures of long bones in the newborn: osteogenesis imperfecta, congenital osteopetrosis, and severe hypophosphatasia. In the older individual, fractures may also be seen in a variety of osteopetrotic syndromes, including dysosteosclerosis and pyknodysostosis.

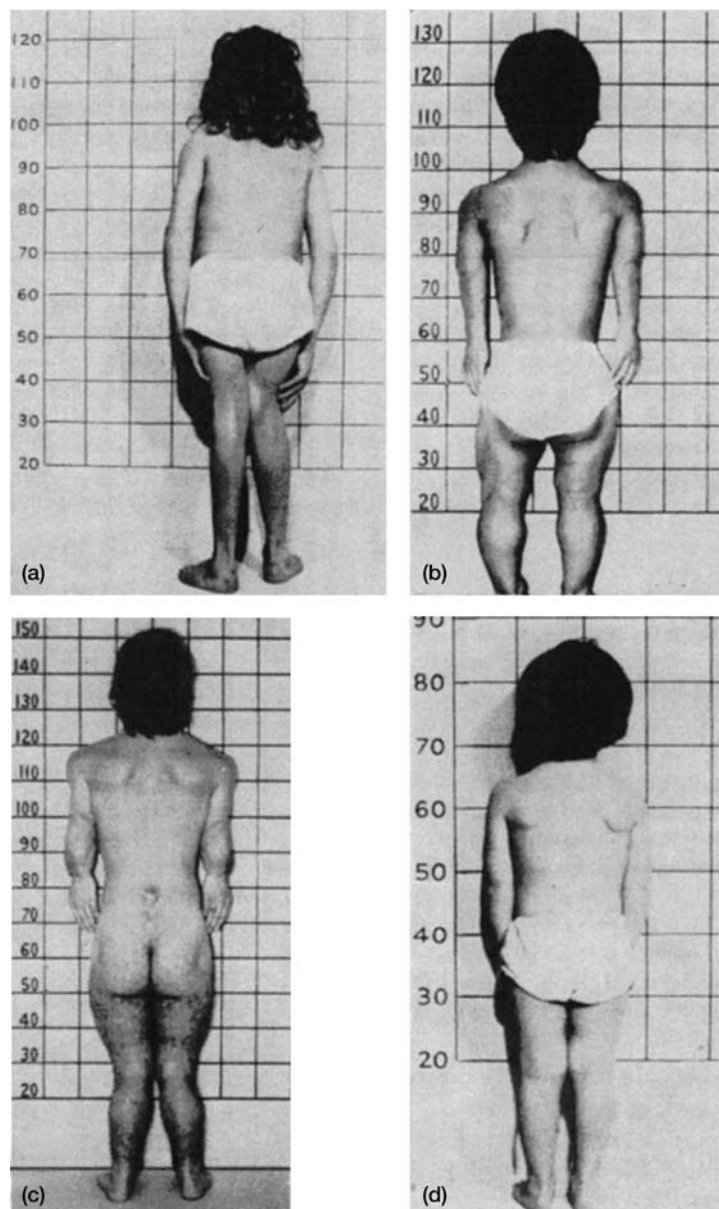

Figure 3 Different forms of disproportionate dwarfism. a. Short-trunk dwarfism in a girl with Dyggve-Melchior-Clausen syndrome. b. Short-limb dwarfism of the rhizomelic type in a boy with achondroplasia. c. Short-limb dwarfism of the mesomelic type in a boy with mesomelic dysplasia, Langer type. d. Short-limb dwarfism of the acromelic type in a girl with peripheral dysostosis.

Marked delay in epiphyseal center ossification: spondyloepiphyseal dysplasia (SED) congenita, Kniest dysplasia, and other SED and multiple epiphyseal dysplasias.

Stippled epiphyses: the chondrodysplasia punctatas, cerebrohepatorenal syndrome, warfarin-related embryopathy, and, occasionally, with chromosomal trisomy, lysosomal storage diseases, diphe-

nylhydantoin-induced embryopathy, the Smith-Lemli-Opitz syndrome, and congenital infections.

Severely shortened ribs: short-rib polydactyly syndromes, asphyxiating thoracic dysplasia, chondroectodermal dysplasia, thanatophoric dysplasias, and metatropic dysplasia.

Decreased ossification of the vertebral bodies: most severe in the achondrogenesis syndromes.

Severe platyspondyly: metatropic dysplasia, thanatophoric dysplasia (U-shaped in thoracic spine and inverted U shape in the lumbar spine), osteogenesis imperfecta type II, congenital hypophosphatasia Morquio syndrome, spondylometaphyseal dysplasia, brachyolmia, and others.

Coronal clefts of the vertebra: Kniest dysplasia, Roland-Desbuquois syndrome, Weisenbach-Zweymuller syndrome, chondrodysplasia punctata, and atelosteogenesis.

Oval translucent appearance of the proximal femora and humeri in infants: achondroplasia, thanatophoric dysplasia and hypochondroplasia.

These examples are representative of only a few of the many typical radiographic features seen in the skeletal dysplasias (see Table 1). Other radiographic differences within what is now considered a given skeletal dysplasia may be found as the complete heterogeneity of this group of disorders is delineated by results of the molecular and biochemical studies.

D. Microscopic Evaluation

Histological examination of the chondroosseous tissue can be useful in making an accurate diagnosis of several specific skeletal disorders, especially the lethal neonatal types. In certain other conditions, the pathological examination is useful in ruling out a diagnosis. (A protocol for the collection of skeletal tissues can be found in Sec. VII.)

On morphological grounds, the chondrodysplasias can be broadly classified into the following disorders:

1. Minimal or no qualitative abnormality in endochondral ossification: achondroplasia and hypochondroplasia (in which abnormalities in the height and arrangement of proliferative columns, particularly in the center of the large growth plates, are the only changes).
2. Abnormalities mainly in cellular morphology: large chondrocytes, containing prominent inclusions; for example, achondrogenesis IA, pseudoachondroplasia, and certain SEDs; sparse matrix with collagen rings around the chondrocytes as in diastrophic dysplasia and achondrogenesis IB. Dilatation of the chondrocyte rough endoplasmic reticulum (RER): for example, the SEDs, pseudoachondroplasia, and Kniest dysplasia. Thus dilatation of the RER is not a diagnostic finding, although it suggests defective synthesis or abnormal processing of a matrix protein in these conditions.
3. Abnormalities in matrix morphology: areas of cell degeneration with wide collagen fibrils, scar formation, and intracartilaginous ossification: diastrophic dysplasia. So-called Swiss-cheese appearance of cartilage: Kniest dysplasia. Large lacunae containing numerous chondro-

cytes: Dyggve-Melchior-Clausen syndrome. Areas of dystrophic ossification, fibrous dysplasia, and fat deposition in the reserve zone cartilage of the matrix: chondrodysplasia punctata. Wide interwoven connective septa in epiphyseal cartilage and basal zone: fibrochondrogenesis.

4. Abnormalities primarily localized to the area of chondroosseous transformation: reduced and disorganized columnization: thanatophoric dysplasia, short-rib polydactyly syndromes. Broad matrix septa surrounding clusters of hypertrophic cells: the metaphyseal dysplasias, opsismodysplasia.

E. Biochemical Studies

Great progress has been made in recent years in our knowledge about the biochemical defect involved in certain of the skeletal dysplasias. These findings may help us to understand the basic biology of the normal bone and provide us with new means for prenatal diagnosis and treatment.

F. Molecular Studies

Significant developments in the field of molecular genetics have allowed mapping and identification of the genes causing many of the skeletal dysplasias (3–5). The specific gene defects that produce skeletal dysplasias can be classified into several distinct pathogenetic categories: *Abnormalities in the structural proteins of cartilage*, including collagens type II, IX, X and XI and cartilage oligomeric matrix protein (COMP); *inborn errors of cartilage metabolism*, including the diastrophic dysplasia sulfate transport (DTDST) disorders, arylsulfatase E, lysosomal enzymes, and cathepsin K; *local regulators of cartilage growth*, such as fibroblast growth factor receptor (FGFR3) and parathyroid hormone receptor protein; *systemic defects influencing cartilage*, including adenosine deaminase deficiency, peroxisomal enzyme deficiencies, and phosphoadenosine-phosphosulfate synthetase (PAPS); *transcription factor mutations*, such as CBFA1, CDMP1, Sox9, Lmx1b, SHOX; *tumor suppressor genes*, as in the multiple exostoses; and *signal protein inactivators*, such as Noggin.

The emerging data of the last few years outlining the molecular basis of skeletal dysplasias has been instructive in several respects. For example, phenotypically distinct entities have been found to be allelic variants, with mutations in the same gene (e.g., achondroplasia, hypochondroplasia, thanatophoric dysplasia, and certain craniosynostotic syndromes). On the other hand, certain dysplasias have been found to be due to mutations in different genes (e.g., multiple epiphyseal dysplasia with mutations in cartilage oligomeric matrix protein or type IX collagen); and Stickler syndrome, with mutations in type II and type XI collagen. In most of the conditions in

which the molecular basis has been defined, numerous different mutations are described. Consequently, diagnosis by DNA analysis is difficult, unless the distinct mutation in the family has been defined, or expensive sequencing of the entire gene is performed. Chip technology will eventually solve this problem. Achondroplasia is unusual in that over 98% of the cases are due to a single mutation, making an inexpensive molecular diagnostic test possible.

V. PRENATAL DIAGNOSIS

Many of the skeletal dysplasias manifest in the prenatal period and can be identified by prenatal ultrasound. The great majority of cases, however, occur for the first time in a family and are thus unsuspected and picked up by routine ultrasonography by measurement of femur length. This is true for both dominant disorders such as thanatophoric dysplasia and spondyloepiphyseal dysplasia congenita and for recessive disorders such as diastrophic dysplasia and cartilage hair hypoplasia. Many of these disorders will manifest shortening of the extremities by as early as 13–16 weeks, but in achondroplasia femoral shortening may not be evident until the late second trimester (2). Of course, disorders that do not present in the newborn period cannot be detected by prenatal ultrasound.

Retrospective analysis (7) in 250 cases revealed that the accuracy in diagnosis in 250 cases referred to the International Skeletal Dysplasia Registry at Cedars–Sinai Medical Center (www.csmc.edu/genetics/skeldys) was approximately 30%. Further retrospective analysis of accuracy of prenatal diagnosis in 1000 cases referred to the Registry (1990–2000) indicated that a correct referring diagnosis was made in 37% of the cases, but in over 60% of the cases either an incorrect diagnosis or no diagnosis was made (8). Analysis of this 1000 case cohort showed that the most common diagnoses were osteogenesis imperfecta type II (20%), thanatophoria (11%), and achondrogenesis II (8.2%). The other 37% of cases were specific skeletal dysplasias, 12% were syndromes, and 5% were nonskeletal dysplasias and probably represented early-onset intrauterine growth retardation. In 4.5% of the referred cases, radiographs or histological examination could not make a specific diagnosis. With the increasing use of prenatal ultrasound, increasing numbers of skeletal dysplasia cases are recognized by ultrasound. However, the above data show that prenatal ultrasound parameters need to be defined for a more accurate prenatal diagnosis of the skeletal dysplasias.

With the explosion of knowledge concerning the basic molecular defect in the skeletal dysplasias, prenatal diagnosis by mutation detection in amniocytes or chorionic villous cells can be accomplished if the exact mutation is known in a previously affected child, since most of these disorders are due to private mutations in the same gene. Linkage analysis can be used in families with multiple affected members, even if the specific mutation is

not known. In achondroplasia, in which almost all cases share the same mutation, molecular diagnosis can be readily accomplished by sequence analysis or restriction fragment polymorphism. This is especially valuable when both parents are achondroplasts and want to rule out the 25% possibility of the fetus being a lethal homozygote.

VI. MANAGEMENT

Effective management requires precise diagnosis, prompt recognition of specific skeletal and nonskeletal complications, appropriate orthopedic and rehabilitative care, emotional support and psychosocial counseling, and genetic counseling. There is no specific cure for any of these conditions.

Orthopedic management aims at maximizing mobility and correcting deformity; if deformities in the lower limbs are left uncorrected beyond puberty, early onset of osteoarthritis may lead to mechanically unsound joints. Early recognition of spinal deformity and its early treatment with bracing or surgical intervention may reduce morbidity (from scoliosis) in adult life.

VII. EXTENDED LIMB LENGTHENING

Extended limb lengthening was first developed for the treatment of leg length discrepancy and later became utilized bilaterally for increasing the height of dwarfed individuals. The original techniques involved osteotomies involving the periosteum and distraction of the broken ends, the gap being filled in with bone grafts and stabilized with hardware, which was subsequently removed. Serious complications including osteomyelitis, hypertension, nerve and vascular damage frequently followed. The Siberian orthopedist Ilizarov developed a new technique, which involved percutaneous breaks in the bone with the periosteum remaining intact. He developed a new circular fixator–distractor, but the secret to his success was the subperiosteal break, leaving nerve and blood supply intact and the extremely slow rate of distraction. Up to 6 inches of new bone could be achieved in each of the limb segments, allowing many dwarfs to enter normal growth curves.

Over the last 20 years a number of other techniques have been developed, which all involve percutaneous osteotomies of the metaphases or diaphyses of the long bones, the insertion of screws and wires above and below the fracture line, and the attachment of an external telescoping fixator. The device is then turned several times a day, extending the fracture gap by about 1 cm/day. When the desired increase in length is attained, the distraction is stopped and the callus allowed to consolidate. When consolidation is complete, the device and pins are removed. There is a substantial recovery time requiring active physical therapy, as the muscles become stretched and weak. The different techniques vary in the type of dis-

tractor, whether pins or wires are used, and which bones are extended simultaneously and in what sequence. If using the large circular Ilizarov distractors, both femurs cannot be done simultaneously, and either both segments of one leg or a contralateral femur and tibia are done simultaneously. If one has to stop before the entire process is completed, significant asymmetry will result. If one uses a linear fixator and pins, both tibias can be done simultaneously, followed by both femurs. The humeri are frequently lengthened by 4 inches between doing the two leg segments.

All patients experience one or more complications during this prolonged lengthening process, including pin tract infections; malunion; delayed consolidation; varus or valgus deviations; joint contractures or dislocations; and muscle, nerve, and vascular damage. We have used the Vilarrubias technique, which utilizes a linear Wagner fixator with two large screws on each side of the break and simultaneous lengthening of the tibias followed by the humeri and then the femurs. Tendonotomies of the Achilles tendon and flexors and the hips are also performed, allowing plantar flexion of the foot and a marked decrease in the lumbar lordosis. We believe that the latter will significantly increase spinal canal volume, and thereby, we hope, prevent or decrease the spinal claudication that most achondroplastic dwarfs experience.

By using a team approach of orthopedists, geneticists, psychologists, physical therapists, and other specialists, and carefully monitoring nerve conduction and blood flow, one can minimize the complications. We do not start limb lengthening in dwarfed children until they are at least 13 years of age. We believe that it should be the child and not the parents who make the decision to undergo this prolonged, inconvenient, and complication-ridden procedure. Achondroplastic dwarfs are excellent candidates for ELL since only their limbs are short and they have excessive soft tissues, with joint laxity and tortuous vessels and nerves. The procedure has also been done in a variety of other forms of short limb dwarfism and the tibias alone have been modified in patients with Turner's syndrome. It is not recommended for patients with short trunks or proportionate short stature.

VIII. GROWTH HORMONE THERAPY IN ACHONDROPLASIA

The use of recombinant growth hormone therapy for achondroplasia has been evaluated by several centers in relatively short-term trials. In most of the trials, there is a statistically significant increase in predicted growth rate in the first year of treatment (9). However, this trend of increased growth velocity decreases in the second year of treatment and thereafter. If the data are extrapolated for a prolonged period of treatment, it appears that the increase in final height in these patients will be only a few centimeters above predicted, and will not result in a significant

increase in final height. No studies have pursued multiyear trials. Furthermore, several studies have shown great individual variability in responsiveness in these patients. This data is not dissimilar to the data describing human growth hormone (hGH) treatment in Turner syndrome. Some Turner syndrome patients have had a statistically significant increase in growth velocity with prolonged treatment, while others do not respond. We have conducted a long-term follow-up on our 2 year hGH-treated achondroplasia patients, who were then left untreated for up to 8 years. Although these patients demonstrated an increase in growth velocity during treatment during the first year of therapy, long-term evaluation showed no significant change in height from pretreatment predicted height. Multiyear trials must be conducted to document whether any long-term benefits could take place. The data suggesting a decrease in responsiveness to hGH over time bring up the question of whether performing pulsatile therapy (e.g., treatment for 2 years, off for a year) and whether continuation of this cycle will replicate the increase in growth velocity seen in the first year of treatment. The pertinent issue is whether this treatment can produce a clinically relevant increase in height. Only a few studies with a limited number of patients have been performed in hypochondroplasia with variable results. Furthermore, these studies were not performed on patients with a documented molecular defect in FGFR3, which may complicate the interpretation of the responsiveness, since hypochondroplasia is genetically heterogeneous. Growth hormone trials on only a few patients with other less common skeletal dysplasias have been conducted, and there are not sufficient available data to conclude whether there is a treatment benefit. However, in view of the increased predisposition to malignancy in cartilage-hair hypoplasia, we believe that growth hormone therapy should not be attempted in this condition.

IX. COLLECTION OF SKELETAL TISSUES

A variety of histological, histochemical, immunohistochemical, ultrastructural, and biochemical studies of chondroosseous tissue and skin can be performed. Specimens can be sent to one of the laboratories that specialize in processing and interpreting tissue from the skeletal dysplasias (e.g., The International Skeletal Dysplasia Registry, Cedars-Sinai Medical Center, Los Angeles, CA). Protocols for collection of samples and discretions for obtaining informed consent and shipping can be found on its website: www.csmc.edu/genetics/skeldys.

ACKNOWLEDGMENTS

We thank Drs. Deborah Krakow, Bill Wilcox, and Dan Cohn for their helpful comments. This work was supported by an NIH Program Project Grant (HD 22657). The International Skeletal Dysplasia Registry can be accessed at www.csmc.edu/genetics/skeldys.

Tall Stature and Excessive Growth Syndromes

S. Douglas Frasier

UCLA School of Medicine, Los Angeles, California, U.S.A.

Tall stature and excessive growth syndromes are relatively rare concerns in pediatric and pediatric endocrine practice. Nevertheless, an important group of pathological conditions and variants in the pattern of normal growth and development is first brought to the physician's attention by these complaints. The causes of excessive growth that are important in children and adolescents are shown in Table 1. This chapter considers growth syndromes and disorders of importance to pediatric endocrinologists, including constitutional tall stature. However, disorders of sexual maturation are discussed elsewhere in this book.

I. DEFINITION AND CLASSIFICATION OF OVERGROWTH SYNDROMES

Overgrowth syndromes can be classified into three categories:

1. Generalized overgrowth syndromes
2. Regional overgrowth syndromes
3. Parameter-specific growth overgrowth disorders

Generalized overgrowth syndromes, which include the classic overgrowth conditions, are those in which all or most parameters of growth and physical development are in excess of 2 standard deviations above the mean for the person's age and gender. Some of the classic conditions in this category are listed in Table 1 and are discussed in detail in this chapter. The regional overgrowth disorders include those in which excessive growth is confined to one or a few regions of the body. An example is benign familial macrocephaly and hemihyperplasia or hemihypertrophy, among others. There are also parameter-specific overgrowth disorders in which a single or at most several growth parameters are in excess of normal. For example, familial idiopathic obesity and Prader-Willi Syndrome are examples in this category.

The incidence of each overgrowth syndrome or disorder varies greatly, from being as common as 1:1000–

1500 as occurs with the fragile x syndrome, to less than 1:1,000,000 births in other more rare syndromes such as Elejalde syndrome, a striking prenatal overgrowth syndrome that has been reported in only three siblings. The reader is referred to volume 1, number 10 of *Growth, Genetics and Hormones* (March, 1994) which published two very good reviews of overgrowth syndromes, including their causes and diagnosis.

II. GROWTH HORMONE EXCESS

As recently reviewed (1, 2) and as exemplified by several representative reports (3–10), growth hormone excess, although rare, must be considered as a cause of tall stature and rapid growth in all patients with this clinical picture.

A. Causes and Pathogenesis

Excessive growth hormone secretion is most often a primary disorder and is associated with a functioning pituitary adenoma. If growth hormone excess is present, the pituitary tumor, regardless of its staining characteristics, contains typical growth-hormone-secretory granules. Occasionally, the tumor secretes excess prolactin in addition to growth hormone (11–13) and prolactin-secretory granules are also demonstrated. Growth hormone excess is usually present as an isolated abnormality, but associations occur with McCune-Albright syndrome (14–17), tuberous sclerosis (18) neurofibromatosis (19, 20), and optic chiasm glioma (20, 21).

As with all functioning endocrine tumors, the specific pathogenesis of growth-hormone-secreting adenomas is not completely understood. In some patients, the excess growth hormone (GH) secretion and adenoma formation may be secondary to unrestrained stimulation of the somatotrophs by growth-hormone-releasing hormone (22–24). Impaired somatostatin (somatotropin release-inhibiting factor; SRIF) secretion is also a theoretical pathogenic

consideration (19–21). Various mutations in the gene for the alpha subunit of the stimulatory G protein, which increases cyclic AMP formation, have been demonstrated in growth-hormone-secreting pituitary adenomas (25–27). These putative oncogenes may cause somatotropin hyperplasia and the development of an adenoma through the unrestrained production of cyclic AMP, which leads to an increase in both cell growth and cell function. Specific constitutive G protein alpha gene mutations have been demonstrated in patients with McCune-Albright syndrome and pituitary adenoma (28, 29). Recently, a loss in heterozygosity for a tumor suppressor gene at the 11q13 locus has been described in both isolated familial GH-secreting pituitary adenomas and in similar tumors in families with the multiple endocrine neoplasia (MEN type 1) syndrome (30, 31).

B. Clinical Manifestations

Growth hormone excess leads to either gigantism or acromegaly, depending on whether the epiphyses are open or closed. Typically, gigantism occurs in young children and acromegaly is seen in adults. The adolescent who still has open epiphyses shows a mixed picture of rapid growth and acromegalic features, termed acromegalic gigantism (Fig. 1).

Young patients with excess growth hormone secretion are both tall and grow at a rate greater than normal for their age. Their growth curve progressively deviates away from normal. When growth hormone excess begins during adolescence, there is enlargement of the lower jaw, hands, and feet in addition to the rapid increase in height.

In rare cases, this clinical picture may be imitated by the syndrome of pseudoacromegaly or acromegaloidism, in which growth hormone secretion is normal but other non-growth-hormone-dependent growth factors may be present in excess (32).

Figure 1 A 17-6/12-year-old boy with growth hormone excess due to a pituitary adenoma. Height was 193 cm and weight was 108.3 kg. (From Frasier SD, Pediatric Endocrinology. New York: Grune and Stratton Inc., 1980.)

Expanding adenomas may interfere with the secretion of one or more pituitary trophic hormones. Thus, a growth-hormone-secreting adenoma may be associated with gonadotropin deficiency leading to delayed or arrested puberty and, less often, adrenocorticotropic (ACTH) and/or thyroid-stimulating hormone (TSH) deficiency. When there is combined growth hormone excess and gonadotropin deficiency, patients may show both excessive growth and eunuchoid body proportions.

Impaired vision and visual field abnormalities may accompany growth hormone excess. The characteristic abnormality is bitemporal homonymous hemianopsia (so-called tunnel vision) because of midline compression of the optic chiasm. However, a wide variety of visual field defects may be produced depending on the size and location of the tumor. Expanding intrasellar tumors may also lead to increased intracranial pressure and/or symptoms of hypothalamic dysfunction.

C. Diagnosis

The clinical diagnosis of growth hormone excess is confirmed by demonstrating an elevated serum concentration of growth hormone that is not suppressed by raising the concentration of blood glucose during performance of a standard glucose tolerance test. The administration of glucose by mouth in a dosage of 1.75 g/kg, up to a maximum of 100 g, will raise the blood glucose concentration to a level that will suppress the serum GH concentration to less than 5 ng/ml in normal persons. The lowest concentration of GH is seen between 60 and 120 min after the ingestion of glucose. Failure to suppress the serum concentration of GH supports the diagnosis of growth hormone excess due to hypothalamic or pituitary dysfunction (4). Confirmation of the diagnosis is also aided by demonstrating an elevated serum somatomedin-C (IGF-1) concentration (33). The level of growth hormone activity may be better correlated with the somatomedin-C concentration than with the concentration of growth hormone after glucose suppression.

In at least 25% of patients there is glucose intolerance and hyperinsulinism. Failure to increase the serum concentration of growth hormone above the already elevated levels in response to hypoglycemia and relative resistance to the hypoglycemic effects of exogenous insulin are also present.

When growth hormone excess is confirmed, the possibility of pituitary trophic hormone deficiencies should be investigated by performing standard tests of pituitary function.

Complete neuroradiological studies aimed at demonstrating the size and location of the pituitary adenoma are essential in planning therapy. A number of studies have been recommended in the past: these have included skull films, cone-down views of the sella turcica, sellar polytomography, computed tomography (CT), and magnetic resonance imaging (MRI). MRI with and without gadolinium contrast is the preferred modern technology.

D. Treatment

Treatment is directed at eliminating excess growth hormone secretion (34). In the past, this has meant destruction of the tumor, and a number of ablative techniques have been employed. Radiation from an external source is the least effective. Transsphenoidal microsurgery appears to offer the best possibility of complete removal of the tumor with preservation of remaining pituitary function. This technique is particularly useful when small tumors without extrasellar extension are the source of excess GH secretion (35). When the tumor is too large for this approach, a craniotomy with direct visualization and removal of the tumor must be performed.

There has been significant progress in the pharmacological management of growth hormone excess with the dopamine receptor agonist, bromocriptine, and with ana-

logs of somatostatin, octreotide, and lantreotide. Bromocriptine inhibits the secretion of both growth hormone and prolactin through direct effects on the pituitary. There is also evidence indicating an inhibitory effect on cell growth leading to a decrease in the size of some pituitary tumors. This agent has been used successfully in several children with growth hormone excess (36, 37). In these patients excess growth hormone secretion was partially inhibited and associated excess prolactin secretion was abolished. There was significant clinical improvement, even though the suppression of GH secretion was incomplete. Between 10 and 20 mg/day of bromocriptine was therapeutic and no significant side effects were observed.

Somatostatin is a potent inhibitor of growth hormone secretion initially isolated from the hypothalamus. Although native somatostatin inhibits GH secretion in acromegaly, its effect is very short lived and somatostatin administration has variable undesirable effects on glucose metabolism. The somatostatin analog octreotide, which may be given every 6–8 h and has relatively little effect on insulin secretion, has been found useful in the management of GH excess. This agent has now been administered to pediatric patients with growth-hormone-producing tumors (38–40). Effective dosages were 50–100 μ g given every 6–8 h. Side effects have been minimal and both growth hormone secretion and pituitary tumor size have decreased significantly in response to octreotide administration.

Recent studies in adults with acromegaly have indicated that lantreotide, a long-acting somatostatin analog that can be given every 10–14 days (41), and a very-long-acting formulation of octreotide that can be given every 4 weeks (42) are both effective and safe as treatment for growth hormone excess. Studies in pediatric patients have not yet been reported.

E. PROGNOSIS

The rarity of growth hormone excess and the relatively recent application of transsphenoidal surgery and medical suppression of growth hormone secretion make generalizations regarding the prognosis of GH excess in children and adolescents difficult. However, a report from Manchester, England (43), describes the serious physical and psychological disability observed in 10 untreated or partially treated patients. Marked skeletal deformity and psychological problems were common. More aggressive therapy and current methods of management may improve this poor outcome.

III. CEREBRAL GIGANTISM (SOTOS SYNDROME)

Cerebral gigantism is a clinical syndrome of rapid growth in infancy, dysmorphic features, and a nonprogressive neurological disorder first described by Sotos and others

in 1964 (44). Since this initial description more than 250 patients have been reported in numerous case reports and in several reviews (45–48).

A. Causes and Pathogenesis

The underlying cause(s) of cerebral gigantism are not understood. Although most instances of this syndrome are sporadic, there have been reports of familial occurrence and dominant inheritance has been suggested in several families (48). In addition, there have been reports of the syndrome in first cousins, siblings in a highly inbred family, and monozygotic twins (46), suggesting the possibility of recessive inheritance. One report identified fragile X chromosomes in two affected patients (49), but this appears to be a fortuitous association. These data clearly suggest genetic heterogeneity as well as clinical heterogeneity in cerebral gigantism and make a single cause unlikely.

The constellation of abnormalities suggests hypothalamic dysfunction, but no specific neuropathological lesions have been identified (50). Extensive investigation has not shown any consistent abnormality of growth hormone secretion or IGF-I or IGF-II concentrations. Other abnormal growth factors may be present, but they have not yet been identified.

B. Clinical Manifestations

The major clinical manifestations of cerebral gigantism are listed in Table 2. Patients are large at birth, both in weight and length (47), and growth is rapid during the first year. By 1 year of age most patients are above the 97th percentile height for age and gender. Growth velocity also exceeds the 97th percentile. Rapid growth continues for the first 3–4 years (Fig. 2). Body proportions are abnormal, with arm span exceeding height by as much as 5 cm. This difference is normally negative up to age 12 and only exceeds 2 cm in young men older than 13 or 14 years (45).

Fine motor control is impaired in infancy and early childhood and developmental milestones are delayed. Intellectual impairment is mild to moderate and median IQ score is 70–75 (45, 51). The neonatal period is characterized by irritability and feeding problems in addition to large size.

The bone age is generally advanced between 1 and 2 years. Mildly dilated cerebral ventricles are present in the majority of patients when they are studied by pneumoencephalography or CT scanning.

C. Diagnosis

The diagnosis depends on the characteristic clinical picture. There are no definitive physical findings and no specific laboratory results. As yet no characteristic mutations have been described in this group of patients. Other causes

Table 2 Clinical Manifestations of Cerebral Gigantism

Clinical sign/symptom	% of cases
Gigantism	100

Feeding problems	44

Figure 2 A 4-9/12-year-old girl with cerebral gigantism. Height was 55.7 cm (height age, 11-9/12) and weight was 33.7 kg (weight age, 10-10/12). Developmental level was 3–3-6/12 years. (Courtesy of Juan F. Sotos M.D., Children's Hospital, Columbus, Ohio.)

of overgrowth and mental retardation, such as fragile X syndrome and Marfan syndrome, need to be excluded.

D. Treatment

Treatment is directed at improving the level of motor and intellectual function, as with any child who manifests developmental delay and intellectual handicap. Modification of ultimate height might be considered under very unusual circumstances (see below).

E. Prognosis

The prognosis for normal adult intellectual function is poor even in the best of circumstances. A recent study evaluated 20 male and 20 female patients with Sotos syndrome to their ultimate height (52). The mean adult height in men was 183.4 (standard deviation [SD] 6.0) cm and the mean adult height in women was 172 (SD 5.7) cm. The average height achieved was not excessive and these data would point away from any need to attempt modification of height with hormonal therapy.

Concern has been expressed that patients with cerebral gigantism may be particularly susceptible to the development of tumors (48, 53). This may represent another facet of growth without proper control that may be the basic mechanism underlying this and other overgrowth syndromes.

IV. KLINEFELTER SYNDROME

Klinefelter syndrome is a relatively common abnormality in phenotypic males, occurring in 1:500–1000 live male births (54–56). Although it may present in a variety of different ways, tall stature is a frequent finding in both children and adolescents.

A. Causes and Pathogenesis

Klinefelter syndrome is due to an abnormality in chromosome number in which two or more X chromosomes are present in male patients. By far the most usual abnormal karyotype is 47 XXY. However, mosaic karyotypes such as XY/XXY have also been described, as have other aneuploid karyotypes such as 48 XXXY or 49 XXXXY. The presence of one or more extra X chromosomes is associated with testicular failure, which results in infertility and impaired testosterone production. The testes show hyalinization and fibrosis of the seminiferous tubules with histologically intact interstitial cells.

B. Clinical Manifestations

Klinefelter syndrome is infrequently diagnosed in prepubertal children. However, the increased frequency of amniocentesis has led to a number of fetal diagnoses. Several clinical clues point to this diagnosis in childhood and

should lead to appropriate laboratory evaluation (54). Prepubertal boys with an extra X chromosome are often tall for their age. Body proportions are often abnormal, with relatively long legs reflected in a low upper/lower segment ratio. Patients tend to be thin and underweight for their height and age. Genital abnormalities such as small phallus, hypospadias, and cryptorchidism may be present. Although the testes are often normal in size prior to puberty, they are abnormally small (<2 ml in volume) in a few patients. The major means of revealing Klinefelter syndrome before puberty is studying boys with mental retardation or school and/or behavior difficulties. Learning and psychological problems are common in this group of children.

Adolescent patients with Klinefelter syndrome are usually taller than expected for their age and have abnormal proportions with persistent increased leg length (57). The testes are disproportionately small for the level of pubertal development. Testicular maturation begins with the onset of puberty but regresses by midadolescence and testicular volume rarely exceeds 2–3 ml. Testicular length is generally below 2.0 cm. The testes are usually firm and show diminished sensitivity to pressure. Androgen function is initially preserved and almost all boys enter puberty. Penile and pubic hair development are generally satisfactory. However, oligospermia or aspermia is uniformly present. Adolescent development may be delayed and impotence or other problems of sexual function may develop (57–59).

Gynecomastia is common. This begins as simple adolescent breast enlargement but is often marked and persistent. It is frequently the reason that patients seek medical advice and is very distressing to most.

As a group, patients with Klinefelter syndrome have lower than expected verbal IQ scores and a significant increase in learning, behavioral, and psychosocial problems (60, 61).

C. Diagnosis

The clinical picture of tall stature, gynecomastia, and small testes in a male with adequate secondary sex characteristics is often diagnostic. The clinical diagnosis of Klinefelter syndrome is confirmed by the demonstration of one or more extra X chromosomes in the karyotype. Primary gonadal failure is reflected in elevated serum concentrations of pituitary gonadotropins. Although levels of both luteinizing hormone (LH) and follicle-stimulating hormone (FSH) are elevated, the major increase is in FSH (58, 59). Testosterone concentrations are variable but usually in the low–normal adult male range (58). Average concentrations are clearly below those seen in normal adolescent boys (57).

D. Treatment

The administration of testosterone may be helpful when adolescent development is delayed or when sexual func-

tion is impaired. Full replacement therapy with 200–400 mg long-acting, intramuscular testosterone every 3 or 4 weeks should be given to restore serum testosterone concentrations to the normal range. Gynecomastia may require surgical therapy with simple mammoplasty using a circumareolar incision.

E. Prognosis

Although some patients function normally, impaired intellectual function and psychosocial difficulties persist in a significant number (62). Sexual function may be impaired. A recent study of cancer risk in patients with Klinefelter syndrome found an increased incidence of mediastinal germ cell tumors during adolescence and young adulthood (63). Impaired fertility has been managed by the use of donor sperm and artificial insemination of wives of Klinefelter syndrome patients (62), and by the ingenious in-vitro fertilization technique of intracytoplasmic injection into the wife's ova of sperm extracted from the testes of affected men (64).

V. XYY SYNDROME

The presence of an extra Y chromosome also predisposes to tall stature (60, 65). Males with the XYY syndrome are relatively common in the general population. Newborn screening studies indicate an incidence of between 1:500 and 1:1000 live male birth (55, 56). There is no uniform phenotypic expression of this abnormal karyotype, but the incidence is much higher when males whose height exceeds 183 cm (72") are screened.

In addition to tall stature there appear to be few phenotypic expressions of the XYY syndrome. Those described include severe acne, hypospadias and/or cryptorchidism, radioulnar synostosis, and mild or moderate mental retardation (60, 61, 66, 67). The finding of an XYY karyotype in a newborn does not necessarily predict intellectual function or behavior. Generalizations cannot be made regarding the correlation between karyotype and behavioral phenotype (60, 62).

VI. MARFAN SYNDROME

Marfan syndrome is a heritable disorder of connective tissue in which tall stature is one of a spectrum of abnormalities that lead to significant morbidity and early mortality.

A. Causes and Pathogenesis

Marfan syndrome is an autosomal dominant disorder. In 65–75% of patients one parent is affected and sporadic new mutations account for 25–35% of patients. There is a 50% recurrence risk in the offspring of affected individuals. Although the degree of expression and severity of

clinical features may vary from family to family, involvement in a particular individual cannot be predicted from knowledge of the family history.

Marfan syndrome is caused by mutations in the fibrillin gene located on chromosome 15 (68–71). The affected gene product, fibrillin, a 350 kD glycoprotein, is a structural component of a microfibril, the elastin-associated microfibril, found in the extracellular matrix of connective tissue. Patients with Marfan syndrome have a deficiency of elastin-associated microfibrils, which leads to the syndrome's clinical manifestations (72, 73).

B. Clinical Manifestations

A complex constellation of abnormalities characterize Marfan syndrome. As shown in Table 3, skeletal, ocular, and cardiovascular systems are involved (48, 74, 75).

Height is increased and body proportions are abnormal. Both arm and leg length are greater than normal so that arm span is significantly greater than height and the upper/lower segment ratio is diminished. Arachnodactyly (long fingers and toes) is seen in the majority of patients. There is often a pectus excavatum chest deformity and scoliosis is common. The joints are hyperextensible and lax.

Ocular abnormalities are extremely common. The cornea is flat and congenital subluxation of the lens with upward displacement is frequently present. The ability to accommodate is retained. Refractive errors, particularly myopia, are present in many patients. Retinal detachment is a common complication.

The shortened life span of patients with Marfan syndrome is due to its cardiovascular manifestations. The combination of physical examination and echocardiography shows some abnormality in almost all patients. Both aortic and mitral regurgitation are present. Aortic

Table 3 Clinical Manifestations of Marfan Syndrome

Skeletal

Myopia
Retinal detachment
Cardiovascular
Diffuse aortic aneurysm
Dissecting aortic aneurysm
Mitral regurgitation

root dilatation is seen relatively early when sophisticated diagnostic tools are employed. Aortic regurgitation, dissection, and rupture are major life-threatening complications (76).

C. Diagnosis

The characteristic familial, musculoskeletal, ocular, and cardiovascular manifestations of Marfan syndrome are usually diagnostic. Specific molecular diagnosis, while possible, is not yet generally available. Careful measurements including assessment of body proportions, ocular examination including slit lamp evaluation, and cardiovascular studies including echocardiography should allow the clinician to make the correct diagnosis once it is considered to be a possibility.

D. Treatment

There is no specific treatment, but several approaches may reduce the morbidity and perhaps even the mortality of patients with Marfan syndrome (75). Early recognition and correction of a refractive error will prevent the amblyopia that often limits vision. Prevention or correction of scoliosis and repair of the pectus deformity may be very helpful.

When significant aortic regurgitation is noted, an aortic valve prosthesis may be utilized. Progressive aortic dilatation may be managed by graft placement. Attempts have been made to limit progression of aortic dilatation by administering propranolol or other beta-adrenergic blocking agent. Theoretically, this will decrease left ventricular ejection impulse and protect the aortic root from a maximal exposure to left ventricular pressure. It remains to be seen whether such therapy is effective.

E. Prognosis

The life expectancy of patients with Marfan syndrome is about half that of the general population. Half of the affected male patients are dead by age 40–45 and half of affected female patients die by age 50–55. In more than 95% of patients death is due to cardiovascular complications (76). Newer therapeutic approaches may be improving these figures. In a recent study from the United Kingdom (77), the median total survival was 53 years for men and 72 years for women.

VII. HOMOCYSTINURIA

Homocystinuria due to a deficiency of cystathionine beta-synthase (CBS) is an unusual disorder of amino acid metabolism (78) in which the phenotype has a significant resemblance to that of Marfan syndrome. It also carries a significant morbidity and mortality (79–81).

A. Causes and Pathogenesis

Cystathionine B-synthase deficiency is inherited as an autosomal recessive inborn metabolic error. It is caused by a large number of mutations in the CBS gene (82). The recurrence rate is 25% for each pregnancy when both parents are carriers. This enzyme is active in the pathway through which methionine is converted to cystine. It catalyzes the metabolic step at which homocystine and serine combine to form cystathionine. When the enzyme is deficient, homocystine and methionine accumulate in plasma and homocystinuria is seen. The plasma concentrations of cystathionine and cystine are markedly reduced. There is a significant quantitative, and probably qualitative, heterogeneity in the enzyme deficiency. The best example of this is the dichotomy between patients in whom the administration of pyridoxine (vitamin B6) leads to correction of the chemical abnormality and those in whom it does not. There is apparent segregation of these two types of abnormality among affected families (80, 81).

B. Clinical Manifestations

The clinical manifestations of homocystinuria are reviewed by Sotos (48) and are shown in Table 4. In addition to tall stature and marfanoid habitus, patients with homocystinuria show abnormalities involving multiple organ systems. The eye, nervous system, skeleton, and vascular system are all affected. Patients are usually normal at birth and the clinical manifestations come to the physician's attention in the first few years of life.

Mental retardation occurs very frequently and is often the presenting abnormality. The original patients were found by screening a population of retarded children for aminoaciduria. Convulsions are seen in 10–20% of patients.

The optic lens is dislocated in the majority of patients. Displacement is usually downward and the eyes lose their ability to accommodate. There is marked myopia and astigmatism. Osteoporosis, scoliosis, and vertebral collapse may be seen.

Thromboembolic phenomenon, especially in the post-operative period, is a life-threatening complication. Both arterial and venous occlusion are seen and sudden death may result. Heterozygotes develop premature thrombotic

Table 4 Clinical Manifestations of Homocystinuria

Tall stature
Marfanoid habitus
Mental retardation
Dislocated lens
Osteoporosis
Thrombosis

disease affecting coronary, cerebral, and peripheral arteries (83).

C. Diagnosis

Cystathionine B-synthase deficiency may be suspected on the basis of homocystinuria and elevated plasma concentrations of homocystine and methionine. Plasma cystine concentrations are low. Confirmation depends on demonstrating a deficiency of cystathionine B-synthase in a liver biopsy specimen, cultured phytohemagglutinin-stimulated lymphocytes, or skin fibroblasts. Newborn screening is available in populations at increased risk (84).

D. Treatment

Dietary methionine is restricted and dietary cystine is supplemented. Special synthetic diets that are virtually methionine-free are generally used.

All patients should be given a trial of therapy with pyridoxine. Patients should not be considered to be unresponsive to pyridoxine until 500–1000 mg daily for 3–4 weeks is shown to be ineffective. Responsive patients can usually be managed with 150–250 mg pyridoxine daily.

E. Prognosis

Methionine restriction ameliorates mental retardation when it is begun after diagnosis on the basis of newborn screening. When patients are not diagnosed in the newborn period, a significant number are mentally retarded and have other complications by age 15. The prognosis also depends significantly on whether or not the patient is pyridoxine-responsive (80). Lens dislocation, osteoporosis, and late thromboembolic phenomenon are less frequent in B6-responsive patients. However, there is an increase in mortality due to thromboembolism in both responsive and nonresponsive patients. Almost 25% of nonresponsive patients and 5% of responsive patients die by age 30.

VIII. BECKWITH-WIEDEMANN SYNDROME

Beckwith-Wiedemann syndrome (BWS), (85, 86) which is also termed exomphalos–macroglossia–gigantism (EMG) syndrome, is generally recognized in the neonatal period on the basis of a characteristic phenotype, which includes somatic overgrowth and hypoglycemia (87).

A. Causes and Pathogenesis

Beckwith-Wiedemann syndrome is a genetically determined set of phenotypic features in which there are abnormalities of a region of the short arm of chromosome 11, 11p15.5 (88–90). This disorder is an example of chromosomal imprinting in which the abnormality is derived

from only the male or female parent. In the case of BWS the abnormality is paternal (91–94) and affected patients show either trisomy for this region with the duplication arising in the father, or paternal disomy for this region with loss of the maternal chromosome contribution. The specific gene or genes that are duplicated have not yet been determined, but the IGF-II gene is the putative candidate. The IGF-II gene, or some other growth promoter, appears to be the probable cause of the characteristic phenotype of this disorder (95).

B. Clinical Manifestations

The typical clinical appearance of patients with Beckwith-Wiedemann syndrome (Table 5) includes macroglossia; umbilical abnormalities, such as omphalocele, umbilical hernia, and diastasis recti; craniofacial anomalies such as midface hypoplasia, prominent occiput, flat nasal bridge, and high-arched palate; increased birthweight and postnatal gigantism; earlobe anomalies that include grooves, pits, and notches; enlarged liver, kidneys, and other organs; facial flame nevus; and hyperinsulinemic hypoglycemia. A significant number of patients have somatic asymmetry that may be associated with the development of various cancers, particularly nephroblastoma (Wilms' tumor), adrenocortical carcinoma, hepatoblastoma, and rhabdomyosarcoma (96, 97).

Hypoglycemia, if it is present, usually occurs in the first few days of life. It is extremely important to recognize and manage this feature of BWS as soon as possible to prevent subsequent brain damage, developmental delay, and microcephaly that may result from an unrecognized chronic low blood glucose concentration. Blood glucose should be monitored frequently during the first 72 h of life in all neonates showing the clinical features of this disorder.

C. Diagnosis

As with other dysmorphic syndromes, the diagnosis of BWS depends on a characteristic clinical picture rather

Table 5 Major Clinical Manifestations of Beckwith-Wiedemann Syndrome

Clinical sign/symptom	Percentage of cases
Macroglossia	95
Craniofacial anomalies	80
Visceromegaly	80
Umbilical anomalies	75
Earlobe anomalies	70
Increased birthweight	60
Postnatal gigantism	60
Facial flame nevus	60
Hypoglycemia	55
Cardiac defects	35

than any specific diagnostic test. Demonstration of the underlying genetic abnormalities requires extremely sophisticated methodology beyond the scope of a standard clinical or genetics laboratory. The major features (Table 5) should be present before a diagnosis of BWS is assigned to an individual patient.

D. Treatment

Treatment is directed at specific features of this syndrome. Surgical repair of umbilical abnormalities is sometimes necessary. Management of associated cardiac anomalies depends on the nature of the defect and on whether or not cardiac failure is present. Associated tumors require a specific management plans.

Since the pathogenesis of the neonatal hypoglycemia of BWS is hyperinsulinism, treatment is directed at reducing the excess insulin secretion. A number of agents, such as glucocorticoids, Susphrine®, and zinc glucagon have been employed, but most effective medical management has been with diazoxide. Subtotal pancreatectomy is reserved for patients who are not made normoglycemic with diazoxide therapy.

E. Prognosis

There is a very high mortality rate in infancy among BWS patients: 20–25% die by age 1 year (85). The causes of death are not well documented but associated heart disease and unrecognized hypoglycemia are significant contributors. Patients generally continue to grow excessively and the majority remain above the 95th percentile for height and weight through adolescence. Intellectual function is variable and delayed development is often seen when hypoglycemia has been recognized late or when its management has been suboptimal. When malignancies develop in BWS patients, the prognosis becomes that of the associated cancer. Children who survive infancy with good control of their hypoglycemia appear to have a reasonable prognosis for growth and intellectual function (98).

IX. HEMIHYPERTROPHY

Hemihypertrophy or assymetrical overgrowth is of particular significance because of its association with malignancy. By far the most common associated cancer is Wilms' tumor (99). Other tumors that occur in patients with hemihypertrophy are adrenocortical carcinoma and adenoma, rhabdomyosarcoma, and hepatoblastoma. These cancers are the same as those noted in patients with Beckwith-Wiedemann syndrome. As in BWS, abnormalities of chromosome 11 at the 11 15p site are found in these tumors (100). By far the most significant aspect of hemihypertrophy is not the overgrowth itself but the development of malignancy. All such patients require close

follow-up to discover these tumors at the earliest possible time.

X. CONSTITUTIONAL TALL STATURE

Constitutional tall stature is a variant of the normal pattern of childhood growth and development (101). Its incidence varies with the sociocultural definition of normal and the level of parental concern regarding height. In the past, pediatric endocrinologists were often asked to see tall girls whose tall mothers were concerned about their daughters' ultimate height. A great deal of the initial concern over the patient's height reflected whatever social and psychological problems the mother may have had as a tall adolescent and young adult and anticipated that her daughter would have. Over the past 20–30 years, as the role of women in American society has expanded and as it has become first permitted and then fashionable for girls to be athletic and to concentrate on physical training, the frequency of this complaint has declined significantly. It has always been extremely unusual for American families to consider that their sons were too tall. Nevertheless, there remains considerable interest in constitutional tall stature and its treatment, particularly in Western Europe (102).

A. Causes and Pathogenesis

The growth pattern of patients with constitutional tall stature follows that of one or both parents who are also tall. Thus, genetic and familial factors appear to play the most important role in the condition's cause and pathogenesis.

Endocrinological studies of tall children have yielded variable results. An increased serum concentration of growth hormone in response to both glucose loading (103, 104) and the administration of thyrotropin-releasing hormone (TRH) (104) has been demonstrated, but similar observations have been made in normal pubertal children (105). This apparent paradoxical growth hormone response may be a phenomenon of normal adolescence (105, 106) and have no significance relative to tall stature.

B. Clinical Manifestations

Patients with constitutional tall stature are between 2 and 4 standard deviations above the average height for their age. Length is normal at birth and tall stature is evident by age 3 or 4 years. Growth velocity is accelerated in early childhood but slows after 4 or 5 years of age when the growth curve is parallel to the normal curve (107). Body proportions are normal. There is the same variability in the timing of adolescent development, as in children of average height, and the age of onset of puberty tends to follow the pattern characteristic for the patient's family.

C. Diagnosis

The diagnosis is generally clear from the family history, record of growth, and results of physical examination.

Specific laboratory studies of endocrine function are rarely indicated. Bone age determination as part of the initial evaluation is essential so that the most accurate prediction of adult height can be given to the patient and family. The bone age shows the same variability as that of the general population of children. Advanced bone age is not associated with constitutional tall stature in the same way that delayed bone age is associated with constitutional short stature.

D. Treatment

Management of tall children and adolescents remains among the more controversial topics in pediatric endocrinology. Generally, therapy has been aimed at inducing incomplete precocious puberty and accelerating the rate of development of secondary sex characteristics through the pharmacological administration of gonadal steroids. In theory, the acceleration of epiphyseal maturation that accompanies gonadal steroid administration should lead to early closure of the epiphyses. Somatomedin generation may also be inhibited by pharmacological dosages of estrogen (108).

A large number of reports have appeared describing the administration of estrogens in tall girls. A variety of preparations and dose schedules have been employed. These include injectable estradiol valerate (109, 110), implanted estradiol pellets (111), and oral stilbestrol 3 mg/day (112), diethylstilbestrol 5 mg/day (113), ethinyl estradiol 0.1 mg/day (114, 115), 0.25 mg/day (113, 115), 0.3 mg/day (114–116), or 0.5 mg/day (114–116), and conjugated estrogens 2.5–10.0 mg/day (108, 118–121).

There is general agreement that a favorable effect on ultimate height results from such pharmacological therapy (122). The overall average decrease in ultimate height has varied from 2.3 to 7.3 cm, with the mean effect in most studies being between 3.0 and 5.0 cm. Much greater effects have been claimed in selected patients. Most investigators consider that the effects are greatest when therapy is begun at a bone age below 12–13 years and/or a chronological age below 11 to 12 years. Treatment should be continued until the epiphyses have fused. The exact age at which estrogen treatment should be started and the predicted mature height that would serve as an indication for treatment remain in question.

Short-term side effects of estrogen administration include nausea, weight gain, pigmentation, leg cramps, and transient hypertension (108–119, 121). There may be the induction of hyperlipidemia, glucose intolerance, or cholelithiasis (120). Thromboembolism is a potential hazard (123). During treatment the gonadotropin response to gonadotropin-releasing hormone is uniformly suppressed (108, 124). However, menstrual function generally returns promptly after discontinuing estrogen administration. There appear to be no deleterious long-term effects on reproductive function in treated women studied 10 years after receiving estrogen for tall stature (115). The overall

late effects of pharmacological estrogen administration on gonadal function and both genital tract and breast neoplasia are unknown.

There remains considerable disagreement about whether the benefits of the effect on ultimate height outweigh the risks of high-dosage estrogen administration in young girls. I believe that too much is unknown about the late effects of such therapy on reproductive function and the development of neoplasms of the breast and female genital tract. In my opinion, the potential risks outweigh the benefits. Girls with Marfan syndrome and with the potential for development of scoliosis may be a special case (125). The difficulties that a patient's tall stature present to her and, more often, to her mother, can usually be dealt with through sympathetic support. Occasionally, more intensive individual or family psychotherapy is necessary.

Although tall stature has not been a complaint among adolescent boys in the United States, it has been a sufficient cause of concern in Europe to lead to gonadal steroid therapy (116, 126). The administration of a long-acting intramuscular testosterone preparation, 500 mg every 2 or 3 weeks (mean dosage 500 mg/m²/month), has produced a significant reduction in predicted mature height (116). Short-term treatment of 6 months' duration was ineffective (127). Long-term gonadal function appears to be normal in treated boys (128, 129). The same questions regarding benefits and risks as well as the same psychological considerations apply to the treatment of tall boys as to tall girls.

Bromocriptine has also been used to treat tall patients. If growth hormone secretion were suppressed in tall adolescents while pubertal epiphyseal maturation progressed at a normal rate, ultimate height might be reduced. There are conflicting reports of the efficacy of bromocriptine in limiting adult height. An initial report suggested a significant effect (130), but subsequent studies have reported equivocal (131) or negative (132) results.

Ocreotide has recently been used in small groups of tall children to inhibit growth hormone secretion and growth velocity (133, 134). Preliminary results suggest a role for this agent in the management of tall stature. However, a great deal of additional data must accumulate before the administration of somatostatin analogs can be considered other than experimental therapy.

E. Prognosis

The long-term prognosis for mature height in a patient with constitutional tall stature is consistent with the height attained by the rest of their family. An accurate prognosis for ultimate height obtained as part of the initial evaluation often indicates that the patient will not be nearly as tall as his parents fear. In these instances, the prognosis becomes part of the supportive therapy given to the family. However, height predictions often prove to be inaccurate when final height is attained (135).

I. INTRODUCTION

The adrenal gland is made of two parts, the cortex and the medulla, which have different embryonic origins. By 4–5 weeks of fetal life, cells from the mesoderm aggregate to form a primitive cortex between the posterior part of the dorsal mesentery and the gonadal ridge (1). Shortly thereafter, this primitive cortex becomes surrounded by a narrow band of cells termed permanent cortex. By 7–8 weeks of fetal life, the primitive cortex is invaded by chromaffin cells that develop rapidly and eventually replace most of the primitive cortical cells, forming the medulla (1). At that time, the adrenal gland is in close relation with the cranial part of the primitive kidney and not far from the genital ridge.

The adrenal medulla, which originates from ectodermal cells, has an entirely different function from the mesodermal adrenal cortex. In this chapter only the latter is discussed.

In the adult, the adrenal cortex is made of three distinctive zones. The outer zona glomerulosa secretes aldosterone; the middle zona fasciculata and the inner zona reticularis together are involved in the secretion of the cortisol and adrenal androgens (1). We first discuss the physiological function of the adrenal cortex. Then we consider the disorders related to the hyposecretion and hypersecretion of adrenal cortical hormones.

II. PHYSIOLOGY

A. Biosynthesis of Adrenocortical Steroids

1. The Enzymes

Cholesterol is the precursor of all steroids of both gonadal and adrenocortical origin (2). The biosynthetic pathway

of adrenal steroids is shown in Figure 1. The conversion of cholesterol to the various hormones requires the sequential action of a series of six enzymes, as listed in Table 1. All but 3β -hydroxysteroid dehydrogenase are members of a family of enzymes termed cytochromes P450. They are heme-containing proteins that act as mixed-function oxidases (3). Three of these enzymes have a very similar structure: cholesterol side-chain cleavage enzyme encoded by the gene CYP11A, 11β -hydroxylase encoded by CYP11B1, and aldosterone synthetase encoded by CYP11B2. The last two genes are contiguous on the long arm of chromosome 8q22. The gene CYP11A is located on chromosome 15q23–24; this enzyme requires the activity of another gene product, the steroidogenic acute regulatory protein (StAR).

The cholesterol side-chain cleavage enzyme has the ability to add a hydroxyl group on carbons 20 and 22 of the cholesterol molecule as well as to remove a side chain between carbons 20 and 22 (4). The 3β -hydroxysteroid dehydrogenase (3β -HSD) converts pregnenolone to progesterone as well as 17α -hydroxypregnenolone to 17α -hydroxyprogesterone; this is accomplished by reduction of the $3,\beta$ -hydroxyl group into a 3-ketone and isomerization of the 5,6 double bond to a 3,4 double bond. Its gene is located in chromosome 1p13.1 The 17α -hydroxylase enzyme (chromosome 10 q24–25) has the ability of both 17α -hydroxylation and $17,20$ -lyase. The latter activity transforms steroids with 21 carbons into steroids with 19 carbons. 21 -Hydroxylase (CYP21) and 11β -hydroxylase (CYP11B1) are specific for the function of adding a hydroxyl group in carbons 21 and 11, respectively. Aldosterone synthetase (CYP11B2) adds an 11β -hydroxyl group and an 18-hydroxyl group and is also capable of 18-oxidation (5). Whereas the CYP11A, 3β -HSD, and CYP21 genes are expressed in all the zones of the adrenal

Figure 1 Biosynthesis of adrenocortical steroids. The pathway from cholesterol to cortisol, aldosterone, and adrenal androgens requires the action of five cytochrome P450 (CYP11A, CYP17, CYP21, CYP11B1, and CYP11B2) and one dehydrogenase (3β -hydroxysteroid dehydrogenase). (From Ref. 2.)

cortex, the CYP17 and CYP11B1 genes are expressed only in the zona fasciculata-reticularis and the CYP11B2 gene is expressed only in the zona glomerulosa. This accounts for the specificity of steroid production by the various zones of the cortex.

2. Subcellular Location of the Various Enzymes

As shown in Figure 2, cholesterol is stored in the adrenal cell as cholesterol esters. Under the influence of an esterase, cholesterol becomes available and is transported to the mitochondria, where it is converted to pregnenolone (2). This steroid then moves into the endoplasmic reticulum, where 3β -hydroxysteroid dehydrogenase, 21-hydroxylase, and 17-hydroxylase enzymes are located. The

Table 1 Nomenclature for the Various Steroid Biosynthetic Enzymes and the Respective Genes

Enzyme activity	Gene	Chromosomal locus
Cholesterol side-chain cleavage enzyme (20-hydroxylase, 22-hydroxylase, 20,22-lyase)	<i>CYP11A</i>	15223-q24
3β -Hydroxysteroid dehydrogenase	<i>3\beta-HSD</i>	1p13.1
17 α -Hydroxylase and 17,20-lyase	<i>CYP17</i>	10q24-q25
21-Hydroxylase	<i>CYP21</i>	6p21
11 β -Hydroxylase (some 18-hydroxylation)	<i>CYP11B1</i>	8q22
Aldosterone synthetase (11 β -hydroxylation, 18-hydroxylation, and 18-oxidation)	<i>CYP11B2</i>	8q22

resulting steroids include 11-deoxycorticosterone (DOC) and 11-deoxycortisol as well as two C-19 carbon steroids, androstenedione and dehydroepiandrosterone (DHA). At that point, DOC and 11-deoxycortisol return to the mitochondria, where they are converted into corticosterone and cortisol, respectively. This is basically the end of the biosynthetic process in the cells of the zona fasciculata.

In the cells of the zona glomerulosa, there is no 17-hydroxylase activity and, therefore, no formation of cortisol or androgens. However, the mitochondria of these cells include CYP11B2 enzyme, which transforms DOC into corticosterone, 18-hydroxycorticosterone, and aldosterone.

Finally, it must be noted that the activity of all cytochrome P450 enzymes requires a gain of electrons. These electrons are transferred from NADPH. In the mitochondria this transfer is made via two intermediaries, adrenodoxin and adrenodoxin reductase, whereas in the microsomes the transfer requires only the presence of an adrenodoxin (2).

3. The Placental-Fetal Adrenal Unit

Early in fetal life, the adrenal cortex is capable of secreting steroids. It lacks 3β -hydroxysteroid dehydrogenase, however, and the major hormones secreted include pregnenolone, 17 α -hydroxypregnenolone, DHA, and 16 α -hydroxy-DHA. All these steroids circulate mainly as sulfate conjugates, which are then transferred to the placenta (Fig. 3) (1). This organ is rich in sulfatase, which makes the native steroids available to the greatly active placental 3β -hydroxysteroid dehydrogenase. The resulting progesterone and 17 α -hydroxypregesterone are returned in part to the fetus and are used by the fetal adrenal to make aldosterone and cortisol and by the fetal gonad to make testosterone.

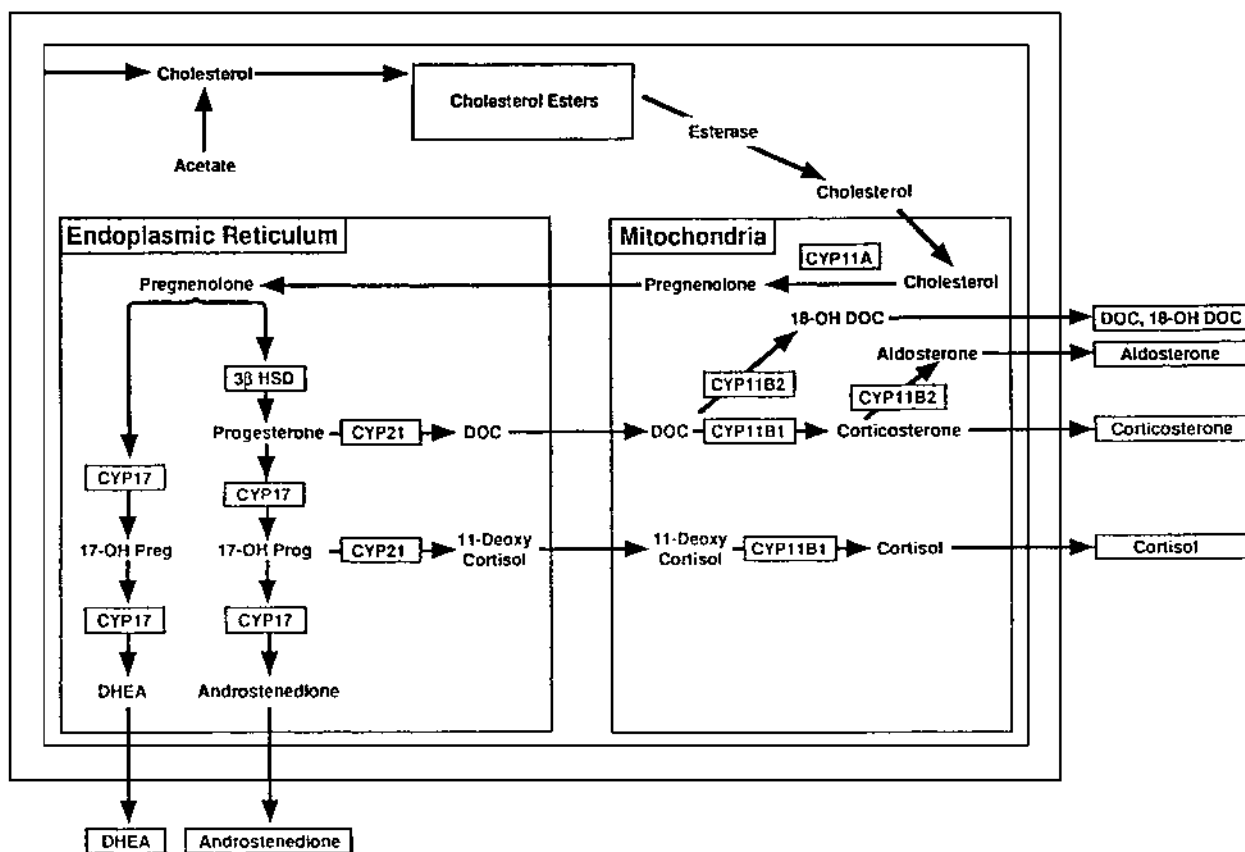

Figure 2 Subcellular location of the various steps of steroidogenesis in an adrenal cell. Cholesterol from blood or from intracellular synthesis is stored as cholesterol esters. An esterase makes cholesterol available when needed. CYP11A is located in the mitochondria. The pregnenolone formed moves to the endoplasmic reticulum where it is submitted to the effects of 3 β -HSD, CYP17, and CYP21. The resulting 11-deoxycorticosterone (DOC) and 11-deoxycortisol return to the mitochondria where the CYP11B1 and CYP11B2 cytochromes are located. The main steroids secreted by the adrenal cortex are shown outside of the adrenal cell. (From Ref. 2.)

The placental 3 β -hydroxysteroid dehydrogenase also transforms DHA and its 16 α -hydroxylated derivative into androstenedione and its 16 α -hydroxylated derivative. In the next step, placental aromatase transforms androstenedione into estrone and estradiol, whereas 16 α -hydroxyandrostenedione is metabolized into estriol. Most of these estrogens are excreted by the mother. The large amounts of estriol excreted by the mother are related to the large amounts of 16 α -OH-DHA secreted by the adrenal cortex of the fetus.

B. Control of Adrenal Steroid Secretion

1. Regulation of Cortisol Secretion

The ability of the adrenal gland to synthesize cortisol is dependent upon the secretion by the hypothalamus of corticotropin-releasing hormone (CRH). By the use of the short loop of the portal vessel system from the hypothalamus to the anterior pituitary, CRH reaches the cortico-

trophs and triggers the secretion of adrenocorticotrophic hormone (ACTH).

a. CRH and ACTH. CRH is a 41 amino acid straight-chain peptide (6). It is secreted mainly by the median eminence. However, it has also been detected in the cortical part of the brain. CRH binds with high affinity to receptors located on the membrane of the corticotrophs of the anterior pituitary. This in turn activates the formation of cyclic AMP, which then activates a series of protein kinases, resulting in increased transcription of the pro-opiomelanocortin gene; appropriate processing of this mRNA results in ACTH formation. ACTH has a half-life in blood of a few minutes. Although the native hormone has 39 amino acid residues, the first 1–24 amino-acid sequence has as much activity as the ACTH itself (7). Like other peptide hormones, ACTH binds to specific membrane receptors of the adrenocortical cells to increase the formation of cyclic AMP and activation of various protein kinases. The ACTH stimulation of cortisol secretion in-

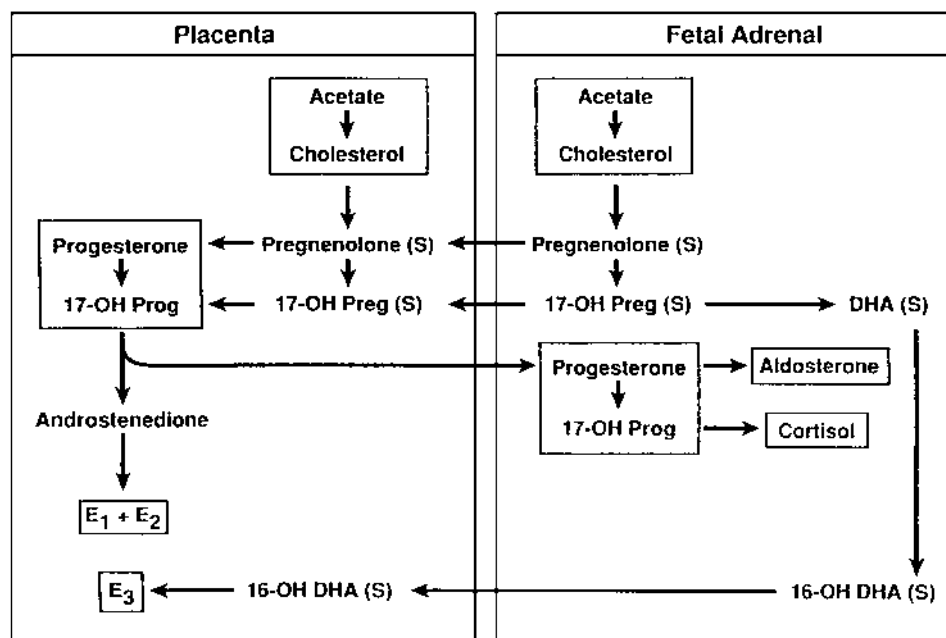

Figure 3 The placenta–fetal adrenal unit. The fetal adrenal can readily synthesize pregnenolone, 17-hydroxypregnenolone, and 16-hydroxy-DHA. However, it has little or no 3β -HSD. The placenta, which is rich in this enzyme, transforms the fetal steroids into progesterone, 17-hydroxyprogesterone, and estriol. In the next step, progesterone and 17-hydroxyprogesterone are returned to the fetal adrenal, which can then synthesize aldosterone and cortisol. (From Ref. 1.)

cludes an acute and chronic phase (2). In the acute phase, which takes only a few minutes, cholesterol is made available for steroidogenesis by activating the effect of an esterase on stored cholesterol esters. The more chronic phase is related to a stimulation of transcription of the various cytochrome P450 genes. A so-called steroidogenic factor 1 (SF-1) appears to be responsible for this stimulation (8). Of great interest is the recent finding that SF-1 is also a transcription factor. Along with DAX-1, it plays a major role in the formation of steroidogenic tissues, specifically the adrenal glands and the gonads (9).

b. Mechanisms Regulating Cortisol Secretion. Three physiological mechanisms play an important role in the secretion of cortisol: pulsatile secretion and diurnal variation, stress, and negative feedback.

Pulsatile secretion and diurnal variation in cortisol. The collection of blood samples at frequent intervals has shown that cortisol is secreted in a pulsatile manner (10). Previously (11) it was observed that the plasma concentration of cortisol showed a specific diurnal variation, the highest peak taking place between 4 and 6 a.m. The concentrations then tend to decrease for the rest of the day, being at their lowest in the evening and during the night (Fig. 4).

Stress. Surgical stress, such as trauma and tissue destruction; medical stress, such as acute illness, fever, and hypoglycemia; and emotional stress related to psychological upset result in most cases in an important increase in

cortisol secretion. How these various types of stress influence steroid output is not clear. However, studies of the immune system have shown that leukocytes secrete a series of peptide hormones, the interleukins (12). Their formation is markedly increased during stress, and two of them, interleukin-1 and interleukin-6, have been shown to stimulate CRH secretion and therefore to increase cortisol secretion (13).

Negative feedback. Another important physiological mechanism controlling cortisol secretion is negative feedback. Under normal conditions, there is equilibrium between the rate of secretion of ACTH and that of cortisol. When the plasma concentration of cortisol increases markedly, it has a negative effect on the secretion of CRH and ACTH. By this mechanism, cortisol levels in blood regulate the rate of output of CRH and ACTH.

c. Cortisol Secretion Rate. In normal children of various ages and in adult subjects, the rate of cortisol secretion increases with body size (14). When the values are corrected for body surface area, the rates are similar at various ages; the average \pm standard deviation (SD) was 12 ± 2 (Fig. 5) with a range of 8–16 $\text{mg}/\text{m}^2/24$ h. However, the circadian variation of the clearance rate of cortisol resulted in an overestimation. An appropriate correction gave a lower normal range of 6–14 $\text{mg}/\text{m}^2/24$ h. Using stable isotope dilution/mass spectrometry Esteban et al. (15) reported a cortisol secretion rate for 12 normal subjects of 5.7 ± 1.5 $\text{mg}/\text{m}^2/24$ h. Kerrigan et al. (16),

Figure 4 Diurnal variation of plasma cortisol in three normal adult subjects. Black areas represent periods of sleep. (From Ref. 105.)

using deconvolution analysis, found a similar value in 18 normal male children.

2. Regulation of Aldosterone Secretion

Aldosterone is secreted by the cells of the zona glomerulosa of the adrenal cortex. It is mainly under the control of angiotensin II. As shown in Figure 6, the liver produces a large protein, angiotensinogen, which is cleaved by a proteolytic enzyme, renin, which is secreted by the juxtaglomerular cells of the kidney. A converting enzyme then transforms angiotensin I into angiotensin II.

Potassium concentration in plasma and ACTH also play a role in the control of aldosterone secretion. The effect of ACTH is an acute stimulation related to the rapid increase in availability of cholesterol from the cholesterol ester reserve (17). As shown in Figure 7, an intravenous (IV) injection of ACTH very quickly raises plasma aldosterone levels, but after 60 min the levels tend to decrease.

3. Regulation of Adrenal Androgen Secretion

Adrenal androgens are secreted in large amounts during fetal life. Their production decreases rapidly after birth

and is not resumed until puberty. The factor that triggers the pubertal secretion of adrenal androgens is not ACTH because its levels are not different before and after puberty. However, large amounts of ACTH given chronically markedly increase the secretion of adrenal androgens. It has been postulated that a pituitary peptide other than ACTH but not yet characterized is responsible for this stimulation, and it has been named adrenal androgen-stimulating hormone (18).

C. General Metabolism

As shown in Figure 8, adrenal steroids are transported by blood to reach their target tissues. The liver is one of the target tissues as well as an important site for the catabolism of the steroids. The main glucocorticoid is cortisol. Between 80 and 90% is bound to a specific glycosylated α -globulin known as corticosteroid-binding globulin (CBG), also called transcortin (19). Transcortin has a very high affinity for cortisol, but it can also bind progesterone, prednisolone, and, with less affinity, aldosterone (20). Another 7% of the total circulating cortisol is loosely bound to albumin, and 2–3% is not bound to protein. This unbound cortisol is the fraction of the total available to target cells. In these cells, cortisol binds to a specific glucocorticoid receptor. The receptor–steroid complex binds to the glucocorticoid receptor elements located in the promoter area of responsive genes. By activating the transcription of such genes, glucocorticoids express their biological activity.

The main mechanism of catabolism is a reduction of the steroid molecule and eventually conjugation with glucuronic or sulfuric acid to make products that are water soluble and readily excreted by the kidney as urinary metabolites.

Although aldosterone can bind to CBG, most of the binding sites of this protein are occupied by cortisol. For this reason, aldosterone is physiologically mainly bound to albumin. Its half-life in blood is 20–30 min, compared with 60–80 min for cortisol. In target cells, aldosterone binds to its own specific receptor, the mineralocorticoid receptor. The mode of action of this steroid–receptor complex is similar to that described for cortisol.

D. Tests of Adrenocortical Function

Many types of tests have been proposed for the determination of adrenocortical function. We outline here only the tests considered important and practical for diagnostic purposes.

1. Tests Related to Glucocorticoid Function

a. 8 a.m. Plasma Cortisol Concentrations. It is necessary to obtain plasma levels of cortisol at a specific time of the day (8 a.m.) because of the diurnal variation discussed earlier. However, even this precaution may not

Figure 5 Cortisol secretion rate in newborn infants, children and adults. The values have been corrected for body surface area. The rates expressed in mg/m²/24 h, were fairly constant throughout life except in the first few days when they were somewhat higher. (From Ref. 1.)

be sufficient because of the episodic secretion of the steroid. In general, a single plasma value is of limited clinical significance. There are conditions for which one must determine the plasma concentrations of cortisone and corticosterone. Normally, their concentrations are approximately one-tenth that of cortisol at 8 a.m. Changes in the ratios of these steroids to cortisol in a single blood sample may therefore be indicative of a specific abnormality of adrenal secretion.

b. Urinary 17-Hydroxycorticosteroids. About 30% of secreted cortisol is excreted as urinary 17-hydroxycorticosteroids (17-OHCS). For this reason, determination of 24 h urine excretion gives a good indication of the 24 h cortisol secretion. Indeed, this test is of interest in ruling out Cushing's disease. In normal subjects, the mean \pm SD urinary 17-OHCS is 2.5 ± 1.0 mg/m²/24 h (14).

c. Urinary Free Cortisol. Approximately 0.25–0.5% of secreted cortisol is excreted as cortisol itself. Because urinary free cortisol reflects the amount of unbound cortisol available to target cells (ie, non-protein-bound cortisol), this test is considered of greater biological importance than that of urinary 17-OHCS. In our opinion, however, both tests should be obtained in a single 24 h urine specimen when screening for Cushing syndrome.

d. ACTH Test. At present, the standard technique involves the IV bolus administration of 0.25 mg 1,24-ACTH (Cortrosyn). Blood samples are obtained at 0, 60, and 120 min after ACTH injection. As seen in Figure 7, plasma cortisol increases to about 30 μ g/dl (17).

A normal baseline and a normal increment by 120 min rule out primary adrenal insufficiency. This test is also useful when determining the mineralocorticoid function of the adrenals. Recent studies have shown that administration of a very low amount of ACTH (1 μ g) may be more sensitive than the standard 250 μ g test in the detection of dysfunction of the hypothalamopituitary–adrenal axis. This would be particularly true in mild adrenal insufficiency, as can be seen in the case of pituitary disease or with the use of inhaled steroids as reported by Mayenknecht et al. (21) and Nye et al. (22).

e. Metyrapone (Metopirone) Test. Given acutely, Metopirone has the property of blocking 11 β -hydroxylation. This results in decreased secretion of cortisol and corticosterone with a decrease in negative feedback on the hypothalamic–pituitary axis. As a consequence, there is an increase in ACTH secretion with an increased secretion of 11-deoxysteroid, specifically 11-deoxycortisol (compound S), and 11-deoxycorticosterone. The present standardized test consists of the administration of a single oral dose of Metopirone (300 mg/m²/per dose) at midnight and measurement the next day at 8 a.m. of plasma 11-deoxycortisol. If adrenocortical function is normal and if the pituitary is capable of increasing its ACTH secretion, the plasma concentration of 11-deoxycortisol rises to values of 7–22 μ g/dl (23).

There is the possibility that Metopirone may not be available commercially in the near future. If this occurs, the acute ACTH test described earlier can give similar information.

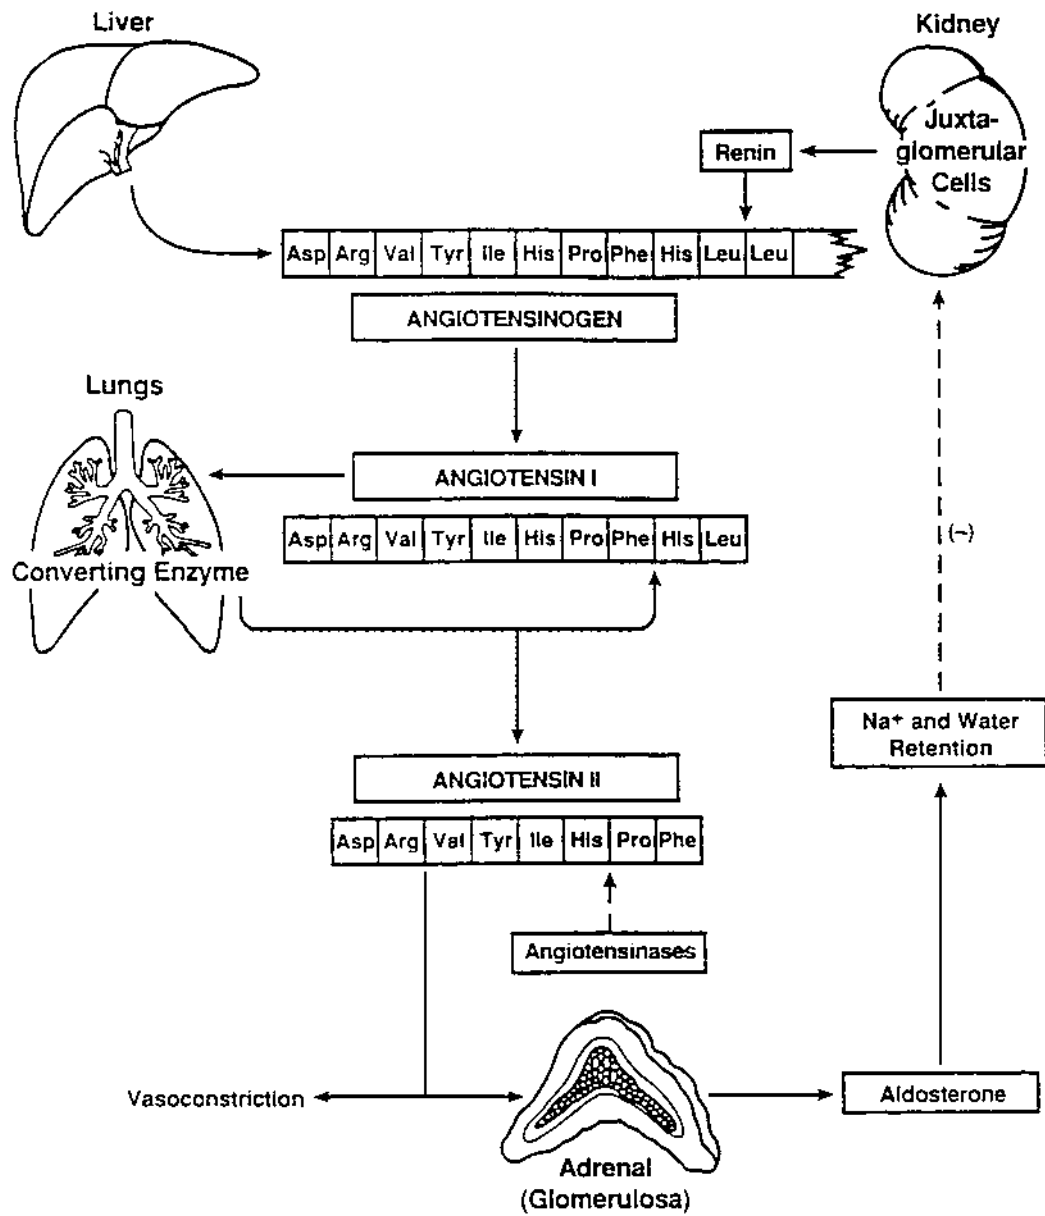

Figure 6 Control of aldosterone secretion. Angiotensinogen of hepatic origin is cleaved by renin from the kidney. The resulting angiotensin I is further cleaved into angiotensin II, an 8 amino-acid peptide that has properties of vasoconstriction on vessels and of activating secretion of aldosterone by the cells of the glomerulosa. (From Ref. 1.)

f. Dexamethasone Suppression Test. Dexamethasone is a potent glucocorticoid that, given in small amounts, suppresses ACTH secretion and secondarily decreases cortisol secretion. The suppressing effects of the test are measured by the determination of either plasma ACTH and cortisol or urinary excretion of free cortisol and total 17-OHCS. In the low-dose or single-dexamethasone suppression test, 1.25 mg dexamethasone/m²/24 h is

administered for 2 days. In the high-dose or triple-dexamethasone suppression test, 3.75 mg dexamethasone/m²/24 h is administered for an additional 2 days.

g. The CRH Test. Following the IV administration of CRH (100 µg/dose), there is a moderate but significant increase in both plasma cortisol and ACTH, the maximum response being about 60 min after injection. In Cushing's

Figure 7 Effects of 1,24-ACTH on the plasma concentration of cortisol and aldosterone in 16 normal subjects. (From Ref. 15.)

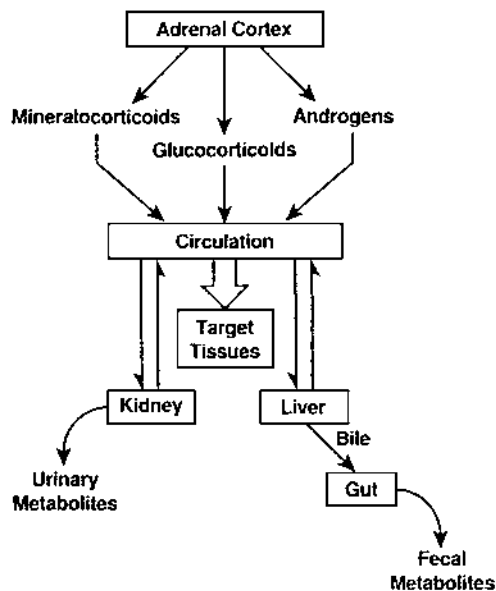

Figure 8 General metabolism of adrenal steroids. In the blood circulation, the steroids are mainly bound to specific proteins. The small unbound fraction is available to target tissues where the steroids express their biological effects. At the same time, steroids are metabolized and conjugated by the liver. The conjugates are returned to the circulation and excreted in bile by the kidney as urinary metabolites. (From Ref. 1.)

disease, there is a greatly exaggerated response of both plasma cortisol and ACTH, whereas in ectopic ACTH syndrome there is no change, as shown in Figure 9 (24).

2. Tests Related to Mineralocorticoid Secretion

a. Plasma Aldosterone and 11-Deoxycorticosterone. Concentrations of plasma aldosterone are quite variable, changing rapidly in relation to body posture, the standing values being greater than those while supine (17). Plasma concentrations of aldosterone are also influenced by chronic changes in sodium intake, the concentration being 15–30 ng/dl on a low-sodium diet (less than 17 mEq/24 h) and 2–12 ng/dl on a normal-sodium diet (150–200 mEq/24 h in adults).

The plasma concentrations of DOC, like those of aldosterone, tend to be higher in early infancy (from 8 to 5 ng/dl) than later in childhood (5–10 ng/dl), as reported by Lashansky et al. (25).

As shown in Figure 7, ACTH acutely increases aldosterone concentration. There is also a three- to fivefold increase in DOC.

b. Urinary Excretion of Aldosterone and DOC. A small fraction of secreted aldosterone is excreted as a 21-oxoglucuronide conjugate. Following hydrolysis at pH 1.0, aldosterone is freed and is measured by radioimmunoassay. Under normal sodium intake, the values are 3–10 µg/24 h and, on a low-sodium diet, they are 20–50 µg/24 h.

III. HYPOADRENOCORTICISM

Adrenal insufficiency can be caused by an abnormality of the adrenal glands (primary adrenocortical insufficiency) or by a decreased secretion of hypothalamic CRH and pituitary ACTH (hypoadrenocorticism secondary to deficient CRH and/or ACTH secretion). In rare cases the insufficiency is related to an inability of the target organs to respond to adrenal steroids (hypoadrenocorticism related to end-organ unresponsiveness). The classification of these various disorders is outlined in Table 2.

IV. HYPOADRENOCORTICISM: PRIMARY ADRENOCORTICAL INSUFFICIENCY

There are many causes of primary adrenal insufficiency (Table 2). In some cases, there has been a lack of differentiation of the glands (congenital adrenal aplasia) or inappropriate development (X-linked adrenal hypoplasia). In other cases, a mutation of the ACTH receptor on the membrane of the adrenocortical cells does not permit adequate stimulation of adrenal secretion (adrenocortical unresponsiveness to ACTH). Another group of abnormalities involves a mutation of one of the enzymes necessary for steroid biosynthesis (congenital adrenal hyperplasia, adrenoleukodystrophy, acid lipase deficiency, steroid sulfa-

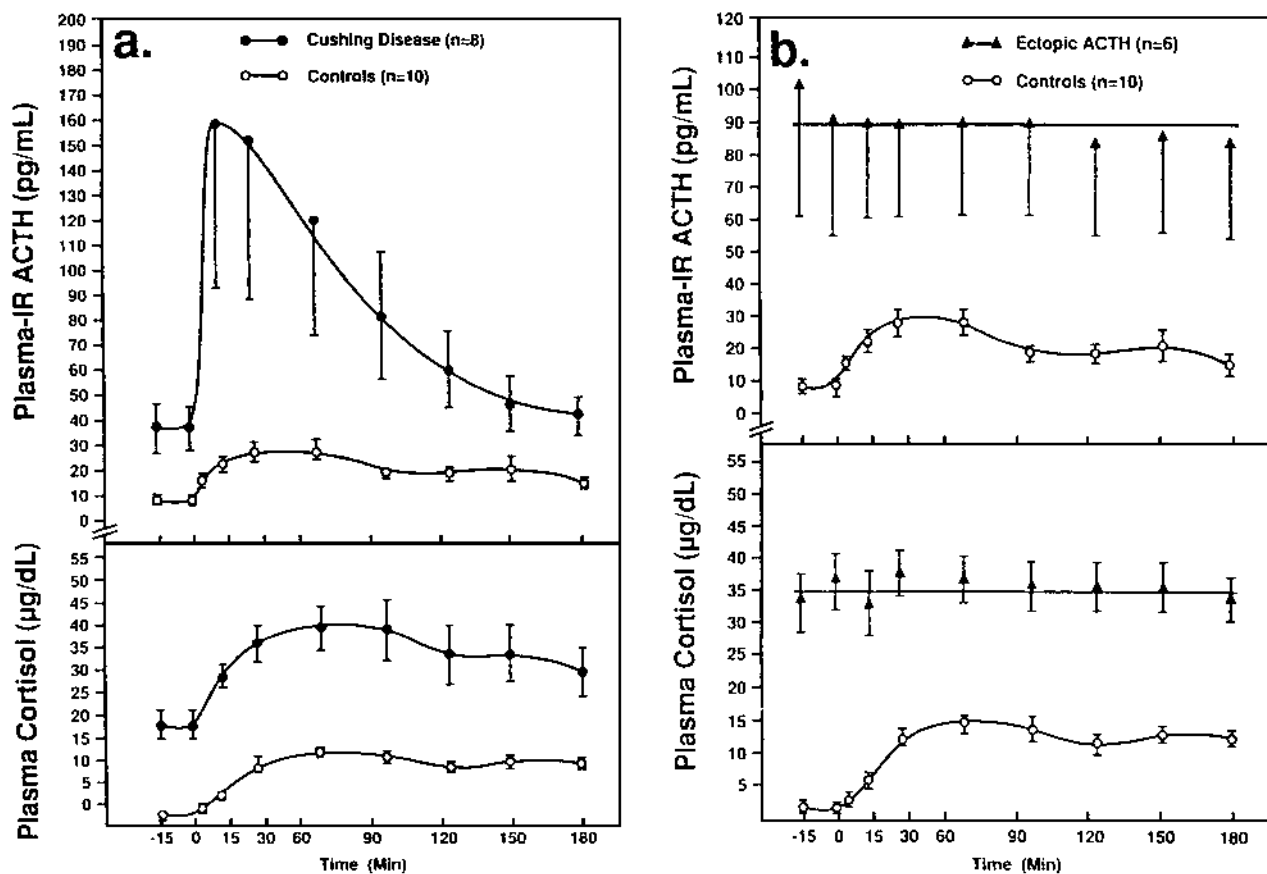

Figure 9 The CRH stimulation test. The figure shows the response of plasma cortisol and ACTH to IV administration of 100 μg CRH (a) in adult controls and in patients with Cushing's disease and (b) in patients with Cushing's due to ectopic ACTH. (From Ref. 20.)

tase deficiency, and mineralocorticoid deficiency). Finally, there can be postnatal destruction of the adrenal cortex, either acute (adrenal hemorrhage) or chronic (Addison's disease).

A. Congenital Adrenal Aplasia

This is believed to be caused by a developmental disorder of the adrenal anlage during fetal life. Symptoms occur shortly after birth and are characterized by acute shock with tachycardia, hyperpyrexia, cyanosis, and rapid respiration. Untreated, it evolves to total vascular collapse and death. The symptoms of congenital adrenal aplasia are similar to those present in other conditions, such as septicemia and intracranial hemorrhage. The rapid evolution of adrenal aplasia to death is the reason it is often diagnosed at autopsy.

B. X-Linked Adrenal Hypoplasia Congenita

Among families presenting multiple cases of adrenal insufficiency, several suggested the possibility of an X-

linked trait. In 1980, Guggenheim et al. (26) reported an association of glycerol kinase deficiency (GKD) with Duchenne muscular dystrophy (DMD) and adrenal hypoplasia congenita (AHC). Later, these disorders were reported to be associated with Xp21 interstitial deletion (27).

1. Pathophysiology

The deletions of the X chromosome associated with AHC, GKD, and DMD have permitted mapping the locus of these three disorders, as well as the locus of chronic granulomatous disease, retinitis pigmentosa, and ornithine transcarbamylase deficiency, the last being the closest to the centromere, and AHC being the closest to the end of Xp (28). However, it is not clear how the deletion of the AHC locus results in hypoplastic adrenals. The adrenal cortex in patients studied at autopsy shows a small number of large adrenocortical cells, hence the name cytomegalic adrenal hypoplasia given by pathologists.

Table 2 Classification of Syndromes of Hypoadrenocorticism

Primary adrenocortical insufficiency
Congenital adrenal aplasia
X-linked adrenal hypoplasia
Adrenocortical unresponsiveness to ACTH (deficient ACTH receptor)
Congenital adrenal hyperplasia (CAH)
Adrenoleukodystrophy/adrenomyeloneuropathy
Wolman disease (acid lipase deficiency)
Steroid sulfatase deficiency (X-linked ichthyosis)
Mineralocorticoid CMOI or CMOII (CYP11B2) deficiency
Adrenal hemorrhage of the newborn
Adrenal hemorrhage of acute infection
Chronic hypoadrenocorticism (Addison's disease)
Secondary to deficiency CRH and/or ACTH secretion
Hypopituitarism
Cessation of glucocorticoid therapy
Removal of a unilateral cortisol-producing tumor
Infants born to steroid-treated mothers
Respiratory distress syndrome
Anencephaly
Related to end-organ unresponsiveness
Cortisol resistance (deficient glucocorticoid receptor)
Aldosterone resistance (deficient mineralocorticoid receptor)

2. Clinical Manifestations and Mapping of Xp21

AHC appears early in infancy with signs of acute adrenal insufficiency. However, the signs may occur later in childhood and be somewhat milder. Growth failure with short stature is often observed. In AHC caused by a deletion involving other genetic loci, such as GKD and DMD, signs of glycerol kinase deficiency and myopathy are also present.

In a series of patients presenting with the association of AHC, GKD, and DMD, mental retardation was reported in most of the cases, suggesting the existence of a contiguous locus involved in mental function (29). However, it must be considered that subjects with adrenal insufficiency may have intrinsic reasons for mental retardation in relation to hypoglycemic episodes and abnormal electrolyte imbalance. It is believed that the gene locus of adrenal hypoplasia congenita is the DAX-1 gene (30). As previously noted, DAX-1 plays a major role in the differentiation of fetal cells into both adrenal glands and gonads. In addition, it is necessary for the formation of the hypothalamus, in cooperation with the SF-1 transcription factor. This explains why abnormalities of the DAX-1 gene result in hypogonadotropic hypogonadism (HH) in addition to AHC. Finally, it is of interest to note that a duplication of DAX-1 locus results in testicular abnormalities in 46, XY subjects (31). This is related to the

complex relationships of DAX-1 with the SRY and SF-1 proteins during male sex differentiation.

3. Laboratory

Hormonal and electrolyte studies are characteristic of adrenocortical insufficiency: low basal cortisol and aldosterone levels responding poorly to an ACTH test, elevated ACTH concentrations, and hyponatremic, hyperkalemic acidosis. GKD association is demonstrated by elevated serum and urine glycerol levels. Because glycerol is measured in the triglyceride assay, there is pseudohypertriglyceridemia. Muscle biopsy showing elevated serum creatine kinase confirms Duchenne muscular dystrophy. Results of a luteinizing hormone-releasing hormone (LHRH) test helps in determining hypogonadotropic hypogonadism (32).

4. Genetics

The clinical abnormalities of AHC and associated disorders in patients with Xp21del most probably demonstrate a relation of cause to effects between the chromosomal deletion and the specific symptoms.

All cases of AHC, GKD, and DMD associated with an X deletion occurred in male subjects, suggesting X-linked recessive traits. Unaffected mothers of patients have been shown to be heterozygous for the deletion Xp21 del (27). However, one case in a female patient has been reported (29).

5. Treatment

Steroid replacement for both glucocorticoids and mineralocorticoids is necessary. If GKD is present, appropriate therapy must be given. Unfortunately, Duchenne muscular dystrophy is not treatable at this time.

C. Adrenocortical Unresponsiveness to ACTH (Deficient ACTH Receptor)

1. Pathogenesis

This disorder is caused by an inability of the adrenal cells of the zona fasciculata and reticularis to respond to ACTH. The lack of ACTH response is caused by a genetic abnormality of the ACTH receptor (33).

2. Clinical Manifestations

It is characterized by feeding problems in early life, failure to thrive, hypoglycemia, and hyperpigmentation of the skin (34). In some cases, the symptoms seem to occur later in infancy, perhaps because the frequent feedings of the neonatal period prevented major hypoglycemic episodes.

3. Laboratory

As already noted, glucose levels are quite low but there is no electrolyte abnormality. During a hypoglycemic ep-

isode, a blood sample demonstrates high growth hormone and low insulin concentrations with low cortisol levels. ACTH measurement shows elevated values, even when cortisol values are low.

4. Genetics

Recently the gene for the ACTH receptor was isolated and sequenced (35). The coding sequence does not contain an intron. The product of this gene is a 297 amino acid protein with seven transmembranic domains, a cytosolic COOH terminus that can react with a G protein to activate adenyl cyclase activity, and an extracellular NH₂ terminus with two possible glycosylation sites.

The disorder is an autosomal recessive trait. In one family, both parents were heterozygous for the same mutation, the proband being homozygous for this mutation (36), whereas in another family the parents had different mutations, the patient being an allelic compound (37). A postreceptor mutation has also been reported (38).

5. Treatment

Patients require only glucocorticoid replacement therapy, the mineralocorticoid function being normal.

6. Other Disorders

Although more than 30 cases of adrenocortical unresponsiveness to ACTH have been reported in the literature, it is probable that some of these patients presented with a different disorder. Some patients who presented with neurological symptoms (39) probably had unrecognized cases of adrenoleukodystrophy. Other patients presented with sodium loss (40). Several cases of an association of adrenal insufficiency, achalasia, and alacrima (triple A syndrome) have been reported (41, 42). This syndrome usually appears in the first decade of life, a severe hypoglycemia being often the early sign. Aldosterone deficiency is associated to cortisol deficiency in only 10–15% of cases. Some patients present only two of the triad signs, but in some cases multiple additional abnormalities have been observed. The triple A syndrome is an autosomal recessive trait and its locus is on chromosomes 12q13 (43).

D. Congenital Adrenal Hyperplasia

There are five major forms of congenital adrenal hyperplasia (CAH), each caused by a mutation of one of the five enzymes required for the biosynthesis of cortisol. In each of these forms, the decrease in cortisol secretion results in a decrease in negative feedback at the level of the hypothalamus–pituitary (1, 2). The resulting increase in ACTH output attempts to return the cortisol secretion to normal if the mutation permits some degree of enzymatic activity. At the same time, the increased ACTH secretion results in a markedly elevated production of the cortisol precursors before the mutant block.

The five forms of CAH are 21-hydroxylase deficiency (salt-losing form, simple virilizing form, and attenuated form), 11 β -hydroxylase deficiency related to a mutation of CYP11B1, 17-hydroxylase deficiency (hypertensive form) related to CYP17, 3 β -HSD deficiency, and lipoid adrenal hyperplasia related to a mutation of CYP11A. These disorders are discussed in a separate chapter of this book.

E. Adrenoleukodystrophy and Adrenomyeloneuropathy

These two disorders have also been called diffused cerebral sclerosis associated with adrenal insufficiency.

1. Pathophysiology

Also known as Siemerling-Creutzfeldt or Schilder's disease, the basic biochemical abnormality is an elevation in plasma and various tissues of the concentration of the very-long-chain fatty acids (VLCFA), C24, C25, and C26. They probably accumulate because of a defect in their normal breakdown in cellular organelles known as peroxisomes. On pathological examination, the adrenal cortex at first shows cytoplasmic striations containing cholesterol esterified with VLCFA. Later the adrenal cells appear to be filled with the abnormal cholesterol esters, and in the final stage the cells tend to atrophy and die (44).

2. Clinical Manifestations

This is a progressive disease of the brain that manifests in its early stage by mild symptoms, such as unusual behavior, a mild decrease in visual acuity, and a loss of muscle strength in some limbs. Over a period of a few years, the symptoms progress to dementia, blindness, and quadriparesis, and end in death. At various times during this degenerative process, symptoms of adrenal insufficiency may occur, involving both cortisol and aldosterone function.

3. Genetics

The locus of adrenoleukodystrophy maps to the long arm of the X chromosome (Xq28) (45, 46). Because of the location of the gene on the X chromosome, the disorder is expressed only in male subjects. Recently the adrenoleukodystrophy (ALD) gene was identified (47). It encodes a 745 amino acid protein that includes six membrane-spanning segments and an ATP-binding domain. The role of the ALD protein may be to transport the VLCFA-CoA synthetase. Different mutations have been reported in different families, including six detectable deletions, nine point mutations, three frameshift mutations, and one splicing mutation (48).

4. Various Clinical Forms

Most commonly, the symptoms of adrenoleukodystrophy appear at around 7 years of age. In such patients the neurological deterioration is somewhat rapid, leading to a bedridden state in 2–3 years. There is also a group of boys in whom the illness appears between 12 and 20 years of age: in these subjects, the neurological deterioration is usually slower. Finally, the neurological symptoms may occur after 21 years of age (49). This form of the disorder is called adrenomyeloneuropathy (AMN) because the neurological manifestations involve the peripheral nerves rather than the brain. However, some patients with AMN may have early symptoms of mild adrenal insufficiency. These men also present with primary gonadal failure (50). It must also be noted that some cases present with either only neurological manifestations or only Addisonian symptoms. A few subjects with the biochemical abnormality of ALD present no clinical features of the disorder, at least for a long period of time. All the forms mentioned earlier are considered allelic and are all X-linked recessive traits. Except in the rare cases of *de novo* mutation, the mothers of ALD patients are obligate heterozygotes. These women are free of symptoms, but some may present with neurological abnormalities late in life, usually between 40 and 50 years of age.

5. Autosomal Recessive Forms

Whereas ALD is an X-linked trait, there are also autosomal recessive forms that express themselves in the neonatal period. The biochemical defect appears to be similar to that seen in X-linked ALD, but the symptoms of adrenal insufficiency and central nervous system manifestation are more acute. The neonatal ALD is caused by a marked decrease in peroxisomes, in contrast to X-linked ALD, which presents with a normal number of peroxisomes. In Zellweger syndrome (cerebrohepato-renal form), the peroxisomes are almost completely absent. Normal peroxisomes are seen in pseudoneonatal ALD, and such a case has been reported to present with a deletion of the peroxisomal acyl-CoA oxidase gene (51).

The treatment of ALD has been very disappointing. Efforts have been made to change the diet by decreasing the amount of very-long-chain fatty acids. There have also been attempts at supplementation with glycerol trioleate oil as well as addition of glycerol trierucate oil. Although such drugs appear to improve the condition temporarily, the amelioration is not sustained. Attempts have also been made to treat by bone marrow transplantation but without clear success.

F. Wolman Disease (Acid Lipase Deficiency)

Wolman disease is caused by a deficiency of lysosomal acid lipase (52). This enzyme is an esterase that hydrolyzes cholesterol esters and triglycerides. In such patients the normal esterified lipids accumulate in various cells. It

is also called generalized xanthomatosis with calcified adrenals. Symptoms occur in the first month of life as failure to thrive, anemia, hepatomegaly, and splenomegaly. There is also vomiting and diarrhea as well as jaundice. Shortly thereafter, one can notice the calcified, enlarged adrenal gland and decreased cortisol secretion. The locus for lysosomal acid lipase deficiency has been mapped to chromosome 10 (53). This is an autosomal recessive trait. There is no treatment for this extremely rare disorder, which ends in death rapidly.

G. Steroid Sulfatase Deficiency (X-Linked Ichthyosis)

A deficiency of steroid sulfatase results in the accumulation of sulfated products, such as 3, β -hydroxysteroids (particularly DHA-S) and cholesterol sulfate. The ichthyosis is thought to be related to the accumulation in the skin of a large amount of cholesterol sulfate (54). This syndrome is not an adrenocortical insufficiency because cortisol and aldosterone secretion is normal. The normal fetus has low steroid sulfatase activity and relies on the placenta to accomplish this function. Because the placenta is made of maternal cells and at least one of the maternal X chromosomes is normal, the steroid sulfatase activity is adequate during pregnancy.

The steroid sulfatase gene has been mapped to the X chromosome (Xp22.3) near the pseudoautosomal region of the terminal part of the short arm. Large deletions of the X chromosome in the area of the steroid sulfatase gene have been associated with hypogonadotropic hypogonadism and anosmia (Kallmann's syndrome).

H. Mineralocorticoid Deficiency Caused by Mutations of CYP11B2 Gene

As previously discussed, the cytochrome P450 encoded by the CYP11B2 gene is capable of making the conversion of DOC to aldosterone by a series of three enzymatic steps: addition of the 11 β -hydroxyl group to form corticosterone, 18-hydroxylation (also called corticosterone methyloxidase type I) to form 18-hydroxycorticosterone, and 18-dehydrogenation (also called corticosterone methyloxidase type II) to form aldosterone. Although the same enzyme appears to be involved, two types of aldosterone deficiency, 18-hydroxylase and 18-dehydrogenase, have been reported in the literature.

1. 18 α -Hydroxylase Deficiency

These patients present with a general failure to thrive related to mild salt wasting. Laboratory studies show decreased aldosterone and 18-hydroxycorticosterone with a concomitantly elevated secretion of corticosterone and DOC (55, 56). Mineralocorticoid replacement therapy results in the resumption of normal growth in infancy and early childhood. Later in life, treatment becomes unne-

essary. Only a few patients have been reported with this disorder.

2. 18-Dehydrogenase Deficiency

The onset of this disorder is also in infancy or early childhood. It is characterized by a failure to thrive and symptoms of mineralocorticoid deficiency, including hyponatremia, hyperkalemia, and acidosis. However, these patients rarely present in acute adrenal crisis. This is probably because some of the precursors of aldosterone that have some sodium-retaining activity are produced in increased amount. Hormonal study shows an increase in plasma renin activity as well as an increase in DOC, corticosterone, and 18-hydroxycorticosterone, along with low aldosterone (57). It is of interest that these patients present with an increased excretion of urinary 17-OHCS; this is because the urinary metabolites of 18-hydroxycorticosterone give the Porter-Silber reaction (58). A very large Iranian Jewish pedigree has been reported with this salt-wasting disorder (59, 60). Recently, mutations in the CYP11B2 gene were reported by Pascoe et al. (61). Treatment consists of mineralocorticoid replacement therapy. It is of interest to note that later in life many of these patients have successfully withdrawn from treatment.

I. Adrenal Hemorrhage of the Newborn

Adrenal hemorrhage occurs more often after prolonged labor and a traumatic delivery, usually of a large male infant. The normal adrenal has a rich network of small vessels between the capsule and the cortex. This is the site of bleeding in adrenal hemorrhage.

Children with massive bilateral adrenal hemorrhage appear in acute shock caused by adrenal insufficiency and incipient blood loss. On the other hand, if the hemorrhage is unilateral, there are usually no adrenal symptoms. The typical laboratory finding is hypoglycemia with hyponatremic, hyperkalemic acidosis. On physical examination a mass can be felt in the flanks. Sonography reveals a mass that tends to displace the kidney downward (62). Residual calcification may be visible on x-ray of the abdomen 3–6 weeks after the bleeding occurred and as the hemorrhage resolves. With time, the calcifications themselves disappear. The differential diagnosis includes renal vein thrombosis. An ACTH test is useful in differentiating this condition from bilateral adrenal hemorrhage.

J. Adrenal Hemorrhage of Acute Infection

An adrenal crisis may occur during an acute infection, such as fulminating meningococemia, pneumococcal, streptococcal, *Haemophilus*, and diphtheria infections. The acute adrenal insufficiency occurring with meningococemia has also been called Waterhouse-Friderichsen syndrome. The subcapsular hemorrhage is thought to be related to the effects of arterioantitoxin.

Such an acute adrenal crisis occurring at the time of a fulminating infection has an extremely poor prognosis. It is clear that rapid and energetic treatment of the infection, as well as therapy with adrenal steroids in stress doses (IV Solucortef), is necessary.

V. ADDISON'S DISEASE (CHRONIC HYPOADRENOCORTICISM)

In the days of Thomas Addison, tuberculosis was the most common pathogenesis of this condition. Other infections have been reported, such as fungal infections (histoplasmosis and coccidiomycosis). Recently, it was also reported associated with human immunodeficiency virus infection (63). At present, the most important mechanism of destruction of the adrenals is an autoimmune disorder (64). Addison's disease is much less frequent in children than in adult subjects. The clinical features are directly related to the decreased production of adrenal steroids. All or some of the symptoms of adrenal insufficiency outlined in Table 3 may appear. Initially, there is usually general fatigue, muscle pain, weight loss, gastrointestinal symptoms, and hypotension related to salt loss. An acute adrenal crisis may occur at the time of a minor infection or febrile illness. The skin hyperpigmentation is distributed mainly in pressure areas (axillae and groin), as well as in the buccal and vaginal mucosa, the creases of the hand, and the nipples. This hyperpigmentation is related to the increased pituitary secretion of β -lipotropin, which occurs concomitantly with the increased ACTH secretion.

Depending on the cause of Addison's disease, some other specific symptoms can be expected. In cases involv-

Table 3 Signs and Symptoms of Adrenal Insufficiency

Glucocorticoid deficiency
Fasting hypoglycemia
Increased insulin sensitivity
Decreased gastric acidity
Gastrointestinal symptoms (nausea, vomiting)
Fatigue
Mineralocorticoid deficiency
Muscle weakness
Weight loss
Fatigue
Nausea, vomiting, anorexia
Salt craving
Hypotension
Hyperkalemia, hyponatremia, acidosis
Adrenal androgen deficiency
Decreased pubic and axillary hair
Decreased libido
Increased β -lipotropin levels
Hyperpigmentation

ing an infectious agent, there are also signs of this infection in other sites. If the cause is an autoimmune syndrome, one usually finds positive adrenal antibodies. In this latter case, the pathology is a progressive lymphocytic infiltration of the adrenal cortex. In such cases, Addison's disease is often associated with other autoimmune disorders, resulting in a polyglandular syndrome (64). Two types of autoimmune disease associations have been described. Type I includes mucocutaneous candidiasis, hypoparathyroidism, and Addison's disease. In addition, one can also observe pernicious anemia, alopecia, vitiligo, and chronic progressive hepatitis. In type II the association includes Addison's disease and chronic lymphocytic thyroiditis. This association has also been called Schmidt's syndrome. If insulin-dependent diabetes also occurs, it is then called Carpenter syndrome. The diagnosis of Addison's disease is made based on the demonstration of a low cortisol concentration in plasma concomitantly with elevated ACTH levels. Early in the development of the disorder, the cortisol levels may be normal because of adrenal hyperstimulation by high levels of ACTH. The short ACTH test described earlier shows a low or normal cortisol baseline but no increase on ACTH stimulation. Because of the consequences of establishing a diagnosis of Addison's disease, we usually advise also carrying out an intramuscular (IM) ACTH test (25 mg/m² every 8 h for 2–3 days). Urine samples are collected before and on the third day of stimulation for the determination of urinary 17-OHCS and free cortisol.

The typical treatment is replacement of the missing hormone, specifically glucocorticoids and mineralocorticoids. In children, the glucocorticoids are replaced by oral cortisol or prednisone (see Table 4), whereas mineralocorticoids are replaced with Florinef (fludrocortisone). In

Table 4 Maintenance and Stress Dosage of Glucocorticoid and Mineralocorticoid in Treatment of Adrenal Insufficiency

Therapy	Maintenance mean (range)	Stress
Glucocorticoid replacement (mg/m ² /24 h)		
Oral cortisol (one-third dose every 8 h)	20 (12–24)	60
Oral cortisone acetate (one-third dose every 8 h)	25 (15–30)	75
Oral prednisolone (one-half dose every 12 h)	3 (2–4)	9
Oral prednisone (one-half dose every 12 h)	3.5 (2–4)	10
Mineralocorticoid replacement (mg/day)		
Oral fludrocortisone acetate (Florinef)	0.1 (0.05–0.125)	0.1

adolescent and adult women, the lack of adrenal androgens may need to be compensated for by administration of a mild androgenic preparation to improve the libido and the growth of pubic hair.

VI. HYPOADRENOCORTICISM SECONDARY TO DEFICIENT CRH AND/OR ACTH SECRETION

Unless there is an organic abnormality of the hypothalamus or the anterior pituitary, it is often difficult to determine whether a deficient ACTH secretion is related to a deficient output of CRH.

A. Hypopituitarism

Hypopituitarism is characterized by a deficient secretion of one, some, or all pituitary hormones (65). In infancy and childhood the main deficiencies are those of growth hormone, thyroid-stimulating hormone, and ACTH. A deficiency of gonadotropins and prolactin is detected only at puberty. In this chapter we consider ACTH deficiency.

1. Pathophysiology

Various congenital malformations of the brain, particularly midline defects, can result in a deficiency of secretion of hypothalamic hormones, including CRH. The most frequently recognized malformation is the septo-optic dysplasia as originally described by de Morsier. This condition includes agenesis of the septum pellucidum, hypoplasia or aplasia of optic nerves and chiasma resulting in various degrees of visual impairment, and abnormality of the hypothalamus causing secondary hypopituitarism. The midline defects may be mild, with partial hypopituitarism and no eye disorder. It may also be extensive and associated with cleft palate and cleft lip. An absence of gonadotropin secretion during fetal life may result in micropenis in male infants. Congenital malformation of the pituitary gland can also occur and may be the cause of empty sella turcica. Head trauma either at delivery or later in life may result in hemorrhage in the area of the hypothalamus or pituitary gland. This in turn may cause hypopituitarism with ACTH deficiency. Disorders that result in the destruction of normal tissues (hemochromatosis, sarcoidosis, and histiocytosis) can cause hypothalamic and/or pituitary dysfunction. A similar situation can occur following various types of infections, such as meningitis or encephalitis. Tumors arising in the sella (craniopharyngioma) or the hypothalamus likewise result in hypopituitarism. Radiation of a brain tumor may have the same effect. In some patients, no specific cause for the hypopituitarism can be detected. Such cases can involve several hormones of the anterior pituitary (idiopathic panhypopituitarism) or, on rare occasions, only ACTH secretion (idiopathic isolated ACTH deficiency).

2. Clinical Manifestations

The congenital malformations described earlier can be manifested by hypoglycemia if ACTH and cortisol secretion are deficient. The hypoglycemia may be more marked if there is concomitant growth hormone secretion deficiency. Persistent hypoglycemia in a newborn requires the collection of a blood sample for the determination of true glucose, cortisol, growth hormone, and insulin concentrations. In hypopituitarism the concentration of all these hormones is very low. In contrast, in nesidioblastosis, the concentration of insulin, growth hormone, and cortisol is markedly elevated concomitantly with low glucose levels. When the diagnosis of hypopituitarism is established, magnetic resonance imaging (MRI) of the head may show some of the characteristics of septo-optic dysplasia or other brain malformation or injury. In head trauma, the MRI shows evidence of hemorrhage. Brain tumors can also be visualized by MRI studies. Various degrees of impairment of mental development can be present, particularly in hypopituitarism secondary to meningitis or encephalitis. Because hypopituitarism can involve various combinations of tropic hormones, the clinical manifestations in childhood may include symptoms of growth hormone deficiency and hypothyroidism.

Aldosterone secretion is controlled by the renin–angiotensin system, so that there are usually no electrolyte or water abnormalities in hypopituitarism. When a destructive process has taken place, however, there can be involvement of the neuronal cells that secrete antidiuretic hormone (ADH), resulting in a disturbance of electrolytes and water balance characteristic of diabetes insipidus. In addition, following neurosurgery, inappropriate ADH secretion can occur that results in electrolyte abnormalities.

By definition, patients with idiopathic isolated ACTH deficiency have normal thyroid function as well as normal growth and normal sexual maturation at puberty (66). Because females rely on adrenal androgens for the development of pubic hair at puberty, women with idiopathic isolated ACTH deficiency present with scant pubic hair.

3. Laboratory Diagnosis

It is expected that a decreased cortisol secretion would result in hypoglycemia. Indeed, hypoglycemia is marked in patients who have a combined deficiency of ACTH and growth hormone but is usually mild in the absence of growth hormone deficiency. A low cortisol concentration in an 8 a.m. blood sample may be observed, but values are often low–normal to normal.

A single oral dose of Metopirone (metyrapone) given at midnight and an 8 a.m. plasma sample obtained the next morning show a decreased response of plasma 11-deoxycortisol (compound S) in subjects with ACTH deficiency. However, most subjects can respond to the marked stress resulting from the administration of IV Metopirone or IV pyrogen (67, 68). When reviewing a large group of patients with hypopituitarism, Brasel et al. (69)

found that about 50% of the patients had normal adrenocortical function; most of the others had normal basal cortisol but a poor response to the regular Metopirone test. Among the latter subjects, only those who had an organic lesion could not respond to the IV Metopirone test. The 1 μ g ACTH test is particularly helpful in detecting the mild adrenal insufficiency characteristic of panhypopituitarism. Finally, in hypopituitarism, it is important to check the function of all pituitary hormones.

4. Treatment

Treatment consists of appropriate replacement of the deficient hormones. If basal cortisol levels are abnormally low, maintenance as well as stress therapy is required. When basal levels are normal but the oral Metopirone test is inappropriate, then stress therapy only is needed. In addition, patients who have thyroid-stimulating hormone and/or growth hormone deficiency need appropriate replacement. Finally, in ADH deficiency, treatment with intranasal desmopressin (DDAVP) is necessary.

B. Cessation of Glucocorticoid Therapy

It is well established that the administration of glucocorticoids suppresses the secretion of CRH by the hypothalamus and of ACTH by the pituitary gland, resulting in secondary adrenal cortex atrophy. When the dosage is less than the replacement level, however, for whatever period of time, or if the dosage is greater than replacement but for a duration of less than 4 weeks, no adrenocortical atrophy is expected. By contrast, if the dosage is greater than replacement and the duration of treatment is greater than 4 weeks, suppression is expected. Experience has shown that recovery occurs within 6 weeks in about half of patients and within 6 months in all subjects (70).

1. Clinical Features

Hypoglycemia may be observed in some patients. Growth delay is mainly related to the duration of glucocorticoid therapy rather than its cessation (65). The greatest problem may occur at the time of a major medical or surgical stress.

2. Laboratory Tests

A Metopirone test is necessary to determine whether the patient has recovered normal adrenocortical function. As mentioned for hypopituitarism, a 1 μ g ACTH test is simpler and as informative.

3. Treatment

Clearly there is no need for treatment in subjects who have been treated for less than 4 weeks or for those who have received less than replacement therapy for any period of time. For other patients, treatment is required only at times of stress using a dosage equivalent to two to four times replacement and only for the period of stress. Be-

cause more than 90% of subjects recover adrenocortical function after 6 months of cessation of therapy, additional stress doses of steroid are not required after this period of time.

C. Removal of a Unilateral Adrenal Tumor

Tumors that produce excessive amounts of cortisol usually secrete steroids independently of ACTH stimulation. For this reason, such a subject usually presents with suppressed CRH/ACTH secretion and an atrophic contralateral adrenal. During the surgical removal of such tumors, the patient should receive stress dosages of glucocorticoids. After surgery, the dosage should be decreased progressively and the patient should then be considered as are those discussed earlier for cessation of glucocorticoid therapy.

D. Infants Born to Mothers Treated with Glucocorticoids

Cortisol administered during pregnancy can cross the placenta, but the fetal concentration is only about 10% of maternal levels. This is in part because the placenta is rich in the enzyme that transforms cortisol into cortisone. This same enzyme transforms prednisolone into prednisone. Experience has shown that pregnant women treated with prednisone at a dosage of two to five times replacement therapy gave birth to infants whose cortisol secretion rate was normal shortly after birth (71). Nevertheless, such infants should be evaluated for the possible development of hypoglycemia. Because of the physiology of the control of aldosterone secretion, no electrolyte abnormality is expected in infants born of mothers treated with glucocorticoids. In contrast to cortisol or prednisone, dexamethasone readily crosses from the mother to the fetus and is used for fetal therapy.

E. Respiratory Distress Syndrome

There are some differences of opinion on the optimal use of surfactant and glucocorticoids in the treatment of respiratory distress syndrome (RDS). If steroids are used, dexamethasone is the choice because it readily crosses the placenta. Therapy may be continued for a period of time in the neonatal period and may therefore result in suppressed adrenocortical function when treatment is stopped (72). In such cases, therapy might be needed at times of stress.

F. Anencephaly

Adrenal glands are very small in patients with anencephaly, probably secondary to the absence of pituitary tissue, leading to adrenal insufficiency.

VII. HYPOADRENOCORTICISM SECONDARY TO END-ORGAN UNRESPONSIVENESS

Cortisol and aldosterone, like all other steroids, express their effects by binding to a protein specific for each steroid, called a receptor. Receptor abnormalities can cause steroid resistance.

A. Cortisol Resistance

This is a rare disorder that has been discovered in a small number of families (73, 74). In all cases the resistance appeared partial: none of the affected subjects completely lacked glucocorticoid activity. The main laboratory characteristics of cortisol resistance are markedly increased plasma concentrations of cortisol and ACTH, as well as elevated excretion of urinary free cortisol and total 17-hydroxycorticosteroids. In addition, a standard dexamethasone suppression test is partially negative. Such laboratory findings are typical of patients with Cushing's disease, yet subjects with cortisol resistance do not present with any of the symptoms of this disorder. The elevated levels of ACTH result in increased secretion not only of cortisol but also of deoxycorticosterone and corticosterone. These two steroids are responsible for the signs of mineralocorticoid excess, including hypertension, hypokalemia, and metabolic alkalosis. As previously mentioned, the genesis of the resistance syndrome is related to an abnormal glucocorticoid receptor. The gene for this receptor has been mapped to chromosome 5q31-q32 (75). In one family, a point mutation was found in the receptor gene. In all the families reported with this condition, the mode of inheritance has been found to be autosomal dominant.

B. Aldosterone Resistance

Aldosterone resistance is most probably a heterogeneous group of disorders that express themselves clinically as an unresponsiveness of the kidney to aldosterone. One of the first patients described in 1958 by Cheek and Perry (76) presented with a salt-losing syndrome that responded poorly to mineralocorticoid therapy but was adequately corrected by sodium chloride supplementation. A large number of these patients have shown an improvement with age and often did not require further therapy after 1 or 2 years of age. In other affected subjects, however, therapy had to be continued.

Aldosterone resistance represents at least two different entities since autosomal dominant and autosomal recessive modes of inheritance have been reported (77, 78). The gene encoding the mineralocorticoid receptor was cloned recently and mapped to chromosome 4q31 (79). This new knowledge should help us in understanding better the various forms of this disorder.

VIII. TREATMENT OF HYPOADRENOCORTICISM

A. Acute Adrenal Insufficiency

In the acute adrenal crisis, a deficiency of cortisol and aldosterone as well as dehydration must be considered. Fluid and electrolyte replacement to expand blood volume and increase blood pressure must be instituted immediately, particularly in the neonate or small child, who otherwise may decompensate rapidly. During the first hour of therapy, the patient should receive 20 ml/kg 0.9% sodium chloride in 5% glucose solution. The intravenous solution should then be continued to deliver 60 ml/kg over the following 24 h. In general, serum electrolytes improve, with plasma concentrations of sodium and chloride returning to normal but serum potassium often remaining elevated. At some time during the period of fluid replacement therapy, steroid replacement is instituted. Cortisol sodium succinate (Solucortef) is given as a IV bolus at a dosage of 25 mg/m² and is followed by a similar dose added to the 24 h IV maintenance fluid solution. Note that 20–35 mg Solucortef has a mineralocorticoid activity equivalent to 0.1 mg Florinef. After the acute crisis, maintenance therapy is instituted.

B. Maintenance Therapy

1. Glucocorticoid Replacement

Cortisol is the drug of choice because it is the major glucocorticoid secreted physiologically by the adrenal cortex. In infants and children, synthetic preparations with high potency are not recommended for replacement treatment because their proper dosage is difficult to adjust. Furthermore, cortisol has some mineralocorticoid activity, whereas the synthetic preparations have little or none. On the basis of a cortisol secretion rate of 6–14 mg/m²/24 h, a dosage similar to this secretion given over a 24 h infusion should be a maintenance dose. The oral dosage is approximately twice the physiological secretion rate, because some oral cortisol is destroyed by the gastric acidity. Because of the short half-life of cortisol, the total 24 h dose must be given in thirds every 8 h.

Experience has shown that children of school age and adolescents have problems remembering to take the mid-day dose. Prednisone, which has a longer half-life than cortisol, can be used, half of the daily dose being given every 12 h (see Table 4). Prednisolone is the only glucocorticoid available presently in liquid form. It is about seven times more potent than cortisol. There are two commercial preparations: Pediapred contains 1 mg prednisolone per 1 ml; Prelone contains 5 mg prednisolone per 1 ml.

2. Mineralocorticoid Replacement

As previously noted, the secretion rate of aldosterone in human subjects is similar from 2 weeks of age to adult-

hood. Therefore, replacement therapy remains constant regardless of the age of the patient. The only preparation available is 9 α -fluorocortisol acetate (fludrocortisone, Florinef). It is given orally as a single dose of 0.05–0.150 mg/24 h. Mineralocorticoid therapy is effective only if salt is ingested simultaneously. Infant formulas are very low in salt (8–10 mEq/day), and such patients may require a modest sodium chloride supplement (15–30 mEq/day), particularly when they show serum electrolyte abnormalities and elevated plasma renin levels. When the infants start eating regular table food, the additional salt becomes unnecessary.

C. Therapy During Stress

Subjects who receive glucocorticoid therapy for more than 1 month have an unresponsive hypothalamic–pituitary–adrenal axis. As a result, they require additional glucocorticoids during stress. For minor infection with low-grade fever, increased medication may not be required. In moderate stress the dosage is increased to twice maintenance, and in more severe stress to three to four times replacement (see Table 4). If a patient is unable to retain oral therapy during an acute illness, the parents must administer an IM injection of Solucortef (50 mg/m²). Following the IM injection, the parents are advised to discuss the problem with their physician or to attend the hospital emergency room. If this cannot be done within 8 h following the first injection, another IM Solucortef is required every 8 h.

D. Treatment at Time of Surgery

At present we recommend using Solucortef. A dose of 25 mg/m² is given IV just before the start of anesthesia. This is followed by a second dose of 50 mg/m² administered as a constant infusion throughout the surgical procedure. A third 50 mg/m² dose of Solucortef is then given at a constant rate for the rest of the first 24 h period. During the time that the patient is unable to take oral treatment, constant infusions of Solucortef are continued at 50–75 mg/m²/24 h.

In both medical and surgical stress it is important to limit the time of increased glucocorticoid dosage to the period of acute stress and to return to maintenance therapy as soon as improvement occurs. Otherwise, the patient may be overtreated and will then present with symptoms of Cushing's disease.

IX. HYPERADRENOCORTICISM

The syndromes of hyperadrenocorticism can be classified into four subgroups, depending on the predominance of a specific type of adrenocortical steroid. In each of these entities, however, levels of other steroids can also be elevated.

1. Hypercortisolism, characterized by elevated cortisol secretion
2. Adrenogenital syndrome, characterized by abnormal secretion of adrenocortical androgens
3. Feminizing syndrome, related to increased estrogen secretion
4. Hyperaldosteronism, caused by excessive aldosterone secretion

X. HYPERCORTISOLISM

A. Pathophysiology

Except for the iatrogenic hypercortisolism related to glucocorticoid therapy given in pharmacological dosages, this disorder is rare in the newborn period and in childhood. Its frequency increases in adolescence. Harvey Cushing described patients with hypercortisolism related to a pituitary adenoma (80), and the condition has been termed Cushing's disease. When the hypercortisolism is related to an adrenal tumor, it is termed Cushing's syndrome. In adults and, rarely, in children, malignant tumors not necessarily related to an endocrine gland can produce an excessive amount of ACTH, in which case the disorder is called ectopic ACTH syndrome. On occasion, the tumor may produce CRH, which in turn results in increased ACTH secretion and cortisol secretion. Also in adults, chronic alcoholism has been shown to result in increased CRH secretion, which in turn increases ACTH and cortisol output.

B. Clinical Manifestations

The symptoms of hypercortisolism are similar whatever its cause. Because of the ubiquitous effects of glucocorticoid on general metabolism, the symptoms are multiple and varied (81). In muscle cells, cortisol increases the breakdown of proteins into amino acids but decreases glucose uptake, resulting in decreased glycogen storage and muscle wasting. In fat cells, cortisol increases lipolytic enzymes, resulting in hyperlipidemia, hypercholesterolemia, and redistribution of fat with truncal obesity and moon facies. In liver cells, cortisol increases gluconeogenic enzymes and aminotransferases, resulting in hyperglycemia, glycosuria, and what is termed insulin-resistant diabetes. In bone cells, cortisol increases the reabsorption of the protein matrix. Simultaneously, cortisol decreases the synthesis of a specific calcium-binding protein, resulting in the inhibition of vitamin D-mediated calcium absorption from the gut; this, in turn, produces hypocalcemia, osteomalacia, and growth retardation. These effects of cortisol on bone are further aggravated by an increased renal calcium excretion. Because cortisol has some mineralocorticoid activity, hypercortisolism increases sodium retention and potassium loss along with water retention, resulting in often marked hypokalemia but only slight hyponatremia and mild hypertension. In

addition to increasing cortisol secretion, ACTH increases androgen secretion. Hence, when the hypercortisolism is caused by elevated ACTH secretion, the patients present with signs of virilism.

Hypercortisolism increases gastric acidity, which in turn may result in peptic ulcers. However, this is seen more frequently in adults than in children. Also note that hypercortisolism can affect the central nervous system, resulting in emotional instability that alternates between depression and euphoria.

C. Laboratory Diagnosis

1. Demonstrate the Presence of Hypercortisolism

This is reliably done by obtaining a 24 h urine specimen and determining both total urinary 17-hydroxycorticosteroids and free cortisol. In children and adults, the urinary excretion of 17-OHCS is similar when the values are corrected for body size. The normal value is 2.9 ± 1.2 mg/m²/24 h (mean \pm SD), as shown by the shaded area in Figure 10. Therefore, values of the urinary 17-OHCS below 5.5 mg/m²/24 h and urinary free cortisol of less than 70 μ g/m²/24 h rule out hypercortisolism. Among obese subjects, about 30% (Fig. 10) have urinary 17-OHCS values above 5.5 mg/m²/24 h (14). Such subjects require a low-dosage dexamethasone suppression test (1.25 mg dexamethasone/m²/24 h for 2 days). A good suppression suggests obesity and lack of it suggests hypercortisolism.

2. Determine the Cause of the Disorder

This is done by carrying out a CRH stimulation test (24) and/or a high-dosage dexamethasone suppression test (3.75 mg/m²/24 h for 2 days). The response of plasma ACTH and cortisol to CRH administration is presented in Figure 9. A marked response in the CRH stimulation test and a good suppression in the high-dosage dexamethasone suppression test suggest an hypercortisolism that is pituitary dependent, that is, Cushing's disease. In contrast, a lack of response to the CRH stimulation and a lack of suppression (24) to the high-dosage dexamethasone suppression test strongly favor hypercortisolism being caused by an adrenal tumor or possibly a tumor producing ectopic ACTH.

3. MRI of the Head and Abdomen

In theory, MRI of the head will demonstrate the presence of a pituitary adenoma. Unfortunately, the adenoma can be very small and is visualized in about only one-third to one-half of cases. MRI of the abdomen visualizes adrenal tumors 1 cm or more in diameter. In hypersecretion of ACTH, bilateral adrenal hyperplasia is observed by MRI in some cases.

4. Bilateral Petrosal Sinus Sampling

This has been proposed as a means to localize a small pituitary adenoma that is not visible on the MRI scan.

Figure 10 Urinary 17-hydroxycorticosteroids corrected for body surface area ($\text{mg}/\text{m}^2/24 \text{ h}$) in 160 obese individuals of various age. Their values are compared to the mean \pm SD of control subjects (shaded area). About 30% of obese subjects had excretions above the control mean $+2$ SD. (From Ref. 14.)

Catheters are placed in the left and right inferior petrosal sinuses and blood samples are obtained before and 10 and 30 min after administration of CRH ($100 \mu\text{g}/\text{m}^2$). High baseline concentrations of ACTH are expected. The differential in ACTH increase following CRH should help to determine the location of the microadenoma on the left or right side of the pituitary gland. Although this technique has been reported by some investigators to be successful (82), others have found it to be traumatic for the patient, resulting in a fair amount of body radiation, and not always accurate.

D. Treatment

Clearly, the treatment is dictated by the cause of the hypercortisolism. The treatment of Cushing's syndrome caused by an adrenal tumor is surgical. An adenoma or well-encapsulated carcinoma without metastasis offers the best opportunity for a complete cure. By contrast, the prognosis of malignant adrenal tumors that produce glucocorticoids is generally poor.

If the adrenal tumor is localized before surgery, a transthoracic approach affords excellent exposure and ease of removal. If the tumor is not well localized, a transperitoneal approach is indicated. Patients with metastasis can be treated with the drug mitotane (*o,p'*-DDD), but results have been disappointing and the drug is not always well tolerated. Cisplatin has also been used with limited success.

Autonomous adrenal tumors secrete cortisol in high concentrations and suppress ACTH secretion, resulting in atrophy of the contralateral adrenal gland. Therefore, we advise the following therapy at the time of surgery: an IV dose of $25 \text{ mg}/\text{m}^2$ of Solucortef administered immediately before the start of anesthesia; this is followed by a constant-rate infusion of $50 \text{ mg}/\text{m}^2$ of Solucortef throughout surgery; after surgery, an additional IV constant-rate infusion of $50 \text{ mg}/\text{m}^2$ is given for the rest of the first 24 h. On postsurgical days, a constant infusion of Solucortef is continued at $50 \text{ mg}/\text{m}^2/24 \text{ h}$ until oral therapy can be given at three to four times replacement dosage. After the acute period, it may be necessary to continue oral therapy at three-fourths to one-fourth replacement therapy for a few months.

In Cushing's disease with bilateral adrenal hyperplasia, several forms of therapy have been used. In the past, bilateral adrenalectomy was widely employed, resulting in immediate cure of hypercortisolism but also in adrenal insufficiency that required glucocorticoid and mineral corticoid replacement for life and the possibility of development of a pituitary tumor (83). Radiation of the sella turcica has also been used extensively in adults but not in children because it often results in destruction of growth hormone-secreting cells; however, newer stereotactic techniques of delivery of radiation have given good results (84).

Transsphenoidal microsurgery is now used to remove pituitary microadenomas and has been successful in bring-

ing about complete cures in many patients (85, 86). This form of therapy requires an experienced neurosurgical team to obtain the best chances of success (87). In a few patients, surgery has resulted in panhypopituitarism. Recurrence of the pituitary adenoma can also occur (88).

Several drugs have been used in the treatment of Cushing's disease. Cyproheptadine, a serotonin antagonist, can suppress ACTH secretion but it is generally not recommended as long-term medical management of the disease and it often does not return the cortisol secretion rate to normal. Bromocriptine, a dopamine agonist, although useful for the treatment of prolactin and growth-hormone-secreting pituitary adenomas, has not been of value in treating ACTH-secreting pituitary tumors. Metyprone and aminoglutethimide, which suppress adrenal secretion, have been recommended for the short-term, pre-surgical treatment of Cushing's disease.

Treatment of ectopic ACTH syndrome consists of the removal of the ACTH-secreting tumor. In cases of iatrogenic Cushing's syndrome, stopping the excessive glucocorticoid therapy is recommended.

XI. ADRENOGENITAL SYNDROME

The adrenogenital syndrome is characterized by an abnormally elevated secretion of adrenal androgens. Hence, the virilizing forms of congenital adrenal hyperplasia, mainly 21-hydroxylase and 11-hydroxylase deficiency, are part of the syndrome. However, the excessive androgen secretion of CAH is secondary to an increased ACTH secretion, itself secondary to a deficiency of one of the enzymes required for cortisol biosynthesis. For this reason, CAH is considered a form of hypoadrenocorticism, and the only cause of adrenogenital syndrome is a virilizing adrenal tumor, which is a rare condition in childhood.

A. Clinical Manifestations

These tumors result in masculinization of prepubertal children. In boys, it produces a pseudoprecocious puberty (89, 90). Sexual hair (pubic, axillary, and sometimes facial hair) develops and the penis is enlarged to adult size, with frequent erections. However, the testes remain prepubertal or slightly enlarged. In girls, this masculinizing syndrome is characterized by pubic and axillary hair with an enlarged and erectile clitoris (Fig. 11).

In both boys and girls, the excessive secretion of androgens accelerates growth, with an advancement of height age and bone age along with an increase in muscle mass.

An association of such a tumor with body hemihypertrophy and congenital malformations of the urogenital tract has been reported (91). If the clinical picture includes signs of hypercortisolism caused by increased cortisol secretion, the patient should be considered as presenting with Cushing syndrome. This distinction is important be-

cause the prognosis of purely virilizing tumors and mixed tumors is different.

B. Pathology

Virilizing adrenal tumors are usually carcinomas containing malignant cells. Experience shows that the degree of malignancy is low, however, and it is rare to observe metastasis at the time of surgery. In cases of long standing, the tumor may invade the capsule of the adrenal and may metastasize to the kidneys, liver, lungs, and bones. On occasion, an adrenal adenoma may also be virilizing. However, it is often difficult to determine microscopically whether the tumor is malignant or benign. Moreover, the clinical evolution does not always parallel the pathological appearance.

C. Laboratory Studies

These tumors secrete large amounts of androgens, as demonstrated by the elevated urinary excretion of total 17-ketosteroids and of dehydroepiandrosterone, along with abnormally high plasma concentrations of DHA and DHA sulfate (92). The latter two steroids are typical markers of virilizing adrenal tumors. There is also hypersecretion of androstenedione. The peripheral metabolism of DHA and androstenedione to testosterone is the cause of the virilism.

In contrast with congenital adrenal hyperplasia, the excessive androgen secretion of virilizing adrenal tumors is not suppressed by dexamethasone administration. In premature adrenarche, the increase in DHA, DHA sulfate, and androstenedione is at or below adult values and can also be suppressed by dexamethasone.

The differential diagnosis also includes virilizing gonadal tumors. In boys, Leydig cell tumors produce mainly testosterone with minimal amounts of DHA and DHA sulfate. In girls, virilizing ovarian tumors occur only after puberty and include the various types of tumors seen in adult women (adrenal rest tumor, hilar cell tumor, and arrhenoblastoma).

Although ultrasound study of the abdomen is usually excellent for the detection of ovarian tumors, it is not very sensitive as far as adrenal tumors are concerned. A computed tomographic (CT) scan or MRI without and with contrast is necessary to localize an adrenal mass.

D. Treatment

The tumor should be excised carefully, without damaging its capsule. Every effort should be made to remove the tumor en bloc. If present, metastases should be removed as completely as possible. In such cases, radiotherapy or chemotherapy with o,p'-DDD can be attempted.

Glucocorticoid therapy should be used during and after surgery until the status of the contralateral adrenal gland is determined. Theoretically, such treatment should

Figure 11 (a) Abdomen of a 4-year-old girl with virilizing adrenocortical carcinoma. (b) Surgical specimen. (From Ref. 106.)

not be needed if the tumor does not secrete excessive cortisol. Practically, it is easy and safer to administer glucocorticoid. As previously noted, the prognosis of purely virilizing tumors that are well encapsulated is usually excellent, whereas that of tumors that also secrete excessive amounts of cortisol is generally poor.

XII. FEMINIZING ADRENAL TUMORS

These tumors are even rarer than virilizing adrenal tumors in infants and children. Extrapolating from experience in

adults, approximately half of feminizing adrenal tumors are malignant (93).

A. Clinical Manifestations

In boys, the major sign is gynecomastia; the testes are prepubertal in size, but pubic hair is often present, being related to the concomitant secretion of androgens and estrogens by the tumor. In girls, there is breast development, as seen in precocious puberty; pubic hair can be present, and breakthrough vaginal bleeding may occur. In children of both sexes, there is rapid statural and osseous devel-

opment, height age and bone age being significantly advanced.

B. Pathology

For virilizing adrenal tumors, the diagnosis of malignancy is often difficult.

C. Laboratory Diagnosis

Urinary and plasma estrogen levels are usually elevated. Most of the tumors also secrete an excess of androgens, resulting in increased urinary 17-ketosteroids and plasma DHA, DHA sulfate, androstenedione, and, to some extent, testosterone. This excessive secretion of steroids is not dexamethasone suppressible. Often the laboratory results are not characteristic. CT scan and/or MRI is needed to make the definitive diagnosis of adrenal tumor.

D. Differential Diagnosis

Because of the lack of specificity of the clinical signs and hormone assays, the diagnosis of feminizing adrenal tumor is usually difficult.

Gynecomastia is a physiological finding in pubertal boys, and it is not easy to differentiate the breast enlargement that accompanies precocious puberty in a young boy from that of a feminizing adrenal tumor. A modest increase in testicular size in precocious puberty may not be differentiated from infantile testes in feminizing tumor. An LHRH test may be useful, showing a pubertal increase in LH in precocious puberty.

In prepubertal girls, a feminizing adrenal tumor must be differentiated from premature telarche and idiopathic sexual precocity. Estrogens are markedly increased in an adrenal tumor but not in premature telarche. A positive LHRH test should be helpful in determining sexual precocity.

E. Treatment

The tumor should be removed surgically promptly after the diagnosis has been established. If the tumor did not secrete excessive amounts of cortisol or 11-deoxycortisol, the prognosis is usually good.

XIII. HYPERALDOSTERONISM

The various syndromes of hyperaldosteronism are outlined in Table 5.

A. Secondary Hyperaldosteronism

An increase in plasma renin activity with increased aldosterone secretion is a physiological mechanism for the maintenance of serum electrolyte concentrations and fluid volume. It occurs with sodium loss, potassium retention,

Table 5 Syndromes of Hyperaldosteronism

or decreased intravascular volume. Sodium loss occurs during diarrhea or excessive sweating. It also happens with administration of diuretics, in patients with renal tubular acidosis or salt-losing nephritis. The edema of the nephrotic syndrome or the ascites of cirrhosis of the liver causes a decrease in blood volume that results in compensatory increased aldosterone secretion. In all these conditions, the hyperaldosteronism is an attempt to re-establish an electrolyte–water balance, and this is termed secondary hyperaldosteronism. It may also occur in hypertension related to a unilateral renal disease with increased plasma renin activity. The increased aldosterone secretion characteristic of the non-salt-losing form of 21-hydroxylase deficiency can also be considered a secondary hyperaldosteronism because it occurs in response to the salt-losing tendency created by excessive secretion of 17-hydroxyprogesterone and progesterone.

B. Primary Hyperreninemia

The most common cause is renal ischemia, whether unilateral or bilateral. Such ischemia results in excessive secretion of renin by the juxtaglomerular apparatus.

Tumors of the juxtaglomerular apparatus have also been reported as a rare cause of renin excess (94).

C. Primary Hyperaldosteronism

In 1955, Conn (95) described a disorder termed primary aldosteronism that was caused by an aldosterone-producing tumor of an adrenal gland. The symptoms included arterial hypertension, hypokalemic alkalosis, muscle weakness, and polyuria. Subsequently it was demonstrated that the plasma renin activity was markedly decreased. This syndrome is encountered mainly in adults, and only a very few cases have been reported in children.

1. Clinical Manifestations

The full clinical picture of this disorder is directly related to the hyperaldosteronism. Aldosterone increases potas-

sium excretion, resulting in hypokalemia. This in turn results in muscle weakness with various types of paresthesias and sometimes unusual types of periodic paralysis. It is thought that the chronic hypokalemia is also responsible for the polyuria and resulting polydipsia. Aldosterone increases the retention of sodium, but the hypernatremia is largely compensated for by increased water retention. The increase in blood volume in turn results in hypertension, both systolic and diastolic.

2. Laboratory Diagnosis

The typical finding is a high aldosterone secretion with low plasma renin activity. Administration of a high-sodium diet or of DOCA fails to suppress aldosterone secretion. The low plasma renin activity differentiates the syndrome from the high renin levels seen in secondary hyperaldosteronism. A CT scan or MRI is necessary to demonstrate the presence of a mass in one of the adrenals. Because the adrenocortical tumor may be quite small, it may not be seen by MRI. Catheterization of the renal veins and selective adrenal vein sampling for measurement of aldosterone may demonstrate a very large secretion on one side and a lack of aldosterone on the other.

3. Pathology

In most cases, the tumor is an adenoma, but on occasion it can be a carcinoma (96). There can also be bilateral nodular hyperplasia of the adrenal cortex or focal hyperplasia of normal glomerular cells arranged in a nodular fashion.

4. Treatment

The adrenal tumor should be removed. Because it does not secrete cortisol, there is usually no need for glucocorticoid therapy during surgery.

In bilateral nodular hyperplasia, bilateral adrenalectomy may be considered. In such cases, however, medical treatment with spironolactone, an inhibitor of aldosterone biosynthesis, is preferable if it can control the hypertension.

D. Bartter's Syndrome

This disorder is thought to be related to a renal tubular defect of chloride reabsorption. This results in passive loss of sodium, which in turn activates the renin-angiotensin-aldosterone system. In addition, the hyperaldosteronism results in hypokalemic alkalosis.

Patients usually present in infancy with failure to thrive, vomiting, weakness, and dehydration. Blood pressure is normal. There is hypochloremic metabolic alkalosis with hypokalemia and usually normal blood sodium. Plasma renin activity and aldosterone are elevated. One finds an increased urinary excretion of chloride and potassium with elevated excretion of prostaglandin. Renal biopsy shows hyperplasia of the juxtaglomerular apparatus (97).

There is no specific therapy, and an attempt is made to correct the electrolyte abnormalities. In some patients, the use of prostaglandin synthetase inhibitors, such as indomethacin or salicylates, can be beneficial.

E. Dexamethasone-Suppressible Hyperaldosteronism (Glucocorticoid-Remediable Aldosteronism)

In 1966, Sutherland et al. (98) reported a clinical condition characterized by hypertension, increased aldosterone secretion, and low plasma renin activity that was fully relieved by administration of dexamethasone (93, 94). Most recent progress in the molecular biology of steroid biosynthesis has been able to demonstrate that this disorder was related to a chimeric gene encoding for a cytochrome P450 possessing aldosterone synthetase activity but capable of responding to ACTH stimulation (Fig. 12). It is inherited as an autosomal dominant trait.

1. Clinical Manifestations

Symptoms and laboratory abnormalities in this disorder are identical to those found in primary hyperaldosteronism caused by an adrenal adenoma (98, 99). They include hypertension, hypokalemia, elevated plasma aldosterone concentrations, and low plasma renin activity. However, and in contrast to primary hyperaldosteronism, the hypertension, hypokalemia, increased aldosterone secretion, and low plasma renin activity can be returned to normal by the administration of dexamethasone. It has been noted that affected subjects always present with hypertension, but the degree of hypokalemia is variable.

2. Pathogenesis

Two genes, CYP11B1 and CYP11B2, encode for a cytochrome P450 possessing 11β -hydroxylase activity. However, CYP11B1 is mainly expressed in the zona fasciculata, under ACTH control, and CYP11B2 is mainly expressed in the zona glomerulosa, under angiotensin II control. The product of the CYP11B2 gene is also called aldosterone synthetase, which is capable of activating 18-hydroxylation and 18-oxidation in addition to 11β -hydroxylation. Both genes are located on chromosome 8q22.

It was recently proposed that a hybrid gene, CYP11B1/CYP11B2, as shown in Figure 12, is the cause of the disorder (101–103). The promoter of the hybrid gene is derived from the CYP11B1 and is therefore responsive to ACTH, but the chimeric protein encoded by this gene has the function of the aldosterone synthetase, hence the reason for the ACTH-dependent hyperaldosteronism. Because the chimeric gene is expressed in the zone fasciculata, which also expresses the CYP17 gene, there can be secretion of cortisol, which has also been hydroxylated in the carbon 18. Indeed, the secretion of 18-hydroxy and 18-oxocortisol is characteristic of dexamethasone-suppressible hyperaldosteronism. A series of

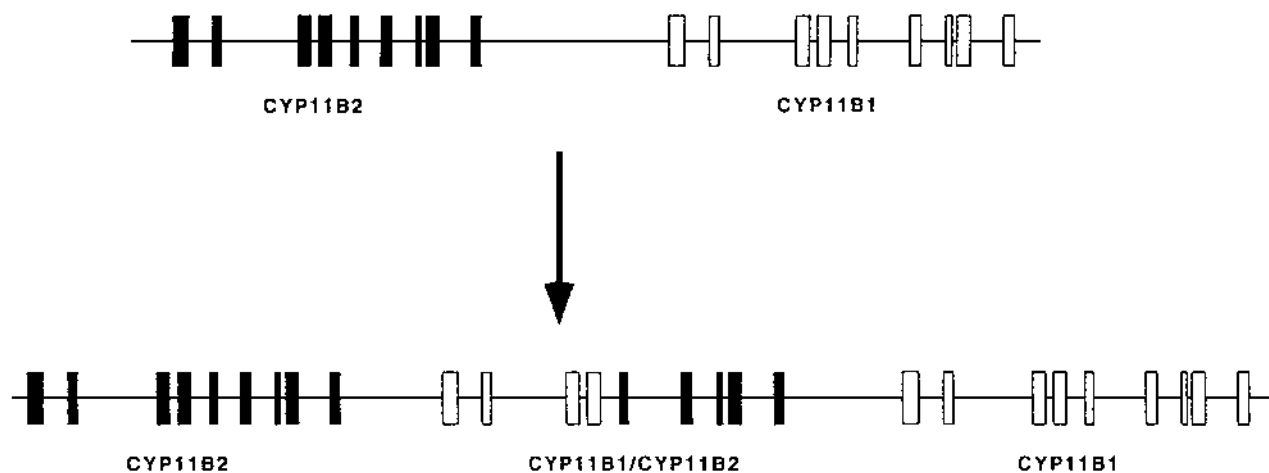

Figure 12 Gene organization of *CYP11B1* and *CYP11B2* genes (upper part of the figure) and organization of the hybrid *CYP11B1/CYP11B2* gene resulting from unequal crossing over (lower part of the figure). The resulting hybrid gene can be stimulated by ACTH as it includes the promoter of the B1 gene and can form aldosterone as it includes the 3' end of the B2 gene. (From Ref. 2.)

recent reports has identified such a chimeric gene, which includes the 5' sequences of the *CYP11B1* gene and the 3' sequences from the *CYP11B2* gene.

3. Treatment

As expressed by the name of the syndrome, dexamethasone or other glucocorticoid administration in replacement dosages turns off ACTH secretion, which in turn blocks aldosterone secretion as well as cortisol output. Although glucocorticoid-remediable aldosteronism remains rare as a cause of hypertension in children, a recent report (100) suggested that it should be considered in severe cases with a positive family history of early-onset hypertension.

F. Familial Deficiency of 11 β -Dehydrogenase

This congenital disorder is characterized by an apparent mineralocorticoid excess (104, 105). A gene encoding 11 β -dehydrogenase has been cloned and mapped to chromosome 1 (106). This enzyme has the property of metabolizing cortisol into cortisone. In blood, the ratio of cortisol to cortisone is 5:1–10:1. In contrast, the kidney is rich in 11 β -dehydrogenase, and only cortisone is found in this organ (107, 108). Under physiological conditions the receptor protein for mineralocorticoids has equal affinity for cortisol and aldosterone, but cortisone does not bind.

1. Pathophysiology

In this syndrome, a deficiency of 11 β -hydroxysteroid dehydrogenase in the kidneys results in binding of cortisol to the mineralocorticoid receptor. In view of the large concentration of cortisol relative to aldosterone, there is sodium retention and water retention. The increased blood

volume results in hypertension, and the increased mineralocorticoid activity generates hypokalemia. Under such conditions, plasma concentrations of aldosterone and renin activity are low.

2. Treatment

The severe hypertension in this disorder is generally resistant to any medical therapy. Dexamethasone binds to the glucocorticoid receptor with high activity but does not interact with the mineralocorticoid receptor. The full suppression of cortisol secretion by dexamethasone does not improve the hypertension, however, suggesting that the increased mineralocorticoid activity of the syndrome is mediated by both the renal glucocorticoid receptor and the mineralocorticoid receptor (109).

It has been reported that subjects who ingest large amounts of licorice develop hypertension and hypokalemia, with low levels of plasma aldosterone and plasma renin activity. It has been shown (110) that licorice contains glycyrrhizic acid, which has the property of inhibiting 11 β -hydroxysteroid dehydrogenase activity.

Congenital Adrenal Hyperplasia

University of Parma, Parma, Italy

I. INTRODUCTION

Congenital adrenal hyperplasia (CAH) is a family of inherited disorders of adrenal steroidogenesis. With only one exception, each disorder results from a deficiency in one of the several enzymatic steps necessary for normal steroid synthesis. Since the earliest case of CAH documented in 1865 by the Neapolitan anatomist De Crecchio (1), numerous investigators have unraveled the mechanisms of adrenal steroid synthesis and the associated enzyme defects responsible for the clinical syndromes. This report includes recent advances in the investigation and understanding of these disorders.

II. PATHOPHYSIOLOGY

The adrenal glands synthesize three main classes of hormones: mineralocorticoids, glucocorticoids, and sex steroids. Figure 1 shows a simplified scheme of the adrenal synthesis of these steroids from the cholesterol precursor molecule. Each enzymatic step is indicated.

The pituitary regulates adrenal steroidogenesis via adrenocorticotrophic hormone (ACTH). ACTH stimulates steroid synthesis by acting on the adrenals to increase the conversion of cholesterol to pregnenolone, which is the principal substrate for the steroidogenic pathways. The central nervous system controls the secretion of ACTH, its diurnal variation, and its increase in stress via corticotropin-releasing factor (2, 3). The hypothalamic–pituitary–adrenal feedback system is mediated through the circulating level of plasma cortisol; any condition that decreases cortisol secretion results in increased ACTH secretion. Cortisol therefore exerts a negative feedback effect on ACTH secretion.

In most forms of congenital adrenal hyperplasia, an enzyme defect blocks cortisol synthesis, thus impairing cortisol-mediated negative feedback control of ACTH secretion (Fig. 2). Oversecretion of ACTH ensues, which stimulates excessive synthesis of the adrenal products of those pathways unimpaired by an enzyme deficiency and causes an accumulation of precursor molecules in pathways blocked by an enzyme deficiency.

The clinical symptoms of the different forms of congenital adrenal hyperplasia result from the particular hormones that are deficient and those produced in excess. In the most common case, that of 21-hydroxylase deficiency, the aldosterone and cortisol pathways are blocked and the androgen pathway, which does not involve 21-hydroxylation, is overstimulated. The characteristic virilization caused by 21-hydroxylase deficiency is due to excessive secretion of adrenal androgens.

An enzymatic deficiency of 11 β -hydroxylase also results in decreased cortisol synthesis with consequent overproduction of cortisol precursors and sex steroids, as seen in 21-hydroxylase deficiency. Thus, 11 β -hydroxylase deficiency shares the clinical feature of virilization with the 21-hydroxylase disorder. An additional finding in many, but not all, patients with 11 β -hydroxylase deficiency is hypertension. The hypertension is thought to derive from the excess accumulation of the aldosterone precursor, deoxycorticosterone (DOC), a steroid with salt-retaining activity.

Disorders of adrenal steroidogenesis have also been described in association with deficiencies of 3 β -hydroxysteroid dehydrogenase, 17 α -hydroxylase/17, 20-lyase, and steroidogenic acute regulatory protein. A summary of the biochemical features of these disorders is presented in Table 1. The enzyme deficiency of 21-hydroxylase is the most common type of CAH, accounting for 90–95% of

Figure 1 Simplified scheme of adrenal steroidogenesis shows abnormal secretion of hormones in congenital adrenal hyperplasia resulting from 21-hydroxylase deficiency. OH, hydroxylase; HSD, hydroxysteroid dehydrogenase.

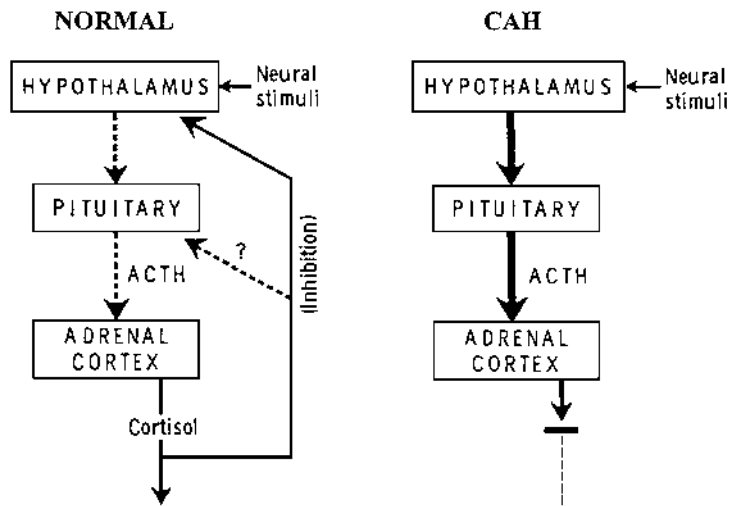

Figure 2 Regulation of cortisol secretion in normal subjects and in patients with congenital adrenal hyperplasia. (From Ref. 133.)

Table 1 Clinical and Laboratory Features of Various Disorders of Adrenal Steroidogenesis

Deficiency (syndrome)	Genital ambiguity	Postnatal virilization	Salt metabolism	Diagnostic hormones	Treatment
21-Hydroxylase Classic Salt wasting (SW)	F	Yes	Salt wasting	17-Hydroxyprogesterone (17OHP) Δ ⁴ -Androstenedione (Δ ⁴ -A) Aldosterone	Hydrocortisone (HC), 15–20 mg/m ² /day orally (PO), and fludrocortisone acetate (9αFF), 0.05–0.2 mg/day orally
Simple virilizing (SV)	F	Yes	Normal (elevated renin)	17-OHP, Δ ⁴ -A	HC (same); addition of 9αFF (same) if elevated renin
Nonclassic (asymptomatic and asymptomatic)	No	Yes	Normal	17-OHP, Δ ⁴ -A	HC, 10–15 mg/m ² /day or dexamethasone, 0.25–0.5 mg/day or prednisone 5–10 mg/day
3β-Hydroxysteroid dehydrogenase Classic	M(±F)	Yes	Salt wasting	17-OHP 17-hydroxyprogrenolone (Δ ⁵ 17-OHP) Dehydroepiandrosterone (DHEA) Δ ⁴ -A	HC and 9αFF as for SW 21-hydroxylase deficiency
Nonclassic	No	Yes	Normal	17-OHP DHEA	HC as for nonclassic 21-hydroxylase deficiency

all cases, with 11 β -hydroxylase deficiency the second most common, occurring in 5–8% of cases.

III. CLINICAL FEATURES

The most prominent clinical feature of 21- and 11 β -hydroxylase deficiency is virilization. Because adrenocortical function begins by month 3 of gestation, a fetus with 21- or 11 β -hydroxylase deficiency is exposed to oversecreted adrenal androgens at the critical time of sexual differentiation. In a female fetus, the excessive adrenal androgens masculinize the external genitalia and female pseudohermaphroditism results. In rare cases, the masculinization is so profound that the urethra is penile (4). The internal genitalia (i.e., uterus and fallopian tubes), which arise from the müllerian ducts, are normal because the female fetus does not possess Sertoli's cells of the testes, the source of müllerian-inhibiting factor. The female genital abnormalities are present only in the androgen-responsive external genitalia. Males with 21- or 11 β -hydroxylase deficiency do not manifest genital abnormalities at birth but may demonstrate hyperpigmentation.

The simple virilizing form of 21-hydroxylase deficiency is characterized by excess adrenal androgen secretion, which causes prenatal virilization of the genetic female and postnatal virilization of both boys and girls. In the salt-wasting form, in addition to the excess adrenal androgens, there is aldosterone deficiency causing low serum sodium, high serum potassium, and vascular collapse. In the more severe salt-wasting form, both newborn boys and girls are subject to early, life-threatening, salt-wasting crises within the first few weeks of life.

The various clinical and biochemical features associated with the different forms of congenital adrenal hyperplasia are indicated in Table 1. Continued oversecretion of adrenal androgens as a result of untreated 21- or 11 β -hydroxylase deficiency results in progressive penile or clitoral enlargement; advanced bone age and tall stature in early childhood with ultimate short stature caused by premature epiphyseal closure; early appearance of facial, axillary, and pubic hair; and acne. In 11 β -hydroxylase deficiency hypertension is frequently, although not necessarily, an additional finding. Girls with congenital adrenal hyperplasia who remain untreated do not develop breasts or menstruate and are further virilized. In untreated boys, the testes may remain small and there may be infertility, although some untreated men have been fertile (5).

In 3 β -hydroxysteroid dehydrogenase deficiency (3 β -HSD), steroid synthesis in both the adrenal cortex and in the gonads is affected, and only Δ^5 steroid precursors are formed and secreted. Circulating Δ^5 precursors undergo conversion peripherally to active Δ^4 steroids and are believed to cause virilization of the external genitalia in genetic females with 3 β -HSD. Genetic males have incomplete external genital development due to deficient Δ^4 androgen production in the gonads (6, 7). Thus, genital ambiguity results in children of both sexes. Similar to 21-

and 11 β -hydroxylase deficiency, the appearance of the external genitalia at birth does not predict the severity of the enzyme defect. There have been reports of a milder, non-classic form of 3 β -HSD deficiency; however, mutations in the gene for 3 β -HSD have yet to be identified in these patients (8, 9).

Steroid 17 α -hydroxylase/17,20-lyase deficiency, which accounts for approximately 1% of all CAH cases, affects steroid synthesis in the adrenals and gonads (10). Patients have impaired cortisol synthesis, leading to elevated ACTH that increases serum levels of deoxycorticosterone and especially corticosterone, resulting in low-renin hypertension, hypokalemia, and metabolic alkalosis. Affected females are born with normal external genitalia. Affected males are also born with undervirilized genitalia due to their deficient gonadal testosterone production. 17 α -Hydroxylase/17,20-lyase deficiency is often recognized at puberty in girls who fail to develop secondary sex characteristics.

Congenital lipoid hyperplasia is an extremely rare and severe form of CAH in which cholesterol is not converted to pregnenolone. Synthesis of all adrenal and gonadal steroids is deficient and results in accumulations of cholesterol and cholesterol esters in the newborn. Recent studies have revealed that abnormalities of the steroidogenic acute regulatory protein (StAR) are responsible for this disorder (11, 12). StAR is involved in the transfer of cholesterol from the outer to the inner mitochondrial membrane, which is the rate-limiting step in steroidogenesis. Males with congenital lipoid hyperplasia are born with female-appearing external genitalia. Females have a normal genital phenotype at birth but remain sexually infantile without treatment, and all patients present with salt wasting. If not detected and treated, lipoid CAH is usually fatal (13).

IV. CLINICAL FORMS OF ADRENAL HYPERPLASIA CAUSED BY 21-HYDROXYLASE DEFICIENCY

Two major phenotypes are recognized in 21-hydroxylase deficiency: classic and nonclassic (late onset; Fig. 3). Within the latter class of patients are those who demonstrate the biochemical defect but lack any overt stigmata of hyperandrogenism. Table 2 delineates the differences between classic and nonclassic 21-hydroxylase deficiency.

A. Classic

Classic congenital adrenal hyperplasia is a well-known genetic disorder transmitted by an autosomal recessive gene. The biochemical and clinical abnormalities of this form of CAH are clearly present in patients both prenatally and postnatally. Progesterone, 17-OH-progesterone, androstenedione, and testosterone are secreted in excess, consequent to increased ACTH stimulation resulting from an inherited 21-hydroxylase deficiency that impairs cor-

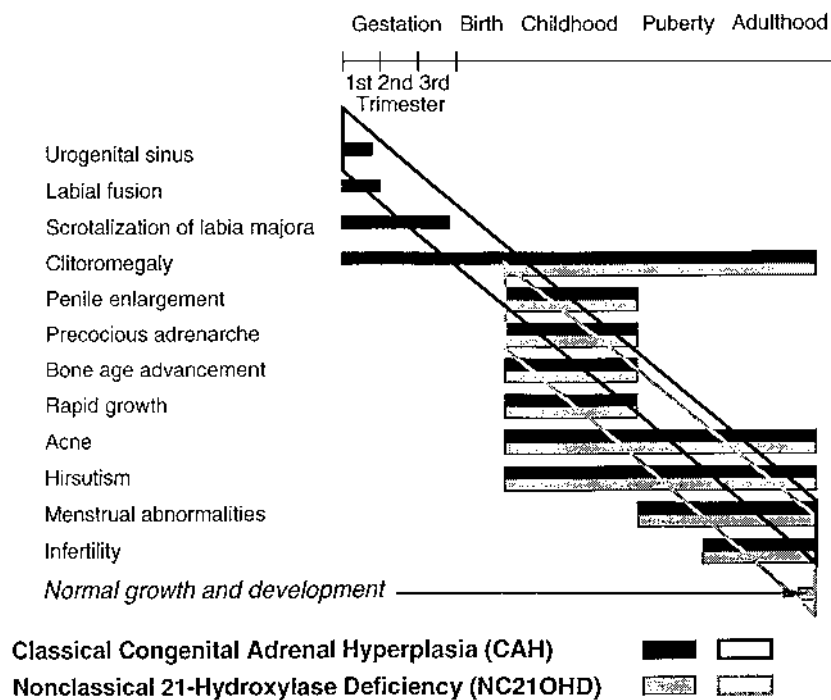

Figure 3 There is a wide spectrum of clinical presentation in 21-hydroxylase deficiency, ranging from prenatal virilization with labial fusion to precocious adrenarche, to pubertal or postpubertal virilization. During their lifetimes, patients' conditions may change from symptomatic to asymptomatic. (From New MI, Dupont B, Grumbach K, Levine LS. The adrenal hyperplasias. In: Stanbury JB, Wyngaarden JB, et al., eds. The Metabolic Basis of Inherited Disease, 5th ed. New York: McGraw-Hill, 1983: 973–1000.)

tisol synthesis (14–21). As expected, the urinary excretion of the metabolites of these steroids is also increased (22, 23). Abnormalities in cortisol secretion are also associated with alterations in the secretion of other pituitary hormones such as GH and TSH (24, 25).

In genetic females with congenital 21-hydroxylase deficiency, the developing fetus is exposed to the excessive adrenal androgens, equivalent to the male fetal level, secreted by the hyperplastic adrenal cortex. External genitalia in the genetic female range from mildly ambiguous to completely virilized. The internal genitalia (uterus and fallopian tubes) are not affected by the excess androgens. Boys with 21-hydroxylase deficiency do not manifest genital abnormalities at birth. Postnatally, in untreated boys and girls, continued excessive androgen production results in rapid somatic growth; advanced epiphyseal maturation; progressive penile or clitoral enlargement; early appearance of facial, axillary, and pubic hair; and acne. Without treatment, early epiphyseal closure and short stature result (26).

In three-quarters of cases with classic 21-hydroxylase deficiency, salt wasting occurs, as defined by hyponatremia, hyperkalemia, inappropriate natriuresis, and low serum and urinary aldosterone levels with concomitant high plasma renin activity (PRA). The increase in the propor-

tion of salt-wasting cases in recent years may be attributed in part to enhanced ascertainment because of advancements in diagnostic capabilities, as well as increased survival because of the availability of exogenous mineralocorticoid supplements. Salt wasting results from inadequate secretion of salt-retaining steroids, especially aldosterone. In addition, hormonal precursors of 21-hydroxylase may act as mineralocorticoid antagonists in the marginally competent sodium-conserving mechanism of the immature newborn renal tubule (27–29). It has been observed that an aldosterone biosynthetic defect apparent in infancy may be ameliorated with age (30, 31) and a spontaneous partial recovery from salt wasting in adulthood was described in a patient with severe salt wasting in infancy. This variation in the ability to produce mineralocorticoids may be attributable to another adrenal enzyme with 21-hydroxylase activity (32). Therefore, it is desirable to evaluate the sodium and mineralocorticoid requirements carefully by measuring plasma renin activity in patients who have been labeled neonatally as salt wasters.

Although it has been claimed that salt wasting correlates with severe virilism (33), it is important to recognize that the extent of virilism may be the same in simple virilizing and salt-wasting CAH. Thus, even a mildly

virilized newborn with 21-hydroxylase deficiency should be observed carefully for signs of a potentially life-threatening crisis within the first few weeks of life.

B. Nonclassic 21-Hydroxylase Deficiency

An attenuated, late-onset form of adrenal hyperplasia was first suspected by gynecologists in clinical practice who used glucocorticoids for the treatment of women with physical signs of hyperandrogenism, including infertility (34, 35). The first documentation of suppression of 21-hydroxylase precursors in the urine of such patients after glucocorticoid therapy was by Baulieu and co-workers in 1957 (36). The precise diagnosis of a mild 21-hydroxylase defect was made possible when a radioimmunoassay for 17-hydroxyprogesterone (17-OHP) the direct precursor of the enzyme in the adrenal zona fasciculata, was developed (37). The autosomal recessive mode of genetic transmission of the nonclassic form of 21-hydroxylase deficiency (NC21-OHD) became apparent through family studies of classic 21-OHD (38–40). The establishment of linkage to HLA (41, 42) confirmed the existence of this disorder as an allele of classic 21-OHD (38, 43). The HLA associations for nonclassic 21-OHD (41, 44, 45) are distinct from

those found in classic 21-OHD and differ according to ethnicity (42, 46, 47).

The clinical symptoms of NC21-OHD are variable and may present at any age. NC21-OHD can result in premature development of pubic hair in children; to our knowledge, the youngest such patient was noted to have pubic hair at 6 months of age (39). In a review of 23 patients presenting for evaluation of premature pubarche, 7 children demonstrated a 17-OHP response to ACTH stimulation consistent with the diagnosis of nonclassic 21-hydroxylase deficiency, a prevalence of 30% in this pre-selected group of pediatric patients at high risk (48). Other investigators found that 7 of 46 children (15%) with premature pubarche demonstrated an ACTH-stimulated 17-OHP response greater than that of obligate heterozygote carriers of the 21-hydroxylase deficiency gene (49). Elevated adrenal androgens promote the early fusion of epiphyseal growth plates. It is common, but not universally found, that children with the disorder have advanced bone age and accelerated linear growth velocity, and ultimately are shorter than the height that might be predicted based on midparental height and on linear growth percentiles before the apparent onset of excess androgen secretion (50).

Severe cystic acne refractory to oral antibiotics and retinoic acid has been attributed to NC21-OHD. In one study of 31 young female patients with acne and/or hirsutism tested with low-dose ACTH stimulation after overnight dexamethasone suppression, no cases of 21-hydroxylase deficiency were found (51). In another study comparing the responses of 11 female patients with acne and 8 female control subjects to a 24 h infusion of ACTH, elevated urinary excretion of pregnanetriol in 6 patients was suggestive of a partial 21-hydroxylase deficiency (52).

Male pattern baldness in young women with this disorder has been noted as the sole presenting symptom. Severe androgenic alopecia in association with marked virilization has also been reported in an undiagnosed and therefore untreated 59-year-old woman with the simple virilizing form of the disease (53). Menarche may be normal or delayed, and secondary amenorrhea is a frequent occurrence. The syndrome of polycystic ovarian disease includes a subgroup of women with NC21-OHD. The pathophysiology of this phenomenon probably relates to adrenal sex steroid excess disrupting the usual cyclicality of gonadotropin release and/or the direct effects of adrenal androgens upon the ovary, leading ultimately to the formation of ovarian cysts, which then may autonomously produce androgens.

Retrospective analysis of the causes of hirsutism and oligomenorrhea revealed that 16 of 108 (14%) of young women presenting to this institution for endocrinological evaluation of these complaints had nonclassic 21-hydroxylase deficiency (54). In other published series the prevalence of nonclassic 21-hydroxylase deficiency in hirsute, oligomenorrheic women ranges from 1.2 to 30% (55–59). The disparity in frequency of nonclassic 21-hydroxylase deficiency reported by different authors may be attributed to differences in the ethnic groups studied because the disease frequency is ethnic-specific (Table 3).

In boys, early beard growth, acne, and growth spurt may be detected. A highly reliable constellation of physical signs of adrenal (as opposed to testicular) androgen excess in boys is the presence of pubic hair, enlarged phallus, and relatively small testes. In men, signs of androgen excess are difficult to appreciate and may theoretically be

manifest only by short stature and/or adrenal sex steroid-induced suppression of the hypothalamic–pituitary–gonadal axis, resulting in diminished fertility.

Oligospermia and subfertility have been reported in men with nonclassic 21-hydroxylase deficiency (60, 61). Reversal of infertility with glucocorticoid treatment in three men has been observed (61–63).

The presence of 21-hydroxylase deficiency can be discovered during the evaluation of incidental adrenal masses (64). An increased incidence of adrenal incidentalomas has in fact been found in male and female patients with homozygous congenital adrenal hyperplasia (82%) and also in heterozygote subjects (45%), probably arising from hyperplastic tissue areas and not requiring surgical intervention (65).

A subset of NC-21OHD individuals is overtly asymptomatic when detected (usually as part of a family study), but it is thought, based on longitudinal follow-up of such patients, that symptoms of hyperandrogenism may wax and wane with time. The gene defect in these so-called cryptic 21-hydroxylase deficient subjects is the same as that found in symptomatic patients with the nonclassic disease.

V. PUBERTAL MATURATION IN CLASSIC CONGENITAL ADRENAL HYPERPLASIA

A. Onset of Puberty

In most patients treated satisfactorily from early life, the onset of puberty in both girls and boys with classic CAH occurs at the expected chronological age (66–69). The pattern of gonadotropin response to luteinizing hormone-releasing hormone (LHRH) is appropriate for age in prepubertal and pubertal girls with well-controlled CAH (70, 71). Physiologic secretion of gonadotropins, however, may not be entirely normal (72, 73).

True precocious puberty may occur in some well-treated children with CAH, perhaps correlated with bone age. Another setting in which central puberty sometimes occurs in CAH is after initiation of glucocorticoid therapy, producing a sudden decrease in sex steroid levels and leading to hypothalamic activation. LHRH analogs may be employed as an adjunct to therapy with hydrocortisone in such children (74). Long-term data on final height in a small number of CAH patients suggest that LHRH analogs (75, 76), along with growth hormone treatment (77), are not only effective in arresting the pubertal process but also improve final height.

In most untreated or poorly treated adolescent girls, and in some adolescent boys, spontaneous true pubertal development does not occur until proper treatment is instituted (Table 4) (67, 68, 78–80). Studies suggest that excess adrenal androgens (aromatized to estrogens) inhibit the pubertal pattern of gonadotropin secretion by the hypothalamic–pituitary axis (67). The inhibition probably occurs via a negative feedback effect; whether it is pri-

Boys	Small testes ^a Decreased spermatogenesis	Normal testicular size Spermatogenesis	Precocious adrenarche Cystic acne	No abnormalities

^aAdolescent males may have nodular testes as a result of adrenal rest tumor.

marily at the hypothalamus or pituitary is not known. This inhibition is reversible by suppression of the adrenal hormone production with glucocorticoid treatment.

Following gonadarche, in a majority of successfully treated patients, the milestones of further development of secondary sex characteristics in general appear to be normal (66, 69), although a somewhat delayed sequence of pubertal events was present in girls (66).

B. Menstrual Disorders

Many patients with treated classic CAH have regular menses after menarche (67, 68, 81). However, expected age at menarche of treated CAH patients from various clinics as shown in Table 4, suggests that menarche was significantly delayed, especially when those patients who were not menstruating after 16 years of age were included. Menarche was not observed in untreated patients, but only in patients who had received suppressive glucocorticoid treatment (66–69, 82, 83).

Menstrual irregularity and secondary amenorrhea with or without hirsutism are not uncommon complications in postmenarchal girls (5, 68, 69, 82, 84, 85). These menstrual abnormalities have been found frequently in patients with inadequately controlled disease (Table 4) (66, 67, 69, 81, 82, 85). Several studies subsequently reported menarche or the normalization of the menstrual cycle following adequate suppression of adrenal sex steroids with long-acting and more potent glucocorticoid treatment (82, 85, 86). Delayed menarche or even primary amenorrhea may result from poor treatment or overtreatment. In poorly treated patients, the mechanism for delayed menarche may be interference by adrenal sex steroids in the cyclicity of the hypothalamic–pituitary–ovarian axis (66, 67). Delayed menarche in patients who are overtreated may be related to the delay in bone age and general maturation known to occur with excessive glucocorticoid treatment (66).

Many treated women have had successful pregnancies with the delivery of a normal, healthy, full-term infant (67, 87, 88). A recent study reports successful pregnancy outcomes in four women with classic CAH (1 with simple virilizing and 3 with salt-wasting) (89). All four gluco-

corticoid-treated mothers delivered unaffected and non-virilized baby girls. A retrospective survey of fertility rates in a large group of women with 21-hydroxylase deficiency showed that simple virilizers were more likely than salt wasters to become pregnant and carry the pregnancy to term (90). Adequacy of glucocorticoid therapy is probably an important variable with respect to fertility outcome (91). Among all patients questioned, only 50% reported that the vaginal introitus was adequate for intercourse; 5% reported homosexual preference, and 38% had no sexual experience. Based on these data, it seems prudent to perform early surgical correction of clitoromegaly but to delay vaginoplasty until adolescence (when the patient can be expected to assume responsibility for vaginal dilatation and strict adherence to medical therapy).

The clinical observation of gonadal function as described earlier clearly suggests that excess adrenal sex steroid production is the major contributing factor to gonadal dysfunction, menstrual disorders, anovulation, and infertility in girls with classic CAH. The generally accepted theory is that the excessive adrenal androgens may disrupt gonadotropin secretion, leading ultimately to hypogonadism (69, 72, 79, 83).

C. Male Reproductive Function

Several long-term studies indicate that in a majority of successfully treated male patients with CAH, pubertal development, normal testicular function, and normal spermatogenesis and fertility occur (5, 68, 69, 92–94). However, complications of small testes and aspermia have been reported in some patients with inadequately controlled disease (5, 68, 80, 95). In contrast to this observation, some investigators have reported normal testicular maturation and normal spermatogenesis and fertility in patients who had never received glucocorticoid treatment (5, 78, 93, 96, 97) or in those whose glucocorticoid therapy was discontinued for several years (5, 93). Thus, male patients with CAH and excessive adrenal androgens may have either normal gonadal function or hypogonadism. The factors resulting in such a disparity in puberty among patients with the same disorder are not known. Some patients with normal gonadal function may have nonclassic

rather than classic CAH (see later). Hormonal studies in untreated classic patients with normal sexual maturation have shown either normal or increased gonadotropin production (98) or concentrations and follicle-stimulating hormone excretion (5, 93, 98). Of great interest is that in these male patients, excess adrenal sex steroids or their precursor steroids did not seem to affect gonadotropin secretion. Adrenal androgen levels in untreated boys with normal gonadal function did not appear to be lower than those patients with gonadal dysfunction in poor control (5, 68, 95). This suggests that adrenal androgens alone have no effect on gonadotropin secretion via a negative feedback mechanism in male patients.

Another frequently reported complication in postpubertal boys with inadequate control of CAH is hyperplastic nodular testes. Almost all patients with such complications were found to have adenomatous adrenal rests within the testicular tissue, as indicated by the presence of specific 11β -hydroxylated steroids in the blood from gonadal veins (99). These tumors have been reported to be ACTH dependent and to regress following adequate steroid therapy (100–106).

VI. GENETICS

Studies of families carrying 21-hydroxylase deficiency have demonstrated that the disease locus is situated in the HLA major histocompatibility complex on the short arm of the sixth chromosome (107, 108). Both classic and nonclassic 21-hydroxylase deficiency are transmitted as recessive traits. Characteristic combinations of HLA alleles, or HLA haplotypes, are associated with different forms of 21-hydroxylase deficiency. The genotype for classic 21-hydroxylase deficiency results from the presence of two severely affected alleles. Nonclassic 21-hydroxylase deficiency results from the presence of either two mild 21-hydroxylase deficiency alleles or one severe and one mild allele (109).

Based on estimates of its frequency among Ashkenazi Jews (3%) and all ethnic whites (individuals of mainly European descent) (1%) (46), it is apparent that nonclassic 21-hydroxylase deficiency is among the most frequent human autosomal recessive disorders. Molecular genetic studies have demonstrated that the gene encoding the cytochrome P₄₅₀ enzyme specific for 21-hydroxylation (P450c21) is located in the HLA complex between the genes encoding the transplantation antigens, HLA-B and HLA-DR. This gene, *CYP21*, and an inactive homolog or

pseudogene, *CYP21P*, are immediately adjacent to the *C4B* and *C4A* genes encoding the fourth component of serum complement (110, 111) (Fig. 4). The protein-encoding sequence of *CYP21P* is 98% homologous to that of *CYP21*. The high degree of homology permits two types of mutation-causing recombination events: unequal crossing over during meiosis that results in complementary deletions/duplications of *CYP21* (112, 113), and non-correspondences between the pseudogene and the coding gene that, if transferred by gene conversion, result in deleterious mutations (114).

Approximately 25% of classic 21-hydroxylase deficiency alleles result from deletions of *CYP21* (115–117). The remaining three-quarters of classic alleles are caused by smaller mutations in *CYP21*, some of which are *de novo* point mutations resulting in amino acid substitutions (118–121) that significantly disrupt synthesis of the protein. Nonclassic 21-OHD is associated with conservative (or mild) amino acid substitutions in highly conserved portions of the gene encoding the active 21-hydroxylase (122–124).

In studies evaluating the phenotype–genotype relationship, there is generally a good correlation between the severity of the clinical disease and the discrete mutations observed (118, 125). Recent studies, however, have demonstrated that there is often a divergence in phenotypes within mutation-identical groups, the reason for which requires further investigation (126, 127).

VII. EPIDEMIOLOGY

Screening studies indicate that the worldwide incidence of classic 21-OHD is 1:14,199 live births (128), of which approximately 75% are salt wasters. The frequency of nonclassic 21-OHD is considerably higher; based on population genetic studies this allelic variant occurs in 1:100 persons in the general white population and in higher frequency among selected ethnic groups, most notably Ashkenazi Jews (46). The frequency of 11β -OHD is approximately 1:100,000 live births (129); however, among Sephardic Jews of northern Morocco the incidence is estimated to be between 1:5000 and 1:6000 births (130).

VIII. DIAGNOSIS

Congenital adrenal hyperplasia must be suspected in infants born with ambiguous genitalia. The physician is

Figure 4 Diagram of *CYP21* region on chromosome 6p21.3. *CYP21P*, 21-hydroxylase pseudogene; *C4A* and *C4B*, genes encoding fourth component of serum complement. The arrow indicates the direction of transcription.

obliged to make the diagnosis as quickly as possible, to initiate therapy, and to arrest the effects of the enzyme disorders. The diagnosis and a rational decision of sex assignment must rely on the determination of genetic sex, the hormonal determination of the specific deficient enzyme, and an assessment of the patient's potential for future sexual activity and fertility. Physicians are urged to recognize the physical findings of ambiguous genitalia characteristic of congenital adrenal hyperplasia in newborns and to refer such cases to appropriate clinics for full endocrine evaluation.

As indicated in Table 1, each form of congenital adrenal hyperplasia has its own unique hormonal profile, consisting of elevated levels of precursors and elevated or diminished levels of adrenal steroid products (20, 21). Traditionally, laboratory tests have measured the urinary excretion of adrenal hormones or their urinary metabolites (e.g., 17-ketosteroids). Collection of 24 h urine excretion may be difficult, however, and the results in neonates may often be misleading (21). The development of simple and reliable radioimmunoassays for circulating serum levels of adrenal steroids is a significant advance in the laboratory diagnostic technique (20). The direct serum measurement of accumulated precursors and oversecreted adrenal steroids, such as 17-hydroxyprogesterone, Δ 4-androstenedione, and dehydroepiandrosterone is now possible, and more exact hormonal profiles of the different forms of congenital adrenal hyperplasia have been established (Table 1).

A. Hormonal Standards for Genotyping 21-Hydroxylase Deficiency

In our experience, the best diagnostic hormonal test for 21-hydroxylase deficiency has proven to be an ACTH (Cortrosyn, 0.25 mg) stimulation test measuring the serum concentration of 17-OHP at 0 and 60 min after intravenous bolus ACTH administration (131). The nomogram (Fig. 5) provides hormonal standards for assignment of the 21-hydroxylase genotype: patients whose hormonal values fall on the regression line within a defined group are assigned to this group. Because of the diurnal variation in 17-OHP, an early morning serum concentration of 17-OHP may be useful as a screening test for genotyping 21-OHD. In addition, early morning salivary 17-OHP has proven to be an excellent screening test for the nonclassic form (132). ACTH stimulation, however, remains the most definitive diagnostic test (59, 132, 133). It is important to note that the ACTH stimulation test should not be performed during the initial 24 h of life: samples from this period are typically elevated in all infants and may yield false-positive results.

Diagnosis of 21-hydroxylase deficiency can also be made by microfilter paper radioimmunoassay for 17-hydroxyprogesterone; this has been useful as a rapid screening test for congenital adrenal hyperplasia in newborns (19). This convenient test requires only 20 μ l blood, ob-

tained by heel prick and blotted on microfilter paper, to provide a reliable diagnostic measurement of 17-hydroxyprogesterone, which is a cortisol precursor that accumulates in elevated concentrations in 21-hydroxylase deficiency. The simplicity of the test and the ease of transporting microfilter paper specimens through the mail has facilitated the implementation of many congenital adrenal hyperplasia newborn screening programs in the United States and worldwide.

B. Prenatal Diagnosis and Prenatal Treatment

1. Prenatal Diagnosis

Since the report by Jeffcoate et al. of the successful identification of an affected fetus by elevated concentrations of 17-ketosteroids and pregnanetriol in the amniotic fluid, investigators have undertaken prenatal diagnosis for congenital adrenal hyperplasia by similar measurements of hormone levels in pregnancy (134–136). The most specific hormonal diagnostic test for 21-hydroxylase deficiency is amniotic fluid 17-OHP (37, 137–140). Δ 4-Androstenedione may be employed as an adjunctive diagnostic assay (139). It has been suggested that elevated amniotic fluid 21-deoxycortisol may also be a marker for 21-hydroxylase deficiency (141). Amniotic fluid testosterone levels may not be outside the normal range in an affected male (142).

HLA genotyping of amniotic fluid cells is a possible means of diagnosis but has now been superseded by direct molecular analysis of the 21-hydroxylase locus. With the advent of chorionic villus sampling (CVS), evaluation of the fetus at risk is now possible in the first trimester (9–11 weeks' gestation). The fetal DNA is used for specific amplification of the *CYP21* gene utilizing polymerase chain reaction (PCR) and Southern blotting, which has the advantage of requiring only small amounts of DNA (126).

2. Prenatal Treatment

Prenatal treatment with dexamethasone can be administered in pregnancies at risk for 21-hydroxylase deficiency (143–147). When properly administered, dexamethasone is effective in preventing ambiguous genitalia in the affected female. An algorithm for the diagnostic management of potentially affected pregnancies is given in Figure 6. The current recommendation is to treat the mother with a pregnancy at risk for 21-hydroxylase deficiency with dexamethasone at a dosage of 20 μ g/kg divided into three doses daily (147).

Institution of such therapy prior to 10 weeks gestation, before onset of adrenal androgen secretion, would effectively suppress adrenal androgen production and allow normal separation of the vaginal and urethral orifices, in addition to preventing clitoromegaly. Obviously, if dexamethasone is to be administered at such an early date, treatment is blind to the status of the fetus. If the fetus is

Figure 5 Nomogram relates baseline to ACTH-stimulated serum concentrations of 17-hydroxyprogesterone (17-OHP). The scales are logarithmic. A regression line for all data points is shown. (Data from Department of Pediatrics, New York Hospital-Cornell Medical Center, 1982-1991.)

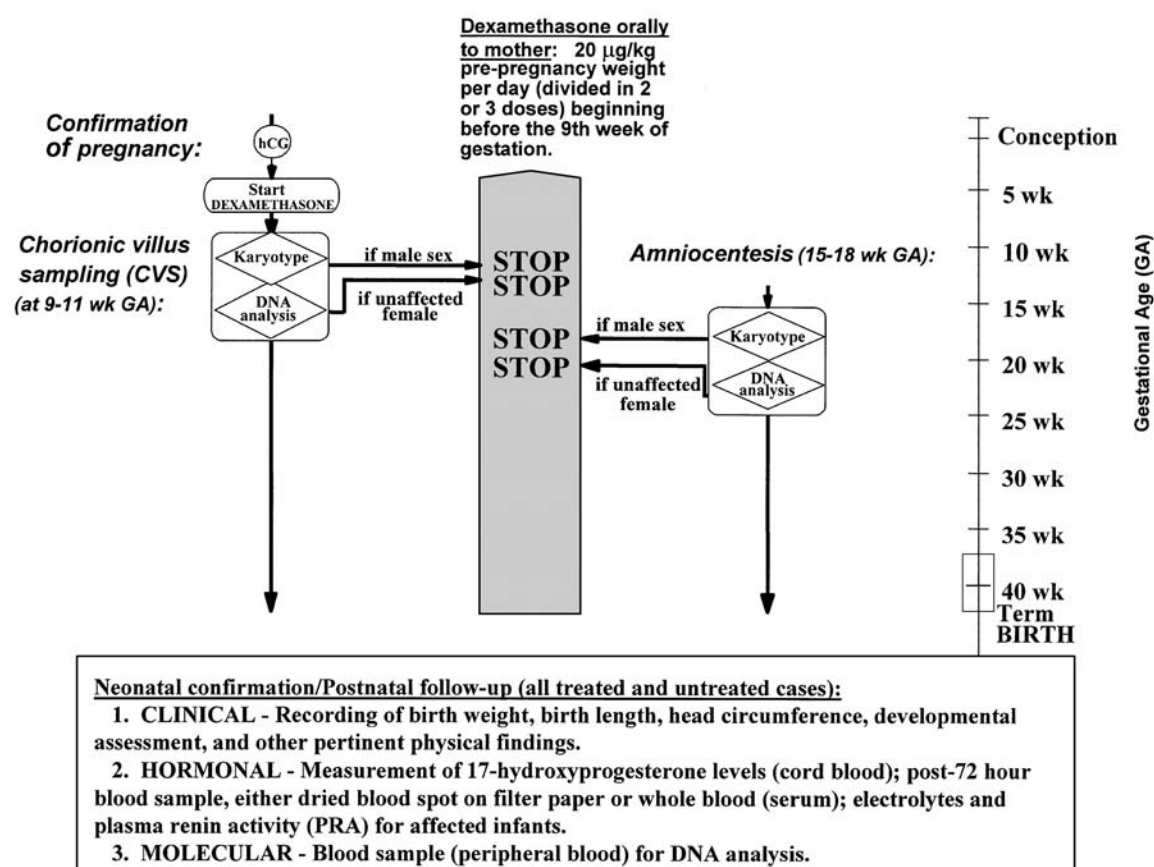

Figure 6 Algorithm depicts prenatal management of pregnancy in families at risk for a fetus with 21-hydroxylase deficiency. (From Ref. 147.)

determined to be a male upon karyotype or an unaffected female upon DNA analysis, treatment is discontinued. Otherwise, treatment is continued to term.

Between 1986 and 1999 prenatal diagnosis and treatment of CAH due to 21-OHD was carried out in over 400 pregnancies in The New York Presbyterian Hospital–Weill Medical College of Cornell University, of which 84 babies had classic 21-OHD. Of these, 52 were females, 36 of whom were treated prenatally with dexamethasone. Dexamethasone administered at or before 10 weeks of gestation was effective in reducing virilization thus, avoiding postnatal genitoplasty (148). No significant or enduring side effects were noted in either the mothers (other than weight gain greater than that in untreated mothers) or the fetuses. Specifically, no cases have been reported of cleft palate, placental degeneration, or fetal death, which have been observed in a rodent model of *in utero* exposure to high-dosage glucocorticoids (149). Another study, in contrast, noted significant maternal side effects in a few cases including excessive weight gain,

cushingoid facial features, severe striae resulting in permanent scarring, and hyperglycemic response to oral glucose administration (150).

A long term follow-up study of 44 children treated prenatally in Scandinavia demonstrated normal pre- and postnatal growth compared to matched controls (151). In the experience of the Weill Medical College of Cornell University–New York Presbyterian Hospital, prenatally treated newborns also did not differ in weight, length, or head circumference from untreated, unaffected newborns. Therefore, we believe that proper prenatal treatment of fetuses at risk for CAH can be considered effective and safe. Long-term studies on the psychological development of patients treated prenatally are currently underway.

A recent study has shown the efficacy of prenatal treatment in 11 β -OHD CAH. In 1999, Cerame et al. reported the first prenatal diagnosis and treatment of an affected female with 11 β -OHD CAH (152). The treatment was successful, as the newborn had normal female external genitalia.

IX. TREATMENT

In cases of ambiguous genitalia caused by congenital adrenal hyperplasia, appropriate surgical repair may be made once a sex assignment has been made based on a reliable diagnosis of the underlying enzyme disorder. In female pseudohermaphroditism caused by 21- or 11 β -hydroxylase deficiency, the aim of surgical repair should be to remove the redundant erectile tissue, preserve the sexually sensitive glans clitoridis, and provide a normal vaginal orifice that functions adequately for menstruation, intromission, and delivery (153). Because of the normal internal genitalia in these patients, normal puberty, fertility, and childbearing are possible when there is early therapeutic intervention.

The aim of endocrine therapy is to replace the deficient hormones. In 21- and 11 β -hydroxylase deficiencies, replacing cortisol both corrects the deficiency in cortisol secretion and suppresses ACTH overproduction. Proper replacement prevents excessive stimulation of the androgen pathway, preventing further virilization and allowing normal growth and a normal onset of puberty.

Better understanding of the role of the renin-angiotensin system in congenital adrenal hyperplasia has made better therapeutic control of this condition possible. In addition to hypothalamic-pituitary regulation of adrenal steroidogenesis, the renin-angiotensin system exerts a primary influence on the adrenal secretion of aldosterone. The juxtaglomerular apparatus of the kidney secretes the enzyme renin in response to the state of electrolyte balance and plasma volume. Renin initiates a series of reactions that produce angiotensin II, which is a potent stimulator of aldosterone secretion (154).

Although aldosterone levels are not deficient in the simple virilizing form of 21-hydroxylase deficiency, plasma renin activity is commonly elevated in the simple virilizing as well as in the salt-wasting forms (155). Despite elevated plasma renin activity, it has not been customary to supplement conventional glucocorticoid replacement therapy with the administration of salt-retaining steroids in cases of simple virilizing 21-hydroxylase deficiency. However, Rosler et al. have demonstrated that adding salt-retaining hormone to glucocorticoid therapy in patients with classic simple virilizing CAH with elevated plasma renin activity in fact improves hormonal control of the disease (156). When plasma renin activity was normalized by the addition of 9-fludrocortisone acetate, a salt-retaining steroid, the ACTH level also fell and excessive androgen secretion decreased. The addition of salt-retaining steroids to the therapeutic regimen often made possible a decrease in the glucocorticoid dosage. Normalization of plasma renin activity also resulted in improved statural growth.

Steroid radioimmunoassay methods have been an asset not only for the initial diagnosis of congenital adrenal hyperplasia but also for improved monitoring of hormonal control once therapy has been instituted. Studies indicate

that serum 17-hydroxyprogesterone and androstenedione levels provide the most sensitive index of biochemical control. In girls and prepubertal boys (but not in newborn and pubertal boys), the serum testosterone level is also a useful index (20). The combined determination of plasma renin activity, 17-hydroxyprogesterone, and serum androgens, as well as the clinical assessment of growth and pubertal development, must all be considered in adjusting the dosage of glucocorticoid and salt-retaining steroid. Recently, 3 α -androstenediol (3AG) has been proposed as a useful serum metabolic marker of integrated adrenal androgen secretion in CAH patients. However, whether serum 3AG determinations would be useful for therapeutic monitoring of CAH requires further long-term study (157). Both in our clinic and in others, combinations of hydrocortisone and 9 α -fludrocortisone acetate have proven to be highly effective treatment modalities (158). Monitoring of plasma renin activity is also a useful index of hormonal control in other forms of congenital adrenal hyperplasia.

X. CONCLUSION

Abnormalities of sexual differentiation and development, often in combination with hypertension (as in 11 β -hydroxylase deficiency) or severe salt wasting (associated with 21-hydroxylase and 3 β -hydroxysteroid dehydrogenase deficiency), are clinical hallmarks of congenital adrenal hyperplasia. The pathophysiology can be traced to discrete, inherited defects in the genes encoding enzymes for adrenal steroidogenesis. Treatment of CAH is targeted to replace the hormones produced in insufficient quantity. With proper hormone replacement therapy, normal and healthy development may often be expected. Radioimmunoassay of serum and urinary steroid levels permits reliable diagnosis of the various forms of congenital adrenal hyperplasia. Prenatal diagnosis and therapy are possible in 21-hydroxylase deficiency, and recently has been shown to be successful in the treatment of 11 β -hydroxylase deficiency as well.

The most common form of CAH, 21-hydroxylase deficiency, has served as a prototype for examination of the molecular genetic basis of phenotypic diversity. Similar studies in other enzymatic defects are now in progress.

I. THE CATECHOLAMINES

Catecholamines are produced by various neuroendocrine tumors mainly by pheochromocytoma, neuroblastoma, ganglioneuroma, and ganglioneuroblastoma. The catecholamines, norepinephrine and epinephrine, are produced by the sympathoneuronal and adrenomedullary systems. Levels of both catecholamines can be nonspecifically elevated during a variety of physiological conditions or pathological states that reflect activation of sympathoneuronal and sympathomedullary systems (e.g., emotional stress, physical activity, eating, fever). Also, pheochromocytomas or other chromaffin cell tumors secrete catecholamines episodically; between episodes, plasma levels or urinary excretion of catecholamines may be normal. Thus, commonly utilized tests of plasma or urinary catecholamines and their urinary metabolites do not always exclude or confirm the presence of a tumor (1–3). A more recently developed biochemical test in our laboratory involving high-performance liquid chromatographic (HPLC) measurements of plasma free metanephrines, the O-methylated metabolites of catecholamines, offers advantages over other tests for diagnosis of pheochromocytoma (4, 5). Plasma levels of the adrenomedullary hormones epinephrine and metanephrine are higher in children than in adults and higher in boys than in girls (75), possibly due to the suppressive effect of sex steroids, particularly estrogen, on adrenomedullary function (6–8, 75). Therefore, age- and gender-specific reference ranges

should be used for evaluation of sympathoadrenal function or catecholamine-producing tumors.

A. Pathways of Catecholamine Synthesis and Metabolism

Tyrosine hydroxylase is the rate-limiting enzyme in catecholamine biosynthesis and catalyzes the conversion of tyrosine to 3,4-dihydroxyphenylalanine (DOPA) (Fig. 1) (9). DOPA is converted to dopamine by L-aromatic amino acid decarboxylase. The presence of the intravesicular enzyme, dopamine β -hydroxylase, leads to conversion of dopamine to norepinephrine. In the presence of the enzyme, phenylethanolamine *N*-methyltransferase (PNMT); (localized in adrenomedullary chromaffin cells, or pheochromocytoma cells producing epinephrine) epinephrine is generated (10, 11).

Norepinephrine and epinephrine are metabolized by multiple enzymes, including monoamine oxidase (MAO), catechol-O-methyltransferase (COMT), and sulfotransferase (12–14). From a diagnostic point of view, the most important pathway of catecholamine metabolism involves COMT-catalyzed O-methylation of norepinephrine to normetanephrine and epinephrine to metanephrine (15–18). Another metabolite, vanillylmandelic acid (VMA), is the principal end-product of norepinephrine and epinephrine metabolism in humans. VMA is formed in the liver, mainly from hepatic extraction of circulating dihydroxyphenylglycol and 3-methoxy-4-hydroxyphenylglycol. All

catecholamines and their metabolites (with the exception of VMA) are converted to sulfate conjugates, which represent other end-products of catecholamine metabolism.

B. Production of Metanephrines Within Chromaffin Tissue

In contrast to catecholamines, the metanephrines are relatively poor markers of sympathoadrenal activation (16, 18). This makes the metanephrines less prone to false-positive results in physiological and pathological states associated with sympathoadrenomedullary activation. Furthermore, plasma free metanephrines are constantly produced by the actions of COMT on catecholamines leaking from storage vesicles within tumors and are relatively independent of catecholamine secretion. Therefore, measurements of plasma metanephrines show larger and more consistent increases above normal than plasma catecholamines in patients with pheochromocytoma, and appear to exclude reliably the presence of all but the smallest of pheochromocytomas.

II. PHEOCHROMOCYTOMA

Pheochromocytomas arise in about 90% of cases from adrenomedullary tissue and in about 10% of cases from

extra-adrenal chromaffin tissue (paragangliomas). Paragangliomas arise from chromaffin tissue in the abdomen along great vessels, most commonly around the aorta below the diaphragm and at the origin of the inferior mesenteric artery (organ of Zuckerkandl) (19).

Although pheochromocytomas are the most common endocrine tumors in children, they account for only 5–10% of all pheochromocytomas with an incidence of 2 per million (20, 21). In children, pheochromocytomas are frequently familial (9–50%), extra-adrenal (8–43%), bilateral adrenal (7–53%), and multifocal (22, 23). Childhood pheochromocytomas peak at 10–13 years with a male predominance before puberty (22–24). Less than 10% of pediatric pheochromocytomas are malignant (22, 23, 25, 26) with reported mean survival rates of 73% at 3 years and 40–50% at 5 years after diagnosis (27, 28). Recurrent pheochromocytomas are rare in children but recurrent tumors may appear years after initial diagnosis, emphasizing the importance of close long-term follow up (26).

A. Clinical Presentations

The presence of pheochromocytoma in children is characterized by clinical signs and symptoms that result from various actions of circulating catecholamines, including

Abbreviations: PNMT: phenylethanolamine-N-methyltransferase; COMT: catechol-O-methyltransferase, MAO: monoamine oxidase, mPST: monoamine-preferring sulfotransferase, ALD: alcohol dehydrogenase, VMA: vanillylmandelic acid, DHPG: 3,4-dihydroxy-phenylglycol, MHPG: 3-methoxy-4-hydroxyphenylglycol.

Figure 1 Pathways of norepinephrine and epinephrine metabolism.

norepinephrine, epinephrine, and dopamine (Table 1). In contrast to adult patients in whom sustained hypertension is found in only 50% of cases, more than 70–90% of children present with sustained hypertension (21, 22, 26). Pheochromocytoma is the underlying cause in 1–2% of cases of pediatric hypertension and should be considered after exclusion of the more common causes such as renal diseases and renal artery stenosis (23). Pheochromocytomas secreting epinephrine may also present with hypotension, particularly postural hypotension (29). Sweating, visual problems, weight loss, nausea, and vomiting are more common in children than in adults (30) as are polyuria and polydipsia. In addition, children commonly present with palpitations, anxiety, and hyperglycemia (31). Other signs of catecholamine excess are pallor and flushing (31). As summarized by Manger and Gifford (31) occasionally some children present with a reddish blue mottling of the skin and a puffy red and cyanotic appearance of the hands. Less frequent clinical manifestations include fever and constipation. As with adult patients, the presence of the triad of headache, palpitations, and sweating in children in combination with hypertension should arouse immediate suspicion of a pheochromocytoma. Pheochromocytoma spells may last from a few seconds to several hours, with intervals between attacks varying widely and occurring as infrequently as once every few weeks or months. The occurrence of attacks is unpredictable since they often occur at rest. However, some are always associated with physical activity, trauma, by direct stimulation of tumor (e.g., urinary bladder distention), or after using certain drugs or taking food (e.g., tyramine in chocolate). Unusual symptoms related to paroxysmal blood pressure elevation or sudden arrhythmia during diagnostic procedures (e.g., endoscopy, catheterization), or anesthesia should promptly arouse a suspicion of pheochromocytoma. Malignant pheochromocytoma may present with pain due to bone metastatic lesions. In children, the differential diagnosis includes renal diseases, renal artery stenosis, coarctation of the aorta, and, less commonly, panic/

anxiety disorders, “autonomic epilepsy,” cluster or migraine headache, hyperthyroidism, and side effects of medications or dietary supplements (32–34).

B. Biochemical Diagnosis of Pheochromocytoma

Biochemical diagnosis of different types of pheochromocytomas is based on measurements of plasma and urine catecholamines and metanephrines. Plasma free metanephrines have been shown to be the single most reliable biochemical test for the detection or exclusion of pheochromocytoma in adults (35) and children (75) with a sensitivity of 97–100% and specificity of 80–96%. Measurements of 24 h urinary excretion of fractionated metanephrines performed by modern HPLC methods is another sensitive tool for detection of pheochromocytoma although this test is less specific than measurement of plasma free metanephrines. Reliable 24 h urine collections may be difficult to obtain in children and the commonly used attempt to correct urinary results for creatinine excretion adds another confounder due to creatinine's dependence on diet (36), muscle mass (37), physical activity (38), and diurnal variation (39). Therefore, measurements of plasma free metanephrines under standardized conditions with the use of age- and gender-specific reference ranges appear to be the biochemical test of choice for detecting childhood pheochromocytoma. Patients should be instructed to abstain from caffeinated foods and drinks for at least 24 h and to avoid acetaminophen, which interferes with the normetanephrine assay, for at least 5 days prior to the blood draw. After an overnight fast (water permitted), the blood sample should be drawn through an indwelling intravenous cannula with the subjects rested in supine position for at least 20 min after insertion of the cannula.

Metastatic pheochromocytomas are often characterized by high tissue, plasma, and urinary levels of DOPA and dopamine (40–45). Elevations in plasma or urinary DOPA and dopamine are not in themselves particularly sensitive or specific markers of benign or metastatic pheochromocytoma. However, when accompanied by elevations in plasma norepinephrine or other clinical evidence of pheochromocytoma, such elevations should arouse immediate suspicion of metastatic disease.

Rarely in children, when the diagnosis of pheochromocytoma is questionable (e.g., only slight or moderate elevation of plasma free metanephrines are present) additional tests such as clonidine or glucagon tests may be necessary. If a norepinephrine-producing tumor is suspected, we suggest using the clonidine test coupled with measurements of plasma free normetanephrine. The clinician must be aware of the possibility of a rapid and marked increase in blood pressure and heart rate after glucagon, and hypotension and bradycardia after clonidine administration.

Table 1 Signs and Symptoms of Pheochromocytoma in Children

Sign/symptom	%
Hypertension	82
Headache	81
Sweating	36–68
Palpitations	34–45
Weight loss	44
Pallor/flushing	11–36
Nausea/emesis	27–56
Polyuria	25

Adapted from Refs. 24, 26, and 31.

C. Localization

A variety of conventional imaging techniques are available for localization of a pheochromocytoma (for review, see [5]). These techniques include computed tomography (CT), magnetic resonance imaging (MRI), and scintigraphy after administration of ^{131}I - or ^{123}I -labeled metaiodobenzylguanidine (MIBG). In children, more than 90% of pheochromocytomas are localized in the abdomen, therefore, imaging studies should be directed to this part of the body. Although CT localizes about 95% of pheochromocytomas, MRI is the preferred imaging modality in children to avoid radiation exposure. Furthermore, MRI is superior to CT in detecting extra-adrenal tumors and familial adrenal pheochromocytoma due to the tumor's typical appearance on T2-weighted image. Both CT and MRI have poor specificity ranging from 65 to 75%. In some cases, ultrasound is sufficient to locate pheochromocytomas in children.

When pheochromocytoma is highly suspected by either positive biochemical results or by both imaging studies and positive biochemistry, MIBG is used to confirm the presence of pheochromocytoma (in some European medical centers, MIBG is used as the first imaging modality in patients with biochemically proven pheochromocytoma). The specificity of MIBG is 95–100% but this technique is not sensitive (sensitivity: 78–83%). Currently only ^{131}I -MIBG is available at most academic medical centers in the United States (46). ^{123}I -MIBG offers superior image quality and seems to be especially useful for detecting recurrent or metastatic pheochromocytoma, tumors with fibrosis or distorted anatomy, and tumors in unusual locations (47–49). In addition, the biological half-life of ^{123}I is shorter than of ^{131}I , resulting in a favorable decrease in radiation exposure.

Other imaging modalities that can be used in children to locate pheochromocytoma are octreotide scintigraphy (50) and positron emission tomography (PET), using [^{18}F]fluorodeoxyglucose, [^{11}C]hydroxyephedrine, [^{11}C]epinephrine and recently, 6- ^{18}F]fluorodopamine (51–53). Our preliminary results show that 6- ^{18}F]fluorodopamine PET scanning can detect and localize pheochromocytoma, not only as a primary tumor in the adrenal gland but also as a recurrent extra-adrenal or metastatic tumor and that it is superior to MIBG scanning.

D. Treatment of Pheochromocytoma

The first-line treatment of pheochromocytoma in children is surgical excision of the tumor. To prevent perioperative complications due to massive outpouring of catecholamines from the tumor, preoperative pharmacological blockade of catecholamine effects and synthesis is required (54). Routinely used pharmacological agents include phenoxybenzamine, an α 1-adrenoceptor noncompetitive antagonist, that opposes catecholamine-induced vasoconstriction and propranolol, atenolol, or metoprolol

as β -adrenoceptor blockers that oppose catecholamine-induced arrhythmia and the reflex tachycardia (5, 23, 26, 55). Beta-blockade alone is contraindicated because it does not prevent and can actually augment effects of catecholamines at α -adrenoceptors. The average oral dosage of phenoxybenzamine in children is between 20 and 50 mg/day given at 6–8 h intervals. To reach adequate preoperative blockade, phenoxybenzamine may be increased until orthostatic hypotension is present or mean arterial pressure is normalized (56, 57). However, several reports questioned this approach, finding no correlations between duration of preoperative treatment and the dosage of α -blockers and intraoperative cardiovascular instability (58). The average dosage of atenolol in children is 20–60 mg/day divided into two or three doses. Side effects of phenoxybenzamine include postural hypotension, reflex tachycardia, nasal congestion, and sedation. Atenolol can mainly cause bradycardia and sedation. If hypertensive crisis occurs, as with adult patients, an intravenous bolus of 5 mg phentolamine (Regitine) is the treatment of choice. Phentolamine has a very short half-life; if necessary, the same dose can be repeated every 2 min until hypertension is adequately controlled. As an alternative, phentolamine may be given as continuous infusion (100 mg of phentolamine in 500 ml 5% dextrose in water). α -Methyl-*para*-tyrosine (metyrosine, Demser), a competitive inhibitor of tyrosine hydroxylase is routinely administered preoperatively in some institutions (the starting dosage is usually 250 mg twice to four times a day) and may be tried in patients in whom elevated blood pressure and arrhythmia cannot be controlled by using α - and β -blockade. At some other centers, calcium channel blockers are used as a primary drug to control hypertension (1, 23, 29). Significant hypovolemia should be corrected by perioperative administration of intravenous fluids to avoid hypotension. Since children have a higher risk of catecholamine-induced pulmonary edema, fluid replacement should not exceed 10 cc/kg/h (57). Pressor agents are not usually effective in the presence of severe and persistent hypovolemia. Children should also be monitored for hypoglycemia up to 48 h after surgery (catecholamines block insulin release via α -adrenoceptors).

Surgical removal of intra-adrenal pheochromocytomas in children is usually successfully carried out by laparoscopy, a procedure that minimizes catecholamine-induced hemodynamic changes during operation, postoperative morbidity, hospital stay, and expenses compared to conventional transabdominal adrenalectomy (59). In children with familial pheochromocytoma that carries a higher risk for bilateral adrenal involvement, prophylactic adrenalectomy of the contralateral side is not recommended. When metastatic disease is present, medical treatment is the initial treatment of choice.

After surgical removal of a pheochromocytoma, yearly follow-up evaluations for assessment of recurrence are recommended for at least 5 years and should include

measurements of plasma free metanephrines. Children with familial pheochromocytoma should undergo annual screening indefinitely. If plasma free metanephrine levels are elevated, urine metanephrines and plasma and urine catecholamines may be measured to confirm the presence of the tumor. If recurrent or metastatic pheochromocytoma is suspected, imaging studies should be initiated. Children with familial pheochromocytoma should undergo at least annual screening.

In the presence of metastatic and therefore incurable disease, drug therapy is the first-line treatment with the goal of controlling cardiovascular effects and complications related to catecholamine excess. Malignant pheochromocytoma requires more aggressive treatment including chemotherapy, MIBG therapy, octreotide therapy, external radiation, and in some cases embolization of the tumor. However, fewer than 40% of patients with metastatic pheochromocytoma respond (mostly partial remission) to these currently used therapeutic modalities such as MIBG or chemotherapy. Therefore, most children are only treated when the quality of their life is affected by catecholamine excess or metastatic lesions that are aggressive and affect local surrounding tissue. Clinicians using the above therapies, particularly chemotherapy, should be aware of potentially fatal complications arising from excessive catecholamine release as tumor cells are destroyed (usually within the first 24 h). With the use of MIBG, a major complication is bone marrow suppression, usually 4 weeks after initiation of therapy.

III. MULTIPLE ENDOCRINE NEOPLASIA SYNDROMES

Multiple endocrine neoplasia (MEN) syndromes are familial disorders inherited in an autosomal dominant pattern with high penetrance but variable expressivity. MEN syndromes are subclassified into MEN 1, MEN 2, and Carney complex. These rare disorders are characterized by hyperplasia or tumor involving more than one endocrine gland.

A. Multiple Endocrine Neoplasia 2A (Sipple Syndrome)

MEN 2A was first described in 1961 by Sipple and is defined by the occurrence of medullary thyroid carcinoma (MTC), pheochromocytoma (affecting about 50% of patients), and hyperparathyroidism caused by parathyroid gland hyperplasia (affecting about 20% of patients) (60–63). There is also familial MTC characterized by hereditary MTC without other associated endocrinopathies (although adrenomedullary hyperplasia secondary to a germline *RET* mutation may still be present but undiagnosed). Familial MTC belongs genotypically to MEN 2A. Rare variants of MEN 2A represent MEN 2A associated with cutaneous lichen amyloidosis and MEN 2A or

familial medullary thyroid carcinoma associated with Hirschprung's disease (64–67).

MEN 2A accounts for the majority of MEN 2 cases. In general, MEN 2 affects about 1:40,000 individuals, and there are less than 1000 kindreds worldwide. The gene responsible for MEN 2 is a proto-oncogene called *RET* (68). In contrast to MEN 1, *RET* is specifically expressed in neural-crest-derived cells, such as the calcitonin-producing C-cells in the thyroid gland and the catecholamine-producing chromaffin cells in the adrenal gland. Whether it is also expressed in the parathyroid glands, remains to be ascertained, especially when considering the low rate of hyperparathyroidism in patients with MEN 2A and the lack of hyperparathyroidism in MEN 2B, although both conditions are caused by mutations in the *RET* gene. *RET* plays a role in normal gastrointestinal neuronal and kidney development as exemplified by the *RET* knockout mouse, which has a Hirschprung-like phenotype and renal dys- or agenesis (69, 70). *RET* is located on chromosome 10q11.2 and encodes a receptor tyrosine kinase, RET protein. As an oncogene, activation of *RET* leads to hyperplasia of target cells in vivo. Subsequent secondary events then lead to tumor formation (Fig. 2) (71–74). *RET* consists of 21 exons with six so-called "hot spot exons" (exons 10, 11, 13–16) in which mutations are identified in 97% of patients with MEN 2. *RET* germline mutation screening is commercially available (<http://endocrine.mdacc.tmc.edu>; Mayo Clinic, Rochester, MN) and has widely replaced the cumbersome provocative testing of calcitonin stimulation (with calcium and/or pentagastrin). It has been notoriously unreliable in children, since for this population the normal range of basal and stimulated calcitonin is still unknown. The normal range for catecholamines including metanephrines in children with and without pheochromocytoma and/or adrenal medullary hyperplasia has likewise only recently been elucidated (75). Hyperplasia of C-cells

Figure 2 Duplication of mutant *RET* in trisomy 10 in MEN 2-related pheochromocytoma. Pheochromocytoma tumor cells are shown in **gray** color. The **dot** signals are FISH markers for chromosome 10. Each tumor cell has trisomy 10. C, cousin; Pt2, patient; N, normal tissue; 2A and 2B, pheochromocytoma; 1–3 are alleles with allele 2 being the inherited, mutant *RET* allele shared by cousin C and patient Pt2. (Modified from Ref. 71.)

in the thyroid gland or the adrenal medulla has been identified as precursor lesion for MTC or pheochromocytoma (76, 77).

The inaccuracy of calcitonin stimulation testing in the diagnosis of MTC has been demonstrated by results of prophylactic thyroidectomy carried out based on positive *RET* germline mutation testing. Fifty percent of patients with a negative pentagastrin test but positive for a *RET* germline mutation had already developed MTC. This led to the recommendation to perform prophylactic thyroidectomy with lymph node dissection around age 5, if mutation testing of *RET* is positive (66, 78–88). Hyperplasia of C-cells has been observed in *RET* gene mutation carriers (MEN 2A) as young as 3 years. In children with MEN 2B, metastatic MTC has been described shortly after birth (89, 90). Therefore, prophylactic thyroidectomy in children with MEN 2B is recommended at an earlier age than in children with MEN 2A *RET* mutations. Although provocative calcitonin testing is nowadays not recommended in children with MEN 2A identified by a *RET* germline mutation, determination of calcitonin plasma levels can be used as a follow-up parameter, as they are indicative of tumor mass. Upon presentation in early childhood, there is usually no abnormal finding on physical examination or ultrasound in patients with MEN 2A. If *RET* germline mutation testing or the family history is positive for MEN 2, a neck computed or magnetic resonance tomogram (baseline) for evaluation of already developed metastases from MTC should be performed.

Before any surgery including prophylactic thyroidectomy in children with MEN 2, a search for pheochromocytoma should be undertaken by measuring plasma free metanephrines. Pheochromocytoma (at least 70% are bilateral) develops on the grounds of adrenomedullary hyperplasia secondary to a *RET* germline mutation, and becomes manifest (e.g., biochemically or on imaging) in about 50% of patients. The peak age is around age 40 but children as young as age 10 can be affected (91, 92). Thus, annual surveillance for plasma and urine catecholamines and metanephrines is recommended after age 6. Based on our recent studies and recommendations, we suggest measuring plasma free metanephrines (93). Patients with MEN 2-related pheochromocytoma are often normotensive (occurs only in about 50%) and have beta-adrenergic symptoms including palpitations and tachycardia. When catecholamine levels are abnormally increased, CT and/or MRI plus MIBG scintigraphy should be performed (5). MEN2-related pheochromocytomas can be located extra-adrenally but are rarely malignant (<25%) (77, 94, 95). If a pheochromocytoma is localized, adrenalectomy should be performed, if possible by laparoscopy (depending on tumor size), after appropriate preoperative blockade as discussed earlier.

Fewer than 25% of patients with MEN 2A develop frank hyperparathyroidism indicated by an inappropriately elevated serum calcium level compared to parathyroid

hormone. However, this condition rarely occurs in childhood and nowadays is especially less diagnosed in prophylactically thyroidectomized children [96]. Reasons for this low prevalence and the discrepancy with MEN 2B, which is also caused by mutations in *RET* (more “severe” mutations in exon 16), are unclear. Authorities recommend measurement of the serum calcium concentration every other year after age 10 for early diagnosis (91, 96, 97).

The cutaneous skin lesions in MEN 2A have been observed in fewer than 16 kindreds and occur over the upper part of the back. Pruritus is the first symptom preceding visible lesions with lichenoid–papular appearance for years. In more advanced lesions, amyloid deposits are found (64).

B. Multiple Endocrine Neoplasia 2B

MEN 2B represents about 5% of all MEN 2 cases and is defined by the presence of MTC, pheochromocytoma, and associated abnormalities including mucosal neuromas (within the lips, gastrointestinal tract, on the tongue tip and eyelids), medullated corneal nerve fibers, and marfanoid habitus (61, 98). In contrast to Marfan’s syndrome, however, patients with MEN 2B do not have lens or aortic abnormalities. Mucosal neuromas within the lips often give patients a “blubbery/bumpy lip look.” Physical examination is remarkable for these associated abnormalities. For instance, slit lamp examination may reveal medullated, hypertrophied corneal nerves. Often, patients have an acromegaloid appearance. Intestinal ganglioneuromatosis may cause diarrhea alternating with constipation or even obstruction.

In contrast to patients with MEN 2A, patients with MEN 2B do not have hyperparathyroidism, although MEN 2B is also caused by germline mutations of *RET* (99). These mutations affect exons 15 and 16, coding for the intracellular tyrosine kinase domain of RET protein. This molecular difference with MEN 2A supposedly leads to autophosphorylation without dimerization and may explain why patients with MEN 2B present at an earlier age with MTC and/or pheochromocytoma. It remains puzzling, however, why hyperparathyroidism only rarely occurs in MEN 2B. Authorities recommend total thyroidectomy and central lymph node dissection within the first 6 months of life for children with MEN 2B (*RET* germline mutations in codons 883, 918, and 922), since metastases from MTC may develop within the first year of life (89, 90). Also, pheochromocytoma in patients with MEN 2B occurs at an earlier age than in MEN 2A. Clinical management of MTC and/or pheochromocytoma is otherwise identical in MEN 2A and MEN 2B. An important finding is that about 7% of patients with apparently sporadic MTC have germline mutations in *RET*, making it reasonable to perform *RET* mutation analysis in all patients with MTC (100–102).

C. Von Hippel-Lindau Syndrome

Von Hippel-Lindau (VHL) is another autosomal dominant inherited tumor syndrome with pheochromocytoma (VHL type II) or without pheochromocytoma (VHL type I) (103, 104) that may occur in children. Apart from pheochromocytoma, major tumors in VHL disease include renal cell carcinoma, hemangioblastoma, neuroendocrine pancreatic tumors, and endolymphatic sac tumors (105, 106). All children with familial, multiple or early onset of pheochromocytoma should be examined for VHL disease, which has variable expression and age and tumor-dependent penetrance. Pheochromocytoma occurs in about 10% of VHL patients and is the presenting manifestation in about 5% of cases (107, 108). However, there are large interfamilial variations, with some families having pheochromocytoma as the most frequent complication of VHL disease (107, 108). Children with VHL syndrome who underwent unilateral adrenalectomy for pheochromocytoma need lifelong follow-up to diagnose recurrence or another pheochromocytoma in a timely fashion on the contralateral side. In contrast to pheochromocytomas of children with MEN 2 (so-called adrenergic), VHL-associated pheochromocytomas have more of a so-called non-adrenergic phenotype. MEN-2-related pheochromocytomas frequently possess all the enzymes to synthesize catecholamines from tyrosine to epinephrine, whereas less differentiated pheochromocytomas including those in VHL disease lack the enzymes involved in the final catecholamine biosynthesis pathway (109). Thus, symptoms and signs of patients with VHL-related pheochromocytoma are related to norepinephrine excess, including hypertension. Metastatic pheochromocytoma is more common in patients with VHL disease than MEN 2 and neurofibromatosis type 1 (NF1). The diagnostic algorithm is the same as in other patients with pheochromocytoma and is commented on in other parts of this chapter (5).

The VHL tumor suppressor gene is located on chromosome 3p25-26. The cloned coding sequence comprises three exons. Most patients with VHL-associated pheochromocytoma have missense mutations (110–112). There are genotype-specific VHL phenotypes (106). Founder effects may explain regional prevalence rates, for example, the Black Forest area in southern Germany with the missense mutation tyrosine to histidine at codon 98 (Tyr98His) and subsequent high risk of pheochromocytoma (94, 113, 114). *VHL* missense mutations may have tissue-specific effects (113). A so-called second hit is required in patients with *VHL* germline mutations in order to develop pheochromocytoma (115).

The VHL gene product forms a stable complex with the highly conserved transcription elongation factors elongin B and elongin C, which regulate RNA polymerase II elongation. Formation of this heterotrimeric complex with elongin B and C appears to be the tumor-suppressor function of the VHL gene, since the majority of tumor-predisposing mutations of *VHL* disrupt the formation of this

complex (81, 116, 117). Normal *VHL* protein function leads to degradation of a proteasome complex (118).

D. Neurofibromatosis Type 1

Neurofibromatosis type 1 (NF1) is the most common familial cancer syndrome predisposing to pheochromocytoma and affects about 1:4000 individuals. The risk of pheochromocytoma in NF1, however, is small, about 1% (119, 120). NF1 is inherited in an autosomal dominant manner with variable expression. Fifty percent of patients have new mutations and mutation analysis is cumbersome because of the large gene size (11 kb of coding sequence). Pheochromocytoma in patients with NF1 is rarely seen in children since it usually occurs at a later age (around age 50). Only 12% of NF1 patients are diagnosed with bilateral and multifocal pheochromocytomas and fewer than 6% of patients have metastatic pheochromocytoma (121).

The NF1 gene is a tumor-suppressor gene mapping to chromosome 17q11.2. Patients with NF1-associated pheochromocytoma show loss of the wild type allele (122) following Knudson's two-hit hypothesis. Neurofibromin, the NF1 gene product, bears homology to the ras/GTPase-activating protein (GAP) (73). P21-ras/GAP increases the rate of intrinsic GTP hydrolysis in the small G proteins, the ras genes, thereby mediating the return of the G protein switch to the off GDP-bound form. By this mechanism, signal transduction is controlled via the ras pathways.

E. Familial Pheochromocytoma

Familial pheochromocytoma is usually inherited in an autosomal dominant manner. However, detailed investigation may reveal subclinical evidence of VHL disease or MEN 2 (123, 124). *VHL* germline mutations in the absence of other features of VHL disease have been detected by molecular genetic screening for *VHL* and *RET* mutations in familial pheochromocytoma (81, 110). Recently, germline mutations in the *SDHD* gene have been found in families with extra-adrenal chromaffin tissue tumors (125).

IV. NEUROBLASTOMA

Neuroblastomas are tumors that derive from primordial neural crest cells of the sympathetic system. They are the most common solid extracranial tumor in children and they account for 7–10% of all tumors diagnosed in children (126–128). Neuroblastomas have been found to have the highest percentage of spontaneous regression among tumors (129).

The annual incidence in the US is 1:100,000 children under the age of 15. It is predominantly a tumor of very young children: in 80% the tumor presents in children younger than 5 years, in 15% in children between the age of 5 and 10, and in 5% in children older than 10 (130).

The median age at diagnosis is found to be between 18 and 24 months (131–133). Often two peaks can be identified in the incidence of neuroblastoma and each is associated with a distinct pattern of clinical behavior. Tumors detected in the first year of life (initial peak) have a more benign course than those diagnosed in older children (second peak in children around 2 years of age) (132, 134). The tumor has a slight predominance in boys (with boys to girls ratio of 1.2:1) and is reportedly more common in white than in black children (127).

Most cases are sporadic; rarely, cases are familial or associated with familial syndromes such as NF, Hirschsprung's disease, and Beckwith-Wiedemann syndrome. However, until now no genetic analyses have been able to link neuroblastomas indisputably with the respective familial syndromes (135–138).

In recent years, a rise in incidence over time has been noted (127). This rise may reflect increased physician awareness, improved diagnostic procedures, or changes in reporting (139).

A. Pathogenesis

Although the influence of exposure to several environmental factors (such as parental occupation, use of medication, lifestyle) on the risk of developing neuroblastoma has been investigated, no unequivocal relationship has been demonstrated (132, 140). Further investigation of some possible risk factors, such as parental exposure to metals, solvents, or radiation and maternal use of hormones during pregnancy, appears warranted (141).

Numerous studies using a range of experimental techniques have been undertaken to discover the genes involved in neuroblastoma development. It has become apparent that both inactivation of tumor suppressor genes and activation of tumor oncogenes are involved in neuroblastoma tumorigenesis. Chromosomal loci that have been found to show loss of heterozygosity (LOH), indicative of a tumor-suppressor gene, include 1p (19–31%), 2q (30%), 3p (9–25%), 4p (14–19.5%), 9p (19–36%), 11q (5–44%), 14q (10–31%) and 18q (31–81%) (142–156). Although intensive research has been directed to-

wards identifying candidate genes in the regions that show LOH, no indisputable tumor suppressor gene has yet been identified (157, 158).

Amplification of the MYCN tumor oncogene, located on the distal short arm of chromosome 2 (2p24), was first reported in 1983 (159, 160). In recent years it has become apparent that gain of the long arm of chromosome 17q, occurring in 54–83% of primary tumors, is probably the most frequent chromosomal abnormality in neuroblastomas (142, 151, 152, 161, 162). At present, genetic abnormalities found in neuroblastomas seem rather to have prognostic relevance than to provide insight into its pathogenesis.

B. Clinical Presentation

The symptoms and signs at presentation depend largely on the size and the location of the primary tumor, and whether or not the tumor has metastasized (Table 2). Metastases can occur as a result of both lymphatic and hematogenous extension and are most common in lymph nodes, liver, skin, bone, bone marrow, and soft tissues (163). In case of lymph node involvement outside the cavity of origin, a child is considered to have disseminated disease (163). Thus, a patient can present with local, regional, or disseminated disease. The proportion of patients with disseminated disease at diagnosis (about 50%) is age dependent (164). Metastasized disease is more commonly seen in older children. In 35% of patients with apparent localized disease regional lymph node metastases are found.

The most common site of tumor localization is intra-abdominal (65%), most commonly in the adrenal gland. Children older than 1 year have a higher incidence of adrenal tumors than infants (40% vs. 25%, respectively). In 20% of cases the tumor is localized in the chest, in 2–3% in the pelvis, in 1–5% in the neck, and in 6–12% other localizations. In 1% the primary tumor is not found (132, 133, 163–165).

The tumor may mimic other diseases: for instance, bone metastasis may resemble musculoskeletal diseases such as rheumatoid arthritis (166) and paraspinal tumors

Table 2 Presentation

Disease	Tumor site	Possible symptoms
Localized	Abdomen	Abdominal discomfort, fullness, abdominal pain, rarely respiratory distress
	Pelvis	Bladder and bowel disorders as a result of compression
	Neck, Thorax	Dyspnea, dysphagia, Horner syndrome
Disseminated	Nonspecific	General malaise, low-grade fever, weight loss
	Bone	Limp, joint swelling, bone pain
	Paraspinal	Neurological symptoms
	Orbital area	Proptosis, periorbital ecchymoses (raccoon eyes)
Producing	Catecholamines	Hypertension, sweating, flushing, tachycardia, paroxysmal phenomena
	VIP	Chronic secretory diarrhea (Kerner-Morrison syndrome)

compressing nerve roots or extending into vertebral bodies may mimic neurological diseases. Furthermore, the tumor may be accompanied by paraneoplastic phenomena such as opsoclonus–myoclonus syndrome, which occurs in 2–3% of children with neuroblastoma (167), or secretory diarrhea if the tumor is producing vasoactive intestinal peptide (VIP).

In rare cases, production of catecholamines contributes to symptoms and signs seen at presentation. Although 95% of tumors produce catecholamines or catecholamine metabolites such as VMA and HVA, this only rarely causes symptoms of catecholamine excess such as hypertension or paroxysmal phenomena such as tachycardia and flushing (168). Compared to pheochromocytomas, neuroblastomas appear to have a paucity of storage granules and low levels of tissue catecholamines, which is suggestive for an ineffective storage mechanism. Furthermore, in patients with neuroblastoma, catecholamines are effectively metabolized by COMT and MAO to yield non-pressor catecholamine metabolites such as HVA, which are thereafter excreted in the urine. This may explain the absence of symptoms of catecholamine excess (168). No correlation has been found between tumor size and the level of urine catecholamine excretion. A less differentiated tumor may predominantly secrete dopamine instead of VMA or HVA.

At physical examination care should be given to the detection of palpable masses in the abdomen or flank and the presence of hepatomegaly. Skin including scalp and joints should be inspected for lesions, swelling, and tenderness. A neurological examination, including assessment of pupil sizes in both eyes and strength in the lower limbs, should be part of the work-up for neuroblastomas.

Histopathologically, the differential diagnosis includes other small blue round cell neoplasia of childhood such as rhabdomyosarcoma, Ewing's sarcoma, peripheral neuroepithelioma (primitive neuroectodermal tumor [PNET]), lymphoma, and leukemia (169). Wilms' tumor, hydronephrotic kidney, enlarged spleen or liver, lymphoma, germ cell tumor, and mesenteric cysts should also be considered in the differential diagnosis (133, 170).

C. Diagnosis and Localization

In 1988, a set of international criteria was formulated for neuroblastomas with respect to diagnosis, staging and response to treatment (171). In 1993, these criteria were revised (169). Obtaining tumor tissue is critical for diagnosis and staging of neuroblastoma.

According to the International Neuroblastoma Staging System (INSS) criteria a neuroblastoma is confirmed if either an unequivocal pathological diagnosis is made from tumor tissue by light microscopy, or a bone marrow aspirate or trephine biopsy specimen contains unequivocal tumor cells (e.g., syncytia or immunocytologically positive clumps of cells), and increased urine or serum catecholamines or their metabolites. In case of equivocal

histological and immunohistological findings, genetic features characteristic of neuroblastoma, such as 1p deletions or *N-myc* amplification, can support the diagnosis.

Seventy-one to 95% of neuroblastomas excrete abnormally large amounts of dopamine, HVA, norepinephrine, and VMA (132, 172). In patients with suspected neuroblastoma, measurement of urinary catecholamine metabolites is mandatory. In 15% of the tumors urinary VMA is not elevated. In order to be considered elevated VMA or HVA levels normalized to milligrams of creatinine have to be above 3.0 SD for the mean for age (132). With this cut-off approximately 92% of biopsy-proven neuroblastoma patients will have elevations at diagnosis. It is recommended that both VMA and HVA are measured in a patient with suspected neuroblastoma.

For localization of the tumor, several imaging modalities are available. Plain radiographs can detect the tumor if calcifications are present. Ultrasonography may yield good information and is the least expensive imaging technique. Other imaging techniques such as CT and MRI provide better anatomical detail including the tumor's relation to surrounding tissues. This information is important when operability and resectability are discussed. To evaluate the presence of bone metastases, bone scintigraphy with ^{99m}Tc -diphosphates is most sensitive (173). If available ^{131}I -MIBG or ^{123}I -MIBG scintigraphy should be performed routinely in the evaluation of all patients suspected of harboring a neuroblastoma (169). Ninety-one percent of the neuroblastomas concentrate ^{131}I -MIBG, which makes it a specific and very sensitive indicator for neuroblastoma comparable with urine analysis for catecholamine metabolites (173, 174). Addition of single-photon emission computed tomography (SPECT) has been found to be beneficial for the interpretation of the MIBG scan (175).

The recommendations of the INSS for clinical testing include CT and/or MRI scan with three-dimensional measurements for the primary site and abdomen/liver. To assess bone marrow involvement, bone marrow biopsy is required. Bone involvement should be assessed by MIBG scan or ^{99}Tc scan. At physical examination care should be taken to assess lymph node involvement. These findings should be confirmed with histology. Every patient should undergo a chest radiograph; if this is found to be positive a chest CT or MRI should be performed. Imaging modalities are also important for staging and follow-up.

D. Staging

In the INSS classification, four stages are identified (Table 3). In stages 1–3, the disease is localized and the stage depends on the extent of lymph node involvement and the presence of midline extension of the disease. In stage 4, the disease is disseminated (169). Stage 4S is a special subcategory: it consists of infants with a distinct pattern of disseminated disease associated with spontaneous re-

Table 3 International Neuroblastoma Staging System

Stage 1	Complete gross resection of localized tumor. Residual disease may or may not be present microscopically. Identifiable lymph node(s), ipsi- and contralateral, negative for tumor at microscopy.
Stage 2 A	Incomplete gross excision of localized tumor. Identifiable ipsi- and contralateral lymph nodes negative for tumor microscopically.
Stage 2 B	Complete or incomplete gross resection of localized tumor with ipsilateral no adherent lymph nodes positive for tumor. Enlarged contralateral lymph nodes negative for tumor microscopically.
Stage 3	Unresectable unilateral tumor infiltrating across the midline, regional lymph node involvement may be either present or absent; or localized unilateral tumor with contralateral regional lymph node involvement; or midline tumor with bilateral extension by infiltration or by lymph node involvement.
Stage 4	Dissemination of tumor to distant lymph nodes, bone, bone marrow, liver, or other organs except as defined for stage 4S.
Stage 4S	Localized primary tumor (as defined in stage 1 or 2) with dissemination limited to skin, liver and or bone marrow ^a in an infant <1 year of age.

^aLess than 10% of nucleated cells are tumor cells.
Source: Data from Refs 163, 169, and 171.

gression. With or without nonsurgical treatment, these infants experience a high cure rate (176, 177).

E. Prognosis

Over the years numerous factors have been studied in neuroblastomas for their capability to predict outcome. Stage, age, and site of primary tumor are most important for the prognosis. Biological variables found to be associated with outcome can be organized into several categories: histopathological characteristics, serum markers, and genetic features.

The International Neuroblastoma Pathology Committee developed an age-linked classification system based on morphological features of neuroblastomas in relation to prognosis. Patients are classified in four different categories based on the differentiation grade of the neuroblastomas, their cellular turnover index, and the presence or absence of schwannian stromal development (170, 178). Other factors relating to prognosis taken into account in this classification system are mitosis–karyorrhexis index, mitotic rate, and calcification.

Serum markers known to have a correlation with outcome are serum ferritin, neuron-specific enolase (NSE), circulating ganglioside_{D2} shed from neuroblastoma cell membranes, and serum lactic dehydrogenase (LDH). Increases in ferritin (179), NSE (180), and circulating ganglioside_{D2} (181–183) are all associated with worse prognosis. Increases in LDH are non-specific and may indicate rapid cell turnover or large tumor burden. Increased LDH levels are associated with poor outcome (184).

Genetic features that have been found to correlate with prognosis are tumor cell ploidy, MYCN amplification, chromosome 1 deletion or allelic loss, telomerase activity, and expression of the TRKA-gene. Of these features a hyperdiploid karyotype and a high level of expression of the TRKA-gene, encoding for a primary component of the high-affinity nerve growth factor receptor are associated with a favorable outcome (185–190). In contrast, poor survival is predicted by MYCN amplification, chromosome 1 deletion or allelic loss, and a high telomerase activity [191–197].

F. Treatment

INSS stage, age, and biological features are the most important determinants in the design of a specific management plan for a patient. The intensity of the treatment program depends highly on the assessment of a patient's risk for recurrent disease (198).

Surgery is usually performed in all patients to establish the diagnosis and to procure tumor tissue for biological studies and staging of the tumor. If feasible, the tumor can be excised at initial surgery. Chemotherapy is the principal treatment modality (199). Multiple-agent therapy has proven to be more advantageous than single-agent therapy (132). In many patients, however, multimodality treatment is required. Radiation therapy and autologous bone marrow transplantation are used most frequently to supplement chemotherapy. Other treatment modalities studied for their effectiveness in neuroblastomas include radionuclide therapy with ¹³¹I-MIBG, retinoid therapy, and immunotherapy.

The International Neuroblastoma Response Criteria give definitions to assess response (169). Response should be determined based on the best approximation of the volume of both primary tumor and metastatic sites. Six categories are identified: complete response, very good partial response, partial response, mixed response, no response and progressive disease. Complete response is characterized by complete disappearance of tumor at primary and metastatic sites. Partial response is defined by a decrease of over 50% in volume of primary tumor and metastatic sites. If the response of the primary tumor is found to be 90–99% and all metastatic sites have disappeared, it is classified as very good partial response. In mixed response there is a response of 50% or greater at one or more sites and a reduction of 50% or less at one

or more other sites. In cases of no response, no new lesions occur and the volume of primary tumor and metastases changes between a reduction of less than 50% and an increase of less than 25%. Progressive disease is defined by a 25% increase in any pre-existing lesion or the occurrence of any new lesion. However, discussion is underway as to whether the number of categories should be decreased.

The 3-year event-free survival for stage 1, 2, 4S lies between 75 and 90%. For stage 3 and 4, age is important: if a child with stage 3 is younger than 1 year, she or he has an 80–90% chance of cure; with an age of over 1 year the 3 year survival rates drop to 50%. For children with stage 4 disease these percentages are 60–75% and 15% for the 3-year survival, respectively.

Late effects of treatment include disturbed linear growth and gonadal function and the occurrence of second malignant neoplasms such as thyroid carcinoma or myelodysplasia/leukemia.

G. Screening

Screening programs for the detection of neuroblastomas have been set up in Japan, North America, and Europe. Studies evaluating the effect of these screening programs are emerging. It is disputed whether these screening programs for neuroblastoma are successful in decreasing the incidence of poor-prognosis disease in neuroblastoma and thereby decreasing mortality and morbidity (200–203).

V. GANGLIONEUROMA

Ganglioneuroma is a rare benign tumor that originates from the sympathetic chain. It is defined by the World Health Organization as “a benign tumour of ganglion cells in various proportions, which may be immature or dysmorphic (e.g., multinucleation and nuclear pyknosis), and Schwann cells” (204). They either occur de novo or are a result of maturation and differentiation of neuroblastomas (129, 205). According to the International Neuroblastoma Pathology Committee it is not a separate entity but should be considered a final stage of matured neuroblastomas (170). In a series of 88 patients described by the Armed Forces Institute of Pathology, the majority of patients were above 10 years of age, only 16% (14 of 88) were younger than 10 years (131). In contrast, in recent studies the median age at presentation was found to be between 5.5 and 7.6 years (206–208). Boys and girls appear to be equally affected.

The posterior mediastinum (38%) is the most frequent site of occurrence and, together with localization in the retroperitoneum, accounts for most of the cases (131, 206, 207, 209). For abdominal tumors a preference was observed for nonadrenal (37.5%) over adrenal ganglioneuromas (21%) (207).

Up to half of the patients are asymptomatic (209–211). If symptoms are present, they are usually nonspecific

and related to a mass effect of the tumor or intraspinal tumor extension. Some patients may experience hypertension due to excessive catecholamine secretion of the tumor. The percentage of tumors reported to secrete catecholamines or catecholamine metabolites varies in the literature between 20 and 39% (206, 207, 212). A ganglioneuroma is seldom found to be the cause of watery diarrhea by secreting VIP (213, 214). The tumor can be visualized with ultrasonography, CT, or MRI. Furthermore, 57% of the tumors are positive on ¹²³I-MIBG scintigraphy (207). MRI is superior to CT for studying local and intraspinal extension in retroperitoneal ganglioneuromas (208). Complete excision of the tumor is curative. Usually the prognosis remains excellent even if resection of the ganglioneuroma is incomplete.

VI. NEURAL TUMORS AND CHRONIC DIARRHEA

Chronic diarrhea caused by neuroendocrine or neural tumors often is related to the production of VIP. The most common tumors in this group are VIPomas, which can occur sporadically but also in the context of MEN 1. VIPomas cause secretory, watery diarrhea, which subsequently leads to disturbances in water and electrolyte homeostasis including hypokalemia and metabolic acidosis. Symptomatic treatment concerns replacement of water and electrolyte losses. Definitive treatment consists of tumor removal. For VIPomas, resection of a single and/or multiple tumors is indicated, which may include a pancreatic tail resection. For neuroendocrine or neuroectodermal tumors such as VIP-producing pheochromocytoma, ganglioneuroma, ganglioneuroblastoma, and medullary thyroid carcinoma, definitive therapy also is achieved by surgical tumor removal (213, 215–222). If the diarrhea-causing tumor is composed of chromaffin cells, it may also secrete large amounts of catecholamines. Therefore, measurements of plasma VIP and plasma/urinary catecholamines including metanephrines should be performed in children with watery diarrhea (216, 223). The somatostatin analog octreotide improves diarrhea in the majority of patients, including those with carcinoid syndrome (224, 225). In patients with MTC, nonvoluminous diarrhea may be the initial complaint. The cause of the diarrhea in this setting is unclear (226).

Puberty and Its Disorders

Peter A. Lee

Pennsylvania State College of Medicine, The Milton S. Hershey Medical Center, Hershey, Pennsylvania, U.S.A.

I. NORMAL PUBERTY

A. Definition and Mechanism

Puberty is the stage of human development when sexual maturation and growth are completed, resulting in the capacity for reproduction. Accelerated somatic growth, growth and maturation of the primary sexual characteristics (gonads and genitals), and the appearance of secondary sexual characteristics (e.g., sexual hair, female breast development, and male voice change) occur. Menstruation and spermatogenesis begin. These changes are a consequence of increased gonadotropin and sex steroid secretion. Androgens and estrogens are both involved. Although estrogen (primarily estradiol) stimulates breast and reproductive system maturity in girls and testosterone stimulates pubertal changes in boys, androgen is responsible for certain changes among both boys and girls. Androgen stimulates sexual hair development, increased oiliness of skin related to acne, and apocrine gland secretion causing adult-type body odor. Sex steroids directly and indirectly stimulate overall somatic growth, estradiol appearing to be the key hormone stimulating skeletal maturity among both sexes.

Increased gonadal activity results from increased stimulation by pituitary gonadotropins: luteinizing hormone (LH) and follicle-stimulating hormone (FSH). Increased testicular sex hormone production is stimulated by LH; FSH stimulates primarily maturation of spermatogonia. In the female both LH and FSH are necessary for hormonogenesis, while FSH plays a primary role in ova maturation.

The physiological secretion pattern of gonadotropins is a periodic intermittent release, more dramatically apparent for LH (1–5). Amplitude is low and release infrequent before puberty. At pubertal onset, accentuated episodes of LH first occur during sleep, then progressively increase in frequency and amplitude, extending throughout the 24 h period (6). The intermittent gonadotropin

release is a direct response to episodic release of hypothalamic gonadotropin-releasing hormone (GnRH or LHRH) (7). During childhood this system is downregulated since GnRH secretion is minimal. Throughout childhood, the pituitary and gonads are capable of full function at any age after a relatively short period of physiological stimulation. The onset of puberty is a consequence of enhanced GnRH secretion. The mechanisms by which this occurs are incompletely understood, but they appear to involve the stimulatory and inhibitory influences of such neurotransmitters as acetylcholine, catecholamines, γ -aminobutyric acid (GABA), opioid peptides, prostaglandins, and serotonin.

Negative feedback of hypothalamic–pituitary gonadotropin–gonadal control is first acquired in fetal life and is operative thereafter (8). Changes in feedback sensitivity are inadequate to explain differences in fetal, neonatal, childhood, and pubertal physiology. Overriding central nervous system (CNS) control is an obligatory component. Episodic release is present in the neonatal period and childhood, with gonadotropin secretion diminishing during childhood (9). Mean LH and FSH levels are both low in childhood, FSH levels being relatively higher than LH levels, particularly in girls (3, 5, 9). Since the pituitary gland is always capable of response to GnRH stimulation, the characteristic response during childhood is markedly less than at puberty, with a greater response of FSH than LH. The childhood response pattern may not be distinguishable from that typical of hypogonadotropism. With the onset of puberty, the mean LH and FSH levels increase, with a relatively greater rise in the LH levels. Generally, however, for most patients baseline values may overlap the prepubertal and pubertal range. Levels of pubertal individuals may not be discernible from a single sample. GnRH or GnRH analog stimulation is the most useful test to differentiate pubertal and prepubertal status, since LH responses to exogenous GnRH stimulation becomes more pronounced with pubertal maturity (10, 11).

The incremental rise of FSH after GnRH stimulation changes less with pubertal maturation and hence is less useful to ascertain differences (10, 11). A marked FSH response is already evident in prepubertal children, and particularly among girls may not increase discernibly with puberty.

Because of the greater rise of LH in relation to FSH with pubertal secretion, LH/FSH ratios, either baseline or stimulated, may be used as an indication of status. A ratio of less than 1 is typical of prepuberty, while a ratio of greater than 1 characteristic of pubertal secretion (12).

B. Normal Female Development

Milestones of female puberty include thelarche (onset of pubertal breast development) and menarche (the onset of menstrual periods). Pubarche is a term used to signify the onset of sexual hair development, a result of adrenarche (the onset of pubertal adrenal androgen secretion), although androgen production by the ovaries also occurs with the increased steroidogenesis during puberty.

1. Age of Puberty

The most common first evidence of puberty in girls is thelarche (Fig. 1), although it may occasionally be preceded by pubarche (13–15). The best available data currently indicate that the mean age for the onset of breast development in girls is between 9.5 and 10 years of age, with 5% of girls having breast development by their eighth birthday. The average age of full pubertal breast development is 14 years (Fig. 1) (15). Based on the most recent data, the average duration of pubertal development is 3–4 years. European data (16) but not U.S. data suggest

Figure 1 Mean ages (dots) and ranges (horizontal lines) of onset of pubertal development in girls. Dashed lines show early limit for African-Americans.

that the tempo may be somewhat faster while there may be considerable variation in the tempo. Data suggest that the earlier the onset, the slower the tempo of puberty (17), the pace of pubertal development correlating with the level of sex steroids (18). It is clear that the onset of breast and pubic hair development occurs, on the average, earlier among African-American than among white girls (14).

2. Hormone-Stimulated Changes

Mean LH, FSH, and estradiol levels increase before physical changes begin, but because of fluctuation within and between individuals, this rise may not be discernible in individual instances. A pubertal GnRH-stimulated LH response or elevated estradiol values signify that gonadarche has occurred, the estrogen-stimulated development that follows includes breast, genital, and uterine maturation; increase in body fat content and lean body mass (19); and acquisition of fat distribution in the typical female contours. Breast growth may begin asymmetrically, progresses throughout puberty and may be classified into five Tanner stages (Table 1). Pubic hair growth, which begins in the average girl at age 10 years, can also be staged to follow progression (Table 1).

3. Adrenarche

The increased adrenal androgen production (onset designated as adrenarche) precedes the pubertal rise of gonadotropins and gonadarche. Adrenarche may be detected in girls by age 6 by an elevation in circulating levels of dehydroepiandrosterone (DHEA) and DHEA sulfate (DHEAS). The stimulus of adrenarche is unknown; no stimulating factor has been identified.

4. Growth and Progression

The pubertal growth spurt in girls, occurring early, usually is present at the time of the appearance of the first signs of puberty (Fig. 1). The interval between pubertal onset and menarche is variable, the average being 2 years. The magnitude of sex steroid exposure before menarche inversely correlates with the amount of statural growth after menarche, those with greater exposure being closer to final height at menarche. While the average girl grows 4–6 cm after menarche, those with relatively early menarche may grow as much as 10 cm, whereas those with more prolonged or greater estrogen stimulation before the onset of menses may grow less than 4 cm. Generally earlier menses is correlated with shorter adult height. It is not necessarily atypical for adolescent girls to have irregular menses for a year or longer after menarche; careful attention is warranted until menses become regular. Ovulation may occur before menarche or much later.

C. Normal Male Development

Although pubic hair growth is usually the first evidence of puberty noticed, increased testicular volume is the ear-

Table 1 Staging of Pubertal Development (Tanner)

Staging	Pubic hair staging	Concomitant changes	Prader orchidometer (ml)
Girls: breast			
1. Prepubertal, papilla elevation	No pigmented hair		
2. Budding; larger areole; palpable and visible elevated contour	Pigmented hair, mainly labial	Accelerated growth rate	
3. Enlargement of the breast and areola	Coarser, spread of pigmented hair over mons	Peak growth rate, thicker vaginal mucosa, axillary hair	
4. Secondary mound of areola and papilla	Adult type but smaller area	Menarche (stage 3 or 4)	
5. Mature	Adult distribution	Decelerated growth rate	
Boys: genital size			
1. Prepubertal	No pigmented hair	Long testis axis <2.5 cm	1, 2, 3
2. Early testicular, penile, and scrotal growth	Minimal pigmented hair at base of penis	Early voice changes; testes length 2.5–3.3 cm	3, 4, 5, 6, 8
3. Increased penile length and width; scrotal and testes growth	Dark, coarse, curly hair extends midline above penis	Light hair on upper lip, acne, maximal growth, testes length 3.3–4.0 cm	10, 12, 15
4. Increased penis size including breadth; pigmented scrotum	Considerable, but less than adult distribution	Early sideburns; testes 4.0–4.5 cm	15, 20
5. Adult size and shape	Adult distribution, spread to medial thighs or beyond	Beard growth; testes >4.5 cm	25

liest physical evidence (20). A testis of 4 cc or 2.5 cm long is evidence of pubertal growth. This occurs, on the average, by 12 years and may occur normally as early as 9.5 years. Pubertal development in boys can be gauged by Tanner staging (Table 1) of genital size and pubic hair (Fig. 2).

1. Age of Puberty

As with girls, there were no large-scale studies of the onset and progression of male pubertal development until the National Health and Nutrition Examination survey (NHANES). Mean ages and early limits were loosely based upon small studies from the United States and larger studies from the United Kingdom. Data from the NHANES has shown that puberty among African-American boys begins and progresses earlier than among whites and Mexican-Americans (21). These data concerning pubic hair development, the most reliable criteria, indicate that the early limit and mean age of the onset of Tanner stage 2 is similar to that previously used for white boys; about 9.5 years and 12 years, respectively. Among African-Americans, both ages would appear to be about 1 year earlier. The data for Tanner 2 genital staging differs so drastically from older data that one can only conclude that different criteria were used.

Figure 2 Mean ages (dots) and ranges (horizontal lines) of various pubertal changes in boys. Dashed lines show earlier limit for African-Americans.

Also, similar to the female data, the age of completion of puberty according to NHANES (21) is similar to older data. Thus, if puberty is beginning earlier, it is proceeding at a slower tempo, which is an unlikely phenomenon.

2. Hormonal Changes

As puberty progresses, there is a progressive rise of LH, FSH, and testosterone levels indicative of a continuing upregulation of secretion of the hypothalamic–pituitary–testicular axis (1, 2, 4). Levels of other steroids of adrenal or testicular origin also rise: estrone, estradiol, androstenedione, 17-hydroxyprogesterone, DHEA, and DHEAS (22). The rise of the latter two signifies adrenarche and precede gonadarche. Inhibin B levels, indicative of seminiferous tubule integrity, progressively rise during puberty (23). Mullerian inhibiting hormone levels in boys rise rapidly during the first year of life, are the highest during late infancy, and then gradually decline until puberty, while in girls levels rise minimally through prepubertal years (23, 24). This marker for testicular development has an inverse relationship with testosterone, with levels progressively falling throughout puberty (23, 24).

3. Growth

During midpuberty, the period when testosterone levels are rapidly rising, the peak of the pubertal growth spurt, voice change, and the onset of axillary hair growth occur (25, 26; Fig. 2). There is a progressive increase in total body bone mineral content, lean body mass, and a progressive decrease in body fat (19, 26). The onset of acne and gynecomastia are also typically midpubertal events.

Facial hair growth begins about 3 years after the onset of pubic hair growth. The density and distribution of the beard, chest hair, and abdominal and pubic hair may progress for years after puberty and vary considerably among adult men. These correlate more with familial or genetic factors than with hormonal levels, as do quantity and density of hair on the extremities.

In contrast to girls, the period of accelerated growth occurs during midpuberty rather than generally concomitant with the onset (25). Peak growth velocity is generally at 14–15 years of age and during Tanner stages 3 and 4. Onset of spermatogenesis (first evidence of completed spermatogenesis, usually first observable by presence of sperm in urine, particularly first morning void) is usually at Tanner stage 3, occurring at age 13.5–14 years. It occurs after considerable testosterone stimulation, but before adult levels are reached.

4. Pubertal Gynecomastia

Gynecomastia, defined as palpable or visible breast tissue, occurs in at least two-thirds of boys some time during puberty. Subareolar breast hyperplasia measuring 0.5 cm or more may be palpable. When a discrete symmetrical disk is palpable, with or without surrounding tissue full-

ness, this can be considered true gynecomastia. This may be difficult to differentiate from pseudogynecomastia resulting from accumulation of fatty tissue, particularly in boys who are heavy. Pubertal gynecomastia is a variant of normal development, which may develop excessively. Onset may coincide with the onset of puberty but primarily begins at ages 13–14, before testosterone levels have reached the adult range. Most commonly it persists for 18–24 months, and then regresses, usually by age 16 years. If the quantity of breast tissue is considerable and regression is not apparent after 2 years, plastic surgical excision should be offered. Drugs blocking estrogen effect may inhibit growth and cause regression, no medical therapy has been shown to cause full regression.

Gynecomastia develops at a point when circulating estrogen to testosterone levels are relatively greater than after testosterone levels reach adult values. This is apparently a consequence of extraglandular aromatization of adrenal and testicular androgens. Among boys with significant gynecomastia, this aromatization may occur within breast tissue.

II. PRECOCIOUS PUBERTY

A. Classification

When puberty begins and progresses early, the condition is, by definition, precocious puberty. However, because recent data, particularly for girls, suggest that the onset of puberty is occurring earlier, so one cannot make the diagnosis based simply upon the early limits of age for the normal onset of pubertal changes (27). The traditional early limit for girls was 8 years, the age that was considered to approximately 2 standard deviations below the mean (the lowest 2–3% of the normal population range). Recent data suggest that 5–6% percent of girls have breast development by their 8th birthday, suggesting a slight shift to a younger age.

Since breast development (thelarche) is reported to be occurring earlier, and there are differences among the African-American population, the diagnosis of precocious puberty should not be made in a girl unless, at presentation, she shows pubertal levels of hormones, early onset and inappropriately rapid progression of physical development, with an inappropriate acceleration of skeletal age in relation to growth rate. Since earlier onset of breast development is not being accompanied with the same tempo of puberty (with puberty being completed at the same age), early physical signs alone do not necessarily mean that the hypothalamic–pituitary–ovarian axis is being activated earlier. Thus, if the initial signs first appear earlier, without rapid progression, the diagnosis of precocious puberty should not be made. Early onset of breast development not followed by progressive change may be a variant of normal or constitute nonprogressive precocious puberty (28, 29). A young girl with pubertal breast

development may be a variant of normal, have physiologically normal but early puberty, or have an underlying pathological cause of early development. Precocious puberty is diagnosed based on early onset, plus clinical, hormonal, and radiological evidence of excessive progression.

1. Gonadotropin-Dependent and -Independent Precocious Puberty

Precocious puberty is classified as physiologically normal but early and progressive (GnRH-dependent) or GnRH-independent (Table 2). GnRH-dependent or central (true) precocious puberty results from early onset of pubertal hypothalamic–pituitary–gonadal activity; it is (true)

Table 2 Differential Diagnosis of Precocious Puberty

Central (GnRH driven)
Idiopathic (sporadic or familial)
Central nervous system abnormalities
Acquired (abscess, chemotherapy, granulomas, inflammation, radiation, surgical, trauma)
Congenital anomalies (arachnoid cysts, hydrocephalus, hypothalamic hamartomas, septo-optic dysplasia, suprasellar cyst)
Tumors (LH-secreting adenoma, astrocytoma, glioma (may be associated with neurofibromatosis), craniopharyngiomas, ependymomas)
Secondary to chronic exposure to sex steroids (causes of peripheral puberty; CVAH, GIP, tumors)
Reversible forms: space-occupying or pressure-associated lesions (abscess, hydrocephalus)
Peripheral (GnRH independent)
Genetic disorders (mutations)
Congenital virilizing adrenal hyperplasia (CVAH), males
Gonadotropin-independent puberty
LH receptor-activating mutations
DAXI gene mutations
McCune-Albright syndrome
Tumors
Adrenal sex steroid secreting (adenoma, carcinoma)
Gonadotropin-producing (choriocarcinoma, chorioepithelioma, dysgerminoma, hepatoblastoma, hepatoma, teratoma)
Ovarian (granulosa cell, may be associated with Peutz-Jeghers syndrome); granulosa, theca cell
Testicular (Leydig cell)
Limited or reversible forms
Chronic primary hypothyroidism
CVAH
Exogenous sex steroid or gonadotropins
Ovarian cysts
Variants of normal development
Premature pubarche (secondary to premature adrenarche)
Premature thelarche

physiological gonadotropin stimulation emanating from the GnRH secretion of (central) CNS–hypothalamic origin. Central precocious puberty is in contrast to peripheral (GnRH independent) or precocious pseudopuberty in which the sex steroid stimulating the physical changes of puberty is not produced as a result of physiological pituitary gonadotropin secretion. The source of sex steroid may be exogenous or endogenous, gonadal or extragonadal. The hormone may be autonomously produced, independent of gonadotropin stimulation.

2. General Terminology

The terms complete and incomplete sexual precocity have been used with different meanings. Central precocious puberty has been called complete and peripheral incomplete, but the more common designation has used complete to describe any form of precocious puberty while incomplete designates some partial early pubertal development such as thelarche or pubarche. Because of the confusion with this terminology, the latter changes are more appropriately termed partial development or variations of normal. A further classification designates isosexual precocity (early pubertal development appropriate for sex) and contrasexual or heterosexual precocity (early development inappropriate for sex or appropriate for opposite sex). Such terminology has become cumbersome. Use of feminization among males and masculinization in females should adequately designate those conditions known as contrasexual puberty.

B. Girls

1. Gonadotropin-Dependent (Central) Precocious Puberty

Central precocious puberty (CPP) is diagnosed if physical pubertal changes and laboratory results are consistent with progressive changes of normal puberty. The majority of girls presenting with precocious puberty have the central form, with underlying neurological abnormalities being unusual.

a. Causes. Central precocious puberty may not be associated with anatomically demonstrable CNS abnormalities that apparently disrupt the restraint typical of childhood. Associated CNS abnormalities in girls are listed in Table 2. Patients surviving CNS tumor involvement who have received radiation and chemotherapy may show central precocious puberty. Precocious puberty is a well-recognized phenomenon among children emigrating from developing countries both in eastern Europe and Asia to western countries. Improved nutrition, environmental stability and psychological support lead to dramatic catch-up growth, weight gain and central precocious puberty. Loss of height potential may be excessive (30, 31). Among patients is a subset who did not have growth retardation at adoption, leading to the hypothesis that

early puberty may be a consequence of exposure to estrogenic endocrine disrupters (32).

GnRH-secreting hypothalamic hamartomas contain apparently redundant CNS tissue containing GnRH neurons that function independently of CNS inhibitory influences, an ectopic hypothalamus episodically secreting GnRH (33). The loss of such episodic release after complete removal of a pedunculated hamartoma was early evidence that the pulse generator itself resides within the network of communicating GnRH secreting neurons. Hamartomas, present with CPP at very young ages, more frequently among boys than girls.

b. Hormonal Documentation. Hormone levels and responses consistent with gonadarche principally include basal and GnRH- or GnRH analog stimulated gonadotropin levels within the pubertal range; LH responses increase to a greater degree than FSH with pubertal onset and are hence more useful in diagnosing central precocious puberty. The difference in FSH between prepubertal and pubertal children may be undetectable.

2. Gonadotropin-Independent (Peripheral) Precocious Puberty

Precocious pseudopuberty, defined as early puberty resulting from any other mechanism other than hypothalamic GnRH-pituitary LH and FSH-stimulated gonadal activity, in girls results from excessive estrogen stimulation for age from ovarian, adrenal cortical, or exogenous source. Among girls, this form of precocious puberty is rare (Table 2).

a. McCune-Albright Syndrome. The McCune-Albright syndrome, which occurs in girls far more frequently than boys, includes a unique form of peripheral precocious puberty in which an activating missense mutation occurs in the gene for the alpha subunit of G_s , the G protein that stimulates cyclic adenosine monophosphate formation (34). Abnormalities in this syndrome consist of multicentered localized osseous lesions called polycystic fibrous dysplasia, melanotic cutaneous macules called cafe-au-lait spots, and one or more endocrinopathies. These include precocious puberty (Fig. 3), hyperthyroidism, hyperadrenocorticism, pituitary gigantism or acromegaly, and hypophosphatemia. The mutation has been found in variable abundance in affected tissues, a finding consistent with a mosaic distribution of aberrant cells from a somatic cell mutation (34) and also compatible with variable expression and exacerbations and remissions of disease activity characteristic of this syndrome. Mechanisms usually stimulated by the trophic hormones are activated as a result of this mutation; female patients with

Figure 3 Premature breast development (stage 3) in a 4-year-old girl with McCune-Albright syndrome.

sexual precocity secrete increased ovarian estrogen without gonadotropin stimulation. Mean ovarian volume is increased and ovaries are asymmetrical, primarily as consequences of large ovarian cysts (35). Levels of estrogen fluctuate, with spontaneous regression occurring.

Because ovarian estrogen secretion in patients with the McCune-Albright syndrome is not gonadotropin-driven, such secretion is not suppressed by GnRH analog therapy. Thus, therapy to diminish estrogen secretion or action is indicated (see section on therapy, below).

As with other entities of peripheral precocious puberty, skeletal age and biological maturity become advanced and, eventually, mature hypothalamic–pituitary control of ovarian function commences, even at an early age (secondary central precocious puberty) (36).

After hypothalamic–pituitary maturation, ovarian function is under the usual control mechanisms and GnRH analogs may have a place in therapy for early puberty. Eventually these patients ovulate and true menstrual cycling and pregnancy may occur, in spite of persistent autonomous ovarian activity (37).

b. Ovarian Cysts. Ovarian cysts, readily identified by sonography, may occur with central precocious puberty, as part of normal ovarian development of childhood (38), secondary to intermittent unsustained gonadotropin stimulation and in the McCune-Albright syndrome. An isolated follicular cyst may be present with apparent autonomous estrogen production, presenting as peripheral precocious puberty. Such cysts are usually self-limiting; estrogen levels fall as the cyst spontaneously regresses. A drop in estrogen levels may be accompanied by withdrawal bleeding. Initial treatment of an isolated follicular cyst should be conservative, with careful monitoring and without surgical intervention, unless a surgical emergency such as torsion is likely. Follow-up sonography and measurement of estrogen levels after 1–4 months usually show regression.

c. Chronic Primary Hypothyroidism. Although hypothyroidism is usually accompanied by growth, skeletal, and pubertal delay, in rare cases patients with thyroid gland failure and elevated TSH levels have evidence of advanced pubertal development. The mechanism is likely related to excessive trophic hormone or alpha subunit secretion. An excessive secretion of the alpha subunit accompanies the TSH hypersecretion. In such large quantities, TSH or the alpha subunit may compete for and activate gonadotropin receptors (39). Patients present with breast development that may be accompanied by galactorrhea. Marked pituitary enlargement may occur in this syndrome (40). Appropriate thyroid replacement therapy results in normalization of pituitary hormone levels. Pubertal changes regress and no other therapy is necessary.

d. Tumors. Estrogen-secreting tumors of the ovaries and adrenal cortex are rare. They present typically with markedly elevated estrogen levels, rapidly progressing pubertal changes and asymmetry and unilateral en-

largement of the ovarian or adrenal glands. Androgen excess and androgen stimulated changes may also be present.

3. Diagnostic Evaluation

The approach to the assessment of the girl with early pubertal development is outlined in Table 3.

a. History and Physical Findings. A complete history should emphasize the points noted in Table with careful consideration of any possible exposure to exogenous hormone, previous or current CNS abnormalities or symptoms, pubertal history of other family members, and height and growth rates. Gelastic seizures may occur in association with organic causes of central precocious puberty, including hypothalamic hamartomas.

Physical examination should include height, weight, span, upper/lower body segment ratio, skin, hair, thyroid, neurological findings, breast and pubic hair staging, inspection of the genitalia to determine pubertal maturation, and visualization of the vaginal mucosa.

Visual inspection, without palpation, to assess estrogen effect upon the vaginal mucosa should avoid traumatizing the patient. If the patient is positioned prone with knees drawn up and legs spread, the introitus can be visualized without touching the vulva but by gently spreading the labia. A glistening red appearance is consistent with a thin, non-estrogen-stimulated mucosa, whereas a pink mucosa with a mucous covering is indicative of a thicker more cornified mucosa; mucous secretion is suggestive of concomitant estrogen stimulation. However, irritation or infection can also result in the latter appearance. A bimanual abdominal–rectal examination should be avoided unless an abdominal pelvic ultrasound study is inadequate.

b. Hormonal Testing. A plasma estradiol measurement using a sensitive assay and GnRH or GnRH analog stimulation testing is indicated. Gonadotropin responses are pubertal with CPP. The LH response is more helpful than FSH in demonstrating a characteristic pubertal pattern; patients with peripheral precocious puberty (PPP) have a prepubertal or suppressed response. Figure 4 shows the range of responses of 12 prepubertal girls. Most pubertal patients do not have an FSH response outside the prepubertal range; hence FSH responses are seldom discriminatory. Low responses of both LH and FSH, which are normal for prepubertal individuals, cannot be differentiated from a suppressed response found in patients with some forms of PPP.

Prepubertal higher baseline and stimulated FSH levels are greater than LH responses, and pubertal basal and response levels are greater for LH than FSH. Ratios of LH to FSH less than 1.0 are consistent with a prepubertal status while ratios greater than 1.0 suggest a pubertal state (12).

Other laboratory testing may involve thyroid function tests including TSH to rule out primary hypothyroidism,

Table 3 Criteria to Plan Diagnostic Evaluation of Premature Pubertal Development

	Girls	Both sexes	Boys
A Clinical findings of precocious puberty	Breast development		Genital development with testicular growth
	Genital maturation		Sexual hair
	Accelerated linear growth		Accelerated linear growth
	±Sexual hair		Increased muscle mass
	±Menstruation		
	Assess the following depending upon particular situation:		
		History	
		Exposure to exogenous hormones	
		CNS trauma, anomalies, or infection	
		CNS symptoms	
	Familial history of age of pubertal onset		
	Growth pattern and rates		
	Physical examination		
	Tanner breast and pubic hair stage	Pubertal maturational staging (Tanner)	Familial forms usually involve males
	Clitoral size	Body proportions (upper/lower segment ratios)	Tanner genital size and pubic hair stages
	Rectal-abdominal bimanual examination	Body and skeletal symmetry	Penis size
	Inspect for galactorrhea, estrogenized vaginal mucosa	Acne and skin pigmentation	Stretched length
		Fundoscopic and visual field examinations	Description of width
		Thyroid examination	Testicular examination
		Evidence of thyroid dysfunction	Size: long axis or volume
		Neurologic examination	Symmetry
		Laboratory evaluation	Consistency
		Serum or plasma assessment	
	Estradiol	LH, FSH	Testosterone
		Thyroid function tests	hCG
		DHEA or DHEAS	
	Increased LH response	GnRH stimulation	Increased LH and FSH rise
		Radiologic assessment	
		Skeletal age	
		MRI of hypothalamic region (if “peripheral” causes excluded)	
	Abdominal-pelvic sonography		Testicular sonography
		Other	
	Vaginal cytology		Morning void for sperm
B Clinical findings of premature thelarche	Breast development without growth acceleration or other pubertal findings	History	(see Table 4 for contrasexual development)
		Exposure to gonadotropins or estrogen	
		Growth pattern	
		Physical examination: thorough examination (see earlier)	
		Laboratory examination	
		Serum LH, FSH, estradiol	
		Skeletal age x-ray	
		Pelvic sonography	

Table 3 Continued

	Girls	Both sexes	Boys
C	Clinical findings of adrenarche	Sexual hair (pubic or axillary) without growth acceleration or other pubertal changes (Table 4)	<p>Follow-up Reassess growth rate, pubertal progression after 2–6 months Repeat sonography if follicular cysts</p> <p>History Exposure to androgens Growth pattern</p> <p>Physical examination Laboratory examination Plasma DHA or DHAS Skeletal age x-ray</p> <p>Follow-up: reassess growth rate and pubertal progression in 3–6 months</p>

plasma DHEAS levels to determine if adrenarche has occurred, and DHEA or androstenedione if excessive adrenal androgen secretion is suspected. In menarcheal patients, a progesterone level may document luteal phase and verify ovulation.

c. Other Testing. A skeletal maturity (bone age) roentgenogram should be obtained to estimate the extent of excessive stimulation and remaining growth potential (41). Pelvic sonography should be done in all patients to determine if ovarian and uterine size is enlarged for age, but appropriate for stage of puberty (consistent with CPP); unilateral or asymmetrical ovarian enlargement may be indicative of a tumor or cysts. All young girls (less than 5 years) with central precocious puberty in whom the cause is not already explained should undergo MRI of the CNS, particularly the hypothalamic region, to investigate lesions (Table 2) even if the neurological examination is normal. Lesions are rarely demonstrated among girls older than 6 years so the need for such a study should be determined individually. An electroencephalogram (EEG) is not generally indicated, even though abnormalities have been reported in cases of central precocious puberty.

C. Boys

1. Gonadotropin-Dependent (Central) Precocious Puberty

a. Causes. Causes of early pubertal development among boys are outlined in Table 2. A larger portion of boys than girls with CPP have CNS lesions than have the idiopathic variety. Therefore, assessment of boys with early unexplained puberty, regardless of age, should include an MRI. The CNS disorders include hamartomas (Fig. 5), subarachnoid cysts, glial cell tumors, and germ

cell tumors. CPP occurs consistently in patients with hypothalamic hamartomas and subarachnoid cysts, and in about two-thirds of those with germ cell tumors but only a minority of children with glial cell tumors (42). Rarely astrocytomas and craniopharyngiomas are associated with CPP. Treatment of these lesions is the same, whether or not CPP occurs. Since hamartomas are congenital malformations rather than tumors and rarely have neurological consequences, therapy is directed at the CPP. Medical therapy is indicated except in those rare situations in which the lesion is pedunculated, making surgical removal a treatment option.

As among girls, central precocity occurs as a consequence of CNS radiation therapy, with or without chemotherapy, among patients with cancer. This sequela may occur with growth hormone deficiency, hence without growth acceleration. Other CNS-related causes include trauma, surgery, inflammation, and severe neurological deficits of congenital or acquired origin. Precocity related to hydrocephalus, brain abscesses, or granulomas may be related to pressure changes and, in some instances, is reversible when pressure is decreased.

In children of either gender, secondary central precocity may develop secondary to prolonged sex steroid exposure associated with peripheral precocious puberty. Boys may develop central precocious puberty as a consequence of a prolonged hyperandrogenic state, as in undiagnosed or inadequately treated congenital virilizing adrenal hyperplasia. Patients with known peripheral precocious puberty present with evidence of pubertal maturation of the hypothalamic–pituitary axis including a pubertal response to GnRH or GnRH α stimulation. Secondary CPP tends to occur among patients with advanced biological maturation, as evidenced by bone age maturation.

Figure 4 Range of serum LH and FSH responses to GnRH stimulation in 12 pubertal girls shows the wide variation in response, especially FSH. Actual units vary depending upon the gonadotropin assay used, but pubertal individuals have an LH response greater than the prepubertal response, although the rise of the FSH response cannot be expected to be greater. The initial rise in FSH may be more brisk, so that values within the first 40 min may be somewhat greater than the prepubertal range, and maximum incremental rise does not differ. Therefore, to verify central precocious puberty, a rise in LH above the prepubertal range should be demonstrated.

tion advanced to or beyond 12 years among boys or 10 years in girls.

b. Physical and Laboratory Findings. Central precocity in boys is characterized not only by pubertal testosterone levels and basal and GnRH- or GnRHa-stimulated gonadotropin levels (LH > FSH), but also full physical pubertal development. Testicular growth is symmetrical characteristic of gonadotropin stimulation, and hence is found in CPP and unique forms of gonadotropin-independent precocious puberty, which are a consequence of an activating LH-receptor mutation, but not in other forms of PPP.

3. Gonadotropin-Independent (Peripheral) Precocious Puberty

Precocity in boys also results from inappropriate androgen stimulation from either endogenous or exogenous sources, nonpituitary gonadotropin stimulation, and rare activating mutations.

a. Virilizing Adrenal Hyperplasia. A common cause of peripheral precocious puberty in boys is endogenous androgen excess in undiagnosed or inadequately treated congenital adrenal hyperplasia (CAH) caused by 21-hydroxylase deficiency. Fortunately, with neonatal screening for this form of CAH, many boys are being diagnosed now before developing early pubertal changes. Other rare forms of virilizing adrenal hyperplasia, 11 β -hydroxylase deficiency and 3 β -hydroxysteroid dehydrogenase deficiency, may present in a similar manner.

b. Familial Male-Limited Gonadotropin-Independent Puberty (GIP). A unique entity of male-limited gonadotropin-independent precocious puberty occurs in which gonadal steroidogenesis and spermatogenesis proceed, even though gonadotropin stimulation is age-appropriately low or suppressed, as a consequence of activating mutations of the LH receptor (43). Since these mutations are inherited in a dominant pattern, the child's father may have a history of precocious puberty. Onset is usually but not always at a very young age. The physical findings of boys with this disorder are full pubertal development, including bilateral testicular growth, similar to that of boys with central precocious puberty. Gonadotropin baseline levels and responses to exogenous GnRH are consistent with prepuberty or suppression, while testosterone is elevated and often within the adult male range.

The activating mutations of the LH receptor result in G-protein activation and increased cyclic AMP production with Leydig-cell testosterone secretion. These mutations do not cause precocious puberty or other abnormality among girls, since FSH receptor activation, in addition to LH, is necessary for ovarian steroidogenesis.

Among boys, genital enlargement, including bilateral testicular growth and skeletal age acceleration, are the primary presenting features, usually by age 3 years. Spermatogenesis sufficient to produce mature forms and considerable seminiferous tubular growth occurs. Eventually, a pubertal hypothalamic-pituitary-testicular axis can be demonstrated among affected boys, with normal fertility. Adult height may be compromised. This form of peripheral precocious puberty is commonly followed by central precocity, since there is not adequate therapy to fully suppress androgen production. After maturation of the hypothalamic-pituitary axis has occurred, GnRH analog treatment will result in suppression of LH and FSH response to exogenous GnRH, but testosterone levels will not be fully suppressed.

A unique form of gonadotropin-independent precocious puberty has been found to be associated with pri-

Figure 5 A hypothalamic hamartoma associated with episodic gonadotropin-releasing hormone secretion in a young boy with central precocious puberty. The arrow points to the hamartoma.

mary adrenal insufficiency and a mutation in the DAXI gene (44).

c. Chronic Primary Hypothyroidism. Rarely prepubertal-aged boys with chronic primary hypothyroidism present with testicular enlargement. It is most likely the result of occupation of the FSH receptors in the testes by TSH, when TSH occurs in such supraphysiological quantities (39). Hyperprolactemia is present and galactorrhea occurs. Prolactin levels fall and testicular size decreases when TSH levels are suppressed with thyroid replacement therapy.

d. Androgen-Secreting Tumors. Testosterone-secreting Leydig-cell tumors are associated with dramatic somatic and genital growth with muscular development. Typical presentation includes rapid onset with unilateral testicular enlargement. Adrenocortical androgen-secreting tumors are rare, are often accompanied by physical and hormonal evidence of other adrenal cortical hormonal excess, and present with prepubertal-sized testes. Hormonal profiles suggest autonomous secretion.

e. Chorionic Gonadotropins Secreting Tumors. In rare cases Leydig-cell testosterone secretion as a consequence of abnormal gonadotropins stimulation causes PPP. This occurs in settings that include chorionic gonadotropin-secreting tumors, such as teratomas, embryonal tumors, hepatoblastomas, and CNS germinomas. Often the primary tumor is highly malignant.

3. Assessment

The evaluation of boys with early puberty should be guided by pertinent aspects of the history, physical ex-

amination, and laboratory assessment outlined in Table 3. A history of growth patterns and pubertal progression can provide clues to cause. Tanner staging and testicular symmetry and volume should be verified. Generally, prepubertal-sized testes (less than 2.0 cm in the longitudinal axis) suggest a cause other than pubertal hypothalamic-pituitary gonadotropin function; pubertal-sized testes (longer than 2.5 cm) suggest central precocious puberty (Fig. 6). Asymmetrical or unilateral enlargement suggests a Leydig-cell tumor or hyperplasia adrenal rest tissue. The latter is seen in inadequately treated CAH and may also be bilateral.

Gonadotropin response to GnRH or GnRHa stimulation should be documented, with particular attention to whether the LH response is above the prepubertal range, noting the LH:FSH ratio (<1 suggests prepubertal secretion). Testosterone levels above the prepubertal range verify the early pubertal status but do not differentiate the source. Skeletal age documents the extent of advanced maturity and can be used to estimate remaining growth potential. Because of the high incidence of CNS lesions in male sexual precocity, MRI or CT scans should be done unless the cause is otherwise explained.

D. Natural History

The natural history of gonadotropin-dependent (central) precocious puberty is outlined in Figure 7. All phases of pubertal development are precocious including spermatogenesis, premature pubertal growth, and skeletal age acceleration. Depending upon the rate of progression, early

Figure 6 Genitalia of a 25-month-old boy with sexual precocity associated with a hypothalamic hamartoma. Tanner stage 2 pubic hair, Tanner stage 3 genital development, and enlarged testes for age are evident.

pubertal development leads to premature attainment of adult height, as well as sexual and reproductive capabilities. The rate of development is determined by the magnitude of androgen secretion, with persistent high levels resulting in the greatest acceleration of changes. Very early or rapidly progressive precocious puberty leads to diminished total height increase for amount of advance of

skeletal maturity. With a premature growth spurt and skeletal maturation, children with precocity are tall for age during childhood. However, if their skeletal maturity becomes disproportionately advanced for their concomitant growth rate, their projected adult height diminishes, becoming less than expected based upon familial heights (Figure 8). In most situations, the adult height deficit is only a few centimeters (41). With rapidly progressive precocious puberty characterized by skeletal age disproportionately advanced for height, without treatment growth is completed at a younger age and shorter height than if puberty and the pubertal growth spurt had occurred during the usual years. Therefore, the indications for treatment of progressive central precocious puberty are to stop or cause regression of pubertal characteristics and to preclude or reclaim loss of height potential.

Tall stature, advanced pubertal development, and menarche during childhood may cause social and psychological adjustment problems. Psychosocial concerns are an indication for counseling and consideration of medical treatment to suppress excessive growth rate and pubertal advancement.

Whether or not the precocity will be treated medically, the patient and parents need to understand what is happening. If puberty is idiopathic, they should understand that normal things are happening, but at an early age. An explanation, geared to the child's ability to understand is usually satisfactory: that it is normal for the body of a child to change into the body of an adult, but sometimes it starts too soon and happens too fast. The discussion with the patient, often with the parent present, should include age-appropriate sex education. Psychosexual development is generally commensurate with age not physical maturity, hence, inappropriate sexual behavior is seldom a problem. In contrast to being sexually aggressive, patients may be naive and misinterpret sexual advances by older individuals. Both girls and boys are potential victims of sexual encounters with older persons

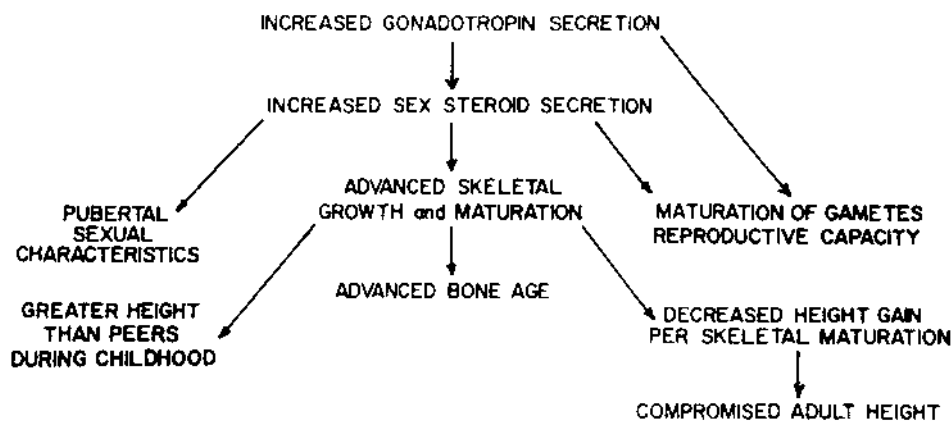

Figure 7 Schematic representation of the natural history of early pubertal development. (Used by permission, Year Book Medical Publishers.)

Figure 8 Growth chart for girls shows percentile of height for age. The solid circles represent height for age for a girl presenting with central precocious puberty; the connected triangles depict height for bone age. Note that although growth rate is accelerated, bone age has accelerated considerably more in the same time period, resulting in decrease in projected adult height. In contrast, the patient whose heights are depicted (open circles) with Tanner stage 2 breast and pubic hair development did not have an acceleration in growth rate or bone maturity. Although she was tall for age with early pubertal development, she did not have a decreased adult height potential.

who would take advantage of their childlike concept of, and vulnerability to, intimacy. Once children recognize that they are more mature, they tend to avoid incidents of childhood sex play. Children with early puberty share interests with age peers. Even though boys experience frequent erections and masturbation, and may have the capacity for ejaculation, they are not an increased threat of potential sexual aggression. Children of both sexes become potentially fertile.

III. THERAPY

If there is an underlying treatable cause resulting in early puberty, therapy should be given. Examples include surgery and radiation or chemotherapy for CNS, ectopic gonadotropin-producing, gonadal, or adrenal tumors. Adrenal suppression is indicated in CAH, thyroid replacement in primary hypothyroidism, and cessation of administration for inappropriate steroid or gonadotropin treatments in those instances. If the underlying treatment is completely successful and central pubertal maturation has not occurred, progression of pubertal development should cease, and some regression may follow. In patients with autonomous gonadal steroid production, such as in McCune-Albright syndrome or male familial gonadotropin-independent puberty, therapy is aimed at reducing sex steroid production or effect. Drugs that have been tried

included initially medroxyprogesterone and spironolactone, and, more recently, steroid synthesis inhibitors, (ketoconazole) aromatase inhibitors (testolactone and anastrozole), and the estrogen-receptor antagonist (tamoxifen) (45–49). None of these completely suppress the sex steroid effect in a sustained fashion, and in both of the situations secondary precocious puberty is not unexpected (50). When this occurs, GnRHa therapy can be begun in addition to other therapy in an attempt to retard pubertal development and growth as much as possible. Patients so treated should be carefully monitored for pubertal development, growth rates and skeletal age, sex steroid levels, and side-effects of the agent(s) used.

A. Criteria

Among patients with central precocious puberty, idiopathic or otherwise, marked by a pubertal pattern of gonadotropin response to GnRH or GnRHa stimulation, gonadotropin production can be halted with adequate dosages of GnRH analog (51). The decision for or against treatment should be a joint decision with the parents, with consideration given to all aspects of the child's physical and mental maturity (52). Therapy should not be considered unless the following criteria have been documented: (a) a pubertal response to GnRH or GnRHa stimulation testing or some other documentation of pubertal gonadotropin secretion (basal plasma or urinary levels clearly above the prepubertal range), (b) a sustained accelerated linear growth rate, (c) an accelerated advancement of skeletal age, and (d) physical changes consistent with progressive pubertal development. Even if these criteria are met, therapy may not be chosen unless the child is developing at a rate clearly outside the range for age; the skeletal age maturity rate has exceeded the growth rate so that adult height is becoming compromised; and the parents and child perceive a need to delay further pubertal growth and development.

If therapy is indicated to stop the progression of puberty or menses and to preclude or attempt to reclaim compromised growth potential, GnRH analog therapy is the only effective treatment. The pharmacological basis is the suppression of episodic secretion of gonadotropins by overriding the episodic release of GnRH with continued high levels of GnRH analog. After an initial LH and FSH release in response to GnRH analog, the long-term effect of persistent adequate dosing is downregulation of responsiveness; GnRH receptor numbers decrease, and gonadotropin responses are essentially obliterated. The result of such treatment is first a fall in circulating gonadotropins, followed by a return of sex steroids to prepubertal levels. Adequacy of suppression should be monitored by the demonstration of the lack of gonadotropin response to exogenous GnRH stimulation. With adequate dosing, suppression is demonstrable within the first 8 weeks of therapy.

B. Institution

GnRH analogs are available as depot injection, short-acting injection, and nasal spray. Dosing adequacy and effectiveness can be monitored by lack of progression of clinical indices and results of hormonal testing, including GnRH or GnRHa stimulation. In boys a fall in plasma testosterone levels to a prepubertal range is indicative of adequate dosage. In girls estradiol levels are less helpful because of fluctuating and low levels present in the pubertal state. When suppression is not achieved, the dosage should be increased. Once suppression is verified, patients can be monitored at 4–6 month intervals with GnRH testing, and with skeletal age monitoring at least annually.

C. Monitoring Therapy

Hormonal suppression with GnRH analog treatment results in a deceleration of the puberty growth rate and a cessation of pubertal development.

1. Pubertal Development and Growth Rates

In girls, breasts may regress, vaginal mucosa becomes nonestrogenized, and menses cease. There may be an episode of withdrawal bleeding during the institution of suppression. This can be expected if an endometrial stripe is discernible by ultrasonography before therapy.

In boys, genital, including testicular, growth ceases and regression may occur. Further diminishing of projected adult height should not occur; it may increase among those with compromised predictions before beginning therapy.

Since GnRHa does not influence adrenal androgen secretion, if adrenarche has occurred, it progresses during treatment (53). With sufficient and increasing levels of adrenal androgen, sexual hair will be maintained and progress. This should not be interpreted as evidence of lack of gonadal suppression, although documentation of pubertal levels of adrenal androgens can be used as verification.

Growth rates return to a prepubertal growth rate, although rates may become subnormal, particularly among those with very advanced skeletal ages.

2. Skeletal Maturity

The stimulus for accelerated skeletal maturity is removed once sex steroid levels are suppressed. However, there is a clear lag since the steroid effect upon bone maturity is delayed. Therefore, it is not uncommon not to document deceleration during the first 6 months on therapy. Thereafter, skeletal maturity should slow to normal until the skeletal age is consistent with the age of puberty. Thus, if the bone age is 7.5 years after the first 6 months, it can be expected to be 8.5 years a year later. This progression of a year per year is expected to continue until skeletal age reaches the years of puberty. From this point on, the skeletal age progresses very slowly without sex steroids.

Bone age x-rays with concomitant heights can be used to estimate growth potential and hence predict adult height. During therapy, usually the growth potential gradually increases unless skeletal age was not excessive for height at the onset of therapy.

3. Ancillary Tests

Monitoring of ovarian ultrasound and bone density is not typically indicated. Ovarian and uterine volume both diminish. Bone mineral density can be expected to remain relatively constant. Since density is greater than expected for age, lack of increase in bone density during the hiatus of therapy is not considered detrimental.

4. Additional Medical Therapy

Growth hormone has been used as supplemental therapy among patients who have lost considerable height potential, grown at subnormal rates on GnRHa therapy, still have growth potential, and have evidence of inadequate growth hormone. It is expensive, and even though adult height may be enhanced, it should be used only after careful consideration. Also, since estrogen is the primary hormone stimulating skeletal maturity, the use of drugs that block estrogen synthesis (aromatase inhibitors) or action (estrogen receptor blockers) are being considered for use in CPP. No trials using such therapy have been completed.

D. Discontinuation of Therapy

1. Decision to Discontinue

The age at which to discontinue therapy must be individualized. Characteristically, therapy is discontinued when the child reaches the age when puberty typically is occurring, assuming the child is psychologically prepared. When predicted height is still less than target height, therapy may be continued in an attempt to gain greater height. However, as discussed below, the gain in growth potential diminishes with advancing age and skeletal age, largely because of waning growth rates.

2. Recovery of Hormonal Secretion After Discontinuation

Resumption of pubertal hypothalamic–pituitary–gonadal activity begins promptly, becoming complete within weeks or months (54). LH and FSH responses to GnRH are pubertal within 6 months. Attainment of pubertal milestones including attainment of Tanner stages proceeds at a rate similar to that during normal puberty. Testicular or ovarian volume (55) increase concomitantly. Menses among girls who were postmenarchal before therapy occurs within 12 months. Among premenarchal patients, most experience menarche within 18 months, but among some it may take up to 4.5 years. Ovulatory cycling begins and menstrual regularity is similar to that among other similarly aged girls (56). Among boys, spermatogenesis resumes and normalizes for stage of development.

Outcome data for boys indicate normal postpubertal status (29), including these with hypothalamic hamartomas (57).

E. Long-Term Outcome Data

1. Fertility

Although not yet well documented, both pregnancy with birth of normal infants and normal spermatogenesis have been demonstrated.

2. Growth After Discontinuation of Therapy

Particularly among girls, growth rates and total growth after therapy have uniformly been less than projected based upon height and skeletal age at discontinuation. There is little or no growth spurt among girls, even among those who begin therapy early.

Adult heights after ideal therapy are not yet available, while the results from patients whose treatment was begun late indicate height less than the range of target height. However, those who were well treated generally reach the range but not mean of target height. Overall, adult heights are greater than among untreated patients (58) and the predicted at the onset of therapy (59–63), less than predicted at the end of therapy (60, 63). Changes in height prediction during therapy are directly related to skeletal age at onset of therapy (61). Adult heights are often less than target height (59–62) and below the mean adult height for sex. Improvement of height is greatest among those with early onset of precocity as well as early onset of therapy (before ages 5–6 years) (59, 60, 62, 64).

3. Hyperandrogenism

With the withdrawal of gonadotropin and estrogen during GnRHa therapy, it would not be unexpected if ovarian cysts develop secondary to interruption of the stimuli for follicle growth. However, it has not been verified that a greater portion of patients who were treated with GnRHa have an increased incidence of ovarian cysts or hyperandrogenism. Some girls who were diagnosed with CPP and treated with GnRHa have subsequently been found to have hyperandrogenism (65), but there is no evidence that this is related to GnRHa therapy. However, it is important to verify any evidence of androgen excess at presentation, particularly among patients who present with sexual hair and other androgen-stimulated effects, in addition to estrogen-stimulated effects. Early androgen effect has been associated with later ovarian hyperandrogenism (66).

IV. PARTIAL PUBERTAL DEVELOPMENT: VARIANTS OF NORMAL

A. Premature Thelarche: Girls

Traditionally, premature thelarche (isolated premature breast development) has been diagnosed during two age periods. Significant breast tissue is most commonly noted

during the first two years of life. In most instances, the history suggests that this is a persistence or increase of the palpable breast tissue present at birth caused by a persistence of infant gonadotropin secretion. Since ovarian hormone production is greater during infancy than later childhood, breast development may persist or growth may occur as a consequence. Such development almost always regresses before 24 months of age.

The second period when isolated breast growth has long been noted is after age 6 years. As in normal puberty, when breast development is first noticed it may be asymmetrical or unilateral. This may account for the small percentage of children found to have Tanner stage 2 breast development reported in the large population surveys (14, 15), as well as those girls who have been reported to have nonprogressive precocious puberty (27, 52). This development may be a consequence of temporarily increased ovarian steroid secretion, highly sensitive estrogen receptors to low pubertal circulating estrogen levels, or both.

In any instance in which breast development at presentation is not accompanied by other evidence of puberty, careful monitoring of development over subsequent months is mandatory but only a limited assessment is indicated (see Table 3). Some patients may have early menarche, but adult height is not compromised (67). Estrogen levels, height, and bone age may be normal or slightly advanced for age. Rarely, an ovarian follicular cyst, which does not persist, may be identified. Since this condition is benign and may regress, treatment can be limited to education and counseling. However, because there may be episodes of greater gonadotropin secretion during childhood in girls, it may be difficult to ascertain where a given patient lies along the continuum from premature thelarche and central precocity (3, 5, 12). It has been reported that 14% of one group of 100 girls originally presenting with premature thelarche progressed to central precocious puberty (68). Occasionally, what initially appears to be isolated breast development may actually be the first sign of what will eventually become manifest central precocity. However, more commonly there is minimal progression until the usual age of onset of puberty. Without hormonal evidence of pubertal onset, it is inappropriate to interpret Tanner stage 2 breast development as the onset of either normal puberty or as a diagnosis of precocious puberty. The greater proportion of 5-, 6- and 7-year-old girls reported to have pubertal onset in the general population, the entity of nonprogressive precocious puberty, and premature thelarche may all be part of the same clinical entity.

B. Premature Pubarche

Premature pubarche, the early development of sexual hair, is normally the result of premature adrenarche, defined as an early onset of the pubertal increase of adrenal androgen production. Adrenarche usually precedes and is independent at gonadarche, is not accompanied by a mature re-

sponse to GnRH stimulation, nor is it suppressed with GnRH analog therapy. Premature pubarche is more common in girls than boys and is rare before 6 years of age except in African-American girls. The early pubic hair may be an isolated finding or be accompanied by mild acne, oily skin, onset of adult-type body odor, and axillary hair. If there are no other associated findings or pathological conditions, minimal assessment including measurement of androgen levels to verify that levels are not greater than those consistent with early adrenarche is required (Table 3). Documentation of the status of adrenarche is indicated by demonstrating that circulating levels of DHEA, DHEAS, or androstenedione are within the range of early adrenarche and above the prepubertal range. Height and skeletal age may be normal or transiently advanced (69). Growth and subsequent pubertal development should be expected to occur normally. The degree of advancement should be followed: abnormal progression, excessive virilization, or elevated DHEA and DHEAS levels may indicate pathological causes of excessive androgen. Also, there is evidence that early onset of androgen production may be the first evidence of ovarian hyperandrogenism (70). If so, the mechanism would likely involve not only a defect of control of androgen production, but also involve both the adrenal glands and the ovaries.

V. INAPPROPRIATE SEX-STEROID-STIMULATED CHANGES FOR SEX

Contrasexual (in contrast to isosexual) pubertal development, whether during childhood or puberty, is defined the development of sexual characteristics inappropriate for the sex of the individual (i.e., feminization among boys and virilization among girls). Causes among girls include the differential of androgen excess and for boys that of estrogen excess.

A. Girls

Although premature development of sexual hair (premature pubarche) in girls is not uncommon, excessive virilization of the prepubertal girl is rare and may present with the development of oily skin, acne, clitoromegaly, and hirsutism. Causes are listed in Table 4. The degree of virilization is generally greatest with adrenal and ovarian tumors and less with adrenal hyperplasia. The mildest forms of adrenal hyperplasia may present as premature adrenarche, being diagnosed only after adrenocorticotropic hormone (ACTH) stimulation testing or DNA analysis. Assessment is indicated with significantly advanced skeletal age, growth rate, or degree of virilization. The virilizing adrenal hyperplasias include 21-hydroxylase deficiency, 11 β -hydroxylase deficiency, and 3 β -hydroxysteroid dehydrogenase deficiency. These usually present with virilization before puberty; mild forms may present at puberty.

Table 4 Causes of Contrasexual Pubertal Development, Prepubertal or Pubertal Onset

Virilization in girls
Adrenal sources of androgen excess: adenoma, carcinoma, virilizing adrenal hyperplasia
Exogenous androgen
Idiopathic hirsutism
Ovarian sources of androgen excess: arrhenoblastoma, teratoma, polycystic ovarian syndrome
Feminization in boys
Adolescent, pubertal, or idiopathic gynecomastia
Drugs (amphetamines, antineoplastics, gonadotropin, isoniazid, ketoconazole, marijuana, sex steroids, tricyclic antidepressants, others)
Neoplasms (adrenal or testicular steroid-producing tumors, teratomas)
Primary hypogonadal conditions
Congenital (anorchia, dysgenetic testes, enzyme biosynthetic defects, Klinefelter syndrome, partial androgen insensitivity syndrome)
Acquired (cryptorchidism, infection, radiation, torsion, trauma)
Systematic illness: hepatic, renal, recovery from malnutrition

Most verified mild forms of adrenal hyperplasia are 21-hydroxylase deficiency. Basal 17-hydroxyprogesterone levels may be elevated with 21-hydroxylase deficiency adrenal hyperplasia, while corticotropin (ACTH) stimulated values may be needed to ascertain the mildest cases. Such testing with measurement of adrenal steroid intermediate metabolites may be useful in identifying mild forms of adrenal hyperplasia (71). Adrenal suppression may be necessary to differentiate adrenal hyperplasia from adrenal tumors or ovarian sources. The polycystic ovarian syndrome is a heterogeneous disorder presenting with hyperandrogenism, hirsutism, and amenorrhea or oligomenorrhea.

B. Boys

Gynecomastia, either unilateral or bilateral, in a pubertal boy is usually a variation of normal puberty. The most common pathological cause of gynecomastia is hypogonadism, particularly Klinefelter syndrome. Gynecomastia caused by abnormal estrogen production because of increased steroid aromatization (72) (Table 4) is rare, but it should be ruled out in a prepubertal boy, or at any age, when the degree or progression is troublesome. Plasma estrogen levels or total urinary estrogen levels are elevated if there is a persistent source of abnormal endogenous estrogen. Appropriate plasma and urinary levels, an otherwise normal history and physical examination, and a negative history of contact with estrogen-containing medicine or cosmetics is sufficient to delay further work-up

with follow-up to watch for progression of gynecomastia. It may be difficult to ascertain gynecomastia from pseudogynecomastia in an overweight boy. The presence of a discernible mass of firmer tissue centered beneath the areolae suggest breast tissue rather than simply adipose tissue.

There are pathological conditions that may be associated with gynecomastia during the pubertal years. Testicular tumors, including Leydig-cell tumors, Sertoli-cell tumors, and germ cell tumors all may rarely secrete estrogen and present with gynecomastia. Gynecomastia may occur in association with gonadal disorders, including primary and secondary hypogonadism, true hermaphroditism, and enzyme defects of testosterone production. Feminizing adrenal cortical tumors are very rare. A patient with an essentially male phenotype and mild partial androgen insensitivity could present with gynecomastia. Ingestion of drugs may be a cause, including androgens, ketoconazole, and illicit drugs including marijuana.

VI. DELAYED PUBERTY AND HYPOGONADISM PRESENTING DURING ADOLESCENCE

A. Definition and General Approach

If the initial physical changes of puberty are not present by age 13 years in girls or age 14 in boys, evaluation should be considered for possible causes of lack of pubertal development. Abnormality may also be present if pubertal development has begun but does not progress appropriately. Therefore evaluation may also be indicated if more than 5 years have elapsed between the first signs of puberty and menarche in girls or completion of genital growth in boys. The aim of the assessment is to determine whether the delay or lack of development is a result of a lag in normal pubertal maturation of the hypothalamic–pituitary–gonadal axis or if it represents an underlying abnormality (Table 5).

If patients have no pertinent findings on medical history and examination, a delay in the onset of puberty is most likely to be so-called constitutional delay of puberty. Such patients are healthy, but generally have a history of delayed growth and development throughout childhood, including short stature but a relatively normal growth rate.

The initial approach to patients of both sexes with delayed or lack of progression of puberty is to determine gonadotropin status (Table 5) and skeletal age. Elevation of gonadotropin levels indicates gonadal failure and redirects further assessment, while low levels of gonadotropins do not differentiate physiological delay from gonadotropin deficiency. Skeletal age, determined by radiographic analysis of the ossification centers of the hands and wrists, compares patterns of growth and ossification with the average for age and sex. When bone age indicates a biological age less than that of the onset of

puberty (10–11 years for girls and 12–13 for boys), it is impossible to determine if gonadotropin secretion is delayed and immature or defective. In either situation gonadotropin levels, both before and after GnRH or gonadotropin-releasing hormone analog (GnRHa) stimulation, are within the prepubertal range, although as patients grow older greater responsiveness is expected. Persistence of low levels or an inadequate response over time suggests a hypothalamic or pituitary deficiency; a progressive rise is consistent with normal, but delayed, puberty.

When bone age, an index of biological age, is at or beyond the age of puberty, gonadotropin (LH and FSH) levels are elevated if gonadal failure is present because of maturation of the hypothalamus–pituitary–gonadotropin (HPG) axis and the absence of negative feedback by sex steroids. GnRH stimulation is unnecessary. If gonadotropin levels are mildly elevated, GnRH stimulation may be used to document partial primary gonadal failure.

Hypogonadism may not become manifest until during or after adolescence. Physical pubertal development may begin with expected physical changes but not progress normally. Among girls, the presentation may be because of primary or secondary amenorrhea. Among boys, growth and development may not be completed, testes may be abnormal, or no abnormalities may be noted unless fertility becomes a problem.

B. Boys

1. Assessment

Most boys who present with the complaint of delayed puberty who have short stature and normal prepubertal genitalia with prepubertal testes of normal size and consistency likely have constitutional delay. A plot of previous heights-for-age on a growth curve show low–normal growth rates. Skeletal maturation documents delay. Body proportions are immature (a greater upper/lower ratio than usual for age; relatively short legs for height). Primary hypogonadism (testicular failure), usually presenting with normal or tall stature, is very unlikely in such a patient.

Except in cases of testicular failure, gonadotropin levels are low for age in delayed puberty, whether due to constitutional delay or gonadotropin deficiency. At presentation, temporary delay or permanent deficiency cannot be absolutely differentiated; there is an overlap of responses to GnRH stimulation, with the rare exception of no response among those with an absent or destroyed pituitary.

The initial work-up should involve an evaluation aimed at the differential diagnosis listed in Table 5. The history should include a review of rates of weight and height gain, testicular descent, any other evidence suggestive of gonadal pathology, including endocrinopathies. Growth rates should be assessed with the knowledge that growth rates are slowest just before the onset of puberty in normal boys and may continue to decelerate until pubertal growth commences. Current or prior illnesses and

Table 5 Causes of Delay or Lack of Pubertal Development

Hypergonadotropic states (primary gonadal failure)
Chromosomal, genetic disorders, and syndromes: androgen enzymatic synthesis defects, complete and partial androgen insensitivity syndrome, 46, XX males, 47, XYY syndromes, galactosemia, Klinefelter syndrome (47, XXY), mixed 45, X/46, XY gonadol dysgenesis, multiple X-Y syndromes, multiple Y syndromes, myotonic dystrophy, Noonan syndrome, pure 46, XY gonadol dysgenesis, 5 α -reductase deficiency, resistant ovary syndrome, Turner syndrome, vanishing testes syndrome
Acquired: autoimmune, chemotherapy, infectious (coxsackie, mumps), irradiation, surgical, torsion, traumatic
Hypogonadotropic states (hypothalamic-pituitary defect or lag)
Hypothalamic-pituitary deficiencies
Gonadotropin deficiency
LH only (fertile eunuch syndrome)
LH and FSH
Acquired [autoimmune, cranial irradiation, granulomatous disease, hemosiderosis (thalassemia), sickle cell disease]
Congenital, genetic, syndromes [Alstrom syndrome, Borjenson-Forsman-Lehmann syndrome, CHARGE syndrome, Kallmann syndrome, Laurence-Moon-Bardet-Biedl syndrome, multiple lentiginos syndrome, Prader-Willi syndrome, prosencephalon defects (associated with central incisor syndrome, cleft-lip palate, midfacial cleft), septooptic dysplasia]
Endocrinopathies (may include gonadotropin deficiency): hypopituitarism [idiopathic or secondary to empty sella syndrome, inflammation, pituitary dysgenesis, radiation, Rathke pouch cysts, surgery, trauma, tumors (craniopharyngioma, pituitary adenomas, prolactinomas)]
Delayed or deferred function
Constitutional delay of growth and/or puberty
Chronic illness [cardiac, gastrointestinal (regional enteritis), hematologic (sickle cell disease), malignancy, pulmonary (cystic fibrosis), renal]
Drug abuse
Excessive energy expenditure, exercise
Exogenous obesity
Endocrinopathies: diabetes mellitus, growth hormone deficiency, glucocorticoid excess, hyperprolactinemia, hypothyroidism
Malnutrition
Psychiatric illness (anorexia nervosa, psychosocial dwarfism)

their treatment, including irradiation, surgery, chemotherapy or glucocorticoid therapy, should be considered. A family history of pubertal delay, hypogonadism, or infertility should be sought. Evidence of craniofacial-CNS midline defects, including anosmia or hyposmia, are important and suggestive of Kallmann syndrome, a unique hypogonadotropic syndrome with concomitant defects in the sense of smell (73, 74).

Physical examination must include careful documentation of height, weight, pubertal stage (Table 1), and upper/lower (U/L) segment ratios. This ratio is determined by subtracting, from standing height (U), the vertical distance from the pubic symphysis to the floor (L), or by subtracting the sitting height (U) from standing height (L). A ratio higher than normal suggests immaturity and delay, whereas a ratio lower than normal is suggestive of a defect or prolonged delay. In general, a ratio of less than unity (0.88 in black subjects) results from excessive leg (long-bone) growth characteristic of hypogonadism. Such eunuchoid ratios may be pronounced in patients with primary hypogonadism, such as Klinefelter syndrome. Testicular location (scrotal, inguinal, or nonpalpable), size,

and consistency (firm, soft, nodular) are important. A testis less than 2.0 cm along the longitudinal axis is prepubertal in size; length longer than 2.5 cm suggests pubertal growth. A testis in a pubertal-aged boy of 1.0 cm or less, particularly if unusually firm or soft, is suggestive of a hypogonadal state. A careful neurological examination should be done including assessment of fundi, visual fields, and sense of smell.

Laboratory evaluation should include serum LH and FSH levels, and a hand and wrist x-ray to determine bone age. If growth rate is subnormal, assessment of growth hormone secretion and thyroid function may be indicated. If IGF₁ levels are used as a screen for growth hormone, levels should be compared with normal ranges for stage of development and skeletal age, rather than chronological age. Various studies may be indicated to rule out CNS, renal, or gastrointestinal disease, and may include blood and urinary pH, urinary specific gravity, sedimentation rate, blood urea nitrogen, creatinine, and MRI of the head. If testes are small and firm or if there is other evidence suggestive of Klinefelter syndrome or other forms of primary hypogonadism, determination of karyotype is in-

licated. Human chorionic gonadotropin (HCG) stimulation testing is indicated if testes are nonpalpable or a testicular defect is suspected; only if gonadotropin levels are not elevated. A rise in circulating testosterone levels to higher than 300 ng/dl after 2–5 days of stimulation demonstrates adequate Leydig cell function. Many hCG regimens are used, ranging from 2 to 5 days. To stimulate maximum testosterone response, 5 days of treatment are sufficient. A dosage of 3000 units/m² per injection stimulates maximum response. Total dosage should be limited to 3000 units per injection or 15,000 units for the treatment period. To ensure maximum response, a minimum of 5000 units should be given during the treatment period. The drug may be administered two or three times a week. A blood sample for the testosterone should be obtained within 24 h from the last injection.

2. Elevated Gonadotropins: Primary Hypogonadism, Testicular Failure

Initial testing will identify patients with elevated gonadotropin levels if bone age is over 12.5 years, indicating inadequate testicular androgen production to suppress the maturing hypothalamic–pituitary axis. Conditions of primary testicular failure listed in Table 5 should be a guide to further evaluation. A karyotype is indicated unless there is a documented history of destruction of normal testes (e.g., torsion or radiation).

a. Klinefelter and Multiple Syndromes. Klinefelter syndrome (47XXY), the most common cause of hypergonadotropic hypogonadism, does not present with delay in the onset of puberty, but puberty may not be completed or progression may be slow. The most persistent physical finding is small, usually firm, testes. Tall stature, disproportionately long limbs, poor muscular development and gynecomastia are characteristic. Hypergonadotropism also occurs with other multiple X and Y syndromes, generally with more severe genital and mental impairment.

Elevation of FSH levels precedes pubertal age followed by LH. Testosterone levels begin to rise at normal ages, may attain adult male levels, but gradually diminish with concomitantly increasing estrogen–testosterone ratios.

b. Other Forms. Other forms of primary hypogonadism in boys include the vanishing testis syndrome (anorchia) and acquired testicular failure secondary to bilateral torsion, trauma, infection, and radiation. Patients with primary hypogonadism and their parents should be informed about therapeutic possibilities. Boys should be counseled appropriately for their level of concern and understanding. The counseling should be based on an understanding of the two basic functions of the testes: male hormone and sperm production.

Patients can be assured that the hormone can be replaced and that they will develop normal physically and function normally sexually. They also need to understand

that their children may be created by fertility-assisted methods available to couples, including sperm donation, or by adoption. They should be given the choice to have saline-filled prosthetic testes placed in the scrotum. If the condition is discovered before pubertal hormonal stimulation is appropriate, the implant should be delayed until the scrotum has matured to accommodate adult-sized prostheses. Having an empty scrotum appears to have minimal psychological effects during boyhood; most adolescent boys choose to have prostheses placed.

Hormonal replacement should begin at the usual age of the onset of puberty (12.5–13 years) or as soon thereafter as the need is recognized. Occasionally, there are reasons to delay treatment, including general growth failure, short stature, emotional or psychological immaturity. The initial dosage may vary depending on whether there has been any pubertal development, and the rapidity of pubertal development desired based on the age, social and intellectual maturation, and psychological needs of the patients (see section on therapy). Although early treatment with androgens accelerates bone age and may ultimately decrease adult height, if replacement therapy is given at the age of usual pubertal development, it does not have a detrimental effect on adult height (75). An initial low dosage is appropriate to avoid excessive genital stimulation, including dramatic reddening and sensitivity in the genital area and frequent, prolonged erections (76). The dosage can then be titrated upward over the ensuing months or years.

3. Low Gonadotropin

If gonadotropin levels are low (Table 5), if there are no organic or associated conditions of pituitary malfunction, and if there is no other cause to account for delayed maturation, it usually is not possible to determine whether gonadotropin deficiency or simply delayed maturation exists. Gonadotropin, particularly LH, responds to GnRH stimulation may be helpful if a clear pubertal response is present. A rise consistent with a pubertal response may be discernible before clinical evidence of the onset of puberty, suggesting constitutional delay.

a. Constitutional Delay of Growth and Development. Physiological delay of maturation, including puberty, is characterized by a history of height and growth rate since early childhood along or slightly below 2 standard deviations (SD) for age, normal health, and nutrition. Biological age is usually delayed by about 2 years and development milestones, including pubertal events, are likewise delayed. Skeletal age is useful in estimating the amount of delay, spontaneous puberty being expected when skeletal age reaches 12–13 years in a boy. Such delay occurs more frequently among boys than girls.

Growth rate is characteristically markedly decelerated as the age of usual pubertal development is approached. The lack of sex steroid stimulation of growth hormone secretion results in a relative growth hormone deficiency,

contributing to the diminished growth rate (77). Since adult height is foreshortened among those with the greatest delay and shortest stature, timely intervention with temporary treatment using appropriate dosages of testosterone must be considered to stimulate pubertal development and increase growth hormone production.

b. *Permanent Gonadotropin Deficiency*

Isolated gonadotropin deficiency. This occurs more frequently among boys than girls. Genetic causes include genetic mutations involving the GnRH-receptor, the CNS adhesion protein (KAL, anosmin), and the β -subunits of LH and FSH (73, 74). Isolated gonadotropin deficiency is characterized by normal stature, with the consequence of lack of sex steroid stimulation of skeletal maturity including disproportionately long limbs and delayed skeletal age. CNS and facial developmental abnormalities (midline facial defects), neurosensory hearing loss and synkinesia (mirror movements), anosmia, or hyposmia may be present. The most common form of isolated gonadotropin deficiency is Kallmann syndrome. Defects of Kallmann syndrome involve the association of hypogonadotropism and anosmia, olfactory bulb hypoplasia, and failure of development and migration of GnRH-secreting neurons to the hypothalamus. Not all patients with idiopathic hypogonadotropism (IHH) have Kallmann syndrome, although the latter is usually associated with more profound hypogonadotropism. IHH may present with no pubertal development, or with early but arrested changes. Most cases of Kallmann syndrome are sporadic, although autosomal recessive, autosomal dominant, including (father-to-son transmission), and X-linked modes of inheritance have been described (78). Normal GnRH structure is present in most patients with IHH, although deletion of the KAL1 gene has been described (79, 80), involving an extracellular adhesion molecule involved in the migration of GnRH neurons from the olfactory placode to the hypothalamus. Familial forms appear to be due to mutation at one of several different loci rather than a single gene.

Anatomical abnormalities in the hypothalamic–pituitary region. Intracranial neoplasms, including craniopharyngiomas, germinomas, gliomas, and prolactinomas, may result in GnRH or gonadotropin deficiency.

Syndromes with hypogonadotropism. Laurence-Moon-Biedl syndrome (also with retinitis pigmentosa, polydactyly, obesity, and mental retardation) and its Bardet-Biedl subgroup with dystrophic extremities (polydactyly, syndactyly, brachydactyly), obesity, and retinal disease with several genetic loci identified is associated with hypogonadism, more commonly among boys than girls. Hypogonadotropism may also occur in association with Prader-Willi, Alstrom, Rud, Bloom syndrome and other syndromes listed in Table 5.

c. Pathological Delay of Pubertal Gonadotropin Secretion. Gonadotropin hyposecretion among those with potential for normal secretion may delay the onset of puberty among boys, or occur during or after puberty sec-

ondary to severe physical or mental stressful conditions. Delay occurs with chronic disease associated with malnutrition such as Crohn's disease, other chronic inflammatory disease, cystic fibrosis, hypothyroidism, and poorly controlled diabetes mellitus.

When pubertal delay occurs with low gonadotropin levels, hormonal treatment can be begun, even if delay cannot yet be differentiated from deficiency. Short-term treatment with testosterone (Fig. 9) is appropriate if age and psychosocial development indicate a need for physical pubertal maturation. Such exposure to androgens at a biological age (bone age) of 12–13 years or older has no apparent detrimental effects upon either those with constitutional delay or hypogonadotropic hypogonadism (75). Subsequent development, in the former, is normal, and spermatogenesis in response to exogenous gonadotropin stimulation, in the latter, is not different among those who have received previous testosterone treatment (81).

Androgen treatment administered as an intramuscular (IM) injection, transdermal patch, or gel can be given for an initial course of no longer than 4–6 months. The IM dosage can range from 50 to 100 mg IM every 4 weeks; the lowest available dosages of the dermal patches or gel can be used. The patches can also be used only overnight, rather than for 24 h initially. This avoids the embarrassment that may result from others seeing the patch if worn during other activities. After the initial months of stimulation, no treatment should be given for at least 2 months so that endogenous testosterone levels can be measured. If testosterone levels have risen to the pubertal range (>100 ng/dl), this suggests a diagnosis of delay. Treatment may be continued, if height and development are markedly delayed until endogenous levels are greater than 275 ng/dl. Patients should be evaluated at intervals of 6 months or longer to assess progression of puberty and testosterone levels. Values >300 ng/dl verify normal hypothalamic–pituitary–testicular function. Such a level provides a basis to assume that pubertal growth will proceed without further exogenous therapy.

If testosterone levels are still low, more time, during which a second course of testosterone treatment may be given, may be required to determine if gonadotropin deficiency exists. If this diagnosis is made, based on persistently low LH, FSH, and testosterone levels, androgen replacement therapy should be continued to ensure full physical pubertal development and maintained. Males with hypogonadotropism should be informed that spermatogenesis and fertility is potentially possible among some after exogenous biosynthetic gonadotropin therapy. However, only a portion of patients so treated respond with adequate spermatogenesis; there a correlation between initial testicular volume and response (9). Because of its expense and injection schedules, such treatment is not indicated until fertility is desired. Testosterone replacement is the treatment of choice until that time.

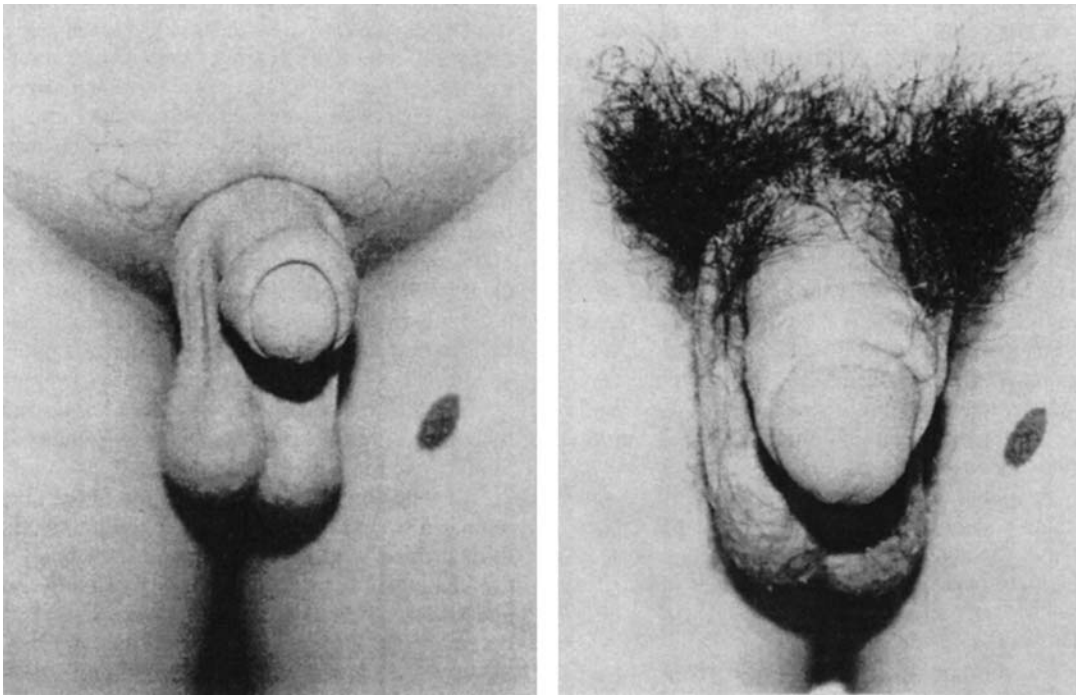

Figure 9 Genitalia of a boy with delayed puberty before (left) and after (right) five monthly injections of 200 mg testosterone enanthate IM. Pubertal development was Tanner 2 before the injections and skeletal age was 12-1/2 years at 14-8/12 years of age. After the injections at 15-2/12 years pubertal development progressed to Tanner 4. A subsequent endogenous testosterone level of 192 ng/dl verified a diagnosis of constitutional delay of puberty.

4. Therapy

Full replacement of androgen is required to attain and maintain an adult male state physically and sexually. This may be given as an injection or transdermally. Adult replacement of the depot injection of testosterone is a dosage up to 100 mg/week, given at intervals of 2 weeks (200 mg) or 3 weeks (300 mg). Injections every 4 weeks of 400 mg are not recommended because they result in supraphysiological levels for 7–10 days and, then, during the fourth week the levels are subnormal. The transdermal patches or gel can be used. The initial dosage depends upon the age and maturity of the patient and the rapidity of pubertal development desired. Optimal dosing may not be available because of packaging limitations. Dosages can be gradually titrated upward to full replacement dosages after 3–4 years. Patients can be reassured that others cannot tell that exogenous therapy is stimulating or maintaining their physical development. Pubertal maturity, except testicular growth, and sexual function can be expected to be normal. If accessory sexual glands are appropriately formed, ejaculation, semen volume and appearance are normal.

Other forms of androgen therapy, including oxandrolone, fluoxymesterone, and methyltestosterone buccal or oral tablets do not provide full replacement and have limited usefulness. Oral replacement of methyltestosterone is

associated with hepatocellular malignant changes. Replacement therapy with aqueous testosterone injections requires at least daily administration.

Some hypogonadotropic hypogonadal boys have the potential for spermatogenesis and testosterone production if appropriately stimulated with gonadotropin. Such therapy is limited to adult men at the time they desire paternity.

Because height may be foreshortened among males with marked delay of puberty, and since estrogen stimulates skeletal maturity, aromatase inhibitors are being used to attempt to increase adult height (82).

5. Outcome

While it is assumed that boys with constitutional delay of puberty acquire normal sexual and reproductive function, this has not been carefully studied. With appropriate use of sex steroids, growth is completed without loss of adult height (83, 84). Evaluation has indicated that those who have considerable delay may not reach their genetically expected height, and have a persistence of segmental disproportion of relatively long leg length (85,86). Furthermore, bone mineral density may be diminished, even after full pubertal virilization is complete (87). These data provide evidence for early intervention, with androgen therapy precluding the prolonged period of growth deceleration.

tion, increased long bone growth effects upon body proportions, and diminished bone mineral density accrual.

C. Girls

1. Assessment

Delay of onset of pubertal development is a less common complaint among girls than among boys and is more likely to have an underlying pathological cause. Delay should be assessed if breast and pubic hair development has not begun by age 13 years or menarche by 15.5–16 years. Also, lack of completion of pubertal development to Tanner stage 5 within 4 years is considered delay. Categorization of patients as having elevated or low gonadotropin levels (Table 5) should be done initially together with documentation of skeletal age (bone age x-ray). Initial assessment should include a careful history looking for evidence of chronic illness (e.g., occult Crohn's disease), endocrinopathy, prior illnesses and therapy, sense of smell, and a family history of lack of puberty or infertility (Kallmann syndrome). Growth patterns should help differentiate those with short stature who are more likely to have constitutional pubertal delay or chronic illness from those with permanent gonadotropin deficiency and rare forms of primary hypogonadism who are normal or tall. The physical examination should concentrate on body proportions, breast and genital development, neurological examination, and stigmata suggestive of Turner syndrome. Laboratory evaluation should generally be similar to that for boys, although hCG testing is not indicated since hCG alone does not stimulate precocious puberty in girls. Karyotype should be included if the patient has unexplained short stature. Among patients with normal physical pubertal development presenting with amenorrhea, pregnancy must be ruled out.

In an attempt to differentiate patients with a permanent defect from those with delayed or temporary hypogonadotropism, GnRH-stimulated gonadotropin testing may be helpful in the older adolescent. Persistence of low basal or GnRH-stimulated LH and FSH levels in a patient in the late teenage years with a bone age over 11–12 years is indicative of a defect of gonadotropin secretion.

Delayed menarche or secondary amenorrhea may result from lack of gonadotropin or ovarian failure, or may be the consequence of hyperandrogenism, anatomical obstruction (including imperforate hymen) precluding menstrual outflow, or vaginal and uterine agenesis (Mayer-Rokitansky-Kuster-Hauser syndrome).

2. Elevated Gonadotropins

Hypergonadotropism occurs with primary gonadal failure. If elevated gonadotropin levels are found and there is not ample evidence to explain the hypergonadotropic state, such as surgery, radiation, and chemotherapy, a karyotype evaluation should be done.

a. Turner Syndrome. The most common cause of primary amenorrhea associated with primary gonadal failure is Turner syndrome. Ovarian pathology involves early loss of oocytes and accelerated stromal fibrosis. The classic findings of Turner syndrome are short stature, primary hypogonadism, a diversity of congenital anomalies associated with the loss of absence of all or part of an X chromosome (45X- [about 50%-] or 45X/mosaic karyotype). Among the majority, the maternal X is retained. The missing sex chromosome may have been either a paternal X or Y. Sensitive molecular techniques have revealed that some girls with Turner syndrome carry Y chromosomal material (88). The consequences of this are unknown unless Y material associated with malignant degeneration is present. Mosaic karyotypes and structural abnormalities of the X chromosome account for some of the variation of clinical features. Haplo insufficiency of the short stature homeobox (SHOX) gene found on the short end of both sex chromosomes is associated with skeletal anomalies and short stature (89, 90). These involve facial, palatal, and middle ear development. Other stigmata, including low hairline, webbed neck, hand, feet, chest, and nipple configuration, appear to be a consequence of fetal edema. Cardiovascular, renal, and potentially associated autoimmune diseases may require specific therapy. Some aspects of mental and social functioning may be impaired. Rarely, ovarian function persists enough so that spontaneous breast development may occur (91), although endogenous estrogen secretion is usually inadequate for full puberty. Normal ovarian function, with menstruation, ovulation, and successful pregnancy occurs very rarely.

b. 46,XY Gonadal Dysgenesis. Delayed puberty in a phenotypic female is a typical presentation for 46,XY complete gonadal dysgenesis, female genital differentiation being the constitutive result of the complete lack of testicular function. Rarely, mutations of the SRY gene may be present (92, 93). Familial gonadal dysgenesis has been described in which the phenotype and gender of rearing differed between family members despite a common mutation in the SRY gene in all affected family members (94). Duplication of the portions of the short arm of the X chromosome that includes the DAX1 gene is another identified genetic cause of 46,XY sex reversal (95). Ambiguous internal and external genitalia or some pubertal changes may be noted in patients with incomplete or partial forms of 46,XY gonadal dysgenesis. Gonadectomy is generally recommended since dysgenetic gonads have increased risk of developing dysgerminomas or gonadoblastomas.

c. 46,XX Gonadal Dysgenesis. In rare cases, pure ovarian agenesis with a 46,XX karyotype also occurs, being characterized by normal or tall height, no dysmorphic features, normal female external genitalia, and hypoplastic or no ovarian development. Presentation may be with some breast development but amenorrhea. A report of

46,XX and 46,XY sisters with gonadal agenesis provides evidence for an autosomal locus involved in gonadal differentiation (96). Perrault syndrome is XX gonadal dysgenesis and sensorineural deafness (97).

d. Mixed Gonadal Dysgenesis. Individuals with mixed gonadal dysgenesis (98), commonly having a karyotype of 45,X/46,XY, may have somatic features typical of Turner syndrome, including short stature, although genitalia may be masculinized. Genital development reflects in utero testosterone exposure and range from female to ambiguous, to male. The gonads are often asymmetrical, with streak ovaries or dysgenetic testes. External genital development may likewise be asymmetrical. Dysgenetic testes and the Y chromosome increase the risk of gonadoblastoma and virilization at puberty. Based upon physical findings, sex of rearing may have been assigned as male or female. Among females, estrogen replacement is generally required to induce puberty. Spontaneous breast development may occur; however, this may be a consequence of an estrogen-secreting gonadoblastoma.

e. Congenital Adrenal Hyperplasia. Although most enzyme deficiencies present with other complaints at younger ages, 17-hydroxylase-17,20-lyase deficiency (99), characterized by elevated progesterone, pregnenolone 17-hydroxyprogesterone, and 17-hydroxypregnenolone levels, is associated with deficient estrogen synthesis. Female patients are phenotypically normal and present with pubertal delay. Hypergonadotropic hypogonadism becomes evident during adolescence with congenital lipoid adrenal hyperplasia.

f. Acquired, Including Autoimmune, Gonadal Failure. Prepubertal or pubertal gonadal injury may result in hypergonadotropic hypogonadism. The ovary is less vulnerable than seminiferous tubules to injury. Chemotherapy, particularly nitrogen mustard compounds, for malignancies or immunological disorders may damage the gonads. The degree of injury is greater when chemotherapy occurs during rather than before puberty (100). Pelvic irradiation may damage reproductive function, although many girls treated for acute lymphocytic leukemia appear to retain ovarian function (101). Autoimmune oophoritis usually presents after puberty, only rarely during pubertal years (102). It may be associated with type I autoimmune polyglandular syndrome, characterized by hypoparathyroidism, Addison's disease, vitiligo, hypothyroidism, and pernicious anemia. Galactosemia may be associated with ovarian failure (103).

g. Gonadotropin Receptor Mutations. Hypergonadotropic hypogonadism may also be associated with luteinizing hormone receptor mutations. In XX females, the presentation is primary amenorrhea, elevated serum LH and low estradiol levels, rather than delayed puberty (104, 105). XY males with LH receptor mutations have presented with female external genitalia, absence of muller-

ian structures, and lack of breast development. Biopsy of the inguinal gonads shows absence of Leydig cells, but Sertoli cells, spermatogonia and primary spermatocytes. Limited response to hCG administration has been demonstrated. Mutations in the FSH receptor gene have been identified in women presenting with primary amenorrhea, normal breast development, and elevated FSH. Numerous small follicles up to the antral stage are present in the ovaries, but there is disruption of later stages (106, 107).

h. Complete Androgen Insensitivity Syndrome. Patients with androgen insensitivity may present with inadequate progression of female puberty (108, 109). Breast onset typically occurs at an appropriate age; complaints may include amenorrhea or lack of sexual hair.

3. Low Gonadotropin Levels

If gonadotropin levels are low, the search for the cause is also an attempt to determine if the hypogonadotropism represents a delay in maturity or a permanent hypothalamic-pituitary defect.

If there is an underlying chronic illness, prolonged pharmacological glucocorticoid therapy, excessive emotional stress, unusual physical activity, or an inadequate nutritional state, the hypogonadotropism is likely a secondary and potentially reversible condition (110). Chronic conditions related to pubertal delay may include anorexia, inflammatory bowel disease, cystic fibrosis (111), and chronic renal failure. If the underlying problem can be adequately treated, normal gonadotropin secretion should follow. Conversely, while the underlying problem persists, estrogen therapy is relatively ineffective. Noonan's syndrome may be associated with delayed pubertal development; most patients attain normal ovarian function.

a. Permanent Deficiency

Idiopathic hypogonadotropism. Idiopathic hypogonadotropism (IHH) is less common in females than in males. Kallmann syndrome is associated with anosmia. DAX1 mutations result in IHH in association with congenital adrenal hyperplasia (112). Multiple pituitary hormonal deficiencies, including gonadotropism may be congenital or acquired. Congenital defects may be associated with septo-optic dysplasia or midline facial defects. Acquired defects may occur with histiocytosis X, sarcoidosis, radiation therapy, and hemochromatosis (113).

FSH gene mutations. Primary amenorrhea in otherwise normal XX females occurs with FSH β gene mutations. LH levels are elevated and FSH low or undetectable (114). A normal response to exogenous FSH can be elicited in affected patients.

Multiple congenital or acquired pituitary deficiencies. Hypogonadotropic hypogonadism may also occur in association with other anterior pituitary hormone deficiencies. Both congenital and acquired disorders may involve the hypothalamus and/or the pituitary. Midline facial defects, septo-optic dysplasia, or ectopic location of the posterior pituitary at the base of the hypothalamus

may coexist with congenital hypopituitarism. Structural abnormalities may result from craniopharyngiomas, hamartomas, gliomas, and hypothalamic cysts. Histiocytosis X, sarcoidosis, infiltration (Wilson's disease and hemochromatosis) and radiation therapy may cause acquired hypopituitarism. Granulomatous infiltrates may interfere with GnRH, LH, and FSH release. Deficiency of more than one pituitary hormone, except in idiopathic hypopituitarism diagnosed in early childhood, strongly suggests an anatomical lesion, particularly if diabetes insipidus or hyperprolactinemia is present.

b. Temporary Hypogonadotropism with Potential of Normal Function. Constitutional delay of puberty is relatively rarer among girls than boys and should be a diagnosis of exclusion. Such children are healthy and have short stature and delayed bone age. Bone age progresses in this condition, in contrast to cases with a persistent chronic disease.

Several conditions associated with functional hypogonadotropic hypogonadism may have similar neuroendocrine dynamics (115). Increases in physical activity, deficiency of calories, and mental disturbances appear to impair hypothalamic-pituitary-ovarian function progressively while correction of energy imbalance is followed by correction

c. Prolactinomas. Prolactinomas may present with delayed puberty or arrested pubertal development, primary or secondary amenorrhea, and low gonadotropins. Galactorrhea may not be present. Treatment includes bromocriptine, transsphenoidal surgery, or pituitary irradiation (116, 117).

Hemochromatosis. Hemochromatosis leading to pituitary infiltration, whether idiopathic or secondary (sickle cell disease or thalassemia), may also result in gonadotropin deficiency because of deposits in the gonadotropin-producing cells and present with delayed puberty (113). Reversal of the pituitary gonadotropin deficiency and recovery of reproductive function may follow aggressive phlebotomy and chelation therapy in patients with the idiopathic and familial forms of the disease (118).

Physical and psychological deprivation. Delayed or arrested puberty may occur in athletes and with chronic illnesses, particularly anorexia nervosa (110). The latter is often associated with delayed puberty, slowing of normal pubertal progression, primary or secondary amenorrhea, and osteopenia (119). Inadequate caloric intake (120) or excessive physical exertion contributes to the temporary physiological delay. Pubertal delay is a consequence of hypothalamic hypofunction resulting from strenuous exercise, stress-related and intentional caloric restriction, especially in activities such as ballet, gymnastics, or track. The GnRH pulsatile pattern is altered, resulting in low gonadotropin levels (121).

Chronic illness. The chronic illnesses frequently associated with delayed puberty (e.g., inflammatory bowel disease, cystic fibrosis, chronic renal disease, and poorly

controlled diabetes mellitus) are characterized by undernutrition. Mechanisms resulting in failure of gonadotropin secretion are likely similar to those in the deprivational conditions discussed above.

Hypothyroidism. Untreated primary hypothyroidism during childhood delays maturation, as indicated by delayed skeletal age, most commonly resulting in pubertal delay. Onset during or after pubertal development is associated with menstrual disorders, primary or secondary amenorrhea, and menometrorrhagia.

Cushing Syndrome. Glucocorticoid excess, either endogenous or exogenous, among children or adolescents, may result in pubertal delay, amenorrhea, and low gonadotropin levels.

Syndromes associated with gonadotropin deficiency. Syndromes with hypogonadotropic hypogonadism include the Laurence-Moon-Biedl syndrome. Hypogonadism is less common among females; hirsutism and elevated LH levels appear to be more common (122). Other syndromes are listed under the section on boys.

4. Treatment

Replacement therapy for girls should eventually consist of cyclic estrogen-progesterone therapy. However, initial therapy for young pubertal-aged patients can be daily low-dosage estrogen therapy for 6, to, at most, 12 months. If breakthrough bleeding occurs during this time, cyclic medication should be initiated. The lowest available estrogen dosage preparation (such as Premarin 0.3 mg or ethinyl estradiol 0.02 mg daily), or the transdermal patch (Estraderm 0.025 mg applied once or twice a week) may be used as initial treatment. Cyclic estrogen-progesterone therapy can be given by administering low-estrogen birth control pills. Alternatively, a daily estrogen regimen or the transdermal form can be used for the first 3 weeks (21 days) of the calendar month, regardless of the length of the month, with progesterone added for the last 10 of the 21 days (day 12 to day 21). With this regimen the patient is easily aware, based on the actual date, of what pills she should take. From the 22nd until the end of the month, no matter how many days in the month, she should take no medication. On the first of the month, even if her period has not stopped, she should begin estrogen again. The dosage of estrogen can be varied, based on the rapidity and adequacy of pubertal development. Ethinyl estradiol (0.02–0.10 mg/day), conjugated estrogen (0.3–1.25 mg/day), or transdermal treatment to deliver 0.05 or 0.1 mg daily can be used. Once full pubertal development has been reached, the estrogen dosage should be the minimum that will maintain normal menstrual flow and prevent calcium bone loss, equivalent to 0.625 mg conjugated estrogen. Progesterone in this regimen can be given as medroxyprogesterone (5 or 10 mg/day) or norethindrone (5 mg/day). Various low-dosage oral contraceptives may also be used.

Among girls with a tentative diagnosis of constitutional delay, the therapy should be reassessed at 6 month intervals to determine if pubertal hormonal activity has begun.

It should be recognized that spontaneous pubertal development or menstruation may rarely occur in patients with Turner syndrome; replacement therapy may not be needed in all patients, and fertility may occur (123). Patients with Turner syndrome, and others with ovarian failure but normal mullerian duct differentiation, are candidates for assisted fertility using donated ova (124).

Growth potential and skeletal maturation can be monitored using periodic bone age x-ray films at intervals no more frequently than every 6 months. Growth hormone is an indicated therapy for Turner syndrome. Testing for growth hormone deficiency and possible growth hormone therapy should be considered among those with severe short stature or subnormal growth rates.

Psychosocial aspects of delayed pubertal development may be associated with poor socialization, school performance, and self-esteem. Parents and teachers should be encouraged to relate to the child according to her age rather than appearance and to encourage appropriate responsibilities and independence (125).

I. INTRODUCTION

Humans need an intact X chromosome to survive. When all (or part) of the second sex chromosome (the X or the Y chromosome) is absent, a characteristic prenatal and postnatal phenotype results. Of the small percentage that survive to term, affected individuals are phenotypic females with dysgenetic ovaries, short stature, and other typical but highly variable dysmorphic features (Fig. 1).

Otto Ullrich first described the syndrome in a case report in the German literature in 1930 and later recognized the neonatal presentation with lymphedema. University of Oklahoma Professor Henry Turner, whose name is inextricably linked with the syndrome, described seven patients with "infantilism, congenital webbed neck, and cubitus valgus" in 1938 (2). Turner became the first physician to use medical therapies in patients with Turner syndrome (TS), administering injections of various pituitary extracts and estrogen-containing preparations to several of his patients. Rudimentary ovaries ("streak gonads") were identified as the cause of Turner's sexual infantilism in 1944 by Wilkins and Fleishman (3), and the term 45,X gonadal dysgenesis is often used to identify TS (4). Other manifestations of the syndrome were catalogued during this period and collectively termed Turner stigmata (5).

TS was associated with X chromosome monosomy in 1959 by Ford et al. (6) in a prepubertal 14-year-old with short stature and typical features. The development of routine cytogenetic analysis in the 1960s led to recognition of the diversity of chromosomal complements associated with TS (7, 8). Most patient series have reported that approximately half of TS patients have a 45,X karyotype, while others have a mosaicism of 45,X cells with normal cells or with structural anomalies of the second X, the

most common being isochromosome (duplication) of the long arm (9). Mosaicism is more common, however, when stringent cytogenetic methods are utilized. The relative proportions of karyotypes found in representative patient series are presented in Table 1 (10, 11).

II. FEATURES OF TURNER SYNDROME

A. Ascertainment Patterns

TS may be detected incidentally during prenatal diagnostic procedures for advanced maternal age, and it appears that the majority of these pregnancies are electively terminated. Unlike trisomies or Klinefelter syndrome, the incidence of TS does not increase with maternal age (12), therefore a relatively small proportion of affected fetuses are ascertained. TS is also suspected, like other aneuploidies, by increased nuchal thickness or other ultrasonographic anomaly, such as aortic coarctation, or by elevated maternal α -fetoprotein, estriol, or β -human chorionic gonadotropin (β hCG), leading to confirmation by karyotyping.

Perhaps a third of TS patients are identified at birth by pterygium coli (webbed neck), lymphedema of the hands and feet, or coarctation of the aorta. Most of these infants have 45,X karyotypes (Fig. 2; 13), because these physical findings, in contrast with other stigmata of TS, are more common in patients with complete X monosomy than in patients with mosaicism or structural abnormality of the X.

TS is additionally suspected in many girls in early to midchildhood when growth failure results in a height noticeably below the normal range. Nevertheless, many patients will not be recognized until pubertal failure or short

Figure 1 Schematic drawing of features of Turner syndrome commonly visible on physical examination. (Modified from Rosenfeld RG, Turner syndrome: a guide for physicians. Turner syndrome Society, Wayzata, Minnesota, 1989.)

stature in the teenage years leads to medical evaluation. The diagnosis may even be delayed until referral in adulthood for primary or secondary amenorrhea, infertility, or recurrent miscarriage. Patients also are occasionally detected on the basis of one of the less evident features of TS, such as facial or bony abnormalities, learning problems, strabismus, or otitis or hearing loss. It is likely that some patients with mosaicism have manifestations that are mild enough to escape detection altogether.

B. Fetal Demise

X monosomy is the most commonly occurring sex chromosome anomaly, but 90% or more of Turner conceptions are spontaneously aborted. It is probable that more than 1% of conceptions involve X chromosome loss. As many as 10% of spontaneously aborted fetuses have 45,X karyotypes (14). As a result, TS is common prenatally but occurs with an incidence of only about 1:2000–2500 live

Table 1 Percentages of Karyotypes in Four Series of Patients with Turner Syndrome

Karyotype	Palmer and Reichman (9)	Hall et al. (10)	Park et al. (11)	Held et al. (17)
45,X	58.2	55.0	61.2	20.7
46,XisoXq	7.3	5.5	6.0	5.7
Mosaicism (with 45,X)				
/46,XX	8.2	13.4	11.2	17.2
/46,XisoXq	11.8	4.7	7.8	12.6
/46,XringX	5.5	3.9	1.7	3.5
/46,XY	5.4	3.1	2.6	2.3
/46,XXp-	0.9	0.8	2.6	2.3
/46,XXq-	0	1.6	1.7	3.5
/47,XXX and /46,XX/47,XXX	1.8	0.8	0.9	6.9
/46,X+marker	0	0.8	0	18.4

female births, making the syndrome less common post-natally than either 45,XXY (Klinefelter syndrome) or 45,XXX. Because the peak of fetal deaths occurs at about 12 weeks of gestation, most 45,X fetuses are spontaneously aborted prior to amniocentesis. A smaller proportion of fetuses is aborted in the second trimester, with autopsy findings of massive lymphedema and cystic nuchal hygroma (15).

It has been contended that all fetuses with 45,X karyotypes are spontaneously aborted and that all liveborn individuals with TS, due to early mitotic errors, are X chromosome mosaics, whether cytogenetically detectable or occult (14, 16). Aborted fetuses with X chromosome loss are, indeed, overwhelmingly 45,X, implying a relative fetoprotective effect of mosaicism. By employing techniques such as PCR and FISH, Held et al. (17) were able to document approximately 80% mosaicism in live-

born TS, largely by the detection of small marker chromosomes in some cell populations (Table 1). Mosaicism may be present in multiple tissues without detectability in blood cells, and presence of mosaicism in the trophoblast or in placental tissue might be all that is required to avoid lethality. A recent study uncovered a previously unreported sex chromosome mosaicism in 90% of TS patients, primarily by FISH for X and Y markers (18). It seems clear that mosaicism occurs more commonly than usually reported, but obligate mosaicism in liveborn TS has not been unassailably proven.

C. Cardiac Anomalies

Echocardiography should be performed as soon as the diagnosis of TS is confirmed. Long known to be associated with TS, coarctation of the aorta occurs in 10–15% of TS patients (19–21). Echocardiography has revealed other common left-sided anomalies in TS, including aortic stenosis, aortic insufficiency, and anomalous pulmonary venous return (Table 2). The most frequent anomaly is probably bicuspid aortic valve, either alone or associated with an accompanying lesion such as coarctation (22). Both aortic coarctation and bicuspid aortic valve occur more commonly in association with a 45,X karyotype than with mosaicism or structural abnormality of the X. The spectrum of left-sided cardiac lesions in TS includes the hypoplastic left heart syndrome (23, 24), which, like aortic coarctation, is an indication for chromosomal analysis in a female fetus or infant (25).

In studies of second trimester fetal pathology, a high frequency of these types of heart vessel defects has been noted in association with edema, nuchal cystic hygromas, and lymphatic aberrations at the base of the major vessels, suggesting a causal link between lymphedema and cardiac anomalies (26). However, cardiac anatomy has been normal in many fetuses with severe edema, and the cause of cardiac defects remains conjectural (see discussion of SHOX, below).

Figure 2 Age of diagnosis in 100 patients with TS. Note the greater percentage of patients with 45,X karyotype diagnosed in infancy. (From Ref. 13.)

Table 2 Prevalence of Cardiac Malformations in Turner Syndrome by Echocardiography in Three Large Series

	Göttsche (19)	Sybert (20)	Mazzanti (21)
Total subjects (n)	179	244	594
Subjects with structural abnormalities (%)	46 (26)	96 (40)	136 (23)
Coarctation	18 (10)	34 (14)	41 (7)
Bicuspid valve	25 (14)	28 (11)	74 (13)
Aortic stenosis/insufficiency	5 (3)	11 (5)	19 (3)
Anomalous pulmonary venous drainage	NA	2 (1)	17 (3)
Other (ASD, VSD, hypoplastic left, etc.)	0 (0)	25 (10)	17 (3)

In clinical terms, TS patients are at risk for catastrophic aortic dissection and aneurysmal rupture; more than 50 cases have been reported to date (19, 27, 28). Most aortic ruptures in TS are thoracic. Most of the fatalities have occurred in young women with pre-existing cardiac anomaly or hypertension, but a significant percentage of deaths has occurred in individuals without known risk factors. Cardiac evaluation is mandatory in any TS patient with chest pain or shortness of breath. Mild aortic root dilation (about +1 standard deviation [SD]) by echocardiography or magnetic resonance imaging (MRI) is observed in TS girls matched with controls for body size, but it is not known whether routine follow-up echocardiography is helpful in anticipating aortic dissection. We currently recommend regular cardiologic and echocardiographic follow-up for those with a cardiac lesion or hypertension, and repeat echocardiography in all other TS patients at cessation of growth therapy.

D. Renal Anomalies and Hypertension

Renal ultrasound is recommended for all patients at the time of diagnosis. The cause of renal abnormalities in TS is unknown, and cardiac and renal anomalies usually occur independently. Most renal anomalies are silent and do not become clinically significant. Renal dysmorphism was documented by ultrasound in one-third of 141 patients with various karyotypes in the early series of Lippe et al. (29). The most frequent abnormalities were double collecting systems, horseshoe kidney, and rotational abnormalities, each occurring in 5–10% of patients. Abnormalities requiring urological referral included ureteropelvic and ureterovesicle junction obstruction (6%) and absent kidney (3%). In their study, the incidence of renal dysmorphism in girls with 45,X karyotype was 45%, compared with 18% in other karyotypes combined. The greater prevalence of some renal anomalies in 45,X has been confirmed by at least two more recent patient series. A Turkish study of 82 TS patients found the prevalence of horseshoe kidney to be 11%, with eight of nine associated with a 45,X karyotype, whereas collecting duct abnormalities (overall 21%) were as likely with mosaicism or X structural abnormality (30).

Hypertension is common in adolescents and adults with TS. Although elevated pressures secondary to renal causes can occur, hypertension in TS is usually essential. A recent study documented systolic pressures above the 95th percentile in 21% of adolescents with TS (31, 32).

E. Craniofacial and Skeletal Anomalies

The facial appearance of girls with TS may include epicanthal folds, ptosis, downslanting palpebral fissures, maxillary and mandibular hypoplasia, prominent or malformed ears, neck webbing, low hairline, and short neck. Many of these features may represent consequences of fetal edema. However, patients may have few of these phenotypic characteristics, and the features most classically associated with TS, neck webbing and low hairline, are only present in a minority of girls. Reconstructive surgery of the ears or neck is controversial, due to the reported frequency of keloid formation.

Patients may have a high arched palate, which can contribute to the feeding difficulties commonly encountered in infancy or to speech problems. Anatomical anomalies at the cranial base probably alter the angle of the eustachian tube, leading to the high incidence of otitis media. Sinusitis and mastoiditis are also common. Incidence of hearing loss in TS, which can be either conductive or sensorineural, may be as high as 30% in children and 90% in adults (33, 34). The small jaw and high palate are associated with orthodontic problems, such as crowding and malocclusion (35).

Diverse bone abnormalities are found in TS, but they are usually documented only after the diagnosis has been made (36). The most common anomalies are short fourth metacarpal and cubitus valgus. Infrequent skeletal abnormalities include Madelung's deformity of the wrist, sternal deformities, and genu valgum. The common bone abnormalities appear to be seen equally in patients with 45,X monosomy, structural abnormality, or mosaicism. Cubitus valgus and Madelung's wrist deformity are easily seen on physical examination, and short fourth metacarpal is found on examination or on bone age films. Patients should be routinely evaluated for scoliosis, which may worsen as growth therapies are initiated. Congenital dis-

location of the hip may be seen in infants with TS. Many investigators have documented short-leggedness and abnormal body segment ratios in TS, and patients tend to exhibit a short, "square" body habitus (37). The appearance of widely spaced nipples (shield chest) may be attributable to this phenomenon.

F. Osteopenia

Osteopenia has been widely reported in adults with TS, but the relative contributions of an underlying bone dysplasia or insufficient acquisition and maintenance of bone mass, due to a presumably avoidable hypoestrogenism, are still unclear. Typical modern assessment of bone mineral is by dual X-ray absorptiometry (DXA) determination of bone mineral content (BMC) and density (BMD). Since both are dependent upon body and bone size, DXA underestimates bone density in TS, unless adjusted volumetrically or interpreted using appropriately matched controls.

In a survey of Swedish TS patients, half of those over 45 years old had osteopenia by DXA (38), and even patients receiving long-term estrogen replacement therapy had deficits in spine and radial bone density. In a report by Stepan (39) mean lumbar BMD was -4.5 SD in untreated subjects and -2.3 SD in those who had received estrogen replacement. Sylven et al. (40), comparing 47 TS women (mean age 47.9 years) with controls matched for age and weight, found a mean whole body BMD of -1.23 SD in the TS subjects; length of hormonal replacement therapy was found to be the significant variable. In another study evaluating BMD and fracture rate in 40 TS patients and 40 subjects with other forms of primary amenorrhea (PA), BMD was low in both TS and PA compared with controls (41). Corrected for height and weight, the TS group had a better bone density measure than the PA group, but fractures were increased in both groups.

Taken together, these studies argue that osteopenia can be a problem in TS, potentially leading to fractures. Nevertheless, there are no convincing reports of increased rates of spinal compression and hip fractures in Turner women. This is surprising given that for each standard deviation that BMD falls below the mean in the normal population, the risk of pathological fracture rises two- to threefold. Furthermore, rather than some intrinsic skeletal factor, the treatable hypoestrogenism is the most important element leading to low bone mineral in adult TS patients.

Reports of osteopenia in children and adolescents with TS are unconvincing and have not always been careful in controlling for body size or delay in estrogenization (42–47). Our group has reported that adolescents with TS receiving growth hormone (hGH) therapy exhibit normal bone mineral properties (44), a finding confirmed by other groups. In another study of 19 TS adolescents receiving hGH and ethinyl estradiol, phalangeal DXA BMD was normal both at baseline and 3 years after discontinuation of growth hormone (45). There is only slight evidence that

hGH contributes to bone mineral other than indirectly by increase in body size, whereas estrogen augments bone density in adolescents and adults independently of growth.

G. Gonadal Dysgenesis

Gonadal dysgenesis is one of the hallmarks of partial or complete X chromosome loss. In most 45,X individuals during childhood, the ovaries are already gonadal streaks consisting of fibrous stroma with diminished numbers of primordial follicles. Histological studies of the gonadal ridge have documented normal densities of primordial germ cells at 12 weeks of gestation, but in the early second trimester oocyte formation and folliculogenesis fail to occur normally and connective tissue proliferates. Oocytes undergo premature atresia in a highly variable manner that may be completed before birth or may continue into adolescence or adulthood (49). The phenotypic manifestations of the declining numbers of functioning ovarian follicles constitute a spectrum from absence of any pubertal development in 70–80% of girls, to midpubertal failure in 10–20%, or to failure to progress to menses, secondary amenorrhea, or early menopause.

Ovarian failure is reflected in reduced steroid feedback on the hypothalamic–pituitary axis and marked elevations in serum follicle-stimulating hormone (FSH) and luteinizing hormone (LH). Most infants and adolescents with TS have markedly elevated FSH values, indicative of ovarian failure. Although not clearly established, it is likely that FSH is moderately elevated throughout the prepubertal period. As many as a third of TS patients may exhibit breast budding, but fewer than 10%, mostly with a 45,X/46,XX karyotype, complete pubertal development and reach menarche spontaneously. Thus, estrogen replacement for secondary sexual development is required in most girls with TS. Pregnancy occurs in an occasional TS patient, predominantly but not exclusively in those with mosaic karyotypes. In these cases, miscarriages are common and prenatal diagnosis is advised due to the increased incidence of chromosomal anomalies in the offspring.

Massarano et al. reported the ultrasound appearance of ovaries in 104 TS girls of varying ages (50). The ovaries of two-thirds of the subjects were classified as streak gonads, with ovarian volumes in the remaining one-third of subjects in the lower range of normal. Because the incidence of spontaneous puberty correlates with ovarian volume (51), it is not unreasonable to obtain an ovarian ultrasound concurrently with the initial renal ultrasound, taking care to warn families of the predictive imprecision of the information. Ovaries that are near-normal in size can be most easily detected in infants and toddlers or in girls of pubertal age, matching the temporal pattern of gonadotropin stimulation. Prepubertal uterine volumes are in the normal range, consistent with the anatomically normal, hormonally responsive uterus found in patients with TS. Although the vagina and external genitalia are usually

normal in TS, vaginal atresia has been reported, and genital ambiguity can occur in 45,X/46,XY individuals.

From a management point of view, it is important to remember that progressive follicular atresia results in two functional deficits: failure to secrete estrogen and progesterone on the one hand, and loss of germ cells and infertility on the other. For the pediatric endocrinologist, only the former requires medical intervention, as is discussed below. Nevertheless, families appreciate a frank discussion of the probability of infertility and potential options, including adoption and assisted reproductive technologies. Pregnancy in TS following oocyte donation has approximately the same success rate as in the general population (52). Freezing ovarian wedges is theoretically an option; if fertilization and implantation of these oocytes later in life are successful, the issue of chromosomal defects arises.

H. Stature and Body Composition

Manifestation of growth failure in TS begins with mild intrauterine growth retardation. Mean birthweight is about 2800 g, a relatively mild deficit that is ordinarily overlooked. Although growth velocity in the first few years of life has been considered relatively normal, Davenport has

recently emphasized from longitudinal studies that mean height SDS falls from -0.5 at birth to -1.8 at 18 months of age, with a continuing decline during childhood (53). Nevertheless, the 95th percentile of the TS curve does not diverge from the 5th percentile of the normal female curve until 9 years of age (Fig. 3), so that in many girls TS is not diagnosed until late in childhood. Growth failure becomes even more obvious in adolescence, due to the absence of a pubertal growth spurt, and the height nadir in TS relative to normal females occurs at about 14 years of age. In the absence of growth therapy, most TS patients continue to exhibit slow, consistent growth during late adolescence, due to delayed bone maturation and epiphyseal fusion, with typical closure after 17 years old in the absence of hormonal interventions. Historically, this delay has afforded some measure of catch-up growth before complete cessation.

Lyon et al. (54) combined their growth data with those from other European studies to create growth standards for TS in the absence of hormonal therapy. The Lyon curve, as well as other growth standards (55, 56), provides an important means of evaluating growth therapies. These standard curves permit an accurate projection of adult height on the basis of the current height, and a high degree of correlation has been demonstrated between

Figure 3 (A) Mean height and (B) height velocity in untreated European girls with Turner syndrome from four European studies, plotted on the growth curve for normal females. Note the steady decline in height velocity beginning in early childhood and the absence of a pubertal growth spurt. (From Ref. 54.)

first measured height in childhood and final adult height (57). Adult heights projected on the basis of standardized curves are as accurate as heights predicted from bone age, which may be difficult to interpret in TS (58). The mean final height of the Lyon curve is 142.9 cm, a figure close to the height reported for the combined European–American experience over the last 20 years. Mean heights of approximately 147 cm are reported in untreated TS populations of Northern European descent (59, 60). Final height in TS is clearly affected by parental height and ethnic group; as a rule of thumb, untreated adults with TS are approximately 20 cm shorter than expected from mid-parental target height.

The effect of karyotype on the height deficit should generally be minimized. Subjects who are mosaic for ring X and isoXq are just as short as 45,X subjects, whereas those with 46,XX and 46,XY mosaicism may be on average slightly taller, but there is no consensus in the literature. The influence of spontaneous puberty on adult height also has not been conclusively determined (61, 62). In the minority of patients in whom it occurs, it is generally associated with only a modest pubertal growth spurt, especially if hGH therapy has already maximized growth velocity, and the pubertal estrogen levels may truncate the duration of growth.

The mean BMI in TS is above age-specific norms except in early childhood, and BMI increases with age (59, 63). Girls with TS have relatively large trunk, hands, and feet in relation to their height, as well as broad shoulders and pelvis (64), contributing to the short, square appearance. As a group, adults have a higher than expected prevalence of obesity, increased fat mass, and lower lean body mass (65). Consequently, TS adults are vulnerable to comorbidities, such as type 2 diabetes, hypertension, and cardiovascular risk, especially if estrogen deficiency is not adequately treated (66).

I. Causes of Growth Failure

The mechanism of growth failure in TS is poorly understood, but it may be due to the combined effects of aneuploidy (67), a primary skeletal dysplasia, mild growth hormone secretory dysfunction, and estrogen deficiency. Pathological bone development may represent either an intrinsic defect in ossification secondary to loss of critical genes on the X chromosome, such as SHOX (see below), or might be another manifestation of intrauterine edema. However, no consistent histological abnormality has been found in bone tissue of patients with TS. Nevertheless, growth failure is obvious in most girls with TS during childhood, before apparent deficiencies in the growth hormone/insulin-like growth factor (GH/IGF) axis or estrogen production, implying that an intrinsic bone defect, not an endocrine abnormality, is primarily responsible for the short stature of TS.

It is true that a minority of patients with Turner syndrome are GH deficient by provocative GH testing or by

nocturnal GH secretion rates. A recent Italian study reported that 32% did not have GH > 10 $\mu\text{g/L}$ on two provocative tests and 62% had reduced spontaneous GH secretion (68). Diminished GH levels are strongly correlated with high body mass index (69), accounting for much of the variation in GH testing. Furthermore, serum IGF-I levels are generally normal, even in those with diminished GH levels. IGF-I levels do fall below age-related norms in adolescence, probably reflecting estrogen deficiency, a thesis supported by an increase in GH concentrations in response to low-dose estrogen therapy (70–72). GH testing also fails to predict either pretreatment growth rate in TS or responsiveness to exogenous hGH. Accordingly, GH testing and IGF-I (or IGF-binding protein-3 [IGFBP-3]) levels are not needed in the evaluation of TS, although GH deficiency, as well as hypothyroidism and chronic disorder, should be considered in any girl whose height or growth velocity is clearly below normal for TS.

J. Cognition and Behavior

It is essential to remember that individuals with TS are not mentally retarded, as was erroneously reported in some early studies. Later studies have reported an increased prevalence of retardation (full scale IQ less than 80), in addition to aggressiveness and seizure disorder, only in patients carrying a small ring X (73, 74). Paradoxically, this effect is likely not due to loss of X alleles but rather to overexpression of unidentified X genes because of interference with normal expression of the X-inactivating center (XIST) in these small rings (75, 76). There are also occasional reports of autism in 45,X patients (77).

Modern neuropsychological investigations have revealed specific impairments in cognitive functioning in TS. The most commonly reported deficits relate to visual–spatial processing and visual memory, often reported as difficulties on tasks assessing spatial and numerical abilities (78–81). These deficits result in measurable reductions in performance IQ, in contrast with a normal verbal IQ, in TS children and adults. Tests of memory, executive function, and affect recognition may be affected. These deficits are detectable in childhood and into young adulthood. TS subjects also have reduced scores on motor tests. Ross (80, 81) has observed improvement in both motor and nonverbal processing skills during estrogen replacement. Imaging studies have documented various anomalies in brain morphology in TS subjects (82, 83).

Few studies have examined academic outcome in large numbers of subjects, but academic achievement is generally within the mainstream (84), with the exception of mathematics (85). Children with TS are not disruptive in the classroom setting and so may not be referred by the schools for evaluation. Nonetheless, it is crucial that girls with TS receive educational evaluation throughout their school careers. Hearing evaluation is important as an

adjunct measure to improve social and academic skills of girls with TS.

Child Behavior Checklist scores from numerous studies in TS children and young adults demonstrate problems in social competence, behavior, and attention. TS girls have reduced self-esteem, more internalizing behavioral problems, and fewer social interactions, and these problems may worsen at the transition to early adolescence (86–90). Physical self-image may be poor, possibly related to peer teasing. Anorexia and clinical depression have been reported. Girls may benefit from psychological counseling during childhood and adolescence.

Skuse et al. (91) compared neuropsychological test results in 80 45,X females aged 6–25 years according to parental origin of the X chromosome. In an initial Achenbach screen, the TS subjects with maternal X ($n = 55$) had much higher rates of academic failure and social difficulties than those with paternal X ($n = 25$). On further testing, subjects with an X of paternal origin had superior executive function, better social adjustment, higher verbal IQ, and better verbal memory (92). The authors attributed these findings to maternal imprinting of X chromosome loci, but these putative social and cognitive effects of parental origin of the X need to be confirmed.

K. Autoimmunity

Several types of autoimmunity are found with increased prevalence in TS, including thyroid autoimmunity, inflammatory bowel disease, and rheumatoid arthritis. Although type I diabetes has been reported in TS, it has not been established that the incidence is greater than in controls.

Prevalence in TS of antibodies against thyroid peroxidase and thyroglobulin is 20–30% in several large patient cohorts (93–96). As in a control population, thyroid autoimmunity increases with age from the first to third decade of life. Although occurring in patients with any karyotype, those with long-arm isochromosomes are at highest risk of thyroid autoimmunity (97). Both mothers and fathers of patients with TS have a higher than expected incidence of thyroid autoimmunity (98). This has led to the speculation that familial thyroid autoimmunity might be associated with nondisjunction or related chromosomal defects. As an alternative, maternal thyroid autoimmunity might be associated with a protection against the lethality of X chromosome monosomy in utero (99).

Hypothyroidism (or hyperthyroidism) occurs in 10–20% of TS patients. Individuals should be screened on an annual or biannual basis for thyroid disorder by measurement of TSH, and more frequently if thyroid antibodies have been detected. There does not appear to be an increase in polyglandular autoimmunity associated with thyroid autoimmunity, since islet cell and adrenal antibodies are not elevated.

Both ulcerative colitis and Crohn's disease have a greater than expected prevalence in TS. In a series of 135 TS adults, four had inflammatory bowel disease (100). As

with autoimmune thyroid disorders, a disproportionate number of TS patients with inflammatory bowel disease have an X isochromosome (101–102). Intestinal telangiectasia and celiac disease also have been observed in TS. The risk of juvenile rheumatoid arthritis in TS has been estimated to be increased sixfold from a survey of pediatric rheumatology centers (103). The increased risk of these autoimmune disorders in TS mandates that pediatric endocrinologists be attentive to the gastrointestinal and rheumatological complaints of their TS patients.

L. Metabolic Abnormalities

An increased prevalence of diabetes mellitus in TS has been repeatedly cited, but the supportive data are surprisingly weak. An early paper by Forbes and Engel (104) reported from a cohort of 41 TS patients that 6 (15%) had onset of an unspecified type of diabetes after the age of 30. Of interest, all of those with karyotypes reported had an isochromosome X. Since that 1963 paper, there have been no large patient series reporting a meaningful increase in diabetes. However, a hospital records review in all Danish TS patients over a 10 year period (66) reported a higher than expected number of admissions with a diagnosis of either type 1 or type 2 diabetes, clouding the earlier supposition that only the latter might be more common in TS.

Fasting glucose levels have been consistently normal in series of TS subjects. Fasting insulin levels have been reported normal or elevated, with study differences plausibly attributable to the wide normal range. In contrast, an increased frequency of abnormal oral glucose tolerance tests (OGTT) has been compellingly documented in children and adults with TS, including the nonobese (105–110). A review of the literature through 1991 cited a prevalence of abnormal tests of 32.5% in 326 patients, but the reported prevalence in later studies is somewhat lower. The preponderance of evidence points to insulin resistance as the mechanism of carbohydrate intolerance, but earlier papers remarked upon the delayed insulin response to glucose challenge in TS.

Studying 71 TS subjects before and during hGH + oxandrolone therapy, Wilson et al. (106) reported that all girls had normal fasting glucose and insulin levels, both at baseline and during growth therapy. Fifteen percent had an abnormal OGTT at baseline. Integrated glucose and insulin concentrations following oral glucose challenge did not change during hGH treatment, but did rise with the addition of oxandrolone, a finding that was confirmed in other studies. However, other investigators have since demonstrated a rise in both fasting and glucose-stimulated insulin levels during hGH therapy, which may be dose-dependent. The Dutch hGH studies found only a 6% rate of abnormal OGTT that was not increased by hGH, but insulin levels were elevated throughout hGH therapy, albeit reversible at the cessation of treatment (109, 110). Accordingly, it may be prudent to survey patients for car-

bohydrate intolerance while receiving hormonal therapies in TS.

Mild lipid abnormalities have been reported in TS. Total cholesterol is elevated in adolescents, but not children, and, like insulin resistance, correlates with body mass (111). Growth hormone therapy results in a reduction in low-density lipoprotein and an increase in high density lipoprotein (109). There is no literature to date on the possible physiological benefits of growth hormone therapy in adults with TS. The reported effects of therapeutic estrogen on lipid profiles have been mixed (112, 113).

III. THE GENETIC BASIS OF TS

A. Phenotypic Correlations with Karyotype

The availability of chromosomal analysis in the 1960s allowed for initial attempts to correlate phenotypic manifestations of TS with the variations of X chromosomal loss (114). In his 1965 review, Ferguson-Smith hypothesized that 45,X subjects demonstrated the “complete Turner syndrome” and that the short stature and stigmata of TS were attributable to monosomy of loci on the short arm (7). According to his review of available data, 45,X patients exhibited a higher prevalence of neck webbing, congenital lymphedema, and cardiac malformations than patients with mosaicism or X structural abnormalities. Short stature was a universal feature when the short arm was missing, as in 45,X and karyotypes with long arm isochromosomes. In contrast, normal stature occurred in 20% of 45,X/46,XX, 50% of 45,X/47,XXX, and 63% of long arm deletions. Spontaneous pubertal development and menses, which occurred in only 8% of 45,X patients, were more likely in girls with 45,X/46,XX mosaicism (21%) and deletions of the short arm (25%).

Large patient series since the 1960s have corroborated Ferguson-Smith’s summary. Various studies have confirmed the lower incidence of common TS features in certain mosaicisms, although many minor features occur equally in X monosomy and mosaicism. Later improvements in banding techniques and use of X chromosome probes provided a more detailed localization of X chromosome breakpoints, allowing Simpson to provide an updated review of phenotype/karyotype correlations in the late 1970s (115). Location of the breakpoint correlates poorly with the resulting phenotype, and any feature of TS can be seen with major deletion of either Xp or Xq. Nonetheless, there is a crude association of short arm deletions with short stature and of long arm deletions with ovarian dysgenesis. Therman and Susman reviewed the literature on phenotypes of nonmosaic adults with X long or short arm terminal deletions (116). Short stature occurred in 43% and 88% of the Xq and Xp cases, respectively (Table 3). Ovarian failure, including both primary and secondary amenorrhea, occurred in 93% and 65% of

Table 3 Frequency (%) of Phenotypic Features in TS Adults with Complete X Monosomy (45,X), Short Arm Deletion (46,XXp-), or Long Arm Deletion (46,XXq-)

Feature	45,X (n = 332)	46,XXp- (n = 52)	46,XXq- (n = 67)
Short stature	100	88	43
Gonadal dysgenesis	91	65	93
Short neck	77	38	21
Cubitus valgus	77	25	16
“Shield chest”	74	35	13
Low hairline	72	19	9
Delayed bone age	64	17	10
Pigmented nevi	64	27	19
Nail anomaly	57	8	7
Short metacarpal	55	29	12
Renal anomaly	44	8	6
Webbed neck	42	2	1
Hypertension	37	8	7
Cardiac anomaly	23	2	0
Thyroid disease	18	6	3

Source: Adapted from Ref. 117.

Xq and Xp karyotypes, respectively. Essentially the entire pericentromeric region and long arm are involved in ovarian development and maintenance, since deletion breakpoints with apparently identical degrees of ovarian failure are scattered throughout. Lymphedema and cardiovascular anomalies were rare in both short and long arm deletions, compared with 45,X, although lymphedema has resulted from loss of the distal short arm of the Y in XY females.

Identification of parental origin of the remaining X chromosome in TS has been undertaken to look for clues to the causes of X monosomy and to evaluate whether genomic imprinting might explain the phenotypic variation seen with the 45,X karyotype. Different methods have verified that the intact X in 45,X monosomy is maternal (Xm) 70–80% of the time (117). However, there is no difference in the prevalence of maternally or paternally imprinted X in spontaneous abortuses (118), and studies have not discerned any postnatal phenotypic distinctions, other than in the neuropsychological study described above, in 45,X subjects on the basis of parental chromosomal origin.

A model to explain the Turner syndrome phenotype invokes halved expression of a gene or genes on the X chromosome; such a gene must have homologs on the X and the Y and must escape X inactivation. Although many loci on the second X are inactivated throughout all developmental phases and tissues, except in the oocyte and during initial zygotic cell divisions, many other genes that escape X inactivation have been identified in recent years, including the entire pseudoautosomal regions at both termini. Despite sophisticated comprehension of the X chromosome and the rapidly expanding list of genes that es-

cape inactivation (119, 120), there has been relatively slow progress in elucidating the genetic basis of TS since phenotype–karyotype correlations were first drawn 30 years ago.

B. SHOX

The only X chromosome locus to have been convincingly associated with TS is the short-stature homeobox-containing (SHOX) gene, located in the pseudoautosomal region of the short arm. Isolated and sequenced independently by two groups of investigators (121, 122), SHOX is highly conserved across species and has two transcripts from alternate splicing: SHOXa is widely expressed, whereas expression of SHOXb is highest in bone marrow fibroblasts. Rao et al. (121) demonstrated deletion of the locus in 36 of 36 short individuals with Xp22 or Yp11.3 breakpoints, and absence of a deletion in normal controls or in subjects with X or Y rearrangements and normal stature. A SHOX mutation was found in 1 of 91 subjects with otherwise unexplained short stature, and other individuals have since been identified.

Belin et al. (123) and Shears et al. (124) reported SHOX deletions in many family members with an autosomal dominant bone dysplasia called Leri-Weill dyschondrosteosis (LWD). Thought to be more severe in females, the syndrome is characterized by a short forearm with Madelung's deformity and limited mobility, tibiofibular shortening, variable metacarpal and metatarsal involvement, and mild short stature (125). In one LWD family, a fetus with Langer mesomelic dysplasia (severe shortening of distal extremities, long considered the homozygous form of LWD) had loss of both SHOX alleles. Thus, loss of one SHOX allele results in LWD, and loss of both results in Langer mesomelic dysplasia.

It was immediately recognized that the SHOX locus meets gene dosage requirements for a Turner gene, being a pseudoautosomal locus, thus not X-inactivated, with a homolog on Yp. Postnatal expression is largely confined to osteogenic cells, such as trabecular cells and bone marrow fibroblasts, correlating with a putative role for the gene in bone physiology. It is also expressed in the pharyngeal arch, suggesting a role in some head and neck anomalies of TS. Although the Turner phenotype is broader and more variable than that of LWD, it seems likely that many of the craniofacial and skeletal features of TS, including cubitus valgus and Madelung's deformity, and some degree of the short stature are due to SHOX haploinsufficiency (126). While other craniofacial and cardiac features may be a consequence of the putative lymphedema locus, SHOX is the first legitimate Turner gene to be identified.

C. Y Chromosome Mosaicism

X chromosomal monosomy occurs in mosaicism with 46,XY cells in 5% or more of patients with Turner syn-

drome. The phenotype associated with the 45,X/46,XY karyotype, ranging from female to male, provides an interesting story and a cautionary tale about ascertainment bias. The phenotype has historically been described predominantly as ambiguous genitalia and mixed gonadal dysgenesis (streak gonad with dysgenetic testicular elements and possible asymmetry of wolffian and mullerian structures). In an early review, 60% of cases exhibited ambiguous genitalia and mixed gonadal dysgenesis, 25% were phenotypic females with bilateral streak gonads and other features of TS, and the remaining 15% had the appearance of undervirilized males (127). Approximately two-thirds of 45,X/46,XY individuals diagnosed at birth are raised as females. In contrast, 90–95% of the cases diagnosed prenatally have been normal phenotypic males at birth, and features of TS have been rare (128, 129). These data suggest that characteristics of TS are seen less commonly in 45,X/46,XY individuals than in comparable mosaics, such as 45,X/46,XX. However, adequate longitudinal studies have not been performed and the incidence of TS features and gonadal dysgenesis may be higher than expected from first reports of normal male external genitalia.

The incidence of gonadal malignancy in 45,X/46,XY mixed gonadal dysgenesis engenders considerable clinical discussion about its translation to the TS patient. In Scully's series of 30 cases of gonadoblastoma, 10 were associated with 45,X/46,XY mosaicism, but most of those individuals had ambiguous genitalia (130). The risk of a patient with this karyotype developing gonadoblastoma/dysgerminoma has been estimated at 15–20%. However, this risk assessment was derived prior to recognition that the postnatal phenotype is usually male, and it undoubtedly overestimates the risk in 45,X/46,XY overall. Nevertheless, gonadoblastomas do occur in unvirilized phenotypic females with this karyotype (TS), and the risk of malignancy, albeit unclear, is greater than in the general population. Based on an increased risk of malignancy and a low likelihood of functional ovarian tissue in the presence of XY mosaicism, gonadectomy should be recommended in these TS patients, at least by adolescence and preferably in early childhood.

This recommendation has consequently raised the question of whether techniques other than routine cytogenetics should be utilized to detect occult Y material in TS. Southern blot, FISH, or PCR analysis of cells from series of TS patients with prior 45,X karyotyping has revealed an incidence of previously undetected Y material ranging from 0 to 15%. Gravholt et al. (131) recently reported Y material in more than 10% of their TS patients, half of them not previously detected by routine cytogenetics. FISH utilizing X- and Y-specific probes can now be performed by most cytogenetics labs and certainly should be utilized to determine the origin of marker chromosomes or small rings (18, 132), either to warn of potential malignancy from Y genetic material or to explain

unusual features of TS due to X chromosome fragments. The potential benefit of adjunct FISH studies in all TS patients is not established but warrants further evaluation.

IV. MEDICAL THERAPIES

A. Androgens for Growth

Androgens were utilized for growth promotion in clinical trials in TS prior to the time that human growth hormone (hGH) became widely available (Table 4). Most studies demonstrated short-term efficacy in stimulating growth, and a few reported modest increases in final adult height (133–137). Lenko et al. (134) analyzed growth and final height data in 76 girls treated with fluoxymesterone and/or conjugated estrogens and found that initial growth velocity was greatest when both were used, but mean final heights were not distinguishable. In a retrospective analysis of 66 TS patients, Sybert (60) reported that the mean adult height of patients given either oxandrolone or fluoxymesterone (148 cm) did not differ significantly from the height of untreated patients (146.3 cm). In contrast, a 3–5 cm increase in final height relative to predicted height was documented in three oxandrolone trials (135–137). As described below, several trials of growth hormone used with and without oxandrolone have shown an improvement in growth and final height from the androgen. Despite this apparent growth benefit and a relatively low cost, androgens are not commonly utilized in the treatment of TS in the United States and only as an adjunct to GH therapy. Oxandrolone has limited androgenic side effects at a dosage of 0.0625 mg/kg per day. As a rule, it

can be added to hGH if growth rate is unsatisfactory or if growth therapy has been delayed to a relatively advanced age (>12 years old). In support of the use of androgen in TS is the fact that serum androgens are low in TS adults because of ovarian failure (138).

B. Growth Hormone

Turner himself undertook the first documented administration of growth hormone in TS. His treatment was unsuccessful, presumably utilizing injections of bovine pituitary extract, since human GH from cadavers was not available until the 1950s. In 1960, Escamilla et al. (139) administered pituitary-derived hGH to a patient with TS, resulting in an increase in growth velocity from 3.8 to 7.5 cm/year over several months, a typical degree of first-year growth augmentation from either pituitary-derived or recombinant hGH, which in turn was introduced in the mid-1980s. TS patients constituted the first group after GH deficiency in which clinical trials of recombinant hGH were initiated, principally because of the identifiability and homogeneity of the population and also the lengthy potential treatment period, due to the absence of endogenous puberty.

hGH trials in patients with TS have universally demonstrated an increase in growth velocity. In almost every study, hGH has augmented pretreatment growth velocity by 50–150% in the first year. Many of the early trials combined hGH with estrogens or androgens, both of which had been established as short-term growth stimulants, complicating interpretation of the results. Most early trials used three times a week dosing regimens, and none of the published trials has utilized a randomized control group past the first year. As in hGH treatment of GH deficiency or idiopathic short stature, growth acceleration in girls with TS is sustainable but is most pronounced in the first years of therapy (140).

An early and influential hGH trial in the United States (141) randomized 70 girls at a mean age of 9.3 years to no treatment, oxandrolone, hGH, or both for the first year of therapy. In the second year all subjects except the hGH group were reassigned to a combination group at a reduced oxandrolone dosage (0.0625 mg/kg per day, due to virilization in 30% of subjects at the 0.125 mg dosage). The hGH regimen was switched midstudy to daily (0.05 mg/kg per day) instead of three times weekly. In subjects receiving hGH alone, growth velocity increased from 4.5 cm/year in the pretreatment period to 6.6 and 5.4 cm/year in the first and second year, respectively, whereas growth rates for patients receiving hGH plus oxandrolone were higher at 9.8 and 6.7 cm/year. Compared with a mean adult height of 144.2 cm in historical controls, final heights after hGH and hGH plus oxandrolone were 150.4 and 152.1 cm, respectively, for gains over pretreatment projected height of 8.4 and 10.3 cm, respectively.

The Swedish study (142), also using combination daily hGH and oxandrolone, began at an older mean age

Table 4 Management of Turner Syndrome in Childhood

Medical surveillance

- Karyotype: rule out Y material
- Renal ultrasound
- Echocardiography (repeated in adolescence)
- Regular thyroid screening
- Hypertension monitoring
- Ophthalmology (strabismus, etc.)
- ENT (recurrent otitis) and craniofacial
- Possible orthopedic referral (scoliosis)
- Audiologic evaluation
- Cognitive evaluation
- Psychological counseling
- Dietary advice
- Support groups

Medical therapy

- Begin hGH therapy (0.05 mg/kg per day) by 7–9 years old; earlier treatment may be indicated.
- Add oxandrolone (0.0625 mg/kg per day), if hGH is started late.
- Initiate estrogen at \pm 13 years old.
- Cycle with progesterone within 2 years.

of 12.2 years and had no hGH-alone arm. Growth velocity increased from 3.9 cm/year to 9.4 and 6.8 cm/year in the first 2 years of therapy. Final height after combined hGH and oxandrolone therapy was 154.2 cm, which was 8.5 cm greater than the original projected final height. Results of the Swedish, US, and other early studies convinced most investigators that hGH augmented final height in TS, but some doubts persisted because of the lack of long-term randomized controls. This last concern was resolved when preliminary results of a randomized Canadian study using a concurrent untreated control group were presented at the Food and Drug Administration (FDA) hearings prior to approval of hGH for use in TS in 1996. In that study, the mean difference in final height between treatment group and controls was over 6 cm, convincing the remaining doubters that hGH is efficacious in TS.

A significant gain in ultimate height is now beyond controversy, but the expected magnitude of the increase is still being revised as further studies are reported. Key questions of optimal age of initiation and optimal dosage have not been completely resolved. However, it is likely not a coincidence that the greatest height gains have been reported from studies using relatively early starting ages. The TS subjects in the US study gained about 8 cm from hGH alone after beginning therapy at 9 years old, whereas the height gain when age at initiation of hGH is 11–13 years generally has been 6 cm or less, depending upon the use of androgen and estrogen. In the large Genentech hGH database, 622 TS patients treated for a mean 3.7 years beginning at 12.9 years of age had a mean final height of 148.3 cm, for an increase of 6.4 cm over pretreatment projected height (143). Mean height gain was 3.7–4.7 cm in 136 girls with a similar late start in a European Lilly study (144).

In a provocative Dutch study (145), 68 girls were begun on treatment at a dosage of 0.045 mg/kg per day and then randomized to continue receiving that dosage or one increased in subsequent years to 0.0675 or 0.090 mg/kg per day. No estrogens were given until 4 years of hGH therapy had elapsed and the subject reached 12 years of age. Seven year data from all subjects showed that 85% had achieved a height within the normal range for Dutch girls. In the 32 girls who had completed therapy (after a mean 7.3 years), mean heights for the three dose groups were 158.8, 161.0, and 162.3 cm, respectively, with height gains of 12.5, 14.5, and 16.0 cm, respectively. The height gain achieved with hGH alone at the standard dosage, which was far superior to that of any other hGH study in TS, is plausibly attributable to earlier initiation of therapy, averaging 7 years old, plus the standardized delay of estrogen.

Additional height achieved in the Dutch study can be attributed to the higher dosages of hGH in later years of therapy. In a smaller, nonrandomized study, Carel et al. (146) also progressively increased the hGH dosage, to a maximum of 0.1 mg/kg day when growth velocity de-

clined to less than 200% of the pretreatment level. Height gain was 10.6 cm, compared to 5.2 cm in a matched group of 17 patients who had received a fixed dosage of approximately 0.045 mg/kg per day. Thus, it is possible that TS patients could benefit from hGH dosages in later years of therapy in excess of the current standard of 0.05 mg/kg per day.

No studies using dose randomization from the start of hGH therapy have reported completion to final height, but preliminary data from a number of studies suggest that higher dosages do result in faster growth rates in the first year or two of therapy. However, this augmented growth rate may come at the cost of accelerated bone age and diminished growth velocity in later years. In a long-term Japanese study (147), a standard dosage of hGH, as compared with a low dose, stimulated a greater growth velocity for 2 years only, but final heights in the two groups reported to date are not different. Thus, it is unclear whether final height can be significantly improved using higher dosages of hGH from the start.

Several studies have attempted to predict individual response to hGH. In an Australian study, the best response over 2 years occurred in younger, heavier girls with the most delayed bone age and tallest parents (148). In a British study of 52 girls who were prepubertal at the start of therapy, final height gain after 5.8 years averaged 5.2 cm and correlated best with total dose, duration of therapy, and first-year response (149). In a model developed by Ranke et al. from the Pharmacia database (150), hGH dosage was the best predictor of height velocity in year 1 of therapy, with younger age and oxandrolone use associated with higher growth velocities in subsequent years. However, some of these factors may influence only short-term benefit and not result in gain in final height (151). The common theme in these results is the need for a reasonably early initiation of hGH and substantial duration of therapy.

C. Estrogen

Estrogen replacement was also tried historically as a growth therapy in TS. Although estrogen does result in short-term growth acceleration, most studies have failed to document any improvement in final or even predicted adult height, in contrast with androgens or hGH. Indeed, because estrogen is the primary mediator of skeletal maturation, it accelerates short-term growth while abbreviating the duration of growth, as in normal puberty. Not surprisingly, several early TS studies therefore demonstrated that full estrogen replacement during early adolescence resulted in final heights below the expected height in TS (78). Investigators then attempted to identify a reduced dosage of estrogen that might be an effective long-term growth stimulant without causing accelerated skeletal maturation. Significant short-term growth stimulation from low-dosage estrogen was demonstrated, but unfortunately it does not occur without accompanying effects

on bone maturation, particularly in younger patients with bone age less than 11 years (152, 153). As a result, there is no perfect dosage of estrogen adequate to achieve a normally timed feminization without inducing an acceleration of bone age and potential reduction in adult height.

Although low or full-dosage estrogen replacement given alone provides a notable growth spurt, little additive growth is observed when estrogen is started during hGH therapy (154, 155). The estrogen-induced advance in skeletal maturation without benefit of substantially greater growth velocity means that early introduction of estrogen therapy can negate gains achieved by hGH therapy. This has now been confirmed in several studies. In the Swedish hGH study mentioned earlier, height gain from the combination of hGH and oxandrolone was 8.5 cm; addition of a relatively low dosage of ethinyl estradiol (100 ng/kg per day) to this regimen at 12 years old resulted in a mean height gain of only 3.2 cm. A second Genentech study (156) randomized 60 girls receiving hGH from a mean of 9.5 years old to begin estrogen at either 12 or 15 years old (Fig. 4). Gains in final height were 5.1 and 8.4 cm in the two groups, respectively. A third cohort of girls who started hGH after 11 years old and began estrogen 1 year later had a mean gain of 4.7 cm. Thus, an effective long-term growth regimen requires reasonably early initiation of hGH, or a lengthy delay in estrogen initiation.

Estrogen therapy is contraindicated in preadolescent patients, plays no legitimate role in growth therapy in TS, and, as a corollary, must be delayed for feminization until certain growth thresholds are achieved. The apparent estrogen-induced acceleration in skeletal age jeopardizes the primary objective of hGH therapy. However, the practice of delaying estrogen replacement until 15 years or older

in an effort to maximize growth, which was the clinical practice prior to introduction of hGH, guarantees significant delays in pubertal development, risks a life-long diminution of bone mineral density, and potentially accentuates the social isolation and stigmatization of girls with TS. A prudent and sympathetic approach is to customize therapy according to the current height, hGH history, and psychological needs of each patient. At a minimum, estrogen should be delayed until 12 years old, but only if a girl has received hGH for 3 years or more. In those with a brief duration of hGH therapy, estrogen may need to be delayed until 13 or even 14 years old.

Balancing the legitimate psychological and physiological need to begin pubertal development against concerns about final height, our typical practice is to begin conjugated estrogens (Premarin) at about 13 years old at an initial dosage of 0.3 mg/day and increasing to 0.625 mg 6–12 months later. Approximately two-thirds of girls will achieve Tanner 3 breast stage after 12 months. After 1–2 years of therapy, estrogens are modified to day 1–26 only and medroxyprogesterone acetate 5–10 mg (Provera) is added on days 17–26, to induce menses and diminish the risk of endometrial hyperplasia or carcinoma. Other estrogen preparations, such as oral ethinyl estradiol (starting at 100 ng/kg per day) or 17 β -estradiol, as well as dermal patches, are also effective in feminization (157, 158). Some practitioners believe oral estrogens have more deleterious effects on hepatic metabolism than transdermal preparations. TS patients do have an unexplained baseline elevation in hepatic enzymes, but the relative effects of oral estrogens are unclear (159, 160).

Few direct comparisons of different estrogens for feminization have been made. Indeed, most studies of es-

Figure 4 Differences in annual growth velocity after TS girls on hGH begin estrogen at either 12 or 15 years old. (From Ref. 158.)

trogen use in TS have concentrated on the objective of growth stimulation and have failed to provide detailed analysis of the feminizing effects. Once progesterones have been added, many TS adolescents and adults prefer oral contraceptive preparations for convenience.

D. Summary

The height deficit in TS is approximately 20 cm. It is tempting to conclude from informal meta-analysis that the portion of the height deficit remediated by hGH depends upon the age therapy is initiated. The expected height gain when hGH is begun at 12 may be only 5 cm, whereas hGH therapy begun at 7 years of age could add in excess of 12 cm. It is therefore prudent to initiate hGH by 7 years old, or earlier if a girl is in the lowest portion of the TS height curve. Better height gains may be achieved by even earlier therapy. Although no data are currently available to prove greater efficacy from an earlier starting age, growth failure is apparent in the first years of life in TS. The standard hGH dosage is 0.05 mg/kg per day, but higher dosages may be justified. We do not routinely attempt to diagnose GH deficiency in TS, unless height is well below that expected from parental height. The optimal time to discontinue hGH has not been established, but convention calls for continued therapy until growth is largely completed, as evidenced by a velocity below 2.5 cm/year.

Oxandrolone increases height by 2–3 cm given alone or combined with hGH, but it is not known if this additive effect occurs when hGH therapy is maximized by an early start or higher doses. Addition of oxandrolone to hGH might allow for earlier termination of therapy and for lower overall medical costs, but its use is customarily limited to adjunct therapy in girls in whom hGH therapy was delayed. Estrogens, in contrast, are not beneficial for growth and may be deleterious for final height if started too early; accordingly, estrogen for feminization should be delayed until 13 years old, preferably after several years of hGH therapy. In tall girls or in those with lengthy duration of hGH treatment, earlier initiation of estrogen may be possible.

Nonendocrine Vaginal Bleeding

Albert Altchek

Mount Sinai School of Medicine and Hospital, New York, New York, U.S.A.

I. INTRODUCTION

A. General Considerations

The vast majority of abnormal bleeding in children is a result of local causes, not precocious puberty or other endocrine causes.

Unfortunately, there have been reports from distinguished authorities indicating that the leading cause of bleeding is precocious puberty (for example, Ref. 1). Clearly such reports are a result of case selection bias.

Such distorting of the relative incidence of precocious puberty causing bleeding, combined with the training and interests of pediatricians, causes an immediate reaction that the first thing to rule out if there is bleeding is precocious puberty. Thus it is essential that pediatric endocrinologists recognize and diagnose patients with nonendocrine vaginal bleeding to avoid misdirected investigation that may involve radiation exposure; be wasteful of resources and funds; be prolonged; be stressful to the child, parents, and pediatrician; and delay discovery of the statistically probable local, nonendocrine cause of the bleeding.

Because menstruation may be considered physiological in children age 10 or over, bleeding in girls under age 10 is considered abnormal (1). Ideally, in all cases of vaginal bleeding local nonendocrine causes should be ruled out (Chap. 9).

Even if the presumptive diagnosis is precocious puberty, there should be consideration of the possibility of a nonendocrine, local cause of bleeding. It may even be possible that there is a local cause of bleeding together with precocious puberty. If this occurs, then the bleeding pattern and the lack of response to precocious puberty therapy cause great confusion. Gynecological investigation is relatively brief and inexpensive and, except for the possible need for general anesthesia for vaginoscopy, relatively without danger.

B. Differences Between Endocrine and Nonendocrine Bleeding

Usually with true, constitutional precocious puberty, there is a similarity to the normal puberty sequence of events except that they occur at an earlier age. Therefore, by the time the child has her first episode of vaginal bleeding, she has already had breast development, pubic and axillary hair, and other physical signs of puberty. In addition, the vaginal cytology smear (or urine cytology) shows an estrogenic effect, with superficial and intermediate cells.

By contrast, the child with a local, nonendocrine cause of bleeding does not have the physical changes of puberty, and the vaginal cytology shows an anestrogonic maturation index with mostly parabasal cells, with few if any superficial or intermediate cells. In addition, a local bleeding site is present. Furthermore, the history may give positive clues, such as trauma, symptoms of vulvovaginitis, dysuria, scratching, the presence of a vaginal or vulvar mass, or pain on defecation.

C. Endocrine Bleeding Posing as Nonendocrine Bleeding

Infrequently, an endocrine cause may pose as a local cause because of an absence of physical signs of puberty when bleeding starts as an apparently isolated phenomenon. However, the vaginal smear cytology is usually estrogenic because the vaginal mucosa is the most estrogen sensitive tissue. Specific causes include the following examples.

1. The newborn may have physiological vaginal (uterine estrogen withdrawal bleeding) bleeding and discharge (from the estrogenic vagina).
2. The first clinical sign of McCune-Albright syndrome is often vaginal bleeding. The diagnosis requires the characteristic café-au-lait pigmentation.

- tion and radiological bone disease. Eventually secondary sexual development occurs (Chap. 9).
3. Estrogen-secreting ovarian neoplasms, such as granulosa cell tumors, even though small, may also cause bleeding before physical signs of puberty. They may be palpable on rectal examination and can be imaged by ultrasound (Chap. 9, 30).
 4. Patients with isolated premature menarche may have isolated or recurrent vaginal bleeding without other signs of precocious puberty (2). Sleep luteinizing hormone (LH) levels may show pulsations; however, follicle-stimulating hormone (FSH) responds more than LH after LH-releasing hormone stimulation, as in prepuberty. There may be transient elevation of estradiol and a later return of LH to a prepubertal pattern. This entity is usually benign and self-limiting and is thought to be the result of a partial, transient activation of true precocious puberty. Careful evaluation and follow-up are required.
 5. Prepubertal vaginal bleeding without signs of precocious puberty may be infrequently caused by prolonged, untreated hypothyroidism. In these patients, there may be breast enlargement, galactorrhea, hyperprolactinemia, enlarged sella turcica, ovarian follicular cysts, elevated gonadotropins (mainly FSH), and an estrogenic vaginal smear. There is no androgen excess or pubarche and no pubertal growth spurt. There is a delayed bone age (Chap. 9, 14, 15) (3, 4). Percutaneous aspiration of secondary ovarian cysts added to the standard thyroxin therapy may be helpful (5).
 6. Accidental estrogen ingestion may also set off vaginal bleeding without puberty development.
 7. Sometimes, precocious puberty caused by a central nervous system lesion may have bleeding before secondary sexual development (1). Brain imaging is necessary for diagnosis.
 8. Transient neonatal bleeding with a stimulated uterus and a dominant 3 cm ovarian cyst has been reported with adrenal steroid suppression of congenital adrenal hyperplasia, which resulted in a transient gonadotropin level (6).
 9. Prolonged vaginal bleeding is common following long-acting gonadotropin-releasing hormone agonist therapy of central precocious puberty in premenarchal girls (7).

II. CAUSES OF LOCAL NONENDOCRINE BLEEDING

A. Causes

The local causes of nonhormonal vaginal bleeding in the child are listed in Table 1. These conditions can also cause abnormal bleeding in the adolescent. The vast majority of

Table 1 Nonhormonal Causes of Bleeding

Severe, usually specific, infections of the vagina, with secondary vulvitis
Group A β -hemolytic streptococcus
<i>Candida</i>
<i>Neisseria gonorrhoeae</i>
<i>Chlamydia</i>
<i>Gardnerella</i> (bacterial vaginosis)
<i>Trichomonas vaginalis</i>
Rare (geographic endemic) <i>Shigella</i> , schistosomiasis, amebiasis
Pinworm infestation
Trauma
Management of bleeding
Types of injury
Suspicion of sexual abuse
Foreign body in the vagina
Rolled-up wads of toilet tissue
“Arrowhead” narrow plastic bottle caps
Trapped pinworms
Vulva lesions
Severe nonspecific vulvitis with secondary vaginitis, scratching
Skin lesions
General skin disease, seborrheic, atopic, psoriasis, candidiasis
Hemangioma
Condylomata acuminata
Lichen sclerosus
Diaper rash
Ulcers: herpetic, syphilis, chancroid
Systemic infection: chicken pox
Local infection: bacterial, tinea
Allergic-irritant: contact
Scabies
Prolapse of urethra, hematuria, prolapse of bladder, rhabdomyosarcoma, prolapse of ureteroceles
Anal fissure, pinworms, perianal dermatitis, condyloma acuminatum, hemorrhoid caused by pelvic cavernous hemangioma, laceration
Hymen polyps
Malignant and benign tumors of the vagina, uterus and ovaries
Rhabdomyosarcoma
Midline germ cell endodermal sinus tumor
Clear cell adenocarcinoma
Rare coagulation defect (in association with skin and mucous membrane bleeding)

adolescent abnormal bleeding is caused by anovulatory dysfunctional uterine bleeding because half of all adolescents do not ovulate at menarche.

B. Incidence and Prevalence

There are no reliable data on the incidence and causes of local bleeding in the child because of case selection fac-

tors and age group bias. Adolescent statistics may also reflect pregnancy and its complications (miscarriage, abortion, or ectopic pregnancy), sexually transmitted disease, misuse of oral contraceptives, voluntary sexual activity, and rape.

Among 1300 Viennese children, average age 7.6 years, seen in elective clinic visits for evaluation of gynecological problems, the most frequent conditions were vulvovaginitis (43%), "pathologic vaginal bleeding" (13%), vulva disorders (7%), and suspicion of foreign body (5%) (8). In adolescents, most of the bleeding was anovulatory dysfunctional bleeding.

Emergency rooms tend to report trauma and urethral prolapse as bleeding causes because of the acute and severe presentations. Private pediatric offices and clinics acquire cases with less dramatic bleeding and tend not to report them.

A London referral hospital reported that among 52 girls 10 years of age and under with vaginal bleeding, 28 had a local lesion, of whom 11 had malignant vaginal tumors. These included eight rhabdomyosarcomas, two clear cell adenocarcinomas, and one endodermal sinus tumor. Bleeding from vulvar lesions included lichen sclerosus, warts, and cavernous hemangioma, as well as urethral prolapse, trauma, and vulvovaginitis. Precocious puberty occurred in 11 children: constitutional in two, granuloma cell tumor of the ovary in three, and premature menarche in six. In 13 cases, no cause for bleeding was found (9). I believe that the high incidence of malignancy and precocious puberty and the absence of foreign bodies in the vagina were a result of case selection. The lack of a cause for bleeding may have been a result of a severe vaginitis that cleared by the time of vaginoscopy. In their precocious puberty cases (only 2 of 11 were constitutional), most had bleeding without other signs of secondary sexual development and with normal bone age. Isolated bleeding as the first sign of puberty was also found in another select series (1).

There have been several recent reviews of vaginal bleeding in children (10–21). There is general agreement that the most frequent causes include trauma, vulvovaginitis (especially vaginitis), vulvar lesions, vaginal foreign bodies, and urethral prolapse.

A Japanese hospital reported that of 330 girls referred ages 1–10, 20% had vaginal bleeding. Of these 74% (46 of 62) had local vaginal lesions due to vulvovaginitis (28), urethral prolapse (6), trauma (6), foreign bodies (3), and vaginal tumors (3). Of the latter one was sarcoma botryoides and one was endodermal sinus tumor. Precocious puberty was diagnosed in 16 (20%), of whom 6 had an hormonally active ovarian tumor. There were three cases with idiopathic precocious puberty without secondary sexual development (presumably premature menarche) (16).

Malignant conditions of the vagina are very rare but may present initially as unexplained vaginal bleeding (even only staining for a few days) in an otherwise healthy

child. With early discovery, local resection, and contemporary chemotherapy, the dismal prognosis of 30 years ago has been removed from about 85% fatality to apparent cure.

Trauma may result from sexual abuse, which may also be part of general mistreatment of the child. The suspicion of abuse requires reporting to legal authorities. Ideally, sexual abuse should not be overlooked (even though there may not be definite physical findings), and sexual abuse should not be misdiagnosed in conditions that simulate its physical findings (such as lichen sclerosus with bleeding, laceration-like fissures, and ecchymoses).

III. SEVERE VAGINAL INFECTIONS AS A CAUSE OF LOCAL NONENDOCRINE BLEEDING

A. Vulvovaginitis

Vulvovaginitis is the leading gynecological problem of the child, which can cause bleeding. The child is susceptible to infection because of a vulva that

1. Lacks the thick adult labial pads and pubic hair
2. Has delicate skin
3. Is close to the anus

The child is also susceptible because of a vaginal mucosa that

1. Is anestrogenic and thin (about 6 cells thick rather than the approximately five times thicker adult)
2. Lacks glycogen (and lactobacilli) and therefore is of neutral pH rather than the adult acid pH
3. Might lack immune globulin of the adult

In addition, children tend to have poor local hygiene. Most vulvovaginitis is primary vulvitis with secondary vaginitis set off by an episode of poor hygiene.

Primary vaginitis is less common and more deserving of investigation. A culture of the vagina above the hymen is required for diagnosis.

B. Group A β -Hemolytic Streptococcus Vaginitis

Group A β -hemolytic streptococcus is the most frequent cause of a specific vaginal infection causing bleeding, although bleeding does not occur in every case. Q-tip culturing often provokes bleeding. On vaginoscopy, there is a severe inflammation of the upper posterior vaginal wall and fornix with extensive petechial hemorrhages in the anestrogenic atrophic mucosa. Blood comes from a broad area. A single bleeding site cannot be visualized. Although vaginoscopy is recommended, a positive culture with cure after 10 days of antibiotic therapy (similar to a pharyngitis) and observation is a reasonable alternative.

Group A β -hemolytic streptococcus (GAHS) has been reported in 18% of girls who were cultured for clinical vulvovaginitis (actually vaginitis). The incidence is higher in the age group up to 9 years, as opposed to the 10–14-year age group. The younger child is expected to have streptococcal vaginitis; the older child, because of an estrogenic thicker vaginal wall, is resistant. It is also increased in the winter months, when streptococcal pharyngitis is increased. The organism is probably transmitted from the pharynx to the vagina (22). This suggests that GAHS is more commonly associated with vulvovaginitis than previously thought. It could indicate a true increase in frequency or better recognition by more liberal use of cultures.

C. *Candida* Vaginitis

Candida may cause a vaginitis with a cottage cheese discharge, a vulvitis with severe excoriation, a perianal dermatitis, a diaper rash, and a secondary infection of any vulvar lesion. The diagnosis is made by inspection, scraping, culture, or microscopic potassium hydroxide wet mount smear.

D. Sexually Transmitted Disease

Any sexually transmitted disease raises the question of sexual molestation (gonorrhea, chlamydia, trichomonads, *Gardnerella*, condyloma, etc.), although it is possible that all of these can be acquired without molestation at the time of vaginal delivery, from a caretaker, or close physical contact with the mother. Trichomonads prefer the estrogenic vagina and tend to be found in the newborn and older child.

E. Unusual Infections

Rare severe vaginal infections usually associated with geographic endemic areas can cause bleeding.

Recurrent vaginal bleeding and bloody discharge may be due to *Shigella* causing a distal localized intense vaginitis. It originates from a previous enteric infection and there may or may not be a residual positive stool culture. Sometimes, prolonged treatment may be required. Contacts should be cultured even if asymptomatic. In the United States, these cases are infrequent. Patients often come from Indian reservations in the Southwest and usually have *Shigella flexneri*. In Peru, the usual cause is *Shigella sonnei* (13). Other rare causes include *Schistosomiasis* and *Amoebiasis* (24).

IV. TRAUMA AS A CAUSE OF LOCAL NONENDOCRINE BLEEDING

The physician is faced with two problems: the specific injury (and treatment) and the question of sexual abuse and, with it, sexually transmitted disease (25).

A. Management of Bleeding

When the child is first seen by the pediatrician, there is the tendency to watch and wait with the hope that the bleeding will spontaneously stop. Unfortunately, if there is persistent active bleeding several hours may be lost, with significant blood loss. A cold compress should be applied to the vulva for about 10 min. If significant bleeding persists, the child should be taken to the operating room for meticulous hemostasis, suturing of lacerations, and reconstruction using fine absorbable nonreactive sutures. The integrity of the bladder and rectum is checked by having the child void, catheterization, and rectal examination. Vaginal lacerations and possible transvaginal peritoneal injury are checked and consideration given to blunt abdominal trauma. Despite fecal contamination, immediate repair of fresh rectal tears gives good results. Antibiotics and tetanus prevention should be considered.

Bleeding as a result of trauma often causes external bleeding. Occasionally, blunt trauma from a fall may result in a deep pelvic hematoma that a number of days later ruptures laterally into the vagina, resulting in the vaginal discharge of old blood.

Genital injury gives rise to anxiety. The little girl is disturbed by pain and bleeding, her parents are worried about serious damage, and the physician is concerned about possible sexual abuse.

Accidental injury is more common than molestation. With the former, there is prompt reporting by the patient and her mother, a clear history, and findings consistent with the history (26).

Most trauma is an accidental fall with a hematoma of the anterior labia majora or perineum. It is usually managed by ice bag pressure and observation. Infrequently a large or enlarging hematoma may require surgery to ligate a bleeding vessel or for packing (21).

Vaginal laceration may result from water slide injury and bleeding may require examinations under anesthesia (27, 28). It may also occur from water-ski douche (29) or jet-ski inquiry (30), high-pressure water jet (31) or sliding down a water chute (32).

Vaginal bleeding may be sign of anorectal injury (33).

Despite denial of trauma and of an intact hymen, profuse vaginal bleeding can occur from a vaginal laceration in the prepubertal child (34).

Compression of the uterus and adnexae as components of a sliding indirect inguinal hernia in an infant apparently may cause vaginal bleeding (35).

B. Types of Injury

A prospective 33 month study from the accident and emergency department of the Royal Liverpool Children's Hospital revealed 87 girls with genital injuries (26). Of these, 82 had a clear clinical history. Most of the injuries (74) involved straddle or falling onto hard objects, which compresses the vulvar soft tissue against the pubic ramus

bone. This resulted in asymmetrical bruising (sometimes severe), abrasion, and (usually superficial) lacerations anteriorly between the labia majora and minora. There may be unilateral medial thigh scraping. With the usual straddle accident, one foot slips and the child falls forward and to one side. Accidents occurred on bicycles, falling on small toys, climbing on furniture, falling astride a fence or bathtub wall, on play or sport apparatus, and from kicking. There were five girls with vaginal-penetrating injuries caused by railing spikes, sticks, and a bath tap. These injuries were severe and required examination under anesthesia and suturing. There were tears of the posterior vestibule and posterior vaginal wall. Stretch injuries ("splits") occurred in three cases, with superficial tears in the perineum and fourchette, especially in those with labial adhesions; two girls had self-inflicted scratch injuries. Of the 87 girls with genital injuries, 80 were considered accidental. Sexual abuse was alleged by only three of the seven girls with suspicion of abuse (26).

C. Sexual Abuse

Suspicion of sexual abuse is raised by an absent or vague history and a delay in presentation in cases of injury to the hymen; (severe) posterior fourchette, perineum, or posterior vaginal wall; and failure to have a return visit. The posterior fourchette is distal to the hymen in the vestibule. The gynecological perineum is between the vagina and anus (the anatomical perineum includes the entire vulva) (26).

Sexual abuse in children involves medical care, emotional support, report to child welfare agencies, collection of evidence, and follow up (36).

Lower abdominal pain and vaginal bleeding may be signs of a posterior vaginal fornix laceration with hemoperitoneum due to initial sexual intercourse (37).

Vaginal digital "fisting" with laceration reported in adults (38) might present in children with a vague history; pain and severe bleeding requiring general anesthesia for assessment; and multiple lacerations of the vagina, rectum, and bladder.

V. FOREIGN BODIES IN THE VAGINA AS A CAUSE OF LOCAL NONENDOCRINE BLEEDING

Foreign bodies in the vagina tend to cause a persistent, foul, bloody vaginal discharge. This is a primary vaginitis and secondary vulvitis. The usual material is rolled-up wads of toilet tissue. These are almost always multiple and of different ages. X-rays usually do not detect them because most foreign bodies are not radiopaque. Also, these wads cannot be detected by rectal examination or ultrasound. Levator muscle action causes these wads to be pulled to the upper posterior vagina, and thus they are

usually not visualized by inspection of the vulva. Vaginal cultures may yield any or all of the colon bacteria.

Another frequent foreign body is the hard plastic, narrow bottle cap with an "arrowhead" configuration. It may cause trauma on insertion. It can be palpated on rectal examination.

Almost any small object has been found in the vagina, including rolled-up pieces of cloth and green peas. Rarely, trapped pinworms may be lost on their return migration from the rectum.

The object is usually inserted by the child herself, who forgets or does not wish to remember because she knows that it is not proper. I believe that the child pushes her finger rolled up with toilet tissue into the vagina because of itching, and the tissue remains. Thus, there is usually no history of insertion.

Rolled-up wads of toilet tissue tend to reaccumulate, probably because of habit formation.

On discovery, there is an emotional melodrama as the mother berates the child. Sometimes, the foul odor results in the child being isolated, with secondary psychological reactions occurring before the diagnosis is discovered.

VI. VULVAR LESIONS AS A CAUSE OF LOCAL NONENDOCRINE BLEEDING

A. Trauma

Because of play, abrasions, scratching, and binding clothing combined with an unprotected vulva with delicate skin, children often experience nonspecific abrasions, excoriations, and nonspecific infections of the vulva. These may bleed spontaneously or after rubbing.

B. Skin Disease

1. Condyloma Acuminatum

The incidence of childhood condyloma acuminatum is progressively increasing. It is readily diagnosed by inspection. Scratching or other trauma readily provokes bleeding. The lesions have a characteristic dry, warty, hard, pointed appearance on the skin of the labium majus, perineum, and perianal areas. At the vaginal introitus with mucosa, the lesions are soft, bulky, and rounded, containing 1 mm clear granuloma-like areas suggestive of tapioca pudding. Personal observation suggests that children with sensitive skin (seborrheic or atopic dermatitis) are more susceptible (see Fig. 1).

The presence of vulvar and perianal condyloma acuminatum requires that sexual molestation be ruled out because this is a sexually transmitted disease. Nevertheless, it is possible that in most children anogenital warts are acquired by nonsexual transmission. The sources may be the mother's birth canal, caretakers by direct contact, washcloths, and general body cutaneous verruca vulgaris (39).

Figure 1 (a) Condylomata acuminata lesions of the skin are dry, hard, and warty, as seen on the perineum and perianal areas. In this case, they are less pointed because of previous podophyllin (podophyllun resin) therapy (b). The lesions of the introitus and periurethral areas (mucosa) are soft and bulky and resemble tapioca pudding

In the differential diagnosis of genital verrucous lesions is Darier's disease (keratosis follicularis), an autosomal dominant acantholytic disorder that may also result from a spontaneous mutation. Initially it resembles a chronic diaper rash or candidiasis, and later, painful infected masses develop (40). A biopsy is necessary for the diagnosis.

2. Symmetrical Fissures

Seborrheic and atopic dermatitis are frequent childhood skin diseases occurring in more than 5% of all children.

Although not generally recognized, I find a high incidence of vulvar involvement and a frequently underestimated cause of chronic vulvovaginitis. The reason is that the usual diagnosis is made from the vaginal culture and the vulva is overlooked. Both these conditions have characteristic general signs, such as fissures and crusts behind the ears, a prominent lower eyelid fold (Dennie's lines and Morgan's folds), keratosis pilaris of the outer arms, and eczema of the elbow creases. There may be some overlap between these two conditions on purely clinical grounds. Both have a similar, transient subacute appear-

ance of the vulva, with symmetrical fissures between the labia minora and majora and in the midline perineum. There may also be fissures in the midline anterior to the clitoris, radial in the perianal area, and in the midline posterior to the anus (see Fig. 2). When deep, the fissures can bleed. They may be confused with sexual molestation; however, the fine, precise symmetrical lesions and the general body distribution confirm the diagnosis.

Lichen sclerosus et atrophicus, now referred to as lichen sclerosus, in its advanced form has fissures in a similar distribution; however, they are coarser, chronic, and bleed more readily (see Fig. 3). They are often misdiagnosed as sexual molestation. A biopsy confirms the lesion. It begins as white, flat papules that coalesce into atrophic so-called cigarette paper plaques in the anogenital region. The skin becomes thin and fragile, with upper dermal edema and collagen homogenization. It is easily traumatized, causing purpura and bleeding. Mothers may report what appear to be blood blisters after the child goes on long bicycle rides. A biopsy confirms the diagnosis. Whereas in adults topical 2% testosterone in petrolatum has been recommended, topical 1% progesterone may help in children (41).

3. Psoriasis

Psoriasis is not unusual in children. If it first appears on the vulva, it is frustrating because the local heat, humidity, and rubbing modify the typical appearance and it resists therapy. If it appears on the vulva after general body involvement is present, then the diagnosis is simple. Abrasion and chafing can cause bleeding.

4. Diaper Rash, Allergies, and Contact Reactions

The usual diaper rash is an irritant dermatitis related to chemical and bacterial action of the urine and stool. It usually starts on the convex surfaces of the vulva closer to the diaper.

Diaper area rashes also may be caused by candidiasis, atopic eczema dermatitis, seborrheic dermatitis, and psoriasis, and, less often, by dermatophyte fungi or histiocytosis. The last may represent a serious systemic illness and presents as deep intertriginous fissures with severe seborrheic-like dermatitis that resists treatment.

The usual seborrheic dermatitis begins in the intertriginous creases but is less severe and responds to treatment.

The child's sensitive skin is easily irritated by contact or allergic reactions to perfumes, dyes, bubble bath, hot water, excessive soap, and other agents.

5. Hemangiomas

As many as 10% of all infants have hemangiomas, which may grow rapidly in the early months. Slow spontaneous regression usually starts at 6–10 months of age. Vulvar lesions are easy to visualize. Scratching or trauma may cause recurrent bleeding. Vaginal hemangiomas require vaginoscopy for identification. Rare, deep pelvic cavernous hemangiomas may have vulvar extensions, bladder extensions (causing hematuria), and rectal extensions (causing large hemorrhoids). Uncomplicated hemangiomas are observed. Complications are traditionally treated with oral or intralesional glucocorticosteroids (42).

Figure 2 Fissure that caused bleeding on the child's right side between the labium minus and majus

Figure 3 Lichen sclerosus of the vulva. There are chronic coarse deep fissures that readily bleed and white skin. The trauma of bicycle riding can cause ecchymoses.

Dry ice sticks have also been used. Two new modality treatments that seem to be relatively safe and effective are being evaluated: vascular-specific pulsed dye laser and interferon- α 2a (43).

Aside from the hemangiomas, the other vascular birthmark is the vascular malformation. It persists throughout life, may involve complex combined vascular malformations, requires evaluation, and is rare (44, 45).

The rare giant hemangioma, which may present as a subcutaneous soft mass, may have a dangerous consumption coagulopathy and thrombocytopenia (Kasabach-Merritt syndrome). Those that do not respond to conventional therapy may respond to systemic subcutaneous interferon- α (46).

There are extremely rare, rapidly growing, congenital hemangiopericytomas that simulate hemangiomas but spontaneously ulcerate with severe bleeding (47).

6. Vulvar Infections

Vulvar candidiasis can cause severe pruritic erythematous lesions with sharp irregular borders and satellite lesions. It suggests diabetes or immune deficiency.

Staphylococcus and *Streptococcus* can cause vulvar and buttock pustules and brawny induration (erysipelas).

Tinea skin infections cause elevated circular lesions.

Chicken pox (varicella) lesions are also present on the vulva, where they are readily infected with bacteria and therefore persist.

The most common vulvar ulcers are caused by herpes. Figure 4 shows multiple confluent vulvar ulcers covered with a white exudate of colon-type bacteria. Bacterial culture is misleading. The syphilis lesion may be a primary chancre, secondary congenital condyloma latum, or

Figure 4 Confluent multiple vulvar ulcers caused by herpes, covered by a white exudate of colon-type bacteria

generalized macular rash. Chancroid ulcers are shaggy, painful, and simulate herpetic ulcers. Tumor chemotherapy can cause vulvar ulcers (48).

In refugee housing with enforced closeness, scabies spreads rapidly and causes intense genital itching. Pediculosis pubis occurs in the older child.

There are many rare vulvar lesions. Chronic bullous dermatosis of childhood has subepidermal blisters with the deposition of IgA in a linear pattern along the basement membrane. It may also occur in other areas besides the genitalia, such as the trunk, extremities, and oral and tracheal mucosa (49).

Crohn's disease of the vulva may occur as a direct extension of this granulomatous intestinal disease as ulcerations and fistulas or separately ("metastatic"). On histological appearance, the latter is a sterile, noncaseating, nonspecific granuloma.

Granular cell tumors are slow-growing solitary nodules or plaques with a smooth or hyperkeratotic hyperpigmented verrucous surface that may be confused with squamous cell carcinoma or condyloma (50).

VII. PROLAPSE OF THE URETHRA AS A CAUSE OF LOCAL NONENDOCRINE BLEEDING

In some emergency rooms, urethral prolapse is the leading cause of vaginal bleeding. It presents as acute bleeding with pain and urinary symptoms. On inspection, there is a friable, shaggy, necrotic, bleeding mass suggestive of a malignancy. The diagnosis can be confirmed by passing a urethral catheter. The predisposing factors are an increase in intra-abdominal pressure and trauma. Management op-

tions include conservative therapy (sitz baths and topical estrogen cream), ligation over a Foley indwelling catheter, and excision under general anesthesia. The last gives the best results (51). Milder cases with conservative therapy tend to remain in a subacute condition (see Fig. 5) (52-54).

The differential diagnosis includes hematuria (from bladder or urethral hemangioma), prolapse of ureterocele, and bladder rhabdomyosarcoma.

The most frequent age is 4.9 years. Most cases are initially misdiagnosed by the referring pediatrician or emergency physician (54).

VIII. ANAL LESIONS AS A CAUSE OF LOCAL NONENDOCRINE BLEEDING

A. Fissures

The most common anal lesion causing bleeding is the fissure. It may cause spontaneous bleeding, blood covering the stool, pain, and fear of bowel movement. The usual cause (which is not generally recognized) is seborrheic or atopic dermatitis, in which there are the characteristic symmetrical, interlabial vulvar fissures, midline perineal fissures, and perianal radial fissures. There is often an anterior edematous skin tag.

B. Perianal Dermatitis

Perianal dermatitis on culture usually reveals *Candida*, but *Streptococcus* group A and *Staphylococcus aureus* (55), as well as all the colon bacteria, may be present. A single infecting organism may be predominant and the presumptive cause, but the condition, especially if recurrent, may

Figure 5 Subacute urethral prolapse. The urethra remained enlarged, simulating the vaginal introitus. A Q-tip is in the actual vagina.

be caused by the predisposing fissures of seborrheic and atopic dermatitis with secondary infection.

C. Pinworm

Pinworm infestation is common in children. About 20% of cases are significantly symptomatic, usually with nocturnal itching and sometimes with abdominal pain. Scratching tears the skin and encourages reinfection. Nocturnal itching may also be the result of blankets that cause an increase in heat and moisture in cases of atopic dermatitis.

D. Condylomata Acuminata

Condylomata acuminata are often perianal in distribution. Their presence requires consideration of molestation. Even without molestation, it occurs in this area especially in children with atopic dermatitis, who are particularly susceptible.

E. Hemorrhoids and Trauma

True hemorrhoids are unusual in children and suggest a large pelvic cavernous hemangioma.

Trauma may be a result of molestation, foreign bodies, or an innocent accident. Prompt evaluation and reconstruction if needed usually result in healing despite contamination.

IX. POLYPS OF THE HYMEN AS A CAUSE OF LOCAL NONENDOCRINE BLEEDING

It is not unusual to find a prominent, fleshy hymen in the newborn, often with a polypoid posterior lip as a result

of maternal estrogen. After a week, these recede, with absence of estrogen. Occasionally, true polyps persist and may tear and bleed. Figure 6 shows large true polyps in a 1-week-old child. Even small polyps may persist. Polyps of the hymen are usually benign.

X. MALIGNANT AND BENIGN TUMORS OF THE VAGINA, UTERUS, AND OVARIES

A. Rhabdomyosarcoma

Malignant vaginal tumors are rare but potentially fatal. The victims, when first seen, always look in deceptively perfect health. The most common is rhabdomyosarcoma (56–58), which gynecologists call sarcoma botryoides. About 30 years ago, it was generally fatal within 2 years, and the only survivors were those whose tumors were discovered early and underwent pelvic exenteration. In recent years, with early discovery, local resection, and contemporary chemotherapy, the prognosis has been reversed, with the expectation of a cure in 85%. The tumor originates in the submucosal mesenchyme of the vagina and initially presents as a protruding polypoid mass and bleeding. Because the tumor surface is normal mucosa, even experienced physicians are misled. In addition, superficial biopsies may be misleading, because aside from the normal surface mucosa, a deep section is necessary. The pathological diagnosis requires more than one cell type and the dermis layer. The tumor usually develops in the upper anterior vaginal wall. The important fact is that although polyps of the hymen are usually benign, polyps that originate above the hymen are considered malignant until proven otherwise. Figure 7 shows a 6-year-old girl (most

Figure 6 Large true hymen polyps in a 1-week-old child

Figure 7 Vaginoscopy showed a polyp. On straining, the polyp protruded as seen here. The surface mucosa is normal vaginal mucosa. Under the normal mucosa of the apparently benign polyp is the very malignant mesenchymal rhabdomyosarcoma. Any vaginal polyp that originates above the hymen is considered malignant until proved otherwise.

are younger) who had staining for 3 days and a normal hymen. Vaginoscopy revealed a polypoid tumor. On straining, a polyp protruded with a normal vaginal mucosal surface whose origin was above the hymen. Early small rhabdomyosarcoma polypoid masses do not prolapse on straining, and this is not a reliable test. Resection of the polyp showed it to be a rhabdomyosarcoma. If the frozen section confirms the diagnosis, then it is advisable

to perform cystoscopy with the same anesthesia to detect possible bladder invasion.

Large vaginal rhabdomyosarcomas may suddenly protrude out of the vagina in grape-like clusters, sometimes after straining at stool. Figure 8 shows this occurrence in an 11-month-old child. Part of the tumor has become necrotic because of a vascular disturbance. Despite the lesion's size, the child was cured.

Figure 8 Large vaginal rhabdomyosarcoma protruding from the vagina. The grape-like cluster (so-called sarcoma botryoides) is noted. Part of the tumor is necrotic because of vascular disturbance.

B. Germ Cell Tumors

Endodermal (yolk sac) germ cell tumors (59, 60) are very malignant, midline body neoplasms. They tend to occur in the upper vagina and cervix (61) and cause bleeding but usually do not prolapse to the introitus. In the past 10 years, with contemporary chemotherapy, the previous usually fatal outcome has been reversed.

C. Adenocarcinoma

Clear cell adenocarcinoma (CCA) has been associated with female fetal exposure to maternal ingestion of diethylstilbestrol (DES) (62). Despite this discovery in 1971 and the discontinuation of DES for pregnant women, this cancer still occurs, although at a reduced rate. It is a cause of vaginal bleeding, and the tumor usually is not visible at the vulva.

DES is the first discovered, hormonal transplacental carcinogen. If given in the first trimester to a pregnant woman with a female fetus, DES can cause a CCA of the vagina or cervix at a delayed time, usually at or just after puberty.

DES became popular in the 1940s because it was the first synthetic, inexpensive oral estrogen. It is nonsteroidal.

There were 547 cases of CCA reported as of 1989. In about one-quarter of the cases, there was no history of hormonal exposure. The age range at discovery was 7–34.4 years, with 91% of patients between 15 and 27, and a median age of 19.0. This suggests a stimulation effect of puberty, especially because of a sharp, dramatic rise at age 14.

Before the use of DES, CCA was very rare and tended to occur in older women.

DES was used to treat women with a history of repeated spontaneous abortion. Such women tend to have affected children more than women taking DES without pregnancy losses.

About 60% of CCA are vaginal, usually in the anterior upper third. The remainder are on the ectocervix (portio). They are unifocal. CCA is fatal if untreated.

The risk of CCA in a DES-exposed female is 1:1000.

Benign changes are much more frequent, about 35% having vaginal adenosis (glandular, endocervical-type epithelium). About 25% have cervical structural abnormalities with cervical hoods, ridges, collars, pseudopolyps, or vaginal septa. All the benign changes occur more frequently with higher dosages of DES and with earlier use in pregnancy.

In early embryonic life, the paired müllerian (paramesonephric) ducts (with glandular, columnar, endocervical-type epithelium) form and fuse at about 8 weeks at the urogenital sinus, forming a tubercle or vaginal plate. The latter then grows cephalad as a solid core of squamous epithelium into the fused ducts. Later, the solid core canalizes to become the vagina. Usually, the separation of

the two types of epithelium is at the external os of the cervix.

DES, or any stilbene-type estrogen, prevents normal development of the genital epithelium. It can also cause abnormal proliferation of the adjacent connective tissue, resulting in gross structural abnormalities.

DES is considered an incomplete carcinogen, and there may be other unknown predisposing factors.

The benign and malignant changes are not found with steroidal estrogen exposure.

DES-exposed males do not have an increased risk of cancer. There are conflicting reports of possible benign anatomical and seminal abnormalities (62).

My personal speculation is that because DES is still used to fatten chickens and cows for slaughter, this may be a continuing source of ingestion because it can be stored in animal fat.

A very rare cause of vaginal malignancy is mesonephric duct remnant carcinoma.

D. Direct Vaginal Bleeding

Direct vaginal bleeding may also occur due to very rare benign vaginal (63) cervical (64) and vulvar tumors (65). Direct bleeding may result from benign (66) or malignant uterine tumors (67–69) or endometritis. Indirect bleeding may result from benign and malignant ovarian tumors (70–75) by hormone secretion, compression, and disturbance of uterine circulation or unknown mechanisms.

XI. COAGULATION DEFECTS AS A CAUSE OF LOCAL NONHORMONAL BLEEDING

Symptomatic coagulation defects are an unusual cause in children, and any vaginal bleeding is part of the overall body tendency to bleed.

The most common inherited bleeding disorder is von Willebrand's disease (VWD). The prevalence has been estimated to be as high as 1.3% of the general population based on a personal history of bleeding, decreased VW factor (VWF) activity, and a positive family history. It may even be higher especially in subjects with blood group O. Since screening tests (bleeding time) may not be reliable, some recommend that VW factor activity be measured initially in children with mucosal bleeding (76).

Affected children tend to have easy bruising, mucocutaneous bleeding (including epistaxis, oral, rectal, vaginal) and prolonged bleeding after trauma. It usually presents as menorrhagia, which may be significant beginning at menarche (77, 78). About 80% of patients have the mild types 1 and 2 A, 2B. These are autosomal dominant with variable phenotypic penetrance and expressivity. The severe types 2N and 3 are rare and recessive and sometimes occur in clusters in Israel, Sweden, and Iran (79). Type 1 shows a partial quantitative reduction of VWF levels. Type

2 varieties have qualitative mutant VWF protein. Type 3 involves almost complete absence of VWF protein (79). The diagnosis is not simple and repeated tests may be required. There are several confounding problems. Persons with blood group O have a 25% reduced level of VWF and Factor VIII. In addition plasma levels of both increase three- to fivefold with physiological stress, therapeutic estrogen, oral contraceptives, pregnancy, and possibly hyperthyroidism (80, 81). Furthermore, a personal and family bleeding history and low VWF ristocetin cofactor activity, which are the criteria for VWF Type 1, may not cosegregate with genetic markers at the VWF gene locus. The phenotype diagnosis identifies bleeding risk (82). In infancy von Willebrand factor is normally high and therefore the disease "can not be diagnosed with confidence . . ." (81, p. 278). The usual screening test is bleeding time, which may be prolonged and also occurs in cases of platelet dysfunction. There might be a prolonged activated partial thromboplastin time and a mild thrombocytopenia with type 2B VWD (79). Bleeding time has a low sensitivity. High shear system testing is superior (83).

In practice rapid immunoassay screening for von Willebrand disease type 1 had a low yield and limited ability to predict bleeding in surgery (84). More precise standard testing includes the plasma VWF factor protein level (VWF:AG), VWF ristocetin cofactor assay for functional activity (VWF:R Co), VWF ristocetin-induced platelet agglutination (RIPA), factor VIII, and circulating molecular weight profile of VWF (VWF multimeras) (79). Although desmopressin is usually used to treat VWD, about 10% of children fail to achieve an adequate response. Response should be tested measuring VWF:Ag, VWF:Ac, and factor VII:C at the time of diagnosis should there be a need for future surgery (85). Acquired von Willebrand's disease or syndrome (AvWD, AvWS) is rare, may suddenly appear without personal or family bleeding history, and with the same laboratory findings as congenital VWD. There are autoantibodies against von Willebrand factor. It is associated with lymph or myeloproliferative, autoimmune or cardiovascular disease, drugs and solid tumors (86, 87), and may be secondary to hypothyroidism. Childhood embryonal renal adenoma is associated with acquired polycythemia and von Willebrand's disease; preoperative testing is required (88).

Factor XI deficiency has a heterozygous frequency of 8% among Ashkenazi Jews. It has an inherited autosomal pattern. The normal plasma range is 70–150 IU/dl, with heterozygotes showing levels down to 15 IU/dl and homozygotes less than 15 IU/dl. It presents as menorrhagia or bleeding after a hemostatic challenge. Bleeding tendency does not always match plasma levels, and may vary over time. In addition there may be an additional associated von Willebrand's disease (89, 90).

With Glanzmann's thrombasthenia the initial bleeding occurs before 5 years of age. The frequent presentations

include epistaxis, gingival bleeding, posttraumatic bruises, menorrhagia (often requiring transfusions), and gastrointestinal and postoperative bleeding (91). It is a rare inherited hematological disorder of glycoprotein IIb–IIIa complex that disturbs platelet function (92). Most cases are discovered at menarche. Uterine packing has been used to stop adolescent bleeding (92).

Rarely there may be severe acute onset of a general tendency to bleed because of hypoprothrombinemia associated with a lupus anticoagulant (93).

Idiopathic thrombocytopenic purpura (ITP) is the most frequent acquired pediatric bleeding disorder. Most cases have only minimal bleeding and usually there is spontaneous recovery in weeks to months. The peak age is 4–8 years. It results from antiplatelet antibodies with the platelet count less than 20,000/m³ and a prolonged bleeding time. In apparently healthy children there is the sudden appearance of bruising, petechiae, epistaxis, and sometimes so-called wet purpura with mucus membrane bleeding resulting in uterine, gastrointestinal, and oral bleeding or blood blisters. There is often a preceding viral infection or live virus immunization (94). About 17% have major bleeding including intracranial hemorrhage, epistaxis, or gross hematuria. There is a suspicion that menstruation, infection, and risk factors for systemic lupus erythematosus may predict intracranial hemorrhage in children (95). Death may occur in children from undiagnosed immune thrombocytopenic purpura as an anesthesia complication from profound epistaxis (96). Thrombocytopenia is the most common complication of childhood typhoid fever (97). It may also occur as a congenital limb and bleeding disorder (thrombocytopenia absent radius syndrome) (98, 99). Occasionally with brucellosis there may be severe thrombocytopenia with purpura and mucosal site bleeding (100). The diagnosis of idiopathic thrombocytopenic purpura often overlaps with immune thrombocytopenic purpura. The acute form affects mainly children, whereas the chronic form is usually found in young adults (101). In children generally thrombocytopenia may result from viral infections (varicella, Epstein-Barr virus (EBV), rubella, mumps, measles, cytomegalic virus) by an immune reaction and cause a petechial rash. However, petechial bleeding may occur without thrombocytopenia in both bacterial and viral infections (meningococcus, streptococcus, echovirus, etc.) because of vasculitis or platelet dysfunction (102). Young women with essential thrombocytopenia have a low chronic risk of thrombohemorrhagic complications or acute leukemia (103).

Most vaginal bleeding in the newborn is due to the withdrawal of the maternal estrogen effect on the endometrium and is considered a physiological variant. Most neonatal bleeding problems are due to acquired coagulation disorder. Evaluation may be difficult because coagulation parameters are different from older children and adults and because of rapid changes (104).

Thrombocytopenia is the most common hematological abnormality in the newborn. It may occur in 1–4% of term births and in 40–72% of sick preterm newborns. The leading causes of alloimmune thrombocytopenia and thrombocytopenia are secondary to maternal and utero-placental factors and pre-eclampsia. It may present as diffuse petechial or mucosal surface bleeding. There may be intracranial bleeding (104–108). Other causes of general and mucous membrane bleeding in the newborn may be coagulation protein disorders due to factors VIII and IX, and vitamin K deficiency; disseminated intravascular coagulation (109); and vascular disorders such as intraventricular hemorrhage in preterm infants and vascular malformations with secondary thrombocytopenia (Kasabach–Merritt syndrome).

In the adolescent most abnormal vaginal bleeding is due to anovulatory dysfunctional uterine bleeding (DUB). About half of all girls at menarche do not ovulate and are at risk (109–111). The characteristic presentation is bleeding for 3–4 weeks due to irregular sloughing of thickened but fragile endometrium followed by 3–4 months of amenorrhea with reaccumulation of flimsy endometrium due to continuous estrogenic stimulation. Another pattern is complete irregularity of bleeding with confusing variations from normal. Ideally the following may be considered: complete blood count (CBC), and other coagulation tests; thyroid function tests; prolactin; human chorionic gonadotropin (hCG); comprehensive metabolic screen; as well as history, physical examination, vaginostomy, and perhaps pelvic sonography. Anovulatory dysfunctional uterine bleeding is usually managed with oral contraceptives (initially at high dosage) for hemostasis. If unsuccessful, intravenous Premarin is considered for initial hemostasis, especially if there is a thin, raw endometrium and, as a last resort a gentle dilatation and curettage of the uterus and Foley catheter balloon tamponade of the uterine cavity (112). The American College of Obstetricians and Gynecologists (ACOG) Practice Bulletin notes that “Anovulatory bleeding is a normal physiological process in the perimenarchal year of the reproductive cycle” (113). Nevertheless it indicates a 5–20% prevalence of blood dyscrasias in adolescents hospitalized for bleeding. Of course, this is a select group with heavy bleeding. Others consider DUB as abnormal (114). Clinically it is often difficult to decide whether the bleeding is simply DUB or due to significant pathology.

Abnormal vaginal bleeding may be the presenting symptom of a blood dyscrasia such as von Willebrand’s disease, factor XI deficiency, thrombocytopenia, platelet dysfunction (112, 115–117), or other factor deficiencies (118). Other causes of adolescent abnormal bleeding include leukemia, pregnancy and its complications, neoplasms (ovary, uterus, vagina), partial ovarian failure, severe liver and renal disease, forgotten tampons, pelvic inflammatory disease, and underlying causes of anovulation (119). Adolescents requiring hospitalization for men-

orrhagia have significant medical problems including anemia, anovulation, hematological disease (33%), effects of chemotherapy, and infection (120).

The most common malignancy of childhood is leukemia, which accounts for 35%. About 80–85% of leukemias are acute lymphoblastic leukemia (ALL). ALL is the most common specific childhood malignancy (30–35%). The clinical picture is truly acute: two-thirds have symptoms less than 1 month preceding the diagnosis. Initially there is lethargy, exhaustion, and anorexia. Later there is anemia, bleeding tendency (purpura, mucosal bleeding, hematomas), infections, hepatosplenomegaly, generalized lymphadenopathy, and bone–joint discomfort. There is a genetic susceptibility to chromosomal syndromes, DNA fragility, immunodeficiency syndromes, and neurofibromatosis. Nevertheless 99% of cases are of unknown causes. The peak incidence is between ages 2 and 5. Unfortunately there may be an initial normal complete blood count (CBC) and smear and therefore a bone marrow study may be required (121). Acute myeloid (non-lymphoblastic) leukemia causes 17% of cases of childhood leukemia (122, 123).

XII. EVALUATION

For prepubertal vaginal bleeding the history, physical examination and findings on vaginostomy will give an immediate diagnosis in 80–85% of cases (124).

A. History

It is important to obtain a reliable history from the mother, the child’s caretaker, and, if possible, from the child herself. Some suggestions follow.

The bleeding history is detailed: onset, color (bright red or brownish red, mixed with discharge), odor, amount, and continuation: course, pain, and association with scratching, wiping, urination, bowel movement, and tight clothing.

Inquiry is made about vulvovaginitis symptoms: vulvar itching, burning, and pain; vaginal discharge; rubbing; use of bubble baths, perfumed soaps, or deodorants; or wearing of tights, leotards, and ballet outfits. Dysuria caused by vulvitis presents as vulvar dysuria with external pain, a reluctance to void, a distended bladder, and occasionally acute urinary retention. Dysuria caused by cystitis–urethritis causes deep pain, frequency, urgency, and bladder spasms.

Has there been recent antibiotic, drug, aspirin or hormonal therapy or respiratory or skin infection? Does the child have allergies or general chronic skin disturbances, such as atopic or seborrheic dermatitis, eczema, or psoriasis? Does she have diabetes, chronic illnesses (kidney, hepatic, or intestinal), or immunodeficiency defect? Is there a coagulation disturbance?

Was there an acute trauma, such as falling from a play device or from standing on a chair? Could the child have

been molested (even by an adult male relative) and have been threatened if she reveals it? Is she left without supervision?

Was the pregnancy uneventful? Did the mother take any unusual medications? The family history includes the health of siblings and such illnesses as diabetes; atopic dermatitis, allergies, asthma, and eczema; bleeding disorders; immunodeficiency states; and malignancies.

B. Physical Examination

Before examination, as an educational device, I indicate to the child in the presence of the mother that only mothers and doctors are allowed to examine, look at, or touch children's "private parts." The mother is kept in the room to reassure the child. Try to communicate in a friendly fashion with the child to help her relax and create a non-threatening environment.

The panties are inspected for blood and discharge.

The physical examination begins with a general examination.

1. Are there signs of precocious puberty? Is there axillary or pubic hair? Is there mammary tissue on palpation, or do the breasts seem enlarged because the child is chubby?
2. Does the child seem irritable? Does she scratch herself generally? Is there white dermatographism? Are there signs of general skin disease, especially seborrheic or atopic dermatitis characterized by erythematous fissures behind the ears with flaking; scalp margins and paranasal erythematous greasy scales; pityriasis alba of the face; prominent lower eyelid skin folds (Morgan's folds) with white edematous edges; keratosis pilaris of the outer arms and thighs, eczema of the elbows, wrists, and popliteal space; and ichthyosis of the legs? Are there signs of psoriasis or chicken pox? Are there skin infections? Is there pharyngitis, rhinitis, or cough? Is there adenopathy (cervical, axillary, or inguinal), abdominal masses, or ecchymosis?
3. Are there petechiae, ecchymoses, hepatosplenomegaly, abdominal masses, cervical, axillary or inguinal adenopathy, anemia or abnormal blood vessels (telangiectasias)?

The frequent local nonhormonal bleeding areas that require attention in the physical examination are listed in Table 2.

As a minimum, the vulva must be visualized. Further office testing must be individualized in accord with the reaction of the child, source of bleeding, experience of the physician, appearance of the vulva, history, and perceived seriousness.

The child may be placed in small stirrups in dorsal lithotomy position or in frog leg position on the exami-

Table 2 Frequent Causes of Nonhormonal Bleeding According to Site

Urethra: prolapse urethra (necrotic, sloughing)
Anus: deep fissure (pain, skin tag edema)
Vulva (inspection with good light and gentle retraction)
Trauma
Skin disease and lesions
Fissures (associated with seborrheic and atopic dermatitis and lichen sclerosus)
General ecchymoses (coagulation defect)
Hymen polyp
Inspection of distal vagina
Vaginal discharge
Vaginal bleeding
Vaginal bleeding
Severe Streptococcus A vaginitis (usually upper vagina)
Foreign body (usually rolled-up wads of toilet tissue causing a foul, bloody discharge)
Rhabdomyosarcoma (rare but very malignant with only drops of blood)

nation table or in the lap of the mother, who sits on the table. A good cold light is necessary.

The labia majora are gently held apart and downward to permit adequate inspection. Sometimes, the child's hands can be used by the examiner as retractors to reduce anxiety. Careful inspection requires a trained eye. One method is to start anteriorly and proceed posteriorly, viewing the mons pubis; presence of hair; erythematous fissures in the midline anterior to the clitoris, then between the labia majora and minora symmetrically, in the midline perineum (between vagina and rectum), radially around the anus, and in the midline posterior to the anus; clitoris; urethra; hymen and its orifice; vestibule (just outside the hymen); posterior fourchette; perineum; perianal area; and groin and the adjacent buttocks. Very often the distal vagina can be visualized.

If the site and cause of the bleeding can be identified by visualizing the exposed vulva, then the examination may be discontinued. If these are not apparent, then further investigation is needed and examination under anesthesia may be required to avoid anxiety, thrashing, and resistance by the child.

Placing a Q-tip in the vagina may show blood and indicate the vaginal source of bleeding. Another device is an eye or medicine dropper. Vaginal secretion may be tested for Papanicolaou cytology, bacterial culture, Gram's stain, gonorrhea culture, *Chlamydia* culture, saline wet mount (for motile trichomonads, white blood cells, lactobacilli, "clue" cells of *Gardnerella* bacterial vaginosis), and 10% potassium hydroxide wet mount for *Candida*. Cytology is not reliable to rule out a vaginal malignancy. Cytological maturation index (MI) is helpful in evaluating

estrogen activity. The usual anestrogenic prepubertal child has an MI of 0% superficial, 0% intermediate, and 100% parabasal cells. Superficial vaginal cells are large, flat, and polygonal with a small pyknotic nucleus and are indicative of the presence of estrogen. In England and Canada, laboratories often reverse the MI sequence and report parabasal, intermediate, and superficial vaginal cells. The newborn has a temporary estrogenic smear of superficial vaginal epithelial cells because of in utero maternal estrogen exposure.

Although not as reliable as an early morning swab, a clear cellophane type of perianal swab may be made to check for microscopic pinworm ova and to show the mother how to do it at home in the early morning.

Bimanual rectal examination usually cannot detect toilet tissue wads in the vagina but can detect a hard vaginal foreign object, a normal cervix, a firm vaginal tumor mass, and the lower pole of an ovarian neoplasm (the infant's ovary is pelvic). It might "milk out" vaginal discharge or bleeding.

With a cooperative older child, the "knee-chest" position may result in a ballooning out of the vagina to permit visualization of the distal two-thirds of the vagina with a hand-held light (see Fig. 9).

If the bleeding source is not apparent from visualization of the exposed vulva and distal vagina or if a Q-tip inserted into the vagina produces bleeding, then vaginoscopy is appropriate. There may be a specific severe infection (*Streptococcus A*), a foreign body (rolled-up wads of toilet tissue), or a malignant and potentially fatal neoplasm. Vaginoscopy is done generally for the suspicion of significant trauma, foreign body, neoplasm, congenital anomaly, or persistent vaginitis.

Unfortunately, no standard vaginoscope is in use. The vaginoscope instruments that have been used include a simple tube with obturator; a Cameron-Miller tube with obturator, distal light bulb, magnifying glass; a fiberoptic Storz instrument; a hysteroscope; a cystoscope; or a miniature bivalve speculum. Miniature alligator forceps to remove foreign bodies, and long microsurgical instruments should be available for biopsy and local excision of tumors. Experience is required for operative procedures.

Sometimes observation vaginoscopy can be done as an office procedure; however, operative vaginoscopy is best done in an operating room with general anesthesia by an expert pediatric anesthesiologist.

If there is an expectation of a malignant vaginal tumor, then a frozen section is considered and cystoscopy with biopsy may be done with the same anesthesia to check for spread.

Abdominal and pelvic ultrasound are considered for the suspicion of a neoplasm, large or rigid foreign body, and congenital anomaly (therefore the kidneys require imaging). Rolled-up wads of toilet tissue and small vaginal malignant neoplasms may not be able to be imaged. Adrenal enlargements may require computed tomographic

Figure 9 Knee-chest position for visualizing the vagina in the cooperative older child using a hand-held light. (Reproduced with permission from Emans SJ. Section 11. Gynecology. In: Avery ME, First LR, eds. *Pediatric Medicine*. Baltimore: Williams & Wilkins, 1989:652).

(CT) imaging. The addition of MRI may be helpful for congenital anomalies and neoplasms.

X-rays are to be avoided if possible.

Clinical coagulation defect as a cause of vaginal bleeding is unusual in children but is important in adolescent menorrhagia. For suspicion of coagulation defect consider: CBC, platelet count, prothrombin time, partial thromboplastin time, bleeding time, and von Willebrand tests. For more extensive testing consider platelet function, plasma coagulation factors, circulating anticoagulant, fibrinogen, functional protein C and S, or hematology consultation.

XIII. CONCLUSION

Vaginal bleeding is unusual in children. It creates great anxiety in the child and her parents. The vast majority of bleeding is caused by local, nonhormonal causes. Bleeding requires prompt investigation to determine the site, cause, and management.

The special concerns include precocious puberty, sexual molestation, and malignancy.

If required for the diagnosis of blood coming from the vagina from a site that cannot be visualized externally, vaginoscopy under general anesthesia (if necessary) is appropriate.

Hirsutism, Polycystic Ovary Syndrome, and Menstrual Disorders

Songya Pang

University of Illinois at Chicago College of Medicine, Chicago, Illinois, U.S.A.

I. INTRODUCTION

Skin, muscle, and the reproductive system are major target sites of excess androgens in adolescent and young women. Androgen excess symptoms in peripubertal and postpubertal girls include hirsutism, acne, virilization or masculinization, and menstrual disorder. Hirsutism is defined as excess body hair growth in females, involving primarily areas of the face, chin, neck, midline chest and abdomen, upper and lower back, buttocks, and inner aspects of the thigh. In general, hirsutism by itself is a mild symptom of androgen overproduction or enhanced androgen metabolism/action in the skin tissue. Increased androgen activity in the sebaceous and apocrine glands is likewise associated with development of acne vulgaris. The androgen activities of hair follicles and sebaceous glands of the skin are not necessarily identical and vary greatly between sites (1). This may explain the heterogeneous expression of cutaneous hyperandrogenic symptoms, such as hirsutism alone, acne alone, or hirsutism and acne together as symptoms of androgen excess or enhanced androgen activity in the skin tissue (2). The clinical expression of androgen excess symptoms does not always correlate with the degree of androgen production or circulating androgen levels. This suggests that androgen metabolic activity in the target tissue is in part governed by a local tissue mechanism

Hypertrichosis is characterized by generalized increased fine body hair with no special preferential sites. This condition is generally not associated with androgen overproduction. Either genetic or ethnic influences on body hair growth may be a contributing factor in hypertrichosis. In some cases, however, hypertrichosis may be the early manifestation of mild androgen excess or is induced by chronic ingestion of drugs that alter hair growth directly or indirectly via the influence on the local or systemic metabolism of certain androgens. Clinically, the

more severe androgen excess symptoms involve skin and muscle, as well as the reproductive system, and are termed virilization or masculinization. These include some or all of the following symptoms of hyperandrogenism: clitoral enlargement, masculine body habitus, temporal hair loss, voice changes, breast atrophy, and menstrual disorders (3). Virilization and masculinization are usually manifestations of significant pathology causing androgen overproduction in women.

Excess androgen-producing pathologies in young women are a well-known cause of menstrual disorder. However, many other disorders unrelated to hyperandrogenism cause menstrual disorders in young women. This chapter elaborates the physiology of androgen metabolism in women and disorders of androgen production and action resulting in the manifestation of androgen excess symptoms in young women. In addition, a review of the known causes of menstrual disorders unrelated to excess androgen disorders and their management in adolescents and young women is summarized.

II. PHYSIOLOGY OF ANDROGEN METABOLISM

A. Bioactivity of Androgens

Androgenicity is the term used to describe the bioactivity of a steroid that produces masculine characteristics. The bioactivity of androgens in a laboratory is measured by either determining an exogenous steroidal effect of a known quantity on the weight increase of the seminal vesicle or prostate of castrated male rats or mice, or by measuring the growth of a cock's comb (4). The androgenicity determined by these methods provides its bioactivity only in relation to one end point.

Essentially all androgenic steroids are C-19 steroid compounds and their biopotency is dependent on the presence of a 17-oxygen function of a 17-hydroxyl group in its configuration (4). Naturally occurring C-19 compounds that possess a 17-hydroxyl group are testosterone (T), 5 α -dihydrotestosterone (DHT), and 5 α -androstenediol (Fig. 1). T and DHT are almost equally biopotent androgens, based on the bioassay described above (5) (Table 1). The bioaction of T and DHT results from the binding of the androgen intracellularly to the androgen receptor protein, which transfers the androgen to the nucleus where the messenger RNA for the androgen becomes expressed. 5 α -Androstenediol is significantly less biopotent than T or DHT due to lack of a 3-oxo group in its configuration. T and DHT are the most important androgens, but other clinically significant androgens are androstenedione (Δ^4 -A) and dehydroepiandrosterone (DHEA) which are 17-oxo steroids. These steroids by themselves have considerably reduced or smaller androgenic activity than T or DHT due to the lack of a 17-oxygen function and/or 3-oxo configuration (Table 1). These androgens *in vivo* are required to be metabolized to T and DHT for its androgen action. Nevertheless, these weak androgens are important precursor steroids in androgen biosynthesis and bioaction. Other C-19 steroids like 11 β -hydroxy-androstenedione and androstenediol are circulating in the plasma of women. However these steroids are clinically insignificant in androgenic activity due to their low concentration or lack of bioactivity (6).

B. Androgen Metabolism in Normal Females

Both adrenal cortical and ovarian tissue possess $\Delta 5$ and $\Delta 4$ steroidogenic pathways for androgen biosynthesis (Fig. 1). Thus the adrenal cortex and ovaries are important sources of androgens from an early peripubertal age. Androgens and other C-19 steroids are either directly secreted by the glands or they may arise by extra-adrenal/extra-ovarian conversion of precursor steroids. The rate of androgen production generally influences the circulating levels of androgens.

1. Adrenal Androgen Secretion

A simplified schematic pathway for adrenal androgen biosynthesis is shown in Figure 1. Cholesterol side chain cleavage enzyme (P450 SCC) and steroidogenic acute regulatory (StAR) protein are essential for the transformation and transfer of cholesterol to the intramitochondrial membrane, respectively, for the formation of pregnenolone. Pregnenolone and progesterone are metabolized to androgens by 17-hydroxylation. The 17-side chain cleavage of the 17 α -hydroxypregnenolone (Δ^5 -17P) leads to the formation of DHEA. DHEA will be converted to Δ^4 -A by 3 β -hydroxysteroid dehydrogenase/isomerase activity or could be converted to DHEA-sulfate (DHEA-S) by sulfakinase activity. The major androgens secreted by the human adrenals are DHEA, DHEA-S, and Δ^4 -A. The

zona reticularis is very active in the 17-side chain cleavage of Δ^5 -17P or 17 α -hydroxyprogesterone (17-OHP) to form androgens. DHEA and DHEA-S are mainly the products of zona reticularis while Δ^4 -A and T are secreted by both zona reticularis and zona fasciculata (7–9). Under normal circumstances, smaller quantities of T and even smaller amounts of androstenediol are secreted by the adrenals (6). Secretion of all adrenal androgens increases from midchildhood onward as the histological development and hormonal biosynthesis of the zona reticularis matures. These then reach a relative plateau toward the completion of pubertal maturation (10) and remain stable throughout young adulthood. At the fourth to sixth decade of life, adrenal androgen secretion normally declines (adrenopause) without significant change in cortisol secretion. This event is independent of menopause event (11).

Corticotropin (ACTH) is the major tropic hormone for adrenal androgen biosynthesis and secretion (7). There are, however, clinical situations in which disparity in adrenal androgen and cortisol secretory patterns suggests the potential for an additional regulatory factor for adrenal androgen synthesis (12, 13). Of several factors proposed in the past as influencing androgen synthesis, prolactin appears to play a role only in its excess state (14, 15) while the role of insulin and insulin-like growth factor I (IGF-I) in adrenal androgen biosynthesis is yet to be proven. However, the role of gonadal sex steroid and growth hormone has been disputed (16, 17). In addition, no tangible evidence for a pituitary tropic factor other than ACTH capable of stimulating adrenal androgen secretion has been adequately demonstrated to date. Recent studies have uncovered intimate contacts between adrenal cortical nerve endings and adrenal steroid-producing cells (18, 19) and interwoven adrenal cortical and medullary cells (18, 20). This suggests that these contacts may mediate paracrine interactions (18). It is further suggested that adrenal androgen secretion may be regulated through an intricate network involving intra-adrenal neuroimmunoregulation (18). Such regulations may involve cytokine-dependent and cytokine-independent mechanisms as well as the so-called cross talk between adrenal androgen-secreting cells of the zona reticularis and the sympathetic adrenal system and between the adrenal gland and the cellular component of the immune system (18). Presently, however, no apparent link or relationship has been demonstrated between the concept of intra-adrenal neuroimmunoregulation and the pathophysiology of the disorder of increased adrenal androgen secretion. Likewise the role of a local corticotropin-releasing hormone and ACTH system reported on DHEA secretion in human adrenals needs further verification at this time (21).

Under ACTH regulation, adrenal androgens are secreted synchronously with that of cortisol in both the episode of secretion and the circadian pattern (22, 23) (Fig. 2). DHEA and Δ^5 -17P concentrations are thus normally higher in early morning and decline throughout the day

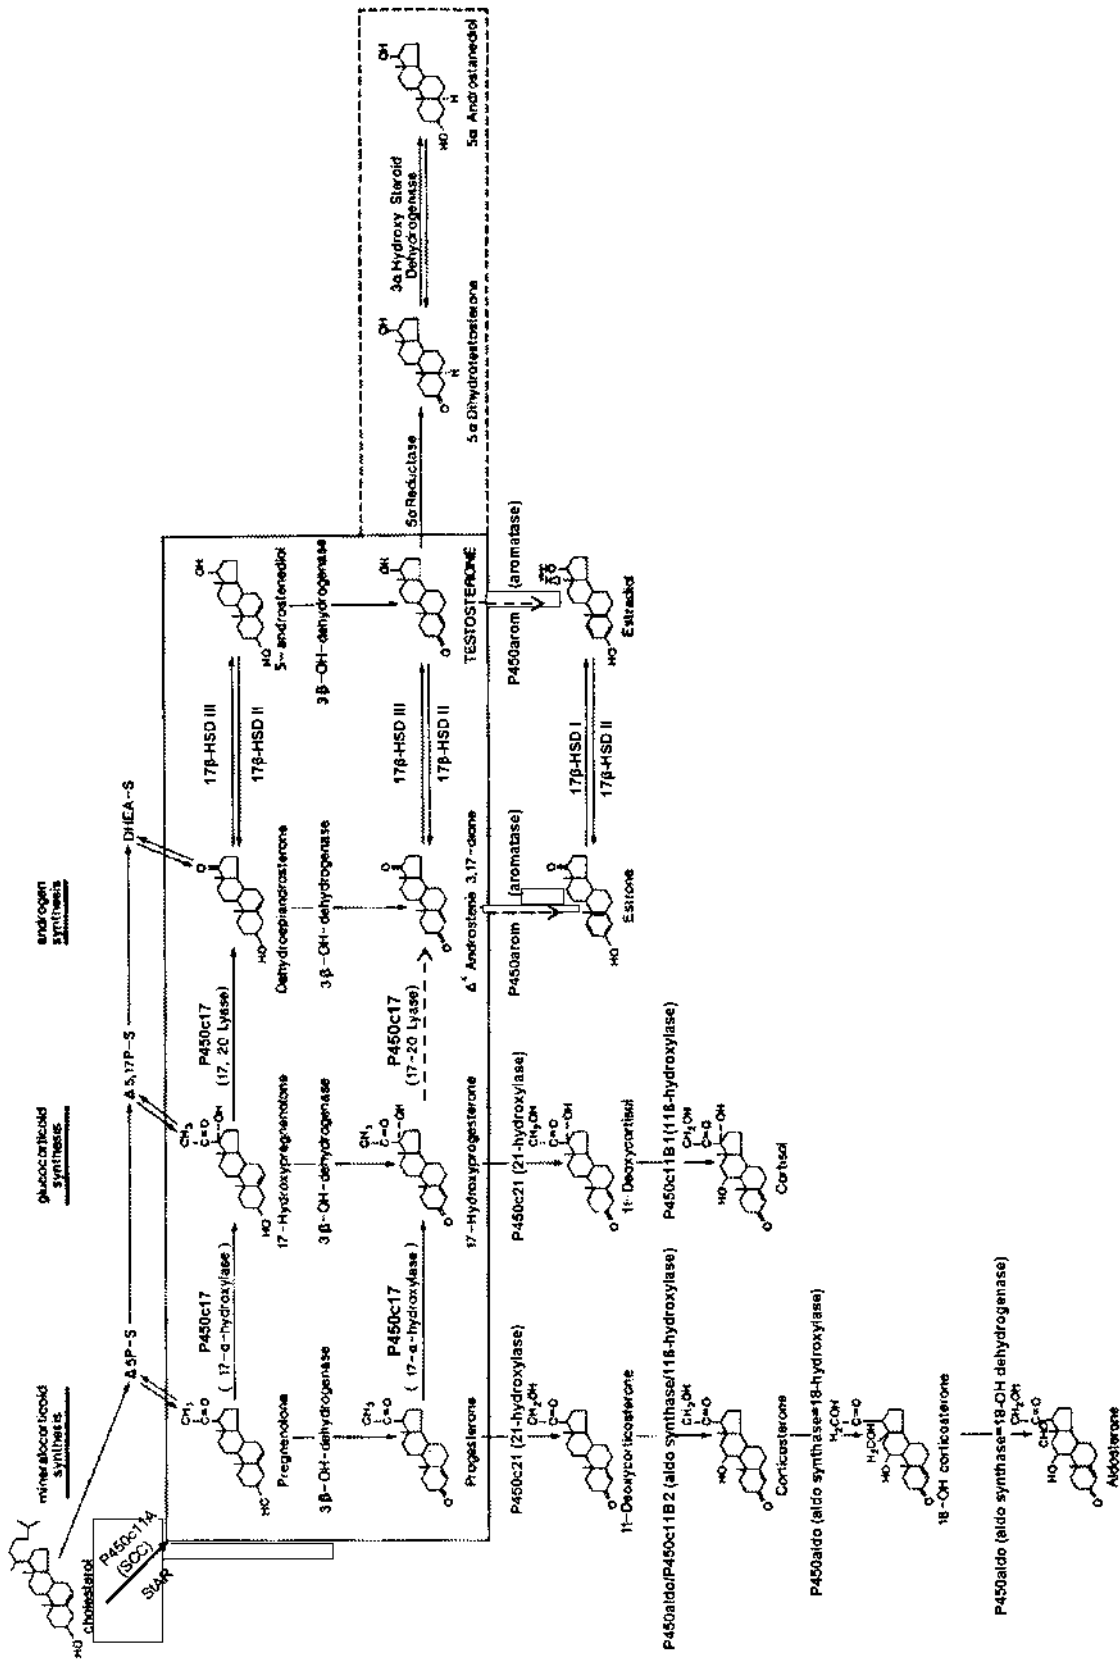

Figure 1 Steroid biosynthetic pathway. The pathway within the solid lined box occurs in both adrenal cortical and ovarian tissue. SCC, P450 cholesterol side chain cleavage enzyme; StAR, steroidogenic acute regulatory protein; 3β-OH-dehydrogenase, 3β-hydroxysteroid dehydrogenase; 17β-HSD, 17β-hydroxysteroid dehydrogenase.

Table 1 Androgen Biopotency, Sources of Androgens in Normal Females, and Plasma Concentrations of Bound and Free Testosterone in Females and Males

Normal females		DHEA	DHEA-S	Δ^4 -A	T	DHT	5 α -Andro	Andro	Etio
Biopotency in a bioassay	In relation to T (%)	10%	—	20%	100%	\approx 100%	60%	10%	0%
Daily secretion rate (mg/day)		0.8–8	5–7.7	3–3.8	0.35–0.5	—	—	—	—
Adrenal secretion (%)		90%	>99%	40–66%	50–60%	—	—	—	—
Ovarian secretion (%)		10%	<1%	34–60%	34–50%	—	—	—	—
Blood production rate (mg/day)	Secretion + metabolism	6–16	8–16	3.3–3.4	0.23–0.34	—	—	—	—
Contribution to plasma concentration	Adrenals (%)	67%	90%	30–60%	20–26%	—	—	—	—
	Ovaries (%)	8%	0%	30–56%	14–20%	—	—	—	—
	Peripheral (%)	25%	10%	<0.1%	60%	—	—	—	—
Representative total plasma T concentration	Female (ng/dl)				49				
	Male (ng/dl)				810				
SHBG-bound T	Female: ng/dl (%)				39 (80%)				
	Male: ng/dl (%)				486 (60%)				
Albumin-bound T	Female: ng/dl (%)				9.3 (19%)				
	Male: ng/dl (%)				307 (38%)				
Free T concentration	Female: ng/dl (%)				0.7 (1%)				
	Male: ng/dl (%)				22 (2%)				

DHEA, dehydroepiandrosterone; DHEA-S, dehydroepiandrosterone-sulfate; Δ^4 -A, androstenedione; T, testosterone; DHT, dihydrotestosterone; 5 α -Andro, androstenediol; Andro, androsterone; Etio, etiocholanone.

Source: data derived from Refs. 5, 25–31, 35, 47.

(23). 17-OHP and Δ^4 -A concentrations in normal women also tend to be higher in the morning hours than thereafter because of the adrenal contribution (23). However, the circadian difference in 17-OHP levels is lessened during the luteal phase of the menstrual cycle when ovarian 17-OHP production is increased. DHEA-S, on the other hand, shows very little circadian or episodic variation in plasma concentration due to the slow rate of clearance of the sulfate (23, 24). Its plasma concentration is 300–400 times greater than that of unconjugated DHEA due to high secretion by the adrenals and low clearance of this conjugate (23). DHEA, DHEA-S, and Δ^4 -A are further metabolized to etiocholanolone and androsterone. 11 β -OH androstenedione and a small amount of cortisol are metabolized to 11-oxy, 17-oxy steroids. These metabolites of C-19 steroids are generally excreted in the urine as 17-ketosteroids (17-oxo-steroids).

The adrenal contribution of androgens in relation to overall androgen production and circulating concentration in women is depicted in Table 1 (25–31). Circulating DHEA and DHEA-S are directly from the adrenal secretion contribution. The adrenals and ovaries from puberty onward secrete approximately equal amounts of Δ^4 -A. The androgens secreted by the adrenal cortex and ovaries undergo peripheral metabolism and contribute to the blood

production rate of androgens. Under normal circumstances, peripheral contribution to the blood production of DHEA, DHEA-S, and Δ^4 -A is small. The major source of T blood production in women is via peripheral conversion of Δ^4 -A (27, 28) (Table 1). The blood production rate of Δ^4 -A is 10–15 times that of T and the rate of fraction of the blood Δ^4 -A pool conversion to the blood T pool is 5.6% (27, 28). Therefore, approximately 60% of circulating T production is derived from the circulating Δ^4 -A. Consequently, the conditions associated with increased Δ^4 -A production would simultaneously increase the blood production of T (Table 1).

2. Ovarian Androgen Secretion

The principal sites of steroid synthesis in ovarian tissue are theca cells, the granulosa cells of the follicle, and the corpus luteum. The pathway involving Δ^5 and Δ^4 steroid biosynthesis process in the ovarian cells is similar to that described for the adrenal cortex (Fig. 1). Ovarian androgen synthesis occurs mainly in the theca cells, stroma cells, and the corpus luteum under LH stimulation (32–34). The ovary further aromatizes the androgens to estrogen in the granulosa cell layers through FSH stimulation. The granulosa cells regulated by FSH and estrogen thus

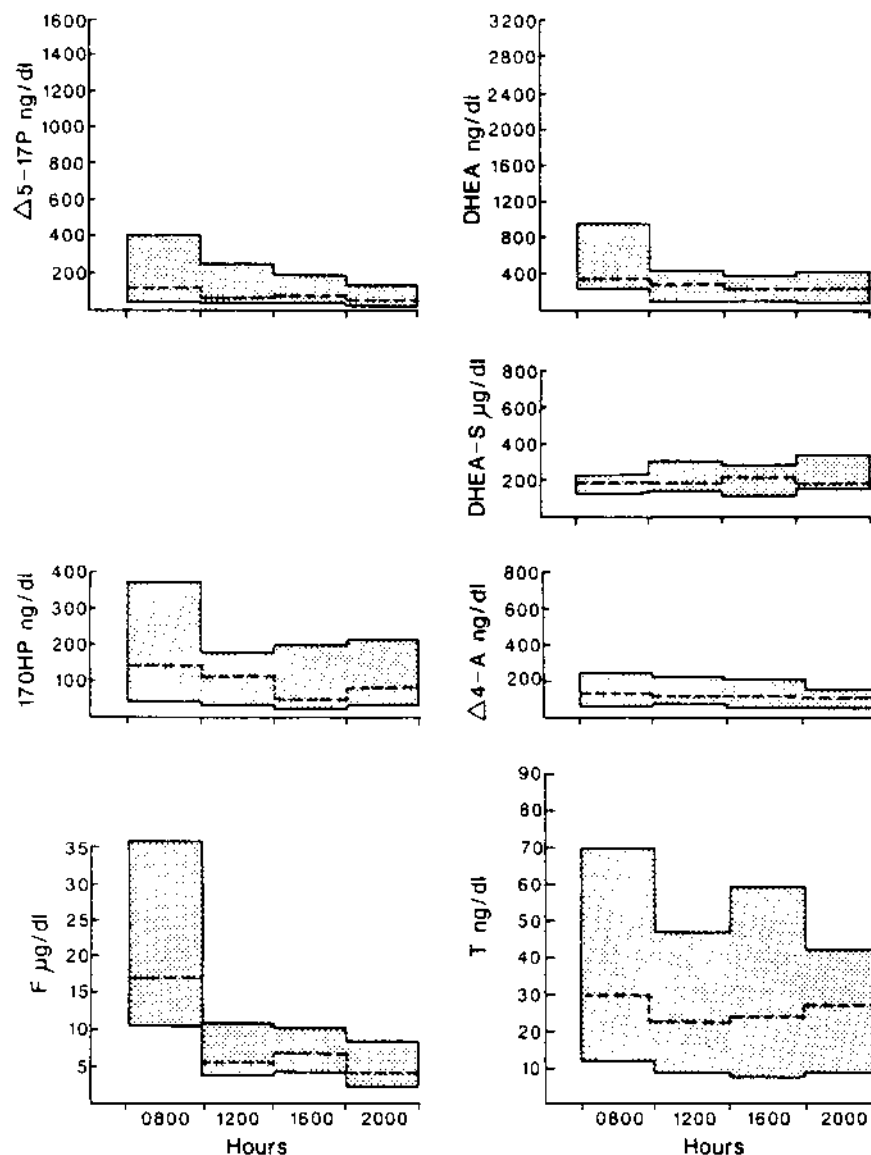

Figure 2 Representative circadian patterns of adrenal and gonadal steroids in normal women. $\Delta 5$ -17P, 17 hydroxypregnenolone; $\Delta 4$ -A, androstenedione; F, cortisol; T, testosterone; 17-OHP, 17 α -hydroxyprogesterone. (Modified from Pang S et al. *J Clin Endocrinol Metab* 1985; 60:434. Reproduced with permission from the Endocrine Society, Bethesda, MD.)

largely produce estrogens. Progesterone is secreted largely from the granulosa cells of the late follicular and midcycle phase and by the corpus luteum derived from granulosa cells (32, 33).

The major androgens secreted by the ovaries are Δ^4 -A and T (Table 1). The amount of androgen secreted by the ovary is far greater than the amount of estrogens produced. The ovarian source of androgen also increases gradually with the onset of gonadarche. Following menarche, ovarian androgen secretion appears to alter throughout the cycle. The secretion of T and Δ^4 -A into the ovarian vein is at its highest when estrogens are being

maximally secreted. The effect of variable production of androgen by the ovary on the contribution in plasma is to some extent masked by the adrenal source of androgens and by interconversion that occurs after secretion (35). Peripheral concentration of Δ^4 -A and T levels was higher at midcycle due to the ovarian contribution (36, 37), although others reported higher Δ^4 -A and T levels in the luteal phase of normal women (38). Our recent study of steroid concentration throughout the cycle of normally menstruating women, however, revealed no statistically significant changes of most androgens throughout the cycle (39). The ovarian contribution of androgens to the

overall blood production rate and circulating androgen concentration in plasma pool is shown in Table 1. In general, the amount of ovarian Δ^4 -A and T secretion is similar to that of adrenal secretion, thereby contributing equally in the blood production and concentration of these androgens. In the periovulatory phase, 65% of blood production rate of Δ^4 -A is contributed by the increased secretion of the ovarian source of Δ^4 -A (6). The ovaries contribute very little to DHEA production and none to DHEA-S. With menopause, ovarian Δ^4 -A production declines (40) and aging probably diminishes overall androgen secretion by the ovary (6).

Recent *in vitro* and *in vivo* studies indicate insulin action on ovarian steroidogenesis (41, 42). Insulin interacts with gonadotropin in an additive or synergistic manner in both normal and polycystic ovaries (41, 42). Insulin action in the ovaries is mediated by the insulin receptor and not by cross-reaction with the type 1 IGF receptor (41). The mechanism of intraovarian insulin signaling is unknown. Insulin in excess amounts may also enhance LH secretion in addition to modulating LH effect on ovarian androgen synthesis or may potentiate 17 α -hydroxylase and 17,20 lyase activity in ovarian steroidogenesis (41, 42). The interaction of excess insulin with LH appears to contribute to premature arrest of follicle growth and also in amplifying thecal cell androgen production (41). Thus, normal ovarian steroidogenesis would require appropriate regulation and interaction between the pituitary tropic factor(s) and systemic metabolic factor(s) at the intra-ovarian cellular level(s) for the appropriate signaling of normal ovarian steroidogenesis.

C. Bioactive Androgens in Blood

The circulating sex steroid hormones are in part present in a protein-bound form and in part in a free form unbound to protein (Table 1). The specific binding protein with a high affinity for sex steroids, (e.g., testosterone/estradiol) are called sex hormone-binding globulin (SHBG). The biologically active T includes both the free and albumin-bound fractions while SHBG-bound androgens are not readily available for bioaction (43). Approximately 1% of the circulating T and DHT in normal females is unbound (Table 1) (44). This unbound T freely diffuses into the target cells to bind to the androgen receptor. At puberty SHBG concentration falls slightly in girls while a greater drop in concentration is noted in boys (35). SHBG concentration is decreased by the androgens and in obesity, and is increased by estrogen (45). Estrogen, by its action of increasing the concentration of SHBG, decreases biologically active free fractions of androgens (35). Thus a hyperandrogenic state further causes availability of the free bioactive form of T. The increased availability of free T or DHT to the target cells by the decrease in SHBG in the presence of normal circulating total T levels may be a pathogenic mechanism of hirsut-

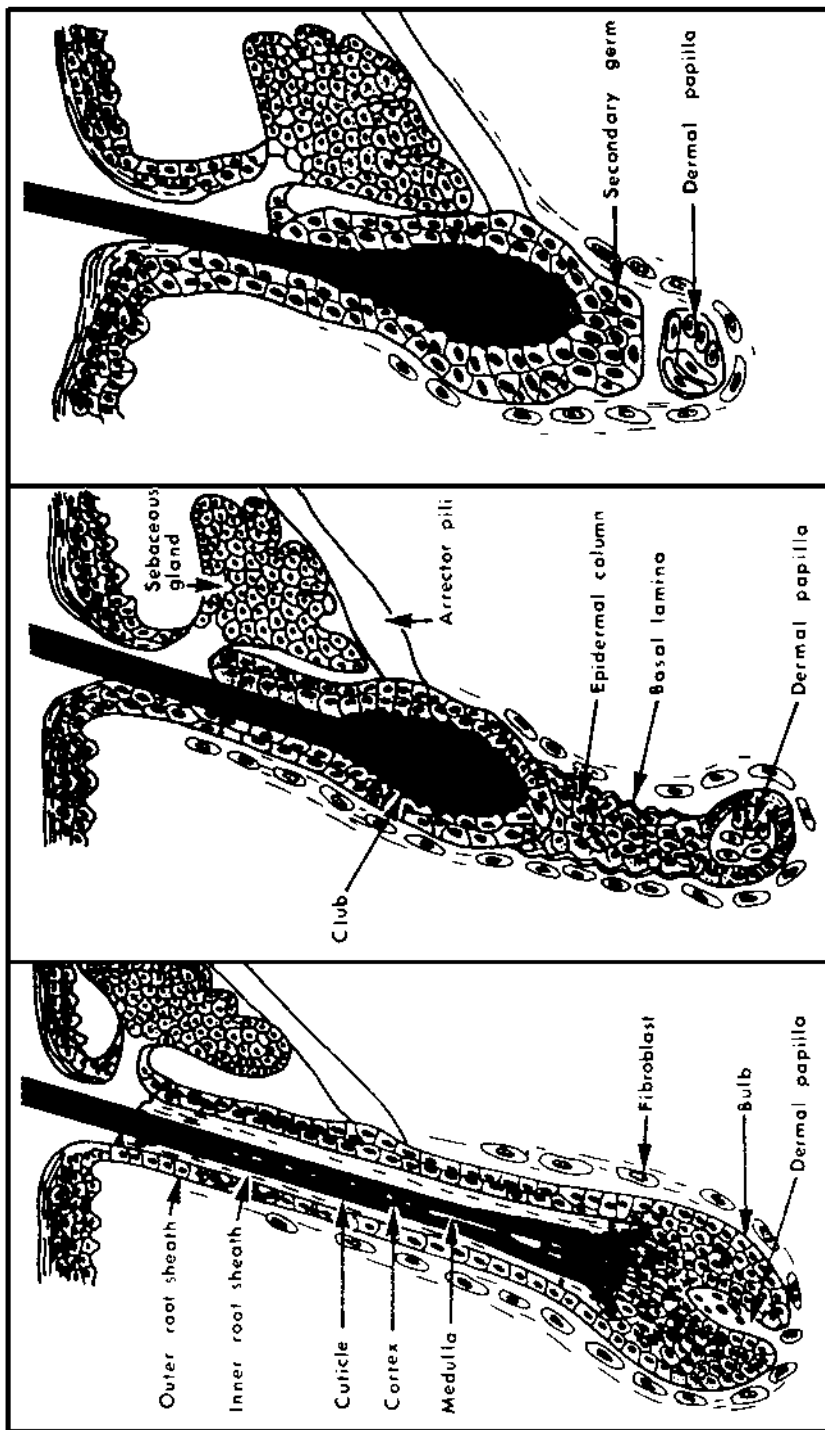

ism in women (46). The binding of DHEA and Δ^4 -A to SHBG in circulation is negligible (47).

III. PHYSIOLOGY OF HAIR GROWTH, PROPOSED INTRADERMAL IMMUNOREGULATION, AND SKIN ANDROGEN METABOLISM

Hair growth on the face, neck, trunk, extremities, and pubic and axillary region are androgen dependent. Androgen stimulation in these androgen-dependent areas promotes terminal hair growth, which is thick, long, and dark. The hair follicle undergoes lifelong transformations between telogen (resting), anagen (growth), and catagen (apoptosis-driven regression) (48, 49), which are distinct yet transitional periods (Fig. 3). During anagen, formation of the hair by proliferation and pigmentation of cells occurs from an epidermal matrix of the hair bulb. The catagen stage begins at the termination of anagen, followed by telogen (48). However, substantial metabolic and proliferative activity is noted during telogen, indicating that telogen is not a mere resting stage (49). Generally, in males the duration of anagen for the moustache is 4 months, and for thigh hair it is 2 months. In females, the duration of anagen for thigh hair is less than 1 month (50). The length of the hair is influenced by the length of the anagen phase, which is by comparison more important than the rate of hair growth. The longer thigh hair in men is thus attributed to the longer anagen period. The telogen phase of facial hair is 2–3 months. The growth cycle of the moustache is therefore 6–7 months or more at the very least, and more than 3 months for thigh hair (51). Duration of the hair cycle differs, therefore, depending on location.

Hair follicle development or cycling is controlled by an intrafollicular so-called hair cycle clock of an as yet unknown nature (49), which can be altered by systemic or metabolic (hormones), immunological (cytokines), and nerve-derived (neuropeptides/neurotransmitters) factors *in vivo* (18, 49). The hair follicles contain stem cells in the bulge or bulb area that migrate to the hair matrix for division and differentiation, which are controlled by a family of cytokines, produced from the dermal papilla cells (52). Androgen-dependent hairs have androgen receptors in the dermal papilla cells and some cells of the inner and center sheaths of the hair follicle (52).

Androgens influence the synthesis and release of cytokines from the dermal papilla cells and control hair growth (52). They also most likely prolong the growth of hair by lengthening the duration of anagen, as evidenced by reduction of the length of hair by antiandrogen treatment in hirsute women (53). Androgen-dependent hair growth is influenced not only by the amount of androgen delivered to the target cells but also by the target cell response to the androgen. In some instances, peripheral target cell response may even be more important in the manifestation of androgen excess symptoms, since no cor-

relation has been found between the rate of hair growth and circulating total, protein bound, or free T (54).

Androgen bioaction at the cellular level involves the uptake of pre- or active hormone and conversion to DHT, which binds to a specific receptor protein, and then transfers to the nucleus (55) (Fig. 4). All skin structures, including epidermis, sweat and sebaceous glands, hair follicles, and dermis possess 5 α -reductase activity and 3 β -hydroxysteroid dehydrogenase- $\Delta^5 \rightarrow \Delta^4$ isomerase and 17 β -, 3 β - and 3 α -hydroxysteroid dehydrogenase activities (56) (Fig. 4). Immunolocalization study in normal skin and acne skin revealed the predominance of type I 5 α -reductase isoenzyme in the sebaceous gland and type 2 5 α -reductase in the companion layer of the hair follicle and granular layer of epidermis (57). Human skin thus has the capacity not only to convert T to DHT but also to convert the precursor weak androgens DHEA to Δ^5 -androstenediol or to Δ^4 -A, which in turn is converted to T and eventually to DHT. DHT is then further reduced to 3 α -androstenediol (3 α -Adiol) and its glucuronide (gluc) (Fig. 4). The measurement of circulating concentrations of DHT does not reflect the metabolic activities of androgens in peripheral tissue. Only a fraction of this peripherally formed androgen escapes into circulation: most of it is further metabolized *in situ* (58, 59) (Fig. 4).

Glucuronidation is one of the effective disposal mechanisms in skin tissue (60, 61). 3 α -Adiol and its gluc have been reported to be a good marker of peripheral skin androgen activity. Circulating concentrations of serum 3 α -adiol and its gluc were reported to be increased in hirsute women (62–64). Studies from our laboratory indicate that serum 3 α -Adiol gluc levels were significantly correlated with the degree of hirsutism in women with excess ad-

renal androgen production and idiopathic causes, but not in women with excess ovarian androgen production (65). No correlation was found, however, between precursor or circulating androgen levels and the hirsutism scores (65). In addition, 3 α -adiol gluc levels in hirsute females correlated significantly with circulating DS and DHEA levels (65), suggesting that in women 3 α -adiol gluc is a marker of metabolic activity of largely weak adrenal androgens in the skin tissue.

IV. PATHOPHYSIOLOGY AND CAUSES OF HIRSUTISM AND POLYCYSTIC OVARY SYNDROME

The pathogenesis of hirsutism and other related increased androgen symptoms in the female can be classified as follows: (a) increased glandular secretion of androgens or exogenous androgen administration; (b) increased extraglandular production of active androgens via increased peripheral conversion of precursor steroids; (c) increased availability of circulating bioactive androgens; and (d) increased sensitivity of target cells to androgen in the androgen-dependent skin tissue. One or more of these pathogenic mechanisms may play a role in hirsutism. Approximately 5–8% of the female population is reported to demonstrate hirsutism (66).

Hirsutism associated with virilism and menstrual disorder is caused by a pathology of unequivocal excess adrenal and/or ovarian androgen production. Hirsutism and menstrual disorder alone may result from moderately increased androgen production. Hirsutism and acne, alone

or together, coupled with normal menses are generally caused by mildly increased androgen production or normal androgen secretion, in association with mechanisms (b), (c), or (d) described above (67–71).

The most easily clinically identified excess androgen-producing pathologies are those associated with classic manifestations of excess glucocorticoid hormone production (Cushing disease/Cushing syndrome) and those presenting with sudden onset and rapidly advancing androgen excess symptoms caused by adrenal or ovarian androgen producing tumors (Table 2; Fig. 5). These diseases, although rare, usually cause virilization and amenorrhea. The majority of hirsute women, however, present with either peripubertal or postpubertal onset of increased hair growth or acne, with or without menstrual dysfunction, and with no obvious clinical cause for increased androgen symptoms. The causes of clinically indistinguishable hirsutism are many, including those conditions associated with mild to moderately increased adrenal and/or ovarian

sources of androgens (23, 39, 65, 72–76), as well as other conditions associated with apparently normal androgen levels (Table 2). Recent studies of hirsutism have further defined several specific causes of adrenal and ovarian androgen excess production in women (Table 2).

A. Adrenal Causes of Excess Androgen Production

1. Mild Form of Congenital Adrenal Hyperplasia

a. 21-Hydroxylase Deficiency. A partial or mild adrenal 21-hydroxylase deficiency is a well-defined cause of excess adrenal androgen secretion resulting in peripubertal or postpubertal onset of hirsutism and acne, with or without menstrual dysfunction (23, 39, 77–85). This entity has been termed late-onset, attenuated, or symptomatic form of nonclassic congenital adrenal hyperplasia and has been studied in great detail over the two past

Table 2 Causes of Excess Androgen Symptoms in Peripubertal and Postpubertal Females

Adrenals	Ovarian	Others
Nonclassic mild inherited defect in cortisol biosynthesis: 21-hydroxylase deficiency 11 β -hydroxylase deficiency 3 β -hydroxysteroid dehydrogenase deficiency	Polycystic ovary syndrome with insulin resistance without insulin resistance Genetic causes of insulin resistance syndrome	Idiopathic hirsutism (normal androgen production) Hypothyroidism Ingestion of nonsteroidal drugs diazoxide minoxidil phenytoin
Increased adrenal androgen secretion of undefined cause (dysregulation/functional adrenal hyperandrogenism)	Stromal hyperthecosis Secondary polycystic ovaries excess adrenal or exogenous androgens hyperprolactinemia inherited defect in ovarian steroidogenesis	Ingestion/injection of androgen/anabolic substance
Cushing's syndrome/disease		
Androgen-producing adrenal tumors (adenoma/carcinoma)	Androgen-producing ovarian tumors lipoma luteoma hilar cell tumor stroma tumor stromal-Leydig cell tumor	
Hyperprolactinemia		
Glucocorticoid receptor gene mutation

decades (77–98). The mild form of 21-hydroxylase deficiency frequently manifests excess androgen symptoms well before puberty, causing premature pubarche, acne, oily hair, and accelerated skeletal maturation in childhood (77, 80, 83, 99), and is proven to be a progressive disorder (83). In girls over age 10 years with mild 21-hydroxylase deficiency, hirsutism and menstrual irregularity were manifested in 50–55% (77, 83), while virilism and infertility were present in 13% (77, 83). A mildly deleterious missense mutation or a point mutation in the promoter region in one or both alleles of CYP21 gene resulting in a compound heterozygous or homozygous mutation is the basis of the mild phenotype of 21-hydroxylase deficiency (77, 84, 91–96). The V280L allele is in genetic linkage disequilibrium with HLA B14 in Ashkenazi Jews (86–88). A high frequency of this disorder in individuals of mainly eastern European descent (Ashkenazi Jews) has been reported (87, 88). In hirsute females, varying frequencies (0–16%) of this disorder have been reported (23, 39, 77, 82, 85, 97–104). The ethnic and racial background of hirsute females is the likely factor determining the varying incidence rate. In self-referred hirsute females however, the incidence of mild 21-hydroxylase deficiency was low (1–2%) (39, 77, 100, 105).

Characteristic hormonal abnormalities for the mild form of 21-hydroxylase deficiency in women are elevated circulating 17-hydroxyprogesterone (17-OHP), and Δ^4 -A. Testosterone levels are also generally mild to moderately elevated. These adrenal sources of hormonal abnormalities can be more accurately detected by early morning blood sampling due to their circadian variations. Confirmative diagnosis of this condition is, however, made by evaluating the adrenal steroid response to exogenous ACTH stimulation regardless of time of day (23, 39, 77, 80, 97–103). Representative 17-OHP and androgen levels in normal and 21-hydroxylase deficient hirsute females are shown in Table 5 (39, 65). 17-OHP response to ACTH stimulation in these women was three standard deviations above the mean 17-OHP response of known carriers for 21-hydroxylase deficiency (23, 65, 80). All other steroid responses, including C-19 steroid levels in response to ACTH stimulation in these women, overlapped with the steroid response of hirsute women with other causes (23, 39, 65, 80). The unequivocally increased 17-OHP levels with or without ACTH stimulation, together with prompt suppression by exogenous glucocorticoid hormone administration, confirm the diagnosis of mild form of 21-hydroxylase deficiency for patients of all ages (77).

b. 11 β -Hydroxylase Deficiency. Late-onset 11 β -hydroxylase deficiency in women with hirsutism has also been reported (78). In the author's study of over 300 hirsute patients from two different populations, partial 11 β -hydroxylase deficiency was not found. Thus, this disorder is an extremely rare cause of hirsutism in women.

c. 3 β -Hydroxysteroid Dehydrogenase Deficiency. Early studies reported salt-losing symptoms in early life

as the presenting signs of 3 β -hydroxysteroid dehydrogenase deficiency (3 β -HSD def.) (106). However, the diagnosis of the non-salt-losing form of 3 β -HSD deficiency may be delayed until later in life when either premature pubic hair growth occurs during childhood or hirsutism occurs during puberty as a symptom of 3 β -HSD deficiency (106–109). A partial adrenal 3 β -HSD deficiency was first described in a woman with pubertal onset of hirsutism and sclerotic ovaries two decades ago (110). Thus partial genetic 3 β -HSD deficiency is a cause of pubertal or postpubertal hirsutism and menstrual irregularities in women (108, 109). In the past decade, mild late onset 3 β -HSD deficiency was suspected in children with premature pubarche and in women with hirsutism if their ACTH stimulated Δ^5 precursor steroids Δ^5 -17P and DHEA levels and Δ^5 precursor to Δ^4 product steroid ratios were greater than 2 SD above the age and pubertal stage-matched normal subject's mean value (23, 98, 101, 103, 104, 111, 112). However, our recent genotype and phenotype studies indicate that the published hormonal criteria are not accurate for diagnosing mild inherited 3 β -HSD deficiency (77, 113–116). Molecular analysis of the type II 3 β -HSD gene in many patients with Δ^5 -precursor steroids and Δ^5 precursor to Δ^4 product steroid ratios greater than 2 SD above normal mean value revealed no mutation in the type II 3 β -HSD gene (113–115). Thus, a genuine mild late-onset 3 β -HSD deficiency would express greater precursor hormonal abnormalities (113–115) than the past published hormonal abnormalities in both hirsute females and children with premature pubarche (23, 98, 101, 103, 104, 111, 112). The hormonal criteria for mild late-onset 3 β -HSD deficiency (113–115) are nearly analogous to those of mild late-onset 21-hydroxylase deficiency (i.e., precursor steroid response 21 SD above the genotype-normal population mean) (117–119). It is also apparent that only the values of ACTH-stimulated Δ^5 -17P levels and Δ^5 -17P to cortisol (F) ratio unequivocally differentiate those with type II genotype-proven 3 β -HSD deficiency from genotype-normal patients. DHEA or other hormonal ratios did not consistently differentiate the genotype-proven patients from the genotype-normal patients (113–115). It is now apparent that true mild late-onset 3 β -HSD deficiency resulting from the type II 3 β -HSD gene mutation is a rare disorder in hirsute females.

2. Type II 3 β -HSD Genotype-Normal Mild Defect in Adrenal 3 β -HSD Activity

The cause of mildly increased Δ^5 precursor steroid levels and Δ^5 precursor to Δ^4 product steroid ratios (as high as 12 SD above the normal mean) in hirsute females is unknown, but the hormonal abnormalities suggest mildly decreased activity of adrenal 3 β -HSD. These hirsute women have clearly increased adrenal androgen secretion and rates of menstrual disorder as high as women with classic polycystic ovary syndrome (PCOS) (39). In addition, in the genotype-normal hirsute females with this mildly de-

creased adrenal 3β -HSD activity of unknown cause, clinical and/or hormonal findings of PCOS are present (23, 39, 112). The mildly decreased adrenal 3β -HSD activity of unknown cause without the type II 3β -HSD gene mutation is more prevalent than true 3β -HSD deficiency in hirsute females. A recent investigation by the author into the pathogenesis of this disorder strongly suggests that it may be a nonclassic form of PCOS associated with insulin resistance (pediatric research, programs, and abstracts, p 117A, 2002). Further studies will elucidate the nature of this type II 3β -HSD genotype-normal mild defect in adrenal 3β -HSD activity.

3. Increased Adrenal Androgen Producing Condition of Undefined Cause (Idiopathic or Functional Adrenal Hyperandrogenism; Dysregulation of Adrenal Androgen Secretion)

In a study of over 125 hirsute females, 11 patients demonstrated only elevated baseline or ACTH stimulated levels of DHEA and or DHEA-S without other hormonal abnormalities (39, 65). A specific cause for increased adrenal androgen secretion was not found in these patients since they did not meet the criteria of any enzyme deficiency or decreased enzyme activity, and had no hormonal or radiological evidence of adrenal hyperplasia or adrenal tumor (39, 65). This isolated increased adrenal androgen-producing condition has also been labeled as functional adrenal hyperandrogenism (120, 121). The cause of this increased adrenal androgen secretion is not known. A longitudinal study of hirsute adolescent girls with a childhood history of premature pubarche reports that one-third of the premature pubarche cohort had evidence of increased adrenal DHEA and androstenedione secretion (121). This was associated with a history of low birth weight, suggesting the possibility of an endocrine sequence of prenatal onset (121). Adrenal androgen hyperresponsiveness was proposed to be due to dysregulation of intra-adrenal modulation in androgen secretion (120). Isolated increased adrenal androgen secretion is not a common cause of hirsutism (≈ 10 – 12%), but was the most common adrenal cause of hirsutism and was present in a small number of females of all ethnic and racial backgrounds (39). The frequency of menstrual abnormality was lower in this hyperandrogenism than PCOS or genotype-normal defect in 3β -HSD activity (39). The excess adrenal androgen secretion in these females is easily suppressed by a small amount of exogenous glucocorticoid administration (39). However, no long-term data are available to determine whether low-dosage glucocorticoid therapy is efficacious in improving hirsutism in these females.

In some females with adrenal hyperandrogenism, concurrent ovarian hyperandrogenism is also manifested (39, 121). Whether the pathogenic mechanisms of both adrenal and ovarian involvement coexists in these hirsute females or whether one condition results in the other remains unknown.

4. Cushing Disease or Syndrome

Inappropriate adrenocorticotropic hormone (ACTH) secretion by a pituitary tumor or by a disturbed corticotropin-releasing hormone (CRH)–ACTH axis in the CNS (Cushing disease) and ectopic ACTH secretion by the malignant tumor often result in excess adrenal glucocorticoid and androgen secretion simultaneously. Autonomously functioning adrenal cortical tumor (adenoma and carcinoma) may also secrete increased amounts of cortisol and androgen (Cushing syndrome). Thus, the patients with Cushing disease or syndrome would manifest symptoms not only of glucocorticoid excess but also hirsutism or virilism. These conditions are rare causes of hirsutism and are usually clinically more easily recognizable due to the presence of Cushingoid features and muscle-wasting signs. Biochemically abnormal cortisol and/or ACTH dynamics is apparent in these disorders. Classic hormonal abnormalities are nonsuppressed or partially suppressible excess cortisol, DHEA, and DHEA-S levels by dexamethasone administration. Radiological studies are also an essential part of the differential diagnosis of Cushing disease and/or syndrome (Fig. 5). A recent study in 13 females with Cushing disease/syndrome revealed that 70% had menstrual disorders including oligomenorrhea, amenorrhea, and polymenorrhea, while 30% had a normal cycle pattern (122). About one half of the patients had ovarian morphology suggestive of PCO and the patients with higher cortisol secretion had hypogonadotropic hypogonadism (122).

5. Adrenal Androgen-Producing Tumor

An androgen-producing tumor of the adrenal could be adenoma or carcinoma. However rare, it is a cause of virilism. Generally the supraphysiological amount of androgen secreted by these tumors characteristically causes extremely elevated circulating DHEA and DHEA-S levels. Other androgens such as Δ^4 -A and T or progestin steroid levels may also be elevated by either direct secretion or by peripheral conversion of DHEA and DHEA-S for elevated Δ^4 -A level. Some androgen-producing tumors may also have the capacity to secrete cortisol but the patient may not present with Cushingoid features. Clinically these diseases are manifested in sudden onset; hormonal symptoms are rapidly progressive. In carcinomas, the metastasis to liver or ovarian tissue may occur, and metastatic tissue often secretes steroids inappropriately. Radiological and hormonal evaluations are essential for the diagnosis; tumor tissue should be removed as soon as possible (123). In rare cases, androgen-producing adrenal adenoma has also been reported in patients with poorly controlled or untreated congenital adrenal hyperplasia (124, 125).

6. Hyperprolactinemia

Elevated adrenal androgen levels (DHEA and DHEA-S) have been found in some hirsute women with high prolactin levels (14, 15, 126) and normal metabolic clearance rate of these steroids (127). Increased plasma Δ^4 -A and

cortisol response to ACTH stimulation and low SHBG in hirsute and hyperprolactinemic patients were also described (128). Controversial data have been reported on the effect of dopamine agonist in lowering serum androgen levels with reduction in serum prolactin levels (14, 129). Recent data suggest a modulation of adrenal androgen production by prolactin based on the observation of dopamine agonist reducing both serum prolactin and androgen levels as well as improving acne and hirsutism (14). Enhanced androgen effect at the target tissue by permissive action of prolactin was also described (130). The associated findings of PCOS in some hyperprolactinemic women suggest an additional cause of hirsutism in the hyperprolactinemic state (131).

7. Glucocorticoid Receptor Gene Mutation

The clinical features of cortisol resistance include fatigue, mild hirsutism, oligomenorrhea, infertility, obesity, hypokalemic hypertension, and precocious puberty (132, 133). Hirsutism is reported as the most common symptom of this disorder (133). Glucocorticoid resistance syndrome is characterized by decreased sensitivity to cortisol signaling, increased cortisol secretion, absence of clinical features of Cushing syndrome, and poor suppression of adrenal steroids. Resistance of adrenal steroids, including cortisol level, is decreased with dexamethasone administration (133). This genetic disorder results from a deleterious mutation in the human glucocorticoid receptor gene. It is an extremely rare cause of hirsutism (134) and menstrual disorders in women, but should be suspected in patients with elevated cortisol levels without the clinical features of Cushing syndrome. The cause of hirsutism is related to increased adrenal androgen secretion due to increased pituitary ACTH secretion, which is due to cortisol resistance.

8. Cortisone Reductase (11 β -Hydroxysteroid Dehydrogenase Type 1) Deficiency

This enzyme deficiency is a rare cause of hirsutism without virilization and may be associated with infertility (135, 136). This enzyme catalyzes the reduction of cortisone to cortisol, and its deficiency impairs the metabolism of cortisone to cortisol. The exact mechanism of hirsutism is unknown but may be related to increased adrenal androgen secretion in view of enlarged adrenal size on CT scan in a patient with apparent cortisone reductase deficiency (136).

B. Ovarian Causes of Excess Androgen Production

1. Polycystic Ovary Syndrome

a. Definition. Polycystic ovary syndrome (PCOS) is defined clinically by the presentation of hyperandrogenism (clinical and/or biochemical) and chronic anovulation (regular or irregular anovulatory cycle, amenorrhea, oligomenorrhea, polymenorrhea, or infertility).

Hyperandrogenic symptoms include hirsutism, acne and/or virilism, and menstrual disorders. The hyperandrogenic symptom of PCOS is generally associated with excess androgen production of ovarian or extraovarian source (137–139) and is associated with or without obesity, insulin resistance, or the radiological images of ovaries compatible with PCOS. The morphological changes of ovaries include bilaterally and symmetrically enlarged ovoid ovaries classically, but the ovary may be unilaterally enlarged or normal shaped (140). Characteristic morphological findings of PCOS (140) are an oyster-gray color and smooth glistening surface surrounding a thickened capsule in association with numerous 2–15 mm subcapsular cysts and many ovarian atretic follicles. These findings were initially described as Stein-Leventhal syndrome.

b. Prevalence. Estimated prevalence of PCOS is variable from 2 to 20% in the general population (141). Recent studies described a prevalence of 3.4% in African-Americans, 4.7% in white women aged 18–45 years from a southeastern US region (141), and 6.5% in a white Spanish population (142). A prevalence of PCOS in women seeking electrolysis therapy was conservatively put at 12% (143). A prevalence of PCOS in mothers and sisters of patients with PCOS was 24% and 32%, respectively (144). These data suggest the involvement of a major genetic component for PCOS (144). PCOS is one of the major causes of hirsutism in almost all ethnic populations (39). In New Zealand, white females and Maori females had more hirsutism than other ethnic PCOS females, while white females had less complaint of infertility and Pacific islanders had little or no acne (145). This suggests the influence of ethnic and racial factors on the expression of the hyperandrogenic symptoms of PCOS.

c. Pathophysiology and Causative Factors. Multifactor considerations related to the pathophysiology and causes of PCOS are depicted in Tables 2 and 3. The proposed causative factors of PCOS include defect(s) in the insulin-signaling pathway (146–148) or glucose transporter (149); defect(s) in the metabolic/hormonal regulatory system on body weight control (150); defect(s) in the regulation of steroidogenic biosynthesis (151, 152); or defect(s) in the regulation of gonadotropin secretion (153), as well as secondary adverse effects on one or more of these systems via extraovarian or intraovarian sources of excess androgens or an exogenous source of excess insulin (154) (Table 3). Thus PCOS may be a family of complex genetic and environmental diseases influenced by genetic heterogeneity, fat and carbohydrate consumption, physical exercise level, peripubertal stress, and/or hormonal exposure (155, 156). Of several proposed factors, the peripheral insulin resistance of unknown mechanism with or without obesity, known heritable insulin resistance syndrome, and exogenous insulin treatment for type 1 diabetes mellitus associated with PCOS suggest that hyperinsulinemia is a causative factor related to PCOS mani-

Table 3 Proven or Proposed Pathogenic Causes of Polycystic Ovary Syndrome

Metabolic defect	Other factor	Ovarian	Adrenal
Hyperinsulinemia	Dysregulation of gonadotropin secretion	Dysregulation of ovarian steroidogenesis	Dysregulation of adrenal steroidogenesis

Supraphysiological doses of insulin replacement in type 1 diabetes mellitus			

festation. This is further elaborated in the discussion of primary PCOS below.

In excess adrenal androgen-producing conditions, such as 21-hydroxylase deficiency, 11 β -hydroxylase deficiency, adrenal androgen-producing tumor, Cushing's disease or syndrome, or with exogenous administration of androgen, the proposed pathogenic mechanism for PCOS is either a direct adverse effect of androgen on the ovarian estrogen synthesis or altering gonadotropin secretion by increased free androgens or estrogens (157–162).

Impaired ovarian estradiol synthesis caused by ovarian 17-ketosteroid reductase deficiency (163), ovarian 3 β -HSD deficiency (108, 109), and ovarian aromatase deficiency (164–166) predictably leads to PCOS either as a result of the increased intraovarian androgen effect or because of the increased gonadotropin effect via a feedback regulation. PCOS in ovarian androgen-producing tumor may be caused by either the direct effect of androgen on the process of ovarian estrogen synthesis or by altering gonadotropin secretion via excess androgen or free estrogen converted from excess androgen. It is not certain whether excess androgen production in these adrenal and ovarian conditions alters peripheral insulin sensitivity or some other growth factor action in the modulation of gonadotropin on the ovarian function, thereby leading to the development of PCOS.

d. Primary PCOS

Clinical presentation. Most females with primary PCOS (nonadrenal and nonexogenous excess androgen induced) have normal onset of menarche, although infrequently primary amenorrhea or oligomenorrhea may be present from the beginning (137, 167, 168). Frequently a history of significant weight gain preceding menarche can be obtained in many patients with primary PCOS (169). Hirsutism in primary PCOS generally begins during the late pubertal stage following the menarche (169). Progressive manifestation of hirsutism and menstrual dysfunction correlate with the ovarian androgen production rate (137, 170, 171). Some genetic factors may modify the effects of increased ovarian androgen secreted in some PCOS women who are not hirsute (137). The clinical spectrum of primary PCOS therefore ranges from regular anovulatory withdrawal menstrual cycle, menstrual abnormality, to mild hirsutism with regular anovulatory withdrawal cycle, to severe hirsutism and/or virilism and menstrual abnormalities and/or infertility (137, 139, 171). Approximately 70% of women with PCOS in the United States were reported to be hirsute, and the remaining 30% were not hirsute despite hyperandrogenism (139). In the author's experience with PCOS in young hirsute females, more than 300 of whom were evaluated in the last 20 years, intrinsic primary PCOS defined by clinical presen-

tation of hirsutism with (majority) or without (minority) menstrual disorders and documented increased ovarian Δ^4 -A and/or T production in the absence of increased adrenal androgen secretion was diagnosed in one-quarter to one-third of the patients evaluated (23, 39, 65). Primary ovarian hyperthecosis and hyperandrogenism (HA)/insulin resistance (IR)/acanthosis nigricans (AN) (HAIR-AN) syndrome were found in fewer patients.

Hormonal manifestations. An increased ovarian source of Δ^4 -A and/or T production is frequently present. Elevated basal levels of T and/or Δ^4 -A in the absence of elevated adrenal androgens (DHEA, DS) generally signify primary PCOS. However, in some patients, both increased ovarian T and/or Δ^4 -A production and increased adrenal androgen levels are present simultaneously in the absence of any known enzyme defect in adrenal and/or ovarian biosynthesis. Thus, PCOS females clinically have elevated serum total and/or free T level or Δ^4 -A level, increased free androgen index, and decreased SHBG levels. These hormonal abnormalities may be related in part to obesity in PCOS (172). A mildly elevated random 17-OHP level and 17-OHP response to GnRH analog or hCG administration suggested dysregulation of ovarian 17 α -hydroxylase/17-20 lyase activity in PCOS ovaries (120, 173). However CYP17 gene structure is normal in PCOS females. Thus, the mechanism of altered 17 α -hydroxylase/17-20 lyase activity in the ovarian steroidogenesis is unknown. Whether hyperinsulinism modifies ovarian enzyme activity in the PCOS female (42) or whether a common defect is the cause of both altered insulin-signaling pathway and some ovarian enzyme gene expression remains to be elucidated.

The increased ovarian androgen production in primary PCOS is associated with inappropriate gonadotropin secretory patterns including elevated basal LH levels (139, 171, 174), elevated basal LH to FSH ratios, high LH amplitude (174–176), or hyperresponse of LH to LHRH stimulations (174). Nonbioactive gonadotropin measurement, such as radioimmunoassay, however, did not demonstrate abnormally elevated LH levels in approximately 25% of primary PCOS patients (177). In the author's experience, the baseline LH levels, LH to FSH ratios, and LH response to LHRH administration in the primary PCOS patients were elevated or apparently appropriate despite increased ovarian androgen secretion. Generally increased ovarian sources of Δ^4 -A and/or T in these patients were not significantly suppressible by dexamethasone, although all other adrenal steroid levels were promptly suppressed (39). PCOS associated with both increased ovarian and adrenal androgen secretion of undefined cause was found in about 5% of the patients in the author's study (39).

The inappropriately elevated LH levels in the primary PCOS patients were not related to an alteration in the negative feedback regulation between estradiol and LH secretion, since estradiol infusion effectively suppressed

elevated LH in these patients (174). In addition, the positive feedback mechanism of estrogen on LH release was apparently intact in PCOS patients since the preovulatory elevation of estradiol via clomiphene citrate administration induced an LH surge in patients with primary PCOS (178). The pathogenesis of the inappropriate gonadotropin secretion in the primary PCOS is not yet clearly defined. Inappropriate gonadotropin secretion may be due to abnormal ovarian steroidogenesis of PCOS or primary or secondary hypothalamic–pituitary alteration. The presence of both negative and positive feedback mechanisms of gonadotropin secretion in patients with primary PCOS led to the conclusion that anovulation in primary PCOS is less likely due to an intrinsic hypothalamic abnormality (174, 179). Defective secretion of FSH may play a crucial role in the pathogenesis of PCOS since FSH or clomiphene administration resulted in ovulation in patients with primary PCOS (174, 179, 180). An extraglandular source of estrogen (estrone) via peripheral conversion of Δ^4 -A is related to body weight and has been speculated to be of causative importance in the maintenance of chronic anovulation (179, 181). Suppression of gonadotropin secretion by combined treatment of GnRH analog and an oral contraceptive effectively eliminated excess LH and excess ovarian androgen secretion (39, 182). However, a few months following discontinuation of these therapies, ovarian testosterone secretion increased remarkably quickly while LHRH-stimulated LH levels rose only marginally (182). This observation clearly indicates that a systemic or intraovarian factor modulates for the increased ovarian androgen synthesis in the presence of only modest amounts of LH secretion (182). This systemic or intraovarian factor may be insulin or some other yet unidentified factor or mechanism.

Insulin resistance. Many studies indicate that there is a strong relationship between hyperinsulinemia and ovarian hyperandrogenism (139, 183–188). The peripheral insulin resistance is not changed by the suppression in ovarian androgen levels (187, 188). Patients with insulin resistance may or may not be obese, but obesity contributes to a greater degree of insulin resistance and decreasing SHBG levels in women with PCOS. Overt insulin resistance in patients with primary PCOS has been reported in at least 60% or greater based on an elevated insulin to glucose level (189). Also, a high rate (38%) of hyperandrogenic disorder in women treated for type 1 diabetes mellitus has been reported (154). These data indicate that hyperinsulinemia is a causative factor in PCOS.

The mechanism by which hyperinsulinemia results in increased ovarian androgen production in PCOS has been the subject of investigation in the past and current decades. Insulin has a stimulatory effect on steroidogenesis of normal and polycystic ovaries and interacts with LH in a synergistic manner (190, 191). Insulin action in the ovary appears to be mediated by the specific insulin receptor and not by the cross-reaction with the IGF-I recep-

tors (190, 191). Hyperinsulinemia is also suggested to contribute to premature follicular growth arrest and anovulation of PCOS (190). Insulin also appears to have a role in amplifying LH-induced theca cell androgen production in PCOS females (190). A study indicated that lean PCOS females have an equivalent degree of tissue insulin resistance to obese PCOS females (192). Hyperinsulinemia in hyperandrogenic anovulatory females is also often accompanied by an increased amount of abdominal fat (42). This upper-body obesity is a risk factor for development of type 2 diabetes mellitus and ultimately cardiovascular disease (42, 193). Acanthosis nigricans is a cutaneous manifestation of hyperinsulinemia and is commonly noted in PCOS patients with insulin resistance and obesity (193). A retrospective study revealed a rate of 26% of type 2 diabetes occurring among PCOS females (194). However, insulin alone in the absence of gonadotropin secretion in PCOS females did not cause excess ovarian androgen secretion (182, 195). Thus, modulation of ovarian steroidogenesis by both insulin and gonadotropin is a prerequisite for hyperandrogenism in PCOS females with insulin resistance (195). Several studies demonstrated normal insulin receptor-binding capacity and affinity, normal total phosphorylation of the insulin receptor β -subunit (148, 193, 196), and an abnormal dose-dependent effect of insulin on glucose transport, suggesting a postreceptor defect (147, 148). An increased basal phos-

phorylation of the serine residue of insulin receptor β -subunit in contrast to the tyrosine residue was proposed as a cellular mechanism of insulin resistance of PCOS (148). However equal numbers of PCOS females had a normal receptor tyrosine kinase activity, suggesting a defect beyond insulin receptor phosphorylation (148). A decreased content of GLUT-4 glucose transporter in the adipocyte cell membrane of PCOS patients may also be a mechanism for peripheral insulin resistance (149). Paternally transmitted insulin gene variable number tandem repeat (VNTR) of class III alleles has also been reported to be associated with insulin resistance of PCOS (197). Thus, the cellular and molecular mechanism of insulin resistance of PCOS is yet to be defined.

Other candidate genes or factors. Several recent studies of candidate genes or causative factors of PCOS also uncovered other genetic factors independent of insulin resistance that may play a role in the development of PCOS (Table 4). These include follistatin gene (156), FSH β -subunit gene mutation (198), chromosome II long arm deletion (199), TNF- α -system (200), α -estrogen receptor defect (201), maternal obesity and high birth weight (202), history of premature pubarche (203–205), and a history of central precocious puberty (206). The childhood diagnosis of premature pubarche and central precocious puberty may suggest that either premature ovarian exposure to androgens or sex steroids or a factor

Table 4 Proven or Proposed Positive and Negative Genes/Factors Associated with Hyperandrogenism/Polycystic Ovary Syndrome

	Positive association	Negative findings	Inconsistent findings
PCOS or hyperandrogenism	Serine residue of insulin receptor of β -subunit (148) Paternally transmitted insulin gene variable number tandem repeat (VNTR) class III alleles (197) Follistatin (156) FSH β -subunit gene mutation (198) Chromosome II long arm deletion (199) TNF- α system (200) α -estrogen receptor defect (201) Maternal obesity/high birth weight (202) History of premature pubarche (203–205) History of central precocious puberty (206)	StAR gene (207) DAX-I gene (207) Steroidal factor I gene (207) CYP17 gene (208, 209) Insulin receptor binding capacity/affinity (148, 255) CYP21 mutation heterozygosity (211, 212) Androgen receptor gene (156) CYP19 aromatase gene (156) Activin/inhibin genes (156) SHBG gene (156) LH/hCG receptor gene (156) FSH receptor gene (156) Leptin/proleptin receptor gene (156) IGF-I/GR-IR/IGF BP3 genes (156) INSR gene/IRSI gene (1560)	CYP11A gene (156, 207, 213) Hyperprolactinemia (131, 215) VNTR gene (148, 197)
Idiopathic hirsutism	Increase in skin 5 α -reductase activity (68, 234–236) Obesity/decreased SHBG (228) Increased free/bioactive androgens (50, 237)	CYP11A gene (214)	Androgen receptor gene (239–241)

causing this precocity may contribute to the development of PCOS or ovarian hyperandrogenism in later life. On the other hand, many other genes were found not to be linked or associated with PCOS and are not likely candidate genes for PCOS (156, 207–212) (Table 4). There are also inconsistent and conflicting reports with regards to CYP11A gene (156, 207, 213, 214) and hyperprolactinemia as potential factors for PCOS development (131, 215) (Table 4). The mechanism of altered reproductive function in hyperprolactinemic females is complex (216). An estrogen-stimulatory effect on the pituitary lactotropes has been speculated to cause hyperprolactinemia in patients with this disorder (216).

e. Genetic Causes of Insulin-Resistant Syndrome.

A severe degree of excess ovarian androgen production has been found in genetic disorders of severe insulin-resistant syndrome due to point mutation of the gene encoding insulin receptor function (217–220). These patients manifest HAIR-AN syndrome and are usually virilized. Leprechaunism characterized by severe congenital growth retardation appears to be also caused by insulin receptor gene mutation (217) and patients develop PCOS although those with severe cases do not survive long. Other syndromes caused by insulin receptor gene mutation include Rabson-Mendenhall syndrome and type A syndrome (219, 221–223). Kahn type B insulin resistance syndrome due to the presence of circulating antibodies for insulin receptors also causes HAIR-AN syndrome (220). However, fewer than 30% of women with insulin resistance manifest AN (188). The patients with AN, therefore, are at high risk of HAIR-AN syndrome. In patients with HAIR-AN syndrome, ovarian histological study almost always reveals marked stromal hyperthecosis, which results in severe excess ovarian androgen production (188).

f. Hyperthecosis of Stroma. This condition is characterized by the nests of luteinized theca cells within the stroma of bilaterally enlarged ovaries (3, 224, 225). The thickened capsule without subcapsular cysts differentiates hyperthecosis from PCOS (224, 225) and the theca cells produce excess androgen. Patients with stromal hyperthecosis have progressive symptoms of androgen excess and are usually amenorrheic. Serum T levels are generally >150 ng/dl (3, 188). This condition, however, is differentiated from most of the androgen-producing tumors clinically by the nature of slowly progressive symptoms, hormonally by the elevated basal and LHRH-stimulated LH levels, as well as significant presence of acanthosis nigricans in some patients.

g. PCOS Associated with Adrenal Androgen Secretion. In patients with mild 21-hydroxylase deficiency, menstrual disorder was present in about one-half but most of these patients had normal ovarian androgen secretion despite experiencing menstrual problems (77). Previous studies demonstrated that the menstrual disorder in either 21-hydroxylase deficiency or genotype-normal decreased

adrenal 3 β -HSD activity patients (no longer 3 β -HSD deficiency) had PCOS by ultrasound, laparoscopy, or laparotomy study (23). Thus, PCOS in patients with primarily increased adrenal androgen secretion was associated with both normal or mildly increased ovarian androgen production. However, in the poorly controlled severe classic virilizing form of congenital adrenal hyperplasia patients, classic PCOS pathological findings and increased ovarian androgen production were demonstrated (157–161). The pathophysiology of PCOS in these conditions was elaborated in previous sections.

2. Genetic Defects in Ovarian Steroidogenesis

a. Ovarian 17 β -HSD Deficiency. This enzyme is also termed as 17 β -ketosteroid reductase. Recent molecular studies revealed that 17 β -HSD 1 isoenzyme is expressed in the ovary and preferentially reduces estrone to estradiol (226). 17 β -HSD 3 is the enzyme that converts Δ^4 -A to T and is expressed in the testis. This enzyme deficiency in the testicular tissue due to a mutation in the gene results in male sexual ambiguity (227–230). 17 β -HSD 3 isoenzyme expression is either low or undetectable in the ovarian tissue. Thus, the genetic basis of ovarian 17-KSR deficiency resulting in pubertal onset of hirsutism, virilism, menstrual disorder, and PCO reported in females (163) is yet to be characterized.

b. Ovarian Type II 3 β -HSD Deficiency. 3 β -HSD deficiency has been demonstrated in both adrenal and gonadal tissue in patients with severe 3 β -HSD deficiency. To date, two females with proven severe non-salt-losing 3 β -HSD deficiency CAH demonstrated a defect in ovarian 3 β -HSD activity and both manifested hirsutism, menstrual disorders, and PCO (108, 109). Thus, inherited intra-adrenal and intraovarian genetic type II 3 β -HSD deficiency is a rare cause for ovarian dysfunction and PCOS.

c. Ovarian Aromatase (CYP19) Deficiency. Aromatase enzyme deficiency due to a mutation in the aromatase gene (CYP19) is a cause of virilization including clitoromegaly, primary amenorrhea, and multiple ovarian cysts as noted on a pelvic imaging study (164–166). These patients have highly elevated T levels, moderately elevated LH levels, and low estrogen levels (164–166).

3. Ovarian Androgen-Producing Tumors

The clinical presentation of androgen-producing tumors of the ovary is similar to the androgen-producing tumor of the adrenals. Thus, in general marked virilism occurs in short duration in women with ovarian androgen-producing tumors. However, there are exceptional patients whose symptoms of excess androgen production by the ovarian tumor was slowly progressive and long-standing (231). Both clinically rapid or slowly progressive ovarian tumor secreting androgens are associated with extremely high circulating levels of mainly Δ^4 -A and T regardless of his-

topathological classification of the tumors. Serum DHEA and DHEA-S levels may be mildly elevated or normal except in cases of metastasized adrenal carcinoma of the ovary. The tumorous androgen-producing cells arise from lipoid cells, hilus cells, Sertoli-Leydig cells, granulosa-theca cells, and stromal cells.

4. α -Estrogen Receptor Defect

This is a rare disorder proposed to describe the clinical picture of hirsutism and regular menstrual history associated with extraordinarily elevated serum T and estradiol levels of an ovarian source in the absence of adrenal and ovarian tumor. This abnormality was proposed to be compatible with α -estrogen receptor knockout female mice. The female patient had ovarian imaging findings compatible with classic PCOS (201).

C. Idiopathic Hirsutism/Acne

By strict definition, idiopathic hirsutism should describe women presenting with hirsutism and/or acne and no other androgen excess symptoms, or other clinical or hormonal causes of hirsutism, normal circulating androgen concentration in the basal state or under dynamic test of adrenal or ovarian steroidogenic function, and normal ovarian function as evidenced by a normal ovulatory cycle or normal reproductive function. In a study of the causes of hirsutism in the author's clinic, idiopathic hirsutism, defined by normal circulating basal and stimulated adrenal and ovarian total steroid levels and normal menstrual cycles, was the most common cause of hirsutism and included 30–50% of hirsute women of various ethnic/racial backgrounds (39). However, idiopathic hirsutism by the strictest definition using absolutely normal circulating total and free androgen levels and documented normal ovulatory menstrual cycles, was identified in only 6% of hirsute females (232) in an Italian study and 17% in an Alabama study (233).

Several pathogenic mechanisms have been speculated for idiopathic hirsutism (Table 4). Increased intracellular conversion of precursor androgens to DHT by the increased intracellular 5α -reductase activity was found in some women with idiopathic hirsutism (68, 234). Increased skin androgen metabolic activity was noted in women with idiopathic hirsutism as evidenced by the increased circulating 3α -adiol gluc levels (62–65, 235) (Fig. 4). Serum 3α -adiol gluc reflects largely 5α -reductase activity (235) and peripheral adrenal androgen metabolism (65). Thus, the increased 5α -reductase activity in the skin of these women could be a causative factor in idiopathic hirsutism (236). Another proposed mechanism for idiopathic hirsutism is the increased availability of bioactive androgens. Free T is a determinant factor in androgen action and was elevated in number of hirsute women with normal total T concentration (50, 237). In obese hirsute females, a reduction in SHBG and an increase in free T are associated with the degree of upper body obesity and may be the cause of hirsutism (238). Thus the decreased

SHBG and increased free T or DHT may be one of the causative factors in idiopathic hirsutism.

The third theory involves increased skin tissue sensitivity to the circulating androgen for idiopathic hirsutism. Although the increased skin 5α -reductase activity may enhance androgen effect at the target cells, the androgen-binding capacity at the receptor protein of the target cell shows no differences between normal and hirsute females (67). Androgen receptor gene polymorphism does not appear to play a significant role in the pathologies of idiopathic hirsutism (239), but this was contradicted by other studies (240, 241). CYP11A gene was found to have no significant role in the pathology of hirsutism (214). Abnormalities found in some women with idiopathic hirsutism include increased skin androgen metabolizing activity and/or increased bioactive free androgens. Whether these are primary abnormalities or whether they are due to disorders of enzyme and receptor protein regulation or due to increased free component of androgens remains to be elucidated. The mechanism of low SHBG and high free T in nonobese females with idiopathic hirsutism also needs further exploration.

D. Hirsutism Associated with Thyroid Disorder

Thyroid hormones increase the concentration of SHBG in plasma (25). Thus, high testosterone levels observed in some patients with hyperthyroidism are due to increased protein-bound testosterone levels, with no clinical androgen excess symptoms. On the other hand, hypothyroidism may be associated with hirsutism (242). In the last 20 years, the authors have found only a few women with hirsutism who have hypothyroidism. These women had normal circulating total androgen levels. Thus hypothyroidism seems to be a condition rarely associated with hirsutism and menstrual irregularity. To the best of our knowledge, no studies have been reported of the androgen metabolism, SHBG, or free androgen concentration in hypothyroidism.

V. DIAGNOSTIC APPROACH AND DIFFERENTIAL DIAGNOSIS

A. Clinical Assessment of Hirsutism

A detailed history and careful physical examination are essential in evaluating hirsute patients. History of puberty, including adrenarche, thelarche, onset of hirsutism and its progression, menarche, and menstrual history should be obtained. Similar history should be obtained from female family members as well. Evaluation of the severity and progression of terminal hair growth is an essential part of physical examination in hirsute females. A detailed history of cosmetic care, including frequency, method, and the last treatment date of depilation or shaving is necessary to estimate degree of hair growth in a natural state.

The degree of hirsutism on various parts of the body should be examined, including face, chin, neck, chest, areolar, abdomen, pelvic area, upper and lower back, buttocks, intergluteal region, thighs, and other parts of extremities. The best method to determine the degree of hirsutism was described by Ferriman and Gallwey (243). Their original scoring system included 11 areas of the body, using a total of four points for grading each area, with a total score of 44. Further modification of the charts and scoring system of Ferriman and Gallwey has been described by Cooke and Goodal (128) and Hatch et al. (244). The scoring system modified by Cooke and Goodal identifies hirsute scores in nine hormonally more sensitive areas and two hormonally less sensitive areas with a total score of 36 (Fig. 6). We find that this modified scoring system is easy and more informative in evaluating the initial state and for follow-up of treated hirsute patients. Presence or absence and extent of acne, seborrhea, oily hair, masculine body habitus, and clitoral enlargement should also be examined in all hirsute patients.

B. Differential Diagnosis

In the previous section, many of the specific clinical and hormonal abnormalities of each disorder were discussed. In this section, a general approach to the laboratory investigation for differential diagnosis of the hirsutism cause is described. The reference data for basal and ACTH-stimulated steroid levels in normal women and in women who are hirsute due to various causes are depicted in Table 5 (39). In interpreting the patient's hormonal values, it is

pertinent to know each laboratory's hormonal reference data due to the variable degrees of purification and specificity of hormonal assay. A guideline for evaluation of hirsutism causes is depicted in Figure 5. Hirsutism/acne with a slow or nonprogressive history and a normal menstrual cycle history is more likely due to an idiopathic cause (no excess androgen production) or a mild spectrum of PCOS with an anovulatory cycle, mild spectrum of CAH, or idiopathic adrenal hyperandrogenism (functional adrenal hyperandrogenism). Thus, a minimal work-up, including measurement of early morning 17-OHP level and a few serum androgen level screenings (total/free T, androstenedione, and DHEA-S) would guide the differential pathway as depicted in Figure 5. Additional 3 α -androstenediol glucuronate and SHBG level studies may be helpful for assessing idiopathic hirsutism if circulating androgen levels are unremarkable. Hirsutism/acne with a slow or moderate progression history and overt menstrual irregularity history even in teenaged girls (primary or secondary amenorrhea, polymenorrhea) requires consideration of PCOS, a mild form of CAH, idiopathic adrenal hyperandrogenism, as well as thyroid disorders (hypo-/hyper-), and hyperprolactinemia. Thus, the initial evaluation of 8 am 17-OHP levels, serum androgen levels, LH, FSH, T₄, TSH, and prolactin levels would guide further approaches for a differential pathway, as depicted in Figure 5.

Hirsute patients with menstrual disorders have generally elevated ovarian and/or adrenal androgen levels, although the levels are not as high as in patients with virilism. In those with only elevated total or free T levels

[†]Type II genotype-normal mild decrease in adrenal 3β-HSD activity is not mild nonclassic 3β-HSD deficiency; etiology of this is uncertain at this time (Luttallah et al. J Clin Endocrinol Metab 2002.)

Source: data derived from Ref. 39.

with or without elevated LH levels as compared to the normal early follicular phase LH levels, PCOS is a first consideration. Evaluation for insulin resistance and an imaging study of adnexae need to be considered. In those with only elevated DHEA-S levels with or without elevated T, idiopathic adrenal hyperandrogenism and PCOS are equal considerations. The author's experience indicates that the response of LH to LHRH stimulation is variable in patients with primary PCOS and PCOS related to increased adrenal androgen production. The occurrence of menstrual disorders and PCOS in all excess adrenal androgen-producing conditions was discussed earlier. In those with elevated cortisol and adrenal androgen levels and no cushingoid features, glucocorticoid resistance syndrome is a possibility.

Very high basal DHEA (>1500 ng/dl), DHEA-S (>500 μ g/dl) levels, and urinary 17-ketosteroid levels, with or without moderately elevated Δ^4 -A and T levels, can be seen in women with partial adrenal 3 β -HSD deficiency (108, 109) or in type II 3 β -HSD genotype-normal but mildly decreased adrenal 3 β -HSD activity of unknown cause (no longer 3 β -HSD deficiency) (23, 39, 114). The magnitude of Δ^5 -17P in true 3 β -HSD deficiency, however, is highly abnormal (108, 109) compared to genotype-normal mildly decreased adrenal 3 β -HSD activity of unknown cause (23, 114). An adrenal androgen-producing tumor is rare in patients without virilism, but exceptionally higher DHEA and DHEA-S levels would warrant its consideration and a dexamethasone suppression test is warranted, as described below.

In patients with hyperprolactinemia, a causative medication history, such as oral contraceptives or psycholeptic drugs, and CNS symptom history must be obtained. A pituitary imaging study (MRI, CT scan) is essential for evaluation of prolactin-secreting pituitary adenoma. Hirsutism/acne with moderate progression and virilism suggests excess androgen-producing pathologies such as virilizing CAH, stromal hyperthecosis (severely advanced PCOS), a slow-growing androgen-producing tumor, or a clinically recognizable classic or atypical Cushing syndrome or disease. Any apparent clinical and physical stigmata of a disorder such as Cushing syndrome/disease will not be discussed here. In those patients with clinically indistinguishable hirsutism, initial work-up including 8 a.m. 17-OHP, serum F, androgens, LH, FSH, and prolactin levels is warranted. In patients with elevated T and Δ^4 -A levels with or without elevated LH levels, an ovarian imaging study, an ovarian suppression test and a β -hCG screening test would be helpful for differentiating among stromal hyperthecosis (or severe PCOS), a slow-growing ovarian androgen-producing tumor, or an hCG-producing tumor. For those with excessively elevated DHEA and DHEA-S levels with or without elevated cortisol levels, an adrenal suppression test by administering dexamethasone and, if indicated, an adrenal imaging study (generally by CT scan) would help to evaluate the nature of excess

adrenal androgen production. In those with any clinical and hormonal data suggesting atypical Cushing syndrome, both dynamic studies of adrenal steroid and ACTH secretion and adrenal and/or pituitary imaging studies need to be considered.

Hirsutism/acne with virilism of a rapidly progressive history generally signifies an androgen-producing tumor of the ovary or adrenal gland. Random androgen and cortisol level determination and, accordingly, an adrenal CT or an abdominal or ovarian imaging study (ultrasound, MRI) are warranted. In those with no obvious anatomical pathology of the adrenal glands or ovaries, endocrine dynamics of the adrenal glands or ovaries need to be evaluated (Fig. 5).

A logical sequence of adrenal and/or ovarian dynamic studies includes an early morning basal hormonal study or circadian basal hormonal study followed by adrenal stimulation/suppression and ovarian suppression/stimulation contiguously. Suppression tests are generally more important than stimulation tests, in evaluating the excess androgen production. For adrenal stimulation, 0.25 mg ACTH is administered by intravenous (IV) bolus and various adrenal steroids and C-19 steroids responses are examined 1 h following ACTH stimulation. The adrenal suppression test is performed by administering a pharmacological dosage of dexamethasone, 2 mg/day in four divided doses/day for 3–5 days. The key circulating adrenal steroids, including C-19 androgens and urinary metabolites of C-19 steroids, may be determined on days 3–5 after dexamethasone administration. While adrenal steroid secretion is suppressed by dexamethasone, ovarian suppression may be evaluated by administering gonadotropin suppressant, such as synthetic estrogen (ethinyl estradiol 50–100 μ g orally twice daily), or a progestational compound, such as norethindrone acetate (10 mg orally three times daily) for 3–5 days. The ovarian androgen stimulation test may be performed by administering human chorionic gonadotropin (hCG), 3000–5000 IU/day for 3 days and ovarian steroidal response should be examined 2 to 24–48 hours after the last dose of hCG. An LHRH (GnRH) stimulation test (100–150 μ g IV bolus) or LHRH (GnRH) analog stimulation test may also be useful in the differential diagnosis of increased ovarian androgen production. These gonadotropin stimulation tests, however, need to be performed prior to the above-described ovarian suppression or ovarian stimulation test.

With dexamethasone administration, patients with adrenal tumor, DHEA, DHEA-S, and other C-19 steroids and their urinary metabolites may be only slightly or partially decreased. In adrenal 3 β -HSD deficiency, genotype-normal mildly decreased adrenal 3 β -HSD activity of unknown cause, and idiopathic adrenal hyperandrogenism, these steroid levels are more easily suppressed to a greater degree (39, 65, 108, 109). Clinically, these patients rarely present with virilism. Occasionally patients with partial 21-hydroxylase deficiency present with virilism and men-

strual disorder. Serum DHEA and DHEA-S levels may be moderately elevated, but DHEA levels are generally also higher in the early morning hours. These steroidal abnormalities will be more easily suppressed by dexamethasone administration in CAH.

Extremely high basal Δ^4 -A (>350 ng/dl) and T (>150–200 ng/dl) levels without concomitantly increased levels of DHEA and DHEA-S are usually seen in patients with long-standing stromal hyperthecosis, ovarian tumor, and ovarian 17-KSR deficiency. These patients generally manifest virilism. The ovarian source of androgen will be suppressed to a greater degree and more easily by administration of ethinyl estradiol or a progesterone compound in ovarian 17-KSR deficiency or PCOS, whereas androgen secretion by the tumor may not change or may only slightly decrease. The LHRH stimulation test results in LH hyperresponse in ovarian hyperthecosis and 17-KSR deficiency (163). In stromal hyperthecosis, suppression of androgens, by administration of estrogen or progestational agents, is not as good as in the patient with PCOS. However, a long-term (>3 month) LHRH analog treatment suppresses ovarian androgen secretion in these patients (182). The definitive differential diagnosis of these three conditions requires ovarian hormonal dynamic studies, radiological evaluation, gynecological examination, and possibly laparoscopic examination in some cases. Laparotomy may also have to be carried out if there is a high suspicion of tumorous lesions in the ovary.

VI. TREATMENT OF HIRSUTISM AND POLYCYSTIC OVARY SYNDROME

The specific and nonspecific therapies for the various causes of hirsutism described here are based partly on the author's experience and a review of the literature (Table 6). The treatment of hirsute symptoms is most effective if aimed at correcting the primary pathogenic mechanism. This is not always straightforward in patients with PCOS, ovarian hyperthecosis, or idiopathic hirsutism. Both specific and nonspecific therapy will be discussed for each disorder.

A. Mild Nonclassic 21-Hydroxylase Deficiency, 3 β -HSD Deficiency, and Idiopathic Adrenal Hyperandrogenism

Suppression of excess adrenal androgen production for these conditions can easily be achieved by administration of a relatively low dosage of glucocorticoid hormone. We have used prednisone in a dosage of 2.5 mg twice daily or 5 mg a.m. and 2.5 mg p.m., or dexamethasone 0.25–0.375 mg at bedtime. The dosage of glucocorticoid should be adjusted based on the patient's clinical and hormonal response, as well as side effects of glucocorticoid, such as weight gain, striae, and Cushingoid features. Use of dexamethasone 0.5 mg at bedtime caused Cushingoid fea-

tures in some women with nonclassic CAH within 4–8 weeks in the author's experience as well as in PCOS patients with elevated adrenal androgens (245).

The aim of treatment is to reduce adrenal androgen secretion to a low-normal level, not complete adrenal suppression, thereby minimizing the side effects. Our experience indicates that marginal to significant clinical improvement of hirsutism in a large number of women with these increased adrenal androgen-producing conditions occurred within 8 months to 1 year of treatment. By the second year of treatment, a majority of the patients showed good improvement in hirsutism. In almost all cases recovery of menses occurred in 2–3 months following adequate suppression of excess adrenal androgen secretion. Therapeutic monitoring of 21-hydroxylase deficiency requires periodic follow-up measurement of 17-OHP, Δ^4 -A, and T levels. Periodic measurement of DHEA, DHEA-S, Δ^4 -A, and T is necessary to monitor 3 β -HSD deficiency and idiopathic adrenal hyperandrogenism. Antiandrogen drug therapy as depicted later in Table 8 may be necessary in those patients whose hirsutism symptoms do not improve significantly despite lowered adrenal androgen levels. Use of spironolactone in nonclassic CAH is, however, not desirable due to its potential salt-wasting effect.

B. Primary PCOS and Stromal Hyperthecosis

Primary PCOS is a more difficult condition to treat successfully for both hirsutism and menstrual disorders (amenorrhea/oligomenorrhea or dysfunctional bleeding). In patients with insulin resistance and/or obesity, additional risk of glucose intolerance or type 2 diabetes and complications of obesity need to be dealt with. In PCOS females with insulin resistance with or without obesity and menstrual disorder, treatment for hyperinsulinemia secondary to insulin resistance is the approach of choice. This is because the pathophysiology of ovarian hyperandrogenism and menstrual disorder is related to a peripheral defect in either the insulin-signaling pathway or glucose metabolic pathway as described earlier. Thus, weight control and weight loss measures in obese patients, including nutritionally healthy eating, controls on both the amount and kinds of food, coupled with a physically active lifestyle in the long term is needed to reduce or prevent ovarian hyperandrogenism, glucose intolerance, type 2 diabetes, hyperlipidemia, and hypertension.

Insulin-sensitizing pharmacological agents used in the past few years and currently available on the market are summarized in Table 6. Metformin hydrochloride (Glucophage) decreases hepatic glucose production, decreases intestinal glucose absorption, increases peripheral glucose uptake/utilization (nonhypoglycemic agent), and has been more widely used than other insulin-sensitizing agents for PCOS females. At a dosage of 1000–2000 mg per day in two to three divided doses, it is effective in improving glycemic parameters, lowering insulin levels, and improv-

Table 6 Reported Effects of Pharmacological Therapies for Hirsutism and Polycystic Ovary Syndrome

Classification of therapy	Hirsutism and androgen levels				Menstrual disorders			Ref.	Precautions	
	Drugs and dosage	Idiopathic	Hyperandrogenic causes		Cycle regulation	Anovulation	Insulin resistance, glucose intolerance			Lipid changes
			↓ F-G score	↔ Androgens						
Antiandrogens	Spirololactone, 100–200 mg/d ± COC	↓ F-G score ↔ Androgens	↓ F-G score ↔ Androgens	↓ F-G score ↓ Free T				257, 267–272	Need of contraception/long-term therapy for efficacy, gradual dose increase from 25 to 100 mg over time, K+ level monitoring, breast tenderness, irregular bleeding, mild volume deletion Same as COC below	
	CPA, 50–100 mg/1–10 days of use + COC or 25–50 mg/day + COC	↓ F-G score ↓ Androgens	↓ F-G score ↓ Androgens	↓ F-G score ↓ Androgens				257, 263, 270, 272, 275		
	Flutamide, 62.5–250 mg/d, 250 mg bid ± COC	↓ F-G score ↔ T, DHT, 3α-AG	↓ F-G score ↔ T, DHT, 3α-AG	↓ F-G score ↔ T, DHT, 3α-AG				263, 270, 272, 275, 276	Contraception precaution, liver function monitoring a must; fulminant liver failure reported	
Glucocorticoids	Finasteride, 5 mg/d ± COC, 0.25% finasteride cream	↓ F-G score ↔ or ↑ T/E ₂ ↓ DHT, 3α-AG, DHEA-S	↓ F-G score ↔ or ↑ T/E ₂ ↓ DHT, 3α-AG, DHEA-S	↓ F-G score ↔, ↑ Total T ↓ DHT, 3α-AG				262, 270, 276, 277	Contraception precaution	
	Dexamethasone, 0.375 mg/d + spironolactone 100 mg/d, Dexamethasone 0.5 mg po qd			↓ F-G score ↓ T/Free T ↓ DHEA-S ↓ All androgens				267, 233	Cushingoid side effect/weight gain at 0.5 mg/day dose	
	Low dose COC, 35 µg EE + progestin	↓ F-G score	↓ F-G score	↓ F-G score ↓ only in lean PCOS ↓ T/free T ↓ LH and FSH	Anovulatory cycle regularity			252, 256–261	↑ risk of venous thrombosis in coagulation factor V cases, ↑ risk of arterial thrombosis in hypertensive patients, smoker and >35 yrs age, weight gain, breakthrough bleeding, GI SYS, breast tenderness, and mood swing	
Triphasic OC	EE, 35 µg + CPA 2 mg/d							262–265	Temporary ↑ in LH/FSH, COC Rx to prevent osteoporosis, costly Rx	
	Leuprolide depot, Triptorelin, decapeptyl 3.75–7.5 mg/q m IM ± COC	↓ F-G score ↓ T/free T ↓ DHEA, A	↓ F-G score ↓ T/free T ↓ DHEA, A	↓ F-G score ↓ T/free T/DHEA-S ↓ LH and FSH ↓ Androgen ↔ F-G score	Anovulatory cycle regularity			256		
Insulin-sensitizing agents	Goserelin, 3.75 mg/q m IM ± COC									
	Metformin, 1000–2000 mg/d in 2–3 divided doses	Improved menstrual cyclicity/regularity, less for patients with ↑ DHEA-S	Improved menstrual cyclicity/regularity, less for patients with ↑ DHEA-S	Recovery of spontaneous/clomid-induced ovulation				246, 247, 249, 250, 252, 259	Contraindicated for renal/hepatic dysfunction—monitor function yearly, GI side effects, lactic acidosis precaution	
Acarbose, 300 mg/d in 3 divided doses	↓ Acne/seborrhea ↓ Androgen	↓ Acne/seborrhea ↓ Androgen	↓ Acne/seborrhea ↓ Androgen	53% normal cycle recovery				255	GI side effects, flatulence, pain, diarrhea, do not use in liver disorder, GI disorders, renal failure	

F-G, Ferriman-Gallwey hirsutism score; EE, ethinyl estradiol; CPA, cyproterone acetate; ↑, increase; ↓, decrease; ↔, no change; 3α-AG, 3α-androstanediol gluconate; A, androstenedione; COC, combined estrogen/progesterone oral contraceptives.

ing or recovering regular menstrual cyclicity in women with PCOS (246–250) and decreased visceral adiposity (248, 251, 252). The effect of metformin on the Ferriman-Gallwey Hirsutism Score has been inconsistent (247, 250) and appears less effective in patients with elevated DHEA and DHEA-S levels (246). Troglitazone (Rezulin; no longer on the market) is an insulin-sensitizing agent of the thiazolidinedione family. It has the pharmacological action of decreasing hepatic glucose output and increasing insulin-dependent glucose disposal in skeletal muscle via its binding to peroxisome proliferator-activated receptors (253, 254). At a dosage of 400–600 mg per day it improved all glycemic parameters and the ovulatory cycle in PCOS females (253, 254). The drug was removed from the market due to a potential for liver toxicity. Its effect on hirsutism, however, was only slight (253, 254). Rosiglitazone (Avandia) and Pioglitazone (Actos) are potent agonists for peroxisome proliferator-activated receptor- γ and have pharmacological actions similar to Troglitazone. Both are available on the market, but their use for PCOS females is limited. Acarbose (Precose) is an agent of alpha-glucosidase inhibitor that delays digestion of ingested carbohydrates and minimizes glucose use. A dosage of 300 mg per day was reported to be effective in lowering insulin levels and in the recovery of the normal menstrual cycle in 53% of PCOS females. Improved acne has also been reported (255).

If the patient desires mainly hirsutism treatment, as is the case with many adolescent girls with PCOS or hyperandrogenism, the antiandrogen therapies in Table 6 may be considered as well as combined estrogen/progesterone oral contraceptive (COC) therapy. Because all of the antiandrogen agents are potentially teratogenic for the male fetus, women of reproductive age should take contraceptive precautions using either COC or barrier contraceptives during this treatment. Additive effects of an antiandrogen agent and COC are likely to result in a greater degree of improvement in hirsutism. Use of antiandrogen compounds in the treatment of hirsutism is described in greater detail in the section on Idiopathic Hirsutism below. COC treatment alone in PCOS patients is often partially effective in hirsutism improvement and suppression of ovarian androgen secretion and free T levels (252, 256–261). Cyclic COC therapy in PCOS patients, however, has a long-term benefit from the prevention of endometrial hyperplasia to an unopposed effect of increased free estrogen in PCOS. COC has no discernable effect on insulin sensitivity and has variable influence on HDL and LDL, and total cholesterol and triglyceride levels (256–259). Thus, the long-term benefits of COC on lipids are difficult to predict in young women (Table 6).

In women with severe PCOS or stromal ovarian hyperthecosis with a greater degree of elevated ovarian testosterone level associated with increased LH secretion, use of a GnRH analog at a dosage of 3.75–7.5 mg intramuscularly (IM) every 28 days is highly effective in near-

total suppression of gonadotropin and ovarian androgen secretion (182, 262–265). GnRH analog therapy is often combined with COC to prevent any undesirable effect on bone mineral density in these patients. The combined therapies of GnRH analog and COC thus have the effect of decreasing ovarian androgen levels, having antiandrogen action in the androgen-sensitive tissue, and increasing SHBG. They were also very effective in the treatment of hirsutism in PCOS and stromal hyperthecosis. The drawback of these therapies, however, is recurrence of ovarian hyperandrogenism and symptoms shortly after the drug therapies are discontinued (182, 260). Although ketoconazole has been reported to be effective in decreasing serum androgen levels and hirsutism (257, 266), this compound has not been widely accepted in the treatment of hirsutism.

C. Idiopathic Hirsutism

In the treatment of idiopathic hirsutism, the antiandrogen agents shown in Table 6 are predicted to be more specific therapeutic agents. However all antiandrogenic agents entail the risk of teratogenic effects. Therefore, absolute contraceptive measures are a must in women receiving antiandrogenic therapy. During the past several years, wider experience with four different antiandrogenic agents for treatment of idiopathic and hyperandrogenic hirsutism have been reported (Table 6), although the Food and Drug Administration has approved of none of these agents for treatment of hirsutism.

Spironolactone (100–400 mg/day) interferes with DHT binding to its receptor and forms inactive complexes at the nuclear level, minimizing the androgen effect on hair growth. Spironolactone treatment has variable results in hirsute females and other cosmetic hair removal care is often necessary. In our experience, spironolactone alone or combined therapy with spironolactone and COC was more effective in women with idiopathic hirsutism defined by normal androgen levels than in women with elevated androgen levels. Recent reports using a lower dosage of spironolactone (at 100–200 mg per day) showed as effective results in decreasing the Ferriman-Gallwey score as COC alone or cyproterone acetate combined with COC or ketoconazole therapy (257, 267–272) or flutamide or finasteride (270).

Cyproterone acetate is a synthetic steroid derivative of 17-OHP and has both antiandrogenic and antigonadotropic action (273). This agent is effective not only in the treatment of idiopathic hirsutism but also in other causes of androgen excess due to its antiandrogenic properties and by reducing androgen production via suppression of gonadotropin secretion (274). Overall, the combination of cyproterone acetate at 50–100 mg from cycle days 1–10, or a daily dose of 25–50 mg together with low-dosage estrogen therapy reduces the production, transport, metabolism, and action of androgens (257, 263, 270, 272, 273, 275). As shown in Table 6, numerous European sources

indicate successful treatment of hirsutism of various causes using these combinations.

5 α -reductase inhibitor should theoretically be an effective agent in the treatment of hirsutism. The type 1 5 α -reductase isoenzyme predominates in peripheral tissue and type 2 isoenzyme in the reproductive system. Recently, type 2 isoenzyme has also been demonstrated in the hair follicle tissue and was described earlier. Of several steroidal and nonsteroidal 5 α -reductase inhibitors, only finasteride has been extensively used for the treatment of hirsutism (262, 270, 276, 277). Finasteride at a daily dosage of 5 mg orally has been reported to decrease hirsutism scores in patients with both idiopathic and hyperandrogenic hirsutism (262, 270, 276, 277). Its effect on circulating androgen levels appears variable. The effect of finasteride in decreasing hirsutism has been reported to be either similar to the effect of cyproterone acetate or flutamide (275) or less than the effect of flutamide (276).

Flutamide is a nonsteroidal antiandrogen and prevents androgen from binding to the androgen receptor by its competitive binding without androgenic activity. Variable dosages of flutamide from 62.5 to 500 mg in two divided doses daily have been reported as effective in the treatment of hirsutism in both the idiopathic and hyperandrogenic causes (263, 270, 272, 275, 276, 278). A concern about this drug derives from a few reports of related fulminant hepatic failure (279–281). Thus, close monitoring of liver function is mandatory during the course of flutamide therapy.

COC treatment alone or combined COC and GnRH analog therapy in idiopathic hirsutism decreased the hirsutism score in a few reports (260, 261) (Table 6). The beneficial effects of COC and GnRH were described earlier.

In summary, most of the antiandrogenic drug therapies have been reported as effective in decreasing the amount of hirsutism in patients with either idiopathic or hyperandrogenic cases.

However, the drawbacks of these therapies are their temporary effectiveness during the drug treatment course. Cessation of drug therapies almost invariably results in recurrent hyperandrogenic symptoms with time. In addition, there are known potential side effects with all drug therapies, as summarized in Table 6. Evaluation of renal and hepatic function prior to and during administration of many of these pharmacological compounds and providing precautionary information to the patient with regard to potential side effects of the compounds are prudent measures in clinical practice.

D. Cosmetic Treatment of Hirsutism

Psychological embarrassment as a result of hirsutism and/or acne in adolescents and young adult women is a common observation in clinical practice. Thus, many patients undertake immediate methods of hair elimination prior to seeking medical help. Traditional methods of hair removal

include shaving, waxing, tweezing, depilatory creams, and electrolysis. Recently, hair removal methods based on light technology such as lasers or intense pulsed light have been used in darker-skinned patients (282). This was reported to be a useful method when proper patient selection was employed in both darker- and lighter-skinned subjects (282–284). Both cosmetic and medical therapies need to be considered for hirsute females to minimize emotional embarrassment.

VII. MENSTRUAL DISORDERS IN ADOLESCENTS

A. Physiology of the Menstrual Cycle

Maturation of the normal ovulatory menstrual cycle requires intact development and function of the cascade of the system, including maturation of cyclic hypothalamic gonadotropin-releasing hormone secretion in the basal hypothalamus; its effect on the sequence and magnitude of gonadotropin secretion in the anterior pituitary; proper quantity and sequence of ovarian steroidogenesis, which interacts in a positive manner for induction of ovulatory cyclic changes of LH and FSH; evolving spectrum of follicle development, ovulation, and corpus luteum function; and development and cyclic changes of the endometrium in relation to the ovarian steroidogenic and follicular life cycle (Fig. 7). The entire system is regulated by a complex mechanism that integrates biophysical and biochemical information composed of interactive levels of hormonal signals, autocrine and paracrine factors, and target cell reactions (285, 286). In addition, the normal anatomy of menstrual outflow that connects the internal genital source of flow with the outside provides patency and continuity of the endocervix with the uterine cavity, vaginal canal, and orifice.

The average age of menarche in the U.S. is 12.8 years for white girls and 12.6 years for African-American girls, with a range from 9 to 16 years in the normal spectrum. Age of menarche is associated with race, nutritional status, amount of body fat, and maternal age at menarche. Menarche usually occurs 2–2.5 years after thelarche and 1 year after the growth spurt. Normal menstrual cycles vary from 21 to 45 days but remain fairly constant within a given individual. Normal flow lasts 2–7 days with an average blood flow of 30–40 ml. Ovulation may not begin until as late as 2 years after menarche (286, 287).

B. Definition of Menstrual Disorder

Primary amenorrhea is defined by the absence of menarche by age 16 years with normal pubertal development; by 2 years after completed sexual maturation; or without the onset of pubertal development by age 14 years. Secondary amenorrhea is defined by the absence of menstruation for 3 cycle lengths in the setting of oligomenorrhea, for 6 months after establishing regular menses or by 18

Figure 7 Normal menstrual cycle of hormonal follicular and endometrial changes. (From Carr BR and Wilson JD, Disorders of the Ovary and Female Reproductive Tract in Harrison's Principles of Internal Medicine, 11th Edition, 1987:1818–1837. Reproduced with permission from McGraw-Hill, New York, NY.)

months after menarche (285). Oligomenorrhea is defined by significantly diminished menstrual flow. Polymenorrhea, or intermenorrhea indicates a too frequent menstrual flow cycle (less than 21 days). Menorrhagia indicates excessive uterine bleeding occurring at the regular intervals of menstruation, and menometrorrhagia indicates excessive uterine bleeding occurring at regular or irregular intervals. Table 7 depicts the causes of menstrual disorders/alteration in young women with apparent normal external genitalia.

C. Causes of Menstrual Disorders

1. Primary Amenorrhea

Primary amenorrhea may be caused by a congenital or acquired pathology of a significant degree in the CNS–hypothalamic–pituitary–ovarian (H–P–O) axes; in the genital anatomy; as well as other systemic and/or hormonal factors affecting the H–P–O axes; and rarely but not impossibly by pregnancy. Complete absence of sec-

ondary sex characteristic development, including amenorrhea in the absence of hyperandrogenic symptoms or signs, generally signifies complete or near complete failure of either ovarian or hypothalamic–pituitary gonadotrope function of either congenital or inherited causes or causes acquired prior to adolescence. The classification of the causes of primary amenorrhea depicted in Table 7 helps to identify the pathogenic site of this disorder.

a. Normal Anatomy of the Genital Outflow Tract. Primary ovarian failure results in a hypergonadotropic state with a greater increase in FSH than LH from peripubertal age (288). Congenital causes include gonadal dysgenesis due to an abnormal X chromosome typified by a deletion of an X chromosome during meiosis, resulting in features of classic Turner syndrome including sexual infantilism, short stature, cardiovascular defects, webbed neck, shield chest, short fourth and fifth metacarpals, increased carrying angles of arms, and other associated features. In Turner syndrome, germ cells are absent in the

Table 7 Causes of Menstrual Disorders with Apparent Female External Genitalia in Adolescent Girls

Primary amenorrhea	Secondary amenorrhea	Oligomenorrhea and menometrorrhagia
1. Primary ovarian failure (Hypergonadotropic hypogonadism): Congenital Gonadal dysgenesis (Turner syndrome/mosaicism, pure 46 XX or XY dysgenesis, other X chromosome abnormalities) 17 α -hydroxylase/17, 20 lyase deficiency Other congenital FSH receptor gene mutation LH receptor gene mutation Acquired Autoimmune oophoritis Mumps oophoritis Irradiation Chemotherapy Galactosemia complication	Pregnancy Hypothalamic amenorrhea PCOS/stromal hyperthecosis Hyperprolactinemia Hypo/hyperthyroidism Turner mosaicism Other X chromosome abnormalities All acquired causes of hyper/hypogonadotropism All acquired virilizing disorders including Cushing syndrome	Pregnancy PCOS Hyperprolactinemia Functional hypothalamic anovulation Thyroid disorder
2. Gonadatropin deficiency: Congenital GnRH deficiency (Kallman syndrome) Hypopituitarism/empty sella syndrome GnRH receptor gene mutation Prader-Willi syndrome Bardet-Biedel syndrome Acquired CNS trauma CNS histiocytosis X Suprasella tumors Eating disorders Rigorous exercise		
3. Genital structure abnormalities: Congenital in genetic females Agenesis of mullerian structure (Mayer-Robitansky-Kuster-Hauser syndrome) Agenesis of vagina Agenesis of cervix/endometrium Hymen imperforation Labial agglutination Congenital in genetic males Complete androgen insensitivity 17 α -hydroxylase/17, 20 lyase deficiency Acquired Uterine synechia secondary to irradiation/infection		
4. Hyperandrogenic disorders: Stromal hyperthecosis/PCOS Congenital adrenal hyperplasia Androgen-producing tumor		
5. Pregnancy		

ovary and are replaced by a fibrous streak. The variants of Turner syndrome are termed Turner mosaicism, with X-chromosome abnormalities such as 45 X/46 XX; and iso or ring X-chromosome. 46 XX/XXX abnormality is also a cause of ovarian failure (289). In subjects with Turner mosaicism, the degree of ovarian failure may be complete or partial, thus development of some secondary sex characteristics may be present despite primary amenorrhea (289). Gonadal dysgenesis is the most common cause of primary amenorrhea. Pure gonadal dysgenesis with a 46 XY karyotype (Swyer syndrome) is a rare cause of primary gonadal failure and is associated with increased risk of gonadoblastoma development from the streak gonads (290). A recent cytogenetic study of adolescent patients with primary amenorrhea revealed a pathological or male karyotype in 26.4% (18/68) of patients (289). Pure gonadal dysgenesis with 46 XX karyotype may result from a single gene defect or destruction of germinal tissues in utero by environmental or infectious processes (291, 292). Both genetic females and males with gonadal/adrenal combined 17- α -hydroxylase/17,20 lyase deficiencies of significant degrees are phenotypically feminized and fail to develop female secondary sex characteristics (293, 294). A characteristic clinical clue for this enzyme deficiency is hypertension; biochemical evaluation would verify elevated progesterone and deoxycorticosterone levels and decreased 17-hydroxysteroids, DHEA, other androgens and estrogen levels. Feminized genetic males with this enzyme deficiency do not have the müllerian structure.

Acquired causes of primary ovarian failure include mumps oophoritis; autoimmune oophoritis; destruction of ovarian tissue by trauma, irradiation, or chemotherapeutic complications; or by excessive accumulation of galactose-1-phosphate or deficiency of galactose-containing compounds in the ovary of patients with galactosemia (295); as well as idiopathic cause for primary amenorrhea. Depending on the age at which the disease is acquired, primary amenorrhea may or may not be associated with secondary sex characteristic development. Other rare genetic causes of hypergonadotropic primary amenorrhea include inactivating mutations of the FSH receptor gene in females with normal pubertal development, high plasma FSH level and numerous ovarian follicles (296), and inactivating mutations of the LH receptor gene in females with normal breast development (297, 298).

Gonadotropin deficiency due to a congenital or inherited disorder or acquired cause results in hypogonadotropic hypogonadism and primary amenorrhea. A cause of inherited hypogonadotropic hypogonadism is Kallman syndrome resulting from congenital deficiency of GnRH in the presence or absence of agenesis of olfactory bulbs causing anosmia. This disorder is transmitted by an X-linked gene mutation but may also be transmitted by an autosomal dominant trait (299, 300). Thus, this disorder occurs in both females and males. GnRH receptor

gene mutation has recently been characterized and results in hypogonadotropic hypogonadism and primary amenorrhea in females with normal breast development (301). Other congenital syndromes that have been reported to be associated with hypogonadotropic hypogonadism include Bardet-Biedel syndrome and Prader-Willi syndrome. Other congenital causes of hypogonadotropic hypogonadism are empty sella syndrome, which causes varying degrees of hypopituitarism and idiopathic gonadotropin-deficient hypogonadism. An acquired cause of gonadotropin deficiency causing primary amenorrhea is chronic debilitating systemic disease, which is often associated with overall delayed development of secondary sex characteristics. This delay is seen in patients with congenital hemoglobinopathy, malabsorption, human immunodeficiency virus (HIV), chronic nutritional deprivation, malnutrition, or due to eating disorders including anorexia nervosa and bulimia with or without rigorous exercise. Organic and anatomical pathologies in the hypothalamic-pituitary region, including suprasella tumors (craniopharyngioma, germinoma, teratoma, histiocytosis, etc.); or other inflammatory processes (sarcoidosis, meningitis, tuberculosis, etc.) in the hypothalamic region; pituitary tumors, pituitary infarction or necrosis, or pituitary hemachromatosis or sarcoidosis; or trauma in the pituitary stalk or hypothalamic-pituitary axis region are well-known causes of hypopituitarism and hypogonadism.

Primary amenorrhea may be related to hyperandrogenic disorders including ovarian hyperthecosis and PCOS, CAH, Cushing syndrome, or androgen-producing tumors, as discussed earlier in this chapter. The clinical presentation of these disorders is often associated with hyperandrogenic symptoms. Excess androgens, progesterone, or cyclic production of estrone by extraglandular aromatization of excess androgens is likely to be altering the feedback loop of the H-P-O axis in these disorders. Thyroid disorders including hyper- or hypothyroidism are a cause of amenorrhea of primary and secondary natures and may be associated with estrogen-positive anovulation.

Other gonadal and endocrine disorders to be considered for primary amenorrhea include mixed gonadal dysgenesis, true hermaphroditism, and androgen resistance syndrome in genetic males with complete or near complete female phenotypic presentation. Any slight suspicion of genital ambiguity with or without signs of virilization or palpable gonadal mass in the inguinal or labial region in the female is often a clue for these causes (See Chapter 13 on Ambiguous Genitalia and Sexological Considerations). A varying degree of internal genital abnormality is associated with these causes of sexual ambiguity.

b. Anatomical Defect in the Outflow Genital Tract and Uterus. Characteristically, females with anatomical defects in the genital tract present with normal development of secondary sex characteristics and normal maturation of the H-P-O axis including ovulatory function. Due to an obstruction in the genital tract, menstrual blood

accumulates behind the obstruction site. Cyclic and predicted episodes of pain in the absence of menses are a typical presentation and the patient may develop hematocolpos, hematometra, or hemoperitoneum. If undiagnosed, these disorders may lead to endometriosis, adhesion, and eventually infertility. Causes of the obstruction defect in the female tract are many and include agenesis or imperforation at various sites of the anatomy (Table 7). Agenesis of the mullerian structure (Mayer–Rokitansky–Hauser syndrome) is the second most common cause of primary amenorrhea and results in the absence of the vagina and aplasia or hypoplasia of the uterus, such as rudimentary bicornuate cords (302). This syndrome occurs in 1:4000–5000 girls. Renal abnormalities occur in 30–40% of subjects with this syndrome (303) and spinal abnormality has also been reported. Defects in the fusion of the mullerian structure caudally or with the urogenital sinus results in abnormal development of the uterus or uterine septum and failure to discharge outflow. Agenesis of the vagina or cervix, transverse vaginal septum or imperforate hymen, idiopathic labial fusion, and adhesion or secondary labial agglutination are known causes of menstrual outflow obstruction. Endometrial hypoplasia or aplasia is a rare cause of primary amenorrhea.

2. Secondary Amenorrhea

Secondary amenorrhea in otherwise sexually healthy adolescents and young women warrants pregnancy testing. Secondary amenorrhea in patients with hyperandrogenic disorders including PCOS, ovarian hyperthecosis, adrenal causes of excess androgen-producing pathology, hyperprolactinemia, and thyroid disorders were discussed in the previous section. Almost all known causes of hypergonadotropic hypogonadism including Turner mosaicism and other X-chromosome abnormalities and all acquired causes of primary amenorrhea are also causes of secondary amenorrhea. Acquired causes of hypogonadotropic hypogonadism of primary amenorrhea are also causes of secondary amenorrhea. Hypothalamic amenorrhea represents a spectrum of disordered GnRH secretion that can vary over time, from apulsatile to low frequency/amplitude to low amplitude with normal frequency of LH pulses, low frequency and normal amplitude, and normal amplitude and frequency of LH pulses (304). The causes of hypothalamic amenorrhea may be psychological in nature, related to stress, weight loss, eating disorders such as anorexia nervosa and bulimia nervosa (305, 306), chronic, high-intensity physical exercises (307), or idiopathic. The diagnosis of hypothalamic amenorrhea is made by exclusion of other probable causes and normal imaging studies of the hypothalamic–pituitary anatomy.

3. Oligomenorrhea and Menometrorrhagia

Both decreased and increased menstrual volume with regular or irregular cycles may be caused by pregnancy com-

plications or by all of the known causes of endocrine abnormalities for secondary amenorrhea including PCOS, hyperprolactinemia, thyroid disorder, Cushing syndrome, and functional hypothalamic anovulation. Additional causes of menometrorrhagia in adolescent females include bleeding disorders and complications of the genital tract such as trauma, dysplasia, polyps, foreign bodies, and infection.

D. Evaluation of Menstrual Disorder

In all adolescents with menstrual disorders, a detailed history with regard to growth and secondary sex characteristic maturation is helpful in identifying the cause of the abnormality. Careful history of age at thelarche, pubarche, and menarche, menstrual history, flow of menses, presence or absence of excessive weight gain during peripubertal age, dysmenorrhea, cyclic pelvic pain, cyclic breast changes, and the presence or absence of hirsutism/acne are helpful in determining the likely cause of the menstrual disorder. Histories with regard to nutrition, physical training, sexual activity, weight change, dieting, body image, and emotional and family dynamics are also essential in evaluating the patient with primary or secondary amenorrhea or oligomenorrhea. Childhood history of illness, chronic disease, or therapies (chemotherapy/radiation therapy) may determine the causative factor. History-taking should also include vasomotor symptoms (hot flashes), virilizing signs, galactorrhea, symptoms of hypothyroidism, hyperthyroidism, and CNS symptoms including headache, hearing changes, and mood changes. Family history including maternal menstrual history, primary or secondary amenorrhea history in siblings or relatives, and hyperandrogenic history are also useful. Focus on physical examination pertinent to menstrual disorders includes anthropometric data, vital signs, androgen excess, Turner stigmata, acanthosis nigricans in the skin, thyroid gland, sexual maturation stage, breast discharge, presence or absence of sexual hair and genital ambiguity, pelvic mass or fullness in the patient with primary amenorrhea, and a careful gynecological patency examination in those with normal pubertal development despite primary amenorrhea. A guideline for a logical and stepwise approach for evaluation of primary amenorrhea, secondary amenorrhea, oligomenorrhea, and menometrorrhagia is provided in Figure 8.

Excluding those with obvious hyperandrogenic manifestation and sexual ambiguity, the first work-up for both primary and secondary amenorrhea is random gonadotropin level measurements. Those with unquestionably elevated FSH and LH levels have primary ovarian failure (>20 mIU/ml). A karyotype study would differentiate gonadal dysgenesis from other causes of primary ovarian failure. A positive antiovarian antibody study with established specificity and sensitivity indicates autoimmune, oophoritis while a negative antiovarian antibody finding cannot rule out the autoimmune disorder unequivocally.

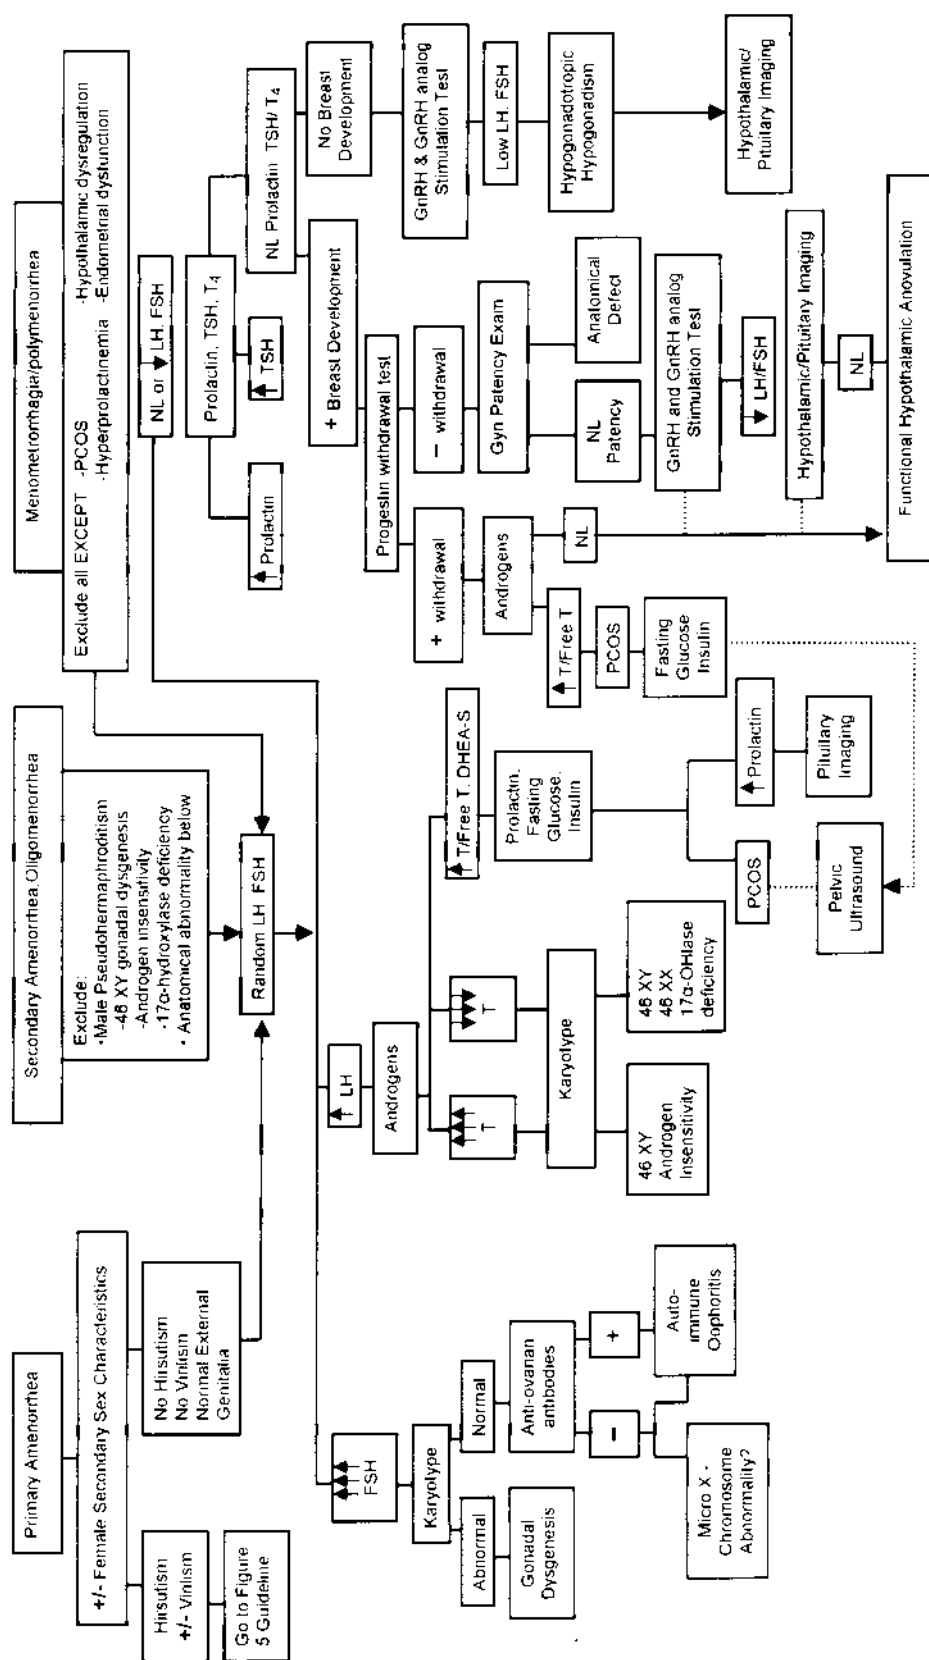

Figure 8 Guideline for evaluation of menstrual disorders. NL, normal; T, testosterone.

Patients with apparently normal karyotypes and a negative antiovarian antibody may have a micro X-chromosome abnormality that cannot be detected by the karyotype study. In amenorrheic patients with mildly elevated LH levels (>10 – <20 mIU/ml) with normal or low FSH levels (5–10 mIU/ml), a serum androgen level study helps to differentiate between those with androgen insensitivity syndrome in genetic males, gonadal/adrenal 17α -hydroxylase/17,20 lyase deficiency in genetic females and males, and PCOS and hyperprolactinemia. Mildly elevated or normal androgen levels would require a serum prolactin level study. Patients with elevated prolactin levels require a further imaging study of the pituitary to look for prolactin-secreting pituitary adenoma. Those with a normal prolactin level are suspected to have PCOS and will need an additional study of fasting glucose and insulin levels to determine insulin resistance. Pelvic ultrasound study may be required to identify imaging of the ovaries compatible with PCOS.

Amenorrheic patients with normal or low random levels of LH and FSH (<10 mIU/ml) require prolactin and thyroid function studies to exclude or identify these hormonal disorders as the cause. In patients with normal prolactin and thyroid function, and normal breast development, a careful examination of the genital tract and progestin withdrawal test are necessary. For those with a positive withdrawal response to progestin administration (ie, Provera 5–10 mg orally per day for 5 days), serum androgen level determination helps to differentiate between PCOS and hypothalamic amenorrhea. For those with no withdrawal response to progestin administration, a gynecological examination for genital patency is mandatory in patients with primary amenorrhea. Those with patency of the genital outflow tract require investigation of hypogonadotropic hypogonadism by a GnRH or GnRH analog stimulation test. An imaging examination of the hypothalamic and pituitary region is necessary to exclude an organic cause of hypogonadotropic hypogonadism or hypothalamic amenorrhea. In patients with absent or delayed development of secondary sex characteristics, normal or low random LH and FSH levels, and normal prolactin and thyroid function, hypogonadotropic hypogonadism evaluation is necessary by GnRH or GnRH analog stimulation test. A pituitary imaging study is needed to rule out an organic cause of hypogonadotropism (tumor, empty sella).

E. Medical Treatment of Menstrual Disorders

Table 8 summarizes medical therapy methods commonly used in clinical practice or reported for various menstrual disorders in adolescent girls and young women. Delayed puberty and primary amenorrhea irrespective of primary or central hypogonadism requires incremental estrogen hormone replacement therapy at the appropriate pubertal onset age (≈ 10 – 11 years) for the development of secondary sex characteristics. The most commonly used es-

trogen compound is the natural conjugated estrogen, Premarin, for 1.5–2 years. For menstrual cycle regulation, combined estrogen and progestagen replacement therapy using cyclic Premarin followed by combined Premarin and progestin compound or a low-dose or triphasic COC may be used. Tolerance and efficacy of the cyclic hormone replacement therapy need to be monitored. Providing information to the patient on potential side effects of COC is a prudent measure. Poly- or intermenorrhea is generally treated with cyclic hormonal therapy, as in cases of amenorrhea (308, 309).

Ovulatory menorrhagia may be treated with pharmacological agents that reduce the volume of blood loss during the normal menstrual cycle including tranexamic acids, nonsteroidal anti-inflammatory drugs, cyclic progestin (Norethindrone, Provera, progestin-releasing intrauterine device [IUD]), and Danagel (Table 8). Dysmenorrhea with or without menorrhagia is generally treated with tranexamic acid in countries outside the US and nonsteroidal anti-inflammatory agents as listed in Table 8 (308, 310–312, 315). Any heavy bleeding of a moderate degree is generally treated with a low-dose COC 1/35 every 6–12 hours for 1–2 days with a gradual decrease to 1 pill per day in 5 days (308, 314) followed by cyclic COC therapy. Severe bleeding requires COC 1/50 every 6 h, as in the case of a moderate degree of bleeding if oral treatment is well tolerated. However, hospital admission may be necessary for parenteral administration of conjugated equine estrogen 25 mg every 4 h IV until bleeding stops. Surgical intervention is needed if medicinal therapy is not effective in cessation of severe abnormal uterine bleeding. An iron supplement is also necessary in the patient whose serum hemoglobin is below 12 gm %.

The treatment of menstrual disorders related to PCOS was described in the previous section and in Table 6. With the exception of primary ovarian failure or permanent hypogonadotropic hypogonadism, medical or hormonal replacement therapy may be offered for 6 months or so, with a re-evaluation of menstrual function thereafter. Hypothalamic amenorrhea needs to be dealt with in light of causative factors such as eating disorders, excessive physical exercise, or emotional causes and would require multidisciplinary care including counseling, nutritional help, and hormone replacement therapy if necessary. All other specific organic causes would require treatment for both the underlying organic disease and necessary hormone replacement therapy. For the simple and transient anovulatory cycle, reassurance and follow-up of patients are needed and COC therapy for a short-term period (6 months) may be useful in cases with oligomenorrhea or menometrorrhagia.

Disorders of Sexual Differentiation

Adriana A. Carrillo and Gary D. Berkovitz

University of Miami School of Medicine, Miami, Florida, U.S.A.

Marco Danon

Miami Children's Hospital, Miami, Florida, and State University of New York, Brooklyn, New York, U.S.A.

The establishment of chromosomal sex (46,XY or 46,XX) is considered the first step in normal sexual differentiation. However, the first sexual structures that form may be considered as either primordial or neutral. These structures have the capacity to develop along male or female lines following the expression of specific genes at approximately 1½ months after conception.

The term sex determination refers to the process in which the primordial gonad is committed to development as a testis or as an ovary. Sex differentiation refers to the process in which the internal accessory duct structures and external genitalia determination following differentiation of testis and ovary (1–5).

I. GONADAL DIFFERENTIATION

A. Embryology

1. Bipotential Gonad

The bipotential gonad develops from an outpouching of tissue on the posterior aspect of the celomic cavity on either side of the aorta. This structure is termed the urogenital ridge. It consists of three regions: the pronephros, the mesonephros, and the metanephros. The central region, the mesonephros, gives rise to the bipotential gonad and the first renal system. The primitive gonad forms on the medial portion of the urogenital ridge and is apparent at about 4 weeks of gestation. It consists of cells from the underlying mesonephric mesenchyme, cells that arise in the celomic epithelium, cells that migrate to the gonad

from the lateral portion of the mesonephros, and germ cells. Germ cells migrate from the yolk sac and enter the gonadal ridge during the 5th and 6th week of gestation. They undergo mitotic division during migration and continue to divide after arriving in the gonadal ridge (4, 6).

2. Testis Determination

Testis determination occurs at about 6 weeks of gestation. The first histological evidence of this is the appearance of Sertoli cells. These cells develop from progenitor cells contributed by the celomic epithelium. Sertoli cells encircle germ cells, form the testicular tubules, and cause mitotic arrest of germ cells. Sertoli cells secrete AMH and inhibin. Leydig cells, which develop later than Sertoli cells, are derived from cells that migrate from the mesonephros before testis determination occurs (7). They begin to secrete testosterone at 7–8 weeks of gestation. Peak serum levels of testosterone are reached by the 16th week of gestation. After testis determination, a second migration of cells from the mesonephros occurs. This migration is necessary to ensure the normal formation of testicular tubules (8, 9).

3. Ovarian Determination

Ovarian determination takes place at about 7 weeks of gestation. It involves formation of follicular cells, which are thought to arise from the same progenitor cells that give rise to Sertoli cells. Follicular cells surround germ cells in a loose configuration and form primordial folli-

cles. This process is associated with arrest of germ cells in meiotic prophase (9).

B. Genetic Control of Gonadal Differentiation

1. Genes Involved in Formation of the Gonadal Ridge

The homeobox gene *LIM-1* plays an important role in formation of the gonadal ridge (10, 11). Mice homozygous for deletions in *Lim-1* lack development of the head, gonadal ridge, and the ureteric bud of the metanephros. The human *LIMI* gene has been identified, but no mutations have been reported. A related gene termed *Lhx9* is expressed in the urogenital ridge in mice and the absence of *Lhx9* causes gonadal agenesis (12). Nonetheless, no mutations in *LHX-9* have been found in humans with abnormal gonadal differentiation (13).

The steroidogenic factor 1 (*SF1*) gene located on chromosome 9p33 is a member of the orphan nuclear receptor family. *SF-1* was first identified as an activator of genes involved in steroid biosynthesis in the adrenals. Later it was found that mice missing *SF-1* lack adrenal glands and gonads and have impaired development of the ventromedial hypothalamus (14). Another gene termed Wilms tumor repressor (*WT-1*) is located on chromosome 11p13 and encodes a transcription factor expressed in the urogenital ridge, mesonephros, kidney, and gonad. It influences in the development of all three structures (15).

2. Genes Involved in Testis Determination

Evidence from early karyotype studies indicated a key role for the Y chromosome in male sex determination. The Y chromosomal gene implicated in this process was called the testis-determining factor (TDF). The gene termed sex-determining region Y (SRY) was isolated in 1990 and has been shown to be identical to TDF (16). SRY is located on chromosome Yp11.3, close to the pseudoautosomal boundary. It belongs to the family of high-mobility group (HMG) proteins, which contain a related DNA-binding motif termed the HMG box. The SRY gene product bends DNA, and the change in configuration of chromatin results in increased transcription of target genes. SRY expression is tightly controlled and appears to be induced by the WT-1 gene product (15). The primary role of SRY in male sex determination was established by the demonstration that XX mice transgenic for the Sry transcript developed as males, by the observation that sex reversal occurred following site-directed mutagenesis of the Sry gene, and by the identification of SRY mutations in women with 46,XY gonadal dysgenesis.

The *SOX-9* gene, located on chromosome 17q 24.3–25.1 encodes an SRY-like protein. The *SOX-9* gene belongs to a family that derives its name from the term SRY-related HMG-Box gene. An increase in expression of *SOX-9* follows expression of SRY and *SOX-9* may be a

target gene of SRY. Both WT-1 and SF-1 continue to be expressed on the developing testes. *SOX-9* interacts with SF-1 in regulating the expression of antimüllerian hormone (AMH) gene, and mutation of *SOX-9* binding sites in the AMH promoter results in the absence of AMH secretion (17, 18).

DAX-1 is a member of the nuclear hormone receptor superfamily. Like SF-1, DAX-1 is expressed in the bipotential gonad, the embryonic adrenal cortex, pituitary gonadotropes, and in the ventromedial nucleus of the hypothalamus. Expression of DAX-1 is repressed in testis but continues in the ovary after gonadal determination. Duplication of DAX-1 in males causes sex reversal. Hence, DAX-1 has been termed an antitestis gene (19). Mutations of DAX-1 result in X-linked adrenal hypoplasia congenita (AHC), but do not cause abnormalities in gonadal differentiation (20).

In summary, various genes such as *LIM-1*, *LHX-9*, *SF-1*, and *WT-1* are involved in the formation of the gonadal ridge of testis determination. SRY is the trigger of testis determination. Subsequent steps involve the expression of *SOX-9* as well as continued expression of SF-1 and WT-1 (21, 22).

3. Genes Involved in Ovarian Determination

Genetic control of ovarian determination is not well understood. However, the gene termed *WNT4* appears to play a role in this process and is also expressed in the mesenchyme surrounding müllerian ducts. Lack of *WNT4* gene impairs ovarian development, and the resulting gonad expresses testis-specific markers such as AMH and testosterone. Moreover, expression of *WNT4* is suppressed in the developing testis (23).

II. ANATOMICAL SEX DIFFERENTIATION OF THE REPRODUCTIVE TRACT

A. Undifferentiated Stage

1. Müllerian and Wolffian Ducts

The reproductive tracts of the male and female fetus are identical until 8 weeks of gestation. They consist of bilateral wolffian and müllerian ducts and neutral external genitalia (Figs. 1, 2). The wolffian, or mesonephric, ducts are the primordia of the epididymis, vas deferens, and seminal vesicles. Wolffian ducts form initially as the excretory canals of the primitive kidney or mesonephros, and are incorporated into the genital system when renal function is taken over by the definitive kidney or metanephros. The müllerian, or paramesonephric, ducts are the primordia of the fallopian tubes, uterus, and upper two-thirds of the vagina. They originate from a cleft between the gonadal ridge and the mesonephros, and grow parallel to the wolffian ducts, crossing them ventrally to form a single structure. By week 8 of gestation, the ducts reach the dorsal wall of the urogenital sinus, where they form

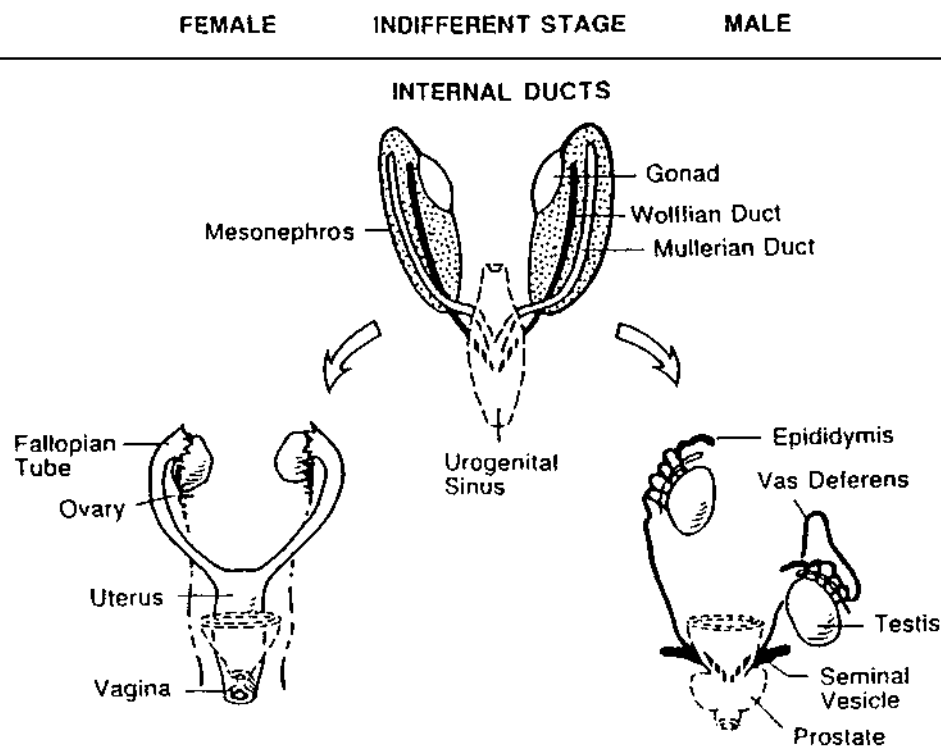

Figure 1 Phenotypic differentiation of internal ducts in male and female embryos.

the müllerian tubercle, which separates the cranial vesicourethral canal from the caudal urogenital sinus. The fused tips of the müllerian ducts are separated from the dorsal wall of the urogenital sinus by a solid mass, termed the vaginal cord (Figs. 1, 2) (24).

Several transcription factors are involved in the differentiation of intermediate mesenchyme to form the sex ducts. *Lim1*, which plays a role in formation of the gonadal ridge, is also necessary for expression of transcription factors such as *Pax-2* and *Hox-6* that mediate formation of the accessory sex ducts. *Pax-2* is expressed in the epithelium of the wolffian ducts. *Hox-6*, and other members of the Hox gene family, is expressed in the fallopian tubes (*Hoxa9*), uterus (*Hoxa 10,11*), cervix (*Hoxa11*), and upper vagina (*Hoxa 13*) (25).

The gene termed *Wnt4*, which is involved in ovarian development, is also necessary for development of müllerian structures and kidney. Lethal renal agenesis occurs as a result of *Wnt4* mutations in both males and females. Mutations of *Wnt4* interrupt müllerian duct development, although they do not interfere with wolffian duct formation. In addition, mutations of *Wnt-7a* in mice result in poorly developed müllerian ducts (26).

2. External Genitalia

Early development of external genitalia involves formation of the genital membrane, which closes the ventral part

of the cloaca. The cloacal membrane forms the urogenital and anal membranes at week 6 of gestation. By week 8 the cloaca is divided into an anterior urogenital sinus and a posterior anorectal canal. The genital tubercle is located ventrally, the urethral folds are located medially, whereas the genital folds or labioscrotal swellings are located laterally.

B. Male Differentiation

Regression of müllerian ducts begins at 8 weeks of gestation and depends on secretion of AMH. Regression of the müllerian ducts represents an unusual pattern of cell loss. Few cells actually die. Instead, they lose their polarity and orientation and cease to divide. The basement membrane dissolves, and a tight ring of connective tissue forms around the cells (27). Müllerian ducts have nearly completely disappeared by 10 weeks of gestation. Wolffian ducts are stabilized and subsequently differentiate into epididymis, vas deferens, and seminal vesicles. Mucous epididymal secretion is demonstrable from 25 weeks of gestation.

With respect to differentiation of the urogenital sinus, prostatic buds appear at approximately 10 weeks of gestation at the site of the müllerian tubercle and grow into solid branching cords. Maturation of the prostatic gland is accompanied by development of the prostatic utricle,

Figure 2 Phenotypic differentiation of external genitalia in male and female embryos.

which is the male remnant of the vaginal pouch. Two buds of epithelial cells, the sinoutricular bulbs, develop from the urogenital sinus close to the opening of the wolffian ducts and grow inward, fusing with the medial müllerian tubercle to form the sinoutricular cord. This structure makes contact with the caudal tip of the fused müllerian ducts and cannulizes at 18 weeks of gestation to form the prostatic utricle (28).

Masculinization of the male external genitalia begins in the 9-week-old fetus with lengthening of the anogenital distance, fusion of the labioscrotal folds, and closure of the rims of the urethral groove. This results in formation of a perineal and penile urethra. Penile organogenesis is completed by 11 weeks of gestation. The male and female phallus is the same size until week 16 of gestation (29).

The migration of testis from the lower pole of the kidney to the scrotum is a complex process that involves transabdominal migration and inguinoscrotal descent. The process starts at 12 weeks of gestation. The cranial suspensory ligament connects the testis to the abdominal wall, and the genitoinguinal ligament known as gubernaculum connects the testis to the inguinal canal. Caudal enlargement of the gubernaculum together with shortening of its proximal part and regression of the cranial suspensory ligament are part of the testis descent mechanism.

Transabdominal movement brings the testis to the internal inguinal ring at midgestation, around 22 weeks. The actual passage of the testis through the inguinal canal into the scrotum does not occur until after week 28, and may be delayed until the immediate postnatal period. The mechanism of testicular descent is not fully understood and probably results from a combination of mechanical, genetic, and hormonal factors. Increase in intra-abdominal pressure is an important factor in transit through the inguinal canal. This passage requires development of the processus vaginalis and increased intra-abdominal pressure. Factors controlling growth and differentiation of the gubernaculum are not completely understood, and the mechanism controlling direction of migration remains unknown (30).

C. Female Differentiation

As mentioned previously, müllerian ducts give rise to the fallopian tubes, uterus, and upper two-thirds of the vagina. Beginning at 10 weeks of gestation, the wolffian ducts are incorporated into the wall of müllerian derivatives.

In the female, the genital tubercle becomes the clitoris, the labioscrotal folds become the labia majora, and the urethral folds become the labia minora. At 15 weeks,

the lower pole of the müllerian ducts fuses with the upper portion of the vaginal pouch to form the vagina. Later the urogenital sinus is divided by a tissue plane that results in a separate urethral and vaginal opening on the perineum (Fig. 3).

III. HORMONAL CONTROL OF SEX DIFFERENTIATION

A. Jost's Hypothesis

Early experiments conducted by Alfred Jost have contributed greatly to our understanding of sex differentiation. In these studies, castration of fetal rabbits at the undifferentiated stages resulted in female differentiation. Unilateral implantation of testosterone crystal at the site of the testis in a castrated rabbit resulted in development of wolffian structures but not müllerian structures regression. By contrast, unilateral reimplantation of testis resulted in both development of wolffian structures and regression of müllerian structures. These observations led to the conclusion that at least two important factors are nec-

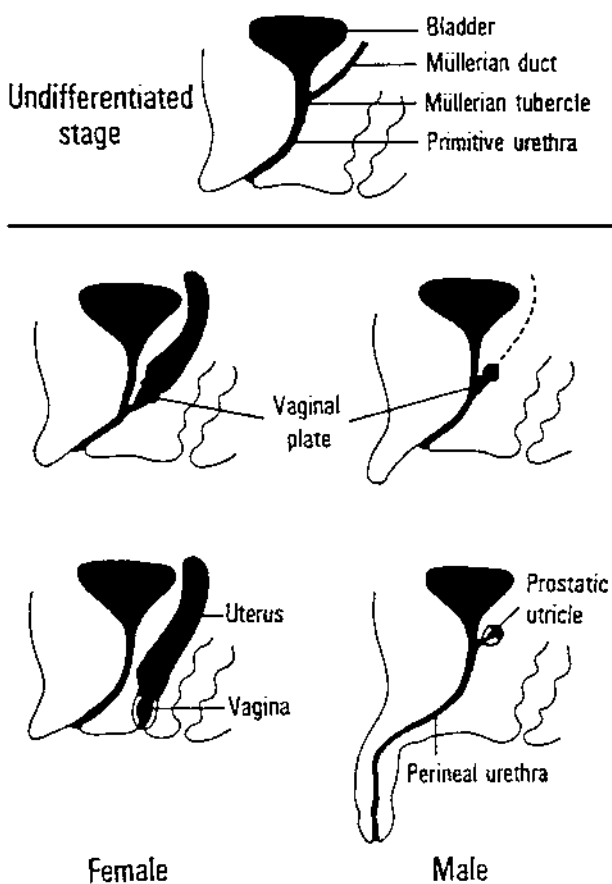

Figure 3 Sex differentiation of the urogenital sinus and external genitalia.

essary in the development of male reproductive sex ducts: testosterone for wolffian duct development and so-called müllerian inhibiting factor for regression of female ducts (31).

B. Antimüllerian Hormone

The müllerian-inhibiting factor that Jost proposed was later identified and named AMH. It produces the cranial-caudal regression of müllerian ducts during weeks 8–10 of gestation. It is a dimeric glycoprotein secreted by Sertoli cells. Granulosa cells also secrete AMH, but not until the critical period for müllerian regression has passed. AMH is a member of the transforming growth factor β (TGF- β) family, which includes inhibin, activins, and other factors. Members of this family control growth, differentiation, and the death of many tissues. Hormones in TGF- β family are usually produced as large precursors, which require cleavage to release the active hormone. AMH is cleaved by plasmin at a site located 109 amino acids away from the carboxyl terminus, generating the TGF- β -like carboxyl-terminal fragment that is thought to contain the biologically active site of AMH. The human AMH gene has been cloned and has been mapped to the short arm of chromosome 19 (5, 32).

The AMH receptor is a complex transmembrane serine/threonine kinase, and it is a heterodimer made up of a type I and type II receptors. Ligand binding to the receptor results in phosphorylation and activation of the type I receptor. The gene for the type I receptor is termed ALK2 and the gene product signals through the bone morphogenic protein (BMP) pathway (33). *Wnt-7a* plays a role in development of the type II receptor. Hence the mutation of *Wnt-7a* in male mice results in the persistence of müllerian ducts (34). The gene for the type II receptor has been cloned and has been mapped to chromosome 12. This gene is expressed in the mesenchyme surrounding the müllerian structures (35).

Serum AMH is also a marker of testicular function in infancy, and serum levels are useful in the diagnosis and management of patients with a variety of intersex and gonadal abnormalities (36). Granulosa cells of the postnatal ovary also produce AMH, and elevated serum levels have been reported in a case of granulosa cell tumor. Although AMH is produced by Sertoli cells until puberty and is also secreted by postnatal granulosa cells, its effects in both sexes after birth has not been confirmed.

The effect of AMH on ovarian function is controversial. AMH has been reported to inhibit progression of meiosis in oocytes and to result in masculinization of the fetal ovary. In a freemartin, a bovine female united to a male twin by placental anastomoses, ovaries are either reduced to fibrous streaks or have evidence of testicular determination. When ovaries grown in a culture are exposed to AMH or when fetal mice overexpressed AMH, ovaries are masculinized. AMH also sex-reverses the pattern of steroidogenesis in the fetal ovary by inhibiting aromatase

activity (5). Despite the masculinizing effect on fetal ovaries, AMH is not required for testicular development because mutations impairing AMH production do not affect testicular organogenesis.

C. Testosterone

Leydig cells appear between weeks 7 and 8 in the human fetus and proliferate until the 18th week of gestation. Human chorionic gonadotropic (hCG) receptors are present on fetal cells by at least 12 weeks of gestation. Gonadal steroidogenesis in the fetal gonads involves five enzymatic steps: steroidogenic acute regulatory protein (StAR), side chain cleavage (P450_{scc}), 3 β -hydroxydehydrogenase (3 β HSD), 17-hydroxylase/17-20 desmolase (P450₁₇), and 17 β -hydroxysteroid dehydrogenase. The number of Leydig cells decreases after 18 weeks of gestation and, indeed, few Leydig cells are visible by that time. Serum and testicular testosterone concentrations increase to a peak of about 300 ng/dl (range, 200–600) at 15–18 weeks of gestation. After 15 weeks, a low level of testosterone is maintained by hCG. A decrease in testosterone synthesis later in gestation is correlated with a decrease in LH/hCG receptors. During the second half of pregnancy, LH becomes the principal regulator of testosterone secretion. LH secretion is regulated in part by testosterone through a negative feedback at the level of the hypothalamus. In male infants, serum testosterone levels rise again during the first 2 days of life, decline until the end of the first week, and then peak at 2 months of age. By 6 months, testosterone levels reach typical prepubertal levels (37).

D. Mechanism of Testosterone and Dihydrotestosterone Action in the Reproductive Tract

Testosterone enters most cells by passive diffusion, although it has been suggested that the wolffian duct takes up testosterone by pinocytosis. In target tissues, testosterone is converted to dihydrotestosterone (DHT) by steroid 5 α -reductase. The conversion of testosterone to DHT is necessary for sex differentiation of male external genitalia. There are two explanations for this. First, DHT binds to the androgen receptor with greater affinity than does testosterone. Second, DHT cannot be aromatized, and thus its action is purely androgenic. Although masculinization of prostrate, urogenital sinus, and external genitalia depends on DHT, proliferation of wolffian ducts occurs in the presence of testosterone alone. This may happen because the internal ducts are exposed to high local concentrations of testosterone.

There are two forms of steroid 5 α -reductase, one having optimal activity at pH 5.5 and the other at pH 8. The former enzyme, which is the predominant form in the prostrate, is called steroid 5 α -reductase 2. The steroid 5 α -reductase 2 mediates conversion of testosterone to DHT

in the external genitalia. The gene has been mapped to chromosome 2. By contrast, the enzyme termed steroid 5 α -reductase 1 does not appear to play a role in differentiation of the reproductive tract. This gene has been mapped to the short arm of chromosome 5, band 15.

Binding of DHT to the androgen receptor is necessary for androgen effect (38). The androgen receptor has been cloned and is located on the long arm of the X chromosome near the centromere (Xq11-q12) (39). The androgen receptor is a member of a superfamily of nuclear receptors that includes the progesterone, glucocorticoid, mineralocorticoid, estrogen, thyroid hormone, vitamin D, vitamin A, and v-Erb receptors. The androgen receptor consists of eight exons encoding a protein of approximately 919 amino acids. Exon 1 encodes the N-terminal transcription activation domain. Exons 2 and 3 encode the DNA-binding domain, exons 4–8 the steroid binding domain (15). The DNA-binding domain consists of two cysteine-rich zinc fingers, and also encodes sequences for dimerization and translocation of the receptor to the nucleus. The transcriptional activation domain contains variable trimeric repeats. GGN repeats encode 16–27 glycine residues, CAG repeats encode 11–31 glutamine repeats. Heat shock proteins HSP 56, 70, and 90 are bound to the inactive receptor and binding of androgen results in their release. Subsequent conformational changes permit homodimerization and binding to response elements in target genes (40, 41).

Various coactivators also play a role in the function of the androgen receptor. These proteins interact with steroid hormone receptors to increase transcription of target genes. Binding sites for activation factors AF-1 and AF-2 are present in all of the steroid hormone receptors. AF-1 and AF-2 are synergistic in their effects on the receptor (42). Members of the steroid receptor coactivator (SRC) family appear to increase transcription by recruiting other coactivators factors to the receptor coactivator complex. Factors such as AP-1 and the small nuclear ring finger protein (SNURF) also influence receptor mediated transcription of target genes (43). Coactivator ARA-24 binds to the transactivation domain and increases transcription of target genes (44).

E. Estrogen

The biological effects of estrogens are mediated by estrogen receptors (ER). Estrogen diffuses freely into cells where it binds to ER in the nucleus. The ER–ligand complex dimerizes, binds to the estrogen response elements, and hence modulates transcription of estrogen-regulated genes. Two estrogen receptors, α and β , have similar affinity and specificity. The human estrogen receptor β has been detected as early as 13–20 weeks of gestation with highest levels being found in the adrenals, and in the male reproductive tract (45). Expression of the ER α and β has been identified in the uterus at the beginning of the second trimester and plays a role in uterine development.

Estrogen has also been implicated in several pathological states of male sexual differentiation. For example, prenatal exposure to estrogens can result in cryptorchidism possibly by inhibiting the insulin-like factor 3. Hypospadias, epididymal cysts, persistent Müllerian ducts, and prostatic disease have also been related to prenatal exposure to estrogen in males. ER α is essential for fluid reabsorption in the efferent ductulus and its absence results in infertility (46). In the female embryo, ER α and β are detected on epithelium of the oviduct and may modulate oviduct development. ER gene expression has also been identified in the uterus beginning in the early second trimester of fetal development, suggesting a role for ER in differentiation of primitive uterine mesenchyme in stromal and myometrial compartments.

F. Environmental Factors

A recent increase in incidence of developmental abnormalities of the reproductive tract has been noted and has raised great concern. For example, there has been increase in prevalence of cryptorchidism, hypospadias, and micropenis over the past 20–30 years. This has been attributed in part to fetal exposure to environmental compounds with estrogenic effects (xenoestrogens), such as herbicides, pesticides, polychlorinated biphenyls (PCBs), plasticizers, and polysterenes, as well as exposure to antiandrogens such as polyaromatic hydrocarbons, linuron, vinclozolin, and pp'-dichlorodiphenyl ethylene (pp'DDE). Such environmental agents are generally referred to as endocrine disruptors (47).

Xenoestrogens and antiandrogens can disrupt androgen effect by different mechanisms. Various explanations have been proposed, including competition for binding to the androgen receptor, diminished conformational change, as well as suboptimal nuclear transfer, DNA binding, and transcriptional activation. Most antiandrogens interact directly with the androgen receptor. Environmental antiandrogens such as the fungicide vinclozilin disrupt male sex differentiation by blocking androgen receptor (AR) binding to androgen response elements. DDE, a DDT metabolite that accumulates in the environment, inhibits human androgen receptor transcriptional activation (48). Exposure of male fetus to antiandrogens results in diminished masculinization. Xenoestrogens influence male differentiation by interacting indirectly with either ER α or ER β . Hypospadias has been related to estrogen exposure during the first trimester and the occurrence of genital abnormalities in sons of women exposed to diethylstilbestrol (DES) is well documented. At least 20% of these men had epididymal cysts, hypospadias, and cryptorchidism (49).

IV. AMBIGUOUS GENITALIA

Conditions with ambiguous genitalia are classified into three major categories: abnormalities of gonadal differentiation, male pseudohermaphroditism, and female pseudohermaphroditism.

A. Genetic Abnormalities of Gonadal Differentiation

1. 46,XY Gonadal Dysgenesis

Abnormalities of gonadal differentiation in individuals with a 46,XY karyotype can be subdivided into 46,XY complete gonadal dysgenesis, 46,XY partial gonadal dysgenesis, and 46,XY true hermaphroditism. Although each of these conditions has a distinct phenotype, there is considerable overlap. Another condition, termed testicular regression sequence, has various causes, but some evidence suggest that the condition is also related to 46,XY partial gonadal dysgenesis (see Table 1).

a. Complete. The 46,XY complete gonadal dysgenesis is defined by absence of testis determination despite nonmosaic male karyotype. The condition is characterized by normal female external genitalia and streak gonads. The terms Swyer syndrome and 46,XY pure gonadal dysgenesis have also been used to describe this condition.

Clinical presentation. Most subjects with 46,XY complete gonadal dysgenesis present for evaluation of delayed puberty or amenorrhea. Subjects are usually normal in appearance and most have normal height, although some have stigmata of Turner syndrome.

Breast development is present in a few subjects. Presentation of breast tissue and/or menses in subjects with 46,XY complete gonadal dysgenesis is of concern as it may signal the presence of an estrogen-secreting tumor. There is normal development of pubic hair in women with 46,XY complete gonadal dysgenesis, but in some individuals the clitoris may be slightly enlarged (50). Physical examination and ultrasonography indicate normal vagina, uterus, and fallopian tubes. There is an absence of wolfian structures. When subjects present as adolescents or adults, serum levels of luteinizing hormone (LH) and follicle-stimulating hormone (FSH) are abnormally elevated. Serum estradiol levels are usually low, but may be elevated in the presence of an estrogen-secreting tumor. Plasma levels of testosterone are normal or slightly elevated due to the effect of abnormally elevated serum LH on residual theca cells in the streak gonad. The latter ob-

Table 1 Classification of Genetic Abnormalities of Gonadal Differentiation

46,XY true hermaphroditism
Embryonic Testicular Regression Sequence
Mosaicism and chimerism involving the Y chromosome
46,XX sex reversal
46,XX maleness
46,XX true hermaphroditism.

servation provides an explanation for the clitoromegaly in some subjects (51).

Gonadal histology. This is usually characterized by a wavy fibrous connective tissue, which in part resembles ovarian stroma. Some evidence indicates that the streak gonad of 46,XY complete gonadal dysgenesis was an ovary in utero, which then degenerated into a streak later in gestation (50).

Gonadal tumors occur in 30% of subjects with 46,XY complete gonadal dysgenesis. Although tumors usually develop after puberty, they may be present earlier. The most common tumor is gonadoblastoma. About half of subjects with gonadoblastoma have coincidental dysgerminoma. Although gonadoblastoma is generally considered a carcinoma in situ, dysgerminoma is a malignant tumor. Other malignant tumors also occur but are unusual. They include embryonal carcinoma, endodermal sinus tumor, choriocarcinoma, and immature teratoma (52).

Management. Management of women with 46,XY gonadal dysgenesis involves gonadectomy to prevent malignancy followed by cyclical hormonal therapy to promote normal pubertal development and normal maturation of bones. Since the uterus is normal, pregnancy can be achieved following in vitro fertilization of a donor egg and implantation of the embryo.

b. Partial. 46,XY partial gonadal dysgenesis is defined by incomplete testis determination in an individual with a nonmosaic 46,XY karyotype. This condition has also been referred to as dysgenetic male pseudohermaphroditism and 46,XY mixed gonadal dysgenesis. It is differentiated from 45,X/46,XY mixed gonadal dysgenesis, in which condition the pathology is related to mosaicism.

Clinical presentation. Individuals with this condition usually present ambiguous genitalia in the newborn period, with variable degree of masculinization. A utriculovaginal pouch is present in a large number of subjects. Proliferation of wolffian ducts depends on the extent of embryonic testosterone secretion, whereas the extent of müllerian duct development depends on the secretion of AMH. Gonads are usually intra-abdominal, but in some individuals they may be found in the inguinal canal or in the scrotum. Serum levels of plasma testosterone are low in the newborn period, as are levels following hCG stimulation. If the diagnosis is made after puberty, serum levels of LH and FSH are abnormally high, whereas plasma levels of testosterone are normal or low (50).

Stigmata of Turner syndrome are present in approximately one-quarter of subjects with 46,XY partial gonadal dysgenesis. The explanation for this physical finding is unknown, but many of these cases may have hidden mosaicism with a 45,X cell line.

In some subjects, 46,XY gonadal dysgenesis is associated with specific syndromes. One example is the condition termed WAGR, which has Wilms' tumor, aniridia, gonadal dysgenesis, and mental retardation. Other condi-

tions associated with Wilms tumor and gonadal dysgenesis include Denys-Drash and Frasier syndromes, both of which are characterized by progressive nephropathy. Another syndrome, termed campomelic dysplasia, is an autosomal dominant condition characterized by abnormal growth of long bones and abnormal testis determination. Subjects with complex rearrangement of chromosome 9 can also present 46,XY partial gonadal dysgenesis in association with multiple congenital anomalies (53).

Gonadal histology. Gonadal abnormalities in 46,XY partial gonadal dysgenesis include formation of streak gonads and dysgenetic testes. Streak gonads are similar to those found in subjects with 46,XY complete gonadal dysgenesis, except that they may be more fibrotic. The dysgenetic testes in these individuals are characterized by disordered, poorly formed seminiferous tubules and incomplete formation of the tunica albuginea (50).

Gonadal tumors. The risk of gonadal tumor in subjects with 46,XY partial gonadal dysgenesis is 16–30%. The types of tumors are like those of 46,XY complete gonadal dysgenesis. However, caution is necessary in management of these patients, since tumors have occurred as early as 15 months of life (54).

Management. Surgical correction of the external genitalia should be performed. There is also need to remove internal duct structures that correspond to those of the opposite sex of rearing. If the child is raised as a boy, streak gonads should be removed, and dysgenetic gonads should be brought into the scrotum or, if this is not possible, they should be removed. Although the risk of malignancy remains even if the gonads are in the scrotum, the development of tumors can be ascertained by careful and regular physical examination. Dysgenetic testes may produce testosterone at puberty, but testosterone therapy is often necessary. If the individual is raised as a female, gonadal tissue should be removed to avoid the possibility of malignancy and to prevent virilization later in life.

Subjects raised as females will require cyclical hormonal therapy at puberty for development of secondary sexual characteristics. Menses can be achieved by hormonal supplementation if the uterus is intact.

c. 46,XY True Hermaphroditism

Clinical presentation. The 46,XY true hermaphroditism is characterized by the presence of gonadal tissue that contains both ovarian follicles and normal-appearing seminiferous tubules in a patient with a male karyotype. Patients usually have ambiguous genitalia, although genitalia range in appearance from completely female to completely male. There is a mix of wolffian and müllerian duct structures depending on development of testicular tissue. Management is the same as that of subjects with 46,XY gonadal dysgenesis (55).

Gonadal histology. The presence of an ovary on one side of the abdomen and a testis on the other side is found in about 50% of patients. In other cases, one or both of the gonads can be ovotestis. The risk of gonadal tumors

in subjects with 46,XY true hermaphroditism is approximately 10% (52).

d. Embryonic Testicular Regression Sequence. This condition is characterized by loss of testicular tissue on one or both sides of the abdomen in an individual with 46,XY karyotype. Patients have ambiguous or female genitalia with abnormal differentiation of internal sex ducts. It is thought that loss of the testicular tissue in this syndrome occurs during the critical period of sex differentiation. Early loss of testicular tissue may be associated with female external genitalia, whereas ambiguous genitalia implies loss of testis at a slightly later stage (56).

Some evidence suggests that the cause of the testicular regression sequence is related to 46,XY partial gonadal dysgenesis. This is based on cases in which there is testicular loss on one side and evidence of dysgenesis on the opposite side. Other causes of embryonic testicular regression sequence include teratogenic effect and vascular accidents (54, 57, 58).

Embryonic testicular regression sequence is differentiated from the vanishing testis syndrome in which there is normal sex differentiation in an individual with 46,XY and loss of testicular tissue on one or both sides. In this condition the loss of testicular tissue is likely to have occurred in later part of gestation and may be related to fetal testicular torsion (54).

e. Causes of 46,XY Gonadal Dysgenesis. Deletions of the distal region of the short arm of the Y chromosome including *SRY* have been associated with 46,XY complete gonadal dysgenesis. Physical findings of Turner syndrome are present in most of these patients (59).

Mutations of *SRY* account for approximately 15% of patients with 46,XY complete gonadal dysgenesis. Most of these mutations are in the HMG box and some of them have been shown to reduce binding of *SRY* to DNA or to reduce the *SRY*-induced bending of DNA (15). Two mutations of *SRY* outside of the HMG box have been reported in association with 46,XY complete gonadal dysgenesis. In addition, large deletions 5' and 3' to the *SRY* gene have been detected (60, 61).

With respect to 46,XY partial gonadal dysgenesis, a point mutation outside of the HMG box was reported in one patient (62). In another case, a large deletion 3' to the *SRY* gene was implicated (61). However, for the most part, *SRY* mutations in this condition are rare.

46,XY true hermaphroditism has been attributed to a point mutation of *SRY* in one subject. In addition, 46,XY true hermaphroditism has also been related to a postzygotic somatic point mutation in the *SRY* gene (63). These observations underscore the possible relationship between 46,XY partial gonadal dysgenesis and 46,XY true hermaphroditism.

Mutations of *WT-1*, *SF-1*, and *SOX-9* have also been implicated in 46,XY gonadal dysgenesis. Large deletions of DNA involving the *WT-1* gene can result in the WAGR

syndrome. Mutations in a coding region of *WT-1* can result in syndromes characterized by Wilms tumor and 46,XY gonadal dysgenesis or syndromes with Wilms tumor, 46,XY gonadal dysgenesis, and progressive nephropathy. Recent studies have indicated that there are two splice variants of the *WT-1* gene. Mutation in alternate transcripts has been proposed as the explanation for the presence of these two presentations (64).

A mutation in the *SF-1* gene was reported in an individual with complete gonadal dysgenesis and adrenal failure. Individuals with duplication of the short arm of the X chromosome that include *DAX-1* also have 46,XY gonadal dysgenesis. However, mutations of *DAX-1* result in adrenal hypoplasia and hypogonadotropic hypogonadism but no abnormality of sex differentiation (65).

Mutations of the *SOX-9* gene can result in campomelic dysplasia and 46,XY gonadal dysgenesis (66). Various missense mutations have been reported. Both 46,XY complete and 46,XY partial gonadal dysgenesis have been associated with these mutations. In addition, rearrangements of the locus encoding the *SOX-9* gene have also been reported. There are no patients to date with 46,XY gonadal dysgenesis who have *SOX-9* mutations who do not also have campomelic dysplasia.

2. Mosaicism and Chimerism Involving the Y Chromosome

Mosaicism and chimerism occur when cells with two or more karyotypes are found in the same individual. In the case of mosaicism, cells are all derived from the same zygote, and the various karyotypes usually result from nondisjunction. By contrast, chimerism occurs when cells are derived from two zygotes. The cause may be double fertilization or fusion of two embryos.

The most common form of mosaicism involving the Y chromosome is that in which there is a 45,X/46,XY karyotype, a condition often referred to as mixed gonadal dysgenesis. It was originally thought that most subjects with 45,X/46,XY mixed gonadal dysgenesis had ambiguous genitalia. More recently, it has been recognized that 90–95% of subjects with 45,X/46,XY karyotypes have normal male external genitalia. However, many subjects have abnormal testicular histological findings.

Subjects with abnormal sex differentiation usually present in the newborn period and many of them have stigmata of Turner syndrome. Gonadal tumors occur in 10–20% of subjects with 45,X/46,XY karyotypes and abnormal sex differentiation. The management of these patients is similar to that of subjects with 46,XY partial gonadal dysgenesis. Complications associated with the Turner phenotype need to be addressed. In particular, therapy with growth hormone should be considered for patients with subnormal growth. Other forms of mosaicism involving the Y chromosome, such as 45,X/47, XYY and 45,X/46,XY/47, XYY, are extremely uncommon (54, 67).

Chimerism may be the cause of a 46,XX/46,XY karyotype in some individuals. The most common presentation of these subjects is true hermaphroditism, although some present a clinical picture similar to 46,XY partial gonadal dysgenesis (54, 68).

3. 46,XX Sex Reversal

The term 46,XX sex reversal comprises two conditions: 46,XX maleness and 46,XX true hermaphroditism. In addition, 45,X sex reversal has been reported.

The 46,XX maleness is a condition in which individuals have testis determination despite a nonmosaic 46,XX karyotype. The phenotype of 46,XX males is very similar to that of Klinefelter syndrome. In particular, most affected subjects have normal male phenotype, although about 15% have hypospadias or ambiguous genitalia. Like subjects with Klinefelter syndrome, the majority of individuals present for evaluation of delayed puberty and gynecomastia. Hormonal evaluation indicates abnormally elevated serum levels of LH and FSH. Plasma testosterone concentration may be normal or somewhat low. Management may involve supplementation with testosterone and surgical correction of gynecomastia (69).

The 46,XX true hermaphroditism is characterized by the presence of both ovarian and testicular tissue in an individual with nonmosaic 46,XX karyotype. Although the clinical phenotype is variable, most affected subjects have ambiguous genitalia and a mix of müllerian and wolffian structures. Surgical correction of external genitalia and subsequent hormonal supplementation depend upon sex of rearing. Only about 4% of subjects with 46,XX true hermaphroditism develop gonadal tumors.

Subjects with 45,X maleness have normal testicular determination but frequently have micropenis, cryptorchidism, and azoospermia. There are also may be other associated problems such as developmental delay, short stature, and congenital anomalies. This condition is extremely unusual. Some individuals with apparent 45,X sex reversal may have hidden mosaicism with the Y-bearing cell line.

More than two-thirds of 46,XX males have a translocation of SRY from the paternal Y to the paternal X chromosome and inheritance of the translocated X. By contrast, most subjects with 46,XX true hermaphroditism and one-third of 46,XX males lack SRY. In these patients, it is necessary to exclude mosaicism. An explanation for 46,XX sex reversal in the absence of SRY has been proposed (70). It is based on the hypothesis that male sex determination is repressed and that testes determination involves derepression. This theory invokes the existence of a repressor of testis determination. In this model mutation of the putative repressor could permit male sex determination in the absence of SRY. However, such a repressor has not been identified.

Recent studies of a single individual with SRY-negative 46,XX maleness implicated a duplication of the lo-

cus containing the *SOX-9* as the cause of 46,XX sex reversal. Several other reports also described duplication of chromosome 22 in 46,XX in true hermaphroditism (71, 72).

B. Male Pseudohermaphroditism

Male pseudohermaphroditism is a condition in which individuals have a 46,XY karyotype, normal testis determination, but incompletely masculinized external genitalia. The appearance of the genitalia ranges from completely female to slightly feminized external genitalia with only hypospadias and cryptorchidism (see Table 2). Male pseudohermaphroditism includes Leydig cell aplasia/hypoplasia, defects of testosterone biosynthesis, steroid 5- α reductase type 2 deficiency, and androgen insensitivity. Defects in synthesis or function of the antimüllerian hormone can also be considered part of this group.

1. Leydig Cell Aplasia/Hypoplasia:

Abnormalities of hCG/LH Receptor

Subjects with Leydig cell aplasia have normal female-appearing genitalia. By contrast, subjects with Leydig cell hypoplasia have a wide range in clinical presentation from micropenis to severe hypospadias. In both severe and mild form, there is absence of müllerian structures due to the secretion of AMH. Testes may be located in the abdomen, inguinal canals, or labia majora. Testosterone production is in the normal to low range depending on the severity of the condition. Sertoli cells are normal, but there is hyalinization of the seminiferous tubules and incomplete spermatogenesis.

Leydig cell aplasia and hypoplasia may be caused by mutations of the hCG/LH receptor. Deletions, nonsense mutations, or frame shift mutations diminish binding of

Table 2 Classification of Male Pseudohermaphroditism

hCG/LH receptor dysfunction (Leydig cell aplasia/hypoplasia)
Testosterone biosynthesis defects
StAR deficiency (congenital lipid adrenal hyperplasia)
3 β -hydroxysteroid dehydrogenase/ Δ^5 isomerase type 2 deficiency
CYP17 (17 α -hydroxylase/17,20 lyase) deficiency
CYP17 (17,20lyase) deficiency
17 β -HSD deficiency
Peripheral unresponsiveness to androgens
Steroid 5 α -reductase type 2 deficiency
Androgen insensitivity syndrome
Complete androgen insensitivity syndrome
Partial androgen insensitivity syndrome
Infertile men
Kennedy syndrome
Persistent müllerian duct syndrome

hCG/LH or adversely affect signal transduction. Most patients with these autosomal recessive mutations are homozygotes or compound heterozygotes (73).

2. Defects of Testosterone Biosynthesis

Five enzymatic defects in testosterone biosynthesis have been described. Three of the defects—StAR deficiency, 3 β -hydroxysteroid dehydrogenase deficiency (3 β HSD), and P-450 c_{17} hydroxylase deficiency—are associated with decreased secretion of cortisol and aldosterone as well as gonadal steroids. Specific guidelines for evaluation and management of adrenal insufficiency and salt-losing crisis are described in Chapter 7. The other two enzymes, 17,20-desmolase and 17-ketoreductase, are only required for androgen secretion, and only manifest sexual ambiguity. The pattern of inheritance in each of these defects is autosomal recessive.

The phenotype of affected individuals depends on the extent of testosterone secretion and ranges from completely female to almost male. Hence it is impossible to differentiate these conditions on the basis of the external genitalia. The testis may be situated within the labioscrotal folds, inguinal canals, and abdomen. The wolffian derivatives are normally developed or hypoplastic, depending on the severity of the testosterone biosynthetic block. Müllerian structures are absent because the secretion of AMH by Sertoli cells is unaffected.

Subjects raised as males may require surgical correction of the external genitalia and surgery for cryptorchidism. Individuals raised as females will require removal of gonads and wolffian structures and may require revision of external genitalia.

a. Steroidogenic Acute Regulatory Protein Deficiency (Congenital Lipoid Adrenal Hyperplasia). Phenotypic presentation varies, but external genitalia are female in most cases and wolffian ducts are hypoplastic. Computed tomography (CT) or magnetic resonance imaging (MRI) of the abdomen demonstrates large adrenal glands secondary to the accumulation of cholesterol and cholesterol esters. Its incidence is greater in people of Japanese, Korean, and Palestinian descent (51).

Lack of glucocorticoid, mineralocorticoid, and androgen secretion occurs because the StAR protein is defective. This enzyme is responsible for the transfer of cholesterol from outer to inner mitochondria membrane and is the first rate-limiting step in acute steroid synthesis. This condition is associated with the most profound defect of steroidogenesis, and subjects with the complete form of the defect have salt-losing crisis early. The majority of mutations causing congenital lipoid adrenal hyperplasia (CLAH) are in the exons 5–7 of the StAR gene (74).

Earlier studies suggested that defects in *CYP11A*, the gene for the P450 side chain cleavage (*CYP450scc*), was responsible for this disorder. However, genetic analysis of this gene proved normal in patients with lipoid CAH. Homozygous *P450scc* mutations can cause spontaneous

abortions through lack of progesterone synthesis. However, haploinsufficiency of *P450scc* may resemble a late onset of congenital lipoid adrenal hyperplasia (75).

b. 3 β -Hydroxysteroid Dehydrogenase Deficiency. 3 β -hydroxysteroid (HSD) dehydrogenase catalyzes the conversion of 3 β -hydroxy-, Δ^5 -steroids to Δ^4 -3-keto-steroids (pregnenolone to progesterone, 17-hydroxypregnenolone to 17-hydroxyprogesterone, and dehydroepiandrosterone [DHEA] to androstenedione). Hormonal abnormalities are characterized by increased plasma levels of pregnenolone, 17-hydroxypregnenolone, and DHEA.

Deficiency of 3, β HSD II impairs both adrenal and gonadal steroidogenesis. Genotypic males with the complete form have female genitalia, and salt-losing crisis shortly after birth. Subjects with the partial form have ambiguous genitalia and no salt wasting.

Two genes encode 3, β HSD: type I for placental, skin and breast tissues, and type II gene for adrenal and gonads. Type I and II are 93.5% homologous. These genes belong to the aldo-keto-reductase family rather than the cytochrome P450 family. At least 31 mutations of 3, β HSD type II have been identified in this disorder, including splicing, frame deletions, nonsense, frameshift, and 22 missense mutations. The salt-losing form generally results from severe mutations and is associated with absence of functional 3, β HSD. By contrast, the non-salt-losing form usually results from missense mutation (76).

c. CYP17 (17 α -hydroxylase/17,20-lyase) Deficiency. Affected individuals with a 46,XY karyotype have phenotypes ranging from normal-appearing female external genitalia with short vagina in the complete form to ambiguous genitalia in the partial form. The testes are located intra-abdominally, in the inguinal canal, and in the labioscrotal folds. Although cortisol production is subnormal, accumulation of corticosterone results in normal glucocorticoid effect. However, an abnormally high level of desoxycorticosterone (DOC) results in hypertension. In the partial form there is subnormal virilization at puberty. Gynecomastia occurs in some subject. Serum levels of FSH and LH, 11-deoxycorticosterone, corticosterone, and progesterone are elevated. Levels of plasma renin activity, aldosterone, and cortisol are decreased. Glucocorticoid supplementation is indicated to reduce abnormally elevated levels of DOC. Hypertension, hypokalemia, and hyporeninemia normalize with glucocorticoid treatment. At puberty gonadal steroid hormone replacement may be necessary (77, 78).

Although 17 α -hydroxylase and 17,20 lyase are encoded by the same gene and both activities are mediated by the same protein, there are situations in which 17 α -hydroxylase activity is preserved but 17,20 lyase is defective. Cases of CYP17 deficiency have been related to mutations resulting from deletions, premature truncation, frameshift, and splicing errors. Enzymatic activity of the mutant protein correlates with phenotype. If the 17 α -hydroxylase activity is less than 25% of normal, affected

46,XY subjects have feminized external genitalia. Hence, enzymatic activity greater than 25% results in normal fetal masculinization (79).

d. P-450c17 (17,20 Lyase) Deficiency. Affected 46,XY subjects present a range in the appearance of external genitalia according to the severity of the defect. Plasma levels of 17-hydroxysteroids are normal. Plasma levels of DHEA and androgens are decreased, as are levels of 24-hour urinary 17-ketosteroids. The ratio of 17-hydroxyprogesterone/androstenedione after human chorionic gonadotropin stimulation is abnormally elevated (>10). At puberty, proper gonadal steroid replacement is required for development of secondary sexual characteristics. CYP17 mutations that cause isolated 17,20 lyase deficiency in 46,XY subjects have been reported. Mutations in the redox partner-binding site of CYP17 can also cause selective loss of 17, 20 lyase activity (80).

e. 17,β-Hydroxysteroid Dehydrogenase Deficiency. This condition is characterized by failure to convert androstenedione to testosterone. Subjects usually present female external genitalia but some have ambiguous genitalia with a minimal degree of masculinization. Marked virilization occurs at puberty with muscular development, enlargement of the phallus, and development of pubic hair. However, gynecomastia is almost always present. Subjects have an increased ratio of androstenedione to testosterone in baseline samples or following hCG stimulation. Baseline serum levels of LH and FSH are markedly elevated at puberty.

Five isoenzymes of 17βHSD catalyze the reduction of androstenedione to testosterone, DHEA to androstenedione, and estrone to estradiol. The type 3 isoenzyme is expressed in the testis, where it catalyzes the reduction of androstenedione to testosterone. Its gene is located on chromosome 9q22. To date, at least 20 clinically significant mutations in the HSD17 β3 have been found including missense, so-called splice junction abnormal-like, and frame-shift mutations. Variation in phenotype has been observed among members of the same kindred (81, 82).

3. Peripheral Unresponsiveness to Androgens

Absent or diminished androgen action in target cells can also result in male pseudohermaphroditism. Two forms have been described: an error in conversion of testosterone to DHT, and insensitivity to androgens.

a. Steroid 5α-Reductase Deficiency. Deficiency of the enzyme steroid 5α-reductase is a rare disorder that results in low plasma levels of DHT and abnormal differentiation of male external genitalia. In the newborn period, affected subjects present with feminized external genitalia with small phallus, chordee, bifid scrotum, and a urogenital sinus that opens onto the perineum. Testes are found in the inguinal canal or labioscrotal folds. Müllerian ducts are absent but Wolffian ducts are well differentiated except for the ejaculatory ducts, which end in

a blind vaginal pouch or in the perineum, close to the urethra.

At puberty, spontaneous virilization occurs and the body habitus becomes very muscular. The phallus enlarges up to 8 cm in length, and the labioscrotal folds become rugated and pigmented. Testes enlarge and descend into the labioscrotal folds. Acne, facial hair, and enlargement of the prostate do not occur, indicating that these changes are dependent on DHT. There is no gynecomastia. In a study of affected individuals in the Dominican Republic, almost all individuals initially raised as females adopted male gender identity during puberty. Although the majority of patients are infertile, paternity has been reported in subjects with the mild form of the condition (83).

In adult males, the plasma concentration of DHT is low despite normal or slightly elevated levels of testosterone (T). The T/DHT ratio is >36 (normal, 8–16). Serum plasma LH levels are elevated, suggesting a role for DHT in negative feedback at the level of the hypothalamus. FSH levels are normal or high, reflecting damage to seminiferous tubules. In the newborn period, the T/DHT ratio is high. During infancy and childhood, hCG stimulation also results in normal serum levels of testosterone, but subnormal serum levels of DHT. In the first few months of life, when plasma levels of testosterone and DHT are detectable, the normal T/DHT ratio is a value less than 12. Following hCG stimulation, normal boys from 17 days to 6 months have a T/DHT ratio of 5.2 ± 1.5 . T/DHT ratio of 11 ± 4.4 is considered normal in boys from 6 months to 14 years. Abnormally high T/DHT ratios indicate 5α reductase deficiency (84).

46,XX subjects with 5α-reductase deficiency have a normal female phenotype and normal puberty, but decreased axillary and pubic hair. Although menarche is delayed, fertility is normal (83).

The pattern of inheritance in 5α-reductase deficiency is autosomal recessive involving homozygous or compound heterozygous mutations. However, paternal uniparental disomy was found in one patient (85). All cases of steroid 5α-reductase deficiency are related to mutations in the coding region of the 5α-reductase 2 gene. Mutations are found in all five exons of the gene. The majority of subjects have missense mutations (86). Other individuals have deletions, splice-junction, and nonsense mutations. The end product is a nonfunctional or subfunctional protein with decreased affinity of the enzyme to NADPH or decreased binding to testosterone.

If affected babies are raised as males, surgical correction of the external genitalia and cryptorchidism should be performed. Prior to surgery, administration of androgens is recommended to increase phallic length and facilitate hypospadias repair. Normal levels of DHT have been achieved in adults following pharmacological doses of testosterone, presumably though activity of 5α-reductase 1. If the child is raised as a female, surgical correction

of external genitalia should be performed and gonadal tissue removed before puberty. Cyclic hormonal therapy at puberty for development of secondary sexual characteristics is required (83).

b. Androgen Insensitivity Syndrome. Androgen insensitivity syndrome (AIS) is comprised of four conditions with distinct phenotypes: complete AIS (CAIS), partial AIS (PAIS), androgen insensitivity associated with the infertile man syndrome, and Kennedy syndrome.

Clinical phenotype

1. Complete Androgen Insensitivity (CAIS) is an X-linked trait with an incidence of 1:20,000–1:64,000 male births (87). This condition has also been referred to as the testicular feminization syndrome (88). CAIS is characterized by a normal 46,XY karyotype, female external genitalia with short vagina, absence of müllerian structures, and absent or vestigial wolffian structures. Gonads may be located in the inguinal canal or may be intra-abdominal. Some subjects with CAIS present in infancy or childhood when surgery for inguinal hernia reveals testis in the hernia sack. If gonadectomy is not performed in infancy or childhood, affected subjects have breast development at puberty but little or no axillary hair. Although the clitoris or labia majora are normal, the labia minora may be underdeveloped. Patients usually present in their teens or early 20s because of amenorrhea. Serum levels of LH and testosterone are abnormally elevated. Estradiol, which comes from peripheral conversion of testosterone and from testicular secretion, tends to be in the normal female range. Serum AMH is abnormally high in women with CAIS because the physiological suppression of AMH by testosterone does not occur (89). Women with CAIS have a greater incidence of testicular tumor, with risk increasing significantly after puberty. Management of adult women with CAIS involves gonadectomy and sex hormone supplementation. In some women vaginoplasty may be necessary to improve the length of the vagina.

Wisniewski et al. (90) examined long-term outcome of women with CAIS. Fourteen women were studied using questionnaires and follow-up physical examination. These women considered their development of secondary sexual characteristics to be satisfactory. Furthermore, most patients were satisfied with sexual function. All of the women studied were satisfied with sex of rearing. Nonetheless, the study indicated that more two-thirds of the women had incomplete understanding of their condition.

2. Subjects with Partial Androgen Insensitivity (PAIS) usually present in the newborn period with ambiguous genitalia. Müllerian structures are absent and development of wolffian ducts is usually abnormal. The diagnosis is suspected if there are normal levels of testosterone and a normal testosterone/DHT ratio. Several approaches have been suggested to differentiate PAIS from other conditions with a similar hormonal profile. Some authors have suggested that the extent of penile growth after administration of testosterone or hCG provides an indicator

of responsiveness to androgens. Others have advocated determination of sex hormone-binding globulin (SHBG) levels in blood to identify subjects with PAIS. This is based on the fact that androgen secretion typically results in a diminution of SHBG levels. Hence, higher than normal levels of SHBG in an individual with normal male testosterone and DHT concentration might indicate androgen insensitivity (91). Blood levels of AMH are also suppressed by androgens. Hence the combination of male levels of testosterone and DHT in the face of unsuppressed AMH might indicate PAIS (92).

At puberty, serum levels of LH and testosterone are abnormally elevated, although the T/DHT ratio remains normal. There is enlargement of the penis at puberty, but the penis usually remains small. Serum levels of estradiol are abnormally elevated and gynecomastia is almost always present. Testes are small and there is azoospermia.

3. Subjects with androgen insensitivity associated with infertile men present various phenotypes. Some subjects have mild hypospadias, although many have normal male external genitalia. Like subjects with other forms of AIS, these men have elevated levels of serum LH and testosterone. Subjects are typically ascertained during evaluation for infertility (93).

4. Kennedy syndrome is an X-linked form of spinal and bulbar atrophy, which appears in mid to late adulthood. The association of gynecomastia and the variable presence of impotence and infertility suggest a form of androgen insensitivity and subsequent studies identified a defect in the AR gene (94).

Genetic abnormalities related to AIS. Most cases of CAIS and PAIS are related to mutations in the AR gene and the majority of them are point mutations. Relatively few mutations have been detected in the amino terminal domain. Mutations that result in stop codons in this region are typically associated with CAIS. Deletions of polyglutamine repeats are associated with PAIS. Kennedy syndrome results from expansion of polyglutamine repeats to a number greater than 42 (95).

Within the DNA-binding domain, mutations that result in stop codons or in the deletion of the second zinc finger are associated with CAIS (96). Mutations in the phosphorylation site are associated with both CAIS and PAIS.

Mutations in the hormone-binding domain can result in both complete and partial AIS. Frame shift or point mutations that result in premature termination are associated with CAIS. By contrast, mutations causing less severe defects in hormone binding are more likely to be found in patients with PAIS. Splicing mutations in the AR gene have also been reported in PAIS. They result in transcription of mRNA encoding mutant AR as well as lower levels of mRNA encoding normal AR (97).

AR gene mutations have been identified in some subjects with the androgen insensitivity of infertile men. In a group of nearly 200 infertile men, three unrelated subjects

had mutations of AR gene. Two of these mutations were in the transactivation domain and one was in the DNA-binding domain (93). In another study, a subject with this condition had a point mutation in the hormone-binding domain that did not diminish steroid binding but resulted in defective transactivation (98). In additional studies Givercman identified an unusual subject with mutation in the AR gene and phenotypic features of AIS, but normal fertility (99).

Despite correlations between phenotype and genotype that have been made in the AIS, many cases indicate that these relationships do not always apply. For example, most mutations that result in absence of androgen-receptor binding in cultured cells result in CAIS. However, some of these mutations are also associated with PAIS. Most mutations that are associated with intact AR binding in cultured cells are likewise associated with PAIS. Nonetheless, some of them are associated also with CAIS. More surprising is the observation that CAIS and PAIS have been associated with the same mutation in the AR, suggesting that other factors play a role in AR function (95).

Recent reports explain the lack of phenotype–genotype correlation in some patients. In 1997, Holterhus described a patient with PAIS who had a mutation in the AR that resulted in a premature stop codon. Such mutations are usually associated with CAIS. The unexpected mild phenotype in this report was the result of somatic mosaicism (100). The AR was also studied in another family who had AIS and a range of phenotypic appearance among affected members. Studies of this kindred indicated that transactivation of the AR varied over a range of DHT concentrations, suggesting that the range in phenotype might have resulted from variable levels of DHT in each of the individuals in utero (101). More recently Boehmer et al. described a kindred in which one sibling had CAIS and another had PAIS. The differences in phenotype were correlated with differences in 5-reductase activity in the two siblings (102).

AIS has also been attributed to abnormalities in the interaction of coactivators with the AR. In one study CAIS was associated with inability of the AR to interact with AF1 (103). Expansion of the polyglutamine repeats results in decreased binding of ARA 24 and subsequent decreased coactivation, providing a possible explanation for the AIS associated with Kennedy syndrome (44, 94).

4. Male Pseudohermaphroditism Associated with Multiple Congenital Anomalies

Some subjects have well-described syndromes in which there is abnormal sex differentiation in association with other congenital anomalies, but no obvious defect in gonadal differentiation, testosterone biosynthesis, or androgen effect (53). Some examples include Opitz-Frias syndrome, Rieger's syndrome, Rapp-Hodgkin ectodermal dysplasia, the CHARGE association and VATER syn-

drome. Many cases of male pseudohermaphroditism and multiple congenital anomalies are sporadic, but they frequently involve other defects in the genitourinary system. In addition, maternal exposure to certain drugs, such as dilantin, trimethadione, and progesterone, have been implicated in abnormal sex differentiation.

5. Timing Defect and Idiopathic Male Pseudohermaphroditism

Several patients have been reported who had a 46,XY karyotype and ambiguous genitalia, but normal production of testosterone and DHT at puberty and normal responsiveness to androgens. It was suggested that these subjects had delayed differentiation of Leydig cells and the term timing defect was applied to this condition (104). It is possible that subjects with so-called idiopathic male pseudohermaphroditism have such a timing defect.

6. Persistent Müllerian Duct Syndrome

The persistent müllerian duct syndrome (PMDS) is defined by the presence of müllerian derivatives (uterus, fallopian tubes, and superior two-thirds of the vagina) in otherwise normal 46,XY subjects (105). This rare form of male pseudohermaphroditism has been reported in approximately 150 subjects. Patients with PMDS present with cryptorchidism, inguinal hernias, or both. Herniation of the müllerian structures through the inguinal ring and transverse testicular ectopia are frequent associations.

Persistent müllerian duct syndrome occurs in two different anatomical forms. The form characterized by partially descended testes (80–90% of reported cases) occurs with unilateral cryptorchidism and contralateral inguinal hernia. Typically, the undescended testis is in the inguinal canal. This condition is termed hernia uteri inguinalis. Sometimes the opposite testis is in the hemiscrotum with hernia (transverse testicular ectopia). The second form is characterized by undescended testes. The gonads are located in a high position, the uterus is fixed in the pelvis, and both testes are embedded in the round ligament. The round ligament is usually distended in PMDS, leading to abnormal mobility of müllerian derivatives. Furthermore, the testis itself is abnormally mobile because it is not connected to the base of the scrotum. The testes of these males contain germ cells, but are not properly connected to male excretory ducts. Aplasia of the epididymis, as well as aplasia of the upper part of the vas deferens, has been reported. The müllerian segment of the vagina contacts the posterior urethra at the veru montanum, but communication is usually not patent and retrograde urethrography shows a normal male urethra (105).

Affected subjects frequently present for evaluation of undescended testes or inguinal hernia. The diagnosis can be made by sonogram during the evaluation of newborns or infants with cryptorchidism and during surgical exploration. In subjects with bilateral nonpalpable gonads, con-

genital adrenal hyperplasia in a female must also be excluded. Serum levels of testosterone are typically normal in these patients, but should be assessed. The level of AMH should be measured to help determine the specific problem (abnormality of AMH or receptor) (36). Although pelvic ultrasonography may be useful to detect müllerian structures, false-negative results can occur.

PMDS is inherited either as a sex-limited autosomal recessive trait (the most common) or as a sex-linked recessive trait. Mutations in either the gene for AMH or its receptor are responsible for the lack of regression of the müllerian ducts. Patients with a serum level of AMH in the upper limit of normal are referred to as being AMH-positive. Patients with very low AMH levels, are called AMH-negative. The most common genetic anomaly causing PMDS is a 27 base-pair deletion in exon 10 of the antimüllerian type II receptor gene. This deletion is implicated in approximately 25% of patients presenting with PMDS (106).

The surgical management of patients with PMDS is controversial due to the potential morbidity associated with both the retention and the removal of the müllerian structures. Controversy also exists regarding the malignant potential of the PMDS testes. Surgical excision of persistent müllerian duct structures may result in ischemic and/or traumatic damage to the vas deferens and testes. Optimal management is orchiopexy, leaving the uterus and fallopian tubes in situ. Orchiectomy is indicated for testes that cannot be mobilized to a palpable location. Careful identification of the vas deferens with meticulous dissection of the müllerian structures facilitates intrascrotal placement of the testes. There is an increased risk of malignancy associated with the cryptorchidism (3% to 18%), but not with the retained müllerian structures. These structures remain infantile, and neither cyclic hematuria nor endometrial malignancy occurs. Most of these patients are infertile.

C. Female Pseudohermaphroditism

Female pseudohermaphroditism describes one-third to one-half of patients with ambiguous genitalia. Subjects have 46,XX karyotype, normal müllerian ducts, and masculinization of the external genitalia and urogenital sinus (see Table 3). Wolffian ducts (epididymis, vas deferens, and seminal vesicles) are absent. The degree of masculinization of external genitalia is determined by the extent of androgen secretion and the timing of androgen production. Once female sex differentiation is complete, androgen exposure causes clitoral hypertrophy but no other masculinization of genitalia.

1. Congenital Adrenal Hyperplasia

The most common cause of female pseudohermaphroditism is congenital adrenal hyperplasia (CAH). In these conditions there is an abnormality in the biosynthesis of cortisol and aldosterone. Diminished secretion of cortisol

Table 3 Classification of Female Pseudohermaphroditism

Congenital adrenal hyperplasia
CYP21 (21-hydroxylase) deficiency
CYP11 (11 β -hydroxylase) deficiency
3 β HSD II deficiency
Exposure to maternal androgens excess
Iatrogenic: androgens and progestins
Virilizing ovarian or adrenal tumor
Luteoma of pregnancy
CYP19 (aromatase) deficiency
Congenital abnormalities

results in marked elevation of plasma ACTH that subsequently stimulates increased production of adrenal androgens and hence masculinization of external genitalia. CYP21 (21 hydroxylase) deficiency is the most common cause of CAH. Two other virilizing forms of CAH are 11 β hydroxylase and 3- β hydroxysteroid dehydrogenase deficiencies. (These conditions are discussed at greater length in Chapter 7). A brief summary is presented below.

a. CYP21 (21 Hydroxylase) Deficiency. CYP21 is required for conversion of 17-hydroxyprogesterone to 11-deoxycortisol and progesterone to deoxycorticosterone. Hence CYP21 deficiency decreases both mineralocorticoid and glucocorticoid production. Females with this condition present ambiguous genitalia, or, later in life, virilization. Salt-losing crisis is a potentially life-threatening complication of the severe form of this disorder. Serum levels of 17-hydroxyprogesterone are markedly elevated (3000–40,000 ng/dl), the level depending upon age and severity of the enzyme defect. Androstenedione levels are abnormally high (107, 108).

b. CYP11 (11 Hydroxylase) Deficiency. This condition is characterized by lack of conversion of 11-deoxycortisol to cortisol and conversion of DOC to corticosterone. High blood pressure occurs due to increased levels of DOC (107, 108).

c. 3 β -Hydroxysteroid Dehydrogenase/ Δ^{4-5} Isomerase Deficiency. This is characterized by lack of conversion of Δ^5 3 β hydroxysteroids to 3 ketosteroids. The synthesis of both aldosterone and cortisol is impaired. Salt-wasting and adrenal crisis can occur in severe forms of this condition. Serum levels of 17-hydroxypregnenolone may be increased due to impaired conversion of 17-hydroxypregnelonone to 17-hydroxyprogesterone. In addition, the ratio of 17-hydroxypregnelonone to 17-hydroxyprogesterone is elevated in these patients (107, 108).

2. Maternal Androgens

a. Iatrogenic. Several drugs have been associated in the past with female pseudohermaphroditism. Proges-

tins such as norethindrone and ethisterone can cause some degree of masculinization of external genitalia. Danazol, used for treatment of endometriosis, has also been implicated as a cause of female pseudohermaphroditism. Stilbestrol and its metabolites are also related to masculinization of female external genitalia through inhibition of 3- β hydroxysteroid dehydrogenase (47).

b. Androgen-Secreting Tumors. These occurring in the mother can also cause masculinization of the female fetus. Luteoma of pregnancy is a rare tumorlike mass that emerges during pregnancy and regresses spontaneously after delivery. Absence of maternal virilization does not exclude the diagnosis of luteoma of pregnancy. Other androgen-secreting tumors of both the ovary and adrenal have also been reported. Ovarian tumors include Brenner tumor and thecoma, among others. Adrenal tumors causing female pseudohermaphroditism are extremely rare (109).

3. Placental Aromatase Deficiency

Human CYP450 aromatase is expressed in placental syncytiotrophoblast and many other fetal tissues. After the 9th week of gestation, the placenta provides the primary source of circulating estrogens. Lack of placental aromatase exposes the fetus to androgen excess and can result in ambiguous genitalia in females. Diagnosis should be suspected in an infant with female pseudohermaphroditism in whom CAH has been excluded. The diagnosis is suggested by maternal virilization during pregnancy, and abnormally high serum levels of Δ^4 androstenedione, testosterone, and DHT. Low plasma levels of estriol, as well as low urinary estriol concentration, are present. Amniotic fluid concentrations of Δ^4 androstenedione and testosterone are high, while estrone, estradiol, and estriol levels are low (110).

4. Syndromes of Multiple Congenital Abnormalities

Association of female pseudohermaphroditism with cloacal anomalies, renal agenesis or dysplasia, and gastrointestinal and urinary tract anomalies has been reported. The müllerian structures in these patients may be poorly developed and dysplastic. The cause of this defect is uncertain. There is a disorganized differentiation of the caudal development including perineum, genital tubercle, and genital folds (111). Maternal alcohol use during pregnancy has been associated with clitoral hypertrophy.

V. DIAGNOSTIC EVALUATION FOR AMBIGUOUS GENITALIA

When a child is born with ambiguous genitalia, a specialized care team should be convened. A rapid and organized evaluation should be initiated to garner infor-

mation about karyotype, gonadal function, androgen biosynthesis, and internal anatomy.

A. Diagnostic Evaluation

1. History

A thorough family history is important with respect to previous perinatal or neonatal deaths, infertility, consanguinity, or history of infants with ambiguous genitalia. The patterns of inheritance in the various intersex disorders must be considered. A maternal history should focus on complications of pregnancy, especially during the first trimester, and should include information regarding drug and alcohol use as well as hormone administration.

2. Physical Examination

The physical examination should determine whether the infant has dysmorphic features, since many syndromes are associated with ambiguous genitalia. Intrauterine growth retardation suggests a chromosomal anomaly. Abnormal body proportions suggest an associated syndrome of bone dysplasia. Stigmata, such as webbed neck and edematous hands and feet, may be present in mixed gonadal dysgenesis (45,X/46,XY). Table 4 includes some of the conditions associated with genital ambiguity.

The stretched phallic length should be measured along the dorsum from the pubic ramus to the tip of the glans. The degree of development of the corpora may be assessed by palpation of the shaft. Normal values for stretched penile length in neonates and preterm infants are available, as are normal values for clitoral length (Chap. 42). It is important to note that premature female infants may appear to have clitoromegaly because they have a larger clitoral breadth compared to body size.

Urethral opening is assessed by careful examination of the ventral area of the phallus for grooves and chordees. The urethral meatus may be anywhere from the tip of the phallus to the perineum. A single opening on the perineum indicates the presence of a urogenital sinus. Fusion of the labia majora should also be assessed. The labioscrotal folds are examined for degree of fusion, development of rugae, and pigmentation. The presence of gonadal tissue must be carefully assessed. Each gonad is evaluated for size, texture, and presence of an epididymis.

Minimal enlargement of the phallus and only mild posterior fusion may be associated with a mild form of masculinization in an XX individual or a severe form of undermasculinization in an individual with an XY karyotype. Phallic enlargement with nearly complete fusion of the labioscrotal folds may likewise be associated with a minimal defect of masculinization in an individual with a XY karyotype or a very severe abnormality of sexual differentiation in an individual with an XX karyotype. Hence, the extent of masculinization of the external genitalia does not provide information about the underlying diagnosis but merely provides information about the extent of the abnormality once the karyotype is known.

Table 4 Syndromes and Chromosomal Abnormalities Associated with Ambiguous Genitalia

Abnormalities	Clinical findings
Chromosomal	
Trisomy 13	Holoprosencephalia, polydactyly, cleft lip, hypospadias, cryptorchidism
Trisomy 18	Clenched hand, short sternum, malformed auricles, male cryptorchidism, virilized females
Triploidy syndrome	Prenatal growth failure, microphthalmia, congenital heart defects, hypospadias, micropenis
4p ⁻	Supreorbital ridges, synophrys, large ears, incomplete masculinization
13q ⁻	Myrocephaly, coloboma, thumb hypoplasia, incomplete masculinization
Syndromes	
Aaskog	Hypertelorism, brachydactyly, shawl scrotum, cryptorchidism
Campomelic Dysplasia	Flat facies, bowed tibiae, hypoplastic scapulae, 46, XY partial gonadal dysgenesis
Carpenter	Acrocephaly, polydactyly, and syndactyly of the feet, lateral displacement of inner canthi, mental retardation, hypogonadism
CHARGE	Colobomata, heart defect, choanal atresia, retarded growth, genital hypoplasia, ear anomalies
Curradino	Partial sacral agenesis with intact first sacral vertebra (“sickle-shaped sacrum”), a presacral mass, and anorectal malformation (Currarino triad)
Ellis-Van Crevel	Mesomelic dwarfism, polydactyly, cardiac anomalies, cryptorchidism
Fraser	Cryptophthalmos (eye hidden, fused lids, absence of palpebral fissure), defect of auricle, males with cryptorchidism and hypospadias, females with vaginal atresia
SCARF	Lax skin, joint hyperextensibility, umbilical and inguinal hernias, craniosynostosis, pectus carinatum, abnormally shaped vertebrae, enamel hypoplasia with hypocalcification of the teeth, facial abnormalities, wide webbed neck, ambiguous genitalia, multiple nodular liver tumors, and mild psychomotor retardation
Lissencephaly X-linked	Lissencephaly with ambiguous genitalia
Meckel-Gruber	Encephalocele, polydactyly, renal cystic dysplasia, ambiguous genitalia
Oral–facial–digital	Polydactyly, campomelia, ambiguous genitalia, cystic dysplastic kidneys, and cerebral malformation
Rieger’s	Iris dysplasia, maxillar hypoplasia, hypospadias
Robinow	Short stature, mesomelic and acromelic brachymelia, hypertelorism, wide palpebral fissures, midface hypoplasia and large mouth, and hypogenitalism
Short rib polydactylia	Cleft lip, malformed larynx with hypoplastic epiglottis, pulmonary hypoplasia, renal cysts, ambiguous genitalia, pachygyria, and small cerebellar vermis
Smith-Lemli-Opitz, type II	Mutations in the delta-7-dehydrocholesterol reductase gene in chromosome
	Failure to thrive, facial dysmorphism, ambiguous genitalia, syndactyly, postaxial polydactyly, and internal developmental anomalies (Hirschsprung’s disease and cardiac and renal malformations)
Smith-Lemli-Opitz, type I	Failure of masculinization, intra-abdominal testes, a normally shaped uterus and vagina, polydactyly, cleft palate, blepharoptosis, and abnormalities of the kidneys, liver, and lungs
VACTER	Vertebral anomalies, Anal atresia, Tracheo-Esophageal fistula, Radial and Renal dysplasia, bifid scrotum
WAGR	Contiguous gene syndrome: Wilms tumor, Aniridia, cataract, ambiguous Genitalia, gonadoblastoma, genitourinary abnormalities, mental Retardation

3. Etiologic Evaluation

Adrenal hyperplasia is always a possibility in an infant who presents with ambiguous genitalia. Therefore, throughout the period in which diagnostic tests are performed, careful attention must be paid to blood chemistry and vital signs to ensure that early and appropriate treatment is started if clinical presentation suggests congenital adrenal hyperplasia.

Migeon et al. have described a program for the evaluation of the ambiguous genitalia in the first week (54). A karyotype is obtained on the first day of life and is usually done using peripheral lymphocytes. Occasionally chromosome analysis from other tissues may be necessary to exclude mosaicism. Plasma levels of testosterone and dihydrotestosterone are determined on day 1–2 since there is a physiological peak of testosterone secretion in

normal boys at this time. Occasionally, assay of other plasma steroids precursors of testosterone synthesis may be indicated. Plasma levels of 17-hydroxyprogesterone and 17-hydroxypregnelone should be determined on day 3–4. It is necessary to obtain the blood sample until day 3–4, because contaminating plasma steroids result in spuriously high levels. Assays of both testosterone and 17-hydroxyprogesterone require a chromatographic step prior to assay to prevent additional artifacts (112).

If the baby is clinically stable, imaging studies should be performed on day 5 of life. A genitogram with retrograde injection of contrast media into the urogenital sinus should be performed to detect the presence of müllerian structures, as well as to outline the anatomy of the urethra. Sonography may also be performed to detect müllerian structures. In some instances sonography may be useful to identify abdominal or inguinal gonads. Occasionally an MRI of the pelvis may also be needed.

4. Diagnosis of Ambiguous Genitalia

Migeon and Berkovitz have proposed an algorithm for the diagnosis of ambiguous genitalia in the newborn period (54). If the karyotype indicates mosaicism or possible chimerism involving a Y chromosome, the abnormality of sex differentiation is considered to be a function of the cloning of the various cell types in the gonad. If the karyotype is 46,XX or 46,XY the diagnosis will be established by the hormonal profile, the presence of specific internal duct structures, and, in some cases, by gonadal histological results.

In patients with a 46,XY karyotype and a subnormal plasma level of testosterone, abnormally low levels of steroid precursors of testosterone indicate the possibility of 46,XY gonadal dysgenesis, 46,XY true hermaphroditism, and Leydig cell aplasia hypoplasia. Subnormal levels of plasma testosterone, but abnormal elevation of plasma precursors of testosterone, indicate a defect in the biosynthesis of testosterone. If levels of plasma testosterone and DHT are normal or elevated but the ratio of T to DHT is abnormally elevated, a diagnosis of 5 α -reductase deficiency is made. If plasma concentration of T and DHT is both normal the differential diagnosis includes androgen insensitivity, syndromes of multiple congenital anomalies, and idiopathic or timing defects.

In subjects with a 46,XX karyotype, diagnostic considerations include abnormalities of gonadal differentiation and those resulting from exposure of the fetus to excess androgen. The former group comprises 46,XX true hermaphroditism and the XX maleness. When normal ovarian differentiation has occurred, masculinization may have resulted from congenital adrenal hyperplasia (deficiency of 21-hydroxylase, 3 β HSD, and 11-hydroxylase), androgen-secreting tumors in the mother, placental aromatase deficiency, various drugs, and syndromes of multiple congenital anomalies.

VI. MANAGEMENT OF INTERSEX

A. Introduction

The management of children born with ambiguous genitalia has been guided by the traditional policy developed by psychologists in collaboration with pediatric endocrinologists and other health care professionals (113). This management has been based on assessment of the anatomy of sex organs, on likely cosmetic appearance of the reconstructed genitalia, on the potential for normal sex steroid secretion at puberty, the potential for normal sexual intercourse, and on the potential for fertility. It has also been referred to as the optimal-gender policy.

Gender assignment has been recommended as early as possible to minimize the period of gender uncertainty. Surgery of the external genitalia has been recommended to facilitate consistent gender-typical rearing by the family. As an example, female gender has been considered appropriate for girls with the masculinized form of CAH. This has been based on the consideration that adequate replacement therapy will permit ovarian sex hormone secretion and normal fertility and because reconstructive surgery will allow for sexual intercourse later in life.

Over the past few years, patient activists have questioned aspects of the traditional policy for gender assignment at the earliest age possible and have emphasized the risk of early genital surgery. The Intersex Society of North America was established to involve the public in an open discussion about management of intersex patients. They have objected to early genital surgery on the grounds that the patient is too young to provide informed consent (114).

Another critique of the traditional approach to intersex management comes from biological determinists who claim that prenatal androgens play a critical role in the masculinization of the fetal brain, and therefore influence behavior and gender identity later in life. Improved understanding regarding the long-term outcome of intersex patient management is helping to guide changes in the traditional policy (90, 115).

B. Gender Assignment at Birth

Gender assignment of infants with ambiguous genitalia at birth requires open and intense communication between the medical team and the family. Counseling requires avoidance of oversimplification. However, complete information must be provided and presented in a way that can be assimilated by the family. The physician must be open to new information. For example, recent data show that penile growth potential in newborns with micropenis is greater than previously thought. As a consequence, reassignment in the baby with full male differentiation and micropenis is no longer recommended (116).

The American Academy of Pediatrics has published a statement concerning evaluation of the newborn with

developmental anomalies of the external genitalia. It emphasizes that sex of rearing be based on the potential for fertility, capacity for normal sexual function, endocrine function, potential malignant change, and testosterone imprinting. It is useful for health care professionals to develop a sex-assignment team where a multidisciplinary approach that includes parental involvement can be provided for the management of the intersex patient (117). Pediatric endocrine societies are also in the process of developing consensus guidelines for gender assignment. Such guidelines should be revised at regular intervals or whenever major new evidence comes to light.

C. Gender Reassignment in Childhood

Gender reassignment must take into consideration the child's development, the family's beliefs, and the cultural environment. Uncertainty exists regarding the latest time for gender reassignment without an increased risk of conflict in the child's emerging sense of gender identity. Early studies suggested a cut-off age of 18 months. Newer data suggest an earlier cut-off date, perhaps around 9 months of age. After that age, the child's emerging habitual gender-role behavior and identity must be carefully evaluated for compatibility with the recommended gender. Such an evaluation can be an arduous task because of the child's cognitive limitations at this stage of development and because of the potential for emotional sensitivity (118). In addition to considering the child's gender development, the clinician must evaluate the family's expectations, the family's flexibility, and the societal context. The child and the family must be able to cope with the gender reassignment. Clinicians should be careful not to superimpose their own cultural values.

D. Gender Assignment and Reassignment in CAH

Almost all female CAH patients, when appropriately diagnosed, are raised as girls. However, some patients who are born with markedly masculinized external genitalia have been inadvertently assigned to the male gender. In cases in which the diagnosis was made later, many physicians have recommended reassignment to the female gender after appropriate parental consent. Most 46,XX patients with CAH who have been assigned or reassigned to the female gender at an early age remain females lifelong. A small group of patients self-initiate gender reassignment at around puberty or later, and sometimes even as late as in midadulthood. Patients with CAH and 46,XX karyotype who have been reared in the male gender until late childhood or early adolescence usually elect to remain boys even after CAH is diagnosed. However, occasional patient-initiated reassignments to the female gender have been reported. Thus, an apparently stable gender identity in childhood does not necessarily preclude gender change

at a later age, nor does a successful gender reassignment in childhood exclude gender problems later in life (118).

Assigning newborns with CAH and penile urethra to the male gender has also been discussed but remains extremely controversial. Arguments in favor of male gender assignment include the consideration that a well-formed penis with a penile urethra does not require surgery, whereas reconstruction along female lines may not produce a vagina adequate for sexual intercourse, and may damage neuronal connection and vascular supply to the clitoris. Arguments against male gender assignment include the observation that the obligatory gonadectomy will be accompanied by loss of fertility and that there may be a need for sex hormone therapy at puberty. Studies involving large numbers of patients are needed before a change in policy can be made regarding gender assignment in patients with CAH with marked genital masculinization.

E. Gender Identity

Gender identity refers to the sense of belonging to or fitting into the male or female gender. Gender-role behavior denotes the behavior typical of one gender or the other in a given historical time and place.

Considerable information on the influence of prenatal androgen exposure on gender role behavior comes from studies of CAH. Various categories of sexually dimorphic behaviors are affected in girls with CAH. They include toy preferences, rough-and-tumble play, aggressiveness, interest in sports, maternal behavior, and vocational preferences. It has been suggested that the most important factor accounting for the difference in sexually dimorphic behavior between CAH girls and controls appears to be the effect of the prenatal androgens on sexual differentiation of the brain. Several researchers have indicated that the degree of genital masculinization is an indicator of the degree of masculinization of the brain. Indeed masculinized behavior is more prevalent among girls with salt-wasting CAH than it is in the simple virilizing form (119). If, as expected, much of the shift toward increased masculinization of behavior in CAH is due to the atypical prenatal androgen milieu, a reduction in prenatal androgen levels by prenatal dexamethasone treatment should reduce the degree of masculinization on the brain. However, concerns about the potential behavioral side effects of this treatment have been raised and are being addressed in continuing studies (120).

Many parents become anxious and uncomfortable when their daughter with CAH shows markedly gender-atypical behavior. Children with CAH should be monitored regularly and assessed unobtrusively for the degree of gender-atypical behavior. In addition, family milieu should be evaluated for acceptance of such behavior. In this regard appropriate psychological/psychiatric counseling promoting the acceptance of the behavior can be undertaken. Girls with CAH with markedly gender-atypical

behavior persisting into late childhood and early to mid-adolescence may become alienated from their gender-typical peer group. The alienation can lead to isolation, self-doubts, and depressive features. Such girls may profit from individual counseling and from contact with other girls in support groups. There is a published counseling guide in the intersex area, which is strongly recommended to patients and health care providers. Women with salt-losing CAH have an increased rate of bisexual or homosexual orientation, as demonstrated in sexual imagery such as erotic and romantic fantasies and dreams and sexual attractions; many of these women consider themselves lesbians.

Long-term studies of outcome in large numbers of subjects with 46,XY karyotypes and ambiguous genitalia are now being performed. Physical and psychological aspects are being explored. Such studies will provide additional perspective on the relative influence of prenatal androgens and environment.

F. Surgery During Infancy and Childhood

The timing of genital surgery in the course of a child's development is likely to have important psychological implications. In infancy, the decision must be made by the parents in consultation with physicians. Parents must have unequivocal commitment to the decision. Comprehensive genital surgery in infancy without any need for later procedures is intuitively beneficial, but no systematic data are available on the differences in psychological consequences of early vs. late surgery. Parents of newborns not only want to reach a decision about sex of rearing as soon as possible but also want the genitalia to appear similar to other children of the same sex and age.

Surgical techniques have advanced dramatically and skillful surgeons have achieved satisfactory outcomes in the majority of intersex patients. In particular, advances in techniques for reconstruction of male external genitalia have allowed definitive repair in infancy and early childhood. Timing of genital reconstruction in female subjects is more problematic. For example, it is not clear whether it is easier for an adolescent woman to undergo vaginal reconstruction just before she is ready to become sexually active or whether is preferable to perform surgery earlier, with the obligation to use dilators until the patient starts engaging in regular sexual intercourse. Prescribing vaginal dilatation during middle childhood presents difficulties. Cessation of early surgical intervention has been advised in several cases because of the emotional effect on the child. However, no systematic data on psychosocial acceptability and outcome are available. Individuals vary widely in the timing and pattern of sexual socialization. However, it is likely that an inadequate vagina and a reduction in erotic sensitivity, orgasmic capacity, and sexual satisfaction will inhibit courtship and perhaps reduce interest in sexual activity altogether.

Esthetic and gender-typical appearance continue to be useful criteria for surgical outcome, although attention must also be paid to long-term sexual functioning. Quality-of-life considerations, including sexual life in adolescence and adulthood, must be considered. In this regard as well, there is a major need for pediatric societies to develop consensus guidelines.

The performance of genital surgery without the child's fully informed consent has been severely criticized by the Intersex Society of North America. This point of view must be weighed against the complexities regarding the need for sex definition (121).

G. Examination of the Genitalia

Examination of the genitalia is crucial in evaluating the need for surgery, the outcome of surgery, and the impact of lapses in hormonal treatment. The physician must be aware of the potentially adverse psychological consequences of such examinations, even if the child seems overtly compliant. Genital examinations have more significant psychological implications than examinations of other body parts. Many patients become oversensitized by frequent examination. Hence, such examinations must be performed with psychological sensitivity. Their repetition by multiple trainees should be avoided. Alternative training strategies should be developed that do not adversely affect the patient.

H. Psychological Counseling

Most authors recommend an annual visit particularly during adolescence, with a mental health professional who is familiar with the psychosocial and sexual problems of intersex patients. It can be beneficial to have the same person involved in this capacity over the years, provided that the rapport with the patient is generally good. In addition, meeting one or more patients with the same or similar condition can be extremely helpful for patients with an uncommon disorder. The creation of clinic-affiliated support groups is recommended. Patient support groups on the Internet can also be useful. When recommending support-group affiliation, one should always make the patient aware of the risks, including biases, of these groups. The patient should be encouraged to discuss novel information acquired from support groups with his or her physician or mental health specialist. Patients with specific sexual dysfunction may need to be evaluated by a specialist who can review all endocrine, anatomical, surgical, and psychological factors that may be involved and who can plan an intervention in consultation with the respective specialists. Given the scarcity of mental health personnel familiar with intersex problems, physicians and patient organizations should press for appropriate training of mental health liaison personnel and for third-party coverage of the respective services.

Table 5 Stretched Penile Length in Normal Males

Age	Mean \pm SD (cm)	Mean \pm SD (cm)
Newborn, 30 wk	2.5 \pm 0.4	1.5
Newborn, 34 wk	3.0 \pm 0.4	2.0
Newborn, term	3.5 \pm 0.4	2.4
0–5 months	3.9 \pm 0.8	1.9
6–12 months	4.3 \pm 0.8	2.3
1–2 yr	4.7 \pm 0.8	2.6
2–3 yr	5.1 \pm 0.9	2.9
3–4 yr	5.5 \pm 0.9	3.3
4–5 yr	5.7 \pm 0.9	3.5
5–6 yr	6.0 \pm 0.9	3.8
6–7 yr	6.1 \pm 0.9	3.9
7–8 yr	6.2 \pm 1.0	3.7
8–9 yr	6.3 \pm 1.0	3.8
9–10 yr	6.3 \pm 1.0	3.8
10–11 yr	6.4 \pm 1.1	3.7
Adult	13.3 \pm 1.6	9.3

VII. MICROPENIS

Micropenis is characterized by a normally formed penis with a stretched penile length more than 2.5 standard deviations below the mean for age. Normative data are provided in Table 5 and in Chapter 42 (29). The mean stretched penile length in newborns is 3.5 cm (minus 2.5 standard deviation: 1.9 cm). Ethnic differences have been reported, with a smaller mean penile length in newborns of Chinese origin than in newborns of White and East-Indian origins (122).

Measurement of penile length should be made on the fully stretched rather than flaccid penis. A ruler should be pressed against the pubic ramus, depressing the suprapubic fat pad as completely as possible. The penis should be stretched by grasping the glans between the thumb and forefinger. The measurement is made along the dorsum to the tip of the glans without including the foreskin, if present. Accurate examination and measurement are essential in determining the presence of micropenis. Micropenis must be differentiated from so-called hidden penis, defined as a normal penis obscured by excessive suprapubic fat, and from a penis held down by marked chordee, in which it has a downward bowing as a result of a congenital anomaly (123).

Patients with micropenis may be classified in four major groups:

1. Hypogonadotropic hypogonadism is characterized by an abnormality in the hypothalamic–pituitary axis, resulting in inadequate androgen production. Syndromes in this category include Kallmann syndrome, Prader-Willi syndrome, Laurence-Moon syndrome, Rud syndrome, and conditions with multiple pituitary hormone deficiency.

2. Hypergonadotropic hypogonadism is characterized by primary gonadal failure. Conditions included in this category are Klinefelter syndrome, other X polysomies, Robinow syndrome, trisomy 21, Noonan syndrome, and Laurence-Moon syndrome.

3. Failure of androgens' action includes subjects with mild partial androgen insensitivity.

4. Idiopathic micropenis: Subjects in this category have normal hypothalamic–pituitary–gonadal function. Very rarely the entire penis is absent, a condition named aphallia (124).

The work-up of patients with micropenis should be directed toward early diagnosis and therapy. Other potential dangerous conditions that may be associated with gonadotropin deficiency, such as hypothyroidism, hypocortisolemia, growth hormone deficiency, and diabetes insipidus should be excluded and treated. In particular, infants should be carefully monitored. Plasma levels of FSH, LH, and testosterone should be determined. A gonadotropin-releasing hormone stimulation test and/or an hCG stimulation test may also be helpful in establishing the cause of the micropenis.

The ability of the penis to respond to androgens can be assessed following administration of testosterone or hCG in the newborn period. Treatment with intramuscular testosterone in infancy and childhood has been recommended to improve the appearance of the penis and to facilitate toilet training. The side effects of this treatment are minimal, and include temporary acceleration in growth and advancement of bone age, in addition to some others. Replacement therapy at puberty may be necessary in some individuals.

Wisniewski et al. examined long-term outcome among subjects with congenital micropenis (13 raised as males and 5 raised as females). Subjects were studied with questionnaires and physical examination. Penile length in individuals raised male was below the mean in all subjects. Many men reported dissatisfaction with the appearance of their genitalia. Both males and females were satisfied with their sex of rearing. Nonetheless, subjects raised female required several surgical procedures for reconstruction of their genitalia (115).

VIII. HYPOSPADIAS

Hypospadias is defined as abnormal placement of the urethral meatus. Isolated hypospadias is the most common congenital malformation in males, with an estimated incidence of 1:300 live male births. In the United States, the incidence of hypospadias has increased over the past years (125). There is a familial tendency with an increased risk among certain ethnic groups. It has been reported that 21% of subjects with isolated hypospadias had another family member with hypospadias: 14% having an affected brother and 7% having an affected father (126).

Formation of the ventral foreskin of the penis is related to normal urethral development. Failure of the urethra to reach the tip of the glans is accompanied by absence of the ventral foreskin. This absence causes ventral curvature of the penis known as chordee, which frequently accompanies hypospadias. If normal development of the urethra is arrested and the urethral folds fail to fuse, the meatus may be found anywhere along the course of the penis from the perineum to the glans.

Hypospadias is classified based on the location of the urethral meatus after ventral curve has been surgically corrected. The most common form is the anterior hypospadias (glandular or coronal types), which accounts for 50% of all cases of hypospadias. The distal penile, mid-shaft, and proximal penile forms make up 30%. The remaining 20% are posterior forms (penoscrotal and perineal) (127).

The cause of hypospadias is multifactorial. In the majority of cases of isolated hypospadias the cause remains unknown. Hypospadias has been also associated with disorders of male sexual differentiation (127, 128). Environmental estrogens and antiandrogens have also been associated with isolated hypospadias. Hypospadias may be associated with syndromes of human malformation, such as Smith-Lemli-Opitz syndrome and cerebrohepato-renal syndrome. Subjects with severe hypospadias with and without cryptorchidism required a complete evaluation of ambiguous genitalia (see above).

Surgical reconstruction of hypospadias requires correction of chordee when present. It is recommended that boys with hypospadias not be circumcised, because the foreskin may be used in the urethroplasty. If hypospadias is associated with micropenis, treatment with testosterone is usually performed before surgery.

IX. CRYPTORCHIDISM

A. Definition

Cryptorchidism, defined as failure of the testis to descend into the scrotum, is another common disorder in boys. Undescended testis has a prevalence of 4–5% in full-term boys and 9–30% in premature boys (30). Spontaneous testicular descent usually occurs by the first year of life, when the prevalence of cryptorchidism declines to 1%. Undescended testis is usually unilateral (90%) and most often right-sided. The undescended testis can be located along of the inguinal canal (72%), just distal to the external ring (20%), or intra-abdominally (8%). In rare instances, the testis deviates from the normal pathway, a condition referred to as ectopic testis. The ectopic testis may be located in the superficial inguinal pouch, perineum, femoral canal, prepenile scrotum, or contralateral scrotum.

The true undescended testis must be differentiated from conditions such as the so-called retractile testis: a

normal testis that has an active cremasteric reflex that pulls it back into the groin. In this condition, the testis can be brought into the scrotum without the testis being under tension. A retractile testis can often be more easily brought into the scrotum when the child assumes a squatting position. Alternatively, it may be seen in the scrotum when the child is in a warm bath.

B. Etiology

Undescended testis results from a disruption in physiological testicular descent. Decreased androgen production as a consequence of abnormalities of the hypothalamic–pituitary axis, such as anencephaly, pituitary aplasia, and Kallmann syndrome, is associated with the occurrence of undescended testis. Defects of androgen synthesis and androgen-receptor insensitivity are also associated with the presence of undescended testis (129, 130). Mechanical anomalies related to urogenital obstruction including prune belly syndrome, posterior urethral valves, and defects of the abdominal wall such as gastroschisis and omphalocele cause undescended testis (131). Several syndromes with different chromosomal abnormalities (deletions, duplications, trisomies) include undescended testis among their features. Genetic factors may play a role, this being suggested by the occurrence of undescended testis in 1.5–4% of fathers and 6.2% of brothers of patients with cryptorchidism (30).

Insulin-like hormone-3 (INSL-3), also known as Leydig insulin-like protein, is involved in testicular descent. Mice with mutations of INSL-3 have bilateral undescended testis with abnormal development of the gubernaculum (132). Tomboc et al. reported the presence of two mutations in the connecting peptide region of the protein in 2 of 145 patients with undescended testis (133).

C. Evaluation of Undescended Testes

In newborns with male external genitalia and bilateral undescended testis, salt-losing congenital adrenal hyperplasia in a female infant must be excluded. If the karyotype is 46,XY, the presence of dysmorphic features may indicate a specific syndrome. Radiological studies may be warranted in the diagnosis of undescended testis. Testes located in the external inguinal canal or just adjacent to the external inguinal ring are easily detected by a high-resolution ultrasound scan (134). In a 46,XY subject with unilateral undescended testis, evaluation is advised at 1 year of age. In older children with undescended testis, hormonal evaluation, including evaluation of LH, FSH, and AMH is recommended. In children with hypogonadotropic hypogonadism, complete hormonal evaluation is indicated as discussed in the section on micropenis.

D. Consequences of Cryptorchidism

Testicular neoplasm, infertility, testicular torsion, and inguinal hernia are the most common complications of undescended testis. The risk of testicular malignancy in the general population is 1 in 45,000 males. However, 10% of adult testicular tumors occur in men with a history of undescended testis. The risk of testicular tumor in subjects with unilateral and bilateral undescended testis is 15 and 33 times greater, respectively, than that of subjects with normal testes. Intra-abdominal testes are five times more likely to develop a tumor. Germ-cell degeneration and dysplasia are considered the causes of malignancy. Seminomas are the most common type of malignancy, followed by embryonal cell carcinoma. Most studies indicate that bringing the testis down into the scrotum does not reduce the risk of subsequent malignancy. Malignancy may occur after orchiopexy or in the contralateral normally descended testis (30).

Infertility is due to lack of or decrease in the number of germ cells as a consequence of temperature-induced degeneration. Histological abnormalities with decreased number of the spermatogonia in undescended testis are reported as early as 3 months of age (135). By 2 years of age the germ cells have decreased to 40% of normal. There is also an increase in interstitial fibrosis and collagenization in peritubular connective tissue. There is indirect evidence that the abnormality in the contralateral descended testis occurs at an early age. Autoantibodies to the undescended testis may be produced and can cause degenerative changes in the descended testis. Paternity rates are lower in men with history of bilateral cryptorchidism than in men with a history of unilateral cryptorchidism. Sudden painful inguinal swelling in association with cryptorchidism can represent testicular torsion or hernia with incarceration, both of which indicate the need for urgent intervention.

E. Treatment

The therapeutic goals in treating cryptorchidism are to prevent infertility, avoid malignancy, correct an associated hernia, if present, and alleviate psychological stress caused by the empty scrotum.

1. Hormonal Therapy

Different protocols with hCG and/or pharmacological preparation of gonadotropin-releasing hormone (GnRH) have been used with a range of success. The World Health Organization recommends hCG 250 IU twice a week for 5 weeks in boys up to 1 year of age. From 1 to 5 years of age, 500 IU is recommended twice weekly for 5 weeks. In older boys, 1000 IU twice weekly is suggested for 5 weeks. Nonetheless, published dosages and treatment schedules have varied from 100 to 4000 IU per injection given 2–3 days per week for 1–5 weeks. Combined treatment using hCG and GnRH analogs for a total of 4 weeks

has been reported to improve response in nonpalpable testis (136).

Successful treatment of the true undescended testis with hCG has varied from 6 to 65%. Hormonal treatment is more effective in the treatment of testis located immediately prescrotally. However, some reports suggest that hormonal therapy is only successful for those testes that would have ultimately descended without surgery.

2. Surgical Therapy

The optimal time to operate is unknown, considering that evidence that histological changes in the testis occur early as 2–3 months of age. However, the recommendation of the Action Committee on Surgery of the Genitalia is to perform orchiopexy at 12 months of age. Numerous studies have reported that 75% of testes descend spontaneously by this age without further chance of descent thereafter. Anesthesia risk by this age is minimal when administered by experienced pediatric anesthesiologists. Most orchiopexies are performed as outpatient procedures. Ectopic testes and testes in the inguinal canal are brought into the scrotum by a small inguinal crease incision. The gubernaculum and cremasteric muscle are separated from the testis, and the lateral Prentiss fibers are divided, thereby allowing the testis a more direct route into the scrotum. The testis is then fixed in place with a suture. There is a 90% incidence of inguinal hernia with undescended testis, which is usually repaired simultaneously. The success rate of this operation is reported to be over 95%. Bilateral inguinal testes can be operated on at the same time. Nonpalpable undescended testis can now be located by laparoscopy to inspect the peritoneal cavity. Of nonpalpable testes, 20% are atrophic, and blind-ending spermatic vessels and vas deferens are noted intra-abdominally. Numerous radiological investigations have been performed, including sonograms, CT scans, venography of the spermatic vessels, and, recently, MRI. If, at the time of laparoscopy, the testis is located, an orchiopexy can be performed.

Most testes can be placed within the scrotal sac by one procedure. However, when the spermatic vessels are extremely short, a two-stage orchiopexy can be performed. The spermatic vessels are ligated or divided during the first stage, allowing collateral blood supply via the vasal artery to develop. Then, 4–6 months later, the testis can be brought into the scrotal sac and nourished with the vasal blood supply with a success rate of 90%. In bilateral nonpalpable testis, hCG stimulation tests should be performed before laparoscopy to rule out testicular agenesis. Laparoscopy in children has been shown to be safe by the age of 1 year and can be done as an outpatient procedure (30).

Thyroid Disorders in Infancy

Guy Van Vliet

University of Montreal and Sainte-Justine Hospital, Montreal, Quebec, Canada

I. INTRODUCTION

Around the time of birth and during the first few years of life, thyroid hormone economy undergoes major changes that need to be understood for the proper investigation and treatment of thyroid dysfunction. The dramatic consequences of congenital hypothyroidism (CH) that is not diagnosed during the neonatal period for later brain development underline the importance of prompt recognition of abnormal thyroid function test results. Although congenital *hyper*thyroidism is a much less common and usually self-limited entity, it may also lead to dramatic consequences. Heart failure and even death from this condition have been reported in hyperthyroid newborns, and later developmental problems may occur as well.

The most striking changes in plasma thyroid-stimulating hormone (TSH) and thyroid hormone levels occur immediately after birth. It is therefore important to know about the neonatal TSH surge, which reaches its maximum in the first few hours of life, and is followed by a peak in plasma thyroxine (T_4) approximately 24 h later. An isolated TSH measurement in the first 24 h of life may therefore lead to an erroneous diagnosis of primary hypothyroidism, while an isolated measurement of T_4 on the second day of life may lead to an incorrect diagnosis of hyperthyroidism.

However, it is also important to recognize that several parameters of thyroid function, such as the normal ranges of free T_4 and of total T_3 , extend to much higher levels in infancy than in older children or adults. The mechanisms underlying these age-related changes in thyroid hormone levels are briefly reviewed in the following section, and the clinical problems are discussed next in order of frequency and importance. The vast majority of these problems present as abnormalities of thyroid function, but some structural thyroid problems may also present in infancy.

II. CHANGES IN THYROID HORMONE ECONOMY FROM CONCEPTION TO 3 YEARS OF AGE

A. Embryonic Period

The median anlage of the thyroid migrates from the lingual area to its normal location in the neck between the 5th and 7th week of embryonic life. Once migration is complete, the median anlage connects with the lateral lobes that are derived from the fourth and fifth pharyngeal pouches. However, from the functional standpoint, the capacity to concentrate iodine only appears at about 12 weeks and control of thyroid function by the hypothalamopituitary axis is only established at 18 weeks. Because of this, the low amount of T_4 that can be measured in amniotic cavities in the first trimester must be of maternal origin, suggesting that some transplacental passage of T_4 already occurs at that stage (1). This may explain the deleterious effects of *maternal* hypothyroidism (which has been most dramatically illustrated in severe iodine deficiency) on the intellectual development of the offspring. This may justify biochemical screening of women who have a personal or family history of thyroid disease and who are contemplating becoming pregnant (2).

B. Fetal Period

In fetal blood, T_3 is low because of the presence of the placenta, with its very rich content in type III deiodinase (which transforms the prohormone T_4 in the inactive hormone reverse T_3 [rT_3] and T_3 itself into the inactive T_2). The low T_3 milieu may be responsible for the maintenance of a low level of *in utero* thermogenesis. TSH is high, probably because of extrahypothalamic sources of TRH, such as the pancreas and the placenta. Between 20 weeks and term, fetal plasma free T_4 increases progressively because of increased secretion by the fetal thyroid (3). However, even in the complete absence of fetal thyroid func-

tion, cord blood T_4 is 20–50% of the mean value of euthyroid neonates (4). This suggests that the transplacental passage of T_4 alluded to above may become substantial in the third trimester and allow some protection of the fetal brain against defective function of the fetal thyroid. The fetal brain is also protected against hypothyroidism by its rich content of type II deiodinase, the enzyme that converts T_4 into the active hormone T_3 , which is up-regulated in hypothyroidism. These two protective mechanisms provide the framework supporting the concept that complete salvage of intellectual potential is possible even in cases of severe congenital hypothyroidism provided effective treatment is administered soon after birth (see below).

Another important consideration deriving from the above is that prenatal screening of all pregnant women for fetal hypothyroidism is probably not justified. At present, it would require amniocentesis, and the risks of this procedure would outweigh the possible benefits of diagnosing hypothyroidism in the fetus. However, *in utero* diagnosis of hypothyroidism by cordocentesis and treatment of the fetus by intraamniotic injections of levothyroxine have been reported (5). The major indication is to determine the cause of a fetal goiter discovered by ultrasonography (if it cannot be reasonably guessed from the clinical context), so as to choose the most appropriate treatment to decrease its size. Indeed, a large goiter in the fetus entails potential risks during labor (face presentation) or after birth (respiratory distress).

C. Neonatal Period

Presumably as a consequence of the precipitous drop in ambient temperature, plasma TSH increases markedly in normal newborns, with a peak in the first 24 h of life. This is followed by a more shallow increase in plasma T_4 , peaking during the second day of life. Thus, screening for congenital hypothyroidism using TSH as the primary method should be delayed until after 24 h of life, otherwise the number of false positive tests would become unacceptably high. In premature newborns, the postnatal peaks of TSH and of T_4 occur within the same time frame, but their amplitude is somewhat lower than that observed in term newborns.

D. Infancy

The relative dosage (in $\mu\text{g}/\text{kg}/\text{day}$) of thyroxine needed to maintain euthyroidism in hypothyroid subjects decreases exponentially during the first 2 years of life from about 10 to about 5 $\mu\text{g}/\text{kg}/\text{day}$ (6). In absolute terms, the $\sim 50 \mu\text{g}$ thyroxine needed by a newborn correspond to about 15% of the neonatal intrathyroidal iodine pool, whereas the 150 μg needed by an adult correspond to only 1% of the mature intrathyroidal iodine pool. A higher iodine turnover is in general associated with higher plasma T_3 (7) and, accordingly, the normal range of plasma T_3

extends to higher values in infancy than in adulthood (8) (Table 1).

III. CONGENITAL HYPOTHYROIDISM

A. Nomenclature

As is the case at later ages, hypothyroidism in infancy can be congenital or acquired, peripheral (primary) or central (secondary or tertiary), and permanent or transient in nature (Table 2). Because the most common and most potentially deleterious for long-term intellectual outcome is permanent primary congenital hypothyroidism (PPCH), PPCH will be the focus of this section. On the other hand, transient hypothyroxinemia without elevation of plasma TSH is very common in premature infants. Yet there is still controversy as to whether this is a disease entity requiring treatment or whether it is one of the many mechanisms by which the premature infant adjusts to extrauterine life. Transient hypothyroxinemia is therefore the subject of a section separate from congenital hypothyroidism. Likewise, newborns are very sensitive to iodine deficiency and this remains a major cause of congenital hypothyroidism worldwide. The distribution of neonatal TSH levels and the percentage of newborns with TSH $> 5 \text{ mIU/l}$ on neonatal blood spot samples has been proposed as a means to evaluate the extent of iodine deficiency in a population (9). This major public health problem is beyond the scope of the present chapter.

The prevalence of *permanent* primary CH is not increased in preterm infants (10). However, an increased prevalence of *transient* primary CH has been reported in some studies of premature newborns. The best characterized is due to the Wolff-Chaikoff effect: the induction of hypothyroidism by acute iodine overload (most often from iodine-containing antiseptic agents) (11). This condition has been mostly reported from areas of Europe where there is mild iodine deficiency and does not appear to occur in North America (12), presumably because the iodine intake of pregnant women in this area remains, on average, above a critical threshold.

Finally, the hypothyroidism resulting from dominantly inherited mutations that inactivate the T_3 receptor can sometimes be severe enough to be recognized in the neonatal period. Molecular confirmation of this diagnosis has now been obtained in over 200 pedigrees, but this condition will not be discussed further in this chapter and the reader is referred elsewhere (13).

B. Epidemiology and Causes of PPCH

PPCH affects 1:2500–4000 newborns. On the basis of newborn screening programs, its worldwide incidence is relatively similar over a wide range of ethnic groups and geographical areas. The only possible exception to this rule is a lower prevalence among black populations (14).

Table 1 Pediatric Reference Intervals for T₄, T₃, TSH, and Free T₄

Analyte	Age	Females			Males

Source: From Ref. 8. Reference values were obtained with the AutoDelfia analyzer (Wallac, Finland); different values may be expected with other methods.

Eighty to 90% of PPCH cases are due to developmental defects of the thyroid gland (thyroid dysgenesis), such as arrested migration of the embryonic thyroid in the sublingual area (ectopic thyroid) or an apparently complete absence of thyroid tissue on scan with sodium pertechnetate (athyreosis). Renewed interest in thyroid development has stemmed from the identification of transcription factors that are relatively thyroid-specific and from the generation of knock-out mice for these transcription factors. In humans, a few single gene defects have been shown to account for some cases of familial thyroid dysgenesis, but the vast majority of cases are sporadic and result from as yet unknown mechanisms (15). The remaining 10–20% of PPCH cases have functional defects in one of the steps involved in thyroid hormone biosynthesis (thyroid dysmorphogenesis), which follow an autosomal recessive mode of inheritance.

Recent studies have reevaluated whether genetic factors are involved in thyroid dysgenesis. Thus, a nationwide study of cases diagnosed by neonatal screening in France identified 48 familial cases out of 2472 (2%), which is 15-fold more than expected by chance. Analysis of the most typical pedigrees suggested autosomal dominant inheritance with incomplete penetrance, although there was also evidence for genetic heterogeneity (16).

Ectopy and athyreosis are generally considered as part of a spectrum. Recent arguments in favor of this view are that athyreosis and ectopy can coexist in the same pedigree (16) and that *ttf2* ^{-/-} mice can have either ectopy or athyreosis, with a 50/50 distribution between the two phenotypes (17). On the other hand, the female preponderance classically described for thyroid dysgenesis as a whole is in fact only significant for ectopy, according to the results of two large recent surveys (15,18) (Table 3).

Table 2 Classification of Causes of Congenital Hypothyroidism

Central: Rare
Mutation of the TRH receptor
Mutation of beta-TSH
Mutation of (PROP)PIT-1
So-called idiopathic hypopituitarism (usually with classic triad on MRI, see text)
Peripheral: Frequent (1:2500–4000 newborns)
Ectopic thyroid (most often sublingual): ~70% of cases
Mutations inactivating <i>PAX-8</i>
Other mechanisms (postzygotic stochastic events)
Athyreosis ~15% of cases
True (undetectable plasma thyroglobulin)
Mutations inactivating <i>TTF-2</i>
Other mechanisms
Apparent
Permanent
Mutations inactivating <i>TSHR</i> or <i>NIS</i>
Other mechanisms
Transient: maternal TSH-receptor blocking antibodies
Dyshormonogenesis (leading to goiter): ~10–20% of cases
Thyroid of normal shape, position and size: ~5% of cases

Source: See Refs. 15 and 25 for discussion.

This may suggest distinct molecular mechanisms for the two forms of thyroid dysgenesis, or sex-specific modifiers of a common initial event (15). The fetal sex ratio in studies of various embryopathies is seldom reported (19), and indeed was not reported for the *tff2* ^{-/-} mice.

It should also be kept in mind that athyreosis itself may be heterogeneous (Table 2). Undetectable uptake on scan may represent so-called true athyreosis (a diagnosis that should be validated by an undetectable plasma thyroglobulin) or apparent athyreosis from transplacental transfer of TSH-receptor blocking antibodies; Na/I sym-

porter mutations; or ectopic tissue too small for the limit of detection of nuclear medicine scans.

The differentiation between athyreosis and ectopy is of more than academic interest. Apparent athyreosis from transplacental transfer of TSH-receptor blocking antibodies leads to transient CH but has a very high risk of recurrence in subsequent pregnancies (20). The observation that PPCH from athyreosis does not have a sex ratio that is significantly different from 0.5 (Table 3) suggests that autosomal recessive mechanisms may be involved in a significant proportion of cases. Indeed, several pedigrees have been described in which apparent athyreosis was due to either compound heterozygosity (21) or homozygosity (22) for mutations that result in complete inactivation of the TSH receptor. Anatomically, the absent uptake was due to the fact that the gland was severely hypofunctional, but careful ultrasonography demonstrated that a hypoplastic gland was present and was of normal shape and position. This is consistent with the concept that TSH and its receptor are necessary for growth and function of the thyroid, but not involved in the initial differentiation of thyroid cells or in the migration of the thyroid anlage.

A milder form of TSH resistance can be seen in pseudohypoparathyroidism, in which an increased level of TSH at neonatal screening or during infancy may be the presenting sign (23), before obvious phenotypic features are recognized; and in non-TSH-receptor-related TSH resistance, with a consistently normal plasma T₄, a normal orthotopic gland on ^{99m}Tc imaging, and a dominant pattern of inheritance (24). Permanent or transient hyperthyrotropinemia of infancy, with normal plasma T₄ and normal thyroid anatomy, can also be seen without a family history and its mechanisms remain to be elucidated. It may occur in otherwise normal children or in children with other phenotypic abnormalities, such as respiratory distress and developmental delay (as in patients with mutations in *TTF-1*; see Table 4). It can also be seen in Down syndrome (see below).

Aside from TSH receptor mutations in athyreosis, a search for mutations in the genes coding for thyroid transcription factor-1 (TTF-1), for TTF-2 or for the paired domain factor PAX 8 has so far yielded only a handful of positive results. The careful description of the phenotypes of these naturally occurring mutation in humans and of the corresponding knock-out experiments in mice is of great importance for our understanding of thyroid gland development, but is beyond the scope of this chapter. The reader is referred elsewhere for this aspect (25). For clinical purposes, Table 4 proposes guidelines for when a specific gene should be examined.

C. Clinical Aspects and Rationale for Biochemical Screening

Signs and symptoms of hypothyroidism in the newborn period are almost always overlooked, yet this is when irreversible brain damage occurs. In the experience of the

Table 3 Proportion of Girls with Ectopy or Athyreosis from Quebec and Toronto

Table 4 Transcription Factor Mutations and Congenital Hypothyroidism

Thyroid phenotype	Other features	Gene	Type of genetic lesion	Transmission
Mildly ↑ TSH Gland normal in shape, size, and position	RDS Developmental delay Ataxia	<i>TTF-1</i>	Chromosomal deletion Missense	<i>de novo</i> or inherited <i>de novo</i>
Athyreosis	Cleft palate Choanal atresia Kinky hair	<i>TTF-2</i>	Missense	AR
Ectopy or orthotopic hypoplasia	Cysts within thyroid remnants	<i>PAX-8</i>	Missense	AD or <i>de novo</i>

RDS, respiratory distress syndrome; TTF, thyroid transcription factor; AR, autosomal recessive; AD, autosomal dominant.

last 12 years at the author's institution, the diagnosis was suspected clinically in only 2 of more than 150 newborns.

For this reason, systematic biochemical screening of newborns was undertaken in the 1970s and is becoming the standard of care in an ever-increasing number of countries. The screening strategy is based on primary TSH measurements in most countries, followed by T₄ measurement if TSH is raised above a certain cutoff. As an alternative, the so-called primary T₄ strategy is still used in most American states. The time at which the sample is taken may also vary between centers, with some taking cord blood, but the majority take blood from a heel prick after 24 h of age, to avoid an unacceptable percentage of recall due to the neonatal TSH surge alluded to above. Therefore, the practice of discharging newborns on the day of birth represents an organizational challenge to screening for CH.

Knowledge of the specific technique and cutoff levels used by the screening program is not as important as the clinician's awareness that a positive screening result should prompt immediate action and that continuous auditing of the turnaround time of the screening program is essential. Many individuals are involved between the time the sample is taken and sent to the screening laboratory and when the laboratory technician reports an abnormal result to the clinician. Human errors are the single most important factor in delayed or missed diagnoses of CH. The current guidelines used by the Quebec screening program are given in Table 5.

Aside from human errors, truly normal screening TSH and T₄ values have been found in infants who developed severe hypothyroidism during infancy. Thus, for unknown reasons, children with thyroid dysmorphogenesis can have normal TSH and T₄ as newborns and yet

Table 5 Screening and Evaluation Strategies for CH: Quebec Guidelines, 2001

Heel prick after 24 h of life except if
Transfer to another hospital (sample should be taken at hospital of birth)
Exchange blood transfusion
Death within 24 h
Note: entire surface of the spot should be filled (avoid soiling)
Samples should be sent to screening laboratory every weekday
Assay for TSH by time-resolved fluorometric assay technique
If TSH is less than 15 mIU/L: normal
If TSH between 15 and 29 mIU/L, total T ₄ is measured on blood spot:
If total T ₄ is less than 87 nmol/l, ^a immediate referral
If total T ₄ is greater than 87 nmol/l, ^a a second blood spot is requested and the infant is referred if TSH is still 15 mIU/l or above
If TSH is greater than 30 mIU/l, <i>immediate referral</i>
Upon referral:
History and physical examination
Anteroposterior x-ray of knee
^{99m} Tc scintigraphy of cervical, lingual, and mediastinal area
blood for TSH, free T ₄ , T ₃ , antithyroperoxidase antibodies in mother and baby
plasma thyroglobulin in baby if apparent athyreosis on scan
<i>Start treatment without waiting for results of blood tests</i>

^a65 nmol/l if birthweight less than 2.5 kg.

present in the first 2 years of life with clinical and biochemical evidence of severe hypothyroidism (10, 26). The second situation arises from the fact that monozygotic twins are generally discordant for thyroid dysgenesis and that the affected twin may have normal screening values because of subtle blood mixing between the euthyroid and the hypothyroid fetus (27). Lastly, dopamine infusions may lead to a false-normal plasma TSH result in spite of primary hypothyroidism (28). Thus, in spite of normal neonatal screening results, the appearance of signs and symptoms suggestive of hypothyroidism in an infant justifies repeating the determination of TSH and T₄.

D. Diagnostic Evaluation of the Hypothyroid Newborn

As stated above, a clinical diagnosis is almost never made in the newborn period. However, when a baby is referred for evaluation of a positive test, it is sometimes possible to elicit a history of increased sleepiness, poor feeding, or constipation. The family history should focus on whether there are other cases of CH or whether the mother is known to have autoimmune thyroid disease. On physical examination, prolonged icterus and large fontanelles are the most frequently encountered signs. A careful inspection of the cervical area, with the neck hyperextended, is important to detect a goiter. However, even obvious goiters on nuclear medicine scanning can be missed by experienced clinicians and imaging studies are almost always necessary. Extrathyroid abnormalities should be noted: congenital hypothyroidism can be part of a poly-malformative syndrome (Table 4) and a fivefold increase in the prevalence of minor defects in septation of the embryonic heart has been reported in children with thyroid dysgenesis (15).

Blood is taken to confirm the positive screening results. In addition to TSH, we routinely measure free T₄, total T₃, and thyroglobulin from this sample. Although the prevalence of transient CH from transplacental transfer of TSH receptor-blocking antibodies is low (29), this possibility should be investigated in cases with apparent athyreosis or with a gland of normal shape and size but decreased uptake.

Because of the importance of a precise diagnosis in establishing that CH is permanent (as in true athyreosis and ectopy) or that it has a 25% recurrence risk in subsequent siblings (as in dysmorphogenesis), a nuclear medicine scan should be obtained. This should ideally be carried out on the day of the initial diagnostic evaluation, but can be performed during the first few days of thyroxine treatment because, as long as plasma TSH is still elevated, there will be uptake of the tracer by thyroid tissue. The isotope of choice is sodium pertechnetate (^{99m}Tc), which is available daily in most nuclear medicine services. However, difficulties in arranging for imaging studies should never be taken as an excuse for not initiating treat-

ment on the first visit. A nuclear medicine scan can always be obtained after withdrawing treatment for a month at 3 years of age (when hypothyroidism no longer has permanent consequences for brain development); however, obtaining good imaging is easier in a newborn than in a toddler. Lastly, one should *not* wait for the results of confirmatory blood tests before starting treatment.

The technical quality of nuclear medicine scans is important (30). The unequivocal demonstration of ectopic sublingual tissue requires that the salivary glands be empty (which can easily be achieved in newborns by feeding them between the intravenous [IV] injection of technetium and scanning, and in toddlers by giving them a piece of candy). Ascertaining that the technetium has been injected in the vein is also essential. Because of these pitfalls of nuclear medicine imaging (and the radiation involved, although the dosage is minimal), ultrasound scanning has been evaluated for the etiological diagnosis of CH. The differentiation between normal thyroid lobes and the hyperechogenic structures (likely the ultimobranchial bodies) in the same location when there is no orthotopic thyroid is difficult and requires a highly skilled pediatric radiologist (31). Ultrasound scanning has therefore not replaced nuclear medicine imaging at most centers.

E. Treatment and Outcome of Congenital Hypothyroidism

Before systematic biochemical screening of newborns, the mean IQ of CH children was 76 (32) and 40% required special education (33). Even in those with normal IQs, specific cognitive deficits were common (34). These numbers provide the historical background against which to gauge the success of biochemical screening and different treatment regimens.

In the first generation of screened CH newborns, treatment was started at a mean age of 23–30 days and the starting dosage of levothyroxine was 5–6 μg/kg·day. While it was recognized that such a dosage did not normalize plasma TSH for weeks or even months, this was thought to reflect resistance to the normal feedback control mechanisms. However, such a resistance occurs only in a minority of CH newborns (35). The first report of developmental outcome of screened CH children suggested that intellectual impairment had been completely eliminated (36). This first report also found no impact of the initial severity of hypothyroidism at diagnosis. However, a meta-analysis published 15 years later and including 675 children with CH and 570 controls from 7 studies clearly showed that initial disease severity was an important determinant of outcome. Specifically, the subgroup of children with severe CH had a mean loss of six IQ points compared to controls, and in some studies the difference was in the range of 10–20 IQ points, which is not only statistically but also clinically significant (37).

Severity of CH at diagnosis can be evaluated in a number of different ways (38). Most commonly, this has been done on the basis of the plasma level of T_4 , of the bone maturation, or of the cause (athyreosis vs. ectopy). An important concept is that the impact of severity of CH on developmental outcome does not appear linear: rather, there seems to be a threshold below which an infant with CH was at greater risk of developmental problems. This has been most convincingly demonstrated by Tillotson et al. (33), who defined a plasma total T_4 at diagnosis of 43 nmol/l as the critical point below which the IQ became affected by CH.

A more detailed description of these studies mostly carried out in the eighties does not seem necessary, because age at starting treatment and initial dosage of levothyroxine have changed substantially since then. In the last decade, most centers have been able to start treatment at a mean age of 9–14 days. Also in the last decade, because several lines of evidence suggested that the dosage used was suboptimal (not only persistent elevation of TSH, but also persistent delay in bone maturation at 3 years were observed [39]), the starting dosage of levothyroxine has been increased at many centers to 10–15 $\mu\text{g}/\text{kg}\cdot\text{day}$. This regimen promptly normalizes plasma TSH, but is associated with plasma free T_4 levels above the reference range of most laboratories. However, as reviewed above, the normal range of plasma free T_4 extends to much higher levels in infants than in older children or adults (Table 1). In addition, the mean plasma level of T_3 remains within the normal range and objective signs of hyperthyroidism have not been documented. Frequent monitoring of thyroid function (i.e., every 1–3 months) was recommended by the American Academy of Pediatrics in 1993 (40). With frequent monitoring, the dosage of levothyroxine will be titrated upwards in a timely fashion when the starting dosage is low (41) and may be titrated downwards if TSH is consistently below the normal range and/or if T_3 is high. Infants with dysmorphogenesis appear to need less levothyroxine than those with dysgenesis (18). Thus, further studies on the biochemical endpoints of treatment and the development of guidelines for change in dosage are needed with the high initial dosages currently used at many centers.

However, the most important aspect of outcome is developmental and several recent studies have shown that the developmental gap that existed between severe CH children and controls has now been closed (6). Both early and high-dosage treatment appear necessary (42). Detailed studies of neurophysiological functions that may be more sensitive to the effects of both over- and undertreatment than the measurement of IQ may lead to greater individualization of initial dosage recommendations. In the meantime, starting as early as possible with 10–15 $\mu\text{g}/\text{kg}\cdot\text{day}$ appears safe and effective in achieving the major goal of neonatal screening: to allow all CH children, including those with a severe form of the disease, to achieve their full intellectual potential (43).

IV. HYPOTHYROXINEMIA OF THE NEWBORN

It is essential to define whether one is discussing decreased *total* or decreased *free* T_4 . The first condition that needs to be ruled out in a newborn with low total T_4 concentrations associated with normal plasma TSH is thyroxin-binding globulin (TBG) deficiency. This X-linked condition is discovered only by screening programs using a primary T_4 approach (for technical reasons, total and not free T_4 is measured on the neonatal blood spot). It does not require treatment, since the plasma levels of free thyroid hormones are normal and the subjects are euthyroid. Loss of protein from nephrotic syndrome may also lead to low total T_4 . With the generalization of free T_4 assays, unnecessary investigation and treatment of TBG deficiency has become rarer.

In a term neonate with a low free T_4 but normal TSH level, true central hypothyroidism needs to be ruled out. Isolated central hypothyroidism is exceedingly rare but may also have profound long-term deleterious effects on later development: it can be caused by mutations that inactivate the gene coding for the beta-subunit of TSH (44) or the gene coding for the TRH receptor (45). More commonly, central hypothyroidism occurs in association with other anterior pituitary hormone deficiencies: hypoglycemia, prolonged conjugated hyperbilirubinemia, and microphallus and/or cryptorchidism will suggest associated deficiencies in growth hormone, adrenocorticotropin (ACTH) and luteinizing hormone (LH), respectively. Clinical clues to a midline defect include cleft lip and palate and optic nerve hypoplasia. Magnetic resonance imaging reveals the classic triad of ectopic posterior pituitary; thin, interrupted, or absent stalk; and hypoplastic anterior pituitary in most cases of congenital hypopituitarism. A normal pituitary anatomy should lead to consideration of mutations in *PIT-1* or in *PROP-1* (46).

On the other hand, hypothyroxinemia relative to term values, but with normal TSH, is a very common finding in premature newborns (10). It does not only reflect low TBG levels because free T_4 levels are low as well. This should probably be considered as a situation akin to that seen at later ages in the presence of severe nonthyroidal illness. Indeed, numerous studies have shown that there is a correlation between the degree of lowering of T_4 and negative outcomes, both short-term (mortality) and long-term (developmental problems). However, correlation does not imply causation: indeed, randomized, double-blind, placebo-controlled studies of thyroxin supplementation have not shown an overall benefit in terms of morbidity, mortality, or developmental outcome. In fact, lower IQs were observed in levothyroxine-treated infants born after 27 weeks of gestation. Further research is underway to determine if the apparent benefit from thyroxin supplementation in extremely premature (<26 weeks) infants is confirmed (47). Systematic supplementation of all low-birthweight babies is not recommended at this time.

V. CONGENITAL HYPERTHYROIDISM

As is the case later in life, a high plasma T_4 level does not necessarily indicate hyperthyroidism. As noted above, there is a physiological, transient peak of plasma T_4 on the second day of life. Aside from the precise postnatal age, the next most important thing to know is whether the laboratory reports total or free T_4 . A high T_4 in the face of a normal free T_4 suggests TBG excess, a condition that, like TBG deficiency, should not be treated. TBG excess may be genetically determined or may be due to liver disease. In the syndrome of generalized resistance to thyroid hormone mentioned above, high circulating levels of thyroid hormones are in fact associated with *hypothyroidism* and plasma TSH is high.

On the other hand, and as is also true in later life, a low or undetectable plasma TSH level, even with ultrasensitive third-generation assays, is not sufficient to establish a diagnosis of hyperthyroidism: it can be seen in central hypothyroidism or in severe nonthyroidal illness. To make a diagnosis of true hyperthyroidism, the combination of a low or undetectable TSH with high T_4 and/or T_3 is required.

A. Transient Graves' Disease

Most commonly, hyperthyroidism in infancy occurs during the early neonatal period and is due to the transplacental transfer of TSH receptor-stimulating antibodies from a mother with either a current or a past history of Graves' disease. Given the high prevalence of Graves' disease in the population of women of childbearing age, it is surprising that clinically significant hyperthyroidism occurs so seldom in newborns: estimates of 1:25,000 births, or of 1–3% of the offspring of mothers with Graves' disease, are quoted in the literature. The measurement of TSH receptor-stimulating antibodies in the plasma of pregnant women with past or current Graves' disease has been advocated as a means to detect the fetuses more at risk, but is not universally practiced (48). In spite of its rarity, the serious nature of the condition justifies careful clinical screening. The mother should be warned of the potential risk; fetal growth and heart rate should be monitored; the newborn should be examined for the presence of a goiter, of exophthalmia, or of tachycardia without underlying heart disease; and weight gain during the first 3 months of life should be meticulously monitored.

The recommendations about antithyroid drug treatment in pregnancy are that it should be aimed at maintaining the patient slightly hyperthyroid so as to avoid fetal hypothyroidism from transplacental transfer of the drug. However, a woman may occasionally be treated with dosages of antithyroid drugs that are high enough to make the fetus hypothyroid. This may even lead to the development of a large goiter in the fetus and newborn, which may become apparent on prenatal ultrasound or

because of the development of respiratory distress from tracheal compression in the immediate neonatal period. This transient drug-induced hypothyroidism may be followed after a few days (i.e., after the drug is cleared from the newborn's circulation) by a period of a few weeks of hyperthyroidism from the maternally derived TSH-receptor-stimulating antibodies.

TSH-receptor stimulating antibodies may remain present long after definitive cure of hyperthyroidism has been achieved by the therapeutic administration of radioactive iodine to an adolescent or adult with Graves' disease. Therefore, it is important to enquire from the great many women receiving thyroxine replacement for hypothyroidism who become pregnant whether their hypothyroidism results from radioiodine treatment, even if this has occurred years earlier.

Once this transient type of hyperthyroidism is recognized in a newborn, it should be treated vigorously to prevent the development of heart failure. Hospital admission is usually required initially, and tachycardia may be severe enough to justify continuous electrocardiographic monitoring. Beta-blockers such as propranolol should be administered at a dosage of 2 mg/kg. day in four divided doses. Lugol's solution, at a dosage of 1 drop every 8 h, will block the release of the thyroid hormone stored in the gland and can be given for a few days. The short-acting propylthiouracyl is the preferred antithyroid drug for the following reasons: in a newborn who is fed four to six times a day, the need to give a drug four times a day does not pose problems of compliance, as it does in older children and adolescents; and compared to methimazole, it has the extra benefit of decreasing the conversion of T_4 into T_3 . The starting dosage of propylthiouracyl is 5–10 mg/kg. day, divided in four doses, and should be carefully tapered over the first few weeks of life so as to avoid the development of drug-induced hypothyroidism once the TSH-receptor stimulating antibodies are cleared. Pharmacological dosages of glucocorticoids have also been used, because they block the conversion of T_4 to T_3 . More heroic treatments such as exchange blood transfusions (49) or less traditional ones such as the administration of sodium ipodate (50) have been proposed. Although their use is logical on the basis of the pathophysiology of neonatal Graves' disease, they have not gained wide acceptance and, in our experience, have not been necessary.

With prompt recognition and early, vigorous treatment, the classically reported high death rate of neonates with Graves' disease should be a thing of the past. Likewise, the classically described intellectual impairment and development of craniosynostosis (51) has no longer been reported in recent series.

B. TSH Receptor-Activating Mutations

A familial form of nonautoimmune, persistent hyperthyroidism with dominant inheritance had been described 20

years ago in Nancy, France. The authors had hypothesized that this phenotype resulted from intrinsic activation of TSH receptor function (52). The cloning of the human TSH receptor has allowed to confirm this hypothesis (53). Inherited mutations leading to constitutive activation of the TSH receptor have now been described in several pedigrees from France and have begun to be recognized in other areas of the world as well. Some of these pedigrees had been considered as having familial Graves' disease. However, the neonates recognized as having hyperthyroidism from a mutation that constitutively activates the TSH-receptor typically experience an unrelenting course, in contrast to those with congenital hyperthyroidism from maternal antibodies. Thus, definitive treatment is required in these patients. Given the fact that there is no experience with radioiodine in the very young, thyroidectomy has been most commonly performed.

A handful of cases with *de novo* germline mutations activating the TSH receptor have also been described (54). Clinically, their phenotype has been uniformly severe and early thyroidectomy is therefore advised. From the molecular standpoint, it is interesting to note that these *de novo* mutations are "private", that is, they are different from the ones that have so far been found in the pedigrees with the dominantly inherited form (and are, in fact, only seen also as somatic mutations in so-called hot nodules): it has been suggested that the phenotypic consequences of these *de novo* mutations are so severe that they became extinguished because the affected individuals could not reach the age of reproduction before modern medicine led to recognition and definitive treatment of this condition (55).

Lastly, *somatic* mutations activating the TSH receptor have now been recognized as the most common mechanism underlying the development of "hot" nodules (56). This entity is predominantly a disease of adults and older children, but a single case of a somatic mutation leading to the formation of a hot nodule and to hyperthyroidism of fetal onset has been reported (57).

VI. ACQUIRED HYPO- AND HYPERTHYROIDISM IN INFANCY

The most common causes of acquired hypo- and hyperthyroidism are Hashimoto's thyroiditis and Graves' disease, respectively. These two entities are exceptional in infancy. Specifically, Hashimoto's thyroiditis has been reported in only a handful of patients below the age of 3 years (58); the youngest patient we have observed with Graves' disease was 3 years and 8 months. The principles of diagnostic evaluation are the same as in older children. Prompt treatment of hypothyroidism is important, since infancy is still a period during which the brain may undergo irreversible alterations from hypothyroidism. Treatment of hyperthyroidism is restricted to the use of anti-thyroid drugs (with thyroidectomy as a second line), since

there is no experience of radioiodine use in patients under the age of 6 years (59).

A category of infants who present often with mild hyperthyrotropinemia with or without detectable antibodies to thyroperoxidase are those with Down syndrome. These children are known to have a higher prevalence of autoimmune thyroid disease. However, even in the absence of antibodies, Down syndrome infants often present with mild hyperthyrotropinemia. A study of CH screening in *all* newborns with Down syndrome born in the Netherlands over a 2-year period showed that, compared to normal newborns, the distribution of T_4 was shifted downwards and that of TSH was shifted upwards (60). Furthermore, the elevated TSH is biologically active, suggesting that there is a mild primary thyroid defect in all children with Down syndrome (61). However, the clinical relevance of these biochemical findings is difficult to assess: the abnormalities are mild and the Québec TSH screening program has not identified a single case of permanent primary CH associated with Down syndrome (15). Furthermore, signs of hypothyroidism are particularly difficult to document objectively in these children. While it is reasonable to treat with thyroxine, on the basis of the concept that a high TSH level implies that pituitary (and, by inference, brain) receptors are perceiving an insufficient amount of intracellular T_3 , there is no evidence of clinical benefit (62).

VII. STRUCTURAL THYROID PROBLEMS

A. Thyroglossal Duct Cysts

The migration of the median thyroid anlage described above occurs along a path that is paved by epithelial cells. This path, which is called the thyroglossal duct, usually closes after migration is complete. However, when it remains patent, fluid may collect at its more caudal end and constitute a thyroglossal duct cyst. These cysts typically present as a midline, soft, regular mass in the lower neck of an asymptomatic infant (or older child). However, they may also present with acute swelling, pain, and redness secondary to an acute infection.

Elective surgical removal of thyroglossal duct cysts is therefore advised, because surgery after an acute infection has occurred is more difficult (63). Before elective surgery, we still recommended performing a ^{99m}Tc scan (rather than an echogram, for the technical reasons discussed above), to ascertain that the midline neck mass does not represent ectopic thyroid tissue, which usually will be the only thyroid tissue present in the patient and removal of which will lead to severe and irreversible hypothyroidism.

B. Suppurative Thyroiditis

Because of its rich content in iodine, a potent disinfectant, the thyroid gland is seldom the site of bacterial infections.

In infancy (and even later), bacterial infection of the thyroid in a host with normal immune function is often associated with a fistula arising from the pyriform sinus. Although thyroid abscesses can present at any age, the fact that they are causally linked to a congenital malformation (which is usually present on the left side) explains their relatively high frequency in young children. Thus, in an infant presenting with a rapidly growing mass in the left thyroid lobe, thyroid abscess is the first diagnosis. The mass is very tender, but redness of the overlying skin may be absent. Increased leukocytosis and sedimentation rate are further clues to the diagnosis. Fine needle aspiration has been used and allows identification of the germs causing the abscess (which are most often from the flora of the oropharynx). The aspiration, coupled with antibiotic treatment, may also contribute to curing the abscess (64). However, a careful search for a fistula from the pyriform sinus should be carried out. This is best achieved with the use of barium swallow studies and/or laryngoscopy. If such a fistula is found, definitive surgical treatment is required to prevent recurrent abscess formation.

C. Subacute Thyroiditis

In contrast to bacterial thyroiditis, subacute thyroiditis (also known as de Quervain's thyroiditis) occurs very rarely in children. However, cases have been reported in children as young as 2 years (65).

D. Thyroid Cancer

This entity is described in great detail in another section. In infants, it is important to remember that medullary thyroid cancer can occur very early in life in the familial syndrome of multiple endocrine neoplasia type IIB. In such a family, we have observed a boy in whom we performed thyroidectomy at 1.5 years of age because of high plasma calcitonin concentrations, and in whom pathological examination revealed definite medullary thyroid cancer (66).

VIII. CONCLUSION

Thyroid disorders during infancy are as varied, if not more so, than any other period of the lifespan. Their importance is that, if not promptly recognized and treated, they can lead to irreversible short- or long term sequelae, as exemplified by congenital hyper- and hypothyroidism, respectively. Hence all clinicians must always bear these diagnoses in mind whenever suggestive clinical clues are present.

I. HISTORICAL BACKGROUND

For more than 2000 years, endemic goiter and cretinism have been prevalent in iodine-deficient regions of the world, as evidenced by Andean sculptures of goitrous dwarfs dating from the 4th century BCE (1) and by descriptions recorded in Europe during the 1st century BCE (2, 3). Nonendemic cretinism, however, was not reported until 1850 when Curling described two children who had no detectable thyroid tissue at autopsy (4). In 1871, Fagge used the term “sporadic cretinism” to describe four children with cretinism, one being a 16-year-old girl with classic symptoms and signs of hypothyroidism, absence of thyromegaly, and “mental faculties unimpaired” (5). In 1878, W.M. Ord associated the term “myxoedema” with his descriptions of the supraclavicular “fatty tumours” found in hypothyroid middle-aged women (6). The Committee of the Clinical Society of London was nominated in 1883 to study hypothyroidism and presented its report in 1888 describing lymphocytic infiltration and atrophy of the thyroid gland (7) (Fig. 1). This first description of chronic lymphocytic thyroiditis preceded Hashimoto’s classic description of asymptomatic goiter (8) by 24 years.

During the last decade of the 19th century several reports of successful treatment of hypothyroidism with thyroid gland extracts were reported. These therapeutic achievements were summarized in 1898 so elegantly by Sir William Osler:

“That we can to-day rescue children otherwise doomed to helpless idiocy—that we can restore to life the hopeless victims of myxoedema—is a triumph of experimental medicine for which we are indebted very largely to Victor Horsley and to his pupil Murray. Transplantation of the gland was first

tried; then Murray used an extract subcutaneously. Hector Mackenzie in London and Howitz in Copenhagen introduced the method of feeding. We now know that the gland, taken either fresh, or as the watery or glycerin extract, or dried and powdered, is equally efficacious in a majority of all the cases of myxoedema in infants or adults . . . The results, as a rule, are most astounding—Unparalleled by anything in the whole range of curative measures. Within 6 weeks a poor, feeble-minded, toad-like caricature of humanity may be restored to mental and bodily health” (9).

Photographs depicting hypothyroid children before and after the initiation of thyroid extract therapy began to appear in textbooks soon thereafter (10) (Fig. 2).

During the 20th century our understanding of the biochemical and physiological functions of the thyroid gland expanded considerably. The discovery of the structures of the iodothyronines, the need for adequate dietary intake of iodine, and the identity of the types of familial goiter and their causes have improved our ability to diagnose and treat hypothyroidism more accurately. The pathogenesis of autoimmunity, which is the most common cause of hypothyroidism in nonendemic goiter regions of the world, has been elucidated with the pioneering serological studies of Roitt and Doniach (11) and the experimental studies of Rose and Witebsky (12). More recently, competitive binding assays, thyroid epithelial cell culture systems, and advances in molecular biology have provided improved methods to study thyroid hormone secretion and action. They have also expanded our knowledge into the causes and pathogenesis of autoimmunity, inborn errors of thyroid hormone synthesis, regulation and metabolism, and other causes of hypothyroidism.

Figure 1 Lymphocytic infiltration of the thyroid gland of an adult with myxedema reported in 1888, or 24 years before the description by Hashimoto. (From Refs. 7, 8).

II. CLASSIFICATION AND CAUSES

A. Classification

Normal thyroid hormone secretion depends on an intact hypothalamic–pituitary–thyroid axis. In normals, thyrotropin-releasing hormone (TRH) modulates the release of thyrotropin (TSH) from the pituitary gland. TSH then binds to plasma membrane receptors on the thyrocyte and stimulates a cascade of biochemical processes that result in the production and release of primarily L-thyroxine (T_4) and, in smaller molar concentrations, 3, 3', 5-L-triiodo-L-thyronine (T_3). An abnormality at any point within this axis can lead to decreased thyroid hormone secretion and result in hypothyroidism. By convention, hypothyroidism is classified according to the anatomical location within this axis where the abnormality occurs (13). For example, hypothyroidism resulting from thyroid gland failure, such as occurs with autoimmune destruction in Hashimoto's thyroiditis, is referred to as primary hypothyroidism. Likewise, secondary and tertiary hypothyroidism refer to hy-

pothyroidism resulting from disorders at the level of the pituitary and hypothalamus, respectively. These diseases also are referred to as pituitary and hypothalamic hypothyroidism, and, in patients at all ages, they are much less common than primary hypothyroidism.

Selective peripheral resistance to thyroid hormone is a very rare cause of hypothyroidism (14). In this syndrome, the hypothalamic–pituitary–thyroid axis is normal, but nuclear thyroid hormone receptors in peripheral tissues do not respond adequately to T_3 . Affected patients have symptoms and signs of hypothyroidism from an early age. Basal serum TSH, thyroid hormone levels, and TSH responses to TRH are normal. Why the resistance to thyroid hormone is present only in the peripheral tissues, and not also in the pituitary, remains to be fully elucidated.

B. Causes

Hypothyroidism during childhood and adolescence can result from a variety of congenital or acquired defects (Table

Figure 2 An early example of the effects of thyroid hormone therapy in a 7-year-old girl with the onset of hypothyroidism around age 3 years.

1). In economically advantaged countries, the majority of children with congenital primary hypothyroidism will be detected through neonatal thyroid screening programs. Rarely, however, patients with hypothyroidism caused by ectopic or hypoplastic thyroid glands, or with inborn errors of thyroid hormone synthesis (Fig. 3), may not be recognized until later in infancy or childhood. In general, ectopic and hypoplastic glands occur sporadically, whereas the inborn errors of hormone synthesis (thyroid dyshormonogenesis) are inherited as autosomal recessive disorders (15). Specific mutations have been identified in the genes that regulate the synthesis of proteins (usually enzymes) involved in the specific steps of hormonogenesis (16).

Autoimmune chronic lymphocytic thyroiditis is the most common cause of acquired primary hypothyroidism in nonendemic goiter regions of the world. The disease occurs most often during childhood or adolescence and more frequently in girls than boys. However, it may pre-

sent during infancy (as early as 6–9 months of age) with subtle symptoms and signs of hypothyroidism of short duration (17). The disease also occurs with increased frequency in patients with other autoimmune-mediated diseases, especially insulin-dependent diabetes mellitus and the polyglandular autoimmune syndromes and in Down, Turner, and Klinefelter syndromes. In a recent study, serum thyroid antibodies were found in 52% of girls with Turner syndrome compared to 17% in age-matched normal girls (18). Thyroid autoimmune disease is most commonly associated with an X-isochromosome karyotype, but is also common with a 45,X karyotype (19). This association suggests that the loss of one or more genes, known as haploinsufficiency, on the short arm of the X or Y chromosome that normally are not inactivated play an important role in the pathogenesis of autoimmune thyroid disease.

Other causes of primary hypothyroidism include irradiation of the thyroid, surgical removal of thyroid tissue,

Table 1 Causes of Juvenile Primary Hypothyroidism

Congenital hypothyroidism: mild, late-onset
Ectopic thyroid dysgenesis
Familial thyroid dysmorphogenesis
Peripheral resistance to thyroid hormone action
Acquired primary hypothyroidism
Chronic autoimmune thyroiditis
Lymphocytic thyroiditis of childhood and adolescence with thyromegaly
Hashimoto's thyroiditis with thyromegaly (struma lymphomatosa)
Chronic fibrous variant
Drug-induced hypothyroidism
Endemic goiter
Iodine deficiency
Environmental goitrogens
Irradiation of the thyroid
Therapeutic radioiodine
External irradiation of nonthyroid tumors
Surgical excision
Nephropathic cystinosis
Subacute thyroiditis: transient phase

goitrogen ingestion, iodine deficiency, and nephropathic cystinosis (Table 1). Transient primary hypothyroidism may occur during the recovery phase from subacute and toxic thyroiditis.

Secondary and tertiary hypothyroidism result from deficiencies in TSH and TRH, respectively. Most children with secondary or tertiary (also known as central) hypothyroidism will have other pituitary or hypothalamic hormone deficiencies, but an isolated deficiency of either TSH or TRH secretion can occur as familial or sporadic diseases (20), and mutations have been found in the genes that control the synthesis of the TSH beta chain and the TSH and TRH receptors (21). Malformation syndromes, such as septo-optic dysplasia, or midline facial anomalies, such as cleft lip or palate, can be associated with central hypothyroidism. Trauma, neoplasms, infectious or inflammatory processes, irradiation, and surgery can damage the hypothalamus or pituitary and cause TRH, TSH, and other hormone deficiencies. These diseases are discussed in further detail elsewhere. In very low birth weight (VLBW) preterm infants less than 27 weeks of gestation, and in critically ill infants and children, hypothalamic hypothyroidism may occur as a progression of the nonthyroidal illness state and inhibition by certain therapeutic modalities.

III. PATHOPHYSIOLOGY

In primary hypothyroidism, abnormalities of the thyroid gland or of thyroid gland function impair thyroid hormone production and/or release. Early in the course of thyroid

gland failure, a slight decrease in the serum free T_4 (FT_4) concentration occurs, but in most cases the level usually remains within the normal range for age. A decrease in FT_4 leads to minor reductions in pituitary FT_4 concentrations and the intrapituitary conversion of T_4 to T_3 (22). With a decrease in the pituitary free T_3 (FT_3) concentration, TSH production and release increase. The subsequent increase in serum TSH that causes further stimulation of the TSH receptor results in an increase in thyroid hormone synthesis and release in an attempt to maintain normal serum FT_4 and FT_3 levels. However, as thyroid gland failure progresses, increased TSH secretion no longer is able to maintain normal thyroid hormone synthesis, and serum FT_4 and FT_3 levels decrease to abnormal levels. Since serum TSH rises before serum thyroid hormone levels decrease below the normal range, the measurement of serum TSH is the most sensitive test for the early detection of primary hypothyroidism.

Pituitary TSH synthesis and secretion are directly controlled by serum levels of free or unbound T_4 (FT_4) and FT_3 . This control occurs by negative feedback; that is, rising serum levels of FT_4 and FT_3 inhibit, whereas decreasing FT_4 and FT_3 levels enhance, TSH synthesis and secretion. Through TRH and somatostatin secretion, the hypothalamus modulates this negative feedback system, and the so-called set point of the molar concentrations of FT_4/FT_3 for TSH secretion is fine-tuned (23). TRH secretion enhances and somatostatin inhibits TSH release. Thus, patients with TRH deficiency have a decreased release of TSH causing a decrease in thyroid hormone production. However, TRH deficiency is associated with increased pituitary stores of TSH because low intrapituitary FT_4 and FT_3 concentrations continue to stimulate TSH synthesis. Therefore, TSH responses to TRH in experimental animals and patients often are exaggerated and the TSH rise is usually delayed, a pattern that is diagnostic of hypothalamic TRH deficiency (see below) (24).

IV. CLINICAL PRESENTATION

Children with hypothyroidism may have a variety of clinical presentations (Table 2) and often a family history of thyroid or pituitary disease. Some children present with an asymptomatic goiter, whereas others may present with mild tenderness or a sensation of fullness in the anterior neck. Other presenting symptoms are often nonspecific and include weakness, lethargy, decreased appetite, cold intolerance, constipation, and dry skin. Although children with hypothyroidism may have mild obesity, hypothyroidism generally does not cause morbid obesity. The course of hypothyroidism is often so insidious that neither the child nor his or her parents are aware of the physical changes that have occurred. These children often experience marked growth retardation before the disease is recognized, and this expected effect on linear growth emphasizes the importance of serial growth measurements in

Figure 3 Schematic representation of thyroid hormone synthesis and the sites of the most frequent abnormalities seen in patients with familial dysmaturagenesis (15, 16). A. Impaired thyroid response to TSH. B. Iodide transport defect. C. Iodide oxidation and tyrosyl iodination defects, including Pendred syndrome. D. Iodotyrosine coupling defect. E. Thyroglobulin synthetic defects. F. Iodotyrosine deiodinase defect. Each defect is associated with thyromegaly, except A. An increase in ^{123}I -iodide uptake occurs in each defect, except A and B. A rapid discharge of ^{123}I -iodide from the thyroid after oral perchlorate occurs in the iodide oxidation and tyrosyl iodination defects.

all children. Whereas children who develop hypothyroidism before age 2 years may suffer some irreversible central nervous system damage and developmental delay, the onset of hypothyroidism after age 2 years does not cause mental retardation.

Infants with acquired autoimmune-mediated infantile hypothyroidism present between 6 and 24 months of age with symptoms and signs similar to those in infants with congenital hypothyroidism (17). Deceleration of linear growth is an important sign that is helpful in the early recognition of this disease.

Most adolescents with untreated primary hypothyroidism will have delayed pubertal development, although

an occasional patient will present with precocious puberty. Girls may have galactorrhea that usually is associated with an elevated serum prolactin level; boys may have macroorchidism. The cause of precocious puberty in primary hypothyroidism originally was postulated to occur as a result of increased LH and FSH secretion through an overlap in the pituitary regulation of TSH secretion (25). Other studies suggest that hyperprolactinemia, which presumably results from chronic TRH stimulation of the pituitary, may play a role in this syndrome through an inhibition of gonadal stimulation by luteinizing hormone (LH), but not follicle-stimulating hormone (FSH), thereby resulting in sustained stimulation of the gonad by FSH (26). More

Table 2 Clinical Features Unique to Juvenile Hypothyroidism

Growth retardation with delayed skeletal maturation
Delayed dental development and tooth eruption
Onset of puberty usually delayed; rarely precocious
Galactorrhea: elevated prolactin
Increased skin pigmentation
Sellar enlargement
Pseudotumor cerebri
Myopathy and muscular hypertrophy

recently, studies involving the use of mammalian cells transfected with the cDNA of either the LH/chorionic gonadotropin (CG) receptor or the FSH receptor have shown that TSH can bind to and activate both the LH and FSH receptors (27, 28). Based on these studies, elevated TSH levels associated with severe primary hypothyroidism may result in stimulation of both LH and FSH receptors and contribute to the development of precocious puberty (27, 28). The adolescent girl who acquires hypothyroidism after menarche often experiences excessive and irregular menstrual bleeding.

The child with severe primary hypothyroidism may develop enlargement of the sella turcica. When this is identified by skull x-rays, computed tomographic (CT) scan, or magnetic resonance image (MRI) of the head, the child may be referred to a neurosurgeon or an endocrinologist for evaluation of suspected pituitary tumor. This pituitary mass represents hypertrophy and hyperplasia of thyrotrophs in response to the lack of negative feedback by thyroid hormones (29). Therefore, these patients with primary hypothyroidism usually have markedly elevated serum TSH levels and low serum levels of thyroid hormones; patients with hypothalamic and pituitary hypothyroidism usually have normal or very mildly elevated serum TSH levels (30) and low serum FT₄ values. Pituitary enlargement usually resolves with adequate thyroid hormone replacement therapy. Primary hypothyroidism with enlargement of the sella and pituitary gland was reported in a boy in whom an empty sella and hypopituitarism occurred after thyroid hormone replacement (31). Visual field defects also may be detected in these patients (32).

Children with hypothalamic and pituitary hypothyroidism can present with the same nonspecific symptoms found in primary hypothyroidism, as well as with symptoms suggestive of other hormone deficiencies. Patients with organic defects also may present with symptoms of increased intracranial pressure, such as headaches, morning vomiting, and decreased visual acuity.

Features of hypothyroidism on physical examination include bradycardia, decreased pulse pressure, short stature with an increased upper-to-lower body ratio, delayed

dentition, mild obesity, facial puffiness and dull facial expression, coarse hair, cool and dry carotenemic skin, and delayed relaxation of deep tendon reflexes. The majority of patients with primary hypothyroidism will have thyromegaly, but some patients with autoimmune thyroiditis and ectopic or hypoplastic glands will not have detectable thyroid enlargement. Thyromegaly is not associated with hypothalamic and pituitary hypothyroidism. These children may have an abnormal optic fundus examination (i.e., papilledema), and visual field defects may be found.

V. DIAGNOSTIC EVALUATION

Patients with nongoitrous, acquired primary hypothyroidism require very few diagnostic tests prior to therapy. Serum determinations of TSH, FT₄ and thyroid antibodies, thyroperoxidase antibodies (TPOAb), and thyroglobulin antibodies (TGAAb), should be obtained. The presence of thyroid antibodies permits a presumptive diagnosis of autoimmune thyroiditis. Some patients with autoimmune thyroiditis have negative thyroid antibodies on initial evaluation, but, on repeat determinations 3–6 months later, have elevated thyroid antibody titers (11, 33). Thyroid antibodies may be positive in other forms of thyroiditis (34), although the levels tend to be lower and not as persistently elevated as in patients with autoimmune thyroiditis. Similar thyroid function tests should be performed in patients with goitrous hypothyroidism since the most common cause is autoimmune thyroiditis. However, if thyroid antibodies are negative on repeated determinations in a child with persistent thyromegaly, these additional tests may be useful to determine the cause of hypothyroidism:

1. Radioiodide uptake test with perchlorate discharge at 2–4 h after dose, salivary-to-plasma ratio of radioiodide 2 h after the dose, and serum thyroglobulin (to identify inborn errors of thyroid hormone synthesis)
2. Urinary iodine excretion (to identify iodine deficiency)
3. Fine-needle aspiration (FNA) biopsy of the thyroid nodule(s) or tissue, if progressive asymptomatic enlargement of the thyroid occurs despite treatment with full replacement or suppressive dosages of L-thyroxine (to identify rare malignant infiltrative diseases).

In addition to serum thyroid function tests, a TRH test often is indicated for patients with suspected hypothalamic or pituitary hypothyroidism. In children with hypothalamic hypothyroidism the peak serum TSH response to TRH often is delayed beyond 30 min, and the TSH response may be prolonged with serum TSH values that remain elevated for 2–3 h. The TSH response to TRH is

low or absent in patients with pituitary thyrotroph deficiency (24, 35).

The nonthyroidal illness (NTI) syndrome refers to the various alterations in thyroid function often seen in preterm and VLBW infants, as well as in older children in association with a variety of conditions such as acute or chronic illnesses, surgery, trauma, malnutrition, and starvation. The magnitude of change in thyroid function tends to correlate directly with the severity of systemic illness or tissue injury. Although there are exceptions, the typical pattern of serum thyroid function tests that allows the diagnosis of this syndrome includes low total and free T_3 , low to normal T_4 , normal to high 3,3',5'-L-triiodothyronine [known as reverse T_3 (rT_3)], increased T_3 resin uptake, and normal TSH (36). The serum FT_4 is usually normal and often in the high-normal range. Low serum FT_4 values have been reported, especially in the most severely ill patients (37). The direct dialysis method to measure FT_4 in serum is the most accurate determination and rarely is associated with false-positive or false-negative results (38). However, heparin use in infants and children, such as occurs with heparin-supplemented total parenteral nutrition, can cause spurious elevations in FT_4 levels measured by direct dialysis methods (39).

Various factors contribute to the changes in thyroid hormone economy that occur in patients with this syndrome. In the normal state, peripheral tissue conversion of T_4 to T_3 is the major source of circulating T_3 , and conversion occurs through monodeiodination via the 5'-deiodinase pathway. This pathway also converts rT_3 to T_2 . In the NTI syndrome, 5'-deiodinase activity is decreased in peripheral tissues, causing a decreased production of T_3 and decreased clearance of rT_3 . Therefore, decreased 5'-deiodinase activity accounts for the low serum T_3 and elevated serum rT_3 levels in these patients. The increased T_3 resin uptake indicates a reduction in available serum thyroid hormone binding sites. The concentrations of thyroxin-binding globulin (TBG) and transthyretin (TTR), and the binding capacity of TBG, are decreased. These changes are largely responsible for the reduction in available binding sites. Nondialyzable substances, shown to be specific lipoproteins, inhibit thyroid hormone binding to TBG and TTR, and are detectable in serum during severe illness (40). Decreased T_4 binding to serum proteins leads to an increased percentage of FT_4 in serum and accounts for normal FT_4 levels even when TT_4 levels are low. The factors responsible for low TT_4 levels are less well understood. Although decreased serum binding of T_4 and inhibitors of binding to serum proteins may contribute, accelerated disposal of T_4 and decreased TSH secretion are factors that contribute to the low T_4 levels. Accelerated disposal of T_4 occurs through the 5-deiodinase pathway, which converts T_4 to rT_3 , and through nondeiodinative pathways (36). Inhibition of TSH release occurs when patients become severely ill. Abnormal hypothalamic-pituitary function during severe illness results in hypo-

thalamic hypothyroidism that is evident when FT_4 levels become low (41).

Thyroid function tests are often obtained in severely ill infants and children who are evaluated for such clinical findings as hypothermia, weakness, lethargy, and growth failure. Not only can the underlying illness or injury produce alterations in thyroid function, but the severely ill child may also be receiving medications such as dopamine, glucocorticoids, and phenytoin that can alter thyroid hormone economy (36). Cytokines also may interfere with TSH synthesis and release.

Whereas the ill child with low serum T_3 but normal serum TT_4 and FT_4 levels usually does not pose a diagnostic problem, the question of hypothyroidism frequently arises in the ill child with low serum levels of T_3 and T_4 . In this situation a normal serum FT_4 level is used as evidence against central hypothyroidism, especially when measured by direct dialysis methods (38). In the child with a low serum T_4 , an elevated rT_3 , and normal TSH, the diagnosis of the NTI syndrome is very likely, and is differentiated from hypothyroidism by normal FT_4 and TSH levels. An elevated serum TSH level in a severely ill patient usually indicates primary hypothyroidism, especially when FT_4 levels by direct dialysis are low (36, 37). However, modest elevations of TSH may occur during recovery from illness (36), and serial TSH measurements may be required to establish the correct diagnosis (37, 41).

Children with hypothalamic or pituitary hypothyroidism generally have normal TSH and low serum FT_4 and rT_3 levels. These children may develop severe systemic illness, and it may be difficult to differentiate them from severely ill patients with the NTI syndrome. The history and physical examination may help to differentiate between the two disorders, but a more extensive evaluation including a MRI study of the hypothalamic-pituitary region and pituitary function testing may be necessary. The TSH response to TRH in the NTI syndrome can be normal, delayed, or blunted, and may not be useful in differentiating the NTI syndrome from hypothalamic or pituitary hypothyroidism (36, 37). Determination of rT_3 is not always helpful because the level may be normal in sick hypothyroid children (36, 37).

Thyroid hormone replacement is not recommended in the treatment of the NTI syndrome unless the FT_4 , preferably measured by direct dialysis, is low, and especially when the serum TSH is elevated. Management should be directed towards supportive or specific treatment of the underlying illness. To date, studies that have evaluated the effects of T_4 or T_3 replacement in patients with this syndrome have not demonstrated increased survival with replacement therapy (42-44). However, controversy still exists as to whether the NTI syndrome represents an adaptive and beneficial response to severe illness or whether, in its most advanced stage, it represents a functional type of secondary hypothyroidism as a result of a prolonged,

severe illness that responds to thyroxine replacement therapy (36, 44).

VI. CLINICAL COURSE AND MANAGEMENT

A. Primary Hypothyroidism

L-thyroxine is the safest and most efficacious thyroid medication for treatment of hypothyroidism in children and adolescents (35, 37, 45, 46). Other thyroid preparations, such as thyroid extract, desiccated thyroid, and T₄-T₃ combination drugs, offer no advantage over L-thyroxine and may have some disadvantages when therapy is monitored by thyroid function tests. Recent claims that T₃ therapy is clinically efficacious in the treatment of an entity described on a web site as Wilson's syndrome, caused by a reduced T₄ to T₃ conversion disorder, cannot be substantiated by studies reported in the literature. In these patients, any perceived benefits of T₃ replacement likely result from mild hyperthyroidism induced by the T₃ therapy. Approximately 20% of patients who are prescribed L-thyroxine after total thyroidectomy for thyroid cancer report symptoms of hypothyroidism despite normal results of thyroid function tests. These symptoms improve with higher dosages of L-thyroxine and mildly elevated T₄ values and suppressed TSH; it is yet to be determined if instances of reduced T₄ to T₃ conversion occur in these patients. Generic preparations of L-thyroxine should be prescribed cautiously as some may have variable potencies and, therefore, may provide inconsistent replacement therapy (46). The importance of prescribing reliable L-

thyroxine preparations for treatment of hypothyroidism is essential for restoration of the euthyroid state. L-thyroxine is prescribed orally as a single daily dose and should be taken at least 30 min before food intake to maximize absorption. The estimated dosage for children and adolescents is based on age and body weight (Table 3).

To minimize central nervous system damage, children who are less than 2 years of age require prompt treatment with L-thyroxine in full replacement dosages. Rapid achievement of euthyroidism is not as essential in the older child and adolescent; in fact, children with chronic or severe hypothyroidism often experience undesirable side effects, such as irritability, restlessness, decreased attention span, and restless sleep or insomnia when L-thyroxine is prescribed in full replacement dosages at diagnosis. For these children it is preferable to restore euthyroidism gradually by initiating treatment with 25 μg daily for 2 weeks, and thereafter increasing the dose by 25 μg daily every 2–4 weeks until the desired dosage is achieved. This regimen is not necessary for children with mild hypothyroidism, or those with clinical symptoms of short duration. On initiation of therapy in older children and adolescents, it is important, however, to avoid excessive replacement and prudent to begin with the lower dosage per kilogram body weight for age.

In patients with compensated, or subclinical, hypothyroidism, defined as an elevated serum TSH level (47), but normal concentrations of TT₄ and FT₄, it is worthwhile to confirm that the process is persistent by repeating the serum TSH evaluation before initiating long-term therapy. This is especially important in patients with negative thyroid antibodies and no apparent cause for the elevated

Table 3 Guidelines for Maintenance Sodium L-Thyroxine Therapy

Age	Daily dosage ($\mu\text{g}/\text{kg}$)	Daily dosage range ($\mu\text{g}/\text{day}$)	Weight range (kg)
<6 months ^a	6–10	25–50	3–9
6–12 months	5–8	37.5–75	6–12
1–5 years	4–6	50–100	9–23
5–12 years	3–5	50–125	15–55
12–18 years	2–3	75–175	30–90
Adult	1–2	100–200	50–100

The dosage of L-thyroxine must be determined for each patient, since the rate of absorption and metabolism will vary among patients of the same body weight. These dosages approximate 100 $\mu\text{g}/\text{m}^2/\text{day}$. In general, patients with hypothalamic hypothyroidism seem to require a lower dosage per kg than patients with primary hypothyroidism.

L-thyroxine usually is usually manufactured in 25, 50, 75, 88, 100, 112, 125, 137, 150, 175, and 200 μg tablets. Tablets should be given at least 30–60 min before a meal.

^aThe dosage of L-thyroxine in the initial treatment of newborn infants with congenital hypothyroidism is 10–15 $\mu\text{g}/\text{kg}$ once daily for the initial 1–2 weeks. The appropriate maintenance dosage is determined by the results of serial measurements of serum TSH and FT₄, and, on rare occasions when the results of the two tests do not agree, serum T₃ should be measured.

TSH value. Some children have persistent hyperthyrotropinemia of unknown cause without symptoms or signs of hypothyroidism. Thyroxine therapy is indicated in patients with compensated hypothyroidism in whom there is a known cause for hypothyroidism, or serial TSH measurements steadily increase, especially if FT₄ concentrations steadily decline (48).

Subclinical hypothyroidism is commonly observed in patients with Down syndrome (49). Recent studies have shown that elevated TSH levels in some patients with Down syndrome are associated with zinc and selenium deficiencies (50, 51); elevated TSH levels in Down syndrome patients with zinc deficiency can normalize following adequate zinc replacement (50). However, patients with Down syndrome have an increased risk of autoimmune thyroiditis compared to the general population. Therefore, the measurement of thyroid antibodies is important in Down syndrome patients with subclinical hypothyroidism. A recent study revealed that Down syndrome patients with subclinical hypothyroidism and positive thyroid antibody levels are at increased risk of clinically overt thyroid disease compared to Down syndrome patients with subclinical hypothyroidism but negative thyroid antibody levels (49).

Serum thyroid function tests should be monitored at regular intervals to determine adequacy of therapy, anytime symptoms of hypothyroidism or hyperthyroidism occur, and 6–8 weeks after a dosage change. In young children, thyroid function should be monitored every 2–4 months, whereas in older children and adolescents thyroid function can be monitored every 6–12 months to determine adequacy of therapy. Serum TSH is the most useful test to monitor primary hypothyroidism, and levels should be maintained between 0.1 and 5 mU/l using sensitive TSH methods that can accurately differentiate normal and suppressed levels; the TSH assay should have a sensitivity of 0.05 mU/l or lower. Serum FT₄ levels are usually adequate to determine whether the patient is receiving excessive L-thyroxine therapy; however, for some children, particularly those with congenital hypothyroidism, measurement of serum T₃ and, rarely, rT₃ levels may help to determine if the L-thyroxine dose is excessive.

Generally, the child with primary nongoitrous hypothyroidism who has had elevated serum TSH levels (>20 mU/l) on at least two separate occasions and requires an increase in his/her L-thyroxine replacement does not have transient hypothyroidism that will recover spontaneously. Therefore, this child should be treated with L-thyroxine indefinitely. On the other hand, reports indicate that approximately 20% of patients with autoimmune goitrous hypothyroidism may revert to the euthyroid state (52, 53). These children may be given a 2–3 month trial off L-thyroxine treatment if the thyroid size and consistency become normal during treatment. The serum TSH level should be determined at the end of this trial, or sooner if symptoms of hypothyroidism develop. If the serum TSH

level is normal, the child should be monitored every 3 months for a year and then annually thereafter if thyroid antibody titers remain abnormal. If the TSH level becomes abnormal, L-thyroxine therapy should be resumed indefinitely.

Serum TSH should be monitored in children receiving lithium carbonate or similar drugs that block thyroid function (54). If these children also have autoimmune thyroiditis, they very likely will develop primary hypothyroidism during lithium treatment (55). Patients should not take iron-containing (56) or calcium-containing (57) medications at the same time as thyroxine tablets. These and other medications, like certain soy-based infant formulas and high-fiber diets, very effectively block the absorption of thyroxine from the intestine (58). Other drugs, such as phenobarbital, phenytoin, carbamazepine, and rifampin, induce accelerated hepatic metabolism of L-thyroxine and can increase dosage requirements in hypothyroid patients (59).

Some adolescent girls and young women with hypothyroidism receiving estrogen replacement therapy have an increase requirement for thyroxine and need to increase their dosages of thyroxine if serum TSH becomes elevated (60). During pregnancy, women with hypothyroidism require an average of 45% more thyroxine to maintain serum TSH values in the normal range (60) as a result of an increase in thyroxine-binding globulin levels (61). Estrogen stimulates glycosylation of TBG and this reduces the metabolic clearance of thyroxine (61). Maintenance of euthyroidism in the mother during early pregnancy is necessary to protect the fetus from the adverse effects of maternal hypothyroxinemia on fetal thyroxine levels that are necessary for normal central nervous system maturation (61, 62).

Prepubertal children with severe hypothyroidism and short stature usually experience a period of catch-up growth after initiation of L-thyroxine replacement therapy, but, despite adequate treatment, some have incomplete catch-up and never reach their full genetic growth potential (63). The mechanisms responsible for this incomplete catch-up growth have not been clearly defined, but delay in treatment of hypothyroidism may be a critical factor (63).

B. Disorders of Thyrotropin Secretion

Hypothyroidism, either hypothalamic or pituitary, may be present at the time of an initial diagnosis of hypopituitarism, or hypothyroidism may occur at a later time during growth hormone replacement therapy. To avoid any confusion in the differential diagnosis between hypothalamic or pituitary hypothyroidism and the NTI syndrome that occurs during severe illnesses or severe caloric/carbohydrate deprivation states, serum FT₄ and, if possible, rT₃ levels should be measured. The FT₄ and rT₃ levels are low in hypothyroidism whereas the FT₄ is usually normal (37) and the rT₃ is normal or elevated (36) in the NTI syn-

drome. These measurements may be extremely helpful in patients with CNS tumors who are in a catabolic state following surgery. In general, patients with the NTI syndrome do not require L-thyroxine replacement, whereas patients with hypothyroidism do. As previously mentioned, results of TRH tests may differentiate between hypothalamic and pituitary hypothyroidism (35).

Children with hypothalamic or pituitary hypothyroidism usually require lower dosages of L-thyroxine than children with congenital and acquired primary hypothyroidism. Serum levels of FT₄ should be monitored during L-thyroxine therapy. It is unnecessary to monitor TSH levels, however, since patients with hypothalamic or pituitary hypothyroidism will have normal or low TSH values on thyroxine therapy. Once the dosage has been established and the patient is clinically and biochemically euthyroid, further serum thyroid function tests only need to be obtained annually to ensure compliance and reliability of the medication.

Although children with hypothalamic or pituitary hypothyroidism and short stature may exhibit a period of catch-up growth after initiation of L-thyroxine therapy, their course is often complicated by deficiencies of growth hormone, gonadotropins, and sex hormones, and many fail to reach their full genetic height potential. Further discussion of the treatment of hypopituitarism may be found in Chapter 3. Because L-thyroxine therapy increases the metabolic clearance rate of cortisol, patients with deficiencies of hypothalamic-pituitary-adrenal and thyroid function should begin cortisol replacement with initiation of L-thyroxine replacement to avoid the precipitation of hypocortisolism and an adrenal crisis.

University of Pittsburgh and Children's Hospital of Pittsburgh, Pittsburgh, Pennsylvania, U.S.A.

I. PATHOGENESIS AND ETIOLOGY

Thyrotoxicosis is an uncommon disorder of childhood characterized by accelerated metabolism of body tissues resulting from excessive levels of unbound circulating thyroid hormones. Graves' disease accounts for at least 95% of cases in children (1). Other causes are rare and are listed in Table 1.

Mechanisms that can produce thyrotoxicosis include thyroid follicular cell hyperfunction with increased synthesis and secretion of T_4 and T_3 , thyroid follicular cell destruction with release of preformed T_4 and T_3 , and ingestion or administration of thyroid hormone or iodide preparations.

Hyperfunction of thyroid follicular cells can either be autonomous or mediated through stimulation of thyrotropin receptors by substances such as thyrotropin (TSH) or thyrotropin receptor antibodies (TSHrAb). Autonomous hyperfunction of thyroid follicular cells is rarely seen during childhood and is represented by toxic adenoma, familial nonautoimmune hyperthyroidism, hyperfunctioning thyroid carcinoma, and the hyperthyroidism of the McCune-Albright syndrome.

Stimulation of thyrotropin receptors by TSHrAb produces the diffuse toxic goiter of Graves' disease and accounts for the majority of childhood thyrotoxicosis. In rare cases, increased TSH secretion resulting either from a TSH-producing pituitary adenoma or from pituitary resistance to thyroid hormone can produce thyrotoxicosis. Another glycoprotein hormone, human chorionic gonadotropin (hCG), also binds to the TSH receptor and stimulates thyroid cell function (2, 3). The thyrotropic potency of hCG is much less than that of TSH, but extremely high serum levels of hCG, such as those seen in individuals with hydatidiform moles or other trophoblastic tumors,

can lead to hyperthyroidism (4, 5). Although extremely rare, the possibility of a molar pregnancy should be considered in adolescent girls with thyrotoxicosis.

Inflammation of thyroid follicular cells can be associated with viral or autoimmune processes, and extensive destruction can release large amounts of preformed T_4 and T_3 into the circulation. The resultant thyrotoxicosis tends to be mild and transient, usually only lasting a few weeks to a few months. Examples include the toxic thyroiditis of Hashimoto's disease and subacute thyroiditis.

Acute or chronic ingestion of thyroid hormone preparations such as L-thyroxine or desiccated thyroid can produce excessive levels of circulating thyroid hormones. Ingestion may be surreptitious, iatrogenic, or accidental. Ingestion or parenteral administration of iodides may also result in thyrotoxicosis. This phenomenon, known as iodine-basedow, most frequently occurs in iodine-deficient areas when supplemental iodides are added to the diet. Iodine-induced hyperthyroidism generally occurs in thyroid glands that are functioning independently of TSH stimulation (6, 7). However, iodine-induced hyperthyroidism has also been described both in adults (6, 7) and in a neonate (8) with apparently normal thyroid glands who were exposed to high concentrations of iodine over prolonged periods.

II. GRAVES' DISEASE

A. Introduction

Graves' disease is an immunogenetic disorder characterized clinically by thyromegaly, hyperthyroidism, and infiltrative ophthalmopathy. A family history of autoimmune thyroid disease is present in up to 60% of patients (9).

Table 1 Causes of Thyrotoxicosis in Childhood and Adolescence

Graves' disease
Autonomous functioning nodule(s)
Toxic adenoma
Hyperfunctioning papillary or follicular carcinoma
McCune-Albright syndrome
Familial nonautoimmune hyperthyroidism
TSH-induced hyperthyroidism
TSH-producing pituitary adenoma
Pituitary resistance to thyroid hormone
Thyroiditis
Subacute thyroiditis
Toxic thyroiditis of Hashimoto's disease
Exogenous thyroid hormone
Iodine-induced hyperthyroidism (jodbasedow)
Tumor-produced thyroid stimulators
Hydatidiform mole
Choriocarcinoma

Genetic studies have shown it to be a polygenic disorder, and most of the genes that have been implicated appear to be involved in immunoregulation (10). Human leukocyte antigens (HLA) and the CTLA-4 gene region have been established as susceptibility loci, although the magnitude of their contributions seems to vary depending on age of onset and racial background (11, 12). Recent reports indicate that HLA-DRB1*03 and -DRB1*08 are positively associated with Graves' disease in White children, whereas the DRB1*07 haplotype is protective (13, 14). For the Japanese population, HLA-DPB1*0501 is significantly increased in children with Graves' disease (15). Recently, genome-wide linkage analysis studies have identified regions on chromosomes 14q31, 18q21, 20q11.2, and Xq21.33–22 that appear to represent susceptibility loci for Graves' disease (12, 16).

The concordance rate between monozygotic twins has been reported to range between 20 and 60% (11–13), thus implying that environmental factors play a significant role in the development of the disease. The extent to which chemicals, drugs, infections, and psychological stress can alter immunoregulatory genes is unknown. However, the existence of a two-way interaction between the immune and neuroendocrine systems may provide a mechanism by which biological and psychological stresses can affect lymphocyte subpopulations and immunoregulation (17).

The exact incidence of Graves' disease during childhood in North America is unknown, but it is uncommon and has been reported to account for fewer than 5% of cases seen in most thyroid clinics (18). A recent study has estimated the incidence of childhood thyrotoxicosis in Denmark to be 0.1:100,000 in the very young increasing with age to 3:100,000 by 14 years old (19). Just as in North America, the vast majority (>95%) of childhood thyrotoxicosis in Denmark is due to Graves' disease (19).

More than two-thirds of childhood cases in North America occur between the ages of 10 and 15 years (1), and it occurs more frequently in girls in a ratio of 3:1 to 5:1 (9).

B. Pathogenesis: Thyrotropin Receptor and Thyrotropin Receptor Antibodies

The thyrotropin (TSH) receptor is a member of the large family of guanine-nucleotide-binding (G) protein-coupled receptors and represents the primary target antigen for autoantibodies that mediate the hyperthyroidism and thyromegaly of Graves' disease. The cDNA encoding the human TSH receptor has been cloned and characterized (20, 21). As deduced from the cDNA sequence, the mature receptor is a glycoprotein with a single polypeptide chain of 744 amino acids. Like all other G-protein-coupled receptors, the TSH receptor has an extracellular domain, seven transmembrane domains, and an intracellular domain. The TSH and other glycoprotein hormone (i.e., luteinizing hormone [LH]/chorionic gonadotropin [CG] and follicle-stimulating hormone [FSH]) receptors each have relatively large extracellular domains, and this characteristic differentiates them from the other G-protein-coupled receptors. The TSH, LH/CG, and FSH receptors are closely related structurally and share about 70% and 45% homology in their transmembrane and extracellular domains, respectively (22).

The extracellular domain of the TSH receptor (398 amino acids) represents the amino-terminal end, and the transmembrane and intracellular domains (346 amino acids) represent the carboxyl-terminal end of the protein. The extracellular domain contains six potential N-glycosylation sites and nine leucine-rich repeats of a loosely conserved 25 amino acid residue motif. Proper glycosylation appears to be important both for normal expression of the receptor on the thyroid cell membrane and for normal hormone–receptor interactions (20, 21). The leucine-rich repeats, which have the potential to form amphipathic α -helices, are believed to be involved in protein–protein or protein–membrane interactions. Recent studies have confirmed that both TSH and autoantibodies to the TSH receptor (TSHrAb) bind to the extracellular domain (20, 21). The transmembrane and intracellular domains are involved in signal transduction, acting through G-protein to stimulate the production of cyclic AMP by adenylyl cyclase (20, 21).

The hyperthyroidism and thyromegaly of Graves' disease are mediated through immunoglobulin G (IgG) that binds to the extracellular domain of the TSH receptor and stimulates follicular cell function and growth. In addition to the stimulating TSHrAbs, sera from patients with Graves' disease may also contain other IgG to the TSH receptor that block thyroid cell function and growth. Stimulating TSHrAbs are restricted to the IgG1 subclass, suggesting that they are either oligo- or monoclonal in origin (23). On the other hand, blocking TSHrAbs appear to be polyclonal in origin and may be of IgG1, IgG2, IgG3, or

IgG4 subclass (24). Current evidence suggests that disease caused by the immune system (i.e., autoimmune disease) appears to result from a restricted immune response involving B and/or T lymphocytes against one or a few epitopes of the target antigen (25). These observations, therefore, support the importance of stimulating TSHrAbs in the cause of Graves' disease and imply that blocking TSHrAbs, much like antithyroglobulin and antithyroid peroxidase, arise as a result of thyroid tissue damage. Nevertheless, blocking TSHrAbs can still modulate the biological effects of stimulating TSHrAbs. Therefore, a patient's clinical presentation and course may be determined by the net biological effect of the simultaneous interaction of various stimulating and blocking TSHrAbs with the TSH receptor.

Several investigators have proposed that the functional effect(s) a particular TSHrAb exhibits is determined by the specific region to which the antibody binds on the TSH receptor (26, 27). Following the successful cloning of the TSH receptor, numerous studies have attempted to identify binding sites for the various TSHrAbs. To date, the major experimental approaches to defining TSHrAb epitopes have included transfecting mammalian cells with mutant cDNA of the TSH receptor and using synthetic peptides derived from the predicted amino acid sequence of the TSH receptor (reviewed in 21, 28–30). Although some of these studies have localized functional epitopes to a few relatively narrow regions of the extracellular domain (31), others have identified multiple regions throughout the entire extracellular domain that appear to be involved in TSHrAb binding (32). Although controversy still exists regarding the specific sites that compose TSHrAb epitopes, current evidence supports the concept that the antibodies bind to conformational epitopes made up of discontinuous segments across the extracellular domain (11). The amino acid region 55–254 contains residues important for the binding of at least some stimulating TSHrAbs (33–35), whereas the amino acid region 370–400 contains residues important for the binding of some inhibitory TSHrAbs (20, 31, 36). Despite these recent advances, the exact mechanisms by which stimulating and blocking TSHrAbs exert their biological effects remain unknown. The precise determination of TSHrAb epitopes, as well as the study of molecular mechanisms, will require the development of human, disease-associated monoclonal antibodies.

The major source of TSHrAb production appears to be intrathyroidal lymphocytes (27), but lymphocytes in the spleen, lymph nodes, bone marrow, and peripheral blood may also produce these antibodies (37, 38). The mechanisms and control of stimulating TSHrAb production are uncertain, but several hypotheses have been proposed. One hypothesis suggests that a deficiency of specific suppressor T-cell function accounts for TSHrAb production (39); a second hypothesis suggests that a breakdown in the idiotype–anti-idiotype network of B

lymphocyte immunoregulation may be responsible (40). An increased frequency of antibodies to certain serotypes of *Yersinia enterocolitica* has been reported in patients with Graves' disease (41), and infection with this bacterium has been proposed as an important initiating event in the development of the disease (42). *Y. enterocolitica* has a specific, saturable binding site for TSH, and antibodies produced against this site may cross react with the TSH receptor on the thyroid follicular cell membrane (41). A fourth hypothesis relies on the fact that thyroid follicular cells can express HLA-DR antigens and are, therefore, endowed with the capacity to present other antigenic material to primed T lymphocytes. Through this mechanism, the follicular cell could present the TSH receptor as antigen and direct the synthesis of TSHrAb (43). Although experimental evidence exists for each of the above hypotheses, none can fully account for all aspects of TSHrAb production; further studies will be necessary to identify the responsible mechanisms.

Currently, two major types of assays are used to measure TSHrAbs (44). Receptor assays assess the ability of Graves' IgG to inhibit labeled TSH from binding to the TSH receptor, and antibodies detected by this method have been designated thyrotropin-binding inhibitory immunoglobulins (TBII). It should be emphasized that receptor assays do not differentiate TSHrAb that stimulate thyroid cell function from TSHrAb that inhibit thyroid cell function; both types of TSHrAbs can be detected as long as they inhibit TSH from binding to its receptor. Receptor assays that employ a combination of detergent-solubilized porcine TSH receptors and receptor-purified [¹²⁵I]-labeled bovine TSH (referred to as first-generation TSH receptor assays) are both sensitive and specific, and they provide a reproducible, inexpensive means of measuring TSHrAb in unextracted serum (27, 45). Studies using these receptor assays have detected TSHrAb in 82–100% of adults (27) and 93% of children (46) with untreated active Graves' disease. TSHrAb can also be detected by receptor assays in small numbers (10–20%) of patients with Hashimoto's thyroiditis (27, 46, 47). A newer second-generation TSH receptor antibody assay is now commercially available (48) that utilizes purified labeled bovine TSH and an immobilized recombinant human TSH receptor protein (48). Recent reports show that this assay retains very high specificity and is more sensitive than the first-generation receptor assay (48, 49). In one report (49), the second-generation assay detected TSHrAb in 41 of 46 patients with Graves' disease who had negative results with the standard first-generation assay.

Bioassay methods constitute the other major type of assay currently used to measure TSHrAb. Most commonly, these assays employ isolated thyroid cells in culture to assess the ability of immunoglobulin concentrates from patient sera to stimulate thyroid cell production of cAMP. Antibodies detected by these assays have been designated thyroid-stimulating immunoglobulins (TSI).

These assays can be performed using cells taken from human or porcine thyroid tissue as well as from the immortal rat thyroid line: the FRTL-5 cells. More recently, transfected mammalian cells (e.g., Cos-7 and CHO cells) expressing the recombinant human TSH receptor have been used to detect stimulating TSHrAbs (20, 50). Recently, a bioassay method utilizing CHO cells transfected with the human TSH receptor was found to detect TSI in 10 of 11 (91%) children with active Graves' disease, whereas TSI were not detected by this assay in 13 normal children, 2 children in remission from Graves' disease, and 11 children with chronic lymphocytic thyroiditis (51). Although the bioassays possess high sensitivity and specificity, they are less precise and are more expensive and time-consuming to perform than the receptor assays (26, 27, 44, 51).

Although some reports have demonstrated highly positive correlations between TSHrAb levels detected by the receptor and bioassay methods (52), most have demonstrated no such correlation (26). Some investigators suggest that the lack of correlation between TBII and TSI levels in patient sera is due to the presence of different populations of TSHrAbs that exhibit different degrees of TSH agonist activity (53). Others suggest that the poor correlation results from the coexistence of both stimulating and blocking TSHrAb in some patients' sera (54).

C. Clinical Manifestations

During childhood and adolescence most patients with Graves' disease present with the classic symptoms and signs (9). Early during the course of the disease the symptoms and signs specific to children (Table 2) may be minimal since the disease usually develops insidiously over several months (9). Often the initial awareness of any problem is in school, where teachers notice changes in behavior and academic performance. Insomnia, restless sleep, and nocturia are common and often are associated

with easy fatigability and lethargy during the day. Other clinical manifestations include palpitations, increased stool frequency, increased sweating, and proximal muscle weakness. Children who develop Graves' disease before the age of 3–4 years can experience transitory speech and language delays, mental retardation, and craniosynostosis (55). The symptoms of hyperthyroidism in Graves' disease, although variable, tend to be more severe than in other causes of hyperthyroidism.

Ophthalmic abnormalities are present in over one-half of patients (refer to Chapter 16, Sec. X), and thyromegaly is almost invariably present. In fact, the absence of goiter raises serious doubt about the diagnosis of Graves' disease, and other causes of hyperthyroidism should be sought. The thyroid gland usually is symmetrically enlarged, smooth, soft, and nontender. A palpable thrill or an audible bruit may be present and reflects increased blood flow through the gland. Less often, and usually in association with coexisting Hashimoto's thyroiditis, the gland may be firm, bosselated, and asymmetrically enlarged. Although pretibial myxedema is observed in 1–2% of adults with Graves' disease (11), it rarely, if ever, occurs in children. Other diseases have been observed in association with Graves' disease and include Hashimoto's thyroiditis, vitiligo, systemic lupus erythematosus, rheumatoid arthritis, Addison's disease, insulin-dependent diabetes mellitus, myasthenia gravis, and pernicious anemia (1).

Although their occurrence is extremely rare, thyroid storm and thyrotoxic periodic paralysis (TPP) are two endocrine emergencies that have been reported in children/adolescents with hyperthyroidism. Although most reported patients have had Graves' disease, these situations can also occur with other causes of hyperthyroidism (56–59). Thyroid storm is a life-threatening manifestation of thyrotoxicosis characterized by fever (generally greater than 38.5°C), tachycardia out of proportion to the fever, high-output cardiac failure, gastrointestinal dysfunction (such as vomiting, diarrhea, and jaundice), and neurological changes (such as confusion, obtundation, seizures, and coma). The diagnosis of thyroid storm requires a high index of suspicion. The syndrome complex may occur either in previously undiagnosed patients or in patients with poorly controlled hyperthyroidism. If left untreated, mortality rates of up to 90% have been reported (60). The exact mechanisms underlying the clinical progression from uncomplicated thyrotoxicosis to storm have not been determined. A number of precipitating factors have been identified and include infection, trauma, surgery, concomitant ingestion of sympathomimetic agents (e.g., pseudoephedrine), withdrawal of antithyroid medication, and radioactive iodine therapy (56, 61–65). Therapeutic intervention includes emergency and supportive care to maintain adequate respiratory and cardiovascular functions and to control body temperature; management of precipitating factors, if indicated; and limiting the amount of thyroid

Table 2 Common Symptoms and Signs of Graves' Disease in 290 Children and Adolescents

	Percentage affected

hormones available to the peripheral body tissues, by using propylthiouracil (PTU), iodide, β -adrenergic blockers, and glucocorticoids (64, 65). PTU inhibits production of new thyroid hormone and blocks conversion of T_4 to T_3 in peripheral tissues. During the first 24–48 h of management, PTU can be administered orally, rectally, or by nasogastric tube in dosages ranging from 100 to 200 mg every 4–6 h (66). Once initial control of thyrotoxicosis has been achieved, PTU dosages can be reduced to 5–10 mg/kg/day in divided oral doses every 6–8 h. Iodides (SSKI, 5–6 drops orally every 8 h) inhibit release of preformed hormones from the thyroid, acutely impair organification of T_4 , and inhibit T_4 to T_3 conversion. Preferably, iodides should be used only after PTU has been administered to avoid an increase in new thyroid hormone production. Propranolol (2 mg/kg/day in divided oral doses every 6–8 h) and hydrocortisone (2 mg/kg as an intravenous [IV] bolus, then 36–45 mg/m²/day in divided IV doses every 6 h) are used to treat the exaggerated adrenergic effects and possible relative glucocorticoid insufficiency, respectively, that accompany thyroid storm. Both also inhibit conversion of T_4 to T_3 .

TPP is a reversible cause of sudden-onset weakness that most commonly affects hyperthyroid patients of Asian descent. However, TPP has also been observed in susceptible White, African-American, Hispanic, and Native American persons (59). The disorder affects 1–2% of hyperthyroid patients in Asian populations, but only 0.1–0.2% of hyperthyroid patients in North America (67, 68). A very strong male preponderance has been observed, but the mode of inheritance is unknown and the majority of affected individuals do not have a family history of periodic paralysis. Most patients present between the ages of 20 and 39 years, but older adolescents with TPP have been reported (69). At presentation, the clinical signs and symptoms of thyrotoxicosis are often subtle and may be overlooked. In the majority of patients, episodes of weakness usually occur precipitously and vary from mild weakness to total paralysis of affected muscle groups. Weakness usually involves the limbs, with proximal muscles being more severely affected than distal muscles. Mental function, sensory function, respiratory, ocular, and bulbar muscle groups are not affected. However, cardiac rhythm disturbances and electrocardiographic (ECG) abnormalities (e.g., U waves, ST segment abnormalities, prolongation of QT interval) are common (70).

TPP typically occurs in the early morning hours, following a day of strenuous exercise. Other apparent precipitating factors include high carbohydrate intake, trauma, infection, menses, emotional stress, and alcohol ingestion (59, 71). The frequency of attacks is variable, and individual episodes typically last from 3 to 36 h. Laboratory evaluation during episodes reveals biochemical evidence of thyrotoxicosis (e.g., elevated serum levels of total and free thyroid hormones with suppressed TSH), and, in the vast majority of cases, significant hypokalemia.

Body stores of potassium are normal, and hypokalemia is the result of intracellular shifts of potassium. Neuromuscular symptoms appear to resolve as potassium moves back out of the cells and may be hastened with supplemental potassium administration. Although the severity of muscle weakness/paralysis tends to reflect the degree of hypokalemia, episodes have occurred in a few patients with normal potassium levels (68, 71).

Although the exact mechanisms responsible for this disorder remain unclear, patients experience TPP only while they are thyrotoxic. Thyrotoxicosis alters plasma membrane permeability to sodium and potassium, a function linked to Na^+K^+ ATPase activity. Thyrotoxicosis also enhances tissue responsiveness to β -adrenergic stimulation and this further increases Na^+K^+ ATPase activity. Na^+K^+ ATPase is also activated by insulin, and this may explain the relationship between attacks and large carbohydrate loads. In addition, a defect in the muscles themselves has been proposed, since they fail to respond to direct electrical stimulation during the period of paralysis (72). Medical management includes hospital admission for the acute paralysis, cardiac monitoring, and close observation of serum potassium levels. Potassium supplements should be used to correct hypokalemia, and anti-thyroid therapy should be started. Episodes of TPP always cease once thyrotoxicosis is corrected, and permanent treatment for the overactive thyroid is imperative. While awaiting normalization of thyroid status, patients should avoid precipitating factors such as strenuous exercise and high carbohydrate intake. β -Adrenergic-blocking agents and pharmacological glucocorticoid therapy can be useful adjunctive treatments for TPP (67, 68).

III. AUTONOMOUS THYROID NODULE

The autonomously functioning thyroid nodule is a discrete thyroid nodule that functions independently of normal pituitary control. The pathogenesis has not yet been established in all cases, but recent evidence suggests that somatic mutations of the α -subunit of G-protein (G_{sa} ; see below) and the third intracellular loop of the TSH receptor are probably responsible for the development of some cases (73, 74). In both situations, the mutations result in constitutive activation of adenylyl cyclase and unregulated production of cAMP. The unregulated cAMP production is responsible for the subsequent tissue hyperplasia and hyperthyroidism.

This disorder predominantly occurs in adults, is rare during childhood, but has been reported in a child as young as 22 months (75). Most children with a thyroid nodule come to the attention of a physician because of a mass in the region of the thyroid gland. The majority of patients with autonomous thyroid nodules are clinically euthyroid, and in contrast to adults, clinical hyperthyroidism occurs very rarely in children. Autonomously functioning nodules that cause hyperthyroidism are almost in-

variably benign adenomas (toxic adenoma), but very rarely hyperthyroidism caused by hyperfunctioning papillary or follicular carcinoma has been reported (76). In these cases, the patients usually have extensive metastatic disease and the diagnosis of carcinoma has been established prior to onset of hyperthyroidism.

The hyperthyroidism of the McCune-Albright syndrome (MAS) is also associated with single or multiple hyperfunctioning adenomatous nodules. This syndrome is characterized by polyostotic fibrous dysplasia, multiple café-au-lait spots, and endocrine hyperfunction. The most common endocrinopathy is isosexual precocious puberty, but hyperthyroidism, acromegaly, Cushing syndrome, and hyperparathyroidism have been reported (77). In contrast to polyostotic fibrous dysplasia and precocious puberty that occur more commonly in girls with the syndrome, hyperthyroidism occurs with equal frequency in boys and girls. The age of onset of hyperthyroidism tends to be between 3 and 12 years (78), which is somewhat younger than the usual age of onset of hyperthyroidism caused by hyperfunctioning nodules in other individuals. The hyperthyroidism is clearly due to autonomous function of the thyroid gland; basal TSH levels are suppressed and the TSH response to TRH is blunted, thyroid-stimulating antibodies are undetectable, and T_3 treatment fails to suppress radioactive iodide uptake by the thyroid.

Current evidence indicates that the receptors for each of the hormones (i.e., LH, FSH, TSH, growth-hormone-releasing hormone [GHRH], adrenocorticotrophic hormone [ACTH], and parathyroid hormone [PTH]) that might otherwise be implicated in the observed endocrinopathies of MAS are all coupled to G-proteins. The G-proteins are heterotrimers composed of an α -subunit and a tightly coupled $\beta\gamma$ -dimer (79). The α -subunit contains the guanine-nucleotide-binding site and has intrinsic GTPase activity. In the normal situation, the binding of one of these stimulatory hormones to its receptor facilitates the exchange of GTP for GDP in the guanine-nucleotide-binding site of the α -subunit ($G_{s\alpha}$). This results in the release of the G-protein from the receptor and its dissociation into free $G_{s\alpha}$ -GTP and free $\beta\gamma$ -dimer. Free $G_{s\alpha}$ -GTP stimulates adenylyl cyclase activity, with the subsequent production of intracellular cAMP. After a preset time, the intrinsic GTPase of $G_{s\alpha}$ hydrolyses GTP to GDP, and the $G_{s\alpha}$ -GDP reassociates with the $\beta\gamma$ -dimer. The G-protein is thus returned to its inactive state and can now reassociate with its receptor and participate in another cycle (79). Recent studies have identified mutations in the $G_{s\alpha}$ gene in endocrine organs, bone, and skin from patients with MAS (79–81). These mutations involve the amino acid residue Arg²⁰¹ that is critical for the intrinsic GTPase activity of $G_{s\alpha}$. Therefore, certain substitution mutations involving this amino acid residue result in the constitutive activation of adenylyl cyclase and unregulated production of intracellular cAMP. In some cases, the mutation has been

found in abnormal sections of tissue but not in histologically normal sections from the same tissue (79). This observation would tend to explain the development of hyperfunctioning nodules within the thyroid gland.

The amount of thyroid hormone that an autonomously functioning nodule produces appears to be related to its size. In adults with single autonomous nodules, hyperthyroidism usually occurs only when the nodule measures more than 2.5–3 cm in diameter (82). Both T_4 and T_3 can be produced in excess, but an elevated serum T_3 level is frequently the only biochemical abnormality. In some patients, the T_3 level may be elevated enough to inhibit the TSH response to TRH, but not enough to cause clinical hyperthyroidism (83).

A radionuclide image, preferably using [¹²³I]-iodine, should be included in the evaluation of the hyperthyroid child with a thyroid nodule. The radioiodine image allows one to study both trapping and organification by the nodule. Technetium images only demonstrate trapping by the nodule, and images are not always identical to those obtained with iodine. The diagnosis of a hyperfunctioning or “hot” nodule is established when the image reveals increased accumulation of the radioisotope in the nodule and decreased or absent uptake in the surrounding thyroid tissues.

Surgical removal is the preferred method of treatment for the toxic thyroid nodule and usually is accomplished by partial thyroidectomy. Significant surgical complications are not expected, and postoperative hypothyroidism seldom occurs. With complete surgical removal of the autonomous nodule, hyperthyroidism should not recur postoperatively. Since the hyperthyroidism produced by the autonomous nodule is usually mild, a long preoperative preparation with antithyroid drugs is seldom necessary. Propranolol may be used to decrease the symptoms of hyperthyroidism. The administration of iodides is not indicated in the preoperative treatment of the autonomous nodule. Percutaneous intranodular ethanol injection under ultrasound guidance has been employed for the ablation of autonomous thyroid nodules (84). This approach appears to be safe and effective in adults and may prove to be a practical alternative to surgical treatment in children.

IV. FAMILIAL NONAUTOIMMUNE HYPERTHYROIDISM

Familial nonautoimmune hyperthyroidism (FNH) is a rare condition that clinically can be confused with Graves' disease. It has been estimated that FNH (also referred to as nonautoimmune hereditary hyperthyroidism) may account for 2–5% of all cases of diffuse hyperthyroidism (85). The disorder occurs because of a germline mutation in the TSH receptor gene. These so-called gain of function mutations result in the constitutive activation of the TSH receptor–G protein–effector system complex that ulti-

mately leads to increased thyroid follicular cell growth and function. The first family recognized to have this disorder was described in 1982 (86); as of this writing, approximately 10 kindreds with FNH have been identified (87, 88). Except for amino acid 281 (Ser²⁸¹) in the extracellular domain, all the other identified mutation sites are located in transmembrane domains 1, 2, 3, 5, 6, and 7 of the TSH receptor (87).

The disease is transmitted in an autosomal dominant fashion. Therefore, unlike in Graves' disease, males and females can be affected equally. In described families, hyperthyroid individuals are spread over three to four generations. The onset of clinical hyperthyroidism is highly variable, with some patients presenting before the age of 1 year and others presenting in adolescence or early adulthood. However, clinically asymptomatic individuals can exhibit suppressed serum TSH levels for years prior to the clinical appearance of goiter or thyrotoxicosis (85).

In affected individuals, both thyroid gland size and structure tend to change over time. In the youngest patients, the gland tends to be normal to slightly enlarged. In older patients, the thyroid is symmetrically enlarged and bruits may be audible over the lobes. Eventually, the diffusely enlarged gland may evolve into a multinodular goiter (85). Although eye signs of thyrotoxicosis (e.g., stare, lid lag, widened palpebral fissures, mild proptosis) may be present, infiltrative ophthalmopathy has not been observed in FNH. Laboratory evaluation reveals elevated serum levels of both total and free thyroid hormones and suppressed TSH. TSH receptor antibodies are not present. In general, serum antibodies to thyroid peroxidase and thyroglobulin also are not present, but these autoantibodies have been detected in a few patients with confirmed FNH (88). In the research setting, DNA from peripheral blood leukocytes can be used to sequence the TSH receptor gene for identification of point mutations associated with FNH.

The recognition of FNH is of great importance for its management. The diagnosis should be considered in cases of apparent Graves' disease when extrathyroidal signs and thyroid antibodies are absent and in patients with an extensive family history of hyperthyroidism. As in Graves' disease, antithyroid drug therapy can control the hyperthyroidism; but, due to the persistent functional effects of the TSH receptor mutation, remission does not occur. While subtotal thyroidectomy may restore euthyroidism in some patients (87), significant regrowth of thyroid tissue may likewise occur with subsequent recurrence of clinical hyperthyroidism (85). Therefore, total ablation of the gland, either surgically or with radioiodine, should be considered in patients with FNH. Regular systematic screening for either clinical symptoms or early biochemical evidence of hyperthyroidism (i.e., suppressed serum TSH levels) should be undertaken to identify other affected family members. In addition, genetic counseling should be offered to affected families.

V. TSH-INDUCED HYPERTHYROIDISM

Hyperthyroidism from increased TSH secretion can occur as the result of either a TSH-secreting pituitary adenoma or selective pituitary resistance to thyroid hormone. Although both are rare, each has been reported in childhood and adolescence (89). Unlike Graves' disease, the gender ratio in patients with TSH-induced hyperthyroidism is 1:1. Most cases of TSH-producing pituitary adenoma occur sporadically, but familial cases have been reported (90). Pituitary resistance to thyroid hormone appears to be familial with an autosomal dominant pattern of inheritance (89). The cause of pituitary resistance to thyroid hormone has not been established for all cases, but most represent forms of the syndrome of generalized resistance to thyroid hormone (GRTH; see below) (91, 92). The syndrome of GRTH is caused by a mutation in TR β , one of the thyroid hormone receptor genes (92). Approximately 60 different mutations have been identified in patients from over 100 families (92). Although the reasons remain unclear, affected members within a family can exhibit different degrees of resistance to thyroid hormone, and various tissues (e.g., heart, liver, bone, and pituitary) can be affected to a greater or lesser degree (92, 93). Therefore, the pituitary gland in such individuals would be relatively more resistant to thyroid hormones than other tissues in the body. Pituitary thyrotroph resistance in these individuals is selective for thyroid hormones, since there is normal inhibition of pituitary TSH secretion by glucocorticoids and dopaminergic agents (89). Criteria essential for the diagnosis of this disorder include evidence of increased peripheral metabolism, diffuse thyromegaly, elevated free thyroid hormone levels, and inappropriately elevated serum levels of TSH (90). Although the TSH level may not be elevated above the normal range, it is always detectable, even in highly sensitive and specific immunoassays. In all other causes of hyperthyroidism, sensitive immunoassays will reveal very suppressed or undetectable serum levels of TSH.

The clinical presentation is often very similar to Graves' disease, and a high degree of suspicion is needed to make the diagnosis. The patient with pituitary adenoma, however, may present with visual complaints due to compression of optic nerve tracts by the adenoma. Increased pituitary secretion of growth hormone and prolactin has also been reported in patients with TSH-secreting tumors (90).

Once the diagnosis of TSH-induced hyperthyroidism has been established, the clinician needs to determine if the increased TSH secretion results from a pituitary tumor or from pituitary resistance to thyroid hormone in order to determine the proper course of therapy. The TRH and T₃ suppression tests may help differentiate these two disorders. In general, serum TSH levels do not increase in response to TRH when a pituitary tumor is the cause of hyperthyroidism. In contrast, the TSH response to TRH tends to be normal or exaggerated in pituitary resistance

to thyroid hormone (89). Pharmacological dosages of T_3 cause significant TSH suppression in patients with pituitary resistance but fail to reduce TSH levels in patients with TSH-secreting pituitary adenomas.

Determination of serum levels of the free α -subunit of the glycoproteins, including TSH, also can aid in differentiating these conditions; patients with TSH-secreting pituitary tumors generally have elevated (greater than 1) molar α -subunit/TSH ratios. This ratio tends to be less than 1 in patients with pituitary resistance to thyroid hormone (90). The measured α -subunit is usually expressed in ng/ml, whereas TSH is usually expressed in μ U/ml. In order to determine the molar α -subunit/TSH ratio, one assumes a molecular weight for TSH of 28,000 D, a molecular weight for α -subunit of 13,600 D, and a specific activity for human TSH of 5 μ U/ng (94). This results in a conversion factor of $(28,000/13,600)/0.2$ or approximately 10 (95). Therefore, $[\alpha\text{-subunit (ng/ml)}/\text{TSH } (\mu\text{U/ml})] \times 10 = \text{molar } \alpha\text{-subunit}/\text{TSH ratio}$. CT scan and MRI studies of the pituitary region also can help to establish the diagnosis and to guide treatment.

Treatment for TSH-secreting adenomas consists of selective adenectomy or radiotherapy, or a combination of the two (93, 96). In the past, a brief course of antithyroid drugs was used to render the patient euthyroid prior to surgery. More recently, the somatostatin analog, octreotide, has proven useful in the management of TSH-producing pituitary tumors (93, 96). This drug normalizes thyroid hormone levels in most patients and causes a decrease in tumor size in some. However, because of tachyphylaxis, octreotide cannot be considered definitive treatment. The current approach to managing the TSH-producing pituitary tumor consists of achieving a euthyroid state with octreotide, followed by surgical resection of the tumor.

Treatment of patients with pituitary resistance to thyroid hormone is more difficult. Ideally, treatment should be aimed at reducing TSH secretion by the pituitary. A number of agents including L- T_3 , D- T_4 , bromocryptine, and triiodothyroacetic acid (Triac) have been advocated (90, 93, 97–99). To date, each agent has been used in a limited number of patients, and the overall efficacy of each has not been determined. Octreotide has not been useful in the long-term treatment of these patients (93). Atenolol, a β -adrenergic-blocking agent that does not impair the peripheral conversion of T_4 to T_3 , can be used to decrease the symptoms of hyperthyroidism (100). Although antithyroid drugs will reduce serum thyroid hormone levels, they will also increase TSH secretion and goiter size. Since prolonged TSH hypersecretion may lead to thyrotroph hyperplasia and potentially to the development of a TSH-secreting pituitary adenoma (101), prolonged treatment with antithyroid drugs is discouraged. Likewise, subtotal thyroidectomy and radioiodine therapy should not be used in patients with pituitary resistance to thyroid hormone.

VI. SUBACUTE AND HASHIMOTO'S THYROIDITIS

Subacute or granulomatous thyroiditis is a self-limited, presumably viral, inflammation of the thyroid gland. This entity is rarely seen in children, occurring more frequently between the third and fifth decades of life. Mild symptoms of thyrotoxicosis may occur, but they are often overshadowed by malaise, fever, and tenderness of the thyroid gland. The erythrocyte sedimentation rate is consistently elevated. Thyroid antibodies are usually negative early in the disease, but titers may rise transiently to abnormal levels during recovery. The thyrotoxic phase of this disease probably results from destruction of thyroid follicular cells with release of large amounts of preformed thyroid hormones.

The toxic thyroiditis of Hashimoto's disease occurs early in the course of chronic lymphocytic thyroiditis and probably results from extensive autoimmune destruction of thyroid follicular cells. The child may present with mild symptoms of thyrotoxicosis and a slightly enlarged, sometimes tender, thyroid gland. Thyroid antibodies are usually positive.

Laboratory evaluation of both disorders reveals elevated serum T_4 , free T_4 , and T_3 levels and undetectable TSH levels. The TSH response to TRH is either blunted or absent. The radioiodine uptake is typically low or absent during the thyrotoxic phase of these disorders and helps to differentiate toxic thyroiditis from Graves' disease.

Treatment of these disorders is symptomatic. Antithyroid drugs are not indicated in the treatment, but propranolol can be used to relieve the symptoms of thyrotoxicosis in both. The pain and tenderness of the thyroid gland may be relieved by therapeutic dosages of salicylates, but on occasion glucocorticoids may be required. These disorders have been discussed in detail in Chapters 15 and 17.

VII. EXOGENOUS THYROID HORMONE

Thyrotoxicosis may result from the ingestion, usually chronic, of excessive quantities of thyroid hormone preparations (102). The term thyrotoxicosis factitia has been used to describe this situation. In children and adolescents, this ingestion may be surreptitious, iatrogenic, or accidental. Although therapeutic thyroid hormone preparations are the most obvious source, the clinician should keep in mind that ground meats and diet pills have reportedly been contaminated with large amounts of thyroid hormones and implicated in some patients with thyrotoxicosis factitia (102).

Although acute accidental or intentional overdoses of thyroid hormones can produce marked elevations in serum T_4 levels, the majority of children who take as much as 5–10 mg L- T_4 in a single dose have few or no symptoms of thyrotoxicosis (103). When symptoms of thyrotoxicosis

occur in these cases, they are usually mild and consist of fever, tachycardia, irritability, vomiting, diarrhea, and hyperactive behavior. Although more serious reactions such as seizures have been reported, these occur very infrequently and several hours to days after the acute overdose (104). When preparations containing significant levels of T_3 have been ingested, the onset of symptoms is within 6–12 h. The onset of symptoms following acute ingestion of L- T_4 is generally within 12–48 h, but may be as late as 7–10 days after ingestion. The delayed onset of symptoms may be explained by the conversion of T_4 to its biologically more active metabolite, T_3 . Serum levels of T_4 and/or T_3 following acute ingestion correlate poorly with development of toxicity (105). Because the majority of these cases are relatively benign and symptoms are absent or delayed, initial therapy should be limited to gastric decontamination with syrup of ipecac followed by activated charcoal and/or a cathartic (106). Some authorities also recommend cholestyramine as an initial adjunctive therapy because this agent binds thyroid hormones and reduces their enterohepatic circulation (105). Patients who have ingested thyroid hormone accidentally can then be evaluated closely at home pending the onset of symptoms. As in other accidental poisonings, the parents should be counseled on child safety measures. Only when symptoms occur should hospitalization or further treatment be considered. Propranolol is helpful in controlling tachycardia as well as improving symptoms of nervousness, diaphoresis, or tremor. Acetaminophen may be useful for control of fever. In the rare situation when a massive ingestion results in a life-threatening situation, exchange transfusion has been shown to reduce serum thyroid hormone concentrations effectively (105). Psychiatric evaluation may be indicated for patients with acute intentional overdoses.

Chronic ingestion of thyroid hormone preparations can produce symptoms similar to hyperthyroidism of thyroid origin. However, thyromegaly is not present unless the patient also has a coincident thyroid disease such as Hashimoto's thyroiditis. Likewise, infiltrative ophthalmopathy is absent; however, as in other causes of thyrotoxicosis, lid lag and stare may be present. The diagnosis of this disorder is not difficult if the clinician is able to obtain a history of thyroid hormone ingestion. However, this history may be difficult to obtain, especially in cases of surreptitious ingestion. Nevertheless, the clinician should still be able to diagnose this disorder using a limited number of tests. Thyroid function test results will depend on the type of preparation responsible for the thyrotoxicosis. If the preparation is composed mainly of T_4 , the patient will have elevated serum T_4 and free T_4 levels. If the preparation is T_3 or has a high T_3/T_4 ratio, the patient will have a low to normal serum T_4 level. In both cases the serum T_3 level is elevated. The radioiodine uptake is low to reflect the suppression of thyroid gland activity induced by exogenous thyroid hormone. Unlike all other causes of thyrotoxicosis, the plasma thyroglob-

ulin level in this disorder is undetectable or extremely low. Therefore, the plasma thyroglobulin level may be extremely helpful in differentiating this disorder from other causes of thyrotoxicosis.

Treatment of thyrotoxicosis resulting from chronic ingestion of thyroid hormone preparations should be guided by the circumstances surrounding ingestion. For example, patients receiving excessive replacement for treatment of hypothyroidism should have their dosage reduced. The patient who is taking thyroid hormone surreptitiously should be advised to discontinue the medication; in some cases, psychotherapy may be necessary.

VIII. EUTHYROID HYPERTHYROXINEMIA

The term euthyroid hyperthyroxinemia is used to describe the various conditions in which the serum T_4 level, either total or free, is elevated in the absence of thyrotoxicosis. The causes are listed in Table 3 and can be classified into four major categories: increased T_4 binding by serum proteins, generalized resistance to thyroid hormones, impaired peripheral conversion of T_4 to T_3 , and changes in thyroid stimulation associated with psychiatric illness.

Alterations in any of the serum thyroid hormone-binding proteins can produce elevations of the total T_4 level, but the free T_4 level remains normal. Increased thyroxine-binding globulin (TBG) concentration results from a variety of causes (Table 4) and produces concurrent elevations of the serum total T_4 and T_3 levels. Familial dysalbuminemic hyperthyroxinemia (FDH) is due to the presence of significant amounts of serum albumin with an unusually high affinity for T_4 . Since this albumin typically binds T_3 only weakly, the serum T_3 level remains normal. FDH is inherited in an autosomal dominant fashion and is expressed equally in males and females. Increased serum concentration or binding affinity of thyroxine-binding

Table 3 Conditions Causing Hyperthyroxinemia in the Absence of Thyrotoxicosis

Increased T_4 -binding by serum proteins
Increased concentration of TBG
Familial dysalbuminemic hyperthyroxinemia
Increased T_4 -binding by transthyretin
Anti- T_4 antibodies
Generalized (pituitary and peripheral tissues) resistance to thyroid hormone
Impaired conversion of T_4 to T_3
Pathophysiological conditions (e.g., type I deiodinase deficiency and certain nonthyroidal illnesses)
Pharmacological agents (e.g., amiodarone, propranolol, heparin, iodine contrast agents, amphetamines, L-thyroxine)
Changes in thyroid stimulation associated with psychiatric illness

Table 4 Factors Associated with Increased TBG Concentration

Pregnancy
Neonatal state
Estrogens
Oral contraceptives
Acute intermittent porphyria
Infectious and chronic active hepatitis
Perphenazine
Genetic determination

prealbumin (TBPA) or transthyretin can produce elevated serum total T_4 levels but, as in FDH, the serum T_3 level remains normal. The presence of endogenous antibodies directed against T_4 can produce either true or spurious elevations in serum total T_4 levels.

The serum free T_4 level is normal in the disorders of protein binding when it is determined by equilibrium dialysis or the two-step coated tube method. Determination of the free T_4 by an analog-based free T_4 method gives falsely high results in patients with FDH and endogenous anti- T_4 antibodies. This occurs because the variant albumin or anti- T_4 antibody in the serum readily binds the analog tracer used in these competitive immunoassays, and, thereby decreases the amount of tracer available to compete for the assay antibody. The low binding of tracer by the assay antibody gives the false impression of a high free T_4 concentration.

The FT_4 index, as usually calculated from the resin T_3 uptake test, accurately reflects the FT_4 level only when increased T_4 binding is due to TBG excess. T_4 and T_3 share the same binding site on TBG. When the concentration of TBG is increased, the available binding sites for both T_4 and T_3 are increased. The resin T_3 uptake is inversely proportional to the number of available binding sites for T_3 ; that is, when the available serum binding sites for T_3 are increased, the resin T_3 uptake is decreased. The FT_4 index, when calculated as the product of the T_4 and the resin T_3 uptake, is usually normal in TBG excess because the elevated T_4 is offset by the decreased resin T_3 uptake. However, when increased serum T_4 binding results because of FDH or increased T_4 -binding by TBPA or anti- T_4 antibodies, the resin T_3 uptake remains normal because none of these proteins binds significant amounts of T_3 . Consequently, the FT_4 index values are spuriously elevated. Therefore, one should always consider the possibility of an abnormal T_4 -binding protein when serum T_3 and resin T_3 uptake results are normal in the face of an elevated serum T_4 level. It should be emphasized that patients with elevated serum T_4 levels resulting from abnormal serum binding proteins are euthyroid; no antithyroid treatment is indicated.

Generalized (pituitary and peripheral tissues) resistance to thyroid hormone (GRTH) is a rare disorder char-

acterized by thyromegaly, elevated serum total and free T_4 and T_3 levels, a preserved TSH response to TRH, and absence of the usual symptoms and signs of thyrotoxicosis. Although this syndrome is probably congenital, it is rarely diagnosed at birth and more often recognized during childhood and adult life (107). In the majority of affected individuals, it is inherited in an autosomal dominant fashion, but recessive transmission has also been reported (107). The male to female ratio in GRTH is close to 1. The tissue resistance to thyroid hormones is selective, and studies have shown that the pituitary thyrotrophs and peripheral tissue fibroblasts respond normally to dopaminergic drugs and/or glucocorticoids (108, 109). Pituitary secretion of TSH is responsible for thyromegaly, increased thyroid gland activity, and excessive thyroid hormone synthesis and secretion seen in this syndrome. Although the serum TSH level may not always be elevated, it is always detectable; administration of TRH produces a further increase in TSH levels. On the other hand, administration of supraphysiological dosages of exogenous T_3 suppresses pituitary secretion of TSH in virtually all affected patients.

The syndrome of GRTH results from mutations in one of the thyroid hormone receptor genes (92). Two thyroid hormone receptor genes, $TR\beta$ and $TR\alpha$, are located on chromosomes 3 and 17, respectively (92). By alternative splicing of primary transcripts, these two genes code for four main isoforms of the thyroid hormone receptor ($TR\alpha$ -1 and c-erbA α -2; $TR\beta$ -1 and $TR\beta$ -2). With the exception of the c-erbA α -2 isoform, each of these proteins has both T_3 -binding and DNA-binding domains and functions as a thyroid hormone receptor (92). All molecular genetic studies on patients with GRTH have revealed mutations in the T_3 -binding domain of the $TR\beta$ gene. About 60 different mutations in $TR\beta$ have now been identified in patients from over 100 families; the mutations consist of single amino acid substitutions at a single codon, single amino acid deletions, frameshift mutations, or truncations due to premature termination of translation from a mutation-generated stop codon (92). These mutations result in thyroid hormone receptors with defective T_3 binding. In some cases, the same mutations have been described in different families. The clinical phenotype can vary among the families that have the same mutation and also within a family. This suggests that there may be other genetic modifiers that determine the clinical phenotype (92). Patients who inherit this disorder in an autosomal recessive fashion have mutations in both alleles of the $TR\beta$ gene. On the other hand, patients who inherit GRTH in an autosomal dominant fashion have a wild-type allele, as well as a mutant allele for the receptor. These mutations are dominant negative in that the mutant receptors inhibit the function of the normal β -receptor (from wild-type allele) and the normal α -receptor (92). Recently, families with GRTH have been identified that have neither $TR\beta$ nor $TR\alpha$ mutations (110). It has been proposed that ab-

normal intracellular thyroid hormone transport, mutations in thyroid hormone receptor cofactors, or dysregulation of cofactor expression may be responsible for the GRTH phenotype in these families. Thus far, no defects have been identified in any of the several thyroid hormone cofactor genes that have been studied in these patients (111). To date, no germline TR α -1 mutants have been described in humans (92). It is possible that TR α -1 mutations are either lethal in utero, silent, and/or extremely rare.

Despite the elevated levels of circulating thyroid hormones, most patients with GRTH are clinically euthyroid. Although symptoms and signs of hypo- or hyperthyroidism are generally absent, a few patients have been reported with retarded bone age, mental retardation, stunted growth, and hearing defects (112). Persistent tachycardia, tremor, anxiety, and hyperactivity have likewise been observed in some patients (113). These findings suggest that the degree of resistance to thyroid hormone may not be the same in all tissues.

The diagnosis of GRTH requires elevated serum levels of T₄ and free T₄. Serum T₃ and reverse T₃ levels are also elevated. The TBG level is normal and the resin T₃ uptake is elevated. As mentioned above, serum TSH is always detectable, and the TSH response is either normal or exaggerated (89). The radioiodine uptake is increased. Laboratory tests of metabolic status such as basal metabolic rate, serum cholesterol and triglycerides, and carotene are usually normal. Most patients with GRTH require no treatment, but resistance to thyroid hormone may vary from tissue to tissue. Some patients may benefit from treatment with pharmacological dosages of T₄ or T₃; this is especially true in cases where the peripheral tissues are more resistant than the pituitary thyrotrophs. Affected children should be monitored closely for growth deceleration, delayed bone maturation, and impaired mental development. Thyroid hormone treatment should be instituted as necessary. Any therapeutic maneuvers that may reduce the elevated circulating thyroid hormone levels are contraindicated in patients with GRTH and should be avoided.

Peripheral conversion of T₄ to T₃ occurs through the activity of 5'-deiodinase. A variety of pathophysiological conditions and pharmacological agents have been associated with impaired T₄ to T₃ conversion. The clinical syndrome of type I iodothyronine-deiodinase deficiency has been reported but appears to be extremely rare (114). The reported patient was clinically euthyroid and had elevated serum levels of T₄ and reverse T₃, along with normal serum T₃ and TSH levels (115).

Alterations in serum thyroid hormone levels often accompany nonthyroidal illnesses. Although the T₄ level is typically low or normal, on occasion it may be elevated. The euthyroid sick or nonthyroidal illness syndrome is discussed in Chapter 15. Various drugs have been found to cause an elevation of serum T₄ levels in adults, but the majority of these agents are not commonly used in chil-

dren and adolescents. Examples include amiodarone, propranolol, heparin, oral cholecystographic agents, and amphetamines.

Elevated serum T₄ levels are sometimes seen in clinically euthyroid children who are receiving replacement or suppressive therapy with L-T₄. In these children the serum T₃ level is normal. The mechanism responsible for normal T₃ levels despite increased T₄ concentrations has not been completely defined, but may be explained by the fact that 5'-deiodinase activity in peripheral tissues appears to be autoregulated by the levels of circulating T₄. Thus, as the serum T₄ concentration increases from low to elevated levels, the peripheral generation of T₃ from T₄ decreases, as reflected in the steady decline in the serum T₃/T₄ ratio (102). Therefore, in patients receiving L-T₄ therapy, the serum T₃ level is better than the serum T₄ level as an indicator of metabolic status.

Mild elevations in serum T₄ levels are observed in about 20% of patients hospitalized for acute psychiatric disorders (116). This situation is most commonly observed in patients with mania, schizophrenia, and other major affective disorders, but is also occasionally seen in patients with alcoholism or personality disorder. Both total and free T₄ levels are elevated, and, in an occasional patient, serum T₃ is also mildly elevated (116). The serum TSH is usually normal to mildly increased at baseline, and this finding helps to differentiate this condition from the most common forms of thyrotoxicosis. Often, the TSH response to TRH is blunted. These biochemical findings do not appear to represent thyrotoxicosis, and they usually resolve spontaneously within a few weeks without specific therapy. It has been proposed that a decrease in central nervous system (CNS) dopaminergic inhibition results in activation of the hypothalamic-pituitary axis with enhanced TSH secretion and consequent elevations in serum T₄ levels (117).

IX. T₃ AND T₄ TOXICOSIS

Increased serum concentrations of both T₄ and T₃ are observed in the majority of children presenting with hyperthyroidism. However, some thyrotoxic children may present with an increased serum T₃ concentration but a normal or occasionally low serum T₄ concentration (i.e., T₃ toxicosis), while others may present with an elevated serum T₄ concentration and a normal or slightly decreased T₃ level (i.e., T₄ toxicosis). Just as in the usual presentation of thyrotoxicosis, the serum TSH level is suppressed in both these situations.

T₃ toxicosis can occur in the course of any disorder that causes hyperthyroidism. Most patients have elevations in both total and free T₃ concentrations, but some will present with elevated free T₃ levels while total T₃ levels are still within the normal range (118, 119). During childhood, T₃ toxicosis is most often encountered early in the course of either initial or relapsing Graves' disease or

in association with an autonomous nodule. In these situations, T_3 toxicosis reflects a predominant hypersecretion of T_3 by the thyroid gland, rather than an increase in the peripheral conversion of T_4 to T_3 (120). If left untreated, some patients with T_3 toxicosis due to true hyperthyroidism, over time, will develop elevated serum concentrations of both T_3 and T_4 . T_3 toxicosis is also seen in thyrotoxicosis factitia related to ingestion of liothyronine ($L-T_3$).

T_4 toxicosis occurs in two circumstances: iodine-induced thyrotoxicosis and thyrotoxicosis accompanied by severe intercurrent illness. With iodine-induced thyrotoxicosis, about one-third of patients have elevated serum T_4 but normal serum T_3 levels, and the remainder have proportionate elevations of serum T_3 and T_4 levels (120). In severe illness, peripheral conversion of T_4 to T_3 is impaired because of marked reductions in 5'-deiodinase activity. This accounts for the normal or low serum T_3 levels in the presence of abnormally elevated serum T_4 levels. Furthermore, serum reverse T_3 (rT_3) levels are also increased because of the impaired 5'-deiodinase activity. With resolution of the intercurrent illness, 5'-deiodinase activity normalizes with subsequent declines in serum rT_3 levels and increases of serum T_3 levels into the thyrotoxic range. On a clinical level, T_4 toxicosis of this type needs to be differentiated from the low serum T_3 /elevated serum T_4 levels occasionally observed in the euthyroid sick syndrome. The serum TSH level will be suppressed in T_4 toxicosis, and it may also be very low or suppressed in the euthyroid sick syndrome. Therefore, serum TSH measurement may not be helpful initially in differentiating between these two conditions.

X. GRAVES' OPHTHALMOPATHY

Ophthalmic abnormalities are clinically evident in over half of the children and adolescents with Graves' disease. In most of these patients, the signs and symptoms are relatively mild and include lid lag, lid retraction, stare, proptosis, conjunctival injection, chemosis, and periorbital and eyelid edema. Less commonly, patients may complain of eye discomfort, pain, or diplopia. Severe ophthalmopathy, associated with marked chemosis, severe proptosis, periorbital ecchymosis, corneal ulceration, eye muscle paralysis, and optic atrophy, is extremely rare during childhood and adolescence. The clinical onset of eye disease usually coincides with that of thyroid dysfunction, but it can precede or follow it by several months to years (121).

Lid lag, lid retraction, and stare most commonly result directly from thyrotoxicosis with enhanced sympathetic stimulation of Müller's muscle of the upper lid. These features can be found in patients with thyrotoxicosis of any cause and generally improve with normalization of thyroid hormone levels. The other signs and symptoms, however, are characteristic of Graves' ophthal-

mopathy and can be explained by the mechanical effects of an increase in tissue volume within the bony orbit. Histological examination reveals accumulation of glycosaminoglycans (GAGs) in the connective tissue components of the orbital fat and muscles, as well as lymphocytic infiltration of the orbital tissues. The GAGs are hydrophilic macromolecules produced by orbital fibroblasts, and their accumulation results in enlargement of the extraocular muscles and surrounding fat (122). Enlargement of these tissues within the fixed space of the bony orbit leads to forward displacement of the globe (proptosis or exophthalmos). Chemosis and periorbital edema result from decreased venous drainage from the orbit and intraorbital inflammation. Extraocular muscle dysfunction results from accumulation of GAGs, edema, inflammation, and fibrosis of the endomysial connective tissues investing the muscle fibers (122).

Although information regarding its pathogenesis is limited, Graves' ophthalmopathy (GO) is generally considered to represent an organ-specific autoimmune disorder. Current evidence supports the contention that orbital fibroblasts are the primary targets of the autoimmune attack (123). However, the nature of the autoimmune reaction is unclear, and a target orbital autoantigen has not been conclusively identified. The close association of GO with autoimmune thyroid disease strongly suggests that the orbital antigen(s) may share unique structural characteristics with antigens of the thyroid gland. Recent studies support that two such candidate antigens, the TSH receptor (124) and thyroglobulin (125), are present in orbital tissues from patients with GO. Therefore, it is possible that either of these two proteins could be the primary target antigen in GO, thus providing a common link between the thyroid and eye diseases. Because the TSH receptor is the primary target antigen in Graves' hyperthyroidism, most investigators currently consider it to be the leading candidate target antigen in GO. Several human and animal studies have provided compelling, although not yet definitive, evidence (reviewed in 123, 126) to support this role for the TSH receptor in GO. However, more studies are needed to determine which, if either, of these two proteins is the target autoantigen in GO. Thus far, thyroid peroxidase has not been detected in orbital tissues (121).

Cell-mediated immunity appears to play a major role in the pathogenesis of GO. The extraocular muscles and orbital connective tissues are infiltrated by lymphocytes and macrophages. The lymphocytes are predominantly $CD4^+$ and $CD8^+$ T cells with a few B cells. Regardless of the target antigen that causes the lymphocytic infiltration, the proximal events in the pathogenesis of GO appear to be cytokine-mediated activation of orbital fibroblasts, secretion of GAGs by these cells, and ultimately, fibrosis. Immunohistochemical studies have demonstrated the presence of the cytokines, interferon-gamma ($IFN-\gamma$), tumor necrosis factor- α ($TNF-\alpha$), and interleukin-1 α ($IL-1\alpha$), in the cytoplasm of orbital-infiltrating mononuclear

cells and in adjacent orbital connective tissue from patients with early active GO (127). These findings support that T cells and antigen-presenting cells within these tissues are activated. Because transplacental passage of maternal thyroid-stimulating antibodies does not appear to cause infiltrative ophthalmopathy in neonates, and the presence of antibodies to orbital antigens is inconsistently related to eye disease, humoral autoimmunity appears to play at most a secondary role in the pathogenesis of GO (11).

Because ophthalmopathy is relatively mild and self-limited in the vast majority of affected children and adolescents, specific treatment is usually not necessary. In general, eye findings improve in association with control of the hyperthyroidism. Occasionally, local measures may be used to treat symptoms. For example, eye drop or ointment preparations containing methylcellulose may be necessary to prevent corneal drying. Sleeping with the head elevated may help to reduce chemosis and periorbital edema. Other forms of treatment, such as oral corticosteroids, orbital irradiation, and surgical decompression, are rarely indicated in children and should be reserved for those with severe ophthalmopathy.

XI. LABORATORY EVALUATION

The laboratory evaluation of thyrotoxicosis should be guided by the patient's clinical presentation as determined by the medical history and physical examination. In all causes of thyrotoxicosis, except for TSH-induced hyperthyroidism, the serum TSH level will be undetectable or very suppressed using modern second- or third-generation TSH assays. For the child or adolescent presenting with obvious signs and symptoms of Graves' disease, including a soft, diffusely enlarged, smooth goiter and proptosis, only a few laboratory tests are needed. In addition to the undetectable serum TSH, an elevated free T_4 (or free T_4 index) and the presence of TSHrAb (either TBII or TSI) substantiate the clinical diagnosis. When antithyroid drugs are selected as therapy, a baseline complete blood cell count with differential white blood count should be obtained: leukopenia occurs in untreated thyrotoxicosis and granulocytopenia is an occasional toxic reaction to antithyroid drugs.

In less severe presentations, however, further laboratory tests may be necessary. Serum T_3 levels will be elevated in nearly all patients with Graves' disease. Measurement of serum total and/or free T_3 levels can be useful in the occasional patient with early Graves' disease who presents with an undetectable TSH but a normal serum free T_4 level.

For the patient who presents with symptoms of thyrotoxicosis and a firm, mildly tender, asymmetric goiter, the radioiodine uptake (RAI-U; Table 5) can differentiate Graves' disease from either the toxic thyroiditis of Hashimoto's disease or subacute thyroiditis (128, 129). Fur-

Table 5 Classification of Thyrotoxicosis by Radioiodine Uptake (RAI-U)

RAI-U usually elevated:
Graves' disease
Toxic adenoma
Toxic multinodular goiter
Familial nonautoimmune hyperthyroidism
TSH-induced hyperthyroidism
Trophoblastic disease
RAI-U typically low:
Subacute thyroiditis
Toxic thyroiditis of Hashimoto's disease
Thyrotoxicosis factitia
Iodine-induced hyperthyroidism
Metastatic thyroid carcinoma

thermore, the RAI-U also can help to differentiate Graves' disease from thyrotoxicosis factitia.

Graves' disease is the most common cause of thyrotoxicosis during pregnancy (4). However in the pregnant adolescent with mild symptoms of thyrotoxicosis and a normal to slightly enlarged thyroid gland, the possibility of hCG-mediated hyperthyroidism should be considered. Biochemical and clinical hyperthyroidism can occur when serum hCG levels exceed 100,000–300,000 IU/l (4).

TSHrAb and autoantibodies to thyroglobulin and/or thyroid peroxidase are present in the majority of patients with Graves' disease and reflect the autoimmune nature of the disorder. However, none of these autoantibodies is specific to Graves' disease. Although almost all hyperthyroid patients with serum TSHrAb will have Graves' disease, these antibodies also can be detected in patients with Hashimoto's thyroiditis (27, 46, 47) and in patients with subacute thyroiditis (130). Thyroglobulin and/or thyroid peroxidase antibodies are present in the majority of patients with Hashimoto's thyroiditis (131) and have been reported in several patients with subacute thyroiditis (130, 132) and a few patients with familial nonautoimmune hyperthyroidism (88). Therefore, by themselves, none of these antibodies should be considered as absolute proof of Graves' disease in patients with thyrotoxicosis.

Several studies have suggested that the recently cloned and characterized Na^+/I^- symporter (NIS) may represent an important autoantigen in Graves' disease (133). Although earlier studies (based on relatively small sample sizes) suggested that NIS autoantibodies might be present in up to 60–80% of Graves' sera (133), a more recent study evaluating 177 Graves' sera found these antibodies in only 5–10% of the samples (134). Furthermore, NIS antibodies also are present in 15–20% of sera from patients with Hashimoto's thyroiditis (133, 134). At present, the functional roles, if any, that these antibodies play in either Graves' disease or Hashimoto's disease remain unclear. Although assays are not yet available for

routine clinical use, based on current data, the measurement of NIS antibodies does not appear to offer any additional diagnostic benefit for patients with Graves' disease.

More detailed discussions of clinical features and laboratory studies that can be used to evaluate patients with other causes of thyrotoxicosis and to differentiate these disorders from Graves' disease are presented in the appropriate subsections of this chapter.

XII. PROGNOSIS AND TREATMENT

A. Introduction and Overview

The clinical course of Graves' disease is variable and unpredictable. However, the hyperthyroidism in untreated Graves' disease usually persists and progresses unless the thyroid gland has limited responsiveness as a result of coexisting chronic lymphocytic thyroiditis. Therefore, therapeutic intervention is recommended for all patients with active Graves' disease. Despite recent advances in our knowledge of the TSH receptor and TSHrAbs, none of the currently available treatments is specifically directed against the underlying immunological abnormality that causes Graves' disease. The three acceptable methods of therapy (antithyroid drugs, radioiodine ablation, and subtotal/total thyroidectomy) merely interrupt the disease process at the level of the thyroid gland, although treatment with thioureas has been reported to reduce levels of TSHrAb (135).

The treatment of Graves' disease in children and adolescents remains controversial. Although all three therapeutic modalities represent effective treatments for Graves' hyperthyroidism, each has specific advantages and disadvantages that should be addressed when individual treatment plans are developed for affected individuals. The antithyroid drugs are generally well tolerated, their inhibitory effects on the thyroid are completely reversible, and some patients treated with them will achieve long-term or permanent remission (136). Therefore, antithyroid drug treatment will allow some children to avoid surgery or exposure to radioiodine. However, antithyroid drugs usually take 4–8 weeks initially to control hyperthyroidism, and a treatment period of several years is typically required to achieve a long-term remission. During this prolonged treatment period, noncompliance and drug toxicity (Table 6) can complicate patient management. Furthermore, relapse of hyperthyroidism frequently occurs following discontinuation of therapy (136). As yet, no reliable clinical, biochemical, immunological or genetic factors have been identified that allow absolute prediction of those patients likely to do well, or poorly, in achieving long-term remission with antithyroid drug therapy (137).

Radioiodine (RAI) represents the easiest form of treatment, and the majority of patients can be successfully treated with a single oral dose (136). However, RAI ther-

Table 6 Toxic Side Effects of Antithyroid Drug Therapy

Elevated liver enzymes	Nausea, abdominal discomfort
Granulocytopenia	Edema
Dermatitis, urticaria	Conjunctivitis
Arthralgia, arthritis	Thrombocytopenia
Lupus-like syndrome	Hypoprothrombinemia
Lymphadenopathy	Toxic psychosis
Peripheral neuritis	Sensorineural hearing loss
Fever	Loss of taste sensation
Hepatitis	Disseminated intravascular coagulation

apy is absolutely contraindicated during pregnancy and breastfeeding (137). Although hospitalization is not required, patients receiving RAI are usually advised to limit close contact with others and properly dispose of their urine for several days following treatment. RAI therapy is also slow to control hyperthyroidism; it usually takes 6–18 weeks to have its full effects on the thyroid. Some patients may require multiple doses of RAI to treat their disease adequately. Although RAI is generally well tolerated, radiation thyroiditis may occur. This is characterized by a transient increase in serum thyroid hormone levels with, occasionally, a worsening of hyperthyroid symptoms and thyroid gland tenderness. With ablative dosages, the thyroid gland will shrink and hypothyroidism will occur in the majority of patients. In rare cases parathyroid dysfunction may develop after RAI therapy (138). Concerns regarding the potential long-term carcinogenic and genetic risks of RAI in children/adolescents continue to linger (136).

Surgical therapy represents the most rapidly effective form of treatment. Following at least 10–14 days of preoperative preparation with antithyroid drugs, stable iodine (e.g., SSKI or Lugol's solution), and β -adrenergic blockers, either subtotal or total thyroidectomy can be performed. Both are complicated procedures, and the long-term cure rates and the incidence of complications depend in large part on the skill and experience of the surgeon. Due to the continued reliance on antithyroid drugs and the increasing acceptance of RAI as primary therapies for juvenile Graves' disease, clinicians now infrequently recommend surgery for children with Graves' disease. However, clinical indications for surgical therapy still exist. These include the patient with a very large goiter; the patient who fails to respond to medical treatment and refuses RAI; the very young patient (i.e., <5 years old) who fails to respond to medical management; the pregnant patient with moderate to severe hyperthyroidism uncontrolled by medical treatment; and the patient with Graves' disease who develops a solid cold thyroid nodule that raises the suspicion of thyroid carcinoma (11, 136–139). Hypothyroidism occurs in 60–~100% of children undergoing subtotal and total thyroidectomy, respectively (136).

Hyperthyroidism recurs in 10–15% of patients following subtotal thyroidectomy, but in fewer than 3% of children who undergo total thyroidectomy (136). Potential surgical complications include pain, hemorrhage/hematoma, transient hypocalcemia, transient hoarseness, temporary tracheostomy, permanent hypoparathyroidism, vocal cord paralysis, keloid formation, and death (136).

Regardless of the modality ultimately used for the treatment of Graves' hyperthyroidism, patients will require long-term regular medical follow-up. Thyroid function studies will need to be monitored on a regular basis to aid in maintenance of the euthyroid state. Patients will need to be treated and/or observed for other associated autoimmune disorders that may potentially accompany Graves' disease. Patients will also need to be monitored for the potential occurrence of thyroid tumors and any long-term consequences that may be associated with the preceding treatment(s) for hyperthyroidism.

A recent study in adults showed that despite successful treatment of Graves' hyperthyroidism and a return to the euthyroid state, some patients will continue to exhibit symptoms of physical, emotional, and neuropsychological illness (140). Anxiety, depression, lack of energy, sleep disturbance, emotional lability, impaired memory, and forgetfulness are some of the difficulties experienced by patients who had remained euthyroid for more than a year (140). Other studies have demonstrated cognitive deficits in hyperthyroid adults in remission (141, 142). It has been proposed that these impairments represent residual sequelae of elevated thyroid hormone levels on the brain (140). Although similar studies involving children or adolescents have not been published, it is highly likely that some previously hyperthyroid children and adolescents, despite a return to euthyroidism, also suffer from these or similar problems. Therefore, as part of the regular medical follow-up, previously hyperthyroid children and adolescents should be monitored for behavioral, emotional, and learning or other neuropsychological problems. Appropriate counseling and support services should be offered as necessary.

Discussions regarding specific treatments for other causes of thyrotoxicosis are presented in the appropriate subsections of this chapter.

B. β -Adrenergic Blocking Agents

From the preceding discussion, it is clear that each of the currently acceptable treatment options carries a lag time between the onset of therapy and the control of hyperthyroidism. This lag time ranges from as short as 10–14 days for surgery to as long as several weeks to months for both antithyroid drug and radioiodine treatments. β -Adrenergic blockade with either propranolol or atenolol represents an important and very effective adjunctive therapy for the rapid control of adrenergic symptoms during the thyrotoxic course of the disease. These drugs should not be used alone for long-term management of hyperthyroidism

in children, because they do not significantly affect thyroid hormone secretion or correct the abnormal increases in metabolic rate and oxygen consumption (143). However, both propranolol (10–20 mg every 6–8 h) and atenolol (25–50 mg once or twice daily) are effective in controlling the distressing symptoms and signs of restlessness, tachycardia, heat intolerance, tremor, hyperhidrosis, diarrhea, and myopathy. In addition, propranolol (but not atenolol) reduces conversion of T_4 to T_3 by inhibiting the 5'-deiodination pathway, thus producing some decrease in serum T_3 levels (143). The dosages of these medicines should be adjusted over time to return the pulse rate to normal. β -Adrenergic blocking agents should be avoided or used very cautiously in patients with a history of asthma, hypoglycemia (including patients with insulin-dependent diabetes mellitus), heart block, or heart failure (144). Atenolol, in relatively small dosages, represents the safer choice in hyperthyroid patients with a history of asthma and hypoglycemia, because it is more cardioselective (i.e., β_1 -adrenergic receptor specific) than propranolol (144). Neither drug should be discontinued abruptly, since symptoms and signs of hyperthyroidism may acutely worsen. Instead, the dosage should be decreased gradually over several days before being stopped.

C. Antithyroid Drug Therapy

The antithyroid drugs for long-term therapy of children in the United States include propylthiouracil (PTU) and methimazole (MMI). In addition to these two agents, a methimazole derivative, carbimazole, is available in Europe (145). These drugs block the incorporation of oxidized iodide into tyrosine residues of thyroglobulin by serving as substrates for thyroid peroxidase. The drugs are iodinated and degraded within the gland, thus diverting oxidized iodide away from thyroglobulin (146). Furthermore, they block the coupling of iodotyrosyl residues in thyroglobulin to form T_4 and T_3 . They do not interfere with the thyroid gland's ability to concentrate iodide, nor do they block the release of stored thyroid hormone into the circulation (146). Because they do not block the release of preformed, stored thyroid hormones, most patients will require 4–8 weeks of antithyroid drug therapy before a euthyroid state is achieved. PTU, but not methimazole or carbimazole, also inhibits the peripheral conversion of T_4 to T_3 (146). Because of this, many clinicians tend to use PTU initially in patients with more severe hyperthyroidism.

In addition to their direct effects on thyroid hormone synthesis, the thioureas also may have immunosuppressive activity. Several investigators have reported significant reductions in circulating TSHrAbs during antithyroid drug treatment (135, 147). Some studies suggest that thioureas have direct effects on thyroid autoantibody-producing lymphocytes, whereas others suggest that these drugs primarily act by reducing the antigenicity of thyrocytes (147).

MMI has a longer half-life (12–16 h vs. 4–6 h), and, on a weight basis, is about 10-fold more potent than PTU (136). To control hyperthyroidism initially, PTU is given every 6–8 h, whereas MMI can be given every 8–12 h; after 3–4 weeks of therapy, dosing of MMI usually can be changed to once or twice a day (136, 137). For patients with moderate to severe hyperthyroidism, the recommended starting dosages for PTU and MMI are 5–10 mg/kg/day and 0.5–1.0 mg/kg/day, respectively. In patients with mild hyperthyroidism, lower dosages of antithyroid drugs may be effective. Once clinical and biochemical euthyroidism have been achieved, maintenance therapy may proceed by either of two methods: reduce the dosage by one-third to one-half to maintain thyroid hormone levels in the normal range; or continue the initial therapeutic dosage to induce hypothyroidism, and initiate replacement L-thyroxine therapy. The latter method is preferred by many clinicians for children because euthyroidism seems easier to maintain, and it involves fewer clinic visits for monitoring of thyroid function. Although a study from Japan demonstrated that the combined use of antithyroid drugs and L-thyroxine decreased the incidence of relapse in adult patients (148), several recent studies from around the world have been unable to reproduce this finding (149–151).

After 1–3 years of therapy, the medication is either slowly tapered or a T₃ suppression of serum T₄ using exogenous doses of oral T₃ (1.5 µg/kg/day in three divided doses) can be performed (46). The administration of exogenous T₃ for 3 weeks to normal children or patients in remission with Graves' disease will cause a decrease in the serum T₄ concentration to values below the normal range. The test is performed as follows:

1. While the patient is still receiving the antithyroid drug, T₃ is started at the dosage listed above. L-thyroxine therapy must be discontinued in those patients on combined therapy.
2. Three weeks later, serum T₄ and free T₄ levels are evaluated.
 - a. If the results are normal or elevated, antithyroid drug therapy is continued.
 - b. If the results are below normal, discontinue the antithyroid drug and exogenous T₃ therapy.
3. One or two weeks later, repeat the serum T₄ values.
 - a. If normal or elevated, resume antithyroid drug therapy.
 - b. If the serum T₄ values are low, discontinue T₃ therapy and monitor serum T₄ and T₃ levels at 3 month intervals for the next year and annually thereafter. If relapse occurs, antithyroid therapy may be resumed, or the patient may be offered the choice of surgical or radioiodine therapy (9).

In adults, the presence of TSHrAb during antithyroid drug therapy may be associated with clinical relapse of disease on termination of therapy (40). Studies have shown that patients (adults and children) with negative TSHrAb values during antithyroid drug therapy remain in remission after cessation of therapy (46, 152). One study in children with Graves' disease compared TSHrAb values and the clinical course with results of the T₃ suppression tests (46). TSHrAb values correctly predicted the subsequent clinical course in 72%, and the T₃ suppression tests accurately predicted the course in 64% of patients. Furthermore, the TSHrAb values and the T₃ suppression tests were in agreement 75% of the time. This study suggests that TSHrAb values are as effective as T₃ suppression tests in determining when antithyroid drug therapy can be discontinued. However, both tests are limited in their ability to predict accurately the clinical course of the disease, and patients will continue to require periodic clinical evaluations and laboratory assessment after discontinuation of antithyroid drug therapy.

The major disadvantages of antithyroid drug therapy are prolonged duration of therapy required to achieve a long-term remission, high relapse rate following cessation of therapy, and the risk of toxic side effects (9, 136, 146). In children, long-term remission rates are at best 50–60% after several years of drug therapy and are usually less than 20–40% (136, 153). Furthermore, remission rates following antithyroid drug therapy are considerably less in prepubertal than in pubertal children (154). A recent study has demonstrated that the severity of hyperthyroidism at diagnosis, as determined by multiple clinical and laboratory variables, is important in predicting remission within two years of therapy (155). Specifically, this study found that within 2 years of treatment, patients with a minimal/small goiter and a body mass index score above –0.5 SD at time of initial diagnosis had a probability of 86% of achieving remission for at least 6 months, compared with only 13% for those with a moderate/large goiter and BMI below –0.5 SD (155). Other studies have shown that high levels of TSI at the time of diagnosis are associated with decreased long-term remission rates (156, 157). A recent study showed that elevated serum IgE levels following 18 months of MMI therapy are associated with lower rates of remission (158). Although none of these factors can predict with absolute certainty which patients will achieve long-term remission with antithyroid drugs, they may be helpful in selecting specific treatment plans for individual patients.

Side effects of antithyroid drugs occur in up to 20–30% of treated children and may be either idiosyncratic or dose related (136). The majority of side effects are mild and include elevated liver enzyme levels, mild leukopenia, skin rashes, and mild gastrointestinal symptoms such as nausea. In the case of mild side effects, complications may resolve after switching to an alternative antithyroid drug. Fortunately, more serious side effects are either uncom-

mon or rare. When a patient reports any serious toxic effect with antithyroid drugs, therapy must be stopped immediately, and the patient should be evaluated. The occurrence of serious side effects necessitates discontinuation of all antithyroid drugs, and an alternative mode of therapy (i.e., radioiodine or surgery) must be selected for subsequent treatment. Although very rare, the most serious complication of antithyroid drug treatment is agranulocytosis. Patients should have a complete blood count performed if sore throat, fever, or mouth ulcers occur. Treatment of agranulocytosis consists of complete discontinuation of the antithyroid drug, hospitalization for monitoring, and treatment with a broad-spectrum antibiotic (11). A recent randomized trial in adults found no benefit of granulocyte colony-stimulating factor (159). Another rare complication is drug-induced hepatitis; cholestatic hepatitis is typically associated with MMI use, whereas cytotoxic hepatitis tends to occur with PTU. In either case, antithyroid drugs must be stopped immediately, and administration of glucocorticoids may hasten recovery (136).

D. Radioiodine Therapy

Although still controversial, RAI therapy is becoming more acceptable for the treatment of juvenile Graves' disease as long-term experience with its use accumulates (136, 139, 149, 160, 161). RAI is administered as an oral solution or capsule containing Na ¹³¹I. After absorption through the gastrointestinal tract, it is concentrated into the thyroid gland and organified. β -Emissions from the ¹³¹I result in extensive tissue damage; histological findings after RAI therapy are consistent with acute inflammation and include epithelial swelling and necrosis, edema, and leukocyte infiltration (136). Within 4–10 days after RAI administration, serum levels of thyroid hormones may rise as a result of thyroid hormone release from degenerating follicular cells (162). The acute inflammatory phase is subsequently followed by extensive fibrosis and ablation of the thyroid gland within 6–18 weeks (145).

RAI may be used as either first- or second-line therapy in children/adolescents with Graves' disease. Because RAI is absolutely contraindicated during pregnancy, a pregnancy test must be obtained in the adolescent before proceeding with RAI therapy. The authors consider RAI therapy to represent a definitive method for control of Graves' hyperthyroidism, and, therefore, recommend that it be used in ablative dosages. When used as first-line therapy in patients with mild to moderate hyperthyroidism, a preceding course of antithyroid drugs is generally not necessary. β -Adrenergic-blocking agents can be used both before and after RAI administration to relieve thyrotoxic symptoms until the gland has been ablated. However, for the patient with severe hyperthyroidism, some clinicians recommend a 4–8 week course of antithyroid drugs to reduce the severity of hyperthyroidism before RAI is administered (11). In these patients, and in those

who have been receiving antithyroid drugs as first-line therapy prior to RAI ablation, the antithyroid drugs should be stopped at least 4–7 days before RAI is administered (136, 139).

Prior treatment with PTU, even when discontinued for several days before RAI dosing, reduces the effectiveness of RAI therapy (163); this should be considered when determining the therapeutic dosage of RAI (163). Conversely, MMI appears to have very little or no effect on the success of RAI therapy when discontinued at least 3–4 days prior to RAI dosing (163, 164). Again, β -adrenergic blocking agents are used both before and after RAI administration to control symptoms of hyperthyroidism. Occasionally after RAI therapy, thyrotoxic symptoms cannot be adequately controlled with β -adrenergic blockers alone. In this situation, either antithyroid drugs or concentrated iodide solutions (SSKI or Lugol's solution) may be used until RAI takes effect (136). The use of a concentrated iodide solution (e.g., SSKI, 5–6 drops by mouth daily) beginning 7 days after administration of RAI has been shown to treat thyrotoxicosis effectively more rapidly than ¹³¹I alone without adversely affecting the outcome of RAI therapy (165). A single ablative dose of RAI (i.e., 150–200 μ Ci ¹³¹I/g thyroid tissue) will successfully treat hyperthyroidism in the majority of patients within 6–18 weeks (136, 145). Some patients will require more than one dose of RAI to treat their hyperthyroidism. Repeat doses of RAI can be given at intervals of 2–6 months if hyperthyroidism persists beyond the first treatment (136).

Acute complications following RAI therapy are uncommon and tend to be mild. Radiation thyroiditis with mild pain over the gland may occur within the first 3–5 days and can generally be relieved with nonsteroidal anti-inflammatory agents. Symptoms of hyperthyroidism may worsen temporarily during the first 2 weeks due to the release of preformed thyroid hormones from degenerating follicular cells. Typically, these symptoms can be controlled with the β -adrenergic blocking drugs. In rare cases, thyroid storm can occur after RAI treatment (62, 63, 136).

Although there is some concern in adult patients regarding progression of ophthalmopathy following RAI, there is currently no evidence to support that RAI promotes progression of eye disease in children (136, 139). Current studies suggest that eye disease may worsen in 3–5% of children with Graves' ophthalmopathy after RAI. However, this rate of progression is very similar to the rates observed in children undergoing either antithyroid drug or surgical therapy (136). Parathyroid dysfunction may occur in rare cases after RAI therapy (136, 138). Up to 90% or more of patients who receive ablative doses of RAI will eventually develop primary hypothyroidism (136, 139). Thyroid function tests should be monitored every 2–3 months after RAI, so that thyroid hormone replacement can be started before the onset of clinical symptoms.

The reluctance of clinicians to recommend RAI as first-line therapy has traditionally stemmed from the theoretical possibility of increased risk for subsequent thyroid tumors (both malignant and benign), other nonthyroid malignancies, infertility, and genetic defects among progeny (160). Patients with Graves' disease have a higher incidence of thyroid tumors than the general population (136). However, Graves' patients receiving RAI appear to have lower rates of thyroid cancer than those receiving long-term antithyroid drug therapy; this most likely is explained by the presence of more thyroid tissue in patients treated with drugs than in those treated with RAI (136). Currently available studies involving the long-term follow-up (from <5 years to about 20 years) of ~1000 children and adolescents who received RAI therapy for hyperthyroidism have not revealed an increased risk of thyroid malignancy (136). Although an increased incidence of benign thyroid adenoma has been observed in children treated with low-dosage RAI (50 μCi $^{131}\text{I}/\text{g}$ thyroid tissue) (166), the incidence of thyroid adenoma is not increased when higher dosages (100–200 $\mu\text{Ci}/\text{g}$) are used (166). There is currently no evidence for an increased risk of leukemia. With the possible exception of a small increase in the incidence of stomach cancer, there is currently no evidence for an increased risk of other nonthyroid malignancies in adults who have received RAI (136). However, a comprehensive follow-up study of nonthyroid cancer risks has not yet been performed for children treated with RAI. There is no evidence for decreased fertility in patients who have received RAI, and the incidence of congenital anomalies among the offspring of patients treated with RAI is not different from that observed in the general population (136).

Based on current experience and knowledge, RAI represents a convenient, effective, and apparently relatively safe therapeutic option for childhood Graves' disease. After considering that antithyroid drug therapy is associated with disappointingly low long-term remission rates despite prolonged therapy and relatively high rates of adverse side effects, it is easy to understand why RAI is becoming more acceptable for the treatment of childhood Graves' disease. However, RAI is absolutely contraindicated during pregnancy and breastfeeding. ^{131}I readily crosses the placenta, and if administered to a pregnant female after 10–12 weeks' gestation, it will be concentrated by the fetal thyroid gland. This can result in ablation of the fetal thyroid and subsequent fetal hypothyroidism (139). RAI should probably be avoided in children less than 5 years old because experience with RAI is currently quite limited in this age group, and the risks of thyroid cancer after external irradiation are highest in children less than 5 years of age (136).

Thyromegaly

John S. Dallas

University of Texas Medical Branch—Galveston, Galveston, Texas, U.S.A.

Thomas P. Foley, Jr.

University of Pittsburgh and Children's Hospital of Pittsburgh, Pittsburgh, Pennsylvania, U.S.A.

I. INTRODUCTION

Thyromegaly, or goiter, is a common clinical disorder during childhood and adolescence. Prospective studies in the United States and Japan have shown that thyromegaly may occur in up to 6% of school-aged children (1–3). A child may present with either diffuse or nodular thyromegaly, and the enlargement can be either symmetrical or asymmetrical. In 1960, the World Health Organization (WHO) established criteria for determining goiter prevalence. According to these criteria, diffuse thyromegaly was present in a child if the lateral lobes of the gland were larger than the terminal phalanx of the child's thumb (4). In 1994, WHO revised and simplified its classification criteria and defined goiter as any enlarged thyroid that is palpable and/or visible (5). A nodular thyroid contains at least one solid or cystic mass that has a consistency different from the remainder of the gland. Thyromegaly usually occurs during adolescence with a female to male predominance (6).

II. PATHOGENESIS

Enlargement of the thyroid gland may occur as a result of stimulation, infiltration, and/or inflammation of the gland (6) (Table 1). Stimulation of follicular cell growth, either hyperplasia or hypertrophy, can be mediated by thyroid-stimulating hormone (TSH), various thyrotropin receptor antibodies (TSHrAb), and other growth factors (7–10). Increased TSH secretion is usually the result of an alteration in the production, release, or the metabolism of the major thyroid hormones, T_4 and T_3 . In rare cases, increased TSH secretion results from a TSH-producing pituitary adenoma or from pituitary resistance to thyroid

hormone; in these conditions, the patient presents with mild to moderate thyromegaly, normal to elevated serum levels of TSH, and elevated serum levels of total and free T_4 and T_3 .

A variety of TSHrAbs have been identified in patients with autoimmune thyroid disease, and some of these antibodies stimulate both thyroid function and growth through interaction with TSH receptors on the follicular cell membrane (7–9). Several reports have provided evidence for IgG antibodies, referred to as thyroid growth-stimulating antibodies (TGAb), that may be found in sera from patients with a variety of thyroid disorders, including Graves' disease, Hashimoto's thyroiditis, sporadic nontoxic (simple) goiter, and endemic goiter due to iodine deficiency (10–14). It is assumed that these IgG bind to either the TSH receptor or some other follicular cell membrane structure to promote thyroid cell growth without affecting thyroid cell function. However, other reports either have failed to demonstrate the presence of TGAb in patients with some of these thyroid disorders or have challenged the concept of specific IgG that bind to the TSH receptor and stimulate cellular growth without affecting thyroid cell function (13, 15, 16). Therefore, further studies will be required to define fully the specific nature of these so-called TGAb and their exact role in goitrogenesis.

Infiltration of the thyroid gland may occur from a neoplastic (i.e., adenoma or carcinoma) or a nonneoplastic (i.e., cyst) process. During childhood, a thyroid neoplasm, whether benign or malignant, usually presents as an isolated nodule in the thyroid gland. In rare cases, thyromegaly is found in patients with histiocytosis X or lymphoma because of cellular infiltration of the gland (17).

Although a variety of infectious agents (bacterial, viral, fungal) can cause acute or subacute inflammation and

Noninfection: lymphocytic (autoimmune)

enlargement of the thyroid gland, infectious thyroiditis rarely occurs during childhood (6). However, Hashimoto's disease, the goitrous form of chronic autoimmune thyroiditis, is the most common cause of thyromegaly during childhood in nonendemic goiter regions of the world (1–3, 10). In this disease, lymphocytic infiltration of the thyroid may be diffuse and cause generalized enlargement of one or both lobes, or may be localized and cause nodular enlargement of the gland (6). The latter entity may be difficult to differentiate from tumors of the thyroid gland.

Disorders associated with thyromegaly during childhood can be classified depending on whether thyromegaly is diffuse or nodular (Table 2). Since the child initially presents for evaluation based upon the physical examination of the thyroid gland, the differential diagnosis and laboratory investigation should be considered according to clinical symptoms and physical characteristics of the gland and the surrounding structures in the neck.

III. AUTOIMMUNE THYROID DISEASE: THYROIDITIS

A. Pathogenesis

Recent advances in immunology have led to a greater understanding of the basic abnormalities in the cellular and humoral immune systems that result in autoimmune thyroid diseases. In patients with Graves' disease the immune defect results in the production of immunoglobulin G (IgG) antibodies to the TSH receptor. These antibodies bind to and stimulate the TSH receptor to cause an increase in function and size of the thyroid gland. These effects are responsible for the clinical findings of thyro-

Table 2 Causes of Thyromegaly

Diffuse thyromegaly

toxicosis and goiter in patients with Graves' disease (9). The pathogenesis of Graves' disease is discussed in detail in Chapter 16.

In chronic lymphocytic thyroiditis, the autoimmune process is believed to begin with activation of CD4⁺ (helper) T lymphocytes specific for thyroid antigens (18). The mechanisms responsible for T-lymphocyte activation remain unclear. One hypothesis, based on the immunological concept of molecular mimicry, proposes that infection with a virus or bacterium that contains a protein similar to a thyroid protein may lead to activation of thyroid-specific T cells (18). An alternative hypothesis states that thyroid follicular cells present their own intracellular proteins through major histocompatibility complex (MHC) class II proteins to helper T cells (18). These MHC class II proteins (human leukocyte antigen [HLA]-DR, -DP, and -DQ) are required for antigen presentation to CD4⁺ T cells. Studies have demonstrated that thyroid cells from patients with autoimmune thyroiditis, but not normal cells, express MHC class II proteins (19). In addition, certain cytokine products of activated T cells, such as interferon gamma, can induce the expression of MHC class II molecules by thyroid cells (20). At present, there is evidence to support each of these hypotheses. However, neither appears to explain fully the mechanisms involved

Table 3 Spectrum of Thyroid Function in Autoimmune Thyroid Diseases

Clinical thyroid function	Free T ₄	T ₃	TSH	TSH response to TRH
Primary hypothyroidism	Low	Low or normal	Increased	Exaggerated
Compensated hypothyroidism	Normal	Normal	Increased	Exaggerated
Euthyroidism with decreased thyroid reserve	Normal	Normal	Normal	Exaggerated
Goitrous and nongoitrous euthyroidism	Normal	Normal	Normal	Normal
Nonsuppressible euthyroidism	Normal	Normal	Normal	Blunted
Thyrotoxicosis with limited thyroid reserve	Mildly increased	Increased	Undetectable	Absent
Thyrotoxic phase of thyroiditis	Increased	Increased	Undetectable	Absent
T ₃ thyrotoxicosis	Normal	Increased	Undetectable	Absent
Thyrotoxicosis	Increased	Increased	Undetectable	Absent

in initial T-lymphocyte activation; further studies will be required to define better the exact mechanisms involved.

Following activation, self-reactive CD4⁺ T cells recruit B lymphocytes as well as cytotoxic (CD8⁺) T lymphocytes into the thyroid gland. The B cells are stimulated by activated helper T cells to produce and secrete antibodies against various thyroid proteins. The three major target antigens for thyroid antibodies are thyroglobulin, thyroid peroxidase, and the TSH receptor.

Autoimmune destruction of thyroid follicular cells is characteristic of Hashimoto's thyroiditis. Current evidence supports that thyroid cell destruction primarily occurs through the process of apoptosis, or programmed cell death (21–23). Cytotoxic T lymphocytes (CTL) mediate thyroid cell destruction through two different mechanisms: CD4⁺ CTLs express so-called death ligands that bind to death receptors on target cells, thereby activating apoptotic pathways; and CD8⁺ CTLs release exocytotic granules that contain perforin (which perforates target cell membranes) and Granzyme B (which directly initiates the apoptosis cascade system at a postreceptor level) (21). Activated CD4⁺ CTLs have been shown to express functionally the death ligands referred to as tumor necrosis factor- α (TNF- α), Fas ligand (FasL), and TNF-related apoptosis-inducing ligand (TRAIL) (21–23). Furthermore, the Fas and TRAIL apoptotic pathways are present and functional in thyroid cells (21–23). In addition to these cellular mechanisms, complement-fixing cytotoxic antibodies and antibody dependent, cell-mediated cytotoxicity involving natural killer cells may also contribute to thyroid cell destruction (24). Although TSH receptor-blocking antibodies and cytokines may contribute to thyroid cell dysfunction, autoimmune destruction of follicular cells appears to be the primary cause of hypothyroidism in Hashimoto's thyroiditis (25).

Thyroid autoimmunity is familial. Up to 50% of the first-degree relatives of patients with chronic autoimmune thyroiditis have thyroid antibodies, apparently inherited as a dominant trait (18). Clinical Hashimoto's disease occurs in up to 33% of siblings of affected patients (26). The

prevalence of clinical Hashimoto's thyroiditis in the general population ranges from 1 to 4% (18, 26). Therefore, familial clustering of this disorder indicates that a significant genetic component exists in its origin. However, the genetic predisposition appears to be complex, possibly caused by a number of genes. At present, no conclusions regarding the number of involved genes can be made. The association of Hashimoto's thyroiditis with Down and Turner syndromes suggests that part of the genetic susceptibility to this disease may reside on chromosomes 21 and X (18, 26). Association studies have revealed weak associations between Hashimoto's thyroiditis and HLA (e.g., DR3, DR4, DR5 and DQ7) and the cytotoxic T lymphocyte antigen 4 (CTLA-4) genes (18, 26). Although these associations provide evidence that HLA and CTLA-4 gene variations increase the risk for Hashimoto's thyroiditis, they are not the sole determinants of the genetic predisposition. Linkage analysis studies have identified regions on chromosomes 6p (marker D6S257), 12q11–12, and 13q32–34 that may represent susceptibility loci for Hashimoto's thyroiditis (26). More recently, strong evidence has been reported showing that chromosome 8q24 represents a susceptibility gene for autoimmune thyroid disease (27). This locus contains the thyroglobulin gene and has been linked and associated with autoimmune thyroid disease. Therefore, polymorphisms in the thyroglobulin gene may be involved in the causes of autoimmune thyroid disease. Unlike other potential susceptibility loci (e.g., CLTA-4) involved in immune regulation, thyroglobulin is a thyroid-specific gene, and this may help to explain why the thyroid gland becomes the target of an autoimmune response (27). Further studies are needed to confirm these preliminary findings and to identify other susceptibility loci within the human genome.

Environmental factors also play a role in the development of chronic autoimmune thyroiditis. Recent studies have suggested that the prevalence of autoimmune thyroiditis in children has been increasing over the past 25–30 years (28, 29). The reason(s) for this increasing prevalence remains unclear. Some have hypothesized that a

decrease in exposure to infection in early life may play a role (28). Excessive iodine intake also appears to be involved. The prevalence of chronic autoimmune thyroiditis is correlated with iodine intake, with the highest prevalences in the countries with the highest intake of iodine, such as the United States and Japan (18). Furthermore, iodine supplementation in areas of iodine deficiency increases the prevalence of lymphocytic infiltration of the thyroid threefold (30). An association has been reported between feeding soy formulas to infants and the development of autoimmune thyroid disease in later childhood (31). The potential role(s) that other chemicals and dietary goitrogens may play in autoimmune thyroid disease remains to be determined.

B. Chronic Lymphocytic Thyroiditis of Childhood and Adolescence

1. Classification

The autoimmune-mediated mechanisms cause histological changes in the thyroid that are the basis for the classification of the disease during childhood. These mechanisms result in the characteristic histological abnormalities of lymphocytic infiltration and lymphoid follicles of juvenile Hashimoto's disease. However, the usual histological appearance during childhood and adolescence is follicular cell hyperplasia and minimal fibrosis (6). The fibrous variant of the disease is characterized by epithelial destruction and fibrosis (6).

2. Clinical Manifestations

Most patients with Hashimoto's thyroiditis present with an asymptomatic enlargement of the thyroid gland, but an occasional patient may complain of pain or a sensation of fullness in the area of the thyroid. Less often the disease manifests clinically with deceleration of linear growth and other clinical features associated with hypothyroidism during childhood (see Chap. 15). In rare cases, the child with thyroiditis presents initially with symptoms and signs of thyrotoxicosis; this transient phase of thyrotoxicosis occurs early in the course of autoimmune thyroiditis (toxic thyroiditis) and presents as a mild disease without exophthalmos. Whereas thyrotoxicosis of Graves' disease results from overproduction and secretion of thyroid hormones due to TSHrAb stimulation of TSH receptors, the thyrotoxicosis of toxic thyroiditis results from release of excessive amounts of preformed thyroid hormones due to inflammatory destruction of thyroid follicular cells. These two disorders may be difficult to differentiate based on clinical criteria alone unless the exophthalmos of Graves' disease is present, or thyroid-stimulating antibodies are detected in serum.

On examination, the thyroid gland is either symmetrically or asymmetrically enlarged and usually nontender and firm in consistency. The surface texture may be finely granular (seedy) or discretely nodular (pebbly, crenated).

Lymphoid follicles may be palpable as single or multiple nodules within one or both lobes of the gland. The gland should move freely with swallowing and should not be affixed to adjacent tissues. Nontender regional lymphadenopathy may be present (6).

Autoimmune thyroiditis frequently occurs in patients with other autoimmune diseases, particularly insulin-dependent diabetes mellitus (IDDM) (32, 33), but also Addison's disease, alopecia, vitiligo, myasthenia gravis, ulcerative colitis, pernicious anemia and the collagen vascular diseases (18, 34, 35). Chronic urticaria with or without angioedema (CUA) and Hashimoto's encephalopathy (HE) represent two additional presumed autoimmune conditions associated with chronic autoimmune thyroiditis (36–38). The majority of reported patients have had Hashimoto's thyroiditis, but both conditions can also occur in association with Graves' disease (39, 40). Both represent potentially life-threatening illnesses that can occur in adults and children. The pathogenic mechanisms linking these disorders to autoimmune thyroid disease remain unclear. Abnormal thyroid hormone levels do not account for either condition. Although some reported patients have had either hypo- or hyperthyroidism, the majority of affected individuals have been euthyroid. Usually these conditions occur in patients with existing serological or clinical evidence of autoimmune thyroid disease. However, a few patients have been described in whom thyroid antibody levels were negative at initial presentation, but then became positive several months to a few years later (39, 41). Both conditions exhibit a strong female to male preponderance.

Urticaria is a well-demarcated skin reaction characterized by edema involving the superficial portion of the dermis (42). Lesions are raised and erythematous and usually pruritic. Angioedema differs from urticaria in that the edematous process is located in the deep dermis and subcutaneous or submucosal tissues (42). Lesions tend to be more painful than pruritic. The involvement of the upper respiratory tract may result in severe and sometimes fatal complications. Chronic urticaria, defined as recurrent episodes of hives with or without angioedema of at least 6 weeks duration, is a relatively common disorder for which the cause is rarely determined (36).

Clinical studies have demonstrated that 10–15% of patients with idiopathic CUA have serological and/or clinical evidence of autoimmune thyroid disease (36, 37). These patients have been as young as 8 years old (range, 8–72 years), and 80–90% have been female (36, 37). Almost all patients have had elevated levels of thyroid antibodies at presentation; thyroid peroxidase or microsomal antibodies have been detected more commonly than thyroglobulin antibodies. Current evidence supports the finding that thyroid antibodies are not directly responsible for the skin lesions, since their levels do not correlate with disease activity (43). The antibodies are most likely to serve as evidence for the underlying autoimmune process

in the affected patient. In some cases, L-thyroxine treatment in hypo- or euthyroid patients with autoimmune thyroiditis and refractory idiopathic CUA has resulted in full remission or marked improvement of CUA (36, 43, 44).

A recent study comparing two distinct groups of patients with CU, one group with CU of known cause and the other with idiopathic CU found the prevalence of elevated serum thyroid antibodies (33% vs. 23%, respectively) and of clinical thyroid disease in seropositive patients (39% vs 42%, respectively) to be similar for the groups (45). Therefore, it is recommended that thyroid function and thyroid antibody tests be performed in all patients with CUA. This will result in the diagnosis of existing or potential thyroid disease in some patients and will identify patients whose CUA may benefit from thyroid hormone therapy. Despite a euthyroid state, suppressive L-thyroxine therapy should be considered in all patients with severe CUA and evidence of autoimmune thyroid disease (43).

Hashimoto's encephalopathy represents a progressive or relapsing encephalopathy associated with autoimmune thyroid disease. It is a rare, but also underdiagnosed, condition (38). Since the diagnosis of autoimmune thyroid disease may not be realized or suspected in affected patients at presentation, a high degree of suspicion is required to make the diagnosis of HE. Many of the reported patients initially have been misdiagnosed as having a psychiatric disorder, such as depression, anxiety, or psychosis. HE should be considered and thyroid antibody levels checked in children and adults exhibiting unexplained neuropsychiatric deterioration. HE is a treatable form of encephalopathy; therefore, timely diagnosis will allow for appropriate intervention that can rapidly reverse clinical symptoms and prevent additional morbidity resulting from undiagnosed HE.

Most reported patients with HE have been adults, but children as young as 9 years of age have been described (46). Some 85–90% percent of reported patients have been female (38, 47, 48). Although there is some symptom overlap, two types of clinical presentation are observed: a vasculitic type, involving stroke-like episodes (e.g., hemiparesis, aphasia, and ataxia), and only mild cognitive impairment; and a diffuse progressive type, with insidious onset of dementia, seizures, hallucinations, psychotic episodes, or lethargy and coma (38). Myoclonus, tremors, and seizures may occur in both types (38). The majority of reported children/adolescents have presented with the diffuse progressive form, and most have had seizures (48). Generalized tonic-clonic followed by complex partial seizures, with or without secondary generalization, are the most common types of seizures associated with HE in children (48).

The pathogenesis of this encephalopathy remains unknown. Abnormal thyroid function does not appear to be responsible, since most reported patients have had normal results of thyroid function studies at presentation (38).

Current evidence supports an autoimmune basis for the disease, but the exact mechanism has not been determined. Some findings suggest an acute disseminated encephalomyelitis, while others favor a cerebral angiitis (49, 50). Although the vast majority of patients have elevated serum thyroid antibody levels at initial presentation, these antibodies are unlikely to be the cause of encephalopathy. There is no obvious correlation between the thyroid antibody levels and the type or severity of clinical presentation (38). The most likely explanation is that the thyroid antibodies serve as markers of an underlying autoimmune process.

No clinical, laboratory, or neuroimaging findings are specific for HE; therefore, other more common causes of encephalopathy (e.g., inflammatory, infectious, metabolic, toxic, vascular, neoplastic, and paraneoplastic) first must be considered and reasonably excluded (38). Elevated serum thyroid antibody (thyroid peroxidase and/or thyroglobulin antibodies) levels are necessary, but not sufficient, for making the diagnosis. The erythrocyte sedimentation rate may be mildly elevated. Cerebrospinal fluid (CSF) protein levels are elevated in the majority of patients, but CSF glucose levels are normal. A CSF mononuclear pleocytosis and oligoclonal bands may be present. Electroencephalography (EEG) is abnormal in more than 90% of cases (47). EEG findings can vary considerably over the course of the illness, and abnormalities are maximal during episodes of encephalopathy. The typical EEG shows generalized slowing or frontal rhythmic slowing followed by triphasic waves and periodic sharp waves; patients also can have focal temporal slowing (51, 52). Following successful treatment, the EEG shows improvement or normalizes (38). Neuroimaging studies are often normal but can reveal nonspecific findings. Mild cerebral atrophy and ventricular dilatation have been seen with CT. Magnetic resonance imaging (MRI) abnormalities include increased T₂ signals in the subcortical region, and, occasionally, more diffuse white matter abnormalities or a focal mesiotemporal abnormality may be seen (47, 52).

Most patients with HE respond dramatically to pharmacological glucocorticoid therapy. Daily prednisone therapy should be started at a high dosage (2–3 mg/kg/day in 2–3 divided doses) for 1 month and maintained at least at 1 mg/kg/day for another 2–4 months or until remission of symptoms, and then tapered slowly (38). Rapid improvement can occur over a few days, but the average time from start of therapy to significant clinical improvement is usually 4–6 weeks (38). Patients with hypothyroidism should also receive L-thyroxine replacement therapy; the potential role of L-thyroxine therapy in clinically euthyroid patients with HE is unknown. Although some patients with HE have experienced improvement with L-thyroxine treatment (50, 53), several case reports have demonstrated that L-thyroxine therapy, by itself, usually fails to correct the encephalopathy or prevent relapses (38). Anticonvulsants should be used to control status epi-

lepticus or recurrent episodes of myoclonus. Despite clinical improvement, thyroid antibody levels may remain elevated. Serial EEGs and neuropsychological testing can be used to monitor the response and length of therapy. The prognosis of HE when treated appears to be good; however, some children or adolescents may be left with long-term sequelae (e.g., residual cognitive deficits, recurrent seizures, progressive brain atrophy) despite early recognition and appropriate therapy (48).

3. Laboratory Evaluation

An elevated serum level of thyroid antibodies is the characteristic abnormality that permits a presumptive diagnosis of Hashimoto's thyroiditis. Thyroid peroxidase (formerly known as microsomal) and thyroglobulin antibodies are the two generally available thyroid antibody tests. Autoantibodies against thyroid peroxidase and thyroglobulin can be detected in 80–95% and in 30–60%, respectively, of patients with Hashimoto's thyroiditis (18, 54). Occasionally, a child with Hashimoto's thyroiditis will present with low or absent titers of thyroid antibodies, but, on repeat determinations 3–6 months later, the titers will be distinctly abnormal. Transient elevations of thyroid antibodies may occur during the course of other thyroid disorders (e.g., subacute thyroiditis), so a positive titer may not be indicative of chronic thyroiditis.

Although most children with autoimmune thyroiditis are clinically euthyroid, serum levels of TSH should be determined to exclude primary hypothyroidism. Additional studies may be needed for patients with an atypical clinical presentation. For the child with mild symptoms of hyperthyroidism, important initial tests include serum T_3 and TSHrAb determinations (6). In the child with hyperthyroidism, serum T_3 should be elevated unless the patient either is severely ill or has experienced very poor nutritional intake for several days prior to testing. Further diagnostic tests are needed infrequently. The [^{123}I]-iodide uptake test can be used to differentiate toxic thyroiditis from early Graves' disease and other causes of hyperthyroidism (55).

Ultrasonographic features in children with Hashimoto's thyroiditis are variable. In a recent report (56), the most common finding was thyromegaly with an increase in reflectivity compared to the adjacent muscle and widespread coarse echogenic areas. Another frequently observed pattern consists of an enlarged thyroid that is iso-reflective to muscle and coarse echo-poor lesions. Nodular areas larger than 5 mm in diameter are often observed and some of the nodules have small echogenic centers. The patchiness of the echo-poor regions tends to be a useful sign when differentiating diseased glands from normal. Another recent study found that reduced thyroid echogenicity is a valid predictor of autoimmune thyroid disease (both Hashimoto's thyroiditis and Graves' disease), with corresponding positive and negative predictive values of 88% and 93% (57).

In the early stages of Hashimoto's thyroiditis, the 24 h radioactive iodine uptake (RAIU) is typically normal or mildly elevated (58). However, as the disease progresses and more thyroid parenchyma are replaced by fibrous tissue, the RAIU decreases (58). An abnormal release of accumulated thyroidal [^{123}I]-iodide following either oral or intravenous administration of potassium perchlorate can also be observed in adults and children with Hashimoto's thyroiditis (2, 59). This positive perchlorate discharge test indicates a defect in the intrathyroidal oxidation of iodide to iodine. This test usually is not required unless the patient has persistent clinical features of thyroiditis and negative thyroid antibodies on repeated determinations.

A thyroid biopsy in children with diffuse thyromegaly very rarely is necessary unless coexisting malignancy of the thyroid gland is suspected, such as in a child with negative serum thyroid antibodies and an asymptomatic, enlarging nonfunctional nodule within a diffusely enlarged thyroid gland.

4. Clinical Course and Management

a. Toxic Thyroiditis. The rare patient who presents with autoimmune toxic thyroiditis may gradually return to a euthyroid state within 1–2 months or may experience mild hypothyroidism before recovery. The duration of the hypothyroid phase of toxic thyroiditis is variable; it may last for a few weeks to several months or may be permanent. Patients who experience only mild symptoms during the thyrotoxic phase usually require no treatment, but low dosages of propranolol (10–20 mg three or four times daily) can relieve symptoms in patients with more severe thyrotoxicosis. Antithyroid drugs are not indicated in the treatment of toxic thyroiditis. It is important to monitor serum thyroid function tests during the recovery phase of toxic thyroiditis. If hypothyroidism develops, the child should be treated with L-thyroxine. Since this phase usually is transient, the child can be given a trial off medication after 3–6 months of treatment and reevaluated 4–6 weeks later. If serum TSH levels are elevated, L-thyroxine replacement therapy should be resumed indefinitely. However, if the child is clinically and biochemically euthyroid, he or she should be reassessed at 6–12 month intervals with serum TSH to monitor for hypothyroidism that may occur during the course of chronic lymphocytic thyroiditis.

b. Chronic Lymphocytic Thyroiditis. Autoimmune thyroiditis is a dynamic disease. A study that examined the natural history of thyroid abnormalities over a 20 year period found that autoimmune thyroiditis persisted in approximately two-thirds (34 of 50), and apparently remitted in 28%, of patients originally diagnosed during adolescence (60). Of the 34 individuals with persistent disease, 17 (50%) had become hypothyroid over the 20 year interval. For these reasons, clinical evaluation and assessment of serum TSH values are advised at 6–12 month intervals to follow the course of disease and to identify

the development of hypothyroidism (6). Treatment with L-thyroxine may lead to reduction in goiter size in both euthyroid and hypothyroid patients (29). However, L-thyroxine treatment probably does not influence the long-term progression of thyroiditis (60). Once hypothyroidism occurs in a child with Hashimoto's thyroiditis, it typically is permanent and requires long-term treatment (29). Further discussion of the management of primary hypothyroidism may be found in Chapter 15.

C. Autoimmune Thyrotoxicosis: Graves' Disease

For further review of Graves' disease, see Chapter 16.

IV. ACUTE AND SUBACUTE THYROIDITIS

Acute thyroiditis, which is a rare disease, is easy to recognize but difficult to manage. In classic cases the child presents with an acute onset of pain in the area of the thyroid gland associated with fever, chills, dysphagia, hoarseness, and sore throat. The onset is usually preceded by an upper respiratory infection. On examination, the skin over the thyroid may be warm and red, and there may be regional lymphadenopathy. The thyroid is enlarged (locally or diffusely) and extremely tender, and the child resists efforts to extend the neck. Although the child may appear "toxic" from the infectious process, he or she is not thyrotoxic. Laboratory investigation reveals leukocytosis and an elevated erythrocyte sedimentation rate. Serum thyroid function tests are usually normal at presentation and remain normal throughout the course of the disease. Antimicrobial therapy should be instituted promptly once appropriate cultures are obtained. A variety of aerobic and anaerobic organisms have been identified on culture of thyroid aspirates (61), and a Gram's stain of the aspirate may help to determine initial antibiotic therapy pending culture results. Serial ultrasonography of the gland can be used to detect abscess formation, at which time surgical intervention becomes indicated. Most of the recently reported cases of acute thyroiditis have been associated with an internal fistulous tract between the left pyriform sinus and the corresponding thyroid lobe (62, 63). Therefore, any child who presents with acute thyroiditis primarily involving the left lobe or who experiences recurrent acute thyroiditis should undergo a barium esophagram once he or she has recovered from the acute infectious process. If a fistula is identified, operative excision of the entire epithelial tract and adjacent thyroid tissue is essential to prevent recurrent thyroiditis and abscess (63).

Subacute thyroiditis is also rare during childhood and adolescence. The two major forms are subacute granulomatous thyroiditis (de Quervain's thyroiditis) and subacute lymphocytic thyroiditis (painless or silent thyroiditis). Both of these conditions are most commonly seen in

women between 30 and 50 years of age (64). Subacute granulomatous thyroiditis presumably results from a viral infection of the thyroid gland; the patient often has a history of a recent upper respiratory infection. Mumps, Coxsackie, echo, Epstein-Barr, influenza, and adenovirus are among the viruses implicated as causative (55, 64); there is also an association with HLA-B35 (55). An affected patient may have low-grade fever with flulike symptoms; generally, the chief complaint is neck pain in the region of the thyroid that may radiate to the jaws or ears. The patient may be clinically euthyroid or have symptoms suggestive of hyperthyroidism. The thyroid gland is usually enlarged, quite firm or tense, and tender. Thyroid enlargement may be localized or diffuse, and tenderness varies from mild to severe. The patient may resist efforts either to extend the neck or palpate the thyroid gland. The erythrocyte sedimentation rate (ESR) is characteristically elevated, usually above 50 mm/h (55).

Subacute lymphocytic thyroiditis is considered an autoimmune thyroid disease. It may occur either sporadically or during the post-partum period. On pathological examination it resembles Hashimoto's thyroiditis, but there is generally less lymphocytic infiltration and fibrosis. Thyroid peroxidase antibodies can be detected in about 60% of patients, and TSHrAb (either blocking or stimulating) can be found in about 20% of patients (55). Subacute lymphocytic thyroiditis has been associated with HLA-DR3 and HLA-DR5 (55). Some 50–60% of affected patients present with symptoms of mild thyrotoxicosis and a small, nontender goiter (55). The ESR tends to be normal (64). In the early stages, this disorder may be difficult to differentiate clinically from Graves' disease.

The expected results of laboratory tests during the early phase of these diseases include normal to elevated levels of total and free T₄ and T₃, a normal or suppressed TSH level, negative or low levels of thyroid antibodies, and a low or absent uptake of radioactive iodine (55).

The clinical course of subacute thyroiditis is variable, but it often progresses through three phases (toxic thyroiditis, euthyroid goiter, and mild hypothyroidism) before the patient returns to normal thyroid function. The transient phase of hypothyroidism during recovery will vary in length and severity. Although most will recover completely, between 5 and 10% of affected patients will remain permanently hypothyroid (64, 65). After recovery, late recurrences are uncommon in patients with subacute granulomatous thyroiditis, but it is not uncommon for the painless variety to recur after months or even years (55).

Symptomatic therapy may be necessary during the initial phase of the disease. This includes propranolol if symptoms of hyperthyroidism are present, and therapeutic dosages of salicylates or other nonsteroidal anti-inflammatory agents if local pain and tenderness of the thyroid gland persist. Prednisone therapy is necessary infrequently to control symptoms. Antithyroid drugs, which inhibit the production of new thyroid hormone, are not indicated for

the management of thyrotoxicosis in subacute thyroiditis, because symptoms are caused by release of preformed thyroid hormones from the damaged gland. Should hypothyroidism eventually occur, the patient can be treated with L-thyroxine (50–100 μg daily) for 3–6 months, after which time the dosage can be discontinued. Thyroid function should be checked 4–6 weeks later; if the serum TSH level is elevated, L-thyroxine therapy should be resumed indefinitely.

V. IODINE DEFICIENCY

Iodine deficiency remains the most common cause of thyromegaly worldwide (66). Although iodine deficiency is still prevalent in various regions of the Americas, Africa, Europe, and Asia (66), it has been virtually eradicated in the United States since the introduction of iodized salt in the 1920s. Iodine deficiency can, however, occur in patients with chronic renal and nutritional diseases, or in patients consuming iodine-deficient diets. The currently recommended daily iodine intakes are 90 μg , 120 μg , and 150 μg for children ≤ 5 years old, 6–12 years old, and >12 years old, respectively (66). A diagnosis of iodine deficiency is supported if urinary iodine excretion is less than 100 $\mu\text{g}/\text{l}$, with values <20 $\mu\text{g}/\text{l}$, 20–49 $\mu\text{g}/\text{l}$, and 50–99 $\mu\text{g}/\text{l}$ indicating severe, moderate, and mild iodine deficiency, respectively (66).

Multiple nutritional and environmental influences contribute to the prevalence and severity of iodine deficiency disorders (IDD) in iodine-deficient areas. General malnutrition, water-borne goitrogens (e.g., resorcinol and polyhydroxyphenols), and a variety of goitrogenic foods (e.g., millet, soy, and cassava) can aggravate goiter (67, 68). Deficiencies of selenium, vitamin A, or iron can modify thyroid hormone synthesis and/or metabolism, and thereby contribute to goitrogenesis and limit the effectiveness of iodine intervention programs (67).

VI. GOITROGENS

A variety of chemicals, drugs, and foods can interfere with thyroid hormone synthesis, secretion, and/or metabolism. This interference can lead to a reduction in serum thyroid hormone levels followed by a compensatory increase in TSH secretion and thyromegaly. Although chronic ingestion of these substances alone can lead to goiter formation, patients with pre-existing thyroid disease or iodine deficiency are more susceptible to the antithyroid effects of these agents (69). Therefore, complete dietary and medication histories should be included in the clinical evaluation of patients with thyromegaly.

Drugs that can interfere with thyroid gland function include the thionamides (e.g., propylthiouracil, methimazole, and carbimazole), sulfonamides (e.g., sulfisoxazole and sulfamethoxazole), and lithium. Both the thionamides and sulfonamides inhibit the actions of thyroid peroxidase

(i.e., oxidation and organification of iodine and the coupling of iodotyrosyl residues to form iodothyronines). The sulfonamides are less potent than the thionamides, and, in the dosages generally used in clinical practice, they have little to no antithyroid effects (68). Lithium interferes with thyroid function by inhibiting the release of thyroid hormone (69).

Phenobarbital, phenytoin, carbamazepine, and rifampin are examples of medications that induce hepatic mixed-function oxygenases that increase the metabolic clearance rate of T_4 (69). These drugs have little effect on the metabolic clearance of T_3 . As a result, serum T_4 concentrations decrease, but serum T_3 levels remain unchanged or increase slightly. Basal serum TSH levels increase slightly, but not significantly (69). Therefore, most patients taking these drugs have no clinical signs of hypothyroidism and have normal TSH levels. However, hypothyroidism may occur or worsen in patients with underlying primary thyroid disease who receive these medications chronically (69).

Foods of the genus *Brassica* (e.g., cabbage, broccoli, cauliflower, brussels sprouts, turnips) contain goitrin, a naturally occurring thionamide compound (68). Cassava, maize, and lima beans contain cyanoglucosides that, following ingestion, release cyanide (70). Cyanide is detoxified to thiocyanate, a powerful goitrogenic agent that inhibits thyroid iodide transport and the organification of iodine (70). Millet and soybeans contain goitrogenic compounds known as flavonoids (e.g., glycosides of apigenin and luteolin) and isoflavonoids (e.g., genistein and daidzein), respectively (71). Although these compounds may possess diverse antithyroid properties, their goitrogenic activity is commonly expressed in terms of their ability to inhibit thyroid peroxidase activity (71). In these terms, apigenin and genistein are more potent than either methimazole or PTU. In recent years, soy consumption and the use of soy isoflavone supplements (also referred to as phytoestrogens) have increased due to the belief that isoflavones may be protective against a variety of hormone-dependent diseases, including breast and prostate cancers (71). It is important to recognize that these isoflavone compounds are also present in infant soy formulas (71). Studies have demonstrated a greater incidence of thyroid antibodies in children who received soy formulas during infancy than in children who were breastfed (72), as well as an association between feeding soy formulas and the development of autoimmune thyroid disease in later childhood (31).

VII. FAMILIAL THYROID DYSHORMONOGENESIS

Inborn errors in thyroid hormone synthesis, secretion, or recycling account for about 10–15% of all cases of permanent primary congenital hypothyroidism. The molecular mechanisms in most of these forms have been char-

acterized; mutations of the individual genes encoding the TSH receptor, the $G_{s\alpha}$ protein, the sodium/iodide symporter, thyroid peroxidase, and thyroglobulin have all been identified as causes of thyroid dysmorphogenesis (73, 74). Although the majority are inherited as autosomal recessive disorders, some forms of resistance to TSH, not linked to mutations of the TSH receptor, are inherited in an autosomal dominant fashion (74). Except for mutations in the TSH receptor–G-protein complex, these cases are characterized clinically by the presence of goiter. However, the limited, but substantial, maternal to fetal transfer of thyroid hormone is usually sufficient to protect the affected fetus from mental retardation and goitrogenesis (75). Therefore, these infants rarely show overt goiter at birth. After birth, if these infants are not treated with thyroid hormone, goiter will develop in most because of the thyroid growth-stimulating actions of TSH. In regions of the world with screening programs for congenital hypothyroidism, the vast majority of infants with thyroid dysmorphogenesis will be identified in the newborn period. However, for reasons that remain unclear, some patients with thyroid dysmorphogenesis can have both normal screening results (T_4 and/or TSH) and normal laboratory determinations for serum T_4 and TSH in the neonatal period, only to present months to years later with marked goitrous hypothyroidism (76). Therefore, physicians evaluating children, particularly those in families with a history of thyroid dysmorphogenesis, need to be aware that normal neonatal thyroid screening results do not exclude the possibility that severe hypothyroidism will occur later in infancy or childhood (76).

Pendred syndrome is an autosomal recessive disease characterized by goiter and congenital sensorineural deafness. The disease gene has been mapped to chromosome 7q22-q31.1 and is named PDS (77, 78). The predicted protein of this gene has been named pendrin and consists of 780 amino acids (86 kD); pendrin is a transmembrane glycoprotein containing 11 or 12 transmembrane domains (77). It belongs to a family of proteins, all of which appear to be anion transporters; pendrin has significant structural homology with proteins known to function as sulfate transporters (77). However, expression of pendrin in eukaryotic cells demonstrates that it does not transport sulfate but functions as a sodium-independent transporter of chloride and iodide (77). PDS is highly expressed in the thyroid and, to lesser extents, in fetal kidney, brain, and cochlea (77, 78). Pendrin is localized exclusively at the apical membrane of the thyroid cell; it has been hypothesized that pendrin promotes the transport of iodide from the cytoplasm to the colloid space, delivering iodide to the thyroid peroxidase region involved in iodide organification (77). Although its role in the inner ear remains obscure, pendrin may function as an anion transporter, maintaining the appropriate ionic balance within the endolymph of the inner ear, which is known to play a crucial role in the hearing process (77).

The exact incidence of Pendred syndrome is not known but has been estimated to be as high as 7.5–10:100,000 individuals (78). It may account for about 10% of cases of hereditary deafness and may be the most common form of syndromic deafness (78). Males and females appear to be equally affected. More than 40 different PDS mutations have been reported in either homozygosity or compound heterozygosity in families with Pendred syndrome (77). Individuals with disease-causing mutations in PDS can present with at least two distinct phenotypes. Most commonly, individuals have a so-called classic Pendred syndrome phenotype of sensorineural hearing loss and goiter. Other affected individuals have sensorineural hearing loss with inner ear malformations (e.g., Mondini cochlea, enlargement of the vestibular aqueduct, alterations of the membranous labyrinth, and enlargement of the endolymphatic duct and sac) in the absence of goiter (77). Although some authors have advocated that a Mondini malformation of the cochlea (i.e., the two-and-a-half turns of the cochlea are replaced by a single cavity in the apical region due to an absence of the interscalar septum) be included as an essential prerequisite to the diagnosis (79), this defect is not specific for Pendred syndrome and is not found in all patients (78). The hearing loss is of moderate to severe degree, being more pronounced in the higher frequencies. The deafness is thought to be congenital and is certainly prelingual in most cases (79). Vestibular function may also be abnormal (77).

In classic cases the goiter appears in midchildhood, but is often postpubertal, especially in affected boys (79). There are rare reports of congenital goiter (79). The goiter tends to be diffuse initially but may become nodular later. An enlarged thyroid gland is present in 50–70% of patients with Pendred syndrome, and there is distinct intrafamilial variability in the presence and extent of goiter among affected individuals (77). Goiter size can range from marginal to marked enlargement (78, 79). The majority of affected individuals are clinically and biochemically euthyroid, but both subclinical and overt hypothyroidism can occur (77–79). It has been postulated that these phenotypic differences may be due to differences in iodine intake (77). Whether a goiter is present or not, a positive perchlorate discharge test is found in the majority of patients with Pendred syndrome (77–79). This reflects the fact that disrupted transport of iodide by pendrin results in decreased iodide flux into the colloid and pooling of unbound iodide within thyrocyte cytoplasm (77). However, PDS mutations have been found in some patients with sensorineural deafness without either goiters or positive perchlorate discharge tests (78).

Further discussion regarding thyroid dysmorphogenesis can be found in Chapter 14.

VIII. IDIOPATHIC GOITER

This form of goiter, also referred to as simple, colloid, or nonspecific goiter, usually occurs in adolescent girls. The

patient presents with an asymptomatic diffuse enlargement of the thyroid and is clinically and biochemically euthyroid. The causes of simple goiter are incompletely understood; the condition is generally believed to be multifactorial in origin. The patient's history is negative for iodine deficiency or known goitrogen ingestion. Tests for serum thyroid antibodies are negative. A recent study involving female twin pairs in Denmark supports that genetic factors play a major causative role in some female populations, but environmental factors are also of importance (80). The genes that may represent susceptibility loci for simple goiter have not yet been determined. A number of reports have suggested that TGABs may produce simple goiter in 40–70% of affected patients (10–12). Mutations in the thyroglobulin gene have recently been identified as uncommon causes of simple goiter. Patients who carry either a heterozygous point mutation within exon 10 or a monoallelic deletion in the 5' region of the thyroglobulin gene have been described (81, 82). It has been proposed that these heterozygous mutations lead to insufficient thyroglobulin production. As a result, thyroid hormone production is inadequate. Increased stimulation of the thyroid gland by TSH might induce a higher level of transcription from the normal allele and also cause thyroid enlargement. In this way, euthyroidism can be maintained, but at the expense of goiter development (82).

Longitudinal studies have shown that simple goiter may regress over time (60, 83). A study that examined the natural history of thyroid abnormalities over a 20 year period found that simple goiter regressed in 60%, and persisted in 20%, of patients originally diagnosed during childhood (60). However, these longitudinal studies also showed that 5–10% of children initially diagnosed with simple goiter eventually showed clinical evidence of autoimmune thyroiditis (60, 83). Both hypo- and hyperthyroidism were also reported to occur in a few of the patients in these series (60, 83). Therefore, it seems likely that some children diagnosed with simple goiter have atypical or unrecognized autoimmune thyroid disease. For this reason, children with simple goiter should be evaluated at least annually, and the minimal laboratory evaluation at these visits should include serum TSH and thyroid antibody levels.

IX. NODULAR THYROMEGALY

Most children with a solitary thyroid nodule will present with an asymptomatic neck mass discovered either by the child (or his or her parent) or by the physician during a physical examination. The nodule may be present either in one of the lobes or in the isthmus of the gland. There is an increase in frequency of thyroid nodules as age advances. For children and young adults, the reported prevalence rates for thyroid nodules are about 0.22% and 1.5–2.2%, respectively (60).

Although a localized enlargement (i.e., nodule) of the gland may be seen in patients with Hashimoto's thyroiditis or in idiopathic goiter, a mass in the thyroid must be evaluated to determine if it represents a benign or a malignant lesion. To accomplish this, the evaluation of a child with a thyroid nodule should begin with a thorough history and physical examination. The history should inquire about goitrogen exposure, prior irradiation to the head or neck, and a family history of thyroid disease or malignancy. In addition, symptoms of hypo- or hyperthyroidism should be sought. The history should elucidate recent growth and physical characteristics of the nodule; for example, a rapidly enlarging, painless firm, or hard nodule in an otherwise normal thyroid gland is highly suggestive of a malignant process. Likewise, a rapidly enlarging mass in the region of the thyroid associated with hoarseness and/or dysphagia is suggestive of a malignant process. A history of transient pain and tenderness in a nodule may be indicative of an inflammatory process, hemorrhage into a cyst, or a degenerating adenoma. Physical findings that suggest a malignant lesion include a hard nodule, fixation of the thyroid to surrounding tissues, and regional lymphadenopathy. A medullary thyroid carcinoma should be suspected in the child with a thyroid nodule and physical features of multiple endocrine neoplasia IIb syndrome (i.e., marfanoid body habitus, multiple mucosal neuromas, and skeletal defects such as dorsal kyphosis, pectus excavatum, and pes cavus).

Most malignant lesions of the thyroid are carcinomas, but other malignant tumors, such as lymphoma and sarcoma, may occur. There are a number of benign lesions, both thyroidal and nonthyroidal, which may present as a thyroid nodule. Thyroidal lesions include cysts and papillary or follicular adenomas. Nonthyroidal masses that may appear to represent thyroid nodules include teratomas, branchial cleft and thyroglossal duct cysts, lymph nodes, hemangiomas, lymphangiomas, and neurofibromas. Hemiagenesis of the thyroid may also present as a nodular goiter (84).

Although its occurrence is rare, an ectopic thyroid gland can reside off the midline of the neck as far laterally as the submandibular and carotid sheath region (85). Affected patients may present during childhood with either congenital or acquired primary hypothyroidism, or later in life as clinically euthyroid individuals with an asymptomatic or enlarging lateral neck mass (85–89). Because so-called classic teaching dictates that any thyroid tissue ectopically located in the lateral neck represents a lymph node metastasis from a thyroid cancer (86–88), these latter patients often undergo extensive evaluation for suspected thyroid malignancy. The ectopic thyroid gland can also be mistaken for an abnormal submandibular gland that is discovered to be thyroid tissue only after surgical excision (86, 89). Lateral ectopic thyroid glands may occur in association with thyroid tissue in the normal pre-

tracheal location (87) or with other midline ectopic thyroid tissue (e.g., lingual or sublingual glands) (86), or may represent the only thyroid tissue in the body (86, 89). Because the lateral ectopic gland may be the only functional thyroid tissue in the body, it is important to realize that surgical excision can lead to irreversible primary hypothyroidism (86, 89). It is also important to recognize that ectopic thyroid glands may undergo any pathological change that can occur in a normal thyroid gland and may be the site of colloid goiters, hyperthyroidism, adenomas, or even carcinomas (89).

Laboratory evaluation in the child with a thyroid nodule should include serum free T_4 , T_3 , TSH, and thyroid antibody levels. These studies are obtained to establish the diagnosis of hypothyroidism, most likely due to chronic lymphocytic thyroiditis, or hyperthyroidism due to a hyperfunctioning nodule. The majority of hyperfunctioning nodules are adenomas; hyperfunctioning thyroid carcinomas are exceedingly rare. High serum thyroid antibody levels strongly suggest the presence of chronic lymphocytic thyroiditis. However, some patients originally assumed to have chronic lymphocytic thyroiditis (based on clinical and laboratory findings) as the cause of a thyroid nodule later were found to have papillary thyroid cancer (90). In addition, several studies have reported a significant association between chronic lymphocytic thyroiditis and thyroid cancers (especially papillary carcinoma) and suggest an increased risk of thyroid cancer in patients with chronic lymphocytic thyroiditis (91–93). Therefore, the clinician must still consider the possibility of thyroid malignancy in patients with presumed autoimmune thyroiditis, especially if the gland contains a single dominant nodule and/or there is associated firm cervical lymphadenopathy.

Important studies for the patient with a thyroid nodule are those designed to determine its structure and consistency: ultrasonography and the radionuclide (^{123}I -iodide or Technetium-99m) scan. Ultrasonography will rule out the presence of thyroid anomalies (e.g., thyroid hemiagenesis), confirm that the clinically detected mass represents a solitary thyroid nodule, and determine if the nodule is solid or cystic. Almost all malignant thyroid tumors will appear as a solid mass or a solid mass with a cystic component (94). On the other hand, small cystic lesions (less than 2 cm in diameter) without a solid component are usually benign. The radionuclide scan will determine if the nodule is functioning (warm or hot nodule) or nonfunctioning (cold). Almost all malignant thyroid tumors will appear as nonfunctioning masses, although hyperfunctioning thyroid carcinomas have been described in children (95).

In adults, fine-needle aspiration (FNA) is currently considered the most reliable diagnostic method in the clinical evaluation of thyroid nodules (96). Recent studies have shown that FNA is not only safe in children but is

a better diagnostic tool than either ultrasonography or radionuclide scanning in the evaluation of thyroid nodules (97–99). However, proper use of FNA requires individuals who are experienced in performing needle aspirations and cytopathologists who are experienced in interpreting FNA specimens. Even when these requirements are met, false-negative results may be reported. Because of the possibility of a false-negative result and the relatively high incidence (~10–25%) in children of thyroid cancer in nodules (90, 100), some authors have urged caution in the use of FNA in children (90). Instead, they recommend surgical biopsy of all solitary solid thyroid nodules or goiters associated with lymphadenopathy (90). Surgical biopsy without FNA has also been recommended for the child with a thyroid nodule if there is a history of exposure to ionizing radiation, family history of thyroid cancer, or if clinical findings are suspicious of malignancy, such as rapid growth of a firm nodule or if a large nodule (>1.5 cm) is present (100).

Further discussion of the evaluation, management, and prognosis of thyroid nodules and thyroid malignancies can be found in Chapter 18.

X. EVALUATION OF PATIENTS WITH THYROMEGALY

Evaluation of the patient with thyromegaly (Table 4) depends upon the initial history and results of an examination of the thyroid gland. The child with a symmetrical, diffusely enlarged, smooth thyroid gland should be investigated for hyperthyroidism and primary hypothyroidism. The determination of serum thyroid antibodies is important to identify autoimmune thyroid disease. The serum TSH level, determined with a second- or third-generation assay method, is the most sensitive test for thyrotoxicosis. Total and free T_4 and T_3 levels will be elevated in the majority of patients. Only in the presence of mild, equivocal thyrotoxicosis of undetermined cause are additional tests indicated. For the patient with a firm, irregular thyroid gland, the evaluation should be directed toward the diagnosis of autoimmune thyroiditis by determining serum thyroid antibodies and thyroid function.

Most children with autoimmune thyroiditis are clinically and biochemically euthyroid. Although the patient infrequently may present with toxic thyroiditis, the most common abnormality of thyroid function in autoimmune thyroiditis is hypothyroidism, which may develop any time during the course of the disease and can be best detected by the measurement of serum TSH every 6–12 months. When a serum TSH value is slightly elevated, a second specimen should be tested, and, if elevated again, the patient should be started on L-thyroxine therapy. Mild primary hypothyroidism in patients with autoimmune thyroiditis may be transient or permanent, particularly if the disease presents with toxic thyroiditis.

Table 4 Evaluation of the Patient with Thyromegaly

Clinical presentation	Causes	Thyroid function tests	Additional diagnostic tests
Diffuse, smooth symmetrical enlargement	Family history Goitrogen and drug history Serum thyroid antibodies Serum TBII, TSAAb, and TGAb	Serum T ₃ (thyrotoxicosis) Serum T ₄ (hypo- and hyperthyroidism) Serum free T ₄ Serum TSH (hypo- and hyperthyroidism)	[¹²³ I]-iodide uptake at 4–6 and 24 h TRH test Perchlorate discharge Urinary iodide excretion Serum thyroglobulin
Firm, irregular enlargement	Family history Serum thyroid antibodies	Serum TSH (hypo- and hyperthyroidism) Serum T ₄ (hypo- and hyperthyroidism) T ₃ (thyrotoxicosis)	[¹²³ I]-iodide uptake at 24 h with image Ultrasonography of neck Perchlorate discharge
Thyroid nodule	Radiation exposure Ultrasonography of neck Thyroid image with [¹²³ I]-iodide or Technetium-99m Serum thyroid antibodies Fine needle aspiration Thyroid excisional biopsy	Serum T ₃ (thyrotoxicosis) Serum T ₄ (hypo- and hyperthyroidism) Serum TSH (hypo- and hyperthyroidism)	T ₃ suppression test to evaluate autonomous hypersecretion Serum thyroglobulin Serum calcitonin response to pentagastrin and calcium infusions

Thyroid Tumors in Children

Donald Zimmerman

Mayo Medical School and Mayo Medical Clinic, Rochester, Minnesota, U.S.A.

I. EPIDEMIOLOGY

Thyroid cancers, particularly papillary cancers, are found at autopsy in a large minority of individuals dying of other causes. The prevalence varies from 5.6% in Colombia (1) to 35.6% in Finland (2). Autopsy prevalence of thyroid cancers is relatively low in children and adolescents. The prevalence in Finnish youth 20 years of age or less is 13.6%; no cases were detected in Finnish children 10 years of age or younger (3).

In light of the high autopsy prevalence of thyroid cancer, the annual incidence of clinical thyroid cancer is remarkably low. The incidence of thyroid cancer in children and adolescents has been estimated to be between 0.2 and 3.0 cases per million per year (4, 5). Clinical thyroid cancers in childhood and adolescents form only approximately 5% of such tumors (6, 7).

Thyroid cancer in adults in (two to four times more frequent in women than in men (8). This female predominance is less evident in children and is not observed in children less than 11 years of age (5, 9).

The best-established environmental risk factor promoting thyroid cancer is radiation exposure (10–14). Residence in a volcanic area, particularly Hawaii or Iceland, appears to increase the risk of thyroid cancer (15).

The vast majority of medullary thyroid cancers detected in childhood form one component of a genetic syndrome: either familial medullary thyroid cancer or multiple endocrine neoplasia type 2 (MEN 2). MEN 2a comprises medullary thyroid carcinoma, pheochromocytoma, and hyperparathyroidism. MEN 2b includes medullary carcinoma of the thyroid, pheochromocytoma, and ganglioneuromatosis of the gastrointestinal tract in association with a marfanoid habitus (16; Fig. 1). Medullary thyroid carcinoma occurring in all age groups is inherited in approximately 25% of cases (17).

Nonmedullary thyroid carcinoma is heritable less frequently than is medullary carcinoma. Recent estimates of

familial occurrence in patients of all ages have been in the range of 5% (18). Heritable nonmedullary thyroid cancers include oxyphilic papillary cancers (19). Classic papillary thyroid carcinoma may be heritable without other abnormality (20) or in association with nontoxic multinodular goiter (21).

Papillary thyroid carcinoma, or a thyroid carcinoma somewhat different from typical papillary cancer, occurs in approximately 1% of patients with familial adenomatous polyposis (FAP) (22–24). Approximately 85% of FAP patients with thyroid carcinoma are women, and most thyroid cancers in these patients are diagnosed before 35 years of age (25–27).

Another hereditary setting for nonmedullary thyroid cancers is in patients with Cowden disease, a condition similar to FAP that is transmitted with an autosomal dominant pattern of inheritance. This condition consists of hamartomas arising in ectoderm, mesoderm, and endoderm. The most characteristic features are facial papules (trichilemmomas and verrucae), oral papillomatosis, and palmo-plantar keratoses (Fig. 2). Other features include fibrocystic disease of the breast, nodular goiter, gastrointestinal polyposis, and ovarian cysts. Malignancies associated with Cowden disease include papillary and follicular thyroid cancer in 7% of patients as well as breast carcinoma, non-Hodgkin's lymphoma, melanoma, colon and uterine adenocarcinoma, squamous and basal cell skin carcinoma, and acute myelogenous leukemia (28, 29).

Another multiple neoplasia syndrome transmitted with an autosomal dominant pattern of inheritance is the Carney complex of spotty skin pigmentation, myxomas, endocrine overactivity, and schwannomas. Pigmented skin lesions include pinpoint brown to black macules (also present on mucosal membranes), café au lait spots, and blue nevi (Fig. 3). Myxomas occur in heart, skin, breast, and in other tissues. Endocrine abnormalities include primary adrenal Cushing's syndrome associated with pigmented adrenal nodules, growth hormone-producing pi-

uitary adenomas, and testicular Sertoli and Leydig cell tumors. Some 3.8% of patients have either papillary or follicular thyroid carcinoma. Nodular thyroid disease is present in 60 to 67% of patients (30).

II. PATHOLOGY

Some thyroid tumors arise from the thyroid follicular epithelium. This epithelium produces thyroglobulin, thyroxine, and triiodothyronine. Other thyroid tumors arise from C cells that derive from the most caudal branchial pouches (ultimobranchial bodies). These cells are located between the basal lamina and the follicular epithelial cells. Unlike follicular epithelial cells, C cells do not extend into the

colloid-containing follicular lumen. They produce calcitonin in addition to a number of other peptides such as somatostatin and calcitonin gene-related peptide. They do not produce thyroglobulin. Thyroid lymphomas arise from intrathyroidal lymphocytes.

The most common benign thyroid tumors arise from thyroid follicular cells and include adenomas and adenomatous nodules. Adenomas are solitary. They are encapsulated and have a uniform internal structure. They may have follicular or solid architecture (Fig. 4). Adenomatous nodules have more varied internal structure. They are commonly multiple rather than solitary (Fig. 5). Thyroid teratomas are found most commonly in the newborn. Large teratomas may be associated with polyhydramnios

Figure 2 Cowden disease has a number of skin and mucous membrane hamartomas. Facial trichilemmomas are seen on the left. Cobble-stone-like papules are seen in the buccal mucosa at the base of the tongue (center). Verrucous lesions (palmoplantar keratoses) are seen on the palms (right).

Figure 3 Principal skin findings in Carney complex (myxoma, spotty pigmentation, and endocrine overactivity) include ephelides or melanin spots in and around the lips.

since they may interfere with fetal swallowing of amniotic fluid.

Malignant tumors of the thyroid follicular epithelium may be classified into papillary carcinomas, follicular carcinomas, and poorly differentiated carcinomas (31).

Papillary carcinomas make up approximately 72% of childhood thyroid cancers (32). These tumors often infiltrate surrounding tissue and are only infrequently encap-

sulated. Most contain papillae with a fibrovascular core and a single layer of typical epithelial cells (Fig. 6). Often this pattern forms only a small proportion of the tumor. Other patterns found in papillary cancer include follicular, trabecular, cribriform, and diffuse. The epithelial cells contain large irregular nuclei that are folded and indented with cytoplasmic inclusions. Since the nuclear heterochromatin is concentrated near the nuclear membrane, the cen-

Figure 4 Follicular adenomas of the thyroid are encapsulated and have uniform structure.

Figure 5 Benign adenomatous nodules have more varied internal structures than follicular adenomas.

tral portion has a pale ground-glass appearance. The nuclei are often aligned similarly on the basal or apical part of the cell and therefore overlap one another.

Children less than 10 years of age appear to have a distinctive so-called childhood type of papillary thyroid cancer in which the nuclei are more rounded rather than elongated, smooth rather than grooved, and not crowded or overlapping. The predominant pattern of this type of papillary cancer is solid rather than pure papillary or a mixture of papillary and follicular (5).

Another variant of papillary thyroid carcinoma occurring most commonly in younger patients is the diffuse sclerosing type (Fig. 7). The tumor involves all lymphatics of one or both thyroid lobes and is associated with severe lymphocytic thyroiditis or interstitial fibrosis. Lymph nodes and pulmonary metastases are frequent (33).

The thyroid cancer occurring in association with familial adenomatous polyposis has been described as atypical papillary carcinoma. Tumors have mixed patterns including cribriform, papillary, glandular, and solid. The nuclei most commonly lack the central ground-glass appearance. Cytoplasmic inclusions and nuclear membrane grooving tend to be less prominent than they are in classic papillary tumors (22, 26).

Papillary thyroid cancers are frequently multifocal and are bilateral in up to 80% of cases (34). Papillary thyroid carcinoma metastasizes to cervical lymph nodes in 90% of affected children and to lungs in approximately 7% (6). Only rarely does the tumor invade blood vessels or metastasize to distant sites other than to lung.

Follicular thyroid carcinoma makes up approximately 18% of childhood thyroid cancers (32). A microfollicular pattern is usually predominant in follicular tumors (Fig.

8). Other less frequent tumor patterns include trabecular and solid. Nearly all follicular carcinomas are encapsulated, and the vast majority are unifocal and unilateral. Characteristically, follicular carcinomas invade blood vessels and, not rarely, also invade the tumor capsule. Thus, this tumor spreads hematogenously to lungs, bone, liver, and brain. Lymphatic invasion by follicular cancer is relatively infrequent.

One important variant of follicular thyroid cancer is the oncocyctic cell type (also called the oxyphilic or Hürthle cell type). The cytoplasm is granular and eosinophilic because of the presence of a large number of mitochondria (Fig. 9). These tumors exhibit extrathyroidal extension and lymph node and distant metastases more frequently than do other follicular carcinomas.

Anaplastic carcinoma is extremely aggressive and has been described as forming 2.6% of childhood thyroid cancers (32). Insular carcinomas have islands of small, dense cells that aggregate in solid, follicular, or papillary patterns. This tumor appears to be intermediate in aggressiveness between differentiated cancers (follicular and papillary) and anaplastic cancer (35).

Medullary thyroid carcinoma makes up approximately 2.6% of childhood thyroid cancers (32). These tumors arise most frequently at the junction of the upper third and the lower two-thirds of the thyroid gland: the thyroid region most densely populated with C cells. The cells in this tumor may be round, spindle-shaped, or polygonal and form sheets separated by fibrous stroma. Sixty to 80% of tumors contained amyloid (Fig. 10). The C cells forming medullary carcinoma produce calcitonin and carcinoembryonic antigen in addition to a number of other substances. Hereditary medullary tumors are multicentric

Figure 6 The finger-like projections, or papillae, of papillary thyroid carcinoma have a fibrovascular core and single layer of epithelial cells located basally. The nuclei appear to overlap.

Figure 7 Diffuse sclerosing papillary carcinoma is associated with lymphocytic infiltration and interstitial fibrosis. It tends to diffusely involve one or both thyroid lobes.

and bilateral. Nonhereditary tumors are most frequently solitary.

III. PATHOGENESIS

Two classes of mutated genes contribute to tumorigenesis. The first is the class of proto-oncogenes, which code for protein products that regulate cell growth. Many of these gene products contribute to the biochemical cascade involving cellular response to growth factors. An important example of a proto-oncogene contributing to thyroid carcinogenesis is RET (rearranged during transfection). The RET gene product is a transmembrane protein anchored in the plasma membrane. It is part of a receptor complex binding a family of ligands including glial cell line-derived neurotrophic factor, neurturin, persephin, and artemin. These ligands are members of the transforming growth factor β superfamily (36–38). The RET ligands form head-to-tail dimers; this structure facilitates dimeri-

zation of adjacent RET molecules, which in turn triggers activation of tyrosine kinase and receptor autophosphorylation (39; Fig. 11).

RET mutations have been found in medullary carcinoma of the thyroid (40–42). RET gene mutations in MEN 2A and in familial medullary thyroid carcinoma (FMTC) most frequently produce a change from cysteine (which in the unmutated molecule participates with another cysteine in an intramolecular disulfide bond) to another amino acid. This transversion frees the other usually intramolecularly coupled cysteine to couple with the corresponding uncoupled cysteine in a neighboring mutated RET molecule. This intermolecular cysteine coupling dimerizes RET and results in constitutive activation (43; Fig. 12).

RET mutations in MEN 2B occur in the intracellular tyrosine kinase domain rather than in the cysteine-rich extracellular domain of the RET molecule (44). These tyrosine kinase mutations activate RET without need of dimerization (Fig. 13). This nondimeric structure of acti-

Figure 8 Follicular thyroid carcinoma frequently invades blood vessel walls.

Figure 9 Oncocytic cell thyroid carcinoma has granular cytoplasm that is intensely eosinophilic.

vated RET in MEN 2B alters the substrate specificity of tyrosine kinase. In addition, unlike MEN 2A RET mutations, MEN 2B mutations allow persistence of RET ligand responsiveness (45). Perhaps these differences contribute to phenotype differences between MEN 2A and 2B.

Intestinal ganglioneuromatosis, characteristic of MEN 2B, reflects the embryologic role of RET in development of the enteric nervous system (46). Inactivating RET mutations are found in 23 to 33% of patients with Hirschsprung's disease, a condition characterized by absence of ganglia within a portion of the distal colonic wall (47). Some kindreds have RET mutations that predispose to both MEN 2A (or FMTC) and Hirschsprung's disease. Such mutations may produce constitutively active RET molecules that are numerically limited, causing constitutively active C-cells but numerically insufficient RET signals to effect gangliogenesis (48).

In addition to its role in MCT tumorigenesis, RET has been implicated as one of the most frequent oncogenes contributing to production of papillary thyroid carcinomas. Since RET is not ordinarily expressed in thyroid

follicular cells (unlike thyroid C cells), the very expression of RET in follicular cells is dependent on chromosomal rearrangement, which apposes regulatory subunits of other genes to the tyrosine kinase domain of the RET gene. In addition, these oncogenes code for protein coiled coil domains that predispose to constitutive dimerization of the proteins with one another and in this manner activate the tyrosine kinase (49). At least eight chromosomal rearrangements involving RET have been found in papillary thyroid carcinoma (50–56). Although most of the chromosomal rearrangements involving RET include inversion of a segment of chromosome 10 containing the RET gene (Fig. 14), some involve translocation of a fragment of chromosome 10 to a different chromosome such as chromosome 17 (53, 56).

At least one mechanism of thyroid tumorigenesis due to radiation is radiation induction of RET rearrangements (57). The Chernobyl thyroid cancer experience suggests that a particular RET rearrangement (PTC-3) is associated with short latency between radiation exposure and clinical cancer (58, 59).

Figure 10 The C cells that make up medullary thyroid carcinoma may be round, spindle-shaped, or polygonal. They form sheets separated by fibrous stroma and may produce amyloid.

C-met is a transmembrane, high-affinity receptor for hepatic growth factor. This growth factor receptor is over-expressed in 96% of papillary thyroid carcinomas and may contribute to lymph node metastases and to advanced pathological stage (60).

NTRK-1 is a component of the high-affinity receptor for nerve growth factor. The gene for this proto-oncogene is on chromosome 1q22, and a number of chromosomal rearrangements including the NTRK-1 gene are found in papillary thyroid cancers. NTRK-1 rearrangements are less frequent in papillary thyroid carcinoma (12%) than are RET mutations (46%). Both are more common in younger patients than in older ones (61).

A number of studies have suggested that lymphocytic infiltration of thyroid neoplasms is associated with a favorable prognosis (62, 63). Recent evidence suggests that thyroid cancers may be able to evade immunological attack mediated by lymphocytic infiltration by expressing FAS ligand, a transmembrane protein of the TNF family

Figure 11 The RET proto-oncogene is a transmembrane molecule. It collaborates with specific receptors for each of the members of the glial cell line-derived neurotrophic factor family (e.g., the GCNF receptor depicted by a line with square domains) in transducing signals to the interior of the cell.

that binds to a specific receptor on activated T cells and induces apoptosis (64, 65).

Tumor-suppressor gene mutations contributing to thyroid tumorigenesis include mutations in P53. Although P53 mutations are found in up to 40% of undifferentiated

Figure 12 In MEN 2A, most of the RET mutations involve a nucleic acid transversion resulting in a change in the cysteine-rich portion of the extracellular portion of RET. Since one of the *intramolecular* disulfide bonds does not form, a “spare” cysteine is available for *intermolecular* disulfide bonding. This bonding results in dimerization of RET molecules. This dimerization, in turn, constitutively activates RET.

thyroid cancers, they are observed in less than 10% of differentiated thyroid cancers. These mutations are more common in aggressive tumors (66). P53 mutations are observed with greater frequency in radiation-induced thyroid cancers (67).

Angiogenesis stimulators and inhibitors appear to facilitate tumor growth. Overexpression of vascular endothelial growth factor C (an angiogenesis stimulator) is increased in lymph node invasive thyroid tumor such as papillary cancer. Thrombospondin-1 (an angiogenesis inhibitor) is underexpressed in hematogenously spreading thyroid tumors such as follicular cancer (68–70).

Genes associated with heritable, nonmedullary thyroid cancer contribute in various ways to the development of thyroid cancers. Patients with familial adenomatous polyposis have mutations in the adenomatous polyposis (APC) gene located on chromosome 5q21. Individuals with mutations between codons 463 and 1387 are at greater risk for thyroid carcinoma and for congenital hy-

per trophy of the retinal pigment epithelium. Some studies of loss of heterozygosity for the APC gene in thyroid tumors have been negative in the setting of familial adenomatous polyposis. Although there was no observable loss of heterozygosity for the APC gene, three of four patients had RET-PTC rearrangements (71). In other studies of APC and thyroid cancer, the thyroid cancers in this setting did manifest loss of heterozygosity (72).

Cowden disease results from mutations in PTEN, a tumor suppressor gene with protein tyrosine phosphatase activity located on chromosome 10q23 (73). Thyroid tumors and other tumors associated with Cowden disease are associated with loss of heterozygosity in tumor tissue (74). Although PTEN mutations are infrequent in sporadic thyroid carcinomas, PTEN expression is decreased at the RNA and protein level in 40% of these carcinomas (75).

The Carney complex results from mutations of the gene on chromosome 17q23–24, which encodes the protein kinase A type 1-alpha regulatory subunit. This gene has not yet been studied in thyroid tumor tissue (76).

IV. DIAGNOSIS

Thyroid cancer presents as a thyroid nodule in approximately 54% of patients. Twelve percent have both a thyroid nodule and enlarged cervical lymph nodes, and 36% have enlarged cervical lymph nodes without a palpable thyroid mass (77). Between 18% and 25% of solitary thyroid nodules in children are found to be cancerous (78–80). Since only 5% of thyroid nodules in adults are malignant, fine-needle aspiration of such nodules is generally favored to avoid unnecessary surgery in adults (81). Fine-needle aspiration of childhood thyroid nodules is recommended by investigators (82), but others caution that aspiration biopsy results may be misleading. These individuals favor surgery in all children with thyroid nodules (83). False-negative results of aspiration cytology may be obtained in 2.3–3.6% of thyroid nodules (80, 82).

Evaluation of thyroid nodules by ultrasonography and radionuclide scanning has been largely replaced by fine-needle aspiration (FNA) because of the latter’s superior sensitivity and specificity (81). In general, FNA cytology that is positive or suspicious for malignancy should prompt thyroid surgery. Nondiagnostic cytology should prompt repeat aspiration perhaps performed under ultrasound guidance (Fig. 15). Ultrasound guidance may be particularly useful if there is a cystic component of the lesion since sampling of the wall of the lesion is most likely to give a meaningful cytologic result (84).

V. TREATMENT

The surgical procedure most frequently advocated for treatment of papillary thyroid carcinoma is bilateral near-total or total thyroidectomy. Unilateral procedures are associated with a higher incidence of local tumor recurrence

Figure 13 In MEN 2B, RET mutations occur in the portion of the gene coding for the portion of the RET protein containing tyrosine kinase activity. These mutations are constitutively active despite absence of dimerization of the RET proteins.

in low-risk as well as in high-risk patients (85). Unilateral surgeries are associated with higher mortality only in high-risk patients (advanced patient age, large tumor size, local invasion, and/or distant metastases, and high tumor grade) (86, 87). Bilateral thyroid surgery significantly decreased the rate of tumor recurrence in a study of 1685 patients of all ages evaluated for a mean of 18 years (87). Study of a subset of this patient group including the 90 children less than 17 years of age also demonstrated decreased tumor recurrence in patients undergoing bilateral surgical procedures (88). A more recent study of a different patient population has also confirmed these results (89). Another study of 329 patients younger than 21 years of age evaluated for a mean of 11.3 years did not report a difference between unilateral and bilateral surgeries. This study demonstrated a higher frequency of permanent hypoparathyroidism in bilateral operations than in unilateral ones (90). In addition to the probable advantage in preventing tumor recurrence offered by bilateral surgery, this surgical approach facilitates the usefulness of thyroglobulin measurement and of radioiodine scanning in evaluating thyroid cancer patients postoperatively for re-

currence of tumor (91). The role of the surgical procedure in bolstering the sensitivity of the postoperative management techniques is particularly important in evaluating patients with follicular thyroid carcinoma, which not infrequently metastasizes by the hematogenous route. The recurrence rate of follicular thyroid carcinoma may not be significantly affected, however, by bilateral rather than by unilateral surgical procedures (92).

During the surgical procedure the lymph nodes of the tracheoesophageal groove are palpated. Those on the side of the tumor are biopsied. If these nodes are positive, then a modified neck dissection is performed. In addition, lymph nodes in the supraclavicular area are palpated and, if enlarged, these are also biopsied.

Another controversial aspect of the treatment of papillary thyroid carcinoma is the use of radioiodine ablation of the postoperative normal thyroid remnant. There appears to be substantial agreement that ^{131}I -iodine treatment of tumors smaller than 1.5 cm does not reduce the rate of tumor recurrence (93). One large series strongly suggests decreased tumor recurrence and decreased mortality in ^{131}I -iodine treated patients (94); another does not demonstrate such benefits. The results of a number of studies seem to support the view that total or near-total thyroidectomy reduces the apparent benefit of ^{131}I -iodine ablation (93).

Measurement of serum thyroglobulin levels is a cornerstone of postoperative monitoring. Presently, thyroglobulin is usually measured with immunoradiometric assays. Approximately 15% of patients with thyroid cancer have antibodies directed against thyroglobulin. These antibodies may interfere with thyroglobulin measurement, often resulting in underestimation of thyroglobulin levels (95). Patients with thyroglobulin antibodies might be studied using a PCR-based assay for thyroglobulin mRNA. This assay is not subject to erroneous readings as a result of antibodies being present in the circulation (96).

Withdrawal of thyroid hormone replacement allows detection of thyroglobulin in almost all patients with tumor in lymph nodes and in distant sites (95). Measurement of thyroglobulin postoperatively or following withdrawal of thyroid hormone replacement is frequently preceded by 1-T_3 replacement (in doses of approximately $25\ \mu\text{g}/1.73\ \text{m}^2$ body surface area three times daily) for 4 weeks. Thereafter, 1-T_3 is withdrawn for a period of 2 weeks. This practice allows 1-T_4 levels to decline gradually (in light of the long T_4 half-life of 1 week) while prolonging TSH suppression by T_3 . T_3 has a much shorter half-life (approximately 24 h), allowing robust TSH release over a presumably safer and shorter period of time.

Instead of withdrawing thyroid hormone, patients may be given recombinant TSH by intramuscular injection prior to measurement of thyroglobulin levels. This method obviates the need to produce hypothyroidism (97, 98).

In addition to thyroglobulin measurement, thyroid cancer is monitored by total body scanning employing 1-

Figure 14 Activation of the RET in papillary thyroid carcinoma results from chromosomal rearrangements involving the 10th chromosome (which contains the RET gene). This diagram shows an inversion of a segment of chromosome 10 resulting in RET activation.

5 mCi ^{131}I -iodine. For adequate scanning sensitivity, TSH levels should be greater than 35 mIU/l. This can be accomplished either by withdrawing patients from thyroid hormone or by injecting them with recombinant TSH. Tumor detected by ^{131}I -iodine scanning and inaccessible to neck surgery may be treatable with radioiodine (99). At times, administration of ^{131}I -iodine for diagnostic scans stuns thyroid tissue, thereby interfering with tumor uptake of therapeutic radioiodine (100). In the future, use of ^{123}I -iodine for diagnostic scanning may be able to avoid this effect. Treatment of tumor detected by thyroglobulin but not by diagnostic scan remains controversial (101, 102).

High-resolution real-time ultrasonography is useful in monitoring patients for tumor recurrence in the neck. Suspicious masses may be aspirated under ultrasound guidance for cytological study. Confirmed tumor may then be surgically removed (84).

Thyroid hormone replacement should be adjusted to suppress TSH (103). Low-risk patients may not require

marked suppression (104). It has therefore, been recommended that high-risk patients have suppression of TSH below 0.1 mIU/l while low risk patients should have TSH levels between 0.1 and 0.4 mIU/l (105).
