A combined medical and surgical approach is the best form of therapy for L.Y.’s brain abscess.^{133,138} Response rates to antimicrobial therapy alone have been disappointing and, with a few exceptions, surgical intervention is necessary to ensure optimal results. Medical therapy is indicated when multiple abscesses are present, when the abscess cavity is inaccessible surgically, for patients who are poor surgical candidates, and when the abscess is small (<4 cm).^{133,138,144}

The two types of surgical approaches for brain abscess are (a) stereotactic needle aspiration and (b) craniotomy for abscess excision.¹³⁸ Stereotactic aspiration of abscess contents can be performed under local anesthesia and produces lower morbidity and mortality than craniotomy.¹⁹ Such an approach is highly effective, except when multiloculated abscesses are present.¹³⁸ With craniotomy, the abscess cavity can be excised completely, which often allows a shorter duration of antimicrobial therapy. Both techniques are effective, and the decision regarding which procedure is most appropriate must be individualized.

Antimicrobial Penetration Into Brain Abscess

Antimicrobial therapy is an essential component of brain abscess therapy.¹³⁹ Penetration of antibiotics into brain abscess fluid has not been studied as carefully as penetration into CSF, and as discussed earlier, the barrier involved is different (Fig. 58-1).¹⁵ Penicillins and cephalosporins penetrate adequately into abscess fluid, but certain agents (e.g., penicillin G) may be susceptible to degradation by enzymes present within the abscess milieu.^{133,139,145–147} Third-generation cephalosporins (e.g., cefotaxime, ceftriaxone, and ceftizoxime) are believed to penetrate sufficiently into the abscess and are good choices when gram-negative bacteria are present.^{133,147} Chloramphenicol penetrates very well into brain abscesses and has been used extensively.^{133,139,145} It has excellent anaerobic activity, but also can be degraded (deacetylated) in purulent abscess fluid.¹³³ Metronidazole achieves abscess fluid concentrations equal to or in excess of serum levels and is bactericidal against strict anaerobes. The unique mechanism of action of metronidazole makes it particularly useful in the necrotic core of the

cavity, where the oxidation-reduction potential is low and bacteria replicate slowly or are dormant. For these reasons, metronidazole has supplanted chloramphenicol for treatment of bacterial brain abscess.¹³³ Although data are limited, vancomycin and carbapenems appear to penetrate sufficiently into brain abscess fluid.^{133,148} Although specific abscess-penetration data are unavailable, successful treatment of cerebral nocardiosis with TMP-SMX and CNS toxoplasmosis with clindamycin suggests that these compounds also achieve adequate penetration into cerebral abscess cavities.^{141,143}

Antibiotic Therapy

When antibiotic therapy should be instituted depends on the status of the patient and the stage of abscess development. For patients diagnosed during the cerebritis stage, before formation of a well-circumscribed capsule, surgery should be delayed and antimicrobial therapy begun in patients with significant symptoms.^{133,138} If capsule formation already has taken place, it is better to delay initiation of antibiotics until after surgery to increase the microbiologic yield from tissue and fluid samples. If the disease is fulminant, antibiotics must be instituted promptly and surgical intervention performed as quickly as possible.^{133,138}

L.Y.’s clinical presentation suggests an advanced brain abscess. The presence of ring enhancement on CT and the onset of symptoms over 2 weeks support this. Because he is not critically ill, antibiotic therapy should be delayed until surgery is performed. Specimens obtained from the surgical procedure should be sent for aerobic and anaerobic culture and a stat Gram stain.

Initial antibiotic therapy for brain abscess needs to be sufficiently broad to cover the most likely pathogens (Table 58-10).^{133,135,137,139} In most cases, a combination of high-dose penicillin G and metronidazole is indicated. Penicillin will cover aerobic, anaerobic, and microaerophilic streptococci, whereas metronidazole will provide coverage for strict anaerobes, including *Bacteroides* and *Prevotella* species. If gram-negative bacilli are suspected or documented, as in abscesses related to otitis, head trauma, or neurosurgery, a third-generation cephalosporin is indicated.¹³³ Staphylococcal abscesses should be treated with nafcillin or vancomycin.^{133,135,149}

For L.Y., therapy with penicillin G 4 million units IV Q 4 h and metronidazole 500 mg IV Q 8 hours should be started postoperatively (Table 58-6). Because his abscess appears to originate from the sinus, the likelihood of gram-negative infection is reduced. With evidence of gram-negative bacteria on the Gram stain of abscess fluid, therapy with cefotaxime 3 g IV Q 6 h also should be included. Ceftriaxone 2 g IV Q 12 h is a viable alternative to cefotaxime, particularly if the patient is going to be discharged to home on a prolonged course of therapy. Outpatient therapy is appropriate for CNS infections as long as patients are carefully selected and monitored, as described in a recent report.¹⁵⁰ Of interest, of the 24 patients treated on an outpatient basis, 46% received ceftriaxone 2 g IV once daily with a cure.¹⁵⁰ TMP-SMX is an alternative if the organism is resistant to cefotaxime. The large fluid volume required (particularly when 5% dextrose in water is used) for IV TMP-SMX administration may contribute, however, to worsening cerebral edema.¹²⁹ Antimicrobial

therapy for L.Y. should be revised once results from culture and sensitivity testing are available.

Adjunctive Corticosteroid Therapy

Adjunctive corticosteroid therapy for bacterial brain abscess is controversial.^{133,138} Steroids can interfere with antibiotic penetration into abscesses and obscure the interpretation of serial CT scans when assessing response to therapy.^{133,138} Therefore, steroids are indicated only if significant cerebral edema is present, particularly if it is accompanied by rapid neurologic deterioration.^{133,138} L.Y. should not receive dexamethasone because his mental status is only mildly depressed and the cerebral edema seen on CT scan is not massive.

Adjunctive Anticonvulsant Therapy

L.Y. has shown no signs of seizure activity thus far and, therefore, does not require anticonvulsant therapy. Anticonvulsants should be used in the acute setting when seizures are present, however.^{133,138} Agents with activity against partial and complex partial seizures are preferred (e.g., phenytoin, carbamazepine). The long-term use of anticonvulsants depends on whether seizure activity persists. Insufficient information exists regarding how long to continue anticonvulsants in such cases. Therefore, discontinuation of these agents must be individualized.

No formal guidelines are available regarding the optimal duration of therapy for bacterial brain abscess. Given the serious nature of the infection and the difficulty associated with antibiotic penetration, therapy with high-dose IV therapy should continue for at least 6 to 8 weeks.^{133,138} The duration of therapy should be evaluated on a case-by-case basis. In an attempt to ensure complete eradication of infection, some experts recommend long-term (2–6 months) oral antibiotics after the IV course, provided agents with good oral absorption and activity against the offending pathogens are available.¹³³

Monitoring Therapy

27. How should L.Y. be monitored for therapeutic response and toxicity?

Although L.Y. is on antibiotic therapy, weekly or biweekly CT scans should be obtained to evaluate abscess resolution. His clinical response to therapy also should be assessed daily. If therapy is effective, L.Y.'s mental status should improve gradually (e.g., he will become more alert and oriented) over a period of several days. L.Y.'s headaches and hemiparesis (weakness in his arm and leg) also should resolve eventually. It may take a week or longer, however, to see a complete resolution of symptoms.^{133,135} In general, radiologic improvement (i.e., reduction in abscess size) correlates reasonably well with clinical response, but not always.^{133,135,138} Persistent symptoms or failure to detect a reduction in abscess size on CT scan or the appearance of new abscesses may indicate improper antimicrobial therapy or the need for more surgery.^{133,138} Repeated surgical intervention with appropriate reculturing may be required in some instances to optimize therapy.

Adverse effects associated with the penicillin G therapy that L.Y. is receiving are similar to those of other β -lactam antibiotics. Seizures are a potential complication when high doses of penicillin are used in the presence of a mass lesion in the brain.^{6,101,115,151} L.Y. should be observed closely by those providing care and questioned regularly for any evidence of seizure activity. Metronidazole usually is well tolerated, but may also cause neurotoxicity,^{133,148,151,152} most commonly peripheral neuropathy.¹⁵² L.Y. should be assessed for the presence of numbness or tingling in his hands or feet. Seizures, although uncommon, occasionally occur with metronidazole.¹⁵² If L.Y. experiences peripheral neuropathy or seizures, a switch to chloramphenicol would be appropriate. Other adverse effects associated with metronidazole include mild nausea, brownish discoloration of the urine, and the potential for a disulfiramlike reaction with concomitant ethanol ingestion.¹⁴⁸ L.Y. should be counseled regarding the possibility of gastric upset and discoloration of the urine, and he should be strongly cautioned to avoid alcoholic beverages while receiving metronidazole. Given his young age, the absence of significant underlying diseases, and the relative early detection of his brain abscess, there is every reason to expect a good response to his treatment and, eventually, a complete resolution of his abscess.

HOME INTRAVENOUS ANTIBIOTIC THERAPY 59-25**INFECTIVE ENDOCARDITIS**

Infective endocarditis (IE), a microbial infection of the heart valves or other endocardial tissue, usually is associated with an underlying cardiac defect. IE used to be classified as either “acute bacterial endocarditis” or “subacute bacterial endocarditis,” based on the clinical presentation and course of the untreated disease. This classification system is nonspecific, however, and it does not account for many nonbacterial causes of endocarditis, such as chlamydiae, rickettsiae, and fungi. Hence, the current system based on the causative organism is preferred because it provides information regarding the probable course of the disease, the likelihood of underlying heart disease, and the appropriate antimicrobial regimens.¹

Pathogenesis^{1,2}

The pathogenesis of endocarditis involves a complex series of events that ultimately results in the formation of an infected

platelet β fibrin thrombus on the valve surface. This thrombus is called a *vegetation*.

The first step in the formation of the vegetation involves modification of the endocardial surface, which is normally nonthrombogenic. In patients with rheumatic heart disease, endocardial injury occurs as a result of immune complex deposition or hemodynamic disturbances. Valvular insufficiency caused by aortic stenosis or ventricular septal defects can produce regurgitant blood flow, high-pressure gradients, or narrow orifices, resulting in turbulence and endocardial damage.

Once the endocardial surface of the valve is traumatized, small, sterile thrombi consisting of platelets and fibrin are deposited, forming the lesion called *nonbacterial thrombotic endocarditis* (NBTE). NBTE occurs most commonly on the atrial surfaces of the mitral and tricuspid valves and on the ventricular surface of the aortic valve.

NBTE serves as a nidus for microbial colonization during periods of bacteremia. Table 59-1 lists procedures that

Table 59-1 Cardiac Conditions for Which Prophylaxis is Recommended**Cardiac Conditions**

Prophylaxis Recommended

- Prosthetic cardiac valves
- Previous bacterial endocarditis
- Congenital heart disease (CHD)
 - Unrepaired cyanotic CHD, including palliative shunts and conduits
 - Completely repaired congenital heart defect with prosthetic material device during the first 6 months after the procedure
 - Repaired CHD with residual defects at or adjacent to the site of the prosthetic device or patch
 - Mitral valve prolapse with valvular regurgitation and/or thickened leaflets
- Cardiac transplantation recipients who develop cardiac valvulopathy

Adapted from reference 230, with permission.

cause bacteremia. Organisms such as *Streptococcus viridans*, *Enterococcus* species, *Staphylococcus aureus*, *Staphylococcus epidermidis*, *Pseudomonas aeruginosa*, and *Candida albicans* possess adherence factors that facilitate their colonization. In particular, platelet aggregation has been shown to be an important virulence factor in experimental streptococcal endocarditis; larger vegetations and multifocal embolic spread have been associated with strains that aggregate platelets.³ Once the NBTE lesion becomes colonized by microorganisms, the surface is rapidly covered with a sheath of fibrin and platelets. This avascular encasement provides an environment protected from host defenses and is conducive to further bacterial replication and vegetation growth. Progression of the infection can be interrupted at any time by various host defense mechanisms, including blocking antibodies that interfere with bacterial adherence, serum bactericidal complement activity, hemodynamic forces that dislodge poorly adherent bacteria, and circulating prophylactic antibiotics.

The vegetation is thought to propagate by continuous re-seeding of the thrombus by circulating organisms. As the vegetation enlarges, it takes on a laminar appearance caused by the alternating layers of bacteria and platelet β fibrin deposits. The bacterial colony count can be as high as 10^4 to 10^5 bacteria per gram of valvular vegetation.

Endocarditis can result in life-threatening hemodynamic disturbances and embolic episodes. Without antimicrobial therapy and surgical intervention, IE is virtually 100% fatal. Because of bacterial proliferation to high densities in the fibrin mesh protected from normal host defenses, cure of infection requires prolonged therapy of 4 to 6 weeks with relapse not uncommon.

Epidemiology

Among the leading causes of life-threatening infectious disease syndromes, IE accounts for approximately 15,000 to 20,000 new cases per year in the United States.⁶ The overall incidence appears to have remained stable over time; however, health care-associated IE has emerged as a result of increased use of invasive medical devices and procedures (e.g., intravenous catheters, hyperalimentation lines, pacemakers, dialy-

sis shunts) and will undoubtedly contribute to an increase in IE.¹ The mean patient age reportedly has shifted from <30 years in the 1920s to above 55 years today.^{6,7} This increase in age is thought to be related to (a) a decline in the incidence of acute rheumatic fever and rheumatic heart disease counterbalanced by degenerative valvular disease in an increasing elderly population, (b) the increasing longevity of the general population, and (c) increased exposure to more intense and invasive medical procedures in both the overall and the aging populations. Men are affected more often than women (roughly 2:1), and the disease remains uncommon in children, primarily in association with underlying congenital cardiac defect and nosocomial catheter-related bacteremia in infants.¹

Predisposing Factors

In general, any structural cardiac defect that leads to the turbulence of blood flow predisposes to the development of IE. Rheumatic heart disease was at one time the most common underlying cardiac defect associated with endocarditis; however, the proportion of cases related to rheumatic heart disease have declined substantially to 25% or less in developed countries while remaining the predominant defect among patients in developing countries. Mitral valve prolapse with thickened leaflets and valvular redundancy is a recognized predisposing risk to IE, with a documented occurrence rate of 10%. Clinical presentation is often subtle with lower associated mortality in these individuals compared with left-sided IE of other types. In the absence of underlying valvular defects, degenerative cardiac lesions, such as calcified mitral annulus secondary to atherosclerotic cardiovascular disease and postmyocardial infarction thrombus, may be a significant risk factor predisposing the elderly to IE. In one series of native valve endocarditis cases, 50% of patients aged 60 years and above had degenerative cardiac lesions; however, the actual contribution of these lesions is unknown.⁸ The intravenous (IV) drug users constitute a unique population at greatest risk for recurrent and polymicrobial IE. In addition, health care-related IE occurs with increasing frequency among hospitalized critically ill patients and others who are subjected to IV access procedures or invasive medical device placement (hemodialysis shunts or fistulas, intracardiac prosthesis, central venous pressure monitoring lines, hyperalimentation lines, defibrillators, permanent cardiac pacemakers).¹

In a prospective cohort of 1,779 patients with IE, hemodialysis-dependency (8%) and diabetes mellitus (16%) were identified as the two most common demographic characteristics besides a history of congenital heart disease (12%).⁷ Up to 25% of all cases were acquired in health care-related settings. Notably, in the United States, health care-associated IE was more likely to occur compared with community acquisition.

Bacteriology

Overall, streptococci and staphylococci are identified as the cause of 80% to 90% of cases of IE. Historically, viridans streptococci have been the predominant causative pathogens in IE, accounting for 60% to 80% of all cases.¹ When comparing epidemiologic studies in the aggregate over the past decades, however, staphylococci have assumed increased importance as a cause of IE. Viridans streptococci remain the predominant

cause of IE in children and in young women with isolated mitral valve involvement.¹

Staphylococcus aureus is identified as the leading cause of IE (40%) in one US study and confirmed in another large multinational study at 32%.^{6,7} Acquisition of IE in nearly half was presumed to be health care-related, supporting a low threshold to evaluate underlying IE in the setting of health care-related *S. aureus* bacteremia. More importantly, strains exhibiting methicillin-resistance account for up to 40% of IE cases involving *S. aureus*.^{6,7}

Endocarditis in IV drug users often is caused by *S. aureus*, whereas prosthetic valve endocarditis is more commonly caused by coagulase-negative staphylococci, such as *S. epidermidis*. Gram-negative bacilli and fungi together account for <10% of all endocarditis cases, which usually are associated with IV drug use, valvular prostheses, and hospital IV access procedures. Endocarditis caused by anaerobes and other organisms is rare. Polymicrobial infective endocarditis (caused by at least two organisms), although uncommon in the typical patient, is being recognized more frequently in IV drug users and postoperative patients. *Candida* species, *S. aureus*, *P. aeruginosa*, *Serratia marcescens*, and non-β group D streptococci are the organisms involved most frequently.

Site of Involvement

The site of heart valve involvement is determined by the underlying cardiac defect and the infecting organism.^{1,2,6,9} The mitral valve is affected in >85% of cases caused by viridans streptococci when rheumatic heart disease is the underlying abnormality. The tricuspid valve is the common site of involvement in staphylococcal endocarditis associated with IV drug use. In addition, more than one heart valve may be affected simultaneously. Overall, the mitral valve is affected slightly more often than the aortic (55%), followed by the tricuspid (20%) and the pulmonic (1%) valves. Some studies have shown that aortic valve involvement is increasing in frequency and is associated with higher morbidity and mortality.

STREPTOCOCCUS VIRIDANS ENDOCARDITIS

Clinical Presentation

1. A.G., a 57-year-old, 60-kg man with chief complaints of fatigue, a persistent low-grade fever, night sweats, arthralgias, and a 7-kg unintentional weight loss, is admitted to the hospital for evaluation. Visual inspection reveals a cachectic, ill-appearing man in no acute distress. Physical examination on admission is significant for a grade III/IV diastolic murmur with mitral regurgitation (insufficiency) that has increased from pre-existing murmur, a temperature of 100.5F, petechial skin lesions, subungual splinter hemorrhages, and Janeway lesions on the soles of both feet (Figs. 59-1, 59-2, and 59-5). Nail clubbing, Roth spots, or Osler's nodes are not evident (Figs. 59-3 and 59-4). The remainder of his physical examination is unremarkable. A.G.'s medical history is significant for mitral valve prolapse and, more recently, a dental procedure involving the extraction of four wisdom teeth. The history of his present illness is noteworthy for the development of the aforementioned symptoms about 2 weeks after the dental procedure (about 2 months before admission). His only current medication is ibuprofen 600 mg QID.

FIGURE 59-1 Janeway lesions. Extensive ecchymotic embolic lesions in a case of acute bacterial endocarditis.

Relevant laboratory results include hemoglobin (Hgb), 11.4 g/dL; hematocrit (Hct), 34%; reticulocyte count, 0.5%; white blood cell (WBC) count, 85,000/mm³ with 65% polys and 1% bands; blood urea nitrogen (BUN), 21 mg/dL; and serum creatinine (SrCr), 1.8 mg/dL. A urinalysis (UA) reveals 2+ proteinuria and 10 to 20 red blood cells (RBC) per high-power field (HPF). The erythrocyte sedimentation rate (ESR) on admission is elevated at 66 mm/hr and the rheumatoid factor (RF) is positive. Results from a transthoracic echocardiogram (ECG) were unrevealing.

To establish the diagnosis of IE, three blood cultures were obtained over 24 hours. All cultures obtained on day 1 are reported to be growing α-hemolytic streptococci. While confirmation and speciation of the organism is being performed, A.G. is started on penicillin G, 2 million units IV Q 4 hr (12 million U/day), and gentamicin, 120 mg (loading dose) followed by 60 mg Q 12 hr. Antimicrobial susceptibility results are pending. What clinical manifestations and laboratory abnormalities in A.G. are consistent with IE?

[SI units: Hgb, 11.4 g/L (normal, 140–180); Hct, 0.34 (normal, 0.39–0.49); reticulocyte count, 0.005 (normal, 0.001–0.024); WBC count, 85 × 10/L

FIGURE 59-2 Splinter hemorrhages in the nailbed.

FIGURE 59-3 Osler's nodes on the tip of the index finger in a case of endocarditis caused by *Staphylococcus aureus*.

FIGURE 59-4 Clubbing of the fingers in longstanding subacute bacterial endocarditis.

FIGURE 59-5 Petechial skin lesions in a case of acute staphylococcal endocarditis.

with 0.65 polys and 0.01 bands (normal, 3.2–9.8 with 0.54–0.62 polys and 0.03–0.05 bands); BUN, 7.5 mmol/L of urea (normal, 2.9–8.9); and SrCr, 159 mmol/L (normal, 53–133)]

The clinical presentation of IE is highly variable and can involve almost any organ system.¹ A.G. appears pale and chronically ill and represents the typical patient with subacute disease (e.g., that caused by viridans streptococci). Nonspecific complaints consistent with endocarditis in A.G. include fatigue, weight loss, fever, night sweats, and arthralgias. Only fever is present in most (90%) patients with endocarditis. The fever is characteristically low grade and remittent, with peaks in the afternoon and evening. The temperature rarely exceeds 103°F in subacute disease.¹ Fever may be absent or minimal in patients with congestive heart failure (CHF), chronic renal and liver failure, prior use of antimicrobial agents, or IE caused by less virulent organisms.¹ Musculoskeletal complaints (e.g., arthralgias, myalgias, and back pain) are common and may mimic rheumatic disease. Other symptoms can include lethargy, anorexia, malaise, nausea, and vomiting.¹ Because signs and symptoms are nonspecific and subtle, diagnosis often is difficult. In addition, the time from bacteremia to diagnosis often is prolonged because of the insidious progression of symptoms.¹ In particular, delayed diagnosis occurs more commonly in the elderly. Fever may be absent in 30% to 40% of patients >60 years of age, whereas it can be present in >90% of patients <40 years of age. Fewer of these patients have new or changed heart murmurs. The most common presenting complaints in the elderly with endocarditis are confusion, anorexia, fatigue, and weakness, which may be readily attributable to stroke, heart failure, or syncope.

The temporal relationship between A.G.'s dental procedure and the onset of symptoms makes it the most obvious cause of bacteremia and subsequent endocarditis. Although it is assumed that prophylactic antibiotics were administered before the procedure, endocarditis can develop despite apparently adequate chemoprophylaxis.¹⁰

A.G. is noted to have an increase in his pre-existing diastolic murmur with mitral insufficiency, a finding consistent with endocarditis. Cardiac murmurs are present in >85% of patients with endocarditis. Murmurs frequently are absent, however, in patients with acute disease (e.g., staphylococcal endocarditis), right-sided disease (e.g., endocarditis in IV drug users), or mural infection.¹

A.G. exhibits several peripheral manifestations of infective endocarditis, including conjunctival petechiae, Janeway lesions, and splinter hemorrhages. Overall, peripheral manifestations are found in 10% to 50% of cases, but none of these is pathognomonic for IE. These manifestations are usually a result of septic embolization of vegetations to distal sites or immune complex deposition. Mucocutaneous petechial lesions of the conjunctiva, mouth, or pharynx are present in 20% to 40% of patients, especially those with longstanding disease. These lesions generally are small, nontender, and hemorrhagic in appearance and occur as a result of vasculitis or peripheral embolization. Janeway lesions are painless, hemorrhagic, macular plaques most commonly found on the palms and soles (Fig. 59-1). Splinter hemorrhages are nonspecific findings that appear as red to brown linear streaks in the proximal portion of the fingers or toenails (Fig. 59-2). Other findings can include

Roth spots (small, flame-shaped retinal hemorrhages with pale white centers found near the optic nerve) and Osler's nodes (purplish, nonhemorrhagic, painful nodules that develop on the subcutaneous pads of the fingers and toes or on palms and soles) (Fig. 59-3). Clubbing (broadening and thickening) of the nails also may be observed in patients with prolonged disease^{1,11} (Fig. 59-4). Petechial skin lesions also are seen (Fig. 59-5).

Several laboratory findings are consistent with IE in A.G. A low Hgb and Hct with normal red cell indices suggest anemia of chronic disease. Of patients with subacute disease, 70% to 90% will have a normochromic, normocytic anemia as part of their initial presentation. Leukocytosis with a left shift, although not evident in A.G., commonly is seen in those with acute, fulminant disease such as staphylococcal endocarditis. The ESR nearly always is elevated in IE, but this finding is nonspecific and can be associated with several other disease entities. Rheumatoid factor (an IgM antiglobulin) and circulating immune complexes can be detected in most patients with longstanding disease, but both are nonspecific findings.¹

Major embolic episodes and infarction involving the kidney, spleen, lung, and brain develop as secondary complications in up to one-third of cases.¹ A.G. exhibits some degree of renal damage, as evidenced by moderate hematuria and proteinuria. Erythrocyte and leukocyte cast formation also may be present. Alterations in A.G.'s renal function (increased BUN and creatinine) probably are a result of immune complex deposition (diffuse glomerulonephritis) or secondary to renal embolization (focal glomerulonephritis). Renal impairment, however, usually is reversible with the institution of effective antimicrobial therapy.^{1,11}

Cardiac complications occur most frequently. CHF, the most common cause of death in IE, is the most compelling indication for surgery. Infection-induced valvular damage is responsible for valvular insufficiency causing heart failure.^{1,11} As many as two-thirds of patients with endocarditis develop CHF. Aortic valve infection is more frequently associated with CHF than that of mitral valve infection. Other manifestations include paravalvular abscesses, pulmonary edema, and pericarditis.¹¹ Mitral valve injury caused by viridans streptococci generally is better tolerated hemodynamically than aortic valve injury caused by staphylococci. Although A.G. has no apparent signs of overt heart failure, he should be monitored closely for the development of hemodynamic instability.

Neurologic complications rank second to cardiac complications in frequency, but they may be the leading cause of death in patients with endocarditis. Stroke is the most common neurologic complication of IE.¹¹ A stroke syndrome in a patient with underlying valvular abnormalities should prompt the clinician to rule out IE. Other clinical manifestations include headache, mental status change, stroke or transient ischemic attack, seizures, brain abscess, or intracranial mycotic aneurysms.^{1,11} Neurologic symptoms were noted in as many as 35% of patients in a study of *S. aureus* endocarditis in patients who were not drug addicts. A mortality rate of 74% was found for those with major neurologic manifestations compared with 56% in those without.¹²

Splenomegaly, although not part of A.G.'s findings, occurs in 20% to 60% of all cases and is more common in patients with a prolonged subacute presentation. In addition,

metastatic abscesses can develop in virtually any organ secondary to systemic septic embolization. The most commonly involved metastatic foci are the spleen, kidney, liver, and iliac and mesenteric arteries.¹¹

Diagnosis

2. How was the diagnosis of IE established in A.G.?

Blood Cultures

Although A.G.'s medical history (mitral valve prolapse, recent dental procedure) and clinical presentation are highly suggestive of IE, blood culture is the single most important diagnostic workup of a patient suspected to have IE.¹ Bacteremia secondary to endocarditis is continuous and low grade; >50% of the cultures have only 1 to 30 bacteria/mL. Despite the low concentration of organisms, bacteremia (when present) results in at least one of the first two blood cultures being positive in 95% of cases.¹ Administration of antibiotics within the previous 2 weeks may significantly decrease this yield.¹³

At least three sets of blood cultures collected by separate venipunctures should be obtained over the first 24 hours of presentation.¹ In a "stable" patient such as A.G. who has had the disease for several weeks or months, it is important to establish the exact microbiologic cause before initiating antimicrobial therapy. Patients who are acutely ill should have empiric therapy started as soon as the appropriate cultures are obtained to avoid further valvular damage or other complications.¹

Echocardiography

Echocardiography is a valuable tool in establishing early diagnosis, identifying patients at high risk for complications, and optimizing the timing and mode of surgical intervention by detecting and monitoring associated pathologic changes such as valvular abscess, as well as the presence and size of vegetations.^{1,14,15} In an ECG, high-frequency sound waves are applied, and the reflection by body tissues is processed by a transducer to create images. The transducer may be placed on the chest (transthoracic echocardiogram [TTE]) or in the esophagus (transesophageal echocardiogram [TEE]).¹⁴ TTE is a rapid and noninvasive procedure with a 98% specificity for vegetations. Sensitivity for vegetations may be <60% to 70%, however, for adult patients with obesity, hyperinflated lungs caused by emphysema, or a prosthetic valve. TEE is more costly and invasive, but is significantly more sensitive in detecting vegetations while maintaining high specificity. All patients with suspected IE should have an ECG on admission and repeated during their course, as necessary.¹⁴ Two cost-effective analyses support the increased use of TEE to define antibiotic therapy duration for intravascular catheter-related *S. aureus* bacteremia (2 vs. 4 weeks)^{16,18} In particular, compared with TTE, TEE is superior in the diagnosis of pacemaker IE and IE in the elderly, and should be performed in all patients with a complicated course in whom perivalvular extension is suspected unless contraindicated by underlying esophageal disease.¹ A.G. has a negative TTE result on admission. Given the high clinical suspicion for IE in A.G., a follow-up TEE is recommended to rule out a false-negative result because TTE is less sensitive than TEE and that initial

perivalvular abscesses may be missed by both TTE and TEE when performed early in a patient's illness. Documentation of valvular morphology, the presence and size of vegetations, ventricular function, and valvular insufficiency is important to establish a baseline and, on completion of therapy, to guide future medical management and appropriate timing of intervention.⁹

In summary, IE should be suspected in any patient who has a documented fever and heart murmur. Prior cardiac disease, peripheral manifestations, splenomegaly, various laboratory abnormalities, and a positive ECG strengthen the diagnosis, but microbiologic documentation is the most important factor in confirming IE. Disease entities with overlapping clinical presentation and laboratory abnormalities should be excluded using the appropriate tests.¹

Standardized criteria (Duke criteria) for the clinical assessment of patients suspected of having IE were proposed by a group at Duke University in 1994.¹⁹ Limitations of the Duke criteria, such as misclassification of culture-negative endocarditis and the overly broad categorization of "possible" causes as well as the increasing role of TEE and the relative risk of IE with *S. aureus* bacteremia, were addressed in a modified version.²⁰ Diagnostic criteria for IE are listed in Table 59-2 and Table 59-3, which integrate clinical, laboratory, microbiologic, and echocardiographic data.^{9,20} Based on published evidence involving nearly 2,000 patients, the American Heart Association (AHA) recommends in its 2005 statement that the modified Duke criteria be used as the primary diagnostic schema to evaluate patients suspected of IE.⁹

A.G. possesses one major criterion (positive blood cultures) and three minor criteria (fever, predisposing heart condition, vascular and immunologic phenomena); therefore, he meets the diagnostic criteria for definite IE.²⁰

Table 59-2 Definition of Infective Endocarditis (IE) According to the Modified Duke Criteria

Definite Infective Endocarditis

PATHOLOGIC CRITERIA

Microorganisms: Demonstrated by culture or histology examination of a vegetation, a vegetation that has embolized, or an intracardiac abscess specimen, or

Pathologic lesions: Vegetation or intracardiac abscess confirmed by histologic examination showing active endocarditis

CLINICAL CRITERIA

Using specific definitions listed in Table 59-3; two major criteria *or* one major and three minor criteria *or* five minor criteria

Possible Infective Endocarditis

One major criterion and one minor criterion; or three minor criteria Rejected

Firm alternative diagnosis explaining evidence of IE; *or* Resolution of IE syndrome with antibiotic therapy for <4 days; *or* No pathologic evidence of infective endocarditis at surgery or autopsy, with antibiotic therapy for <4 days; or not meet criteria for possible IE as above

Modifications shown in bold.

Table 59-3 Definitions of Terminology Used in the Modified Duke Criteria for the Diagnosis of Infective Endocarditis (IE)

Major Criteria

- Blood culture positive for infective endocarditis
- Typical microorganisms consistent with IE from two separate blood cultures
 1. *Viridans streptococci*, *Streptococcus bovis*, HACEK group, *or*
 2. *Staphylococcus aureus* or community-acquired enterococci in the absence of a primary focus, *or*
- Microorganisms consistent with IE from persistently positive blood cultures defined as follows:
 1. At least two positive blood cultures drawn >12 hr apart, *or*
 2. All of three or a majority of four separate cultures of blood (with first and last sample drawn at least 1 hr apart)
- **Single positive blood culture for *Coxiella burnetii* or antiphase 1 IgG antibody titer > 1:800**

Evidence of endocardial involvement

- Echocardiogram positive for IE (**TEE recommended for patients with prosthetic valves, rated at least "possible IE" by clinical criteria or complicated IE [paravalvular abscess]; TEE as first test in other patients**) defined as follows:
 1. Oscillating intracardiac Masson valve or supporting structures, in the path of regurgitant jets, or on implanted material in the absence of an alternative anatomic explanation; *or*
 2. Abscess, *or*
 3. New partial dehiscence of prosthetic valve
- New valvular regurgitation (worsening or changing of pre-existing murmur not sufficient)

Minor Criteria

- Predisposition: Predisposing heart condition or intravenous drug use
- Fever >38°C (100.4°F)
- **Vascular Phenomena:** Major arterial emboli, septic pulmonary infarcts, mycotic aneurysm, intracranial hemorrhage, conjunctival hemorrhages, Janeway lesions
- **Immunologic Phenomena:** Glomerulonephritis, Osler's nodes, Roth spots, rheumatoid factor
- **Microbiologic Evidence:** Positive blood culture but not meeting major criterion as noted above or serologic evidence of active infection with organism consistent with IE
- **Echocardiographic minor criteria eliminated**

Modifications shown in bold.

Excludes single positive cultures for coagulase-negative staphylococci and organisms that do not cause endocarditis.

HACEK, *Haemophilus species*, *Actinobacillus actinomycetemcomitans*, *Cardiobacterium hominis*, *Eikenella species*, and *Kingella kingae*; TEE, transesophageal echocardiography

Antimicrobial Therapy

General Principles

3. What would be a reasonable duration of antibiotic therapy for A.G.? When are serum bactericidal titers (SBT) useful in treating bacterial endocarditis?

The avascular nature of the vegetation results in an environment that is devoid of normal host defenses (e.g., phagocytic cells and complement); this permits uninhibited growth of bacteria.² Therefore, to eradicate the causative organism, high doses of a parenterally administered, bactericidal

antibiotic generally are administered for 4 to 6 weeks.^{1,21} For some infections, it may be necessary to use two antibiotics to achieve synergistic activity against the organism.²² For example, the addition of an aminoglycoside to penicillin results in a more rapid and complete bactericidal effect against enterococci.²³

Once an organism has been identified, its *in vitro* susceptibility pattern is determined by the minimum inhibitory concentration (MIC) for various antibiotics. Standard Kirby-Bauer disk testing is inadequate in the setting of IE to aid in selection of antibiotics without the quantitative information provided by the MIC.¹ In addition, the minimum bactericidal concentration (MBC) may be useful in detecting tolerant strains, particularly in the setting of unexplained slow response or treatment failure. Routine MBC determination is not recommended, however.¹ Treatment of endocarditis requires antibiotics with bactericidal activity; therefore, the serum concentration of the antibiotic must greatly exceed the MBC for the particular organism. For endocarditis caused by viridans streptococci acquired from the community, this usually is achieved without much difficulty because most isolates are sensitive to penicillin at an MIC of <0.125 mcg/mL; corresponding MBC are, at most, one or two tube dilutions higher.²⁴ The emergence of strains demonstrating resistance to penicillin and related β -lactams, such as ceftriaxone, is a significant problem, particularly among bloodstream isolates obtained from the nosocomial setting and neutropenic cancer patients.^{24–27} The increasing prevalence of β -lactam-resistant clinical isolates highlights the importance of determining the MIC and continued close monitoring of the antibiotic susceptibility of viridans streptococci. An increasing number of reports have described suboptimal response to vancomycin therapy for the treatment of invasive infection caused by methicillin-resistant *Staphylococcus aureus* (MRSA) strains showing borderline susceptibility (MIC 2 mcg/mL).²⁸ Many such strains demonstrated tolerance to vancomycin as defined by a high MBC-to-MIC ratio (≥ 32).²⁹ Thus, these data support the need to determine MBC and possibly SBT (see below) in the setting where the treatment option for IE caused by *S. aureus* is limited to vancomycin and suboptimal response is observed.²⁹

The SBT, commonly called a Schlichter test, is an *in vitro* modification of the MBC test. It measures the killing activity of the patient's serum (containing antibiotic) against the isolated organism.³⁰ To perform the test, a known inoculum of the patient's organism is added to serial dilutions of the patient's serum. The SBT is the highest dilution that kills 99% to 100% of the inoculum.

Much controversy surrounds the value of the SBT in monitoring therapy for IE, the usefulness of peak versus trough SBT, and the appropriate SBT endpoint required for successful treatment of bacterial endocarditis.^{1,31} The lack of agreement is partly because of the nonstandardized method for performing SBT, such as the inoculum size used and the timing of SBT samples, which leads to difficulty in test interpretation and correlation with clinical outcome.^{1,31} In one large, multicenter study using a standardized method, peak titers (dilutions) of $\geq 1:64$ and trough titers of $\leq 1:32$ were needed to predict bacteriologic cure in all patients.³¹ On the other hand, the SBT was a poor predictor of failure, because many patients who were cured had much lower SBT (e.g., <1:8). Until an accepted, standardized method is established, routine performance of

SBT is not recommended. The SBT test may be useful in the following situations: (a) when endocarditis is caused by relatively resistant organisms (e.g., relatively penicillin-resistant viridans streptococci, MIC 0.1–0.5 mcg/mL) when a synergistic combination of antibiotics might be beneficial; (b) when response to therapy has been suboptimal; and (c) when less well-established regimens are used for treatment.^{1,30} Alternatively, *in vitro* synergy studies using the standard microtiter checkerboard tests or time-kill curves in broth may be performed to evaluate the synergistic potential of combination therapy in the above situations.¹

4. What antibiotic regimens are most useful for the treatment of viridans streptococci endocarditis?

Patients with endocarditis caused by penicillin-sensitive strains of viridans streptococci and nonenterococcal group D streptococci (e.g., *S. bovis*; MIC <0.1 mcg/mL) can be treated with any one of three regimens as outlined in the 1995 AHA treatment guidelines.²¹ The suggested regimens (Table 59-4) are associated with cure rates of up to 98% and include (a) high-dose parenteral penicillin for 4 weeks; (b) high-dose parenteral ceftriaxone for 4 weeks; and (c) 2 weeks of combined therapy with high-dose parenteral penicillin and an aminoglycoside.^{4,21,32–37} Studies also indicate that combined therapy with once-daily dosing of ceftriaxone and an aminoglycoside for 2 weeks demonstrate comparable efficacy for selected patients.^{38,39}

High-Dose Penicillin for 4 Weeks

The IV administration of 10 to 20 million units/day of penicillin G for 4 weeks resulted in a cure rate of 100% for 66 patients with nonenterococcal streptococcal endocarditis.³³ Another study using penicillin alone reported relapse in only 2 of 49 patients; however, both of these patients received <4 weeks of therapy.³⁷ The large range of 12 to 18 million units/day of penicillin is recommended to allow flexibility in dosing based on the patient's renal function and disease severity.

Single Daily Ceftriaxone for 4 Weeks

Ceftriaxone has been shown to have excellent *in vitro* activity against viridans streptococcal strains isolated from patients with endocarditis. In one study, all 49 strains of viridans streptococci and 11 strains of *S. bovis* were inhibited at a concentration of <0.125 mcg/mL of ceftriaxone; one strain of *S. sanguis* was inhibited at an MIC of 0.25 mcg/mL.⁴⁰ Although no direct comparative trials have been performed evaluating ceftriaxone against high-dose penicillin for the treatment of streptococcal endocarditis, current data (based on open-label studies of ceftriaxone) indicate an efficacy rate comparable to that of high-dose penicillin when treatment is given for 4 weeks.^{41–42} Of the 70 assessable patients who received ceftriaxone 2 g as a single daily dose for 4 weeks, all were cured, except for 1 patient who had a probable relapse 3 months after completion of therapy. All strains of viridans streptococci were inhibited by ceftriaxone at an MIC of 0.25 mcg/mL in both studies. One study included only patients without cardiovascular risk factors or complications. Although the simplicity of single daily treatment with ceftriaxone is attractive for outpatient use, careful patient selection based on microbiologic, clinical, and host factors is critical to the success of treatment and the proper and

Table 59-4 Suggested Regimens for Therapy of Native Valve Endocarditis Caused by *Streptococcus viridans* and *Streptococcus bovis*

| Antibiotic | Dose ^{a,b} and Route | Duration |
|---|---|----------|
| Penicillin-Susceptible (Minimum Inhibitory Concentration = 0.12 mcg/mL) | | |
| Aqueous crystalline penicillin G ^c | <i>Adult:</i> 12–18 million units/24 hr intravenously (IV) either continuously or in four to six equally divided doses <i>Pediatric:</i> 200,000 units/kg/24 hr IV (max: 20 million units/24 hr) either continuously or in four to six equally divided doses | 4 wk |
| Ceftriaxone sodium ^c | <i>Adult:</i> 2 g once daily IV or intramuscularly (IM) <i>Pediatric:</i> 100 mg/kg once daily IV or IM | 4 wk |
| Aqueous crystalline penicillin G | <i>Adult:</i> 12–18 million units/24 hr IV either continuously or in six equally divided doses <i>Pediatric:</i> 200,000 units/kg/24 hr IV (max: 20 million units/24 hr) either continuously or in six equally divided doses | 2 wk |
| Ceftriaxone sodium | <i>Adult:</i> 2 g once daily IV or IM <i>Pediatric:</i> 100 mg/kg once daily IV or IM | |
| With gentamicin sulfate ^d | <i>Adult:</i> 3 mg/kg once daily IV or IM <i>Pediatric:</i> 3 mg/kg once daily IV or IM or in three equally divided doses | 2 wk |
| Relatively Penicillin G Resistant (Minimum Inhibitory Concentration >0.1 mcg/mL and <0.5 mcg/mL) | | |
| Aqueous crystalline penicillin G ^e | <i>Adult:</i> 24 million units/24 hr IV either continuously or in four to six equally divided doses <i>Pediatric:</i> 200,000–300,000 units/kg/24 hr IV (max: 20 million units/24 hr) either continuously or in four to six equally divided doses | 4 wk |
| Ceftriaxone sodium | <i>Pediatric:</i> 100 mg/kg once daily IV or IM | |
| With gentamicin sulfate ^d | <i>Adult:</i> 3 mg/kg once daily IV or IM <i>Pediatric:</i> 3 mg/kg once daily IV or IM or in three equally divided doses | 2 wk |
| β-Lactam Allergic Patients | | |
| Vancomycin hydrochloride ^f | <i>Adult:</i> 30 mg/kg/24 hr IV in two equally divided doses (max: 2 g/24 hr unless serum concentrations are monitored) <i>Pediatric:</i> 40 mg/kg/24 hr IV in two or three equally divided doses (max: 2 g/24 hr unless serum concentrations are monitored) | 4 wk |

^aPediatric doses should not exceed that of a normal adult.
^bAntibiotic doses for patients with impaired renal function should be modified appropriately. Vancomycin dosage should be reduced in patients with renal dysfunction; cephalosporin dosage may need to be reduced in patients with moderate to severe renal dysfunction.
^cPreferred in most patients >65 years of age and in those with impairment of the eighth nerve or renal function.
^dTwo-week regimen not intended for patients with known cardiac or extracardiac abscess or for those with creatinine clearance of <20 mL/min, impaired eighth cranial nerve function or *Abiotrophia*, *Granulicatella*, or *Gemelia* infection. Gentamicin dosage should be adjusted to achieve peak serum concentrations of 3–4 mcg/mL and trough serum concentrations of <1 mcg/mL when three divided doses are used; nomogram used for single daily dosing. Other potential nephrotoxic drugs should be used with caution in patients receiving gentamicin therapy.
^eCefazolin or other first-generation cephalosporins may be substituted for penicillin in patients whose penicillin hypersensitivity is not of the immediate type.
^fVancomycin dosage should be reduced in patients with impaired renal function. Vancomycin given on a mg/kg basis produces higher serum concentrations in obese patients than in lean patients. Therefore, in obese patients, dosing should be based on ideal body weight. Each dose of vancomycin should be infused over at least 1 hr to reduce the risk of the histamine-release red man syndrome. Peak serum concentrations of vancomycin should be obtained 1 hr after completion of the infusion and should be in the range of 30–45 mg/mL. Trough concentrations should be obtained within half an hour of the next dose and be in the range of 10–15 mcg/mL.

timely management of potential complications. (See Question 32 for a detailed discussion of outpatient therapy.)

High-Dose Penicillin or Ceftriaxone Plus an Aminoglycoside for 2 Weeks

The combination of 2 weeks of streptomycin (or gentamicin) with 4 weeks of penicillin is synergistically bactericidal for most streptococci, including enterococci (see Question 16).^{22,35} This in vitro synergy also has been correlated with a more rapid rate of eradication of viridans streptococci from cardiac vegetations in the rabbit model of endocarditis.⁴ A shortened combination regimen consisting of high-dose penicillin G and streptomycin for 2 weeks is an effective alternative to the previously described regimens. The reported cure rate in

104 patients treated at the Mayo Clinic with this regimen was 99%.^{34,35}

Although clinical experience with combination therapy has been primarily with penicillin and streptomycin, in vitro and animal data support that streptomycin and gentamicin are reasonably interchangeable. Gentamicin is more widely used in clinical practice and serum concentrations are more readily available to monitor efficacy and toxicities. Experimental data suggest that a gentamicin dosing interval of once versus thrice daily does not affect the relative efficacy of penicillin plus gentamicin for treatment of viridans streptococcal endocarditis.³⁶

Combination therapy with ceftriaxone and an aminoglycoside for 2 weeks has also been evaluated in two studies.^{37,38} In a noncomparative, open-label study, a 2-week course of

ceftriaxone 2 g plus netilmicin (3 mg/kg) (both given once daily) resulted in a clinical cure of 87% in 48 evaluable patients.³⁸ A second open-label study compared ceftriaxone 2 g alone versus the combination of ceftriaxone 2 g plus gentamicin (3 mg/kg), both given once daily, for the treatment of endocarditis caused by penicillin-susceptible streptococci.³⁹ Patients were randomized to either regimen; 26 monotherapy recipients and 25 combination therapy recipients were evaluable. Clinical cure was observed in 96% of the patients in both groups at completion of therapy and at 3-month follow-up. This study excluded patients with suspected or documented cardiac or extracardiac abscesses and those with prosthetic valve endocarditis. Although the aminoglycoside agent (netilmicin or gentamicin) was administered as a single daily dose in both studies, all of the patients had measurable serum trough levels. Therefore, the efficacy of “extended-interval dosing” of aminoglycoside (whereby trough levels are not detectable, allowing a drug-free interval) in short-course combination therapy will need to be confirmed in future studies.

Based on available data, the 2-week regimen of penicillin or ceftriaxone plus an aminoglycoside appears to be efficacious for uncomplicated cases of penicillin-susceptible viridans streptococci endocarditis. It is not currently recommended for patients with extracardiac complications or intracardiac abscesses. Patients infected with *Abiotrophia* species (formerly known as nutritionally variant viridans streptococci) or viridans streptococci who have a penicillin MIC >0.1 mcg/mL, or patients who have prosthetic valve infections should not receive short-course therapy.²¹

Special Considerations

The risk of relapse may be higher in patients who have had symptoms for >3 months before the initiation of treatment.^{1,21,42} These patients should be treated with 4 to 6 weeks of penicillin combined with an aminoglycoside for the first 2 weeks.^{1,21,42}

Nutritionally deficient or variant streptococci (NVS) have been reclassified into a new genus, *Abiotrophia*, which includes *A. defectiva*, *A. adjacens* (renamed again as *Granulicatella adjacens*), and *A. elegans*. *Abiotrophia* species are slow-growing, fastidious organisms that are responsible for approximately 5% of IE cases. Previously, NVS was the cause of most of the cases of endocarditis diagnosed as “culture-negative” initially owing to its requirement for the addition of vitamin B₆ (pyridoxal HCl) to the culture media for laboratory growth. Laboratory identification is no longer a significant problem, however, because of current culture media and laboratory techniques.²⁴

Nutritionally deficient or variant streptococci are less susceptible to penicillin when compared with other streptococci. Up to two-thirds of NVS organisms have relatively high MIC to penicillin (0.2–2.0 mcg/mL), and some show high-level resistance to penicillin (MIC >4 mcg/mL).²⁴ In addition, tolerance to penicillin has been described in many strains.²⁴ An animal model of endocarditis indicates that a penicillin–aminoglycoside (streptomycin or gentamicin) combination is significantly better than penicillin alone in reducing bacterial counts of these organisms.⁴³ More importantly, endocarditis caused by NVS is associated with greater morbidity and mortality compared with IE caused by other streptococci. Higher mortality rate (14% vs. 5%), more frequent complications of embolization (33% vs. 11%) and CHF (33% vs.

18%), and an increased rate of surgical intervention (33% vs. 18%) were observed in a study comparing 49 patients with NVS endocarditis versus 130 patients infected with other oral streptococci.²⁴ High rates of bacteriologic failure and relapse may be expected in patients despite completion of the treatment course for strains highly susceptible to penicillin.²⁴ All patients infected with NVS or *Abiotrophia* should receive 4 to 6 weeks of penicillin (or ampicillin) in combination with gentamicin.²¹ A 6-week course of combination therapy with penicillin and gentamicin is recommended for patients with symptoms >3 months in duration and those with prosthetic valve endocarditis caused by these strains.^{21,24} Patients with endocarditis caused by relatively resistant viridans streptococci with penicillin MIC of >0.5 mcg/mL or enterococci should receive a similar treatment regimen, as described above.²¹

Patients allergic to β -lactams should receive vancomycin 30 mg/kg/day divided into two doses for 4 to 6 weeks. In patients who have had minor reactions to penicillins (e.g., a delayed rash), a first-generation cephalosporin, such as cefazolin (1–2 g Q 6–8 hr), may be cautiously substituted. Although the addition of an aminoglycoside to a cephalosporin or vancomycin enhances bactericidal activity in vitro, it is unknown whether the addition of an aminoglycoside confers any additional clinical benefit.²¹

Regimen Selection

5. What factors must be considered in selecting a regimen for A.G.? Which regimen should be used for A.G.?

For most cases of endocarditis caused by penicillin-sensitive viridans streptococci (in patients not allergic to penicillin), all three of the aforementioned regimens are equally acceptable; therefore, the choice should be based on their relative advantages and disadvantages. The 2-week regimen requires the shortest hospital stay, but it has the disadvantage of possible ototoxicity and nephrotoxicity secondary to aminoglycoside administration. Therefore, it may be prudent to consider the use of penicillin or ceftriaxone alone for 4 weeks in older persons (>65 years) and those with impaired renal or vestibular function. For those with uncomplicated viridans streptococci endocarditis who can manage the technical aspects of outpatient therapy, ceftriaxone monotherapy offers the convenience of single daily administration. The combined regimen consisting of penicillin (or ampicillin) and an aminoglycoside for 4 to 6 weeks can be used for patients infected with NVS or relatively penicillin-resistant strains, those with prosthetic valve infections, and those with longstanding disease (symptoms >3 months).^{21,24,42}

Assuming the viridans streptococci isolated from A.G. is not resistant to penicillin and he has no other complicating factors, any of the suggested regimens would be appropriate. Because no compelling reason exists to use the 4-week regimens, the 2-week penicillin–aminoglycoside regimen is the most economic choice. Although A.G. has mild renal impairment, this is most likely secondary to the endocarditis and should improve once adequate antimicrobial therapy has been instituted. A.G. was begun on 12 million units/day of penicillin G, which would be reasonable for his age and mild renal impairment. If nephrotoxicity were a major concern in A.G., penicillin or ceftriaxone alone for 4 weeks would be reasonable. If gentamicin is used, A.G.’s dose should be adjusted appropriately and he should be

evaluated frequently for signs of toxicity. Periodic peak and trough aminoglycoside concentrations should be monitored.

STAPHYLOCOCCUS EPIDERMIDIS: PROSTHETIC VALVE ENDOCARDITIS

Etiology

6. F.T., a 65-year-old man, presents with chief complaints of anorexia, fever, chills, and weight loss. His medical history is significant for replacement of his mitral and aortic heart valves (both porcine) 1 year ago for aortic stenosis, mitral regurgitation, and mitral stenosis secondary to rheumatic heart disease. One month later he was readmitted with fever, a right pleural effusion, a pericardial friction rub, and pericarditis. The impression at that time was either postpericardiotomy or Dressler's syndrome. F.T. was sent home on anti-inflammatory agents but failed to improve. After continued complaints of anorexia, nausea, chills, and fever to 101°F, he returned to the hospital. On readmission, his physical examination was noteworthy for a systolic ejection murmur at the left sternal border and 3+ pedal edema. Blood cultures were obtained and routine laboratory studies were performed. His history and clinical presentation were strongly suggestive of prosthetic valve endocarditis (PVE). What are the most likely agents responsible for PVE in F.T.?

Prosthetic valve endocarditis is a life-threatening infectious complication of artificial heart valve implantation that accounts for 7% to 25% of cases of IE in developed countries.⁴⁴ The prevalence of complications resulting in death has been as high as 20% to 40%.⁴⁵ The risk of PVE after surgery is approximately 1% at 12 months and 2% to 3% at 60 months. PVE is categorized as early or late, depending on the onset of clinical manifestations following cardiac surgery.^{45,44} Early PVE occurs within 2 months following surgery and is thought to represent infection acquired during valve placement. It usually is caused by skin organisms that were implanted into the valve annulus (suture site where the valve is attached to cardiac muscle) at the time of surgery.^{44,45} The most common organisms cultured from patients such as F.T. with early PVE are coagulase-negative staphylococci (primarily *S. epidermidis* [$>30\%$], most of which are resistant to methicillin), followed by *S. aureus* (20%), and gram-negative bacilli (10%–15%). Miscellaneous organisms, such as diphtheroids and fungi, account for the remainder.^{44,45} On the other hand, streptococci are a more common cause of late PVE (>2 months after surgery).^{44,45}

Nosocomial bacteremia and fungemia in a patient with prosthetic heart valves contribute to a significant risk for the development of PVE. One study noted that bacteremia caused by staphylococci and gram-negative bacilli resulted in 55% and 33% of subsequent PVE cases, respectively.⁴⁶ Another study observed the development of PVE in 25% (11 of 44) of patients following nosocomial candidemia.⁴⁷

Prophylaxis

7. What measures can be taken to prevent early PVE?

The overall frequency of early PVE, despite antibiotic prophylaxis, is 1% to 4%.⁴⁸ Complications are severe and include

valve dehiscence, acute heart failure, arrhythmias, and outflow obstruction. Although antibiotic prophylaxis before valve surgery (a “clean” procedure) has not been proved to reduce the frequency of early PVE, it is indicated nevertheless because the complications of infection are catastrophic. Animal data indicate that antibiotic prophylaxis reduces the infection rate.⁴⁸

Cephalosporins

The antimicrobial regimen used most commonly for cardiac surgery prophylaxis consists of an antistaphylococcal cephalosporin, such as cefazolin, given in the operating room at the time of induction of anesthesia or within 60 minutes before the procedure. Drug administration should be timed to produce peak concentrations at the time when bacteremia may result from the procedure. Cephalosporins are frequently selected because they are active against most strains of *S. aureus*. The prevalence of methicillin- (and cephalosporin-) resistant strains is increasing, however, exceeding 50% in many centers.

Most strains (87%) of coagulase-negative staphylococci are also methicillin- (and cephalosporin-) resistant.^{45,49}

Resistance is thought to be caused by an altered penicillin binding protein (PBP 2a); thus, cross-resistance to all other β -lactams is expected.⁵⁰

Vancomycin

Vancomycin has been used as the alternative prophylactic agent of choice when a first-generation cephalosporin cannot be used. Given its demonstrated efficacy, vancomycin could be considered the prophylactic agent of choice for cardiovascular procedures, including prosthetic valve replacement and implantation of prosthetic grafts, if (a) the patient recently has received broad-spectrum antimicrobial therapy and is likely to be colonized with cephalosporin-resistant staphylococci or enterococci, or (b) the procedure is performed in a center experiencing outbreaks or a high endemic rate of surgical infection with methicillin-resistant staphylococci.⁵¹

8. What are the disadvantages of the routine use of vancomycin as a prophylactic agent?

Because the frequency of PVE is low, it would be nearly impossible to demonstrate a statistically significant decrease in its incidence following the use of vancomycin compared with conventional agents. Thus, the decision to use vancomycin rests on its superior in vitro activity for methicillin-resistant staphylococci. Arguments against the use of vancomycin in this specific setting are compelling, however. First, the potential for vancomycin-related hypotension is of concern.⁵¹ More importantly, the emergence of vancomycin-resistant enterococci (VRE), glycopeptide-intermediate (GISA) and glycopeptide-resistant *S. aureus* (VRSA) heightens the need to limit vancomycin use, because prior exposure to vancomycin is a recognized predisposing risk for the development of resistance to vancomycin.^{52–55}

Of note, ceftobiprole, a novel investigational cephalosporin agent, was shown to be equally effective when compared with vancomycin against MRSA in skin and soft tissue infections in a phase III trial.⁵⁶ If proved safe and effective for marketing, this agent holds a promising role for use in this setting.⁵⁷

In summary, the most appropriate prophylactic antibiotic for valve replacement surgery is patient and institution specific.

The decision should be based on the patient's prior exposure to antibiotics and resultant colonization, in addition to the conditions at each institution, such as the infection rate, the types of organisms recovered, the number of procedures performed, and the feasibility of implementing effective infection control measures.

ADVERSE EFFECTS

9. What is the most common infusion-related adverse effect associated with vancomycin, and how can it be minimized?

The most common adverse effect associated with vancomycin administration is the so-called “red man” or “red neck” syndrome,^{58,59} which most commonly causes erythema of the head and upper torso, pruritus, urticaria, and in some cases hypotension. It is mediated in part by histamine release, and the severity of the reaction is proportional to the quantity released (see Chapter 4, Anaphylaxis and Drug Allergies). The total dose of vancomycin administered and the rate of infusion are major determinants of the frequency and severity of this reaction. The reaction can be minimized by administering vancomycin over ≥ 1 hour. Cutaneous manifestations of the vancomycin-induced red man syndrome still can occur with a 1-hour infusion, but hypotension is uncommon.^{58,59}

Several drugs used perioperatively and in anesthesia also cause histamine release; therefore, the possibility of additive toxicity with vancomycin cannot be dismissed. Most of the serious reactions caused by vancomycin have occurred in patients scheduled for surgery. Vancomycin-induced hypotension occurred in 7% of patients scheduled for cardiothoracic surgery, despite the 1-hour infusion time.⁵¹

ADMINISTRATION

10. When vancomycin is used to prevent PVE, when should it be administered relative to the time of surgery?

Vancomycin cannot be given in the operating room because it must be administered by infusion over 1 hour, and “on-call” administration right before the procedure may not provide sufficient time for the vancomycin infusion to achieve adequate serum and tissue levels. Therapeutic serum concentrations of vancomycin can be maintained reliably during surgery if the 15 mg/kg dose is infused over 1 hour just before initiation of anesthesia.⁵¹

Antibiotic-Impregnated Heart Valves

PVE following heart valve replacement surgery is rare, but early-onset infection is associated with a mortality rate of 23% to 41%.⁴⁴ Systemically administered antibiotic prophylaxis before surgery does not confer 100% protection. The infectious process typically begins at the sewing ring and extends to involve the adjacent area between the prosthesis and the annulus of the heart valve. Hence, investigators have evaluated the use of antibiotic-impregnated heart valve sewing rings for the prophylaxis and treatment of bacterial endocarditis. Various antibiotics, including rifampin, gentamicin, and clindamycin, have been studied with respect to their diffusion kinetics and duration of antimicrobial activity both in vitro and in animal experiments.^{60–62} Whether the combination of “local” and systemic antimicrobial prophylaxis enhances the prophylactic ef-

ficacy against PVE will require confirmation, however, from clinical trials involving large number of patients.

Antimicrobial Therapy

11. What are the treatment options for F.T.?

As noted earlier, F.T. most likely is infected with coagulase-negative staphylococci. For those rare coagulase-negative staphylococci that remain sensitive to β -lactams (<20%), a penicillinase-resistant penicillin (nafcillin or oxacillin) is the drug of choice (Table 59-5).⁴⁹ For the treatment of PVE caused by methicillin-resistant, coagulase-negative staphylococci, vancomycin remains the cornerstone of therapy.⁴⁹ Most of the staphylococci remain sensitive to vancomycin at concentrations of <5 mcg/mL; however, strains of staphylococci with intermediate susceptibility to vancomycin have emerged in the United States and elsewhere and are increasingly reported.^{63,64}

The AHA currently recommends the use of triple-drug combination therapy for the treatment of PVE caused by methicillin-resistant, coagulase-negative staphylococci based on experimental models of endocarditis and limited clinical data.²¹ In a retrospective review of 75 episodes of PVE caused by methicillin-resistant *S. epidermidis* (MRSE),⁶⁵ 21 of 26 patients treated with vancomycin were cured compared with 10 of 20 patients treated with a β -lactam antibiotic ($p = 0.05$); however, the addition of either rifampin or an aminoglycoside to vancomycin appeared to produce superior results (18 of 20 cured) compared with vancomycin alone (3 of 6 cured, $p = 0.06$). A subsequent prospective, multicenter study compared the efficacy of 6 weeks of vancomycin plus rifampin with and without gentamicin for the first 2 weeks for the treatment of PVE caused by MRSE.^{45,49} The emergence of rifampin-resistant strains during therapy was reduced by the addition of gentamicin (6 of 15 vs. 0 of 8, $p = 0.04$). Based on current data, a three-drug regimen (vancomycin, gentamicin, and rifampin) appears to be optimal for the medical treatment of PVE caused by MRSE, although toxicity would be expected to be greater. When isolates of MRSE are resistant to all available aminoglycosides, aminoglycoside treatment should be omitted. A fluoroquinolone active against the isolate may be considered as substitute for the aminoglycoside in the three-drug regimen. In addition, most patients who responded to medical treatment also required valve replacement surgery.^{44,45}

Although quinupristin/dalfopristin (Synercid), linezolid (Zyvox), and daptomycin (Cubicin) have potent in vitro activity against coagulase-negative staphylococci, clinical experience in the treatment of IE caused by these strains is lacking.^{49,66,67}

STAPHYLOCOCCUS AUREUS ENDOCARDITIS

Intravenous Drug Abuser Versus Nonabuser

12. T.J., a 36-year-old human immunodeficiency virus (HIV)-seropositive man with a long history of IV drug abuse, was admitted to the hospital 4 months after being released from the state prison. His chief complaints on admission were fever, night sweats, pleuritic chest pain, shortness of breath (SOB), dyspnea on exertion (DOE), and fatigue. Physical examination was remarkable for a temperature of 101.2°F, splenomegaly, and a pansystolic ejection

Table 59-5 Treatment of Staphylococcal Endocarditis

| Antibiotic | Dosage and Route | Duration |
|---|---|----------|
| Without Prosthetic Material^a | | |
| OXACILLIN-SUSCEPTIBLE STAPHYLOCOCCI | | |
| NONPENICILLIN-ALLERGIC PATIENTS | | |
| Nafcillin | | |
| or | Adult: 2 g intravenously (IV) Q 4 hr Pediatric: 150–200 mg/kg/24 hr IV (max: 12 g/24 hr) in four to six equally divided doses | 4–6 wk |
| Oxacillin | Adult: 2 g IV Q 4 hr Pediatric: 200 mg/kg/24 hr IV (max: 12 g/24 hr) in four to six equally divided doses | 4–6 wk |
| With optional addition of gentamicin ^{b,c} | Adult: 3 mg/kg IV or intramuscularly (IM) in two or three equally divided doses Pediatric: 3 mg/kg IV or IM in three equally divided doses | 3–5 days |
| PENCILLIN-ALLERGIC PATIENTS | | |
| 1. Cefazolin ^d | Adult: 2 g IV Q 8 hr Pediatric: 100 mg/kg/24 hr IV (max: 6 g/24 hr) in equally divided doses Q 8 hr | 4–6 wk |
| With optional addition of gentamicin ^b | Adult: See Nonpenicillin-allergic patient Pediatric: See Nonpenicillin-allergic patient | |
| 2. Vancomycin ^{b,e,f} | Adult: 30 mg/kg/24 hr IV in two or four equally divided doses (max: 2 g/24 hr unless serum levels monitored) Pediatric: 40 mg/kg/24 hr IV in two or four equally divided doses (max: 2 g/24 hr unless serum levels monitored) | 4–6 wk |
| Methicillin-Resistant Staphylococci | | |
| Vancomycin ^{b,e,f} | Adult: 30 mg/kg/24 hr IV in two or four equally divided doses (max: 2 g/24 hr unless serum levels monitored) Pediatric: 40 mg/kg/24 hr IV in two or four equally divided doses (max: 2 g/24 hr unless serum levels monitored) | 4–6 wk |
| With Prosthetic Valve or Other Prosthetic Material^g | | |
| Methicillin-Resistant Staphylococci | | |
| Vancomycin ^{b,e,g} | Adult: 30 mg/kg/24 hr IV in two or three equally divided doses (max: 2 g/24 hr unless serum levels monitored) Pediatric: 40 mg/kg/24 hr IV in two or four equally divided doses (max: 2 g/24 hr unless serum levels monitored) | ≥6 wk |
| With rifampin ^h | Adult: 300 mg IV/PO Q 8 hr Pediatric: 20 mg/kg/24 hr PO (max: 900 mg/24 hr) in two equally divided doses | ≥6 wk |
| and With gentamicin ^{b,i,j,g} | Adult: 3 mg/kg IV or IM in two or three equally divided doses Pediatric: 3 mg/kg IV or IM in three equally divided doses | 2 wk |
| Methicillin-Susceptible Staphylococci | | |
| Nafcillin or oxacillin ^k | Adult: 2 g IV Q 4 hr Pediatric: 150–200 mg/kg/24 hr (max: 12 g/24 hr) in four to six equally divided doses | ≥6 wk |
| With rifampin ^h | Adult: 300 mg IV/PO Q 8 hr Pediatric: 20 mg/kg/24 hr PO (max: 900 mg/24 hr) in three equally divided doses | ≥6 wk |
| and With gentamicin ^{b,i,j,g} | Adult: 3 mg/kg IV or IM in two or three equally divided doses Pediatric: 3 mg/kg IV or IM in three equally divided doses | 2 wk |

^aAntibiotic doses should be modified appropriately for patients with impaired renal function. Shorter antibiotic courses have been effective in some drug addicts with right-sided endocarditis caused by *S. aureus*. (See text for comments on the use of daptomycin and rifampin.)

^bDosing of aminoglycosides and vancomycin on a mg/kg basis will give higher serum concentrations in obese than in lean patients.

^cThe benefit of additional aminoglycoside has not been established. The risk of toxic reactions because of these agents is increased in patients >65 years of age or those with renal or eighth nerve impairment.

^dThere is potential cross-allergenicity between penicillins and cephalosporins. Cephalosporins should be avoided in patients with immediate-type hypersensitivity to penicillin.

^ePeak serum concentrations of vancomycin should be obtained 1 hr after infusion and should be in the range of 30–45 mcg/mL for BID dosing and 20–30 mcg/mL for QID dosing. Trough serum concentrations should be obtained within half an hour of the next dose and should be in the range of 10–15 mcg/mL. (See text for detailed discussion on the need for high trough target of 15–20 mcg/mL for strains with reduced susceptibility to vancomycin. Each vancomycin dose should be infused over 1 hr.)

^fSee text for consideration of optional addition of gentamicin.

^gVancomycin and gentamicin doses must be modified appropriately in patients with renal failure.

^hRifampin is recommended for therapy of infections caused by coagulase-negative staphylococci. Its use in coagulase-positive staphylococcal infections is controversial. Rifampin increases the amount of warfarin sodium required for antithrombotic therapy.

ⁱSerum concentration of gentamicin should be monitored and the dose should be adjusted to obtain a peak level of approximately 3 mcg/mL.

^jUse during initial 2 wk. (See text on alternative aminoglycoside therapy for organisms resistant to gentamicin.)

^kFirst-generation cephalosporins or vancomycin should be used in penicillin-allergic patients. Cephalosporins should be avoided in patients with immediate-type hypersensitivity to penicillin and those infected with methicillin-resistant staphylococci.

Adapted from reference 9, with permission.

murmur at the left sternal border, best heard during inspiration. The chest radiograph revealed diffuse nodular infiltrates. TTE was positive for a small vegetation on the tricuspid valve leaflet. Significant laboratory results included WBC count, 14,000/mm³ with 65% polys and 5% bands; CD4 cell count, 350/mm³; Hgb,

13.1 g/dL; Hct, 39%; and ESR 55 mm/hour (Westergren). IE was suspected. Blood cultures were obtained and all six samples were positive for coagulase-positive, gram-positive cocci, later identified as methicillin-sensitive *S. aureus* (MSSA). How do the clinical presentation and prognosis of endocarditis in the IV drug abuser

differ from in the nonabuser? What impact does HIV infection have on the risk and outcomes of endocarditis in the IV drug abuser?

[SI units: WBC, $14 \times 10/L$ with 0.65 polys and 0.05 bands (normal, 3.2–9.8 with 0.54–0.62 polys and 0.03–0.05 bands); Hgb, 131 g/L (normal, 140–180); Hct, 0.39 (normal, 0.39–0.49)]

The annual incidence of endocarditis among IV drug users is estimated at 1% to 5%; parenteral cocaine addicts have the highest risk.⁶⁸ The presentation, pathophysiology, and prognosis of endocarditis in those who acquire the disease secondary to IV drug abuse differ from those in nonabusers.^{1,68,69} IE caused by *S. aureus* is associated with an odds ratio of 9.3 (95% CI, 6.3–13.7) compared with other pathogens in this population.⁷ *S. aureus* is part of the normal skin flora and is introduced when the illicit drug is injected. It is hypothesized that insoluble agents used to “cut” the drug damage the normal heart valve, preparing the surface for bacterial adherence and growth.¹

The following are differences between addicts and non-addicts with *S. aureus* endocarditis: addicts are significantly younger; they have fewer underlying diseases, more right-sided (tricuspid) involvement (in contrast to the predominance of left-sided disease in the nonaddicts); they are less likely to have heart failure or central nervous system (CNS) complications; they exhibit fewer signs of peripheral involvement and have a lower incidence of death.⁶⁹ Among patients without history of IV drug use, MRSA was involved in one-third of a cohort of 424 patients with definite *S. aureus* IE. Clinical features that characterized MRSA IE were persistent bacteremia, chronic immunosuppressive therapy, health care-associated infection, a presumed intravascular device source, and diabetes mellitus.⁷

The prevalence of HIV seropositivity is 40% to 90% among IV drug users with IE.^{68,70} One case-control study among an ongoing cohort of IV drug users suggested that HIV-related immunosuppression may be an independent risk factor for the development of endocarditis after controlling for confounding variables such as a history of endocarditis or sepsis before enrollment, injection duration, current injection frequency, and a recent history of abscess at injection sites.⁷¹

Antimicrobial Therapy

Methicillin-Sensitive *Staphylococcus aureus*

13. What are the therapeutic options for treating *S. aureus* endocarditis in T.J.?

The susceptibility of *S. aureus* to methicillin is the major determinant of which antibiotic is selected to treat T.J.’s endocarditis. T.J. is infected with MSSA. Therapy of choice for methicillin-sensitive strains is a penicillinase-resistant penicillin, such as nafcillin or oxacillin²¹ (Table 59-5). Penicillin G rarely is appropriate because nearly all isolates of *S. aureus* produce penicillinase. Methicillin is no longer used because it is associated with a high incidence of interstitial nephritis.

Prospective, randomized, clinical trials have established that 4 to 6 weeks of therapy with high-dose (12 g/day) nafcillin is effective in most patients.^{72,73} Clinical experience and in vitro studies indicate that vancomycin may be less efficacious than nafcillin as an antistaphylococcal agent.^{21,73} Therefore, vancomycin should not be used to substitute for nafcillin merely

for dosing convenience. IV drug addicts, for the reasons previously identified, have a higher response rate to appropriate therapy compared with nonaddicts, and 4 weeks of therapy is probably adequate. In one study, 31 addicts were successfully treated with 16 days of parenteral therapy followed by 26 days of oral dicloxacillin.⁷⁴

Addicts with uncomplicated right-sided endocarditis caused by MSSA can be treated successfully with a 2-week course of combination therapy with a penicillinase-resistant penicillin and an aminoglycoside.^{75–77} In one study, 47 of 50 patients (94%) were cured after treatment with the combination of IV nafcillin (1.5 g Q 4 hr) and tobramycin (1 mg/kg Q 8 hr) for a total of 2 weeks. Notably, two of three patients in this study who were treated with vancomycin relapsed, resulting in early termination of this arm of study. Thus, vancomycin should not be used to substitute for nafcillin in this regimen. In another study, 71 patients who completed the 2-week course of treatment with cloxacillin (2 g IV Q 4 hr) plus amikacin (7.5 mg/kg IV Q 12 hr) had a cure rate of 94%.⁷⁶ Of the four patients who failed, the two week treatment period had to be extended to achieve cure. In contrast to the prior study, most (72%) patients had definite endocarditis with echocardiographic vegetations. Overall, none of the patients who responded promptly to treatment relapsed. In addition, the risk of nephrotoxicity secondary to 2 weeks of aminoglycoside therapy was minimal in this selected patient population. Alternatively, Ribera et al. demonstrated in a study that cloxacillin alone was as effective as combination therapy of cloxacillin plus gentamicin for the treatment of right-sided MSSA endocarditis; the treatment response exceeded 90% in the cloxacillin monotherapy arm.⁷⁸ Gentamicin administered at 1 mg/kg Q 8 hr for 7 days in the combination group did not improve treatment response.

Clinical studies thus far support the use of an abbreviated course of treatment in a defined group of IV drug users with right-sided endocarditis. These patients should have the following characteristics: (a) clinical and bacteriologic response within 96 hours of initiation of therapy; (b) no evidence of hemodynamic compromise, metastatic infection, or neurologic or systemic embolic complications either at the initiation or completion of 2 weeks of therapy; (c) no echographically demonstrable vegetations $>2 \text{ cm}^3$; (d) not infected with MRSA; and (e) not receiving antibiotics other than penicillinase-resistant penicillins, such as first-generation cephalosporins and glycopeptides.^{21,77} HIV-seropositive patients (CD4 counts $>300 \times 10^6$ cells) with tricuspid involvement included in the above studies also responded favorably to these short-course regimens, thus short-course regimen is an option for T.J.⁷⁸

Some studies suggest that the addition of an aminoglycoside to the treatment regimen does not appear to improve overall response for patients who meet the above criteria for short-course therapy. Thus, emphasis should be shifted toward careful evaluation of all patients receiving this regimen for evidence of continuing infection or complications at the end of the 2-week treatment course before discontinuing therapy; extension of therapy with a β -lactam agent to at least 4 weeks’ duration is prudent for those who demonstrate any evidence of active disease or complications. Although response to antibiotic therapy has been shown to be similar between asymptomatic HIV-seropositive and HIV-seronegative IV drug users, it is prudent to avoid short-course therapy in more immunosuppressed

individuals (CD4 cell counts $<200 \mu\text{L}$) until more definitive outcome data are available in this subgroup.⁶⁸

ORAL REGIMEN

An oral treatment regimen consisting of ciprofloxacin (750 mg Q 12 hr) plus rifampin (300 mg Q 12 hr) has also been evaluated in addicts with uncomplicated right-sided endocarditis. In one small, noncomparative study, 10 addicts were successfully treated with the combination of ciprofloxacin and rifampin for 4 weeks.⁷⁹ Ciprofloxacin was given IV (300 mg Q 12 hr) for the first 7 days, followed by oral administration (750 mg Q 12 hr) for the remaining 21 days of therapy. Another study prospectively compared the oral regimen with standard parenteral therapy for this subgroup.⁸⁰ Patients were randomized to receive 28 days of therapy with oral ciprofloxacin plus rifampin or oxacillin (2 g IV Q 4 hr) plus gentamicin (2 mg/kg IV Q 8 hr). Vancomycin (1 g IV Q 12 hr) was substituted for oxacillin in the penicillin-allergic patients. A total of 19 patients completed treatment with oral therapy compared with 25 patients with IV therapy. One of 19 patients in the oral group versus 3 of 25 in the IV group failed treatment; however, the difference in cure rates was not statistically significant. Cure was defined by negative blood cultures after 6 and 7 days after treatment. Follow-up 1 month after treatment was available in only 30 patients; no failures were detected. Notably, approximately half of the study patients in either group had possible endocarditis, whereas only 21% versus 31% had definite infections. Given the small number of patients who completed treatment, therapeutic equivalency between the oral and parenteral regimens will need to be confirmed in larger trials. In addition, other issues that may complicate success with this oral regimen are the emerging quinolone resistance in *S. aureus* and the compliance and monitoring required of this regimen when administered in the outpatient setting. Nonetheless, it appears that a 4-week oral regimen with ciprofloxacin and rifampin may be a useful alternative treatment option in addicts with uncomplicated right-sided endocarditis.

PENICILLIN-ALLERGIC PATIENTS

Treatment of penicillin-allergic patients with *S. aureus* endocarditis is somewhat controversial. First-generation cephalosporins have been used with some success for the treatment of patients with mild penicillin allergy, but treatment failures with cefazolin are difficult to explain.⁸¹ The stability of cefazolin when exposed to staphylococcal β -lactamase has been proposed as a mechanism for these failures.⁸² Notably, staphylococci are capable of producing four penicillinase subtypes, to which the stability of cefazolin varies. These susceptibility differences are apparent on MIC testing only if a larger-than-usual inoculum is used (i.e., $>10^6$ organisms).⁷¹ It is possible that treatment failures with cefazolin may be caused by a combination of the recalcitrant nature of the infection and the instability of cefazolin against a particular subtype of penicillinase produced by the staphylococcal strain, which is not readily detectable via routine MIC testing. Until further data are available, vancomycin should be used to treat patients with endocarditis caused by *S. aureus* who have immediate-type hypersensitivity to penicillin. Other treatment options include linezolid, quinupristin/dalfopristin, and daptomycin.⁵⁷ Selection of agent depends on organism susceptibility, potential of drug-drug interactions, and host predisposition for development of adverse effects.

COMBINATION THERAPY

14. Will the addition of another antibiotic enhance T.J.'s response to nafcillin?

An enhanced response to combination therapy in the experimental animal model of MSSA endocarditis has prompted clinical trials to evaluate whether the addition of gentamicin to nafcillin confers any additional benefit. The combination of nafcillin and gentamicin resulted in more rapid clearing of organisms from the blood, but the response rates were similar to patients treated with nafcillin alone.⁸¹ As expected, the group receiving gentamicin had a higher incidence of nephrotoxicity. Thus, for the routine management of endocarditis caused by MSSA, the addition of a second drug does not appear to offer additional benefit when a penicillinase penicillin is used unless an abbreviated treatment course in a select patient group is desired (see Question 13 above). The addition of rifampin may be indicated in patients who remain bacteremic or who fail to improve clinically (usually nonaddicts).

Methicillin-Resistant *Staphylococcus aureus*: Vancomycin

15. How would T.J.'s therapy differ if he were infected with MRSA?

Staphylococcus aureus IE involving methicillin-resistant strains has become increasingly common and accounts for up to 40% of cases.^{6,7} MRSA-infected patients had more chronic comorbid conditions (e.g., diabetes mellitus, hemodialysis dependency), were more likely to have health care-associated infection (76% vs. 37%) and an indwelling intravascular catheter or hemodialysis fistula as the presumed source of infection (60% vs. 31%) when compared with patients infected with MSSA in a large multinational study.⁷ Notably, persistent bacteremia was a distinct feature associated with MRSA IE occurring in 43% versus 9% of patients infected with MSSA. Of interest, in this study, patients with *S. aureus* IE from the United States were significantly more likely to be infected with MRSA, to receive vancomycin therapy, and to develop persistent bacteremia.

In 20% of patients with MRSA IE in the above study, identifiable health care contact was absent. MRSA infection is traditionally associated with health care contact in the nosocomial setting, but is now becoming more prevalent in the community (CA-MRSA).⁷ Young and otherwise healthy individuals without the traditional risk factors are affected in the community.⁸³ CA-MRSA strains are distinct from health care-associated strains in that most possess a distinct exotoxin gene (Panton-Valentine leukocidin [PVL]). Expression of this pore-forming toxin that causes severe necrosis in PMN in a rabbit model has been implicated to cause invasive infections, including necrotizing pneumonia and skin abscesses.⁸⁴⁻⁹⁰ Specifically, CA-MRSA PVL producing strains causing IE has been reported.⁹¹

TREATMENT OPTIONS

Vancomycin has been the accepted standard of treatment for MRSA endocarditis. Response to treatment, however, appears to be slower than with semisynthetic penicillins (e.g., nafcillin) for MSSA endocarditis. The mean duration of bacteremia in patients with MSSA endocarditis has been reported to be 3.4 days for nafcillin alone and 2.9 days for the combination of nafcillin and gentamicin.⁷⁵ In contrast, the median duration of

bacteremia for MRSA endocarditis was 7 days for vancomycin alone. Failure rates of up to 40% have been documented in patients even with right-sided involvement. Of great concern is the emergence of resistant strains of *S. aureus* following repeated and prolonged exposure to vancomycin therapy.^{63,91}

Vancomycin 30 mg/kg/day in two divided doses for a total of 4 to 6 weeks is recommended for adults with normal renal function. Ideal body weight should be used to dose vancomycin on a milligram per kilogram basis in obese patients. Dosage adjustment for renal dysfunction is necessary. The prolonged distribution phase of vancomycin may affect the reproducibility of peak levels in general, so they are not practical to obtain. Dosage adjustment of vancomycin therapy based on measured trough levels is more reliable. Published expert recommendations suggest a target trough of 10 to 15 mcg/mL; however, trough levels of 15 to 20 mcg/mL^{9,93,94} may be necessary to overcome increasing MIC of clinical strains and limited tissue penetration. Serum vancomycin concentrations have been traditionally targeted for a trough level in the range of 5 to 20 mcg/mL within 30 minutes of the next dose. A dosage regimen of vancomycin aimed to achieve an area under the curve (AUC)-to-MIC ratio of 400 or unbound trough at four to five times MIC of the infected strain have been proposed by different groups as the optimal pharmacodynamic target.^{95–98}

16. T.J. has been treated with vancomycin 1 g IV Q 12 hr for 5 days for his MRSA endocarditis, but does not seem to be clinically improving. His blood cultures are still positive and his WBC remains elevated at 12,500/mm³ with 55% polys and 7% bands. He continues to have a low grade fever since starting vancomycin. His vancomycin trough level on the second day of therapy was 17 mcg/mL. The infected MRSA strain had a vancomycin MIC of 1.5 mcg/mL as determined by Etest. What factors may be contributing to T.J.'s poor response to treatment?

In a large multinational study of nearly 1,800 patients with definite IE, persistent bacteremia, receipt of vancomycin, and health care contact were significantly more likely to be observed in patients with MRSA IE from the United States compared with those from other geographic regions.⁷ The authors speculated that the higher rates of persistent bacteremia in U.S. patients may be partly owing to those patients were more likely to have received vancomycin.

Vancomycin MIC against *S. aureus* have been increasing over the years. At one university medical center, vancomycin MIC were determined by broth microdilution for 6,000 nosocomial MRSA isolates collected over a 5-year period. In the year 2000, 80% of the strains had vancomycin MIC of = 0.5 mcg/mL; however, by 2004, 70% of isolates had MICs of 2 mcg/mL.⁵² In response to increasing reports of vancomycin failures caused by strains that are in the susceptible range, the vancomycin breakpoint for susceptibility was reduced from 4 to 2 mcg/mL for *S. aureus* in 2005 per the Clinical and Laboratory Standards Institute (CLSI).^{99,100}

Widespread use of vancomycin has led to the emergence of *S. aureus* strains with vancomycin intermediate *S. aureus* (VISA) or heterogeneously expressed resistance to vancomycin (hVISA).⁶³ Reduced susceptibility to glycopeptides results from an increase in the production of peptidoglycan precursors leading to a thickened cell wall and decreased penetration of glycopeptides into the bacterial cell membrane.¹⁰¹ In the absence of vancomycin, hVISA strains may revert to glycopep-

tide susceptibility, making it difficult to detect these strains in vitro. As such, several investigators have found that hVISA strains have an MIC range that overlaps with the currently defined susceptible range and that the prevalence of these strains among hospitalized patients is increasing.^{102–104} Of concern is that routine susceptibility testing methods performed in the clinical laboratory are unreliable in detecting MRSA strains with hVISA phenotype.¹⁰⁵ Among the tests performed, MIC determined by Etest appears to be most predictable of treatment outcome with vancomycin.^{29,106}

Experts have recommended a target vancomycin trough concentration of 15 to 20 mcg/mL to overcome increasing MIC when treating pneumonia caused by MRSA.¹⁰⁷ A published study of adult infections with MRSA reported that 54% (51 of 95) of clinical isolates had vancomycin MIC of 2 mcg/mL. Notably, invasive infections, such as bacteremia and pneumonia, were linked to higher MIC. Infections caused by those strains were associated with lower end of treatment responses (62% vs. 85%) and increased mortality (24% vs. 10%) compared with strains with MIC of ≤1 mcg/mL irrespective of attaining a goal trough of 15 to 20 mcg/mL (achieving the goal of four to five times above MIC of an infected strain that has an MIC of 2 mcg/mL). The study found that borderline susceptibility (MIC 2 mcg/mL) and severity of underlying disease were independent predictors of poor treatment response. Further analysis indicated that a significant proportion of these strains demonstrated tolerance to vancomycin as defined by the MBC-to-MIC ratio of 32 and up to 10% of these invasive strains exhibit heterogeneous vancomycin intermediate resistance phenotype.^{29,108} Vancomycin monotherapy was associated with treatment failure of infections caused by these strains, whereas those who received combination therapy responded favorably. Combination regimens included vancomycin plus rifampin, linezolid, or daptomycin. These findings suggest a role for combination therapy or alternative agents when treating invasive infections caused by MRSA strains with borderline susceptibility. Confirmation is required, however, given that the above study was not designed to compare the efficacy of vancomycin monotherapy versus combination therapy for the treatment of MRSA infections and that the sample size of patients infected with hVISA in this study was small. Therefore, the role of vancomycin as the treatment of choice for MRSA IE will need to be re-evaluated against other available treatment options.

Despite attaining a pharmacodynamic goal of unbound vancomycin trough level of at least four times MIC of the infected strain, T.J. fails to clinically improve and has persistent bacteremia. It is possible that T.J. is infected with an hVISA strain, thus, a change in therapy is warranted.

17. What other therapeutic options are available for T.J.?

Trimethoprim-sulfamethoxazole has been used successfully in a limited number of patients with right-sided native valve endocarditis caused by susceptible strains of *S. aureus* and may be an alternative to vancomycin.¹⁰⁹ A study of experimental staphylococcal endocarditis, however, found trimethoprim-sulfamethoxazole to be inferior to cloxacillin, vancomycin, and teicoplanin. Alternatively, minocycline has been shown to be a potential treatment alternative to vancomycin in experimental endocarditis caused by MRSA. Although both drugs are equally effective in decreasing the bacterial density

of cardiac vegetations, the penetration of minocycline into vegetation was twice that of vancomycin.¹¹⁰

New agents showing promise for the treatment of MRSA IE based on in vitro activity include quinupristin/dalfopristin, linezolid, and daptomycin. Synercid (quinupristin/dalfopristin) used for treatment in animal models of endocarditis have shown successful outcomes. Clinical success has been reported in a limited number of patients with MRSA endocarditis treated with quinupristin/dalfopristin.^{111,112} A cure rate of 56% was reported for patients treated with quinupristin/dalfopristin for MRSA endocarditis in an international open trial that evaluated the drug in patients intolerant of or failed prior therapy.¹¹² Because of a lack of clinical studies establishing the efficacy of this agent, additional data is needed before quinupristin/dalfopristin can be recommended for therapy.

Linezolid (Zyvox), an oxazolidinone, is not U.S. Food and Drug Administration (FDA)-approved for the treatment of endocarditis, but has been used in cases of treatment failures, intolerance to standard therapy, or in infections with multidrug resistant gram-positive cocci.¹¹³ In a review article that included 33 cases reports of endocarditis treated with linezolid, 63.6% of patients had successful outcomes at the end of the follow-up period.¹¹⁴ MRSA and vancomycin intermediate *S. aureus* were the most common pathogens accounting for 24% and 30% of cases, respectively. Failure with linezolid treatment was documented in seven cases including four deaths attributed to endocarditis and three owing to persistent positive blood cultures. Thrombocytopenia was the most common adverse effect occurring in eight of nine patients who reported an adverse effect. In a compassionate use program, linezolid was reported to achieve 50% clinical and microbiologic cure rates at 6-month follow-up in 32 patients with definite IE; MRSA was the causative agent in 7 of those patients. The most common adverse events reported in this group were gastrointestinal system effects and thrombocytopenia, each occurring in 15% of patients.¹¹⁵ The degree of thrombocytopenia associated with linezolid has been shown to correlate with the extent of drug exposure, as measured by area under the concentration curve and duration of treatment.¹¹⁶ Of note, treatment failure with linezolid for MRSA endocarditis caused by persistent bacteremia has been described in two patients and in one patient with relapse of infection.^{117,119} Thus, additional efficacy data are needed before linezolid can be recommended for the treatment of IE caused by MRSA.

Daptomycin (Cubicin) is a cyclic lipopeptide that has been approved for treatment of *S. aureus* bacteremia and right-sided endocarditis. In vivo, it has a wide spectrum of activity against gram-positive bacteria, including *S. aureus* (including MRSA), *E. faecalis*, *E. faecium*, streptococci, and most other species of aerobic and anaerobic gram-positive bacteria. It was approved for the treatment of *S. aureus* bacteremia/endocarditis in a noninferiority study in patients receiving daptomycin or standard therapy consisting of an antistaphylococcal penicillin or vancomycin in addition to low-dose gentamicin.¹²¹ Successful outcome was seen in 46% (41 of 90) of patients who had presumed or definite endocarditis at their baseline diagnosis. Of those, MRSA endocarditis was successfully treated in 42% (15 of 36) of cases. In patients with confirmed uncomplicated and complicated right-sided endocarditis, treatment success was similar between the daptomycin group (8 of 18) and the group receiving standard therapy (7 of 16) at 44%.

Microbiologic failure occurred in seven patients in the daptomycin group and in five patients receiving standard therapy. Overall, the most common cause of daptomycin failure was persistent or relapsing infections accounting for 16% of failures. In contrast, failure of standard therapy was more often the result of treatment-limiting adverse events accounting for 15% of failures. Increase in the MIC of the infected strain was observed more often in the daptomycin group compared with standard treatment (six in the daptomycin vs. one patient in the standard therapy group). The use of daptomycin for treatment of left-sided endocarditis is not established because only nine patients were treated and only one had treatment success.

Daptomycin at 6 mg/kg/day for a total duration of 6 weeks should be used for the treatment of endocarditis. Frequency of administration should be increased to every 48 hour for patients with a clearance of creatinine (Cl_{cr}) of ≤30 mL/minute. Daptomycin should be dosed based on total body weight because obese patients have a larger volume of distribution as well as increased clearance compared with the nonobese population.¹²² Creatinine kinase elevations were more commonly seen in the daptomycin (6.7%) compared with the standard therapy (0.9%) group.¹²¹ Creatinine kinase levels should be obtained at baseline and weekly to monitor for elevations and more frequently in patients who may be at risk for developing skeletal-muscle dysfunction (e.g., concomitant therapy with hydroxymethylglutaryl-coenzyme A (HMG-CoA) reductase inhibitors). In addition, 9% of patients experienced peripheral nervous system-related adverse events (e.g., paresthesia and peripheral neuropathies), which resolved during continued treatment.¹²¹

Daptomycin at 6 mg/kg daily should be considered as alternative therapy in T.J. Emergence of cross-resistance to daptomycin after vancomycin exposure has been documented, however.^{53,117} Similar to a thickened cell wall contributing to decreased susceptibility to vancomycin, the same mechanism is thought to contribute to daptomycin resistance in *S. aureus*.^{123–125} As a result, it is important to test for daptomycin susceptibility before initiation of therapy. Until daptomycin susceptibility is documented, rifampin may be added to vancomycin as combination therapy. Linezolid is a potential treatment option for T.J. if his infected MRSA strain demonstrates reduced susceptibility to daptomycin given prior vancomycin exposure; however, clinical experience is limited to case reports and compassionate use.

Once daptomycin therapy is initiated, continued monitoring of clinical response and organism susceptibility to daptomycin is warranted because resistance development has been reported during prolonged therapy.^{123–126} Daptomycin MIC increase during therapy for *S. aureus* endocarditis was demonstrated in six patients.¹²¹ Baseline MIC increased from 0.25 to 2 mcg/mL in five isolates and from 0.5 to 4 mcg/mL in one isolate.¹²¹ Five of those six isolates were MRSA.

ENTEROCOCCAL ENDOCARDITIS

Antimicrobial Therapy

Antibiotic Synergy

18. G.S., a 35-year-old woman, has been complaining of anorexia, weight loss, and fever for the past 2 months. Her

medical history is significant for an aortic aneurysm with insufficiency that resulted in an aortic valve replacement (porcine) 3 years before admission. Approximately 2 months before admission, G.S. had a cesarean section followed by a tubal ligation. She did not receive antibiotic prophylaxis for either procedure. Physical examination revealed a thin woman (5 foot 0 inches, 48 kg) in no acute distress with evidence of a systolic heart murmur, splinter hemorrhages, and petechiae on her soft palate. Her temperature was 100.2°F. Her WBC count was 14,000/mm³ with a slight left shift; all other laboratory results were within normal limits. She was not taking any medications and she has a documented allergy to penicillin (rash, urticaria, and wheezing). The working clinical diagnosis was probable bacterial endocarditis, which was confirmed when four sets of blood cultures grew gram-positive cocci. Biochemical testing subsequently identified the organism as *Enterococcus faecalis*, highly resistant to streptomycin (MIC >2,000 mcg/mL). Antibiotic therapy with gentamicin (50 mg IV Q 8 hr) and vancomycin (1,000 mg IV Q 12 hr) was begun. Why were two antibiotics prescribed for the treatment of enterococcal endocarditis in G.S.?

[SI unit: WBC, 14 × 10/L]

Enterococci, unlike streptococci, are inhibited but not killed by penicillin or vancomycin alone.^{22,127} The synergistic combination of penicillin (or ampicillin, piperacillin, or vancomycin) and an aminoglycoside are required to produce the desired bactericidal effect.^{22,128} An antibiotic regimen is synergistic when a combination of antibiotics lowers the MIC to at least one-fourth the MIC of either drug alone.¹²⁹ The mechanism of synergy against enterococci is caused by an increased cellular uptake of the aminoglycoside with agents that inhibit cell wall synthesis¹³⁰ (e.g., β -lactams and vancomycin). Because G.S. is allergic to penicillin, vancomycin was prescribed with an aminoglycoside. Relapse rates are unacceptably high if penicillin is used alone for the treatment of enterococcal endocarditis.^{21,23} The addition of an aminoglycoside to penicillin therapy significantly increased the sterilization rate of vegetations in animal studies.^{129,130} Numerous clinical studies have confirmed the in vitro synergy for penicillin in combination with streptomycin or gentamicin for enterococcal endocarditis.^{131–135}

19. G.S. has enterococcal endocarditis caused by strains exhibiting high-level resistance to streptomycin. Why would (or would not) treatment with gentamicin achieve the desired synergy with vancomycin in G.S. with enterococcus highly resistant to streptomycin?

STREPTOMYCIN RESISTANCE

As many as 55% of all enterococcal blood isolates are highly resistant to streptomycin (MIC >2,000 mcg/mL), and the combination of streptomycin with penicillin is not synergistic for those isolates. In contrast, gentamicin in combination with penicillin, ampicillin, or vancomycin is synergistic for most blood isolates of enterococci, regardless of their susceptibility to streptomycin.^{1,23,136} In addition, ototoxicity in the form of vestibular dysfunction secondary to streptomycin therapy has been noted in nearly 30% of patients receiving the combination regimen for the treatment of enterococcal endocarditis and is most often irreversible. Maintaining streptomycin peak serum concentrations below 30 mcg/mL

reduces the risk of ototoxicity, but laboratory assays for streptomycin levels are not readily available. For these reasons, gentamicin in combination with penicillin (or ampicillin) or vancomycin is recommended by most authorities for the treatment of aminoglycoside-susceptible and, in particular, streptomycin-resistant enterococcal endocarditis, as it was for G.S.²¹ Of note, other aminoglycosides cannot be used to substitute for gentamicin or streptomycin because of the uncertain correlation between in vitro synergy and in vivo efficacy.²¹ Table 59-6 lists the suggested regimens for the treatment of enterococcal endocarditis.

GENTAMICIN RESISTANCE

About 10% to 25% of the clinical isolates of *E. faecalis* and up to 50% of *E. faecium* are resistant to gentamicin.^{136–138} The prevalence of these isolates is expected to continually increase. All available aminoglycosides should be tested with penicillin (or ampicillin) for synergistic bactericidal activity. Without conclusive data, some groups favor long-term (8–12 weeks) therapy with high-dose penicillin (20–40 million units/day IV in divided doses) or ampicillin (2–3 g IV Q 4 hours) for treatment of multiply resistant enterococci. Ampicillin plus the β -lactamase inhibitor sulbactam (Unasyn) would be substituted for β -lactamase producing, high-level gentamicin-resistant enterococci. In light of the increasing prevalence of enterococci with high-level aminoglycoside resistance, the potential synergistic interaction between ampicillin/amoxicillin and a third-generation cephalosporin was explored in vitro and in experimental models of IE¹⁴¹. A bactericidal synergistic effect was shown between amoxicillin and cefotaxime against 50 strains of *E. faecalis*. Amoxicillin MIC decreased from 0.25 to 1 mcg/mL to 0.01 to 0.25 mcg/mL for 48 of 50 strains tested.¹³⁸ A similar effect was demonstrated by others using the combination of amoxicillin and ceftriaxone. Additionally, Brandt et al.¹³⁹ demonstrated a synergistic bactericidal effect for amoxicillin in combination with imipenem against vancomycin-aminoglycoside-resistant *E. faecium* strains. The authors speculated that saturation of different penicillin binding protein (PBP) by different β -lactam agents may be the underlying mechanism for the synergy observed. Limited clinical data on 13 endocarditis cases caused by high-level aminoglycoside-resistant *E. faecalis* treated with the combination of high-dose ceftriaxone (4 g/day) and ampicillin appear to confirm the above synergistic interaction. All 16 evaluable patients were cured by 1 month of double β -lactam therapy with no evidence of relapse during a 3-month follow-up period. Of note, two patients experienced reversible neutropenia and were withdrawn from the study.¹⁴⁰ Double β -lactam therapy appears promising for infections caused by aminoglycoside-resistant *E. faecalis* strains as well as an aminoglycoside-sparing regimen for patients with renal insufficiency, but the above preliminary results need to be confirmed with a larger number of patients.

Gentamicin DOSING

20. What is the optimal dosage of gentamicin for G.S.?

Because patients with enterococcal endocarditis require prolonged therapy with aminoglycosides, the optimal serum concentration should minimize toxicity without jeopardizing

Table 59-6 Therapy for Endocarditis Caused by Enterococci (or *Streptococci viridans* with an MIC ≥ 0.5 mcg/mL)^{a,b}

| Antibiotic | Dose and Route | Duration |
|---|---|------------------|
| Nonpenicillin-Allergic Patient | | |
| 1. Aqueous crystalline penicillin G | <i>Adult:</i> 18–30 million units/24 hr intravenously (IV) given continuously or in six equally divided doses <i>Pediatric:</i> 300,000 units/kg/24 hr IV (max: 30 million units/24 hr) given continuously or in four to six equally divided doses | 4–6 wk 4–6 wk |
| With gentamicin ^{c,d,e} or | <i>Adult:</i> 1 mg/kg intramuscularly (IM) or IV Q 8 hr <i>Pediatric:</i> 1 mg/kg IM or IV Q 8 hr | 4–6 wk 4–6 wk |
| 2. Ampicillin | <i>Adult:</i> 12 g/24 hr IV given continuously or in six equally divided doses <i>Pediatric:</i> 300 mg/kg/24 hr IV (max: 12 g/24 hr) in four to six equally divided doses | 4–6 wk 4–6 wk |
| With gentamicin ^{c,d,e} or | <i>Adult:</i> 1 mg/kg IM or IV Q 8 hr <i>Pediatric:</i> 1 mg/kg IM or IV Q 8 hr | 4–6 wk 4–6 wk |
| Penicillin-Allergic Patients^g | | |
| Vancomycin ^e | <i>Adult:</i> 30 mg/kg/24 hr IV in two equally divided doses (max: 2 g/24 hr unless serum levels monitored) <i>Pediatric:</i> 40 mg/kg/24 hr IV in two to three equally divided doses (max: 2 g/24 hr unless serum levels monitored) | 6 wk 6 wk |
| With gentamicin ^{c,d} or | <i>Adult:</i> 1 mg/kg IM or IV (max: 80 mg) Q 8 hr <i>Pediatric:</i> 1 mg/kg IM or IV (max: 80 mg) Q 8 hr | 6 wk 6 wk |

^a Antibiotic doses should be modified appropriately in patients with impaired renal function.

^b Enterococci should be tested for high-level resistance (gentamicin: MIC ≥ 500 mcg/mL).

^c Serum concentration of gentamicin should be monitored and dosage adjusted to obtain a peak level of approximately 3 mcg/mL. (For shorter course gentamicin therapy for enterococcal endocarditis see comment in text.)

^d Dosing of aminoglycosides and vancomycin on a mg/kg basis gives higher serum concentrations in obese than in lean patients.

^e Peak serum concentrations of vancomycin should be obtained 1 hr after infusion and should be in the range of 30–45 mcg/mL for BID dosing and 20–30 mcg/mL for QID dosing. Trough serum concentrations should be obtained within half an hr of the next dose and should be in the range of 10–15 mcg/mL. Each dose should be infused over 1 hr; 6 weeks of vancomycin therapy recommended because of decreased activity against enterococci.

^f Desensitization should be considered; cephalosporins are not satisfactory alternatives.

Adapted from reference 9, with permission.

clinical cure. Early in vitro data indicated that the bactericidal activity of gentamicin against enterococci was not significantly different between peak concentrations of 5 mcg/mL and 3 mcg/mL; however, the differences between 3 mcg/mL and 1 mcg/mL were significant.¹⁴¹ In the rat model of endocarditis, the bacterial counts in vegetations at 5 and 10 days were compared between those treated with low-dose (1 mg/kg intramuscularly twice daily) and those treated with high-dose (5 mg/kg intramuscularly twice daily) gentamicin with penicillin¹⁴². Bacterial counts did not differ at 5 days, but at 10 days they were significantly lower in the rats receiving the high-dose regimen. In contrast, results in the rabbit model showed no difference in the amount of bacteria per gram of vegetation in high- and low-dose gentamicin treatment groups.¹⁴³ As for the influence of dosing interval of aminoglycosides on the efficacy of combination regimens in experimental enterococcal endocarditis, studies have demonstrated that multiple daily dosing is more effective in reducing bacterial titers in vegetations than single daily dosing,^{144–146} in contrast to that shown with viridans streptococci endocarditis³⁵ (see Question 4). Thus, extended-interval dosing of aminoglycosides cannot be recommended for the treatment of enterococcal endocarditis at this time.

The only study comparing high-dose (>3 mg/kg/day) and low-dose (<3 mg/kg/day) gentamicin with penicillin in humans with enterococcal endocarditis evaluated 56 patients over a 12-year period (36 with streptomycin-susceptible and 20

with streptomycin-resistant infections).¹⁴⁷ The relapse rate of patients infected with streptomycin-resistant organisms (n = 20) was not significantly different between the high- and low-dose treatment groups (n = 10 each). Furthermore, patients who received the higher doses of gentamicin experienced a greater prevalence of nephrotoxicity (10 of 10 vs. 2 of 10, $p < 0.001$). Mean peak and trough concentrations of gentamicin in the patients who received the high doses were 5 mcg/mL and 2.1 mcg/mL, respectively; corresponding levels for patients receiving the low-dose regimen were 3.1 mcg/mL and 1 mcg/mL.

Based on available data, it would be reasonable to start G.S. on a gentamicin dosage of 1 mg/kg Q 8 hr (assuming her renal function is normal) and to maintain peak concentrations of 3 to 5 mcg/mL and trough concentrations of <1 mcg/mL.

IN COMBINATION WITH VANCOMYCIN

21. Why was vancomycin used in combination with gentamicin in G.S.? Is this combination effective against enterococci?

G.S. has a history of penicillin allergy. Most clinicians favor a combination of vancomycin and gentamicin for penicillin-allergic patients with enterococcal endocarditis, although vancomycin plus streptomycin is a suitable alternative.^{21,23,147} The combination of vancomycin and gentamicin demonstrates bactericidal synergy for about 95% of enterococci strains. In contrast, the vancomycin and streptomycin combination

demonstrates bactericidal synergy for about 65% of enterococci. Because G.S. has PVE, she should receive approximately 30 mg/kg/day, or roughly 1.5 g/day (750 mg Q 12 hr), of vancomycin in combination with gentamicin (3 mg/kg/day). Serum levels of vancomycin and gentamicin should be monitored as previously discussed.

Duration of Therapy

22. How long should G.S. be treated?

Historically, enterococcal endocarditis has been treated with penicillin plus an aminoglycoside for 6 weeks; the overall cure rate with this regimen is about 85%.²¹ Data indicate that 4 weeks of therapy is probably adequate for most patients with enterococcal endocarditis.^{21,147,148} One study evaluated the efficacy of a treatment regimen involving shorter course aminoglycoside therapy (median of 15 days) in combination with a cell wall active agent for a median of 42 days in patients with PVE and native valve enterococcal endocarditis.¹⁵¹ Clinical cure was observed in 75 of 93 (81%) patients overall, 78% of patients with PVE and 82% of patients with native valves. Among those who had a clinical cure, 52% received a β -lactam, 12% received vancomycin and 36% received a combination of both. Ampicillin was given in 88% of patients receiving a β -lactam. The causative organism was *E. faecalis* in 78 patients and *E. faecium* in 5 patients. Clinical success was also achieved in all eight patients with native valve IE who received either vancomycin (50%), ampicillin (25%) or combination of both (25%) without synergistic aminoglycoside therapy.

Patients with complicated courses should receive 6 weeks of therapy, however. These include patients infected with streptomycin-resistant organisms (such as G.S.), those who have had symptoms for >3 months before the initiation of antibiotics, and patients with PVE (such as G.S.).^{13,21} Some clinicians recommend 6 weeks of therapy for all patients in whom the duration of illness cannot be firmly established; this accounts for many patients who present with subacute disease.

Increased Nephrotoxicity With Vancomycin Combination Therapy

23. Is the combination of vancomycin and an aminoglycoside more nephrotoxic than either drug alone?

The incidence of nephrotoxicity associated with vancomycin administration (alone) in humans is thought to be minimal or nonexistent.¹⁴⁹ In a three-arm study involving >200 patients, nephrotoxicity was found in 5% of patients who received vancomycin alone, 22% of those receiving vancomycin with an aminoglycoside, and 11% of those receiving an aminoglycoside alone. The study was well designed in that an aminoglycoside control group was included for comparison on the incidence of nephrotoxicity. Patients in whom increases in the serum creatinine concentration may have been a result of clinical conditions and patients who received drugs known to alter renal function were excluded in the analysis of this study. Serial serum vancomycin and aminoglycoside concentrations, as well as duration of therapy, were reported and analyzed. The authors concluded that vancomycin trough concentrations >10 mcg/mL and concurrent therapy with an aminoglyco-

side were risk factors associated with an increased incidence of nephrotoxicity. Based on the study data, it is difficult to ascertain the precise risk of nephrotoxicity relative to specific vancomycin trough concentrations >10 mcg/mL. Another study specifically evaluated the risk of nephrotoxicity in patients receiving high-dose vancomycin therapy achieving trough concentrations of 15 to 20 mcg/mL for MRSA infections.

Nephrotoxicity occurred in 12% (11 of 95) of patients, significantly predicted by concomitant therapy with other nephrotoxic agents. An incremental increase in the risk of nephrotoxicity was associated with duration of therapy at high trough levels (15–20 mcg/mL): 6.3% for 7 days or less, 21.1% for 8 to 14 days, and 30% for more than 14 days. In a subanalysis that included only patients without receipt of concomitant nephrotoxic agents, nephrotoxicity occurred in only 1 (2%) of 44 high-trough versus 0 of 24 low-trough (<15 mcg/mL) patients. These studies confirm that an increased incidence of nephrotoxicity is likely when vancomycin and an aminoglycoside are given concomitantly.

Glycopeptide Resistance

24. How do enterococci develop vancomycin resistance, and what are the therapeutic implications when treating a patient with glycopeptide-resistant enterococcal endocarditis?

The therapeutic challenges offered by a patient with endocarditis caused by enterococci exhibiting high-level resistance to aminoglycosides are compounded by the acquired resistance of enterococci to glycopeptide antibiotics such as vancomycin. VRE, particularly *E. faecium*, have emerged in the United States since 1987.^{150,151} Because the use of prophylactic vancomycin has been increasing steadily since the mid-1980s, it should not be surprising to see increased resistance to this class of compounds. Between 1989 and 1993, the percentage of nosocomial enterococci reported as resistant to vancomycin in the United States rose more than 20-fold, from 0.3% to 7.9%.^{151,152} Enterococcal isolates from intensive care units increased even more dramatically, from 0.4% to 13.6%, over the same time. Data from the Centers for Disease Control and Prevention (CDC) National Nosocomial Infections Surveillance (NNIS) system indicate that the rate of increase has slowed down from 31% in 2000 to 12% in 2003.¹⁵³ A 12% increase was found in VRE infections in causing infections in intensive care units between 2003 and the prior 5-year period (1998–2002). Nonetheless, epidemiologic studies conducted by the NNIS system as well as others have shown that VRE bacteremia is associated with significantly increased morbidity and mortality.^{153,154}

Although *E. faecalis* is responsible for 80% to 90% of infections caused by enterococci, *E. faecium* is more likely to exhibit resistance to glycopeptides compared with *E. faecalis*; more than 95% of VRE recovered in the United States are *E. faecium*. Glycopeptide-resistant enterococci synthesize abnormal peptidoglycan precursors that lower the binding affinity of glycopeptides to peptidoglycans.^{150,151} VRE can be broadly classified into three separate phenotypes (A, B, and C), based on three structurally different genes and gene products (e.g., altered ligases).¹⁵⁰ Most (approximately 70%) of resistant enterococci are of the VanA phenotype, which are resistant to

high levels of both vancomycin (MIC >256 mcg/mL) and teicoplanin (MIC >16 mcg/mL).^{150,151} Expression of resistance is inducible, usually plasmid mediated, and transferable to other organisms via conjugation. The VanB strains exhibit moderate vancomycin resistance (MIC 16–64 mcg/mL), but remain susceptible to teicoplanin (MIC ≤2 mcg/mL). Overall, the VanC isolates are the least resistant (vancomycin MIC 8–16 mcg/mL; teicoplanin MIC ≤2 mcg/mL) because of chromosomal-mediated constitutive expression (i.e., not inducible as are VanA and VanB); however, VanC isolates usually are associated with the much less common *E. gallinarum* and *E. casseliflavus* infections.^{150,151}

Several studies have implicated prior use of vancomycin as well as extended-spectrum cephalosporins and drugs with potent antianaerobic activity as risk factors for promoting infection and colonization with VRE.^{150,151}

The emergence of VRE causing serious infections is indeed worrisome because few therapeutic alternatives exist for this organism because synergistic combinations are required for bactericidal activity and a clinical cure. As might be anticipated with an organism that is still a relatively uncommon cause of serious infection, well-established guidelines for antimicrobial therapy are not available. To date, no articles have been published in which investigators have demonstrated successful treatment with any particular agent or combination of agents in a large series of patients infected with glycopeptide-resistant enterococci. As a result, practitioners must make decisions using the available data from in vitro synergy studies, experimental models of endocarditis, and scattered case reports. In addition, glycopeptide-resistant isolates often exhibit concomitant high-level resistance to aminoglycosides and high-level resistance to β -lactams (e.g., ampicillin, penicillin) secondary to either β -lactamase production or alteration in the target penicillin-binding proteins.

Several antibiotic combinations appear promising in vitro and in preliminary animal models of endocarditis, but few data are currently available in humans. Those combinations include high-dose ampicillin (20 g/day) or ampicillin/sulbactam plus an aminoglycoside; vancomycin, penicillin or ceftriaxone and gentamicin; ampicillin and imipenem; ciprofloxacin and ampicillin; ciprofloxacin, rifampin, and gentamicin; teicoplanin and gentamicin (teicoplanin is not available in the United States).¹⁵⁰

STREPTOGRAMIN AND OXAZOLIDINONE

Quinupristin/dalfopristin (Synercid) and linezolid (Zyvox) are two agents with activity and proved efficacy against infections caused by VRE approved for use by the FDA in the United States. Quinupristin/dalfopristin (Synercid), available as a fixed 70:30 combination, is the first drug in the streptogramin class made available in the United States for human use. It belongs to the antibiotic family of macrolides/lincosamides/streptogramins. The agent received accelerated approval by the FDA in late 1999 specifically for the treatment of vancomycin-resistant *E. faecium* bacteremia. The combination is synergistic for glycopeptide-resistant enterococci with an MIC₉₀ of 2 mcg/mL. The fixed product is generally bactericidal against susceptible streptococci and staphylococci (including methicillin-resistant strains), but it is bacteriostatic against *E. faecium*. Specifically, *E. faecalis*

is not susceptible to the agent because of the presence of an efflux^{158,160,161} pump conferring resistance to dalfopristin. Emergence of resistance during therapy has been reported on rare occasions.¹⁵⁶ The recommended dosage is 7.5 mg/kg Q 8 to 12 hr (depending on the severity of infection).¹⁵⁷

One report describes the largest clinical experience to date on the use of quinupristin/dalfopristin in the treatment of infections caused by multidrug-resistant *E. faecium*.¹⁵⁸ A total of 397 patients were enrolled in two prospective emergency-use studies. Treatment response varied by indication, with an overall success rate of 65%. Of the five clinically evaluable patients who were treated for endocarditis, response occurred in only one (20%). The low response rate observed with endocarditis is likely reflected by the need of bactericidal therapy for treatment success. An additional case of *E. faecium* endocarditis successfully treated by the combination of quinupristin/dalfopristin, doxycycline, and rifampin was reported by Matsumura et al.¹⁵⁹ Arthralgias or myalgias were the most frequently reported events (10%) and also most frequently resulted in drug discontinuation.¹⁵⁸ A higher incidence of arthralgias or myalgias has been reported by others (up to 50%); those patients had significant comorbidities.¹⁶⁰ All cases were reversible on cessation of therapy. Significant venous irritation occurred (46%) when the drug was administered via a peripheral vein. In addition, the dose should be diluted up to 500 to 750 mL, as long as the entire infusion can be given in 1 hour.^{158,161} The drug is not compatible with saline solutions. Laboratory abnormalities most frequently observed were increases in total and conjugated bilirubin in up to 34% of patients. As a result, liver function tests should be obtained once a week during therapy. Because quinupristin/dalfopristin is a potent inhibitor of the cytochrome P450 3A4 enzyme system, coadministration of drugs (e.g., cyclosporine, cisapride) metabolized by the same enzyme system should be avoided if possible, or done only with close monitoring of therapeutic levels.^{157,160}

Linezolid (Zyvox) is the first drug in the oxazolidinone class to receive FDA approval in 2000 for clinical use. Linezolid has bacteriostatic activity against enterococci, including vancomycin-resistant *E. faecium* and *E. faecalis*. It is also active against other gram-positive cocci, including *S. pneumoniae* and methicillin-resistant staphylococci.¹⁵⁷ Vancomycin-resistant *E. faecium* isolates resistant to linezolid have been encountered in the clinical setting.^{162,163} Treatment experience with linezolid under the compassionate use protocol reported clinical and microbiologic cure rates of 50% at 6-month follow-up for patients with endocarditis. Vancomycin-resistant *E. faecium* was the causative organism for 19 of the 32 patients treated. Treatment response was not subgrouped by causative organisms in this report, which was presented in the form of a meeting abstract.¹¹⁵ Adverse effects associated with linezolid are generally mild in nature and include nausea, headache, diarrhea, rash, and altered taste. Of greater concern is its potential to cause myelosuppression. Thrombocytopenia, leukopenia, anemia, and pancytopenia have all been reported. Up to 30% of patients treated have been reported to experience thrombocytopenia (platelet counts <100,000 platelets/mm³).¹⁵⁷ In addition, linezolid is a weak monoamine oxidase inhibitor, which may potentiate the adrenergic effects of sympathomimetic agents (i.e., pseudoephedrine, phenylpropanolamine) and precipitate

serotonergic syndrome when used concomitantly with selective serotonin reuptake inhibitors. Patients should be advised to avoid tyramine-containing foods (i.e., aged cheese, sausages, sauerkraut, wine) during therapy as well. Linezolid is available both orally and parenterally. Linezolid given orally or via enteral feedings is completely bioavailable.¹⁶⁴ A dosage of 600 mg twice daily is recommended for adults. Persistent MRSA bacteremia caused by suboptimal serum concentrations of linezolid has been described,¹²⁰ suggesting a need to obtain serum drug concentrations in patients not responding appropriately to treatment.

DAPTOMYCIN

Daptomycin is active against enterococci in vitro with an MIC range of 0.25 to 4 mcg/mL and a MIC₉₀ of 4 mcg/mL for 219 vancomycin resistant *E. faecium* isolates from the United States. For 40 vancomycin-resistant *E. faecalis* isolates, the MIC range is 0.015 to 2 mcg/mL, with an MIC₉₀ of 2 mcg/mL.¹⁶⁵ When tested against 20 vancomycin resistant *E. faecium* strain, daptomycin had an MIC₅₀ of 2 mcg/mL versus 0.5 mcg/mL and 4 mcg/mL for quinupristin/dalfopristin and linezolid, respectively.¹⁶⁶ Of caution is the emergence of daptomycin resistance during therapy for VRE infections reported in the literature.^{167,168} In a case report of a patient with vancomycin resistant *E. faecium* pyelonephritis, the initial isolate had an MIC of 2 mcg/mL; however, after 17 days of treatment, a blood culture yielded growth of vancomycin resistant *E. faecium* with an MIC increase to 32 mcg/mL.¹⁶⁹ Clinical experience with daptomycin for vancomycin resistant *E. faecium* endocarditis is limited to one published case report.¹⁷⁰ The patient received daptomycin 8 mg/kg/day in combination with gentamicin and rifampin for 11 weeks. Subsequent cultures were negative; however, the patient died 4 months after completion of therapy from an unknown cause. Thus, daptomycin's role in treating VRE endocarditis is uncertain at this point.

CONTROL OF GLYCOPEPTIDE RESISTANCE

Considering the continuing rise in prevalence and therapeutic challenges associated with VRE, a control effort involving multiple disciplines is necessary to effect a decrease or prevent an increase in the number of patients colonized or infected by these organisms. The primary focus of control should be on limiting vancomycin use to those indications recommended by the CDC's Hospital Infection Control Practices Advisory Committee in 1994 and enforcing strict adherence to infection control practices to minimize cross-contamination of infected or colonized patients.^{150,172}

Selection pressure resulting from continued heavy use of vancomycin is evident with the emergence of vancomycin-intermediate *S. aureus* (VISA) and vancomycin-resistant *S. aureus* (VRSA). Cases of VISA have been reported in the United States and Japan.⁶³ Although the mechanism of resistance for VISA is unique and does not appear to be mediated by the VanA gene, all patients had prior infections with MRSA and had received repeated and prolonged vancomycin therapy.⁶³ More alarming is the recovery of a VRSA strain in a patient who had concurrent VRE infections.⁹² This case represents the first demonstration of in vivo transfer of *VanA* gene from VRE to *S. aureus*, conferring high-level vancomycin resistance

(MIC > 1,012 mcg/mL). The isolation of both VISA and VRSA underscores the importance of controlling the spread of vancomycin resistance through proper antibiotic stewardship and infection control practices.

FUNGAL ENDOCARDITIS CAUSED BY *CANDIDA ALBICANS*

Prognosis and Treatment

25. B.G., a 35-yearold male heroin addict, was admitted to the hospital with chief complaints of pleuritic chest pain and DOE. Physical examination revealed a cachectic man with a temperature of 104°F, a diastolic regurgitant heart murmur heard loudest during inspiration, splenomegaly, and pharyngeal petechiae. Funduscopic examination was noncontributory. On the chest radiograph, several pulmonary infiltrates with cavitation were evident. Urinalysis (UA) was significant for microscopic hematuria and RBC casts. An ECG demonstrated vegetations on both the tricuspid and aortic heart valves. B.G. had evidence of moderate heart failure, although his hemodynamic status at that time was "stable." Six sets of blood cultures were drawn over 2 days and broad-spectrum empiric coverage consisting of vancomycin, gentamicin, and ceftazidime was initiated. Two days later, two of the cultures grew *C. albicans*, and a diagnosis of fungal endocarditis was established. What is B.G.'s prognosis, and how should his fungal endocarditis be treated?

Fungal endocarditis is a rare but life-threatening infection with a grave prognosis that is generally difficult to diagnose and even more difficult to treat.¹ Most cases are caused by *Candida* and *Aspergillus* species. Fungal endocarditis occurs primarily in IV drug users, patients with prosthetic heart valves, immunocompromised patients, those with IV catheters, or patients receiving broad-spectrum antibiotics.¹⁷²⁻¹⁷⁵

Management of fungal endocarditis generally requires early valve replacement and aggressive fungicidal therapy with a combination of high-dose amphotericin B (usually 1 mg/kg/day IV) and 5-flucytosine (5-FC; Ancobon) 150 mg/kg/day orally.^{1,172-175} These antifungal agents should be prescribed for B.G. and his broad-spectrum antibiotic coverage with vancomycin, gentamicin, and ceftazidime should be discontinued.

B.G.'s clinical presentation and chest radiograph indicate that fragments of vegetation have already embolized to his lungs and possibly to other vital organs (e.g., spleen, kidneys). Because of the morbidity and mortality associated with major emboli and valvular insufficiency, B.G. should undergo surgery within 48-72 hours after antifungal therapy has been initiated. Delaying surgery beyond this time frame can increase B.G.'s risk of mortality.

The prognosis for B.G. is dismal even with proper medical and surgical treatment. In a series analyzing 270 cases of fungal IE occurring over a 30-year period, mortality for those who received combined medical and surgical management was 45%, compared with 64% for those who received antifungal therapy alone.¹⁷⁴ Despite initial response to treatment, the rate of relapse is high (30%-40%), and relapse can occur up to 9 years following the initial episode of infection.¹⁷²⁻¹⁷⁵ Most deaths in IV drug users with endocarditis are secondary to heart failure, a finding already evident in B.G.¹ In addition, replacement of

a heart valve for fungal endocarditis in a heroin addict carries a significant risk of late morbidity and mortality.¹⁷⁴

Combination Therapy With 5-Flucytosine and Amphotericin B

26. Why is it important to treat B.G.'s fungal endocarditis with the combination of 5-FC and amphotericin B? What is the optimal duration of therapy?

The importance of adding 5-FC (Ancobon) to amphotericin B (Fungizone) therapy has not been adequately studied; however, the poor prognosis associated with fungal endocarditis warrants the administration of 5-FC, despite its potential for causing bone marrow suppression and hepatotoxicity.¹⁷⁴ (See Chapter 68, Prevention and Treatment of Infections in Neutropenic Cancer Patients, for a discussion of amphotericin B and 5-FC.) The vegetations from his tricuspid or aortic heart valves already have broken off and caused pulmonary cavitation and possibly splenomegaly. His clinical presentation is consistent with a potentially fatal outcome; therefore, his blood isolates should be tested for in vitro susceptibility to amphotericin, to 5-FC, and to both of these drugs in combination. Fungi resistant to 5-FC alone may still be susceptible to the synergistic effect of the 5-FC–amphotericin B combination.¹⁷⁶ If the organism is resistant to 5-FC and in vitro synergy between these two antifungals is lacking, continued treatment with 5-FC is not indicated.

The optimal dose and duration of antifungal therapy for fungal endocarditis have not been determined by clinical studies; however, postoperative treatment with amphotericin B and 5-FC (if it has in vitro activity) for a minimum of 6 weeks (total dose, 1.5–3 g of amphotericin B) is recommended and is supported by the poor penetration of amphotericin B into heart valve tissue.¹⁷⁷ In patients with fungal PVE, some experts advocate secondary prophylaxis for a minimum of 2 years or lifelong suppressive treatment with an oral antifungal agent for nonsurgical candidates in light of the high rates of relapse.^{1,174–179}

Nephrotoxicity caused by amphotericin is often a serious dose-limiting factor to completion of therapy, particularly in patients who require a prolonged treatment course (see Chapter 67, Osteomyelitis and Septic Arthritis). Renal dysfunction secondary to the conventional formulation of amphotericin B may stabilize or improve with the switch to lipid-formulated amphotericin B products (i.e., Abelcet).¹⁸⁰ The efficacy of the new formulations in the treatment of endocarditis has been demonstrated only in anecdotal reports,^{174–177,181} whereas the drug acquisition cost is substantially higher. Alternative antifungal agents may need to be considered in patients who experience significant renal toxicities.

Alternative Antifungals

27. If B.G. experiences significant toxicities because of prolonged combination treatment with amphotericin and 5-FC, what alternative antifungal agent(s) can be used to treat his fungal endocarditis?

Fluconazole (Diflucan) is a triazole compound active against *Candida* species, particularly *C. albicans* and *C. parapsilosis*. It also has a favorable toxicity profile compared with amphotericin and 5-FC.¹⁸² Prolonged combination treatment with amphotericin and 5-FC often is limited by nephrotoxi-

city, bone marrow suppression, and hepatic damage. Limited experimental and clinical experience using fluconazole in the treatment of candidal endocarditis has been accumulating.

Fluconazole was effective in eradicating cardiac fungal vegetations caused by *C. albicans* and *C. parapsilosis* in a rabbit model.¹⁸³ Successful experience with fluconazole treatment of fungal endocarditis in humans has been described in only a few case reports.^{184–189} Patients with endocarditis treated with fluconazole were either intolerant of amphotericin or poor surgical candidates who required suppressive antifungal therapy after completion of a course of amphotericin therapy. Patients with various *Candida* species (i.e., *C. albicans*, *C. parapsilosis*, and *C. tropicalis*) were treated with 200 to 600 mg of fluconazole daily over 45 days to 6 months or until death. Fluconazole therapy reduced or completely removed all cardiac vegetations and resolved clinical symptoms. Because of the lack of adequate clinical experience, however, the use of fluconazole in treating fungal endocarditis cannot be advocated except in patients who require lifelong therapy because of the following situations: (a) the patient is a poor surgical candidate, (b) the patient has relapsed at least once since the initial infection episode, or (c) the patient has PVE.

Another potential alternative is caspofungin, which is a first-line agent in the echinocandin class.¹⁹⁰ Caspofungin was approved by the FDA for salvage therapy against invasive aspergillosis, esophageal candidiasis, and invasive candidiasis (primarily bloodstream infections and peritonitis). Caspofungin inhibits fungal cell wall synthesis by inhibiting β -1,3 glucan synthesis. It is fungicidal against most *Candida* species (including *C. albicans*), and its use is not associated with nephrotoxicity. Both characteristics make the drug an attractive treatment option for B.G. should toxicities develop after prolonged therapy with amphotericin B. Limited experience has described successful outcomes associated with caspofungin use in this setting.^{191–193} In a patient with *C. glabrata* mitral valve endocarditis without surgical intervention, caspofungin was used successfully as induction therapy in combination with amphotericin B and continued as maintenance therapy for 12 weeks.¹⁹⁴ In a second case report of a patient with prosthetic valve endocarditis caused by *C. glabrata* and *C. krusei*, resolution of vegetation was achieved after 6 weeks of caspofungin therapy alone without valvular replacement. Both patients were deemed to be poor surgical candidates and received medical therapy only.¹⁹⁵ Micafungin and anidulafungin are the latest additions to the echinocandin class; clinical experience in the treatment of endocarditis is currently lacking.

GRAM-NEGATIVE BACILLARY ENDOCARDITIS CAUSED BY *PSEUDOMONAS AERUGINOSA*

Prevalence

28. Fourteen months after completing his course of antifungal therapy, B.G. was readmitted to the hospital with a 48-hour history of fever, shaking chills, rigors, and night sweats. His vital signs at that time were blood pressure, 100/60 mmHg; pulse, 120 beats/minute; respirations, 24/minute; and temperature, 103.7°F. A new-onset systolic murmur was noted on auscultation. Two-dimensional echocardiography revealed two small vegetations on the prosthetic valve. Empiric therapy consisting of amphotericin

B, 5-FC, vancomycin, and gentamicin was initiated. Three blood cultures drawn on the day of admission were positive for *P. aeruginosa* with the following antibiotic susceptibilities (MIC): gentamicin (8 mcg/mL), tobramycin (2 mcg/mL), piperacillin (64 mcg/mL), and ceftazidime (2 mcg/mL). A presumptive diagnosis of PVE caused by *P. aeruginosa* was made. Why was the finding of *pseudomonas* expected in B.G.?

The prevalence of endocarditis caused by gram-negative organisms has increased significantly over the years, especially in IV drug users such as B.G. and patients with prosthetic heart valves. Gram-negative organisms are responsible for about 15% to 20% of endocarditis cases in these populations.¹⁹⁸ Most gram-negative endocarditis cases are caused by *Pseudomonas* species, *S. marcescens*, and *Enterobacter* species, although numerous other gram-negative organisms have been known to cause endocarditis.^{196–201} Geographic clustering of certain organisms causing endocarditis in narcotic addicts has been shown in the past, such as the association of *P. aeruginosa* with the Detroit area and *S. marcescens* with San Francisco.^{201–204} These past epidemiologic findings are not necessarily true today. In narcotic addicts with gram-negative endocarditis, the tricuspid, aortic, and mitral valves are involved in 50%, 45%, and 40% of cases, respectively.¹⁹⁶

Antimicrobial Therapy

29. How should B.G.'s gram-negative endocarditis be treated and monitored?

The regimen of amphotericin B, 5-FC, vancomycin, and gentamicin that was initiated empirically for B.G. pending the outcome of culture and sensitivity results should now be discontinued because *P. aeruginosa* has been cultured from B.G.'s blood. Proper antibiotic selection for the treatment of gram-negative endocarditis should be based on antimicrobial susceptibility and synergy testing. A bactericidal combination of antibiotics usually is required to provide in vivo synergy and to prevent resistant subpopulations from emerging during therapy.^{1,31} B.G., therefore, should be treated with ceftazidime (2 g IV Q 8 hr) with concurrent high-dose tobramycin (3 mg/kg IV Q 8 hr). The duration of therapy is not well defined, but most authorities recommend 4 to 6 weeks.^{1,197,202,204} Despite the problems associated with using the SBT as a monitoring tool (see Question 3), therapy should be tailored to achieve a trough titer of at least 1:8.²² Because B.G. should be receiving both ceftazidime and tobramycin on the same schedule (Q 8 hr), the trough titer should be drawn just before dose administration. Finally, the infected valve should be surgically excised for the reasons previously discussed.

Endocarditis caused by *P. aeruginosa* (as in B.G.) should be treated for at least 6 weeks with a combination of an aminoglycoside and an antipseudomonal penicillin (ticarcillin or piperacillin) or cephalosporin (ceftazidime).^{1,206} The combination of an antipseudomonal penicillin and an aminoglycoside is synergistic in vitro and in the rabbit model of *P. aeruginosa* endocarditis,^{205,206} and clinical experience has confirmed this finding in IV drug users. Combination therapy with high dosages of tobramycin or gentamicin (8 mg/kg/day) has been associated with a significantly higher cure rate and lower mortality rate compared with an older, "low-dose" regimen (2.5–5 mg/kg/day).^{197,198,202} Aminoglycosides (tobramycin or gen-

tamicin) should be dosed to produce peak and trough serum concentrations of 15 to 20 mcg/mL and <2 mcg/mL, respectively, to ensure maximum efficacy¹; therefore, high-dose tobramycin should be selected for B.G.

For obvious reasons, peak and trough aminoglycoside concentrations should be routinely monitored in all patients receiving high-dose therapy for gram-negative bacillary endocarditis. Of note, the use of extended-interval dosing of aminoglycoside has not been evaluated for the treatment of endocarditis caused by gram-negative organisms; therefore, this dosing approach cannot be recommended at this time. The choice of aminoglycoside should be based on the in vitro activity of the organism (i.e., MIC), relative toxicity potential, and cost. In B.G.'s case, tobramycin should be selected over gentamicin because the isolated organism exhibited greater susceptibility to this aminoglycoside. Generally, *P. aeruginosa* is more susceptible to tobramycin than to gentamicin. Thus, it is not at all surprising that the *P. aeruginosa* in B.G.'s blood cultures had a 2 mcg/mL MIC for tobramycin compared with the 8 mcg/mL MIC for gentamicin.

Data on the use of ceftazidime for the treatment of *P. aeruginosa* endocarditis are limited; however, it should be preferred over piperacillin for B.G. on the basis of its greater in vitro activity and good penetration into cardiac valvular tissue.²⁰⁷

Several compounds such as imipenem (Primaxin), aztreonam (Azactam), and ciprofloxacin (Cipro), have demonstrated excellent in vitro activity against many of the gram-negative organisms causing endocarditis. Clinical data regarding their use in the treatment of endocarditis are very limited, however.^{208–211}

CULTURE-NEGATIVE ENDOCARDITIS

30. B.G.'s history, clinical presentation, and imaging studies are strongly suggestive of infective endocarditis. If his blood cultures had been negative after 48 hours of incubation, the working diagnosis would have been culture-negative endocarditis. What are the possible reasons for culture-negative endocarditis, and what measures should be taken to establish a microbiologic etiology?

The proportion of patients with culture-negative endocarditis has diminished considerably, presumably as a result of improved microbiologic culture techniques. Negative blood cultures are present in only 5% to 7% of patients who meet strict criteria for the diagnosis of IE and have not recently received antibiotics.²¹²

The prior administration of antimicrobials is thought to account for most cases of culture-negative endocarditis.²¹³ B.G.'s blood cultures may remain negative for several days to weeks if he has taken antibiotics recently. The use of antibiotic absorbance resins or the addition of β -lactamases to the blood sample may remove or inactivate some antibiotics.^{214,215}

Slow-growing and fastidious organisms, such as gram-negative bacilli in the *Haemophilus-Actinobacillus-Cardiobacterium-Eikenella-Kingella* group (HACEK), *Brucella*, *Coxiella*, chlamydiae, strict anaerobes, and fungi, should be pursued in culture-negative patients. This usually is accomplished by the use of special culture media or by obtaining appropriate serologic acute and convalescent titers. Blood cultures should be saved for at least 3 weeks to detect slow-growing organisms.²¹³ The use of polymerase chain reaction

to identify nonculturable organisms in excised valvular specimens or septic emboli has been helpful in some cases.²¹⁶ Of note, previously NVS has been the cause of most of the cases of endocarditis diagnosed as “culture-negative,” initially because of its requirement for the addition of vitamin B₆ (pyridoxal HCl) to the culture media for laboratory growth; however, laboratory identification is no longer a significant problem with current culture media and laboratory techniques.²⁴

Empiric Therapy

31. Assume that the causative organism remains unidentified. Recommend an antimicrobial regimen for the empiric treatment of B.G.’s presumed culture-negative endocarditis.

In the hemodynamically stable patient, antibiotic therapy should be withheld until positive blood cultures are obtained.¹ Based on B.G.’s clinical presentation and echocardiographic findings, empiric antibiotics should be initiated as soon as necessary cultures have been collected. Because staphylococci and gram-negative bacilli account for most organisms responsible for endocarditis in the narcotic addict with a prosthetic heart valve, B.G. should be started on a regimen consisting of an anti-staphylococcal penicillin, such as nafcillin, an aminoglycoside, and a third agent with gram-negative coverage. Because B.G. may be experiencing a relapse caused by *C. albicans*, the addition of amphotericin B and flucytosine would be appropriate. If B.G. is from an area where methicillin-resistant staphylococci are prevalent, vancomycin should be substituted for nafcillin. A third-generation cephalosporin (ceftriaxone or ceftazidime) or piperacillin could be used, depending on the gram-negative pathogens common to the region and their anticipated susceptibilities. This regimen, which contains an aminoglycoside and piperacillin, also will provide coverage for enterococci.

B.G.’s clinical status and the positive ECG indicate that early surgical valve excision and replacement are necessary.²¹⁷ Cultures obtained from excised valve may result in identification of the causative organism. His antimicrobial regimen may need to be altered if and when subsequent culture information becomes available. Other noninfective conditions, such as atrial myxoma, marasmic endocarditis, and rheumatic fever, can mimic culture-negative endocarditis and should be excluded from the differential diagnosis with the appropriate tests.¹

PROPHYLACTIC THERAPY

Rationale and Recommendations

32. B.B., a 74-year-old man with poor dentition, is scheduled to have all of his remaining teeth extracted for subsequent fitting of dentures. His medical history is significant for numerous infections of the oral cavity and prosthetic valve replacement 2 years ago. His only current medications are digoxin (Lanoxin) 0.125 mg/day and furosemide (Lasix) 40 mg every morning. What is the rationale for antibiotic prophylaxis?

Because infective endocarditis is associated with significant mortality and long-term morbidity, prevention in susceptible patients is of paramount importance.¹ Estimates are, however, that <10% of all cases are theoretically preventable.^{10,48}

The incidence of endocarditis in patients undergoing procedures known to cause significant bacteremia, even without antibiotic prophylaxis, is low. In addition, endocarditis may develop following the administration of seemingly appropriate chemoprophylaxis. Therefore, it is not surprising that the efficacy of prophylaxis has never been established through placebo-controlled clinical trials. Approximately 6,000 patients would be necessary to demonstrate a statistical difference (if one exists) between untreated controls and a group receiving prophylaxis.^{48,218}

Without conclusive clinical data from prospective trials, recommendations for antibiotic prophylaxis have been based largely on in vitro susceptibility data, evaluation of antibiotic regimens using animal models of endocarditis, and anecdotal experiences.^{48,218,219,220}

Prophylactic antibiotics are thought to provide protection by decreasing the number of organisms reaching the damaged heart valve from a primary source. Thus, antibiotics theoretically prevent bacterial multiplication on the valve and interfere with bacterial adherence to the cardiac lesion.^{48,218}

The 2007AHA recommendations for antibiotic prophylaxis before common medical procedures are outlined in Table 59-7.²¹⁸ Compared with the previous (1997) guideline,²¹⁸ the current guidelines only recommend the use of prophylaxis in patients with specific cardiac conditions who are undergoing

Table 59-7 Endocarditis Prophylaxis Regimen Indicated for Patients With Cardiac Conditions^a

| Drug | Dose |
|--|---|
| Dental or Upper Respiratory Tract Procedures | Single Dose 30 to 60 Minutes Before Procedure |
| Standard Regimen | |
| Amoxicillin (oral) | Adult: 2 g Pediatric: 50 mg/kg |
| Allergic to penicillin or ampicillin (oral) | |
| Clindamycin | Adult: 600 mg Pediatric: 20 mg/kg |
| or | |
| Cephalexin ^{b,c} | Adult: 2 g Pediatric: 50 mg/kg |
| or | |
| Azithromycin or clarithromycin | Adult: 500 mg Pediatric: 15 mg/kg |
| Unable to Take Oral Medications | |
| Ampicillin | Adult: 2 g intramuscularly (IM) or intravenously (IV) Pediatric: 50 mg/kg IM or IV |
| Allergic to penicillin or ampicillin | |
| Clindamycin | Adult: 600 mg (IV) Pediatric: 20 mg/kg IV |
| or | |
| Cefazolin ^b | Adult: 1 g IM or IV Pediatric: 50 mg/kg IM or IV |

^aSee Table 59-1.

^bCephalosporins should not be used in individuals with immediate-type hypersensitivity reaction (e.g., urticaria, angioedema, or anaphylaxis) to penicillins or ampicillin.

^cOther first- or second-generation oral cephalosporins in equivalent adult or pediatric dose.

Adapted from reference 218, with permission.

only dental or respiratory tract procedures. The use of prophylaxis for patients undergoing gastrourinary or gastrointestinal procedures is not recommended because of a continuing lack of evidence to support efficacy.

Dental and Upper Respiratory Tract Procedures

The new guidelines only recommend prophylaxis in individuals with cardiac conditions associated with the highest risk of adverse outcomes from endocarditis (see Table 59-1). Previous 1997 AHA guidelines listed a substantial number of procedures where prophylaxis is either indicated or not recommended. Analysis of published data shows that viridans streptococci bacteremia can result from any procedure that involves the manipulation of the gingival tissue or the periapical region of the teeth or perforation of the oral mucosa. Placement or removal of prosthodontic or orthodontic appliances, adjustment of orthodontic appliances, taking dental radiographs, bleeding from trauma to the lips or oral mucosa, and so instantaneous shedding of deciduous teeth do not require chemoprophylaxis. Endotracheal intubation also does not require prophylactic therapy.

Antimicrobial prophylaxis should be directed against the viridans group of streptococci because these organisms are the most common cause of endocarditis following dental procedures. Invasive surgical procedures involving the upper respiratory tract, such as incision or biopsy of the respiratory mucosa (e.g., tonsillectomy, adenoidectomy), can cause transient bacteremia with organisms that have similar antibiotic susceptibilities to those that occur after dental procedures; therefore, the same regimens are suggested. Prophylaxis is not recommended for bronchoscopies unless the procedure involves incision of the respiratory mucosa. Amoxicillin is currently recommended for oral prophylaxis in susceptible persons having dental or upper respiratory tract surgery. Oral clindamycin, clarithromycin, or azithromycin is recommended for patients with immediate-type hypersensitivity reaction to penicillins. Unlike past recommendations of the AHA, the current guidelines no longer recommend prophylaxis based on risk stratification and only patients with outlined cardiac conditions should be administered prophylactic antibiotics.

Most cases of endocarditis that are caused by bacterial flora from the mouth do not follow dental procedures but rather are the result of poor oral hygiene. The cumulative exposure to random bacteremias from daily oral activities is estimated to be 5,730 minutes over a 1-month period compared with only 6 to 30 minutes for a dental procedure. Furthermore, it is estimated that the cumulative exposure to bacteremia from routine daily activities may be as high as 5.6 million time greater than a single tooth extraction²¹⁸. Based on the study results, concerns for antimicrobial resistance, and cost, changes to restrict the use of antibiotic prophylaxis to the highest-risk patients before dental procedures may be expected with future guidelines issued by the AHA.

Indications and Choice of Agent

33. Is prophylactic antibiotic therapy indicated for B.B.? If so, which antibiotic(s) should be used?

Based on the current recommendations, B.B. is a candidate for antibiotic prophylaxis. Presence of a prosthetic aortic valve

while undergoing multiple tooth extractions places him at risk for developing endocarditis. He also is scheduled to have all of his remaining teeth extracted, a procedure likely to result in bacteremia. According to Table 59-7, B.B. should receive a single 2-g oral dose of amoxicillin 1 hour before the procedure. Previous AHA guidelines recommended a higher dose (3 g) of amoxicillin to be administered before the procedure and followed by a second dose 6 hours after the procedure.¹⁰ When the blood levels and tolerability of 2- and 3-g oral amoxicillin doses were compared in a crossover study involving 30 adult volunteers,¹⁰ the 2-g doses resulted in adequate serum levels; concentrations 6 hours after dosing were well above the MIC for most oral streptococci. Furthermore, no adverse effects were noted with the 2-g dose versus a 10% incidence of gastrointestinal complaints with the 3-g dose.

HOME INTRAVENOUS ANTIBIOTIC THERAPY

34. T.M., a 48-year-old woman, developed viridans streptococci endocarditis following a dental procedure. Her medical history is significant for rheumatic heart disease and chronic renal insufficiency (measured creatinine clearance, 50 mL/minute). She is hemodynamically stable and has no evidence of vegetation on ECG. She is currently on day 7 of therapy with penicillin G, 2 million units IV Q 4 hr. The plan is to continue penicillin therapy for a total of 4 weeks. What are the considerations for using home IV therapy for the treatment of infective endocarditis? Is T.M. a candidate for home antibiotic therapy?

The successful use of home IV antibiotic therapy for the patient with endocarditis has been described, although the number of patients treated is relatively small compared with those treated for osteomyelitis.^{220–222} The advantages of home therapy include economic benefits to the hospital for early discharge (the diagnosis-related-group [DRG] allocation for endocarditis is 18.4 days, which is shorter than the usual recommended duration of therapy) and the potential for greater acceptance by the patient.

Home treatment of endocarditis is not without risk, however.²²² Patients must be hemodynamically stable before discharge and free from the risk of sudden valve rupture. The drug abuser is obviously not a candidate for home treatment, nor is the patient receiving frequent doses of medication. The successful management of any infection amenable to home treatment requires careful patient evaluation for suitability and coordination of the health care provided by key personnel.

T.M. represents the typical patient with uncomplicated streptococcal endocarditis. If the sole reason for continued hospitalization is to administer IV antibiotics, she is a potential candidate for home therapy.

Ceftriaxone is an attractive option for outpatient therapy of uncomplicated endocarditis caused by penicillin-susceptible streptococci. The excellent in vitro activity of ceftriaxone and its long half-life of 6 to 9 hours allow once-a-day administration. The feasibility of intramuscular administration of ceftriaxone also obviates the need for IV access, thus avoiding any potential line-related complications when administered in the outpatient setting.

Clinical experience with the use of ceftriaxone in the treatment of patients with penicillin-susceptible streptococcal endocarditis was described in four open-label studies.^{38–41} Two

of the studies evaluated ceftriaxone monotherapy for 4 weeks; the other two evaluated combination therapy with ceftriaxone and an aminoglycoside for a 2-week duration. All infecting strains of streptococci in the first two studies were inhibited by ceftriaxone at an MIC of <0.25 mcg/mL. In one study, ceftriaxone was given at a dosage of 2 g once daily for 4 weeks to most patients, with 15 receiving ceftriaxone for 2 weeks followed by amoxicillin 1 g four times daily for 2 weeks. Most of the patients received therapy predominantly as outpatients. All patients (N = 30) reported in this study responded favorably to treatment with ceftriaxone or ceftriaxone followed by amoxicillin.⁴¹ Patients with cardiovascular risk factors, such as heart failure, severe aortic insufficiency, or evidence of recurrent thromboembolic events, were excluded from the study. Only one probable relapse was noted at 3 months after therapy with presentation of febrile syndrome, elevated sedimentation rate, and negative bacterial blood culture. An uncontrolled study extended the favorable results of the aforementioned study.³⁸ Treatment was completed in 55 of 59 patients. Patients were followed for 4 months to up to 5 years after the end of treatment with no clinical signs or laboratory evidence of relapse. Of patients, 71% completed therapy without complications; however, 10 required valve replacement secondary to hemodynamic deterioration or recurrent emboli, whereas

4 required a change in therapy because of drug allergy. Adverse side effects were minor, but 3 patients had neutropenia that resolved after cessation of therapy.

Because of the lack of controlled trials comparing the efficacy of ceftriaxone against penicillin with or without an aminoglycoside in the treatment of penicillin-susceptible streptococcal endocarditis, ceftriaxone should be considered primarily in patients such as T.M. for whom home antibiotic therapy is a treatment option and those who are hemodynamically stable with no evidence of vegetation.

The feasibility of home therapy depends on the following additional factors: (a) patient willingness; (b) adequate venous access; (c) psychosocial stability; (d) access to medical care if an emergency occurs; (e) ability to train T.M. (proper aseptic technique, catheter site care, antibiotic preparation, recognition of untoward effects of the antibiotic, and recognition of symptoms associated with worsening infection); and (f) insurance coverage for home IV therapy. These conditions can be accomplished only with the multidisciplinary involvement of the infectious disease physician, a social worker, a pharmacist, a specialty nurse, and the patient. Home care, outpatient care, and other options will be used increasingly because health care reform mandates the decreased use of tertiary care facilities when possible.

Infection of the respiratory tract continues to be the most common and important cause of short-term illness in the United States. It is typically the first infection to occur after birth, with pneumonia being the sixth leading cause of death and the number one infectious disease cause of death in the United States.^{1,2} Respiratory tract infections occur more frequently than they are reported and are responsible for more days of bed disability, restricted activity, and lost time from work and school than any other category of reported acute illness in the United States. Respiratory infections account for >40% of disability days secondary to acute illness,² and pneumonia and influenza are among the ten leading causes of death in the overall population, with 80% to 90% of deaths occurring in the elderly (persons >65 years of age).^{3,4} In the United States, pneumonia and influenza are in the top ten causes of death in all age groups.⁴ The actual number is much larger, because this figure does not include individuals who died of pneumonia who had other diseases (e.g., HIV, tobacco- and alcohol-related diseases).³

The financial impact associated with respiratory infections in 1999 was \$25.6 billion (\$18.6 billion in direct costs and \$7 billion in indirect costs).¹ These figures largely underestimate the financial impact of treating ambulatory respiratory infections. Statistics reported by the National Health Interview Survey estimate that 182 million episodes of respiratory infection

occur for which no medical attention is sought.² Often, individuals with respiratory infections try home remedies or over-the-counter (OTC) medications for relief of their symptoms and only seek medical advice or treatment when these efforts fail. The estimated cost associated with the use of OTC medications in this population will contribute an additional \$456 million annually to the treatment of respiratory infections.¹

This chapter addresses the concepts relevant to the treatment and prevention of lower respiratory tract bacterial infections. Upper respiratory tract infections (see Chapter 96) and respiratory tract infections caused by viruses (with the exception of influenza) (see Chapter 72) and fungi (see Chapter 71) are presented elsewhere in this book, as are the unique features of respiratory tract infections in immunocompromised hosts (see Chapter 68) and *Pneumocystis jirovecii* (*carinii*) (see Chapter 70).

Bronchial Infections

Acute Bronchitis

1. F.A., a 35-year-old woman, presents with a persistent cough following an acute respiratory viral infection that began 7 days ago. Although the nasal stuffiness and sore throat resolved 3 or 4 days ago, the cough has persisted and her sputum has become

thick and mucoid; a burning, substernal pain is associated with each coughing episode. F.A. is currently afebrile. Coarse rales and rhonchi are heard on physical examination of her chest, and a tentative diagnosis of acute bronchitis (AB) is made. How should F.A. be assessed and managed?

Uncomplicated AB is an isolated event characterized by inflammation of the tracheobronchial tree and clinically presents as cough of <2 to 3 weeks' duration with or without sputum production. Infectious causes of AB are primarily viral and include influenza A and B, rhinovirus, coronavirus, parainfluenza virus 3, and respiratory syncytial virus. As a group, these agents are associated with 5% to 10% of all cases of acute uncomplicated bronchitis in adults. *Streptococcus pneumoniae*, *Haemophilus influenzae*, or *Moraxella catarrhalis* do not produce AB in adults without underlying pulmonary disease.

As in F.A., cough—with or without sputum production—is the most prominent clinical feature of this disease. It usually begins early in the course of the syndrome and may persist after the acute infection is resolved. The initial dry, unproductive cough may progress to one with a productive mucoid sputum.

Most healthy adults with typical symptoms of bronchitis do not require diagnostic evaluation. The presence of a fever ($\geq 38^{\circ}\text{C}$), heart rate (HR) > 100 beats/minute, respiratory rate (RR) > 24 breaths/minute, and signs of focal consolidation on chest examination such as rales, egophony, and fremitus are suggestive of the need for a more thorough diagnostic evaluation. Diagnostic studies to reveal a causative agent are not indicated.

The treatment of AB should be directed at symptom control. The use of antitussive agents to control cough, maintenance of adequate hydration, and the intermittent administration of antipyretics such as acetaminophen or ibuprofen should be employed. On the basis of the microbiology of AB, it is not surprising that randomized controlled clinical trials have failed to support a role for antibiotic therapy. Consistent with this, the U.S. Food and Drug Administration removed uncomplicated AB and secondary bacterial infections of AB as indications for randomized clinical trials in 1998. Meta-analyses confirm no benefit of antibiotic treatment on illness duration, activity limitation, or work loss, and the routine use of antibiotics in adults with AB is not justified. Yet, antibiotics are prescribed for AB commonly in the United States.^{5,6} While a reduction in antibiotic use has been confirmed in the recent past, abuse and misuse is still commonplace.⁷

As described above, patients whose coughs are severe or prolonged (≥ 14 days) or present with the signs and symptoms enumerated above should be evaluated more thoroughly and may be candidates for antibiotic therapy.^{8–11} In addition, the one common circumstance for which evidence supports antibiotic therapy in patients with uncomplicated AB is the suspicion of pertussis. Unfortunately, no clinical features allow clinicians to distinguish adults with persistent cough due to pertussis primarily because pertussis in adults with previous immunity does not lead to classic whooping cough seen in patients with primary infection. Therefore, treatment should be limited to adults with a high probability of exposure to pertussis, such as that associated with a documented outbreak. The use of antibiotics in this setting will decrease the shedding of the pathogen and the spread of disease.

Chronic Bronchitis

CLINICAL PRESENTATION

2. M.J., a 54-year-old man with a 40-year, one-pack/day smoking history reports producing two cupfuls of whitish-clear, occasionally mucoid sputum per day over the past several years; he coughs up the largest volumes in the morning on arising. M.J. has a raspy voice and a crackling cough, which often interrupts his talking. Two days ago, he noted that his sputum had increased in volume and had changed in appearance. A sputum sample, which was yellowish-green, tenacious, and purulent, was sent for culture; the Gram stain showed few epithelial cells, moderate white cells, and a few Gram-positive cocci and Gram-negative rods with no predominant organisms. M.J. denies fever or chills and had no signs of pneumonia; a chest radiograph is negative for consolidation. M.J. has experienced similar episodes three or four times per year. What signs and symptoms in M.J.'s history are consistent with chronic bronchitis (CB)?

CB is an inflammatory condition of the tracheobronchial tree in which chronic cough and excessive production of sputum are the prominent features. CB and emphysema are components of chronic obstructive pulmonary disease (COPD). Exacerbations of COPD—which may occur from any of the following: infection, smoking, air pollution, exposure to allergens, occupational exposure, or preclinical or subclinical asthma—are estimated to result in approximately 110,000 deaths and more than 500,000 hospitalizations, with over \$18 billion spent in direct costs annually.^{12–14} By definition, patients who cough up sputum daily or on most days over 3 or more consecutive months for > 2 successive years presumptively have CB.¹⁵ The diagnosis of CB is made only when other etiologies such as bronchiectasis, cardiac failure, and lung cancer have been excluded. M.J. meets these criteria.

Bronchitis is more common in men than women and more common after the age of 40 years than earlier recognized.¹⁶ A genetic basis has been noted with cystic fibrosis (CF), immunoglobulin deficiencies, and primary ciliary dyskinesia. The most common cause of CB is smoking.¹⁷ In M.J., cigarette smoking is an important factor associated with his disease. Smoking is an irritant to the respiratory airways and may stimulate the mucus-secreting goblet cells found in major and smaller bronchi. The increased amount of mucus is not readily cleared from smaller peripheral airways, creating airflow resistance; this accounts for the large volume of sputum cleared from larger airways. However, not all patients with CB have a history of smoking, and 6% to 10% of nonsmoking men will have persistent cough and sputum production.¹⁶

3. Has M.J.'s bronchitis worsened? What is the likelihood that M.J. has an infection?

Acute exacerbations of chronic bronchitis (AECB) are defined as a worsening of clinical symptoms with increased cough, sputum production, and dyspnea. Some patients report shortness of breath, fatigue, chest tightness, or an increasing cough with dyspnea as their only complaints. Some cases are accompanied by fever, and some patients have symptoms consistent with asthma. Hemoptysis may be seen during acute exacerbations, as CB is the most common cause of hemoptysis in the developed world. As in M.J., the most reliable sign of worsening bronchitis is the patient's observation that his or her

Table 60-1 Most Commonly Identified Bacterial Pathogens Associated With Acute Exacerbations of Chronic Bronchitis

| Pathogen | Incidence (%) |
|-----------------------------------|---------------|
| <i>Haemophilus influenzae</i> | 24–26 |
| <i>Haemophilus parainfluenzae</i> | 20 |
| <i>Streptococcus pneumoniae</i> | 15 |
| <i>Moraxella catarrhalis</i> | 15 |
| <i>Klebsiella pneumoniae</i> | 4 |
| <i>Serratia marcescens</i> | 2 |
| <i>Pseudomonas aeruginosa</i> | 2 |

sputum has changed in amount, color, or consistency. These changes in sputum have been used as presumptive evidence of infection, but similar changes in sputum can be seen without documented infection.^{17–19} As illustrated by M.J., patients may present without systemic symptoms of infection such as chills, fever, or leukocytosis.

MICROBIOLOGY

Although infections do not appear to promote the basic disease process or result in deterioration in pulmonary function, they are associated with the majority of exacerbations.¹⁵ The organisms most commonly implicated are viral agents that often cause upper respiratory tract infections. Viruses including influenza A and B, parainfluenza virus 3, coronavirus, and rhinovirus are associated with AECB in 7% to 64% of patients. Gump et al.¹⁹ found viral infections in 32% of patients during AECB compared with 1% of patients during remission periods. The most commonly identified bacterial pathogens associated with acute exacerbations of CB are listed in Table 60-1.

Recent studies with improved molecular and immunologic techniques form the basis for a new model of bacterial exacerbation pathogenesis (Fig. 60-1). In this model, acquisition of new strains from the environment via aerosols or fomites of nontypeable *H. influenzae*, *M. catarrhalis*, and *S. pneumoniae* appears to be the predominant initiating event for an exacerbation.

Treatment of a bronchial infection must be directed at organisms found in the pulmonary tree and not normal flora in the oral cavity. The correct interpretation of a Gram stain of a sputum sample depends on the nature of the sample. Sputum, by definition, represents matter ejected from the lungs or bronchi and should contain, at most, a few white blood cells (WBCs) on microscopic examination. On microscopic evaluation, a good sputum sample should have few epithelial cells. In contrast, saliva often contains large numbers of epithelial cells. The numbers of epithelial cells or WBCs in the sample is important because debilitated patients with pulmonary infection often have difficulty performing the physical maneuvers necessary to eject sputum from the lungs or bronchi. In the case of M.J., the Gram stain would be interpreted as a good specimen (because of the low number of epithelial cells). The presence of moderate amounts of WBCs is consistent with infection, especially considering the recent change in the volume and appearance of M.J.'s sputum. However, using expectorated sputum cytology alone to assess the likelihood of an infection can be misleading, as significant numbers of polymorphonuclear cells can be present throughout the course of CB with or without exacerbation.^{20,21}

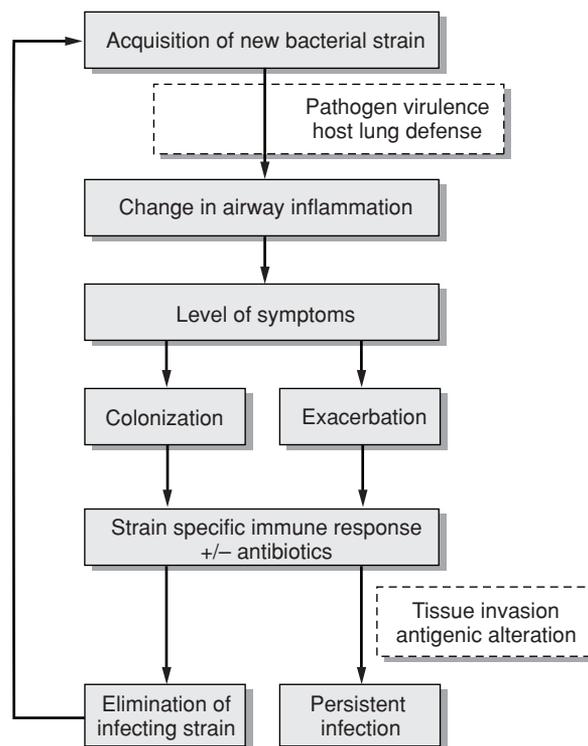

FIGURE 60-1 Model of the pathogenesis of bacterial exacerbations of chronic bronchitis.

Many studies have shown that sputum in patients with CB culture grow potential respiratory pathogens when cultured during periods of exacerbations and remissions. Both *S. pneumoniae* and *H. influenzae* are recovered during periods of exacerbation and remission.¹⁹ Patients with COPD and CB are more likely colonized with these organisms compared with healthy controls.²² However, a quantitative increase in *S. pneumoniae* during an acute exacerbation is correlated with sputum purulence.²³ This association has not been shown for nontypeable *H. influenzae*.²⁴ For M.J., the finding of few Gram-positive and Gram-negative organisms with no predominant organism reflects normal oropharyngeal flora and likely colonization with *S. pneumoniae* and *Haemophilus* sp. Consequently, this test result provides little additional information to guide antimicrobial therapy.

ANTIBIOTIC THERAPY

4. Should M.J. be given antibiotic therapy to treat his acute episode?

Mild to moderately ill patients without pneumonia, such as M.J., usually do not require antibiotics to treat exacerbations of CB.²⁵ Potential occupational and environmental exposures should be conducted. If smoking is identified as the likely irritant (as in M.J.), patients should be encouraged to participate in a comprehensive smoking cessation program. M.J. should be well hydrated and treated with scheduled postural drainage exercises to help mobilize the excessive mucus and improve his pulmonary function. In addition, the use of oral or aerosolized bronchodilators may be of some benefit during acute exacerbations. If his condition does not improve within 3 or 4 days, the initiation of antibiotic therapy should be considered.

Table 60-2 Selecting Antibiotics for Acute Exacerbations of Chronic Obstructive Pulmonary Disease

| Category | Likely Pathogens | Antimicrobial Treatment |
|---|--|---|
| Uncomplicated AECOPD Age <65 yr FFV ₁ >50% predicted <4 exacerbations/yr No comorbid conditions | <i>Haemophilus influenzae</i> <i>Streptococcus pneumoniae</i> <i>Moraxella catarrhalis</i> <i>Haemophilus parainfluenzae</i> Viral <i>Mycoplasma pneumoniae</i> <i>Chlamydia pneumoniae</i> | Macrolides ^a Ketolides ^b Doxycycline Second- or third-generation cephalosporin Respiratory quinolone ^b |
| Complicated AECOPD Age >65 yr FEV ₁ <MWB predicted ≤4 exacerbations/yr Comorbid conditions | <i>H. influenzae</i> <i>S. pneumoniae</i> <i>M. catarrhalis</i> <i>H. parainfluenzae</i> Viral <i>M. pneumoniae</i> <i>C. pneumoniae</i> Gram-negative enteric bacilli | Respiratory quinolone ^c Amoxicillin/clavulanate |
| Complicated AECOPD at risk for <i>Pseudomonas aeruginosa</i> infection FEV ₁ <35% predicted Recurrent courier of antibiotics or steroids Bronchiectasis | <i>H. influenzae</i> <i>S. pneumoniae</i> <i>M. catarrhalis</i> <i>H. parainfluenzae</i> Viral <i>M. pneumoniae</i> <i>C. pneumoniae</i> Gram-negative enteric bacilli <i>Pseudomonas aeruginosa</i> | Fluoroquinolone with antipseudomonal activity ^c |

^aIn active smokers, *H. influenzae* infection is more prevalent—azithromycin and clarithromycin demonstrate improved in vitro activity.

^bLevofloxacin, moxifloxacin, gatifloxacin, gemifloxacin, and telithromycin have activity against penicillin-resistant *S. pneumoniae*.

^cCiprofloxacin and levofloxacin have enhanced antipseudomonal activity.

AECOPD, acute exacerbations of chronic obstructive pulmonary disease; FEV₁, forced expiratory volume at 1 second.

Adapted from references 96 and 11, with permission.

Numerous placebo-controlled trials of antibiotics in AECB have been published, with systematic reviews of these trials suggesting a beneficial treatment effect;^{26,27} the latter suggesting a mortality benefit.²⁷ In the former study, a meta-analysis of nine acceptable studies (of 214 reviewed) addressed the need for antibiotic therapy for AECB.²⁶ Evaluated agents included tetracyclines, chloramphenicol, ampicillin, and trimethoprim-sulfamethoxazole (TMP-SMX). These studies, conducted between 1957 and 1992, demonstrated benefit of antibiotic therapy especially in those patients requiring hospitalization. Macrolides (e.g., clarithromycin, azithromycin) and fluoroquinolones (including levofloxacin and moxifloxacin) are as efficacious, but not superior, to older therapies.^{28–36} While antibiotics offer benefit, identification of those patients most likely to benefit remains elusive. Patients with at least two cardinal symptoms of acute exacerbations of chronic obstructive pulmonary disease (AECOPD; increased dyspnea, increased sputum production, and/or change in sputum color) experience a greater benefit from antibiotic treatment. Table 60-2 serves as a useful guide in selecting antibiotics for AECB.

Independent of selection, predetermined outcome measures should be closely monitored. One of these measures is the infection-free interval (IFI) when the patient is not taking antibiotics. The IFI is hypothesized to relate to a decrease in colonization of the upper airways with bacteria, reduce cost of treatment of AECB, and decrease antibiotic use.³⁷ The length of the infection-free period, number of physician office visits,

and hospital admissions associated with a particular antibiotic regimen should be identified in each patient. The longest infection-free period defines the regimen of choice for that specific patient. Three comparative studies have been conducted with ciprofloxacin to evaluate the IFI as an outcome measure.^{38,39} When compared with clarithromycin, the IFI for ciprofloxacin was 142 days versus 52 days ($p = 0.15$); when compared with cefuroxime, the IFI was 146 days versus 178 days ($p = 0.35$); and when compared with amoxicillin/clavulanate, the IFI was 163 days versus 178 days ($p = 0.81$). The infection-free period is a dynamic outcome measure that needs to be continually evaluated to determine the most appropriate therapy at any point in time in each patient.

ANTIBIOTIC PROPHYLAXIS

5. What strategies should be considered in the use of antibiotic prophylaxis if M.J. develops frequent exacerbations?

Prophylactic antibiotic therapy may decrease the number of acute exacerbations of bronchitis in patients with frequent episodes.^{16,40} In patients such as M.J. with infrequent exacerbations, prophylaxis is not beneficial and should be discouraged. Immunization for influenza and pneumococcus and chronic maintenance therapy with bronchodilators or anticholinergic agents preferentially should be used. Antimicrobial prophylaxis should be considered in patients with frequent, severe exacerbations but used only during critical periods when

Table 60-3 Mortality Rates by Pathogen for Community-Acquired Pneumonia

|---------------------------------|--------------------|
| <i>Streptococcus pneumoniae</i> | 12.0 |
| <i>Haemophilus influenzae</i> | 7.4 |
| <i>Staphylococcus aureus</i> | 31.8 |
| <i>Klebsiella pneumoniae</i> | 35.7 |
| <i>Pseudomonas aeruginosa</i> | 61.0 |
| <i>Legionella</i> | 14.7 |
| <i>Chlamydia pneumoniae</i> | 9.8 |
| <i>Mycoplasma pneumoniae</i> | 1.4 |

patients are most susceptible. For example, daily doses of antibiotics 4 days a week during the winter months⁴¹ or a 7-day course of antibiotics at the first sign of a “chest cold” have been suggested. As mentioned previously, amoxicillin, doxycycline, or TMP-SMX are preferred.^{42,43} Antipneumococcal fluoroquinolones should be avoided because of a lack of additional benefit, increased cost, and the concerns regarding selection for bacterial resistance.

PNEUMONIA

Pneumonia is an infectious inflammation of the lung parenchyma. Considering that pneumonia is not a reportable disease and most community-acquired infections are treated on an outpatient basis, it is difficult to determine the true incidence and associated morbidity. Approximately 4 million cases of community-acquired pneumonia (CAP) occur annually, of which almost 1 million occur in those ³65 years of age, with 25% requiring hospitalization.⁴⁴ Of those patients hospitalized for pneumonia, the average mortality rate is 10% to 12%, a rate that has not decreased since the introduction of penicillin therapy.^{45–47} Associated mortality depends on underlying diseases, age, complications, and pathogen. Table 60-3 summarizes the mortality associated with various bacterial pneumonias. The aggregate cost of care in the United States has been estimated to be in excess of \$4.4 billion annually.^{45,47–50}

Normal Respiratory Tract Defenses

6. A.T., a 58-year-old man, is admitted to the hospital from home with fever, increased sputum production, tachypnea, and complaints of a knifelike chest pain that is made worse by coughing and breathing. Pertinent medical history includes a 12-year history of CB and chronic renal insufficiency. A.T. regularly produces two cups of sputum per day and continues to smoke two and one-half packs of cigarettes per day. He has been taking amoxicillin 250 mg BID prophylactically for the past 14 months.

Physical examination reveals an elderly man lying restlessly in bed, awake, and oriented to person but not place or time; temperature, 101.5°F (38.6°C), blood pressure (BP), 145/88 mmHg; heart rate (HR), 105 beats/minute; and respiratory rate (RR), 33 breaths/minute. Chest examination reveals slight splinting on the right side with inspiration and fine crackling rales in the lower base of the right lung. Examination of the left lung is normal.

Significant laboratory results include the following: WBC count, 16,200 cells/mm³ (normal, 5,000–10,000 cells/mm³); differential polymorphonuclear neutrophils (PMNs), 82% (normal,

45%–79%); bands, 9% (normal, 0%–5%); lymphocytes, 8% (normal, 16%–47%); hematocrit (Hct), 40% (normal, 37%–47%); sodium, 141; potassium, 4.8; blood urea nitrogen (BUN), 32; creatinine, 3.8 mg/dL; glucose 148, mg/dL; arterial blood gases (ABGs), pH 7.46 (normal, 7.38–7.45), Po₂, 68 mmHg (normal, 80–100 mmHg), PCO₂, 36 mmHg (normal, 38–45 mmHg), HCO₃, 24 mEq/L (normal, 22–26 mEq/L); and Gram stain reveals <10 epithelial cells, 20 to 25 PMNs, and predominance of Gram-negative rods.

What are the normal respiratory defenses against infection?

[International System of Units (SI): WBC count, 16.2–10.0⁸/L (normal, 5–10); differential PMNs, 0.82 (normal, 0.45–0.79); bands, 0.09 (normal, 0.00–0.05); lymphocytes, 0.08 (normal, 0.16–0.47); Hct, 0.45 (normal, 0.37); Po₂, 9.06 kPa (normal, 10.66–13.33); PCO₂, 4.8 kPa (normal, 5.07–6.00)]

Preservation of normal respiratory tract function involves a complex system of local pulmonary lung defenses. Anatomic, functional, and mechanical barriers protect the tracheo-bronchial tree from inert particle and microbial invasion. In addition, an intricate system of cellular and humoral immune host defenses maintain the respiratory tract free of infection. Intrinsic defects in these normal defenses predispose the patient to respiratory infections.^{51,52}

The hairs lining the nasal passages, ciliated epithelial cells on mucosal surfaces, production of mucus, salivary enzymes, and the mechanical process of swallowing minimize the passage of foreign material into the lower respiratory tract. Disease states, environmental factors, and age may alter the integrity and function of these barriers.

Alteration in normal oropharyngeal flora by disease or antibiotics permit colonization of the oropharynx with more pathogenic bacteria. Colonization of the oropharynx does not predict infection but predisposes the susceptible patient to aspiration pneumonia.

Neurologic diseases and altered states of consciousness, which result in the loss of control of epiglottal and laryngeal function, predispose the patient to recurrent episodes of aspiration of upper respiratory tract secretions. Without an intact cough or gag reflex, the volume of upper respiratory secretions reaching the lower airways may exceed the local lung defenses, increasing the risk for infection. Patients at risk include any patient with altered consciousness secondary to disease or drugs (e.g., alcoholics, stroke victims, substance abusers, epileptics, surgical patients receiving general anesthesia, head injury patients, patients with any illness associated with obtundation).

A functioning mucociliary transport system, which traps and removes foreign material from the lower respiratory tract, is critical to the protection of the lungs. Diseases that alter mucus production and ciliary function severely compromise the body’s ability to defend against infection.

Finally, defects in the cellular and humoral immune response compromise the host to invading pathogens.⁵³ These defenses include the pulmonary macrophages residing within the alveoli, polymorphonuclear leukocytes, and immunoglobulin and complement present in lung tissue. Deficiency of the latter substances is associated with an increase in the prevalence of infection with encapsulated organisms (i.e., *S. pneumoniae*, *H. influenzae*). These substances enhance the body’s defense against bacterial invaders by functioning as opsonins to improve the efficiency of phagocytosis.

In the normal state, the lungs are repeatedly inoculated with microorganisms from the upper airway and inhaled aerosols,

but pneumonia rarely occurs.⁵⁴ Defects in one or more of the aforementioned mechanisms expose the lung to an increased inoculum of microorganisms for a sufficient period, resulting in pneumonia.

Risk Factors

7. What factors present in A.T. make him susceptible to pulmonary infection?

Most bacterial pneumonias result from the entry of pathogenic bacteria colonizing the mouth and upper respiratory tract into the lung. In the healthy state, the bacterial flora of the oropharynx consists of a mixture of aerobic bacteria (including *Streptococcus* sp., *S. pneumoniae*) and anaerobic bacteria (including *Peptococcus* sp., *Peptostreptococcus* sp., *Fusobacterium* sp., *Prevotella melaninogenica*, and various *Bacteroides* sp.).⁵⁵ Suppression of normal flora by antibiotics (e.g., amoxicillin in A.T.) and the host's physiologic state can alter oropharyngeal flora.^{56,57} These factors facilitate the colonization of the oropharynx with significant numbers of pathogenic Gram-negative aerobic bacteria and staphylococci. Gram-negative rods, including *Klebsiella* sp., are cultured from the sputum in 2% to 18% of healthy individuals, but the concentration of organisms is generally small.^{58,59}

Gram-negative bacilli more commonly colonize the oropharyngeal secretions of patients with moderate to severe acute and chronic illnesses, even with no exposure to broad-spectrum antibiotics.^{60,61} Patients admitted to the hospital with acute illnesses are rapidly colonized with aerobic Gram-negative bacilli. Approximately 20% are colonized on the first hospital day, and this number increases with the duration of hospitalization and severity of illness.⁵⁷ Approximately 35% to 45% of hospitalized patients⁵⁷ and up to 100% of critically ill patients⁵⁹ will be colonized within 3 to 5 days of admission.

The elderly also have a higher prevalence of oropharyngeal colonization with Gram-negative rods. Level of independent living is a risk factor; Gram-negative bacteria are recovered from the oropharyngeal cultures of only 9% of elderly living in apartments and 60% of elderly in acute hospital wards.⁶² Decreased mucociliary transport, decreased cell-mediated immunity, altered immunoglobulin production and antibody response, and increased underlying diseases contribute to increased risk of pneumonia in the elderly.^{53,63} Colonization of the upper respiratory tract with Gram-negative bacteria correlates with the development of infection as well.^{57,59,60}

Colonization of the lower respiratory tract with potential pathogens is well established in patients with CB such as A.T.⁶⁴ Whether a positive sputum culture represents a true pulmonary infection versus colonization is difficult to determine. Additional data from the patient's history, physical examination, and laboratory tests are necessary to appropriately interpret the positive sputum culture.

Clinical Presentation

8. What clinical signs, symptoms, and laboratory tests are consistent with pneumonia in A.T.?

Nearly all patients with pneumonia have fever, cough (with or without sputum production), and a physical examination and

chest radiograph finding consistent with consolidation in one or more areas of the lung.⁵⁰ Tachypnea, fever, tachycardia, and the chest examination findings represent an acute pulmonary process in this patient.

Although a number of tests are used to document pneumonia, a chest radiograph best distinguishes pneumonia from other disease states. Congestive heart failure, pulmonary embolism, and other diseases may mimic the signs and symptoms of pneumonia. In the majority of cases, a chest radiograph best differentiates between AB, an infection that does not require antibiotics, and pneumonia, one that benefits from antimicrobial therapy. Consequently, a chest radiograph is recommended for all patients hospitalized for presumed pneumonia. The radiograph also may be useful in evaluating the severity of disease (multilobar vs. single lobe involvement). Importantly, A.T. has not received a chest radiograph at this time; thus, a radiograph is recommended to confirm the diagnosis of pneumonia.

Attempts have been made to classify pneumonia as "typical" or "atypical." This categorization originated from the presumption that the presenting symptoms of pneumonia secondary to pathogens such as *S. pneumoniae*, *H. influenzae*, *Staphylococcus aureus*, and enteric Gram-negative bacteria ("typical") is different from that observed for *Mycoplasma*, *Legionella*, and *Chlamydia* ("atypical"). However, the Infectious Diseases Society of America (IDSA)/American Thoracic Society (ATS) guidelines caution that this categorization is flawed. *S. pneumoniae* and viruses may cause a syndrome indistinguishable from that caused by *Mycoplasma pneumoniae*. Consequently, reliance on the presence of specific symptoms in the etiology of pneumonia is unreliable. Difficulty with a pathogen-specific diagnosis results in the empiric use of antibacterials active against both "typical" and "atypical" pathogens in the treatment of pneumonia.

A.T. has many signs and symptoms of pneumonia. Fever, tachypnea, tachycardia, a productive cough, and a change in the amount or character of the sputum are common in patients with pneumonia. A.T. gives a history of pleuritic (knifelike) chest pain and examination of the chest shows splinting and an inspiratory lag on the right side during inspiration. All these signs are suggestive of a pneumonic process and usually are present on the affected side. Decreased breath sounds, dullness on chest percussion, and egophony (E – A changes) found during auscultation of the chest are suggestive of consolidation. A.T. is also hypoxemic, as evidenced by his PO_2 of 68 mmHg. A chest radiograph should be performed to identify and/or confirm a pulmonary infiltrate. A.T.'s WBC count is elevated with a left shift (predominance of PMNs and bands), also consistent with bacterial infection.

Determination of Etiologic Agent

9. How can the etiologic organism be determined?

In addition to the clinical and radiographic features noted previously, investigation for specific pathogens should be considered. Such testing may result in changes in antibacterial therapy due to identification of a specific pathogen allowing coverage to be de-escalated or more focused. Correct choice of therapy is critical, since clinical failure and mortality is associated with inappropriate antibiotic therapy. There also are societal benefits associated with establishing an etiologic

diagnosis. For some pathogens, there are important epidemiologic implications. These include severe acute respiratory syndrome (SARS), influenza, Legionnaires disease, and agents of bioterrorism. In addition, empiric treatment guidelines, such as those recently published by the IDSA and ATS, are based on the prevalence of pathogens identified and their in vitro susceptibility patterns.

Adequately and appropriately collected sputum that is Gram stained and cultured remain the mainstays in identifying the etiologic organisms of acute pneumonias. Most often, sputum is collected by having the patient cough and expectorate lower respiratory tract secretions into a collection container; however, because the secretions must pass through the mouth, they may become contaminated with mouth flora. The sputum should be examined macroscopically, and the color, consistency, amount, and odor should be recorded. Appropriately collected specimens should contain 25 PMNs/low-power field (LPF).⁶⁵ If there is a predominant organism on Gram stain, empiric therapy can be directed toward the most likely organism. Patients with risk factors for pneumonia (e.g., elderly, hospitalized, chronically ill) often are colonized by multiple pathogens, and a sputum culture is seldom helpful in identifying the specific causative organism.⁶⁶ In these cases, physical examination, chest radiograph, and changes in sputum production and quality continue to be the cornerstone for the diagnosis of pneumonia. In patients admitted to the hospital, blood cultures should be evaluated in making a diagnosis, as approximately 12% to 25% will have a positive blood culture with a respiratory pathogen. Empiric antibiotic therapy may be directed based on bacterial morphology or Gram stain while awaiting the culture results to become available 24 to 48 hours later.

If a patient is unable to give an acceptable sputum specimen after three to four attempts, transtracheal aspiration, bronchoscopy, or open lung biopsy can be used to obtain sputum or tissue samples for laboratory analysis. However, these procedures are not without risk and should be used only when the etiology is crucial for diagnosis. Clinical indications for more

extensive diagnostic testing are provided in Table 60-4 (from IDSA/ATS guidelines).

Microbiology

The major pathogens for CAP are summarized in Table 60-5. This information is potentially biased, as it is largely based on studies of hospitalized patients, and there is significant variability in the recovery of atypical pathogens, including viruses (influenza A and B), *Legionella* sp., *Chlamydia pneumoniae*, and *M. pneumoniae*. Even with extensive diagnostic studies, the

ICU, intensive care unit.

Based on collective data from recent studies (reference 174) and adapted from Mandell LA et al. IDSA/ATS guidelines. *Clin Infect Dis* 2007;44:S27–72, and references 52, 55, and 69–72.

causative organism is identified in only 30% to 50% of cases. Several factors contribute to this low yield: (a) 20% to 30% of patients do not provide sputum samples, (b) 20% to 30% have received prior antimicrobial therapy, and (c) some pathogens can only be detected by using specialized techniques.

S. pneumoniae is the most common cause of pneumonia in all age groups and settings, identified in 25% to 60% of all community-acquired bacterial pneumonias.⁶⁷ The sudden, rapid onset of dramatic rigors, pleuritic chest pain, a rust-colored sputum with Gram-positive diplococci, and leukocytosis are consistent with pneumococcal pneumonia.

H. influenzae is a significant pulmonary pathogen in infants and children. However, *H. influenzae* also is a significant pulmonary pathogen in adults, particularly those with chronic lung diseases. The high incidence of β -lactamase-producing *H. influenzae* further complicates antimicrobial selection.^{68,69}

Gram-negative pneumonia in the community setting is increasing in incidence.^{50,70} However, many of these cases are not truly “community acquired,” and those cases associated with patients residing in nursing homes and long-term care facilities are now termed *health care-associated facility pneumonia*. In addition, alcoholic individuals are predisposed to Gram-negative pneumonia, often with *Klebsiella pneumoniae*.

The atypical pathogens of CAP are theoretically associated with an atypical clinical presentation, including subacute onset, nonproductive cough, extrapulmonary manifestations, and a chest radiograph that is characteristically worse than the patient’s clinical appearance. However, a clear association between these organisms and an atypical presentation has not been established. Atypical pathogens account for 10% to 20% of all cases; however, frequency varies based on temporal and geographic epidemiologic patterns. Diagnostic tests for *Legionella* include culture, direct fluorescent antigen stain, or urinary antigen assays, which may allow for more directed therapy.

Legionella pneumophila is an important cause of CAP in certain high-risk patients.⁷⁰ Patients with altered immunologic function (e.g., elderly) and chronic diseases (e.g., COPD) are most susceptible to infection with this organism. *Legionella* is more common in middle-age and elderly adults and has the highest mortality rate of the atypical pathogens. Its presentation may be associated with significant gastrointestinal (GI) complaints (nausea, vomiting) and electrolyte abnormalities. Similar to serious pneumococcal pneumonia, the clinical course often is progressive despite administration of appropriate antibiotic therapy. The reported mortality rate is 15% to 25%, even with effective therapy.^{47,71}

Mycoplasma (also called *walking pneumonia*) is more common in young adults.^{50,72} Diagnostic tests are available (primarily an immunoglobulin M [IgM] enzyme immunoassay), but most laboratories do not provide these tests. Mycoplasma carries virtually no mortality. *C. pneumoniae* reportedly accounts for 5% to 10% of all cases of CAP.^{50,73} It has been associated with atherosclerotic disease; however, cause and effect continues to be debated. Diagnostic tests for this pathogen are not offered by most clinical laboratories.

Viral agents account for 2% to 15% of all cases of CAP.⁵⁰ Influenza A and B, adenovirus, and parainfluenza virus are most commonly reported in adults, whereas respiratory syncytial virus is most common in the pediatric population.

Epidemiologic factors may favor the presence of certain pathogens.⁴⁵ Patients with poor dental hygiene are likely to be infected with anaerobes, whereas HIV-coinfected individuals are more likely to be infected by *P. jirovecii*. A thorough travel and animal-contact history is important. Exposure to birds can be associated with *Chlamydia psittaci* (the cause of psittacosis), exposure to cattle or a parturient cat can be associated with *Coxiella burnetii* (the cause of Q fever), and travel to the southwestern United States can be associated with *Coccidioides immitis* infections. In addition, in the current age of bioterrorism, agents such as *Bacillus anthracis* (anthrax), *Francisella tularensis* (tularemia), and *Yersinia pestis* (plague) may need to be considered as potential causes of pneumonia.

Recently, an increasing incidence of pneumonia due to community-acquired *Staphylococcus aureus* (CA-MRSA) has been observed. These strains are distinct from hospital-acquired strains in that they typically possess a different in vitro susceptibility profile and two unique genes, the *SCCmec* and Panton-Valentine leukocidin (*PVL*) genes. *PVL* encodes for a toxin that has been associated with necrotizing pneumonia, abscess formation, and empyema. When CA-MRSA has been associated with CAP, it has been most commonly preceded by influenza.

Site of Care for Treatment of Community-Acquired Pneumonia

10. How should A.T. be treated?

The initial management decision after the diagnosis of CAP is to determine the site of care—outpatient, hospitalization in a medical ward, or admission to an intensive care unit (ICU).⁴⁷ This is the most costly decision in the management of CAP, as the cost for inpatient care is up to 25 times greater than that for outpatient care and consumes the majority of the estimated \$10 billion dollars spent annually on treatment. Severity of illness scores such as the British Thoracic Society (BTS) CURB-65 criteria or prognostic models such as the Pneumonia Severity Index (PSI) can be used to identify patients with CAP who may be candidates for outpatient management.

The PSI and its risk factors for 30-day mortality have been derived by Fine et al.^{44,74} by using 20 variables including age, gender, laboratory data on admission, and comorbidities (Fig. 60-2). It stratifies patients in risk categories I to V based on the predicted 30-day mortality. The CURB-65 assigns one point for each of the following criteria: Confusion, Uremia, increased Respiratory rate, low Blood pressure, and age ≥ 65 years). Table 60-6 summarizes the two systems regarding predicted mortality and recommended site of care.

In deciding whether or not to admit to an ICU, one should consider the criteria for severe CAP outlined in Table 60-7, as developed by the IDSA/ATS. The two major criteria or the presence of at least three minor criteria are absolute indications for ICU admission. The use of these criteria allows for appropriate placement of patients and resource utilization, treatment selection, the rapid identification of patients at risk for sepsis, and the availability of ventilator/hemodynamic support.

The use of objective admission criteria such as the PSI or CURB-65 has resulted in a decrease in the number of patients hospitalized with CAP. Whether the PSI or CURB-65 is superior remains unclear, as no randomized trials have compared these methods. The use of objective admission criteria should be supplemented with clinical assessment and determination of

Step 1. Is the patient low risk (class I) based on history and physical examination and not a resident of a nursing home?

- Age 50 years or younger, and
- None of the coexisting conditions or physical examination findings listed in step 2

NO → Go to step 2

YES → Outpatient treatment is recommended

Step 2. Calculate risk score for classes II-V

| 91-130 | IV | Inpatient | 8.2-9.3 |
| \geq 130 | V | Inpatient | 27.0-29.2 |

FIGURE 60-2 Model to predict the 30-day mortality in patients with community-acquired pneumonia.

subjective factors including availability of outpatient support resources.

Using the PSI, the scoring for A.T. is as follows: He is a 58-year-old man (58 points), has a history of chronic renal insufficiency (10 points), a RR $>$ 30 (20 points), and has an altered mental status (20 points). His score of 108 points places him in risk strata IV, which carries a 30-day mortality risk of 9.3% (Fig. 60-2). Based on A.T.'s PSI assessment and clinical status, he should be admitted to the hospital. Using the CURB-65, A.T. has a score of "3" (30-day mortality of 14.5%–57%) given that he was confused, uremic, and had an increased RR, similarly resulting in the hospital as the preferred site of care.

INITIATION OF ANTIMICROBIAL TREATMENT

Initial antimicrobial therapy is largely empirical and should be guided by the results of the sputum Gram stain, patient

age, medical history, concomitant diseases, place of residence, clinical signs and symptoms, and allergy status. An approach to the patient with CAP is presented in Figure 60-3, and antibiotic regimens of choice are provided in Table 60-8 (see below).⁴⁵

If no sputum is available for Gram stain or the microbiologic results do not identify a causative organism, antibiotics active against the most probable bacterial pathogens should be selected (Table 60-9).

Lastly, the underlying conditions that predispose to specific pathogens, such as risks for aspiration, alcohol abuse, smoking, and epidemiologic exposures, also should be considered in the empiric selection of therapy (Table 60-10).

The time to the first dose of antibiotic therapy has been emphasized as a lower mortality, as has been seen in patients with CAP based on the time to first dose received. Those administered their first dose of antibiotic therapy within 4 hours

Table 60-6 Predicted Mortality and Recommended Site of Care

| System and Score | Predicted 30-Day Mortality (%) | Recommended Site of Care |
|-------------------|--------------------------------|--------------------------|
| PSI strata 1–2 | 0.1–0.7 | Outpatient |
| PSI strata 3 | 0.9–2.8 | Admit to ward |
| PSI strata 4–5 | 9.3–27 | Admit; consider ICU |
| CURB-65 score 0–1 | 0.7–2.1 | Outpatient |
| CURB-65 score 2 | 9.2 | Admit to ward |
| CURB-65 score 3 | 14.5–57.0 | Admit; consider ICU |

CURB-65, Confusion, Uremia, increased Respiratory rate, low Blood pressure, and age ≥ 65 years; ICU, intensive care unit; PSI, Pneumonia Severity Index.

have been shown to have a lower mortality compared with those receiving a first dose >4 hours. This has been considered as a potential quality measure to assess the quality of care provided to patients with CAP. However, this recommen-

dation has resulted in administration of antibiotics in many patients who ultimately were determined to not have bacterial pneumonia. One of the consequences of this increased focus on the so-called 4-hour rule has in one center resulted in an increase in cases of *Clostridium difficile*-associated diarrhea (CDAD) with several patients without CAP receiving antibacterials and ultimately succumbing to *C. difficile* disease CDAD. The initiation of antibiotic therapy for patients with suspected CAP should be based on assessment of the patient's clinical presentation rather than achieving an administrative outcome measure.

A.T.'s treatment should be started empirically with antibiotics pending identification of the etiologic bacteria. The choice should be guided by the results of the sputum Gram stain, patient age, medical history, concomitant diseases, place of residence, and clinical signs and symptoms. In A.T.'s case, the Gram stain, which shows a predominance of one organism and many WBCs, should have the greatest influence on initial antimicrobial selection. Because A.T.'s Gram stain shows a predominance of Gram-negative bacilli, empiric therapy should

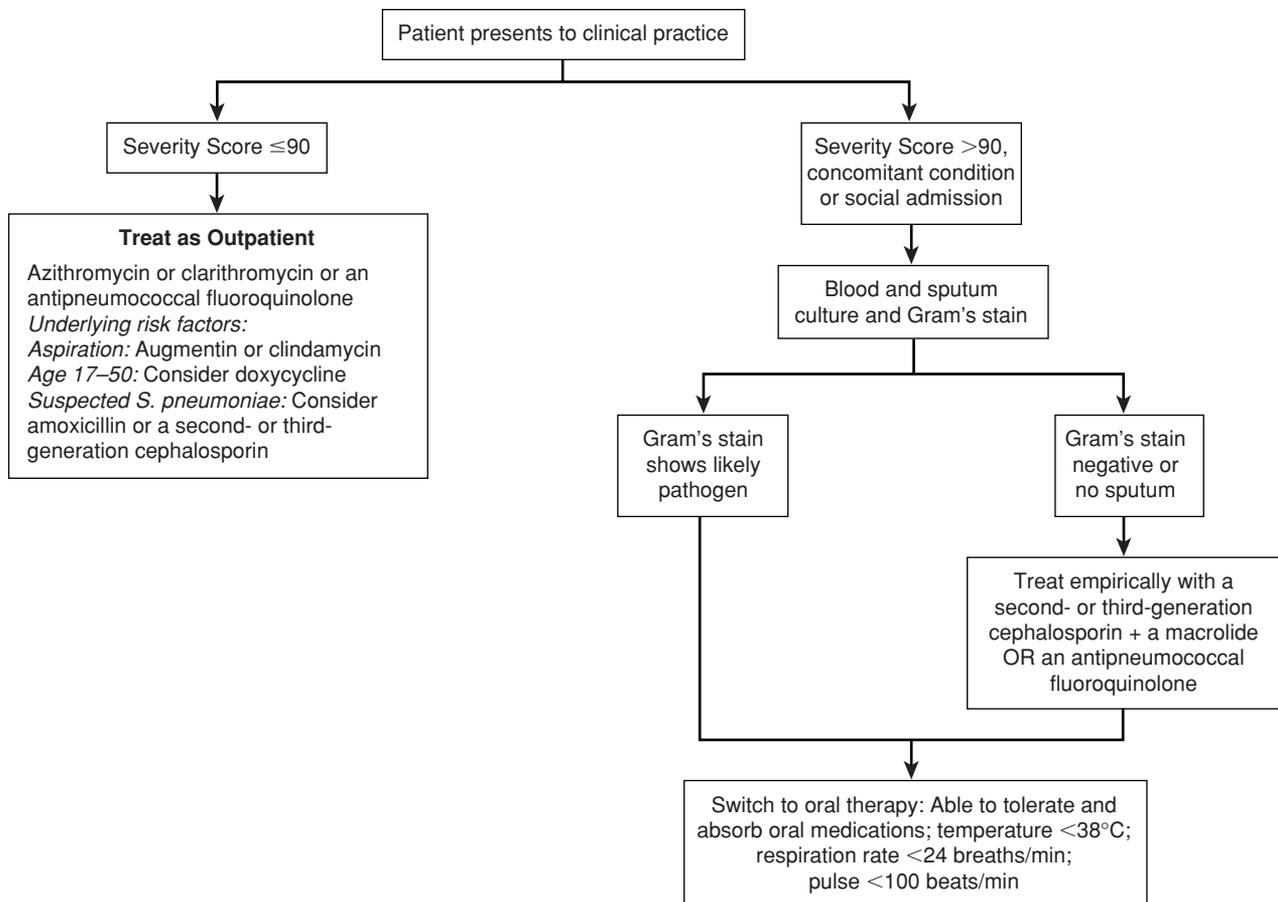

FIGURE 60-3 Application of the Pneumonia Patient Outcomes Research Team Severity Index to determine initial site of treatment. Step 1 identifies patients in risk class 1 on the basis of age ≤ 50 years and the absence of all comorbid conditions and vital sign abnormalities listed in step 2. For all patients who are not classified at risk class 1, the laboratory data listed in step 2 should be collected to calculate a pneumonia severity score. Risk class and recommended site of care based on the pneumonia severity score listed in the final table. Thirty-day mortality data are based on two independent cohorts of 40,326 patients.  Hypothermia (core temperature, <36°C)
 Hypotension requiring aggressive fluid resuscitation

Major Criteria

Invasive mechanical ventilation
 Septic shock with the need for vasopressors

^aOther criteria to consider include hypoglycemia (in nondiabetic patients), acute alcoholism/alcoholic withdrawal, hyponatremia, unexplained metabolic acidosis or elevated lactate level, cirrhosis, and asplenia.

^bA need for noninvasive ventilation can substitute for a RR >30 breaths/minute or a PaO₂/FiO₂ ratio >250.

^cAs a result of infection alone.

BUN, blood urea nitrogen; PaO₂/FiO₂, arterial oxygen pressure/fraction of inspired oxygen; RR, respiratory rate; WBC, white blood cell.

be directed at *H. influenzae* and other Gram-negative bacilli. Based on A.T.'s age and history of previous amoxicillin prophylaxis, one can assume that the pathogen in question is not susceptible to amoxicillin. Consequently, an antibiotic regimen that is effective against ampicillin-resistant *H. influenzae* and other aerobic Gram-negative bacilli should generally be chosen. A respiratory fluoroquinolone (levofloxacin or moxifloxacin) would be a reasonable selection for empiric treatment of A.T.'s pneumonia.

RESPONSE TO THERAPY

Patient outcomes associated with CAP depend largely on the choice of antimicrobial agent and the patient status at the time of presentation. Poor prognostic factors include age >65 years; coexisting disease such as diabetes, renal failure, heart failure, and COPD; clinical and laboratory findings as outlined in Figure 60-2; and recovery of *S. pneumoniae* or Legionella.^{44,45,47}

Most patients with bacterial pneumonia improve clinically (decreased temperature and systemic toxicity) 24 to 48 hours after the initiation of effective antibiotic therapy. Chest radiograph resolution lags, taking 3 weeks in otherwise healthy, young adults and up to 12 weeks in elderly patients and those with complicated infections.^{75,76} A subset of patients with bacterial pneumonia can be predicted to do poorly. Factors associated with a poor outcome include multilobar involvement, bacteremia, a history of alcoholism, age >60 years, and neutropenia. Despite the introduction of new anti-infectives, antibiotic therapy has not reduced mortality in pneumococcal pneumonia with bacteremia, which remains at 20% to 30%.^{47,77}

When the patient is clinically stable for 24 hours (Table 60-11), conversion to the oral route can be considered. The patient must be able to take oral medications and have adequate GI function. Diarrhea is not a reason to avoid the oral route, because it rarely results in significant reductions in absorption of medications.⁴⁵ Selecting an oral agent can be simplified if cul-

Table 60-8 Community-Acquired Pneumonia: Antibiotic Regimens of Choice**Outpatient Treatment**

1. Previously healthy and no use of antimicrobials within the previous 3 months
 A macrolide (strong recommendation; level I evidence)
 Doxycycline (weak recommendation; level III evidence)
2. Presence of comorbidities such as chronic heart, lung, liver or renal disease; diabetes mellitus; alcoholism; malignancies; asplenia; immunosuppressing conditions or use of immunosuppressing drugs; or use of antimicrobials within the previous 3 months (in which case an alternative from a different class should be selected)
 A respiratory fluoroquinolone (moxifloxacin, gemifloxacin, or levofloxacin [750 mg]) (strong recommendation; level I evidence)
 A β -lactam plus a macrolide (strong recommendation; level I evidence)
3. In regions with a high rate (>25%) of infection with high-level (MIC ≥16 mcg/mL) macrolide-resistant *Streptococcus pneumoniae*, consider use of alternative agents listed above in #2 for patients without comorbidities (moderate recommendation; level III evidence)

Inpatients, Non-ICU Treatment

A respiratory fluoroquinolone (strong recommendation; level I evidence)
 A β -lactam plus a macrolide (strong recommendation; level evidence)

Inpatients, ICU Treatment

A β -lactam (cefotaxime, ceftriaxone, or ampicillinsulbactam) plus either azithromycin (level II evidence) or a respiratory fluoroquinolone (level I evidence) (strong recommendation) (for penicillin-allergic patients I a respiratory fluoroquinolone and aztreonam are recommended)

Special Concerns

If *Pseudomonas* is a consideration:

An antipneumococcal, antipseudomonal β -lactam (piperacillin-tazobactam, ceftipirne, imipenem, or meropenem) plus either ciprofloxacin or levofloxacin (750 mg)

or

The above β -lactam plus an aminoglycoside and azithromycin

or

The above β -lactam plus an aminoglycoside and an antipneumococcal fluoroquinolone (for penicillin-allergic patients, substitute aztreonam for above β -lactam) (moderate recommendation; level III evidence)

If CA-MRSA is a consideration, add vancomycin or linezolid (moderate recommendation; level III evidence)

CA-MRSA, community-acquired methicillin-resistant *Staphylococcus aureus*; ICU, intensive care unit; MIC, minimum inhibitory concentration.

ture and sensitivity data are available and if the parenteral agent is available in an oral formulation. Patients with CAP should be treated for a minimum of 5 days, should be afebrile for 48 to 72 hours, and should have no more than one CAP-associated sign of clinical instability (Table 60-11) before therapy is discontinued. A longer duration of therapy may be needed if the initial therapy was not active against the identified pathogen or if it was complicated by extrapulmonary infection such as bacteremia.

Table 60-9 Community-Acquired Pneumonia: Preferred Antimicrobial(s) Against Most Probable Bacterial Pathogens

| Organism | Preferred Antimicrobial(s) | Alternative Antimicrobial(s) |
|---|--|---|
| <i>Streptococcus pneumoniae</i> Penicillin nonresistant; MIC <2 mcg/mL | Penicillin G, amoxicillin | Macrolide, cephalosporins, (or a I [cefepodoxime, cefprozil, cefuroxime, cefdinir, cefditoren] or parenteral [cefuroxime, ceftriaxone, cefotaxime]), clindamycin, doxycycline, respiratory fluoroquinolone ^a |
| Penicillin resistant; MIC ≥2 mcg/mL | Agents chosen on the basis of susceptibility, including cefotaxime, ceftriaxone, fluoroquinolone | Vancomycin, linezolid, high-dose amoxicillin (3 g/day with penicillin MIC ≤4 mcg/mL) |
| <i>Haemophilus influenzae</i> Non-β-lactamase producing β-Lactamase producing | Amoxicillin Second- or third-generation cephalosporin, amoxicillin-clavulanate | Fluoroquinolone, doxycycline, azithromycin, clarithromycin ^b Fluoroquinolone, doxycycline, azithromycin, clarithromycin ^b |
| <i>Mycoplasma pneumoniae</i> / <i>Chlamydia pneumoniae</i> | Macrolide, a tetracycline | Fluoroquinolone |
| <i>Legionella</i> sp. | Fluoroquinolone, azithromycin | Doxycycline |
| <i>Chlamydia psittaci</i> | A tetracycline | Macrolide |
| <i>Coxiella burnetii</i> | A tetracycline | Macrolide |
| <i>Francisella tularensis</i> | Doxycycline | Gentamicin, streptomycin |
| <i>Yersinia pestis</i> | Streptomycin, gentamicin | Doxycycline, fluoroquinolone |
| <i>Bacillus anthracis</i> (inhalation) | Ciprofloxacin, levofloxacin, doxycycline (usually with second agent) | Other fluoroquinolones; β-lactam, if susceptible; rifampin; clindamycin; chloramphenicol |
| Enterobacteriaceae | Third-generation cephalosporin, carbapenem ^c (drug of choice if extended-spectrum β-lactamase producer) | β-Lactam/β-Lactamase inhibitor ^d fluoroquinolone |
| <i>Pseudomonas aeruginosa</i> | Antipseudomonal β-lactam plus ciprofloxacin or levofloxacin ^f or aminoglycoside | Aminoglycoside plus ciprofloxacin or levofloxacin ^f |
| <i>Burkholderia pseudomallei</i> | Carbapenem, ceftazidime | Fluoroquinolone, TMP-SMX |
| <i>Acinetobacter</i> sp. | Carbapenem | Cephalosporin-aminoglycoside, ampicillin sulbactam, colistin |
| <i>Staphylococcus aureus</i> Methicillin susceptible Methicillin resistant | Antistaphylococcal penicillin ^g Vancomycin or linezolid | Cefazolin, clindamycin TMP-SMX |
| Bordetella pertussis | Macrolide | TMP-SMX |
| Anaerobe (aspiration) | β-Lactam/β-Lactamase inhibitor, ^d clindamycin | Carbapenem |
| Influenza virus | Oseltamivir or zanamivir | |
| Mycobacterium tuberculosis | Isoniazid plus rifampin plus ethambutol plus pyrazinamide | Refer to reference 243 for specific recommendations |
| <i>Coccidioides</i> sp. | For uncomplicated infection in a normal host, no therapy generally recommended; for therapy, itraconazole, fluconazole | Amphotericin B |
| Histoplasmosis | Itraconazole | Amphotericin B |
| Blastomycosis | Itraconazole | Amphotericin B |

NOTE. Choices should be modified on the basis of susceptibility test results and advice from local specialists. Refer to local references for appropriate doses.

^aLevofloxacin, moxifloxacin, gemifloxacin (not a first-line choice for penicillin-susceptible strains); ciprofloxacin is appropriate for *Legionella* and most Gram-negative bacilli (including *H. influenzae*).

^bAzithromycin is more active *in vitro* than clarithromycin for *H. influenzae*.

^cImipenem-cilastatin, meropenem, ertapenem.

^dPiperacillin-tazobactam for Gram-negative bacilli, ticarcillin clavulanate, ampicillin-sulbactam or amoxicillin clavulanate.

^eTicarcillin, piperacillin, ceftazidime, cefepime, aztreonam, imipenem, meropenem.

^f750 mg daily.

^gNafcillin, oxacillin, flucoxacin.

MIC, minimum inhibitory concentration; TMP-SMX, trimethoprim-sulfamethoxazole.

11. What is the impact of drug-resistant *Staphylococcus pneumoniae* (DRSP) in the management of CAP?

Penicillin-Resistant *Streptococcus pneumoniae*

Despite four decades of using penicillin, only modest rates of reduced susceptibility to penicillin were reported in the 1980s. However, over the past few decades, increased penicillin resis-

tance has been observed. The mechanism by which pneumococci become resistant to β-lactam antibiotics is through alteration in the penicillin binding proteins. This decrease in affinity results in variable increases in the minimum inhibitory concentrations (MICs) of different β-lactams. Strains with MICs of more than 0.1 mcg/mL accounted for 3.8% of isolates in the 1980s; by 1994–1995, the rate was 24%, and by 1997 it was

Table 60-10 Community-Acquired Pneumonia: Underlying Conditions and Commonly Encountered Pathogens

| Condition | Commonly Encountered Pathogen(s) |
|--|---|
| Alcoholism | <i>Streptococcus pneumoniae</i> , oral anaerobes, <i>Klebsiella pneumoniae</i> , <i>Acinetobacter</i> sp., <i>Mycobacterium tuberculosis</i> |
| COPD and/or smoking | <i>Haemophilus influenzae</i> , <i>Pseudomonas aeruginosa</i> , <i>Legionella</i> sp., <i>S. pneumoniae</i> , <i>Moraxella cararrhalis</i> , <i>Chlamydia pneumoniae</i> |
| Aspiration | Gram-negative enteric pathogens, oral anaerobes |
| Lung abscess | CA-MRSA, oral anaerobes, endemic fungal pneumonia, <i>M. tuberculosis</i> , atypical mycobacteria |
| Exposure to bat or bird droppings | <i>Histoplasma capsulatum</i> |
| Exposure to birds | <i>Chlamydia psittaci</i> (if poultry; avian influenza) |
| Exposure to rabbits | <i>Francisella tularensis</i> |
| Exposure to farm animals or parturient cats | <i>Coxiella burnetti</i> (Q fever) |
| HIV infection (early) | <i>S. pneumoniae</i> , <i>H. influenzae</i> , <i>M. tuberculosis</i> |
| HIV infection (late) | The pathogens listed for early infection plus <i>P. Pneumocystis jirovecii</i> , <i>Cryptococcus</i> sp., <i>Histoplasma</i> sp., <i>Aspergillus</i> sp., atypical mycobacteria (especially <i>Mycobacterium kansash</i>), <i>P. aeruginosa</i> , <i>H. influenzae</i> |
| Hotel or cruise ship stay in previous 2 weeks | <i>Legionella</i> sp. |
| Travel to or residence in southwestern United States | <i>Coccidioides</i> sp., hantavirus |
| Travel to or residence in Southeast and East Asia | <i>Burkholderia pseudomallei</i> , avian influenza, SARS |
| Influenza active in community | Influenza, <i>S. pneumoniae</i> , <i>Staphylococcus aureus</i> , <i>H. influenzae</i> |
| Cough >2 wk with whoop or posttussive vomiting | <i>Bordetella pertussis</i> |
| Structural lung disease (e.g., bronchiectasis) | <i>P. aeruginosa</i> , <i>Burkholderia cepacia</i> , <i>S. aureus</i> |
| Injection drug use | <i>S. aureus</i> , anaerobes, <i>M. tuberculosis</i> , <i>S. pneumoniae</i> |
| Endobronchial obstruction | Anaerobes, <i>S. pneumoniae</i> , <i>H. influenzae</i> , <i>S. aureus</i> |
| In context of bioterrorism | <i>Bacillus anthracis</i> (anthrax), <i>Yersinia pestis</i> (plague), <i>Francisella tularensis</i> (tularemia) |

CA-MRSA, community-acquired methicillin-resistant *Staphylococcus aureus*; COPD, chronic obstructive pulmonary disease; SARS, severe acute respiratory syndrome.

43.8%.^{78–80} As of 2000, rates of resistance in the United States have reached a plateau at 30% to 35%.

The impact of DRSP on patient outcomes is unclear. Published studies are limited by small sample size, observational design, and the relative infrequency of isolates exhibiting “high-level” resistance. The available data suggest that the clinically relevant level of penicillin resistance is an MIC of at least 4 mg/L. Risk factors for infection with β -lactam-resistant *S. pneumoniae* include age <2 years or >65 years of age, β -lactam therapy in the previous 3 months, alcoholism, medical comorbidities, immunosuppressive illness or therapy, and exposure to a child in a day care center. Although the relative

predictive value of these risk factors remains unclear, recent treatment with antimicrobials is likely the most significant risk factor.

Penicillin resistance is also associated with resistance to other antimicrobial classes, including cephalosporins, macrolides, tetracyclines, and TMP-SMZ (Table 60-12). In contrast, vancomycin, the fluoroquinolones, clindamycin, chloramphenicol, and rifampin are less impacted.^{78–81} Penicillin susceptibility should be tested for in all significant pneumococcal isolates.⁸²

Table 60-11 Criteria for Conversion to Oral Administration of Antibiotics

| |
|--|
| Temperature $\leq 37.8^\circ\text{C}$ |
| HR ≤ 100 beats/minute |
| RR ≤ 24 breaths/minute |
| Systolic BP ≥ 90 mmHg |
| Arterial oxygen saturation $\geq 90\%$ or $\text{Po}_2 \geq 60$ mmHg on room air |
| Ability to maintain oral intake ^a |
| Normal mental status ^a |
| HR, heart rate; RR, respiratory rate; Po_2 , oxygen partial pressure. |

Table 60-12 Susceptibility of *Streptococcus pneumoniae* Based on Penicillin Susceptibility

| Agent | % Susceptible to Indicated Agent | | |
|----------------------|----------------------------------|-------|-------|
| | Pen-S | Pen-I | Pen-R |
| Cefuroxime axetil | 99.0 | 76.3 | 0.7 |
| Cefpodoxime proxetil | 99.5 | 82.4 | 0.7 |
| Cefepime | 99.7 | 87.5 | 3.9 |
| Cefotaxime | 100.0 | 95.7 | 19.1 |
| Erythromycin | 96.6 | 81.7 | 50.7 |
| Clarithromycin | 94.9 | 63.5 | 38.9 |
| Clindamycin | 99.2 | 93.2 | 86.2 |
| Tetracycline | 96.1 | 86.7 | 63.2 |
| TMP-SMX | 89.0 | 72.4 | 23.0 |
| Levofloxacin | 97.4 | 96.9 | 97.1 |

Pen-I, penicillin intermediate; Pen-R, penicillin resistant; Pen-S, penicillin sensitive; TMP-SMX, trimethoprim-sulfamethoxazole.

Macrolide-Resistant *Streptococcus pneumoniae*

Although high rates of *in vitro* macrolide resistance can coexist with penicillin resistance, there are few reports of macrolide failures in CAP due to drug-resistant pneumococci.⁸³ Pneumococcal resistance to macrolides is expressed as one of two phenotypes. The first, known as the M phenotype, is an efflux pump associated with the *mefE* gene that results in the efflux of all 14- and 15-membered macrolides from the cell.⁸⁴ M phenotype isolates typically have moderate levels of macrolide resistance (MIC in the range of 1–32 mg/mL) and are almost always susceptible to clindamycin.⁸⁵ A second phenotype, called the MLSB phenotype, results from methylation of 23S ribosomal RNA and is encoded by the *ermAM* gene. Methylation results in blockade of the binding of macrolides, lincosamides, and group B streptogramin agents. The MLSB phenotype is associated with high-level macrolide resistance (MIC > 64 mg/mL) as well as resistance to clindamycin.

One investigation demonstrated the following: (a) macrolide use in the United States increased by 13% from 1993 to 1999 (17.7 million prescriptions vs. 21.2 million prescriptions, respectively)—the most dramatic increase was in children <5 years of age, a 320% increase over the same time frame); (b) macrolide resistance has doubled from 1995 to 1999 (10.6% in 1995 to 20.4% in 1999), mostly accounted for by increases in the M phenotype; and (c) the median MIC of the M phenotype increased from 4 mcg/mL to 8 mcg/mL, an MIC associated with treatment failures to clarithromycin and azithromycin.⁸⁶ The association between increasing macrolide use and the increasing prevalence of macrolide resistance, and more importantly the shift in the median MIC in M phenotype isolates, is disturbing. As a result, current guidelines recommend macrolide monotherapy only in outpatients who prior to the onset of CAP were otherwise healthy and have no risk factors for DRSP.

Antiviral Agents

12. What treatment options are available for influenza virus infection?

As outlined previously, viruses account for 2% to 15% of all cases of CAP. Influenza represents one organism that commonly may be associated with pneumonia. Influenza is an acute respiratory infection characterized by fever, headache, sore throat, myalgias, and a nonproductive cough. In some cases, it can progress to serious secondary complications such as bacterial and viral pneumonia. In addition to increased health care costs, loss of work days, and unnecessary antibiotics, influenza epidemics are responsible for a large number of deaths each year in the United States. Epidemics occur during the winter months nearly every year, with peak activity between late December and early March. The mainstay of protection against the disease has been the inactivated influenza vaccine. Antiviral agents are important adjuncts to the vaccine but do not serve as a substitute for pre-season vaccination.

Both the influenza A and B viruses have two major surface glycoproteins that mediate immunity, hemagglutinin and neuraminidase. These two proteins play a critical role in viral replication. Hemagglutinin attaches virus to cells, whereas neuraminidase has several roles to facilitate the spread of the virus throughout the respiratory tract. The neuraminidase enzyme is responsible for releasing the virus from infected cells,

preventing the formation of viral aggregates after the release, and potentially preventing viral inactivation. The active site of neuraminidase is almost identical in both influenza A and B.

Although annual vaccination is the primary strategy for preventing complications of influenza virus infections, antiviral medications with activity against influenza viruses can be effective for the chemoprophylaxis and treatment of influenza. Four licensed influenza antiviral agents are available in the United States: amantadine, rimantadine, zanamivir, and oseltamivir. Influenza A virus resistance to amantadine and rimantadine can emerge rapidly during treatment. Because antiviral testing results indicated high levels of resistance, neither amantadine nor rimantadine should be used for the treatment or chemoprophylaxis of influenza in the United States during the 2007–2008 influenza season. Surveillance demonstrating that susceptibility to these antiviral medications has been reestablished among circulating influenza A viruses will be needed before amantadine or rimantadine can be used for the treatment or chemoprophylaxis of influenza A. Oseltamivir or zanamivir can be prescribed if antiviral treatment of influenza is indicated. Oseltamivir is approved for treatment of persons >1 year of age, and zanamivir is approved for treating persons >7 years of age. Oseltamivir and zanamivir can be used for chemoprophylaxis of influenza; oseltamivir is licensed for use as chemoprophylaxis in persons >1 year of age, and zanamivir is licensed for use in persons >5 years of age.

Antiviral Agents for Influenza

Amantadine and rimantadine are compounds that indirectly interrupt the function of hemagglutinin by blocking the uncoating of the influenza A virus and preventing host penetration. When initiated within 48 hours of the onset of symptoms, both amantadine and rimantadine shorten the clinical course of the illness related to influenza A and enable patients to resume daily activities sooner. Until recently, these agents were the only antiviral agents available for the prevention and treatment of influenza A. However, their use has been limited by lack of activity against influenza B, emergence of resistance, and central nervous system effects, particularly with amantadine. Adamantane resistance among circulating influenza A viruses has increased rapidly worldwide over the past several years. The proportion of influenza A viral isolates submitted from throughout the world to the World Health Organization Collaborating Center for Surveillance, Epidemiology, and Control of Influenza at the Centers for Disease Control and Prevention (CDC) that were adamantane resistant increased from 0.4% during 1994–1995 to 12.3% during 2003–2004. During the 2005–2006 influenza season, the CDC determined that 193 (92%) of 209 influenza A (H3N2) viruses isolated from patients in 26 states demonstrated a change at amino acid 31 in the M2 gene that confers resistance to adamantanes. In addition, two (25%) of eight influenza A (H1N1) viruses tested were resistant (368). All 2005–2006 influenza season isolates in these studies remained sensitive to neuraminidase inhibitors. Preliminary data from the 2006–2007 influenza season indicates that resistance to adamantanes remains high among influenza A isolates, but resistance to neuraminidase inhibitors is extremely uncommon (<1% of isolates) (CDC, unpublished data, 2007). Amantadine or rimantadine should not be used for the treatment or prevention of influenza in the United States

Table 60-13 Comparison of Current Antiviral Agents for Influenza

| | <i>Amantadine</i> | <i>Rimantadine</i> | <i>Oseltamivir</i> | <i>Zanamivir</i> |
|-------------------------|-------------------|--------------------------------|---|---|
| Influenza activity | A | A | A and B | A and B |
| Route of administration | Oral | Oral | Oral | Oral inhalation |
| Treatment population | ≥1 yr | ≥14 yr | ≥12 yr | ≥18 yr |
| Prophylaxis population | ≥1 yr | ≥1 yr | No indication | No indication |
| Dosage | 100 mg PO Q 12 hr | 100 mg PO Q 12 hr | 75 mg PO BID for 5 days | Two inhalations (5 mg each) PO BID for 5 days |
| Side effects | CNS, GI | CNS, GI (less than amantadine) | Nasal and throat discomfort, headache, bronchospasm | Nausea, vomiting, headache |

BID, twice a day; CNS, central nervous system; GI, gastrointestinal; PO, by mouth.

until evidence of susceptibility to these antiviral medications has been reestablished among circulating influenza A viruses.

Zanamivir and oseltamivir are chemically related antiviral medications known as neuraminidase inhibitors that have activity against both influenza A and B viruses. The two medications differ in pharmacokinetics, adverse events, routes of administration, approved age groups, dosages, and costs.⁸⁷ They are sialic acid analogs that work by inhibiting the viral enzyme neuraminidase. The function of neuraminidase is to cleave sialic acid residues on the cell surface, thereby promoting release of virus from infected cells. Blocking the activity of neuraminidase decreases the amount of virus released that can infect other cells. Resistance to the neuraminidase inhibitors can occur but seems to be less common and slower to develop than with the older antivirals amantadine and rimantadine. A comparison of these agents is provided in Table 60-13.

Zanamivir (Relenza) is indicated for the treatment of uncomplicated influenza illness in adults and children >12 years of age who have been symptomatic ≤48 hours.^{88–90} Oseltamivir (Tamiflu) is approved for the treatment of uncomplicated influenza infection in adults ≥18 years of age who have been symptomatic ≤48 hours.^{91–92} Studies have shown that when administered within 2 days of the onset of symptoms, both zanamivir and oseltamivir reduced the median duration of symptoms by approximately 1 day (6.5–5.0 days and 4.5–3.0 days, respectively). High-risk patients (i.e., the elderly, those with asthma), patients who had a febrile illness, and those treated within 30 hours of symptom onset showed the greatest improvement from zanamivir therapy (8.0–5.5 days). Neither neuraminidase inhibitor is approved for the prevention of influenza, but recent studies have demonstrated both to be approximately 60% to 80% effective when administered prophylactically. Likewise, there are no studies comparing the two neuraminidase inhibitors with each other or with amantadine or rimantadine.

Zanamivir is formulated as a dry powder for oral inhalation; its oral bioavailability is poor. The recommended dosage is two inhalations (5 mg each) twice daily for 5 days. Less than 20% of the inhaled dose is systemically absorbed; 70% to 90% of the inhaled drug deposits in the oropharynx. The half-life of systemically absorbed zanamivir is 3 to 5 hours, and it is excreted unchanged in the urine. The manufacturer does not recommend a dosage adjustment in patients with renal insufficiency. The most common side effects encountered with zanamivir administration are nasal and throat irritation, headache, and bronchospasm.

Oseltamivir, available as a 75-mg oral capsule, is an ester prodrug that is hydrolyzed in the gut and liver to the active form, oseltamivir carboxylate. The recommended dosage is 75 mg twice daily for 5 days. Eighty percent of the drug is absorbed systemically, and the half-life (6–10 hours) of oseltamivir carboxylate is excreted in the urine by glomerular filtration. A dosage reduction to 75 mg daily is recommended in patients with a creatinine clearance <30 mL/minute. The most common side effects experienced are nausea, vomiting, and headache. Food may improve GI tolerance.

Although there is limited clinical experience, no significant drug interactions have been reported with either agent. Neither zanamivir nor oseltamivir are substrates for cytochrome P450 metabolism and are not expected to alter the metabolism of other agents. The cost for 5-day therapy with zanamivir or oseltamivir is approximately \$50.

The role of the neuraminidase inhibitors in the prevention and treatment of influenza is not clearly defined. It is widely accepted that influenza vaccination will continue to be the primary method of preventing influenza and its secondary complications. However, the neuraminidase inhibitors may be a reasonable alternative for those who cannot be vaccinated due to true egg allergy, those who are not likely to respond to the vaccination, or those who are at significantly high risk.

Effective treatment of influenza illness with any of the currently available antiviral agents is limited by the need for almost immediate diagnosis and intervention. When these agents are initiated *within 2 days* of the onset of symptoms, they can shorten the duration of the illness. This will require education of both the public and clinicians.^{90,92} The role of the pharmacist may be in the early identification of patients who are potential candidates for antiviral therapy. Dialog with patients regarding symptoms and their duration will enable the pharmacist to make appropriate recommendations about the necessity of drug therapy and doctor visits. None of the four agents has been demonstrated to be effective in preventing serious influenza-related complications such as bacterial or viral pneumonia or exacerbation of underlying chronic conditions.

Immunoprophylaxis

13. What agents are available for chemo/immunoprophylaxis against respiratory tract infections?

INFLUENZA VIRUS

In the United States, the primary option for reducing the effect of influenza is immunoprophylaxis with inactivated

vaccine. Vaccinating persons at high risk for complications each year before seasonal increases in influenza virus circulation is the most effective means of reducing the effect of influenza. The inactivated influenza vaccines are standardized to contain the hemagglutinins of strains (usually two type A and one type B), representing the influenza viruses likely to circulate in the United States in the upcoming winter. The vaccines are made from highly purified, egg-grown viruses that have been made noninfectious. Because the vaccines are initially grown in embryonated hen eggs, the final product might contain residual egg proteins. In addition, vaccine distributed in the United States might contain the preservative thimerosal, which contains mercury.

The effectiveness of influenza vaccination depends primarily on the age and immunocompetence of the recipient and the degree of similarity between viruses in the vaccine and in circulation. When strains are similar, vaccine prevents influenza illness in 70% to 90% of healthy adults <65 years of age. Children as young as 6 months of age can develop protective levels of antibody after vaccination. Seroconversion rates have been reported to be 44% to 89% and increase with the age of the child. The effectiveness in preventing influenza-related illness in children between 1 to 15 years of age is 77% to 91%. In adults ≥ 65 years of age, the effectiveness of the vaccine has been reported to be 58%. Importantly, in this population, it has been shown to prevent secondary complications and reduce the risk for influenza-related hospitalization and death.

Influenza vaccination is recommended in the following patients:

- All persons, including school-aged children, who want to reduce the risk of becoming ill with influenza or of transmitting influenza to others
- All children aged 6–59 months (i.e., 6 months–4 years)
- All persons ≥ 50 years of age
- Children and adolescents (aged 6 months–18 years) receiving long-term aspirin therapy who therefore might be at risk for experiencing Reye syndrome after influenza virus infection
- Women who will be pregnant during the influenza season
- Adults and children who have chronic pulmonary (including asthma), cardiovascular (except hypertension), renal, hepatic, hematologic, or metabolic disorders (including diabetes mellitus)
- Adults and children who have immunosuppression (including immunosuppression caused by medications or by HIV)
- Adults and children who have any condition (e.g., cognitive dysfunction, spinal cord injuries, seizure disorders, or other neuromuscular disorders) that can compromise respiratory function or the handling of respiratory secretions or that can increase the risk for aspiration
- Residents of nursing homes and other chronic care facilities
- Health care personnel
- Healthy household contacts (including children) and caregivers of children <5 years of age and adults ≥ 50 years of age, with particular emphasis on vaccinating contacts of children aged <6 months of age
- Healthy household contacts (including children) and caregivers of persons with medical conditions that put them at higher risk for severe complications from influenza.

The following persons should not be vaccinated:

- Trivalent inactivated influenza vaccine (TIV) should not be administered to persons known to have anaphylactic hypersensitivity to eggs or to other components of the influenza vaccine. Prophylactic use of antiviral agents is an option for preventing influenza among such persons. Information regarding vaccine components is located in package inserts from each manufacturer. Persons with moderate to severe acute febrile illness usually should not be vaccinated until their symptoms have abated. However, minor illnesses with or without fever do not contraindicate use of influenza vaccine. GBS within 6 weeks following a previous dose of TIV is considered to be a precaution for use of TIV.

Live, attenuated influenza vaccine (LAIV) is not currently licensed for use in the following groups, and these persons should not be vaccinated with LAIV:

- Persons with a history of hypersensitivity, including anaphylaxis, to any of the components of LAIV or to eggs
- Persons <5 years of age or those ≥ 50 years of age
- Persons with any of the underlying medical conditions that serve as an indication for routine influenza vaccination, including asthma, reactive airways disease, or other chronic disorders of the pulmonary or cardiovascular systems
- Other underlying medical conditions, including such metabolic diseases as diabetes, renal dysfunction, and hemoglobinopathies, or known or suspected immunodeficiency diseases or immunosuppressed states
- Children or adolescents receiving aspirin or other salicylates (because of the association of Reye syndrome with wild-type influenza virus infection)
- Persons with a history of Guillain-Barré syndrome
- Pregnant women.

Timing of Vaccination

In general, health care providers should begin offering vaccination soon after vaccine becomes available and if possible by October. To avoid missed opportunities for vaccination, providers should offer vaccination during routine health care visits or during hospitalizations whenever vaccine is available. Vaccination efforts should continue throughout the season, because the duration of the influenza season varies, and influenza might not appear in certain communities until February or March. Providers should offer influenza vaccine routinely, and organized vaccination campaigns should continue throughout the influenza season, including after influenza activity has begun in the community. Vaccine administered in December or later, even if influenza activity has already begun, is likely to be beneficial in the majority of influenza seasons. The majority of adults have antibody protection against influenza virus infection within 2 weeks after vaccination.

Children 6 months to 8 years of age who have not been vaccinated previously or who were vaccinated for the first time during the previous season and received only one dose should receive two doses of vaccine. These children should receive their first dose as soon after vaccine becomes available as is feasible, so both doses can be administered before the onset of influenza activity.

The most common adverse effects of vaccination include local reactions that are typically mild, fever, malaise, myalgia, headache, allergic reaction (in particular in those with an

allergy to eggs), and thimerosal-related reactions (usually local, delayed type hypersensitivity reactions).

Chemoprophylaxis

Chemoprophylactic drugs are not a substitute for vaccination, although they are critical adjuncts in the prevention and control of influenza. Both amantadine and rimantadine are indicated for the chemoprophylaxis of influenza A infection but not influenza B. However, as mentioned previously, neither agent should be used for the prevention of influenza. Both drugs are approximately 70% to 90% effective in preventing illness from influenza A infection.⁹³⁻⁹⁵ When used as prophylaxis, these antiviral agents can prevent illness while permitting subclinical infection and development of protective antibody against circulating influenza viruses. Therefore, certain persons who take these drugs will develop protective immune responses to circulating influenza viruses. Amantadine and rimantadine do not interfere with the antibody response to the vaccine.⁹⁴ Both drugs have been studied extensively among nursing home populations as a component of influenza outbreak-control programs, which can limit the spread of influenza within chronic care institutions.^{94,96-99}

Among the neuraminidase inhibitor antivirals zanamivir and oseltamivir, only oseltamivir has been approved for prophylaxis, but community studies of healthy adults indicate that both drugs are similarly effective in preventing febrile, laboratory-confirmed influenza illness (efficacy: zanamivir, 84%; oseltamivir, 82%).¹⁰⁰⁻¹⁰² Both antiviral agents have also been reported to prevent influenza illness among persons administered chemoprophylaxis after a household member was diagnosed with influenza.¹⁰³⁻¹⁰⁵ Experience with prophylactic use of these agents in institutional settings or among patients with chronic medical conditions is limited in comparison with the adamantanes.¹⁰⁶⁻¹¹¹ One 6-week study of oseltamivir prophylaxis among nursing home residents reported a 92% reduction in influenza illness.^{106,112,113} Use of zanamivir has not been reported to impair the immunologic response to influenza vaccine.^{103,114} Data are not available regarding the efficacy of any of the four antiviral agents in preventing influenza among severely immunocompromised persons.

CONTROL OF INFLUENZA OUTBREAKS IN INSTITUTIONS

Chemoprophylactic drugs are not a substitute for vaccination, although they are critical adjuncts in preventing and controlling influenza. In community studies of healthy adults, both oseltamivir and zanamivir had similar efficacy in preventing febrile, laboratory-confirmed influenza illness (efficacy: zanamivir, 84%; oseltamivir, 82%). Both antiviral agents also have prevented influenza illness among persons administered chemoprophylaxis after a household member had influenza diagnosed (efficacy: zanamivir, 72%–82%; oseltamivir, 68%–89%). Experience with prophylactic use of these agents in institutional settings or among patients with chronic medical conditions is limited in comparison with the adamantanes, but the majority of published studies have demonstrated moderate to excellent efficacy. For example, a 6-week study of oseltamivir chemoprophylaxis among nursing home residents demonstrated a 92% reduction in influenza illness. The efficacy of antiviral agents in preventing influenza among severely immunocompromised persons is unknown. A small nonrandomized study conducted in a stem cell transplant unit suggested

that oseltamivir can prevent progression to pneumonia among influenza-infected patients.

When determining the timing and duration for administering influenza antiviral medications for chemoprophylaxis, factors related to cost, compliance, and potential adverse events should be considered. To be maximally effective as chemoprophylaxis, the drug must be taken each day for the duration of influenza activity in the community. Currently, oseltamivir is the recommended antiviral drug for chemoprophylaxis of influenza. More details regarding the use of chemoprophylaxis for influenza can be found at www.cdc.gov/flu.

Streptococcus Pneumoniae

S. pneumoniae is the most common bacterial pathogen associated with CAP. Severe infections can result from the dissemination of this organism to the bloodstream and the central nervous system. Pneumococcal infections cause an estimated 40,000 deaths annually in the United States. The currently available pneumococcal vaccine includes 23 purified capsular polysaccharide antigens from serotypes 1–5, 6B, 7F, 8, 9N, 9V, 10A, 11A, 12F, 14, 15B, 17F, 18C, 19A, 19F, 20, 22F, 23F, and 33F. After vaccination, an antigen-specific antibody response develops within 2 to 3 weeks in $\geq 80\%$ of healthy adults.¹¹⁵ The levels of antibody to most antigens remains elevated for at least 5 years in healthy adults and decreases to prevaccination levels by 10 years.^{116,117}

Pneumococcal vaccine has not been shown to be effective against nonbacteremic pneumococcal disease. Effectiveness against invasive disease is 56% to 81%.¹¹⁸⁻¹²¹ Pneumococcal polysaccharide vaccine is cost-effective and potentially cost-saving among persons ≥ 65 years of age for prevention of bacteremia.¹²²

The vaccine is both cost-effective and protective against invasive pneumococcal infection when administered to immunocompetent persons ≥ 2 years of age.¹²³ Therefore, all persons in the following categories should receive the 23-valent pneumococcal polysaccharide vaccine: patients ≥ 65 years of age, patients 2 to 64 years of age with chronic illness, patients 2 to 64 years of age with functional or anatomic asplenia, patients 2 to 64 years of age living in special environments or social settings, and immunocompromised patients. If vaccination status is unknown, patients in these categories should be administered pneumococcal vaccine. Children < 2 years of age can be administered a conjugated version of the pneumococcal vaccine. The effectiveness and indications are discussed in Chapter 96.

Pneumococcal polysaccharide vaccine generally is considered safe based on clinical experience since 1977, when the pneumococcal polysaccharide vaccine was licensed in the United States. Approximately half of patients who receive pneumococcal vaccine develop mild, local side effects (e.g., pain at the injection site, erythema, and swelling).^{124,125} These reactions usually persist < 48 hours. Moderate systemic reactions (e.g., fever and myalgias) and more severe local reactions (e.g., local induration) are rare. Intradermal administration may cause severe local reactions and is inappropriate. Severe systemic adverse effects (e.g., anaphylactic reactions) rarely have been reported after administration of pneumococcal vaccine.

Routine revaccination of immunocompetent persons previously vaccinated with 23-valent polysaccharide vaccine is not

recommended.¹²³ However, revaccination is recommended for persons ≥ 2 years of age who are at highest risk for serious pneumococcal infection and those who are likely to have a rapid decline in pneumococcal antibody levels, provided that 5 years have elapsed since receipt of the first dose of pneumococcal vaccine. Revaccination 3 years after the previous dose may be considered for children at highest risk for severe pneumococcal infection (≤ 10 years of age at the time of revaccination). These children include those with functional or anatomic asplenia (e.g., sickle cell disease or splenectomy) and those with conditions associated with rapid antibody decline after initial vaccination (e.g., nephrotic syndrome, renal failure, or renal transplantation). Revaccination is contraindicated for persons who had a severe reaction (e.g., anaphylactic reaction or localized arthus-type reaction) to the initial dose.

Chemoprophylaxis

Oral penicillin V (125 mg, twice daily), when administered to infants and young children with sickle cell disease, has reduced the incidence of pneumococcal bacteremia by 84% compared with those receiving placebo.¹²⁶ Therefore, daily penicillin prophylaxis for children with sickle cell hemoglobinopathy is recommended before 4 months of age. Consensus on the age at which prophylaxis should be discontinued has not been achieved. However, children with sickle cell anemia who had received prophylactic penicillin for prolonged intervals (but without a prior severe pneumococcal infection or splenectomy) have discontinued penicillin therapy at 5 years of age with no increase in the incidence of pneumococcal bacteremia or meningitis.¹⁰⁴

Oral penicillin G or V is recommended for prevention of pneumococcal disease in children with functional or anatomic asplenia.¹⁰⁵ Antimicrobial prophylaxis against pneumococcal infection may be particularly useful for asplenic children not likely to respond to the polysaccharide vaccine (e.g., those < 2 years of age or those receiving intensive chemotherapy or cytoreduction therapy). However, the impact of this practice on the emergence of DRSP is not known.

The effectiveness of all vaccines depends on administration in those patients at highest risk. Data released from the National Health Interview Survey has shown that for influenza vaccine, persons 50 to 64 years of age were vaccinated 34% of the time and those 65 years and older were vaccinated 65.6% of the time in 2002. For pneumococcal vaccine, those ≥ 65 years of age were vaccinated 55.7% of the time in 2002.¹²⁷ The role of pharmacists in identifying those patients who should be offered vaccination and potentially administering these vaccines may improve in increased rates of vaccination.

Aspiration Pneumonia

Predisposing Factors

14. R.G., a 38-year-old man, was brought to the emergency department (ED) after he was found unconscious, lying on his right side, near a pool of vomitus in a local municipal park. R.G. has a long history of binge drinking and has been admitted to the ED frequently for problems related to his alcoholism. On admission, R.G.'s vital signs were BP, 100/60 mmHg; pulse, 110 beats/minute; respirations, 32 breaths/minute; and temperature, 38.0°C. A strong odor of alcohol and vomitus was noted. R.G.'s

overall mental status is depressed; he has intermittent periods of disorientation and uncoordinated motor movements.

Crackling rales were heard in the middle and lower right lung fields; the left fields were clear. An ABG was drawn on room air, with the following results: pH, 7.46 (normal, 7.38–7.45); PO₂, 52 mmHg (normal, 68–100 mmHg); PCO₂, 35 mmHg (normal, 38–45 mmHg); and HCO₃, 24 mEq/L (normal, 22–26 mEq/L). Laboratory data include the following: WBC count, 12,000 cells/mm³ (normal, 5–10,000 cells/mm³); differential PMNs, 68% (normal, 45%–79%); bands, 8% (normal, 0%–5%); and lymphocytes, 24% (normal, 16%–47%). During a period of consciousness, the physician obtained a sputum specimen from R.G. for Gram stain and culture. A chest radiograph revealed density changes consistent with interstitial infiltrates in the dependent segments of the middle and lower right lung. A tentative diagnosis of aspiration pneumonitis is made. What factors predispose R.G. to aspiration pneumonitis? How can the aspirated material cause pneumonitis?

[SI units: PO₂, 6.93 kPa; PCO₂, 4.67 kPa; WBC count, 12 10⁸/L, with PMNs, 0.68; bands, 0.08; and lymphocytes, 0.24]

Several factors in R.G.'s history make him susceptible to aspiration. Alcohol intoxication has depressed his mental status as well as his cough and gag reflex, which may have led to aspiration of his vomitus. Table 60-14 lists conditions that predispose individuals to aspiration. Those conditions that cause or contribute to an altered state of consciousness are particularly important. The specific effect of the aspirated material on the lungs depends on the quantity and quality of the material aspirated. The latter can be categorized into three types: direct pulmonary toxin, particulate matter, and infected inoculum.^{61,128}

Several toxic materials cause pneumonitis, the most common of which is gastric acid. When gastric acid enters the lungs, the sequence of events has been likened to a chemical burn. The aspirated secretions are neutralized rapidly over the first few minutes, and this is accompanied by a shift of fluid into the involved area of the lung. An estimated 96% of patients will demonstrate signs of respiratory compromise within 1 hour of aspiration and 100% within 2 hours. The two immediate

consequences of aspiration of gastric acid are rapid, profound hypoxia and shock secondary to massive fluid shifts into lung tissue. In addition, atelectasis, hemorrhage, and pulmonary edema may occur.⁶¹ Approximately 45% of healthy adults aspirate oropharyngeal secretions during deep sleep, and 70% of patients with depressed consciousness aspirate pharyngeal secretions. Gastric juice has a pH ≤ 2.5 and contains few to no bacteria.^{129,130} However, after the initial insult, some patients will develop a secondary bacterial pneumonia.¹³¹ The infection is due primarily to aspiration of oropharyngeal contents in a setting of diminished host defenses caused by the chemical pneumonitis.¹³² Other toxic materials causing aspiration pneumonitis include hydrocarbons, mineral oil, bile, alcohol, and animal fats.¹²⁸

A second category of aspirated material is fluid containing various amounts of bacteria. Oropharyngeal secretions are the most frequent source of this material. Bacterial pneumonia results when the normal host lung defenses have been damaged or altered and when the bacteria inoculum exceeds the body's ability to contain and eliminate it. Infection due to aspirated bacteria may result in a pneumonia with little or no tissue destruction, necrotizing pneumonia, lung abscess, or empyema.

A third category of aspirated material consists of particulate matter. When relatively large particles are aspirated, sudden aphonia, cyanosis, and respiratory distress occur; the patient can progress rapidly toward death. Smaller particles reaching the lower airways cause local irritation with bronchospasm and infection if they are not removed. Many of these cases occur in young children following the ingestion of coins, peanuts, teeth, vegetables, or other small particles. Rapid removal of these particles usually results in the rapid reversal of symptoms without significant sequelae.

Clinical Course

15. What is the expected clinical course of aspiration pneumonia in R.G.?

The clinical course of a patient such as R.G. who has aspirated gastric contents and/or oropharyngeal secretions is variable; three courses have been identified. Shock will occur in 20% to 30% of patients with documented large volume aspiration^{129,133}; respiratory function continues to deteriorate in many of these patients, and approximately 25% die. Mortality rates may be higher in severely ill patients.¹³⁴ Early clinical signs and symptoms of gastric aspiration include fever, tachypnea, rales, cough, cyanosis, wheezing, apnea, and shock. A second group of patients will resolve the pneumonitis completely over a few days to weeks without complication. A third group will develop bacterial pneumonia following an initial period of improvement.

Treatment

16. How should R.G. be treated?

R.G.'s initial treatment should primarily consist of supportive measures. Attention should be directed toward respiratory support and correction of his fluid and electrolyte status. In addition, any particulate matter present in the airways should be removed.

Pulmonary edema secondary to massive fluid shifts into the lung can contribute to a decrease in the intravascular volume.

If this occurs, aggressive supportive therapy with ventilation, oxygen supplementation, and fluid replacement is indicated.

The use of corticosteroids to reduce inflammation in the setting of aspiration pneumonia is not warranted. There are no well-designed studies, and data supporting their use are anecdotal. In one published report, the use of steroids in the treatment of aspiration in humans was suggested to be harmful.¹³⁵ Although no difference was found in mortality, the incidence of Gram-negative pneumonia was more frequent in those patients receiving steroids. Because bacteria play little or no role in the initial events following aspiration, antibiotic therapy should be withheld until bacterial involvement is established.

Prophylactic antibiotics are not beneficial in this setting and may contribute to a change in the oropharyngeal flora that may, in turn, predispose the patient to pneumonia secondary to resistant bacterial organisms. On the other hand, if the patient has been hospitalized for >3 days at the time of aspiration, empiric antimicrobial therapy may be justified, particularly if the patient is elderly, debilitated, or believed to be deteriorating clinically.

Clinical Presentation

17. R.G.'s pulmonary symptoms improved during the next 3 days, but now he has a temperature of 38.5°C with an increase in sputum production. How should he be assessed?

Patients like R.G. with mild aspiration pneumonia usually resolve their respiratory difficulties within a few days following the insult. If an infection occurs, a short period of clinical improvement often takes place before signs and symptoms of bacterial pneumonia present. Criteria used to identify bacterial pneumonia following aspiration include (a) a new fever or a significant rise in temperature from the patient's baseline, (b) a new or extending pulmonary infiltrate after the initial 36- to 48-hour period, (c) an increase in WBCs or a change in the differential WBC count, (d) a change in sputum characteristics with purulence, and (e) the presence of pathogenic bacteria in a transtracheal aspirate.

Microbiology

18. What bacterial organisms are likely to be responsible for R.G.'s infectious pneumonia?

In the setting of aspiration pneumonitis, the bacterial pathogen is difficult to predict because large numbers of potential bacterial pathogens are present in sputum.

Most cases of aspiration pneumonia are caused by a wide spectrum of Gram-positive and Gram-negative anaerobic and aerobic bacteria representing the complex microbial flora of the oropharynx and upper GI tract. When culture technique is utilized, in approximately 50% of cases, aerobic bacteria have been recovered, and in 60% to 90% of cases, anaerobes have been recovered.^{57,135} Tables 60-15 and 60-16 list the most common bacteria recovered from patients with aspiration pneumonia. In particular, anaerobes are commonly isolated in patients with a history of alcohol or illicit drug use or other risk factors that impair the gag reflex. In individuals without these risk factors, the most likely pathogens in community-acquired aspiration pneumonia are including *S. pneumoniae*, *S. aureus*, *H. influenzae*, and Enterobacteriaceae. In contrast, a larger percentage of hospital-acquired

aspiration pneumonias are caused by aerobic bacteria; they also are usually polymicrobial in nature. The aerobic bacteria recovered from patients with hospital-acquired aspiration pneumonia include *S. aureus*, various Enterobacteriaceae, and *Pseudomonas aeruginosa*. Understanding the differences in the bacterial etiology in these two settings facilitates the selection of antimicrobial therapy. The bacterial etiology of aspiration pneumonia in children is similar to that of adults.^{72,137}

When a patient develops aspiration pneumonia in the community setting, mouth anaerobes and Gram-positive aerobic bacteria such as group A streptococcus and *S. pneumoniae* are the most common pathogens. However, some patients with community-acquired aspiration pneumonia are more likely to be infected with *S. aureus* or Gram-negative pathogens because of oropharyngeal colonization. These individuals include alcoholics (as in the case of R.G.), elderly patients housed in long-term care nursing facilities,⁶³ patients receiving enteral feedings,¹³⁸ and patients treated chronically with antacids, proton pump inhibitors, and/or H₂-receptor antagonists. In the latter individuals, Gram-negative flora are recovered from the

stomach because they are better able to survive in a more alkaline pH.^{129,139,140} In addition, the oropharynx of these individuals frequently is colonized with the same bacteria found in the gastric flora.¹⁴¹ Up to 60% of patients colonized with a given Gram-negative pathogen ultimately develop pneumonia due to the same organism. Information suggests that the use of sucralfate reduces bacterial colonization of the stomach of critically ill patients while maintaining adequate stress ulcer prophylaxis and reduced frequency of nosocomial pneumonia.^{142,143}

Treatment**ANTIMICROBIAL THERAPY****19. How should antibiotics be used in aspiration pneumonia? How should R.G. be treated?**

Antibiotic therapy should be selected on the basis of several criteria: the clinical setting in which the aspiration occurred, knowledge of the patient's medical history, the Gram stain of a reliably obtained sputum, and aerobic and anaerobic culture results of lower respiratory tract secretions. Table 60-17 lists common antibiotics and dosages used to treat aspiration pneumonia.

As noted previously, anaerobes are often the sole or dominant bacteria involved in patients with community-acquired aspiration pneumonia. Preferred therapy for this type of pneumonia is clindamycin. Metronidazole has also been used to treat anaerobic pleuropulmonary infections,^{144,145} but the results have been mixed due, in part, to the severity of infections treated (e.g., lung abscess). Metronidazole effectively inhibits Gram-negative obligate anaerobic bacteria, such as *Bacteroides fragilis* and other *Prevotella* sp., but fails to effectively inhibit facultative anaerobic bacteria, such as *Peptococcus* sp. and *Peptostreptococcus* sp.¹⁴⁶ Other agents that can be used intravenously (IV) include a β -lactamase-inhibitor combination or the combination of metronidazole plus penicillin.

Treatment of aspiration pneumonia in the elderly, in patients from extended-care facilities, in patients with extensive medical histories, and in alcoholics (as in the case of R.G.) should include agents with activity against Gram-negative rods. Appropriate therapy choices might be a β -lactamase-inhibitor combination or a fluoroquinolone plus clindamycin.

Due to colonization with more resistant organisms, aspiration pneumonia in the hospital setting should be treated with a regimen active against both Gram-negative pathogens and anaerobes. *P. aeruginosa* should be considered as a possible pathogen in high-risk units (e.g., ICU) or in those patients at high risk (i.e., neutropenic patients or moderate to severe thermal injury patients). Effective regimens include a β -lactamase-inhibitor combination (piperacillin/tazobactam [Zosyn] and ticarcillin/clavulanate [Timentin]), ciprofloxacin, aztreonam or an antipseudomonal cephalosporin plus clindamycin or metronidazole, or a carbapenem. An empiric regimen should be modified when the results of the sputum culture are known. The addition of vancomycin to cover methicillin-resistant *Staphylococcus aureus* (MRSA) should be guided by local epidemiologic data, sputum Gram stain, and culture and sensitivity results. In patients with effusion or an empyema, drainage of the collection will likely be required to achieve a clinical cure.

Parenteral antibiotics should be continued until the patient has responded clinically to the therapy as outlined previously

Table 60-16 Etiology of Aspiration-Associated Lung Infections

| | Number of Patients | Anaerobes Only | Aerobes Only | Mixed |
|--------------------|--------------------|----------------|--------------|----------|
| Community acquired | 54 | 32 (59%) | 5 (10%) | 17 (31%) |
| Hospital acquired | 47 | 8 (18%) | 17 (36%) | 22 (47%) |

(Table 60-11). While most patients require 7 days of therapy, patients with lung abscesses, particularly with inadequate drainage, may require weeks of therapy. Oral combination options in treating aspiration pneumonia include amoxicillin/clavulanate or clindamycin or metronidazole plus a fluoroquinolone.

Hospital-Acquired Pneumonia, Health Care-Associated Pneumonia, and Ventilator-Associated Pneumonia

20. A.A., a 68-year-old man, is admitted to the hospital from an extended-care nursing facility because of an acute change in mental status, fever, dyspnea with respiratory difficulty, cough, and sputum production. His medical history is notable for insulin-dependent diabetes mellitus since the age of 10 years, a right-sided cerebrovascular accident that left him with residual weak-

ness, and a recent *Escherichia coli* urinary tract infection that was treated with oral TMP-SMX DS for 10 days. Because of poor nutrition, A.A. has been receiving nutritional supplements through a flexible nasogastric feeding tube for the past 2 months.

Physical examination reveals a restless, elderly man with the following vital signs: BP, 147/87 mmHg; pulse, 110 beats/minute; respirations, 28 breaths/minute; and temperature, 39°C. His head is without obvious trauma, and his neck is supple. Crackling rales with diminished breath sounds are noted in the middle and upper right lung fields. The chest radiograph shows a pulmonary infiltrate involving the right middle and upper lobes of the right lung with lobar consolidation. Because A.A. is relatively uncooperative and cannot give a good sputum specimen, a specimen of lower respiratory tract secretions was collected by transtracheal aspiration. This specimen was sent to the laboratory for Gram stain and culture.

The Gram stain showed Gram-negative rods with 4% neutrophils. ABGs included a P_{aO_2} of 34 mmHg on room air (normal, 80–100 mmHg); his current P_{aO_2} is 52 mmHg and 80 to 100 mmHg with 4 L/minute of supplemental oxygen. Other laboratory values include the following: Hct, 39% (normal, 37%–47%); WBC count, 16,000 cells/mm³ (normal, 5–10,000 cells/mm³); PMNs, 88% (normal, 45%–79%); bands, 10% (normal, 0%–5%); lymphocytes, 2% (normal, 16%–47%); BUN, 12 mg/dL (normal, 7–20 mg/dL); and creatinine, 1.0 mg/dL (normal, 0.8–1.2 mg/dL).

21. Medications on admission include oral famotidine 20 mg every day (QD). A tentative diagnosis of a hospital-acquired Gram-negative pneumonia is made. A.A. is intubated and placed on a ventilator. In addition, intravenous fluids are started to maintain a urine output of 50 mL/hour. What are the risk factors for pneumonia in A.A.?

[SI units: P_{aO_2} , 4.53 and 6.93 kPa, respectively; Hct, 0.39; WBC count, 16–10⁸/L; PMNs, 0.88; bands, 0.1; lymphocytes, 0.02; BUN, 4.28 mmol/L of urea (normal, 2.50–7.14); creatinine 88.4 μ mol/L (normal, 70.72–106.08)]

Background

Hospital-acquired pneumonia (HAP), ventilator-associated pneumonia (VAP), and health care-associated pneumonia (HCAP) are important causes of morbidity and mortality despite advances in antimicrobial therapy, better supportive care, and the use of a wide range of preventive measures. HAP is defined as pneumonia that occurs ≥ 48 hours after admission that was not incubating at the time of admission. VAP refers to pneumonia that arises 48 to 72 hours after endotracheal intubation. HCAP includes any patient who has been hospitalized in an acute care hospital for 2 or more days within 90 days of infection; resided in a nursing home or long-term care facility; received recent intravenous antibiotic therapy, chemotherapy, or wound care within the past 30 days of the current infection; or attended a hospital or hemodialysis clinic.¹⁴⁷

HAP is the second most common nosocomial infection in the United States. It has been reported to extend hospital stays on average by 7 to 9 days with an associated excess cost $> \$40,000$ per patient. HAP accounts for 25% of all ICU infections and $> 50\%$ of the antibiotics prescribed. VAP occurs in 9% to 27% of intubated patients, with the highest risk during the first 5 to 10 days of ventilation. The attributable mortality of HAP has been estimated to be 33% to 50%, with the highest mortality rates associated with infection caused by *P. aeruginosa* and *Acinetobacter* sp. and the use of ineffective anti-infective therapy.

Risk Factors

The time of onset of pneumonia is an important epidemiologic variable and risk factor for specific pathogens and outcomes in patients with HAP, VAP, and HCAP. Early-onset HAP and VAP are defined as occurring within the first 4 days of hospitalization, usually carry a better prognosis, and are more likely caused by antibiotic-sensitive bacteria. Late-onset HAP and VAP (those cases occurring ≥ 5 days of hospitalization) are more likely to be caused by multidrug-resistant (MDR) pathogens and are associated with increased morbidity and mortality.

Several risk factors for HAP have been identified, including intubation and mechanical ventilation, aspiration, a patient's

body position, the administration of enteral feeding, prior use of antibacterial agents, bleeding prophylaxis (i.e., histamine type 2 antagonists and proton pump inhibitors), and poor glucose control. Each of the risk factors is potentially modifiable and should be considered as part of the broad management strategy for HAP.

Although A.A. is just now being admitted to the hospital, his diagnosis should be considered HCAP because he resides in a nursing home. Patients residing in nursing homes have an increased incidence of nosocomial pneumonias and oropharyngeal colonization with Gram-negative bacteria. In addition, poor infection control practices contribute to the cross-contamination of patients with pathogenic bacteria.¹⁴⁸ Nursing homes generally have flora similar to a hospital, as reflected by his Gram stain, which is consistent with a Gram-negative pneumonia. Other risk factors associated with developing HAP are listed in Table 60-18. The most significant risk factor is intubation, which increases the risk by 7- to 21-fold. In addition, other risk factors include the use of famotidine, recent antibacterial exposure, and the use of enteral feeding.

An important contributing factor in the cause of a pneumonia is colonization of the oropharynx. Several factors may contribute to the colonization of A.A.'s oropharynx with Gram-negative bacteria.¹⁴⁹ He is disabled because of a cerebrovascular accident, which has left him with right-sided weakness; this chronic condition also may predispose him to changes in oropharyngeal flora. A.A. is prone to aspiration of these secretions because the residual effects of the stroke and nasogastric tube used for nutritional support have decreased his airway protection. Finally, an altered immune response in diabetics and the elderly can further contribute to the establishment of a respiratory infection in A.A. (Table 60-19). The use of drugs that inhibit the production of gastric acid, such as famotidine, increases the possibility of oropharyngeal colonization.^{140,141} Finally, the use of broad-spectrum antibiotics may inhibit the

growth of many normal flora, which allows Gram-negative bacteria and other multiple-resistant bacteria to colonize the oropharynx.^{150–152}

Treatment

22. How does the bacteriology of HAP/HCAP/VAP differ from CAP?

The major difference in the bacteriology between CAP and HAP/HCAP/VAP is a shift to Gram-negative pathogens, MDR pathogens, and MRSA in HAP/HCAP/VAP. Gram-negative bacilli commonly colonize oropharyngeal secretions of patients with moderate to severe acute and chronic illnesses without exposure to broad-spectrum antibiotics.^{60,61} Patients admitted to the hospital with acute illnesses are rapidly colonized with Gram-negative organisms. Approximately 20% are colonized on the first hospital day, and this number increases with the duration of hospitalization and severity of illness.⁵⁷ Approximately 35% to 45% of hospitalized patients⁵⁷ and up to 100% of critically ill patients⁵⁹ will be colonized within 3 to 5 days of admission.

Table 60-20 lists the most common bacteria associated with HAP/HCAP/VAP based on the presence of risk factors for MDR pathogens. Virtually all reports indicate that Gram-negative bacteria account for 50% to 70% of all cases.^{147,153–157} The most common bacterium within this category is *P. aeruginosa*. In patients who are ventilator dependent, *Acinetobacter* sp. often is reported as the most common Gram-negative pathogen. *S. aureus*, which accounts for 10% to 20% of all cases of HAP, is the most commonly identified Gram-positive organism. Other organisms with special risk factors include Legionella, which is associated with high-dose corticosteroid use and outbreaks secondary to water supplies and cooling systems,^{71,158} and Aspergillus, which is associated with neutropenia or organ transplantation.¹⁵⁹ Risk factors for MDR pathogens are listed in Table 60-21.

SELECTING ANTIBIOTIC THERAPY

23. How should antibiotic therapy be started in A.A.?

The IDSA/ATS have published guidelines for the treatment of HAP.¹⁴⁷ The four major principles underlying the manage-

Table 60-21 Risk Factors for Multi-Drug Resistant Pathogens

- Antimicrobial therapy in preceding 90 days
- Current hospitalization of 5 days or more
- High frequency of antibiotic resistance in the community or in the specific hospital unit
- Presence of risk factors for HCAP:
 - Hospitalization for 2 days or more in the preceding 90 days
 - Residence in a nursing home or extended care facility
 - Home infusion therapy (including antibiotics)
 - Chronic dialysis within 30 days
 - Home wound care
 - Family member with multidrug-resistant pathogen
- Immunosuppressive disease and/or therapy

HCAP, health care-associated pneumonia.

ment of HAP, HCAP, and VAP include (a) avoid untreated or inadequately treated HAP, VAP, or HCAP, as failure to initiate prompt, appropriate therapy is associated with increased mortality; the variability of bacteriology from one institution to another, as well as within specific sites in a hospital, can be significant; (b) avoid the overuse of antibiotics by focusing on accurate diagnosis; (c) tailor therapy based on lower respiratory tract cultures and shorten the duration of therapy; and (d) apply prevention strategies directed at modifiable risk factors. The likelihood of an infection with a potential pathogen is based largely on the time to onset of HAP (early, <5 days into hospitalization, vs. late, >5 days), severity of the condition, and underlying risk factors. These guidelines are outlined in Figure 60-4 and Tables 60-22 through 60-24.¹⁴⁷ In general, patients with early-onset disease who are not severely ill and have no risk factors can be treated with a single agent, including nonantipseudomonal third-generation cephalosporins or carbapenems, β -lactam-inhibitor combinations, or an antipseudomonal fluoroquinolone. Empiric therapy in those with late-onset or severe disease should include a combination of antibiotics active against *Pseudomonas*. This regimen usually includes an antipseudomonal β -lactam, such as cefepime,

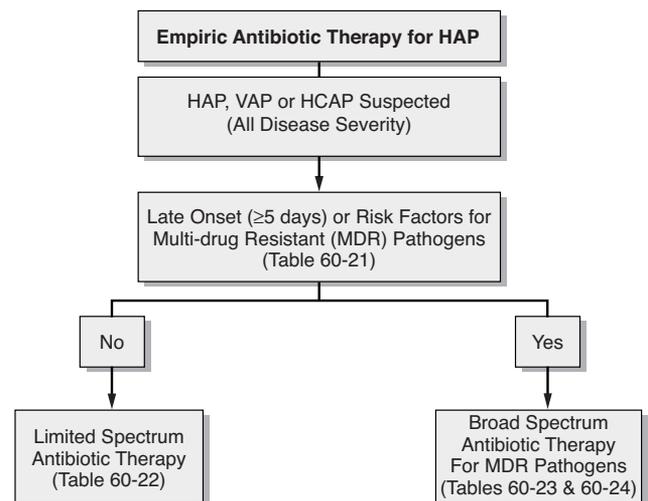

FIGURE 60-4 Approach to empiric antibiotic therapy in patients with healthcare-acquired pneumonia.

Table 60-22 Initial Empiric Antibiotic Therapy for Hospital-Acquired Pneumonia

| Potential Pathogen | Recommended Antibiotic |
|---|---|
| <i>Streptococcus pneumoniae</i> ^a | Ceftriaxone |
| <i>Haemophilus influenzae</i> | or |
| Methicillin-sensitive <i>Staphylococcus aureus</i> | |
| Antibiotic-sensitive enteric Gram-negative bacilli | Levofloxacin, moxifloxacin, or ciprofloxacin |
| <i>Escherichia coli</i> | or |
| <i>Klebsiella pneumoniae</i> | |
| <i>Enterobacter</i> sp. | Ampicillin/sulbactam |
| <i>Proteus</i> sp. | or |
| <i>Serratia marcescens</i> | Ertapenem |

^aThe frequency of penicillin-resistant *S. pneumoniae* and multidrug-resistant *S. pneumoniae* is increasing; levofloxacin or moxifloxacin are preferred to ciprofloxacin, and the role of other new quinolones, such as gatifloxacin, has not been established.

Table 60-24 Initial Intravenous, Adult Doses of Antibiotics for Empiric Therapy of Hospital-Acquired Pneumonia, Including Ventilator-Associated Pneumonia, and Health Care-Associated Pneumonia, in Patients With Late-Onset Disease or Risk Factors for Multidrug-Resistant Pathogens

| Antibiotic | Dosage ^a |
|---|-------------------------------|
| Antipseudomonal cephalosporin | |
| Cefepime | 1–2 g Q 8–12 hr |
| Ceftazidime | 2 g Q 8 hr |
| Carbapenems | |
| Imipenem | 500 mg Q 6 hr or 1 g Q 8 hr |
| Meropenem | 1 g Q 8 hr |
| β -Lactam/ β -Lactamase inhibitor | |
| Piperacillin-tazobactam | 4.5 g Q 6 hr |
| Aminoglycosides | |
| Gentamicin | 7 mg/kg per day [†] |
| Tobramycin | 7 mg/kg per day [†] |
| Amikacin | 20 mg/kg per day [‡] |
| Antipseudomonal quinolones | |
| Levofloxacin | 750 mg daily |
| Ciprofloxacin | 400 mg Q 8 hr |
| Vancomycin | 15 mg/kg Q 12 hr [‡] |
| Linezolid | 600 mg Q 12 hr |

^aDosages are based on normal renal and hepatic function.

[†]Trough levels for gentamicin and tobramycin should be <1 mcg/mL; for amikacin, they should be <4–5 mcg/mL.

[‡]Trough levels for vancomycin should be 15–20 mcg/mL.

Table 60-23 Initial Empiric Therapy for Hospital-Acquired Pneumonia, Ventilator-Associated Pneumonia, and Health Care-Associated Pneumonia in Patients With Late-Onset Disease or Risk Factors for Multidrug-Resistant Pathogens and All Disease Severity

| Potential Pathogens | Combination Antibiotic Therapy ^a |
|--|--|
| Pathogens listed in Table 60-20 and MDR pathogens | Antipseudomonal cephalosporin (cefepime, ceftazidime) |
| <i>Pseudomonas aeruginosa</i> | or |
| <i>Klebsiella pneumoniae</i> (ESBL ⁺) ^b | Antipseudomonal carbapenem (imipenem or meropenem) |
| <i>Acinetobacter</i> sp. ^b | or |
| | β -Lactam/ β -Lactamase inhibitor (piperacillin-tazobactam) |
| | plus |
| | Antipseudomonal fluoroquinolone ^b (ciprofloxacin or levofloxacin) |
| | or |
| | Aminoglycoside (amikacin, gentamicin, or tobramycin) |
| | plus |
| MRSA | Linezolid or vancomycin ^c |
| <i>Legionella pneumophila</i> ^c | |

^aRefer to Table 60-24 for adequate initial dosing of antibiotics. Initial antibiotic therapy should be adjusted or streamlined on the basis of microbiologic data and clinical response to therapy.

^bIf an ESBL⁺ strain, such as *K. pneumoniae*, or an *Acinetobacter* sp. is suspected, a carbapenem is a reliable choice. If *L. pneumophila* is suspected, the combination antibiotic regimen including a macolide (e.g., azithromycin) or a fluoroquinolone (e.g., ciprofloxacin or levofloxacin) should be used rather than an aminoglycoside.

^cIf MRSA risk factors are present, or there is a high incidence locally.

ESBL, Extended Spectrum beta-lactamase; MDR, multidrug resistant; MRSA, methicillin-resistant *Staphylococcus aureus*.

imipenem, or piperacillin-tazobactam, plus either an aminoglycoside or ciprofloxacin/levofloxacin. The addition of vancomycin or linezolid should be considered if the Gram stain demonstrates Gram-positive cocci in clusters.¹⁴⁷

Because delays in the administration of appropriate therapy have been associated with increased hospital mortality from HAP, the prompt administration of empiric therapy is essential. Importantly, changing therapy once culture results are available may not reduce the excess risk of hospital mortality associated with inappropriate initial therapy. To this end, local bacteriologic patterns and in vitro susceptibility results should be made available and updated as frequently as possible. In addition to the selection of an appropriate agent, the selection of adequate dosing regimens is designed to optimize the pharmacodynamic properties of the antibacterial agent(s). The choice of empiric antibiotic therapy should be guided by the results of the Gram stain and an analysis of the patient's risk factors for oropharyngeal colonization or altered pulmonary host factors. When these risk factors are present, as in the case of A.A., coverage for infection due to Gram-negative bacteria is indicated.

Resolution of HAP can be defined both clinically and microbiologically. Clinical improvement usually begins to become apparent after the first 48 to 72 hours of therapy. During this time, the selected antibacterial regimen should not be changed unless progressive deterioration takes place or microbiologic studies confirm the pathogen. Serial quantitative cultures of the lower respiratory tract can also be used to identify microbiologic nonresponse and to modify antimicrobial therapy.

If culture results are negative or inconclusive (because of known specimen contamination with mouth flora), the patient's

response to the initial antibiotic therapy should be used to evaluate modification of the antibiotic regimen. If the patient responds to the initial therapy, those antibiotics should be continued with consideration to narrow coverage to the most likely causative pathogens. If the patient is not responding to the initial antibiotic therapy, one should consider whether (a) the pathogen is not covered in the initial choice of antibiotic therapy, (b) the dose of antibiotic is insufficient, and (c) any other factors are responsible for the failure to respond to therapy. Such factors include poor pulmonary clearance of necrotic tissue and cellular debris, lung abscesses, and severely altered host defenses with a rapidly fatal underlying disease.

Of note, if one of the following organisms is isolated (*Serratia*, *Pseudomonas*, indole positive *Proteus*, *Citrobacter*, or *Enterobacter* sp.), in vitro reports indicating susceptibility should be questioned, as these organisms often possess an inducible β -lactamase gene (also referred to as a type I β -lactamase enzyme).¹⁶⁰ In vitro testing may demonstrate susceptibility to third-generation cephalosporins and extended-spectrum penicillins but may not translate to efficacy in the clinical setting. As a possible scenario, after initiation with one of these agents, the patient may initially respond; however, after approximately 1 week, the patient's condition will begin to worsen. Because treatment with the β -lactam agent induces the expression of the type I enzyme, a subsequent specimen sent after approximately 1 week is now likely to demonstrate resistance to the third-generation cephalosporins and extended-spectrum penicillins.¹⁶⁰ Although cefepime is more likely to be active against these isolates, a large inoculum of organisms (e.g., that present in pneumonia) can result in β -lactamase degradation of the cephalosporin.¹⁶¹ Considering that this phenomenon will not be identified by using usual in vitro testing, cefepime should be used cautiously in these patients.⁸⁷ The preferred therapy in these patients includes TMP-SMX, a fluoroquinolone, or a carbapenem.¹⁶⁰ *Acinetobacter* sp. have become resistant to many commonly used antibacterial agents. Treatment of this sometimes multiply-resistant pathogen requires the use of very high doses of ampicillin-sulbactam (up to 24 g/day) or colistin.^{162,163}

In summary, A.A. could be started empirically with cefepime or piperacillin-tazobactam, with the addition of gentamicin or ciprofloxacin. When culture results are known, the antibiotic regimen can be modified and individualized for the patient. Therapy is generally continued for 2 weeks, but in some patients, therapy can be shortened to as little as 7 days. A.A.'s clinical response should be monitored to determine whether the selected antibiotics are effective in treating this infection. These parameters include a decrease in temperature and heart rate as well as a decrease in the WBC count with resolution of the left shift. Mental status and sensorium are good monitoring parameters in older individuals.

BROAD-SPECTRUM β -LACTAMS

24. Can the broad-spectrum β -lactam antibiotics be used as monotherapy in the treatment of A.A.'s pneumonia?

In the past, the aminoglycosides were considered the antibiotics of choice in the treatment of nosocomial Gram-negative infections. However, the availability of a large number of relatively nontoxic antibiotics, including β -lactam antibiotics or high-dose ciprofloxacin/levofloxacin has diminished the role

of aminoglycosides as the agents of choice for these infections. However, when choosing empiric therapy for a suspected or documented pneumonia caused by *Pseudomonas*, combination therapy is preferred.¹⁴⁷ The potential advantages of combination include an improved likelihood of covering MDR pathogens initially, improved bactericidal activity because of synergy between the agents, and suppression of resistance that may develop to one of the antibiotics.¹⁶⁴

AMINOGLYCOSIDES

25. What pharmacokinetic and pharmacodynamic characteristics must be considered in the dosing of aminoglycosides in patients with HAP?

Individualization of aminoglycoside dosing is required in patients receiving these drugs.¹⁶⁵⁻¹⁶⁷ The efficacy and toxicity of aminoglycosides correlates with aminoglycoside plasma concentrations and therapeutic outcome in patients with Gram-negative pneumonia.¹⁶⁸ In patients receiving multiple daily doses of gentamicin or tobramycin, achieving a 1-hour postinfusion peak plasma concentration >7 mcg/mL, a successful outcome occurs more often than in those with lower plasma concentrations.

The aminoglycosides are concentration-dependent killing antibiotics. Their rate and extent of killing organisms is maximized by increasing the peak serum concentration relative to the MIC of the pathogen. In addition to maximizing bactericidal activity, in vitro evidence has demonstrated that this concentration goal also minimizes the development of resistance. The use of once-daily dosing strategies to minimize nephrotoxicity of the aminoglycosides has been studied extensively. Single doses of gentamicin and tobramycin (5–7 mg/kg/day) and of amikacin (15–20 mg/kg/day) have been reported to be as effective as standard dosing of these agents in controlled clinical trials. However, none of the trials has enrolled a sufficient number of patients required to demonstrate a difference. There are several advantages of single-dose aminoglycoside therapy: (a) it is no more nephrotoxic than traditional dosing, (b) clinicians are ensured that a therapeutic peak serum level will be achieved with the first dose, (c) it is the only safe and effective way to achieve serum peak levels of 10 to 20 times the MIC for difficult-to-treat organisms such as *P. aeruginosa*, and (d) it is a more efficient dosing regimen (less doses and administration times per day; fewer serum level measurements are required).

Despite the use of individualized aminoglycoside dosing, morbidity and mortality rates due to Gram-negative pneumonia remain high. This is because the success of antibiotic therapy depends on the ability of the antibiotic to reach the site of infection and remain biologically active.¹⁶⁹ Concentrations of the aminoglycosides in bronchial secretions range from 1 to 5 mcg/mL (~30%–40% of serum concentrations) 2 to 4 hours after parenteral administration.¹⁷⁰ These concentrations may be insufficient to inhibit the growth of many Gram-negative organisms, especially *Pseudomonas*.

The bioactivity of the aminoglycosides is influenced by the local tissue pH. In contrast to the penicillins and cephalosporins, whose activities are little affected over a pH range of 6.0 to 8.0, a 2- to 16-fold increase in the aminoglycoside MIC of most Gram-negative bacteria occurs when the pH is decreased from 7.4 to 6.8.¹⁷¹ The pH of endobronchial

fluid in patients with normal lung physiology and pneumonia averages 6.6.

Lastly, aminoglycosides bind to purulent exudates and cellular debris, inactivating these agents.^{172–174} In summary, the aminoglycosides penetrate poorly into bronchial secretions and are less active at the site of infection because of local pH effects and binding to cellular debris. These properties may result in the need for increased dosages, placing patients at increased risk for ototoxicity and nephrotoxicity.

BRONCHIAL PENETRATION OF ANTIBIOTICS

26. What factors govern the penetration of antibiotics into bronchial secretions? Is penetration into bronchial secretions critical to the effectiveness of an antibiotic used in the treatment of pneumonia?

An important factor to consider in the selection of an antibiotic used to treat pneumonia is its ability to reach the site of infection (i.e., the lung tissue or bronchopulmonary secretions). Antibiotic concentrations in bronchial secretions do not necessarily reflect the lung tissue concentrations but do represent the ability of the antibiotic to cross the bronchoalveolar barrier.¹⁷⁰

Many anatomic, physicochemical, and host factors influence drug penetration into respiratory tissue and secretions.¹⁷⁰ Active transport mechanisms for drugs have not been identified in respiratory tissues; therefore, passive diffusion is responsible for the transfer of antibiotics into respiratory tissue. The degree of diffusion is determined by the ability of the antibiotic to reach high free concentrations in the serum. The transfer of an antibiotic into tissue may be slower than its elimination from the serum. Furthermore, elimination of the antibiotic from the tissue site occurs more slowly than from the serum; thus, serum concentrations may not reflect antimicrobial concentrations in lung tissue. The results of studies investigating the penetration of antibiotics into bronchial secretions should be interpreted cautiously because most of these studies have analyzed the amount of antibiotic present in samples of expectorated sputum or saliva, which may significantly underestimate the amount of antibiotic present in respiratory secretions. The use of fiberoptic bronchoscopy with a protected sampling device has been helpful in the study of antibiotic penetration into respiratory secretions, but this procedure is impractical in the routine management of patients with pneumonia. Although some have advocated the use of epithelial lining fluid (ELF) as a surrogate for an antibiotic's ability to be effective in treating patients with pneumonia, ELF may accurately reflect the site of action for antibiotics in the lung.

LOCALLY ADMINISTERED ANTIBIOTICS: PROPHYLAXIS

27. Can locally administered antibiotics be used to prevent Gram-negative pneumonias?

The morbidity and mortality rates from hospital-acquired Gram-negative pneumonia have not been reduced despite aggressive treatment with high-dose parenteral antibiotics. Lack of improved outcomes may be the result of poor antibiotic penetration into the bronchial secretions and the local conditions at the site of infection. Consequently, several investigators have studied the efficacy of endotracheal instillation or aerosolization of antibiotics to prevent Gram-negative pneumonias in

patients at risk for oropharyngeal colonization.^{175–179} Most patients treated have been seriously ill individuals who were admitted to the ICU unconscious and with tracheotomy to provide long-term ventilatory support. Endotracheal instillation and aerosolization of antibiotics significantly reduced oropharyngeal colonization with Gram-negative pathogens as well as the incidence of pneumonia. However, other investigators have observed the emergence of colonization with antibiotic-resistant Gram-negative organisms and pneumonia caused by these pathogens.^{177–179} In summary, endotracheally instilled and aerosolized antibiotics can be used to prevent or reduce oropharyngeal colonization in high-risk patients when used for short periods with close microbiologic monitoring. Routine and long-term use cannot be recommended because of a lack of well-controlled clinical trials and the possible emergence of resistance.^{180,181}

AEROSOLIZED ANTIBIOTICS

28. Can aerosolized antibiotics be used to treat patients with Gram-negative pneumonias?

The efficacy of locally administered antibiotics to treat bronchopneumonia has been studied to a limited extent.¹⁸⁰ Klaster-sky et al.¹⁸² compared the effects of endotracheally instilled gentamicin with intramuscular gentamicin in patients with pneumonia. A favorable outcome occurred in all seven patients receiving endotracheally instilled gentamicin versus only two of eight patients receiving intramuscular gentamicin.

In a second study, these investigators compared the effects of endotracheally instilled sisomicin with placebo in a similar patient population.¹⁸³ All patients received systemic antibiotics consisting of parenteral sisomicin and carbenicillin. A more favorable outcome occurred in those patients receiving endotracheally instilled sisomicin versus those receiving a placebo (78% and 45%, respectively). In patients in whom the infecting organism was sensitive to both carbenicillin and sisomicin, a more favorable response occurred in those patients receiving endotracheal sisomicin versus placebo (79% and 54%, respectively). When the infecting organism was sensitive to sisomicin only, a favorable outcome occurred in 79% versus 28%, respectively. The development of resistant organisms was not a problem in either case.

In a third study, these same investigators compared the effects of parenteral mezlocillin and endotracheally administered sisomicin with and without parenteral sisomicin to determine the benefit of concomitant parenteral aminoglycoside.¹⁸⁴ The clinical outcome in both groups was similar; however, resistant bacteria were isolated from the sputum of the groups that were administered endotracheal sisomicin. These findings the need for further investigation into the use of aerosolized antibiotic therapy for HAP/VAP/HCAP.

Administration

29. How is local antibiotic therapy administered?

Local antibiotic therapy may be administered by direct endotracheal instillation or aerosolization. The antibiotic usually is diluted with normal saline before administration. In the case of direct instillation, gentamicin/tobramycin (40–80 mg) or amikacin (500 mg) is diluted in 5 to 10 mL of normal saline and instilled directly into the trachea through a catheter or

through an endotracheal tube. The patient is then rotated from side to side to promote distribution. Delivery of the antibiotic into the oropharynx by aerosolization is accomplished by use of an atomizer or nebulizers to deliver the antibiotic to the lungs. The aerosolized route is preferred, and the dosage is 300 to 600 mg every 8 hours for gentamicin and tobramycin diluted in a smaller volume (1–3 mL).^{180,181}

Bronchial and Serum Concentrations

30. What concentration of aminoglycoside can be achieved in bronchial secretions by this route of administration, and is any of the antibiotic absorbed?

The concentration of the aminoglycoside in bronchial secretions after parenteral administration (IV or intramuscularly) is low and usually <2 mcg/mL.¹⁷⁰ When the aminoglycosides are delivered by either endotracheal instillation or aerosolization, bronchial fluid antibiotic concentrations are substantially higher.^{185–188} Bronchial fluid concentrations are significantly higher when the aminoglycosides are given by endotracheal instillation than by aerosol. These values usually exceed 200 mcg/mL and remain elevated for the dosing interval,¹⁸⁷ when aerosolization is used, bronchial fluid concentrations usually exceed 20 mcg/mL.^{186,187}

Absorption of the aminoglycosides from the lung differs with the method of local administration used. Various doses of aminoglycosides have been administered, which makes quantification of the amount of the drug absorbed difficult. When 80 mg of gentamicin is administered by endotracheal instillation, serum concentrations >2.5 mcg/mL are achieved, suggesting that a substantial amount of the administered drug is absorbed.^{177,185,186} Approximately 10% to 15% of the dose administered by endotracheal instillation is excreted into the urine.¹⁸⁹ When similar doses of antibiotic are administered by aerosolization, serum concentrations are low or undetectable; approximately 2% to 5% of the dose is excreted into the urine. For this reason, aerosolization is the preferred route of administration. As with parenteral aminoglycoside administration, patients with renal dysfunction should be monitored carefully for drug accumulation.

Adverse Effects

31. What adverse effects are associated with local antibiotic administration?

As noted previously, the emergence of antibiotic-resistant bacteria is of major concern because these may be responsible for subsequent bacterial infections. This phenomenon is more frequently associated with prophylactic aerosolized antibiotics.

Endotracheal instillation or aerosolization of antibiotics may cause cough; bronchial irritation; and in some individuals, bronchospasm. These effects most often have been associated with polymyxin B and have resulted in episodes of acute respiratory failure.^{190,191} Polymyxin can stimulate the release of histamine, which is believed to be responsible for these adverse effects; it also can decrease ventilatory function.¹⁹⁰ The aminoglycosides have been relatively well tolerated, although minor alterations in ventilatory function have been reported.¹⁹²

Studies evaluating the incidence of aminoglycoside nephrotoxicity and ototoxicity associated with local antibiotic admin-

istration are unavailable; however, the incidence should be low. Patients with renal dysfunction may accumulate this drug, and serum concentrations of the aminoglycoside should be monitored.

32. What preventive measures are effective for hospital-acquired or nosocomial pneumonia?

The substantial risk of pneumonia in the ICU has prompted aggressive methods to prevent this disease.^{193,194} As noted previously, several modifiable risk factors have been identified for HAP/VAP/HACP. The most important recommendations include the use of the semiupright position to reduce the risk of aspiration¹⁹⁵ and infection control (including hand washing) to prevent the spread of pathogens from one patient to the next and surveillance for ICU infections. As mentioned in the discussion of aspiration pneumonia, the use of sucralfate in lieu of H₂-antagonists to prevent GI ulcers has been shown to reduce the frequency of nosocomial pneumonia and can be an alternative.¹⁶⁹ The use of “selective decontamination” to decrease the bacterial burden in the GI tract is not advocated. This practice has been extensively studied in >4,000 patients and has been shown to reduce the frequency of pneumonia in the ICU, but it has had no impact on mortality.^{196,197} This fact, coupled with the costs of the antibiotic regimens and the potential for the emergence of resistance, makes it difficult to recommend this approach. Finally, as described earlier, the use of inhaled or aerosolized antibiotic therapy requires more data before it can be recommended.^{180,181}

Pneumonia in Cystic Fibrosis

Special Treatment Considerations

33. K.P., an 18-year-old man with CF, has been well until 3 days ago when he noted “chest tightness” and a progressive deterioration of pulmonary function requiring supplemental oxygen. Other symptoms include an increased cough with sputum production, decreased appetite, and weight loss.

On physical examination, K.P. is a cachectic young male in moderate respiratory distress. Vital signs include the following: BP, 110/60 mmHg; pulse, 120 beats/minute; respirations, 35 breaths/minute; and temperature, 38.5°C. Examination of the chest reveals an increased chest diameter with diffuse bilateral rales; there are no wheezes. K.P.’s height is 64 inches, weight is 42 kg, and serum creatinine (SrCr) is 1.0 mg/dL. Are there special considerations in the treatment of pneumonia in patients with CF?

[SI unit: SrCr, 88.4 μmol/L]

CF is a genetically linked disease affecting exocrine gland secretions throughout the body (see Chapter 98).¹⁹⁸ Progressive pulmonary disease is the major determinant of the morbidity and mortality of patients with this illness. The presence of airway mucus plugging is likely to contribute to the development of significant respiratory dysfunction and the establishment of infection; recurrent respiratory infections play a major role in the pathogenesis of the chronic pulmonary disease seen in these patients. Symptoms associated with an infectious exacerbation include an increased frequency and duration of cough or increased shortness of breath, increased sputum production, change in the appearance of sputum, decreased exercise

tolerance, decreased appetite, and a feeling of increased chest congestion.

MICROBIOLOGY

Early in the disease, *S. aureus* is an important pathogen; but later, colonization and infection with *P. aeruginosa* frequently develops. Multiple bacterial isolates with differing antimicrobial sensitivity patterns often are found.¹⁹⁹ In addition, infection due to *Burkholderia cepacia* is emerging as a significant problem in patients with CF.^{200,201} The role of *B. cepacia* as a pathogen in CF patients is difficult to determine because many patients recover from acute infections despite the use of antimicrobials with little activity against this organism. Most strains demonstrate variable sensitivity patterns to many of the presently used antibiotics. Therefore, antibiotic therapy should be based on known in vitro sensitivity testing.

Vigorous chest percussion with postural drainage and systemic antibiotics have been the mainstay of therapy in the prevention and treatment of pulmonary infections in patients with CF. The objectives of antibiotic therapy in CF patients can be divided into three categories: (a) early disease where the goal is to delay chronic colonization with *P. aeruginosa*; (b) once colonization with *S. aureus* and *P. aeruginosa* has occurred, to delay the decline in pulmonary function and reduce frequency and morbidity of exacerbations; and (c) during periodic exacerbations to relieve symptoms and restore pulmonary function to baseline. It is unclear whether combination antibiotic therapy is required to treat these patients, but it frequently is used to treat Gram-negative pulmonary infections in CF patients. Combination therapy usually consists of an aminoglycoside or ciprofloxacin and an antipseudomonal β -lactam (piperacillin-tazobactam, cefepime, aztreonam, imipenem, or meropenem). Therapy generally is continued for 14 to 21 days.

DOSING CONSIDERATIONS

Altered drug elimination in CF patients has been reported for several drugs.^{202–205} Jusko et al.²⁰² studied the pharmacokinetics of dicloxacillin in patients with CF and reported that the total body clearance and renal clearance of this drug were increased. In another study, when specific techniques to assess the glomerular infiltration rate were used, tobramycin renal clearance was not increased out of proportion to the glomerular filtration rate. These results suggest that alterations in the non-renal clearance are responsible for the increased clearance of the aminoglycosides. The underlying reasons for these changes are unclear. In addition, changes in the pharmacokinetics of antibiotics are neither consistent nor predictable. Patients with CF may require higher dosages to achieve therapeutic plasma concentrations of some antibiotics.^{181,205} Therefore, dosages must be carefully individualized, and serum levels (in the case of the aminoglycosides) should be monitored.

LOCAL ANTIBIOTIC ADMINISTRATION

34. Because such high doses of parenteral aminoglycosides are required in CF patients, can aerosolized aminoglycosides be used instead?

Aerosolized antibiotics have been advocated for CF patients with acute pulmonary infections^{207–210} because several factors limit the use of IV administration. Because most antibiotics penetrate variably into lung tissue, they usually are adminis-

tered in maximal doses to facilitate passive diffusion, which also increases the risk of systemic toxicity. In contrast, inhaled antibiotics deliver large concentrations of antibiotics to the site of infection while producing negligible serum concentrations, which should reduce the risk of systemic toxicity.

However, several potential problems are associated with aerosolized antibiotics. Prolonged administration selects out resistant organisms in the bronchial airways, and this may have deleterious consequences because of the recurrent nature of pulmonary infections in CF patients. To be effective, the antibiotic must be delivered to the alveoli. This requires particles $<2 \mu\text{m}$ wide, but most commercially available nebulizers generate particles between 2.5 and 4.5 μm wide,²¹¹ which are deposited primarily in the oropharynx and smaller airways. Also, studies using radioisotope-labeled aerosolized particles have shown that there is a heterogeneous pattern of deposition in CF patients,²¹² which may limit the therapeutic effectiveness of this delivery route. Bronchospasm has occurred in patients given aerosolized gentamicin, which also may limit the delivery of antibiotic to the site of infection. Nephrotoxicity and ototoxicity are unlikely with this route of administration.

Stephens et al.²⁰⁸ administered aerosolized tobramycin along with parenteral antibiotics and reported that the clinical outcomes of those receiving the combination of parenteral and aerosolized antibiotics did not differ from those receiving parenteral antibiotics alone. Steinkamp et al.²¹⁰ evaluated the clinical effectiveness of long-term, prophylactic tobramycin aerosol therapy in 14 CF patients. The best clinical outcomes occurred in individuals who were defined as moderately ill and had mild lung disease. Drug toxicity and the emergence of resistant organisms were minimal in the study population. Although aerosolized antibiotics have reportedly slowed the rate of pulmonary function decline in uncontrolled trials,²¹³ these positive results are difficult to differentiate from the natural course of CF, which is characterized by significant variability in the rate of lung function deterioration. Ramsey et al.²¹⁴ conducted a placebo-controlled, parallel-design, cross-over study of 71 patients with stable pulmonary status and *P. aeruginosa* detected in their sputum. Tobramycin 600 mg three times daily or placebo was delivered for 28 days by ultrasonic nebulizer. The dose was based on previous studies showing that sputum tobramycin concentrations >10 times the MIC for *P. aeruginosa* or a minimum sputum concentration of 400 mcg/mL were required to ensure bacterial killing. The results showed a small but significant improvement in pulmonary function in favor of the tobramycin group. They also showed a 100-fold reduction in the density of *P. aeruginosa* in sputum, a modest reduction in PMN count, a reduction in pulmonary exacerbations, and a lower rate of systemic antibiotic use. Similarly, Ramsey et al.²¹⁴ conducted two double-blind, placebo-controlled trials of intermittent inhaled tobramycin in patients with CF. These studies used a different formulation of tobramycin for inhalation that is preservative free and less likely to induce local adverse reactions. Patients treated with tobramycin had a statistically significant increase in forced expiratory volume in 1 second (FEV₁), a decrease in the density of *P. aeruginosa*, and a decrease in hospitalization relative to the placebo group. An increase in the percentage of resistant *P. aeruginosa* was noted in the tobramycin-treated patients, but it did not reach statistical significance.²¹⁵

In summary, aerosolized antibiotics provide tangible clinical benefits in this patient population. The development of resistance subsequent to aerosolized therapy is concerning, but the clinical significance of these findings are unknown. This route can be used as an adjunct to parenteral therapy in patients with severe, acute exacerbations of pul-

monary infections that are unresponsive to maximal parenteral doses.^{206,214-216}

The optimal dose of aerosolized antibiotics is unknown. The regimens found to be most effective include gentamicin or tobramycin, 300 to 600 mg three times daily, administered via a jet nebulizer.^{206,215}

History

Tuberculosis (TB) is an ancient disease, and evidence of TB dates back as far as prehistoric times with evidence being found in pre-Columbian and early Egyptian remains. However, TB did not become a problem until the 17th and 18th centuries when crowded living conditions of the industrial revolution contributed to its epidemic numbers in Europe and the United States. Early physicians referred to TB as *phthisis*, derived from the Greek term for wasting, because its clinical presentation consisted of weight loss, cough, fevers, and hemoptysis. Although its characteristics were well known, an etiologic agent was not clearly defined until 1882 when Robert Koch isolated and cultured *Mycobacterium tuberculosis* and demonstrated its infectious nature. With this knowledge, early treatment in the mid-1800s to the early 1900s consisted of removing patients with TB from the community and placing them in a sanatorium for bedrest and fresh air. With the advent of radiographic film, pulmonary cavitory lesions were found to be pivotal in the evolution of the disease. Therapy then included proce-

dures such as pneumoperitoneum, thoracoplasty, and plomage to reduce the size of the cavitory lesion. Some of these therapies may continue to be used for severe and refractory cases.

The modern era of medical therapy for TB began in 1944 with the discovery of streptomycin and, shortly thereafter, para-aminosalicylic acid. The addition of isoniazid (INH) in 1952 and rifampin in the late 1960s greatly increased the hopes for the eventual elimination of TB in the United States.¹ Multidrug-resistant TB (MDR-TB) emerged in the 1990s as a threat to the control of TB in the United States and other countries.²⁻⁴ More recently, TB has once again demanded the attention of national and international medical journals, as well as the lay press, with the emergence of extensively drug-resistant TB (XDR-TB).⁵⁻⁷ Therefore, a high index of suspicion for TB, rapid pathogen identification, susceptibility testing, patient isolation to prevent dissemination, and aggressive, appropriate antimicrobial therapy are critical to prevent further development and spread of drug-resistant TB.

Incidence and Epidemiology

Assuming life-long infection, approximately 2.0 billion people (30% of the world's population) are infected with *M. tuberculosis*.⁸ Tuberculosis is the second most common cause of death from an infectious disease in the world, second only to human immunodeficiency virus (HIV) and acquired immunodeficiency syndrome (AIDS). Globally, an estimated 8.8 million new cases of TB were reported in 2005, which represents an increase of 0.5 million cases compared with 2000.⁸ Most (7.4 million) of the new cases in 2005 originated from Asia and sub-Saharan Africa.⁹ The countries with the largest number of new cases were India (1.85 million), China (1.32 million), Indonesia (0.53 million), Nigeria (0.37 million), Bangladesh (0.32 million), and Pakistan (0.29 million).⁹ Twelve of the 15 countries with the highest incidence rates for TB are located in Africa, a finding which can be explained, at least in part, by the relatively high rates of co-infection with HIV.⁹ Countries with the highest rate (per 100,000 population) for new TB cases were Swaziland (1,262), Djibouti (762), Namibia (697), Lesotho (696), Botswana (654), and Kenya (641).⁹ Tuberculosis rates have also increased in the former Soviet Union. In Russia, the incidence rate increased from 51 per 100,000 population in 1990 to 119 per 100,000 population in 2005.⁹ In 2005, approximately 1.6 million deaths secondary to TB were reported globally, including 195,000 patients infected with HIV.⁹

In the United States, the rate of TB declined from 53.0 per 100,000 population in 1953, when the Centers for Disease Control and Prevention (CDC) began conducting TB surveillance, to 9.1 per 100,000 population in 1988.¹⁰ A resurgence of TB took place in the United States from 1985 to 1992, in large part because of the HIV/AIDS epidemic and the emergence of MDR-TB. At its peak in 1992, 26,673 TB cases (10.5 per 100,000 population) were reported.¹⁰ As a result of this resurgence, an advisory committee was established by the Department of Health and Human Services to provide recommendations for the elimination of TB in the United States. The committee urged the establishment of a national goal of TB elimination (<1 case per million of population) by the year 2010, with an interim target incidence rate of 3.5 per 100,000 population by 2000.¹¹ The plan incorporated identi-

fication of populations more susceptible to TB infection, the use of biotechnology in diagnosis and treatment, and computer telecommunication to track cases.¹¹ These recommendations, along with strict infection control procedures, prompt initiation of treatment, and ensuring completion of TB therapy, have successfully reduced the TB case rate in the United States. The number of reported TB cases in 2006 was 13,767 cases, which represents an incidence rate of 4.6 per 100,000 population.¹² This incidence rate is the lowest recorded rate since national reporting began over 50 years ago; however, the incidence rate in 2006 remains higher than the interim target goal that was set for 2000.^{11,12} TB is more common in patients 25 to 44 years of age (34% of cases), but the highest incidence rate is seen in patients ≥ 65 years of age (7.7 per 100,000 population).¹³

Although the incidence rate of TB in the United States continues to decline, the rate of decline has slowed since 2000 (Fig. 61-1). From 1993 to 2000, the average annual incidence rate decreased 7.3% per year, but the average annual incidence rate has only decreased 3.8% per year from 2000 to 2006.¹² Foreign-born and ethnic minority populations are disproportionately infected with TB in the United States. The number of TB cases in foreign-born persons increased by 5% from 1993 to 2006, whereas TB cases for persons born in the United States decreased 66% over this time period (Fig. 61-1). In 1993, 69% of reported TB cases were among U.S.-born persons, whereas 29% were among foreign-born persons.¹³ In 2006, the total number of TB cases in foreign-born persons was 57% compared with 43% for U.S.-born persons.¹² Stated differently, the rate of TB was 9.5 times greater for foreign-born persons (21.9 per 100,000 population) than for U.S.-born persons (2.3 per 100,000 population).¹² Five countries accounted for over half of TB cases reported in foreign-born persons in 2006: Mexico, Philippines, Vietnam, India, and China.¹² An analysis of the number of TB cases in 2004 found that 50% of cases in foreign-born persons were reported in those who had been in the United States for more than 5 years; however, the incidence rate was highest in persons who had been in the United States for 1 year or less.¹⁴

In 2006, the TB rates for Hispanics, blacks, and Asians were 7.6, 8.4, and 21.2 times higher, respectively, than the rate for whites.¹² Compared with 2005, 20 states and the District

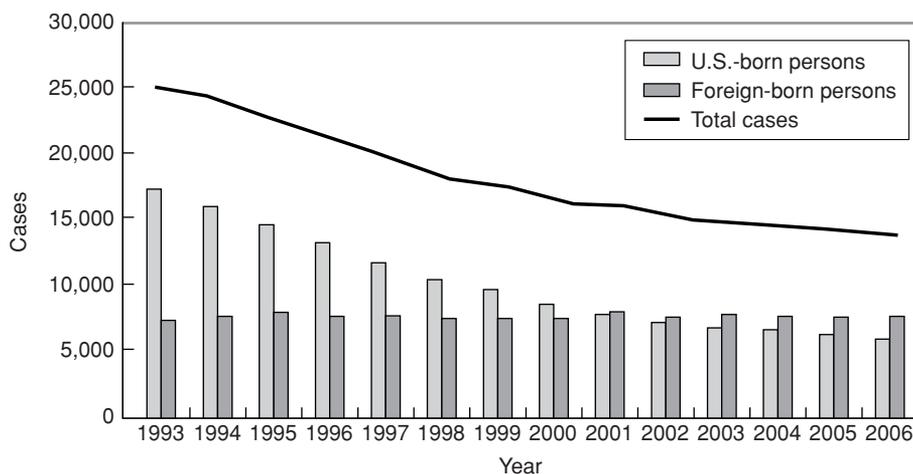

FIGURE 61-1 Reported cases of tuberculosis in the United States, 1993–2006.^{12,13}

of Columbia had greater rates in 2006, whereas 30 states had lower rates.¹² Seven states accounted for 60% of all TB cases in the United States in 2006: California (2,781), Texas (1,585), New York (1,274), Florida (1,038), Illinois (569), New Jersey (508), and Georgia (504).¹² In 2005, TB cases were reported in 4.0% of residents in correctional facilities, 6.1% of homeless persons, 2.4% of residents in long-term care facilities, 2.2% of injecting drug users, 7.8% of noninjecting drug users, and 13.9% of persons with excess alcohol use.¹³

In the United States, a total of 124 cases of MDR-TB, defined as resistance to both isoniazid and rifampin, were reported in 2005.¹² The overall proportion of MDR-TB cases remained constant from 2004 to 2005 at approximately 1.2%, which remains lower than the incidence of 2.5% in 1993.^{12,13} In recent years, most MDR-TB cases in the United States have been reported in foreign-born persons. In 1993, 410 cases of MDR-TB were reported and 105 (25.6%) were in foreign-born persons.¹³ In 2006, 101 (81.5%) of the 124 MDR-TB cases were reported in foreign-born persons.¹²

In the last few years, XDR-TB has emerged as a major threat to global health.⁵⁻⁷ These extensively resistant strains have been identified in many countries worldwide, including the United States. One of the first reports from South Africa described 53 patients infected with XDR-TB.¹⁵ Of these patients, 55% had no prior history of TB treatment, and 52 (98%) died with a median survival period of only 16 days after the first sputum specimen was collected.¹⁵ HIV testing was performed in 44 of these patients, and 100% of them tested positive.¹⁵

Evaluation of the incidence of infections caused by XDR-TB has been complicated by recent changes in the definition of XDR-TB. The most recent definition of XDR-TB is resistance to at least isoniazid and rifampin among first-line agents, resistance to any fluoroquinolone, and resistance to at least one second-line injectable drug (amikacin, kanamycin, or capreomycin).¹⁶ Using the revised definition, 49 cases of XDR-TB have been identified in the United States between 1993 and 2006, which represent 3% of evaluable MDR-TB cases.¹⁷ A total of 32 cases were reported between 1993 and 1999, and 17 cases were reported between 2000 and 2006.¹⁷ Overall, 19 cases were reported in New York City, and 11 cases were reported in California. The percentage of XDR-TB cases among foreign-born persons increased from 38% in 1993 to 1999 to 76% in 2000 to 2006.¹⁷ Mortality was strongly associated with concomitant HIV infection; 12 persons died, 10 of whom had HIV infection.¹⁷ The HIV status of the other 2 persons was unknown.

Continued strengthening of TB control and treatment programs remains essential to the goal of TB elimination in the United States. To accomplish this goal, successful strategies for controlling and preventing TB among foreign-born persons must be developed.

Etiology

Tuberculosis is caused by *M. tuberculosis*, an aerobic, non-spore-forming bacillus that resists decolorization by acid alcohol after staining with basic fuchsin. For this reason, the organism is often referred to as an acid-fast bacillus (AFB). It is also different from other organisms in that it replicates slowly once every 24 hours instead of every 20 to 40 minutes as do some other organisms. *M. tuberculosis* thrives in envi-

ronments where the oxygen tension is relatively high, such as the apices of the lung, the renal parenchyma, and the growing ends of bones.¹

Transmission

Mycobacterium tuberculosis is transmitted through the air by aerosolized droplet nuclei that are produced when a person with pulmonary or laryngeal TB coughs, sneezes, speaks, or sings. Droplet nuclei can also be produced by other methods, such as aerosol treatments, sputum induction, bronchoscopy, endotracheal intubation, suctioning, autopsy, and through manipulation of lesions or processing of secretions in the hospital or laboratory.¹⁸ These droplet nuclei, which contain one to three *M. tuberculosis* organisms, are small enough (1–5 μg) to remain airborne for long periods of time and reach the alveoli within the lungs when inhaled. Tubercle bacilli are not transmitted on inanimate objects such as dishes, clothing, or bedding, and organisms deposited on skin or intact mucosa do not invade tissue.

Several factors influence the likelihood of transmission of *M. tuberculosis*, including the number of organisms expelled into the air, the concentration of organisms in the air determined by the volume of the space and its ventilation, the length of time an exposed person breathes the contaminated air, and presumably the immune status of the exposed individual.¹⁸ Family household contacts, especially children, and persons working or living in an enclosed environment (e.g., hospitals, nursing homes, prisons) with an infected person are at a significantly increased risk for becoming infected. Individuals with impaired cell-mediated immunity, such as HIV-infected persons or transplant recipients, are thought more likely to become infected with *M. tuberculosis* after exposure than persons with normal immune function.¹⁸

Several techniques are effective in limiting airborne transmission of *M. tuberculosis*. Adequate room ventilation with fresh air is very important, especially in the health care setting, where six or more room-air exchanges per hour is desirable.^{18,19} New construction or renovation of existing facilities should be designed so that airborne infection isolation rooms achieve 12 or more room-air exchanges per hour.¹⁹ Ultraviolet irradiation of air in the upper part of the room can also reduce the number of viable airborne tubercle bacilli. All health care workers and visitors who enter the room of a patient with TB should wear at least N95 disposable respirators, and the mask should be fit tightly around the nose and mouth.¹⁹ Patients with presumed or confirmed infectious TB should wear a protective mask when being transferred to another area of the institution or to another institution.¹⁹ The most important means of reducing transmission of *M. tuberculosis* is by treating the infected patient with effective antituberculosis therapy.

Pathogenesis

Latent Infection versus Active Disease

LATENT INFECTION

A clear distinction should be made between latent infection and active disease (tuberculosis). Latent infection occurs when the tubercle bacilli are inhaled into the body. After inhalation, the droplet nuclei containing *M. tuberculosis* settle

into the bronchioles and alveoli of the lungs. Development of infection in the lung is dependent on both the virulence of the organism and the inherent microbicidal ability of the alveolar macrophages.^{20,21} In the nonimmune (susceptible) host, the bacilli initially multiply unopposed by normal host defense mechanisms. The organisms are then taken into alveolar macrophages by phagocytosis and may remain viable, multiplying within the cells for extended periods of time. After 14 to 21 days of replication, the tubercle bacilli spread via the lymphatic system to the hilar lymph nodes and through the bloodstream to other organs. Certain organs and tissues in the body, such as the bone marrow, liver, and spleen, are, however, resistant to subsequent multiplication of these bacilli. In contrast, organs with high blood flow and PaO₂, such as the upper lung zones, kidneys, bones, and brain, are particularly favorable for growth of the organisms. The organisms replicate for 2 to 12 weeks until they reach 10³ to 10⁴ in number, then a specific T-lymphocyte-mediated immune response develops. The T cells secrete interferon- γ , interleukin-2, interleukin-10, and other cytokines, and activated macrophages engulf and kill the tubercle bacilli, preventing further replication.¹⁸ At this point, the patient has developed cell-mediated immunity, which can be detected by a reaction to the tuberculin skin test.¹⁸

In persons with intact cell-mediated immunity, activated T lymphocytes and macrophages may form granulomas that limit multiplication and spread of the bacilli by walling off the infection from the surrounding environment.¹⁸ The organisms tend to localize in the center of the granuloma, which is frequently necrotic. Although small numbers of tubercle bacilli may remain viable within the granuloma, proliferation of *M. tuberculosis* is halted when cell-mediated immunity develops. At this point, most persons with pulmonary tuberculosis infections are clinically asymptomatic and there is no radiographic evidence of the infection.²¹ In some patients, there may be a healed, calcified lesion on chest radiograph, but bacteriologic studies are negative. A positive tuberculin skin test is usually the only indication that the person has been infected with *M. tuberculosis*. Individuals with latent TB infection are not infectious and thus cannot transmit the organism.¹⁸

ACTIVE DISEASE (TUBERCULOSIS)

In most patients, active TB disease results from reactivation of a previously controlled latent infection, termed reactivation tuberculosis. Approximately 10% of individuals who acquire TB infection and do not receive therapy for the latent infection will develop active TB disease. The risk of developing active disease is highest in the first 2 years after infection, when half of the cases occur.¹⁸ The annual and lifetime risks for reactivation TB have been shown, however, to be directly related to the size of the induration on tuberculin skin testing. The risks for reactivation TB were greater in patients with larger induration diameters.²² The ability of the host to respond to *M. tuberculosis* may also be reduced by certain diseases such as diabetes mellitus, silicosis, chronic renal failure, and diseases or drugs associated with immunosuppression (e.g., HIV infection, antitumor necrosis factor- α agents, organ transplantation, corticosteroids, and other immunosuppressive agents).^{18,22} Persons infected with HIV, especially those with low CD4(+) T-cell counts, develop active TB disease rapidly after becoming infected with *M. tuberculosis*; up to 50% of these individuals

develop active disease within the first 2 years of infection.²³ In addition, a person with untreated latent TB infection who acquires HIV infection will develop active TB disease at an approximate rate of 5% to 10% per year.^{24,25} Physical or emotional stress can destroy the balance between the immune system and the infection, leading to active disease. Other factors that may contribute to developing active disease include gastrectomy, intestinal bypass surgery, alcohol abuse, hematologic disease, reticuloendothelial disease, and intravenous (IV) drug use. The elderly, adolescents, and children <5 years of age also are at an increased risk of developing active disease.^{18,26}

DIAGNOSIS

Signs and Symptoms

Subjective Findings

1. M.W., a 36-year-old woman, is admitted to the hospital with a 2-month history of cough, which has recently become productive. She is also experiencing fatigue, night sweats, and has lost 15 pounds. Other medical problems include diabetes mellitus, which is controlled with 10 units of NPH insulin daily, and poor nutritional status secondary to frequent dieting. M.W. works as a volunteer in a nursing home several days a week. Recently, it was discovered that two patients who she had been caring for had undiagnosed active tuberculosis.

M.W.'s physical examination was normal, but her chest radiograph revealed bibasilar infiltrates. A tuberculin purified protein derivative (PPD) skin test, sputum collections for cultures and susceptibility testing, and a sputum AFB smear were ordered as part of M.W.'s diagnostic workup. Initial laboratory test findings were within normal limits.

The result of her tuberculin PPD skin test, read at 48 hours, was a palpable induration of 14 mm. Her sputum smear was positive for AFB, and additional sputum cultures for *M. tuberculosis* were ordered to confirm the diagnosis of active TB disease. What subjective and objective findings does M.W. have that are consistent with active TB disease?

M.W.'s history of cough (which gradually became productive), bibasilar infiltrates, fatigue, and night sweats are consistent with the classic symptoms of active TB.¹⁸ The cough may be nonproductive early in the course of the illness, but with subsequent inflammation and tissue necrosis, sputum is usually produced and is key to most of the diagnostic studies. The sputum may contain blood (hemoptysis) in patients with advanced cavitory disease, which is particularly worrisome because cavitory lesions harbor large numbers of organisms and the pulmonary location allows for airborne transmission. Anorexia from TB, along with frequent dieting, may have resulted in M.W.'s weight loss. Other symptoms of TB can include fever, pleuritic pain secondary to inflammation of lung parenchyma adjacent to the pleural space, and general malaise. Dyspnea is unusual unless there is extensive disease.¹⁸

Objective Findings

M.W. has a chest radiograph consistent with a lower respiratory tract infection. In pulmonary TB, nodular infiltrates are usually found in the apical or posterior segments of the upper lobes, but markings may be found in any segment. M.W. also has a positive sputum smear for AFB, a positive PPD skin test (14 mm),

and diabetes mellitus, which is a risk factor for TB. Although her laboratory test results are within normal limits, peripheral blood leukocytosis and anemia are the most common hematologic manifestations of TB.¹⁸ The white blood cell count is normal or slightly increased, and an increase in monocytes and eosinophils may be observed.

Potential Misdiagnoses

Many patients with active pulmonary TB may have no acute symptoms, and cases are often found following routine chest radiographs for other illnesses. Because many of the symptoms of TB also occur in persons with pre-existing pulmonary disease or pneumonia, they may be overlooked and not attributed to TB.

A lack of clinical symptoms can also contribute to misdiagnosis of TB. Almost 50% of the cases of active TB may be misdiagnosed in the absence of classic symptoms.²⁷ More than one-third of the patients with active TB may have no sweats, chills, or malaise, and <50% are febrile. Cough may exist in 80% of these patients, and only 25% have hemoptysis. Although dullness over the apices of the lungs and post-tussive rales are expected in TB, less than one-third of these patients may have abnormal pulmonary signs. Reinforcing the need to consider this diagnosis, TB was not suspected in 42% of patients with active disease in a community hospital.²⁸ The lack of specific clinical symptoms underscores the importance of skin testing, sputum smears for AFB, and chest radiographs as diagnostic tools in those individuals suspected to have TB.

Tuberculin Skin Testing/Whole Blood Interferon- γ Assay

2. What is tuberculin skin testing? How should the results be interpreted in M.W.? What other test may be useful in the diagnostic work-up of M.W.?

The tuberculin skin test (Mantoux method) has been used as a diagnostic tool for infection with *M. tuberculosis* for decades, but a positive skin test is not necessary for the diagnosis of active TB disease.²⁹ The test is frequently referred to as the PPD test, which contains a protein prepared from a culture of the tubercle bacilli. The skin test is performed by injecting 0.1 mL of solution containing 5-TU PPD *intracutaneously* into the volar or dorsal surface of the forearm.^{18,30} The injection is made using a one-quarter to one-half inch, 27-gauge needle and a tuberculin syringe, injected just beneath the surface of the skin, avoiding subcutaneous tissue.^{18,31} A discrete, pale elevation of the skin (a wheal) 6 to 10 mm in diameter should be produced when the injection is performed correctly. If the first injection was administered improperly, another test dose can be given at once at a site several centimeters away from the original injection site.¹⁸

If the patient has previously been infected with *M. tuberculosis*, sensitized T cells are recruited to the skin site where they release cytokines.³² These cytokines induce an induration (raised area) through local vasodilatation, edema, fibrin deposition, and recruitment of other inflammatory cells to the area.¹⁸ Typically, the reaction to the tuberculin protein begins 5 to 6 hours after injection with maximal induration observed at 48 to 72 hours. Therefore, the test should be read between 48 and 72 hours after injection because tests read after 72 hours

tend to underestimate the actual size of the induration.¹⁸ For standardization, the diameter of the induration should be measured transversely to the long axis of the forearm and recorded in millimeters.^{18,31} The diameter of the induration should be measured and not the erythematous zone surrounding the induration.

An induration ≥ 5 mm in diameter read 48 to 72 hours after injection is considered to be a positive reaction in an individual with a recent history of close contact with a person with active TB, a person with fibrotic changes on chest radiograph consistent with previous TB, organ transplant recipients and other immunosuppressed patients (receiving the equivalent of ≥ 15 mg/day of prednisone for >1 month), or HIV-positive persons.^{18,30,33,34} Because M.W. has a history of close contact with two persons with active TB, her tuberculin skin test reaction to the PPD is positive (14 mm).

An induration ≥ 10 mm in diameter is considered to be a positive reaction in persons with clinical conditions that put them at increased risk for TB, such as diabetes mellitus, silicosis, chronic renal failure, malnutrition, leukemia, lymphoma, gastrectomy, jejunioileal bypass, and weight loss of >10% of ideal body weight.^{18,30,34} In addition, an induration ≥ 10 mm is considered to be positive in recent immigrants (<5 years) from countries with a high prevalence of TB, injection drug users, residents and employees of high-risk congregate settings (e.g., prisons, nursing homes, homeless shelters), health care workers, mycobacteriology laboratory personnel, and children <4 years of age or infants, children, and adolescents exposed to adults in high-risk categories.^{18,30,34} The skin test is also considered positive for persons with an increase in induration diameter of ≥ 10 mm within a 2-year period.^{30,34} For individuals with no risk factors for TB, an induration ≥ 15 mm is required for a positive reaction.^{30,34}

Several limitations are seen when using tuberculin skin testing as a diagnostic tool for the detection of *M. tuberculosis* infection. Most importantly, the sensitivity and specificity of skin testing is poor in certain patient groups who are most at risk for TB infection, especially patients with HIV co-infection or foreign-born persons.²⁹ False-negative results can occur in patients with impaired cell-mediated immune response. False-positive results can result from infections caused by other mycobacterial species that cross-react with the *M. tuberculosis* antigen, including vaccination with a bacillus of Calmette-Guerin (BCG) vaccine. BCG vaccination increases the likelihood of a false-positive tuberculin skin test result for up to 15 years after administration.³⁵ False-positive results have been reported with some PPD preparations,³⁶ and an increase in skin test converters has also been reported after a change in skin testing preparations.³⁷ Therefore, one preparation should be used consistently in populations undergoing periodic testing.³⁷ Only experienced persons should read the Mantoux PPD skin tests, because the risk of error in performance and interpretation is high. In a study of 1,036 persons who each received two injections of 5-TU PPD from the same vial (one in each arm), 14.5% had an induration >10 mm in one arm and an induration <10 mm in the other arm, likely because of variability in the reading of the tests.³⁸

An *in vitro* enzyme-linked immunosorbent assay (ELISA) test that detects the release of interferon- γ from T cells in whole blood of sensitized patients, QuantiFERON-TB Gold (Cellestis Limited, Carnegie, Victoria, Australia), has been

approved by the U.S. Food and Drug Administration (FDA) as an aid in diagnosing *M. tuberculosis* infection, including both active TB disease and latent TB infection.^{29,39} Aliquots of fresh (≤ 12 hours) heparinized whole blood are incubated with the test antigens, early secretory antigenic target-6 (ESAT-6) and culture filtrate protein-10 (CFP-10), for 16 to 24 hours. After incubation, the concentration of interferon- γ released by the T cells is determined by ELISA, and test results are interpreted.³⁹ ESAT-6 and CFP-10 are secreted by all *M. tuberculosis* and pathogenic *M. bovis* strains but not from BCG vaccine strains. Therefore, this test is more specific for *M. tuberculosis* infection in BCG-vaccinated persons than tuberculin skin testing.²⁹ The test depends on adequately functioning T cells, and a negative result may reflect underlying *in vivo* immunosuppression, decreasing *in vitro* stimulation of the T cells.²⁹ In a study of 294 HIV-infected subjects, indeterminate results were more likely to occur in subjects with a CD4(+) count < 100 cells/mm³ compared with those with a CD4(+) count of ≥ 100 cells/mm³.⁴⁰ Another study found only 64% sensitivity for detection of active TB disease, suggesting that this interferon- γ assay should not be used alone to exclude active TB.⁴¹ False-negative results were more likely in patients with extrapulmonary TB or in patients who had received anti-tuberculosis therapy for up to 2 weeks.⁴¹

3. Because M.W.'s Mantoux PPD skin test is positive, does this confirm her diagnosis of active TB?

No. M.W.'s positive reaction to 5-TU PPD alone does not confirm active TB disease. It merely signifies that she has previously been infected with *M. tuberculosis*. To confirm the diagnosis of active TB disease in M.W. and other patients, *M. tuberculosis* must be isolated from sputum, gastric aspirate, spinal fluid, urine, or tissue biopsy, depending on the site of infection.¹⁸ As was done in M.W., the detection of AFB in stained smears is easy and fast, and it can provide the clinician with a preliminary confirmation of the diagnosis. Sputum samples for AFB stain and culture should be obtained early in the morning on at least three separate days.⁴² Smears may be prepared directly from clinical specimens or from concentrated preparations.¹⁸ The test is performed by placing the specimen on a glass slide under a microscope with a Ziehl-Neelsen or fluorochrome stain (not a Gram stain). Studies have shown, however, that 5,000 to 10,000 bacilli per milliliter of specimen must be present to allow for detection of AFB in stained smears.^{18,43} In 2005, 42% of pulmonary TB cases were sputum smear negative.¹³ Therefore, a negative AFB smear does not rule out active TB disease, and patients with active TB and negative AFB smears may play an important role in the ongoing transmission of *M. tuberculosis*.

Additional limitations of the AFB smear include its inability to differentiate among mycobacterial species and between viable and nonviable organisms. *Mycobacterium avium* complex is isolated more frequently from the sputum of patients in whom a diagnosis of TB is highly probable, such as the elderly and patients with HIV infection.⁴⁴ This has resulted in a marked decrease in the specificity and positive predictive value of the sputum smear.⁴⁵ Nucleic acid amplification (NAA) enhances and expedites the direct identification of *M. tuberculosis*. These technologies amplify specific target sequences of nucleic acids in *M. tuberculosis* that can be detected by a

nucleic acid probe *within hours*. In the research laboratory, a positive result can be obtained from specimens containing as few as 10 bacilli, but the sensitivity is somewhat less in the clinical laboratory.¹⁸ The AMPLIFIED *Mycobacterium Tuberculosis* Direct Test (MTD, GenProbe) and Amplicor *Mycobacterium tuberculosis* Test (Roche) are NAA assays available for commercial use in the United States.⁴⁴ The AMPLIFIED MTD test is FDA approved for use in both smear-positive and smear-negative specimens whereas the Amplicor test is only approved for smear-positive specimens.

The NAA tests accurately diagnose nearly every case of sputum smear-positive pulmonary TB (sensitivity 95%; specificity 98%); the tests will also diagnose approximately half of the smear-negative, culture-positive pulmonary TB cases and the specificity remains approximately 95%.^{18,44} Some investigators suggest that NAA tests should not be performed if sputum smears are negative and if the index of clinical suspicion for active TB is low.⁴⁶ The CDC recommends that AFB smear and NAA be performed on the first sputum smear collected.⁴⁷ If the AFB smear and NAA are both positive, TB is diagnosed with near total certainty. If the AFB smear is negative and the NAA is positive, additional sputum samples should be obtained, and if positive, the patient can be presumed to have TB. If the AFB smear is positive and the NAA is negative, the patient can be presumed to have nontuberculous mycobacteria. If both AFB smear and NAA are negative, additional samples should be tested by NAA. If negative, the patient can be presumed not to have infectious TB.^{44,47} NAA tests should not be used in patients who are being treated because the tests will amplify dead mycobacteria and cannot distinguish viable from nonviable strains.⁴⁶

Some patients may have a negative AFB smear, but a sufficient number of organisms may be present to result in a positive culture. Only 10 to 100 organisms are needed for a positive culture.^{18,48} As a result of the limitations of the AFB smear, a positive culture for *M. tuberculosis* is necessary to definitively diagnose TB in M.W. and all patients. In addition, the culture is of paramount importance because it is the only widely available technology that allows for drug susceptibility testing.⁴⁴ It is also important to reiterate that *M. tuberculosis* organisms grow slowly (i.e., once every 24 hours). Depending on the type of media and detection system, it may take several weeks for the cultures to become positive.^{1,18} Broth-based culture systems, such as BACTEC, MGIT, MB/BacT, Septi-Check, and ESP, when combined with DNA probes, can produce positive results in 2 weeks or less for sputum smear-positive specimens and within 3 weeks for smear-negative specimens.⁴⁴

4. Should M.W. be tested for HIV infection?

Yes, testing should be considered because TB may be the first manifestation of HIV infection.^{1,49} Approximately 37% of patients infected with HIV develop active TB disease within 5 months compared with 5% of exposed persons with intact immune defenses.^{23,50} A complete discussion of TB and HIV infection can be found in Questions 24 to 28.

5. Would a negative tuberculin skin test have eliminated the possibility of infection with *M. tuberculosis* in M.W.?

No, a negative response to 5-TU PPD in M.W. would not necessarily have excluded infection with *M. tuberculosis*. The

Table 61-1 Factors Associated with False–Negative Tuberculin Skin Tests

| |
|--|
| Factors related to the person being tested |
| Bacterial, viral, or fungal infections |
| Live virus vaccinations (measles, mumps, polio, varicella) |
| Chronic renal failure |
| Severe protein depletion |
| Diseases affecting lymphoid organs (Hodgkin's disease, lymphoma, chronic leukemia) |
| Corticosteroids, immunosuppressive agents |
| Age (newborns, elderly) |
| Factors related to the method of administration |
| Subcutaneous injection |
| Injecting too little antigen |
| Factors related to the tuberculin used |
| Improper storage (exposure to light and heat) |
| Improper dilution |
| Contamination |
| Factors related to reading the test and recording the results |
| Inexperienced reader |
| Error in recording |

Adapted from reference 18, with permission.

PPD skin test has a reported false–negative rate of 25% during the initial evaluation of persons with active tuberculosis because of poor nutrition and general health, overwhelming acute illness, or immunosuppression.¹⁸ False–negative results most often occur in persons who (a) have had no prior infection with *M. tuberculosis*, (b) have only recently been infected, or (c) are anergic. Factors that may result in a false–negative tuberculin skin test are shown in Table 61-1.

Anergy (i.e., decreased ability to respond to antigens) can be caused by severe debility, old age, immaturity in newborns, high fever, sarcoidosis, corticosteroids, immunosuppressive drugs, hematologic disease, HIV infections, overwhelming TB, recent viral infection, live-virus vaccinations, and malnutrition.¹⁸ If anergy is suspected, control skin tests (candida, mumps, or trichophyton) should also be placed in the contralateral arm. If the control test results are positive and the PPD test result is negative, infection with *M. tuberculosis* is less likely. The CDC changed its recommendations regarding anergy skin testing in patients infected with HIV with a negative PPD. They cite problems with standardization and reproducibility, a low risk for TB associated with a diagnosis of anergy, and the lack of apparent benefit of therapy for latent TB infection in anergic patients who are infected with HIV. Therefore, the use of anergy testing in conjunction with PPD is no longer routinely recommended in this population or for other patients who are immunocompromised.^{35,51,52}

Booster Phenomenon (PPD Skin Test)

6. S.N. is a 50-year-old male hospital employee who had a 7 mm induration after receiving his initial tuberculin skin test (PPD–Mantoux). Because of his age and previous hospital employment, it was decided to retest him 1 week later to rule out any booster effect. The result of the repeated skin test was a 12 mm induration. He denied any known exposure to persons with active TB. What is the significance of this reaction? Should S.N. be placed on INH therapy for latent TB infection?

Some persons experience a significant increase in the size of a tuberculin skin test reaction, which may not be caused by *M. tuberculosis* infection.^{18,53} This reaction, or booster phenomenon, is not fully understood but may be caused by the tuberculin skin test itself when tests are performed every 1 to 2 years. It may also be caused by infection with other mycobacteria, remote TB, or prior BCG vaccination. When caused by a previous skin test, the booster phenomenon can occur as soon as 1 week after the previous test. The incidence of this reaction appears to increase with age.⁵⁴ Therefore, S.N.'s reaction may not represent infection with *M. tuberculosis*.

Serial, two-step tuberculin testing is recommended for health care workers,^{18,55,56} so it is important to distinguish a possible booster reaction from a recent infection with *M. tuberculosis*. Persons who exhibit an increase in the size of the induration from <10 mm to >10 mm, as in the case of S.N., may be mistaken for a recent converter and unnecessarily given INH to treat a latent infection. To determine whether a reaction is caused by boosting rather than an infection, a second identical skin test should be administered 7 to 21 days after the first. The results of this test should be read in 48 to 72 hours. If the repeat test is positive (>10 mm), the reaction should be classified as a booster reaction, and the patient should not be treated with INH. If the repeat test is <10 mm but changes to positive (with a 6-mm increase) after 1 year, the person should be classified as a recent converter and treated accordingly (see Question 15). One report suggested using a 15 mm induration as the appropriate baseline in hospital employees tested annually.⁵⁷

The increase in reaction size in S.N. is most likely caused by the booster phenomenon. Because he is >35 years of age, S.N. would not be an ideal candidate for INH therapy. S.N. should be given a repeat skin test next year and evaluated as previously described. He should not receive a two-step test in the future because this is only done on initial evaluation of an employee.

Bacillus of Calmette–Guerin (BCG) Vaccine

7. C. T., a 25-year-old female refugee from Vietnam, was given a routine physical examination on entering the United States. As part of this examination, she received a tuberculin skin test with 5-TU PPD. The test result was positive with an induration of 12 mm. She denied previous treatment for TB, but she remembered receiving a TB vaccine (BCG) several years ago. What is the BCG vaccine? Does this positive skin test indicate infection with *M. tuberculosis*?

A live vaccine derived from an attenuated strain of *M. bovis*, BCG, is used in many foreign countries with a high prevalence of TB to prevent the disease in persons who are tuberculin negative (no immunity to TB infection). Many different BCG vaccines are available worldwide, and all of them differ with respect to immunogenicity, efficacy, and reactogenicity. Additional factors, such as genetic variability in the subjects vaccinated, the nature of the mycobacteria endemic in different parts of the world, and the use of different doses and different immunization schedules, may contribute to the varied degrees of protection afforded by the vaccine. The protective effect derived from BCG vaccines in case-control studies has ranged from 0 to 80%.⁵⁸ Two meta-analyses concerning the efficacy of BCG vaccination for preventing TB attempted to calculate

estimates of the protective efficacy of the vaccines. The results of the first meta-analysis indicated an 86% protective effect against meningeal and miliary TB in children in 10 randomized clinical trials and a 75% protective effect in 8 case-control studies.⁵⁹ In the second meta-analysis, the overall protective effect of BCG vaccines was 51% in 14 clinical studies and 50% in 12 case-control studies.⁶⁰ Vaccine efficacy rates were greater in studies in which persons were vaccinated during childhood compared to those vaccinated at older ages.⁶⁰ Neither study, however, was able to determine the vaccine's efficacy for preventing pulmonary TB in adolescents and adults.

Prior vaccination with BCG usually results in a positive tuberculin skin test, but skin test reactivity does not correlate with protection against TB.^{18,58} No reliable method exists to distinguish tuberculin reactions caused by BCG vaccination from those caused by natural mycobacterial infections.^{18,58} Therefore, it is prudent to consider positive reactions to 5-TU of PPD in BCG-vaccinated persons as indicating infection with *M. tuberculosis*, especially among persons from countries with a high prevalence of TB.¹⁸ As mentioned previously, however, the interferon- γ assay, QuantiFERON-TB Gold, is more specific for *M. tuberculosis* infection in BCG-vaccinated persons than tuberculin skin testing.²⁹ Therefore, C.T. should have this test performed to determine presence of latent TB. If the interferon- γ assay cannot be performed, C.T. should be treated as though she has a positive tuberculin skin test (see Question 15). Because she is from an area with a high drug-resistance rate, the possibility of infection with organisms that are resistant to INH should also be considered (see Question 22).

Adverse reactions to the BCG vaccine vary according to the type, dose, and age of the vaccine. Osteitis, prolonged ulceration at the vaccination site, lupoid reactions, regional suppurative lymphadenitis, disseminated BCG infection, and death have all been reported.⁵⁸

The BCG vaccine is not recommended for use in the routine prophylaxis of TB in the United States. The risk of exposure to TB in this country is relatively low, and other methods of control (e.g., treatment of high-risk groups) are sufficient. BCG vaccination should be considered for infants or children who are tuberculin negative and are continually exposed to a highly infectious, untreated patient with active TB or if the child is continually exposed to a patient with infectious pulmonary TB caused by *M. tuberculosis* strains resistant to INH and rifampin.⁵⁸ BCG vaccination of health care workers should be considered in settings where a high prevalence of patients are infected with MDR-TB, transmission of MDR-TB strains to health care workers and subsequent infection are likely, and comprehensive infection control precautions have been unsuccessful.⁵⁸ BCG vaccination is not recommended during pregnancy or for children or adults in the United States infected with HIV.⁵⁸

TREATMENT OF ACTIVE DISEASE

Initial Therapy

Regimens

8. M.W.'s HIV test was negative. How should treatment be initiated in M.W., pending the results of the sputum culture and susceptibility testing? Can she transmit infection during treatment?

The overall goals for the treatment of TB are to cure the patient and to minimize the transmission of *M. tuberculosis* to others. The primary goals of antituberculosis chemotherapy are to kill the tubercle bacilli rapidly, prevent the emergence of drug resistance, and eliminate persistent bacilli from the host's tissues to prevent relapse.⁶¹ To accomplish these goals, it is essential that treatment be tailored and supervision be based on each patient's clinical and social circumstances (patient-centered care). Effective treatment of TB requires a substantial period (minimum 6 months) of intensive drug therapy with at least two bactericidal drugs that are active against the organism. The initial phase of treatment is crucial for preventing the emergence of resistance and for the ultimate outcome of TB therapy.

Four basic regimens are recommended for the treatment of adult patients with TB caused by organisms that are known or presumed to be drug susceptible (Table 61-2).⁶¹ Because M.W. has not been treated previously for TB, she should be started on INH, rifampin, pyrazinamide, and ethambutol. Previous guidelines recommended the addition of ethambutol only if the local prevalence of INH-resistant *M. tuberculosis* was $\geq 4\%$.^{42,62,63} In the United States, however, 7.3% of *M. tuberculosis* isolates recovered from patients with no previous history of TB in 2005 were resistant to INH.¹³ The prevalence of INH resistance was higher in foreign-born persons (9.8%) compared with those born in the United States (4.1%).¹³ Because of the relatively high likelihood of TB caused by INH-resistant organisms, four drugs are necessary in the initial 8-week treatment phase. The initial four-drug regimen may be administered daily throughout the 8-week period (regimen 1), daily for the first 2 weeks and then twice weekly for 6 weeks (regimen 2), or three times weekly throughout (regimen 3).⁶¹ On the basis of clinical experience, administration of drugs for 5 days/week is considered to be equivalent to 7 days/week administration and either may be considered daily. Five-day-a-week administration should always be given by directly observed therapy (DOT), however.⁶¹ Drug dosages for these recommended regimens are listed in Table 61-3. In addition, two fixed-dose combination preparations are available in the United States: Rifamate, which contains INH 150 mg and rifampin 300 mg per capsule, and Rifater, which contains INH 50 mg, rifampin 120 mg, and pyrazinamide 300 mg per tablet. These formulations are a means of minimizing inadvertent monotherapy, especially when DOT is not possible, and decreasing the risk of acquired drug resistance by reducing the number of capsules or tablets that must be ingested each day.⁶¹ Ethambutol can be discontinued as soon as the results from susceptibility testing demonstrate susceptibility to INH and rifampin. The incidence of streptomycin resistance has increased globally; therefore, streptomycin is no longer recommended as interchangeable with ethambutol unless the organism is known to be susceptible to the drug or the patient is from an area in which streptomycin resistance is unlikely.⁶¹

The appropriate initial regimen for M.W. may be optimized if drug susceptibility test results are available for the strains recovered from the two patients she had been caring for in the nursing home. M.W., who is diabetic and has a poor nutritional status, should also be given pyridoxine 25 mg/day because she may be at greater risk for the development of INH-induced peripheral neuropathy (see Question 17).

The high risk of transmission of *M. tuberculosis* to other patients and health care workers mandates that hospitalized

Table 61-2 Treatment Regimens for Pulmonary Tuberculosis Caused by Drug-Susceptible Organisms

| Initial Phase | | | Continuation Phase | | | Rating ^a (Evidence) ^b | | |
|---------------|--------------------|---|--------------------|---------|---|---|--------|---------------------|
| Regimen | Drugs | Interval and Doses (Minimal Duration) | Regimen | Drugs | Interval and Doses ^c (Minimal Duration) | Total Doses (Minimal Duration) | HIV— | HIV+ |
| 1 | INH, RIF, PZA, EMB | 7 days/week for 56 doses (8 weeks) OR 5 days/week for 40 doses (8 weeks) ^d | 1a | INH/RIF | 7 days/week for 126 doses (18 weeks) OR 5 days/week for 90 doses (18 weeks) ^d | 182–130 (26 weeks) | A (I) | A (II) |
| | | | 1b | INH/RIF | Twice weekly for 36 doses (18 weeks) | 92–76 (26 weeks) | A (I) | A (II) ^f |
| | | | 1c ^e | INH/RPT | Once weekly for 18 doses (18 weeks) | 74–58 (26 weeks) | B (I) | E (I) |
| 2 | INH, RIF, PZA, EMB | 7 days/week for 14 doses (2 weeks) then twice weekly for 12 doses (6 weeks) OR 5 days/week for 10 doses (2 weeks) ^d then twice weekly for 12 doses (6 weeks) | 2a | INH/RIF | Twice weekly for 36 doses (18 weeks) | 62–58 (26 weeks) | A (II) | B (II) ^f |
| | | | 2b ^e | INH/RPT | Once weekly for 18 doses (18 weeks) | 44–40 (26 weeks) | B (I) | E (I) |
| 3 | INH, RIF, PZA, EMB | Three times weekly for 24 doses (8 weeks) | 3a | INH/RIF | Three times weekly for 54 doses (18 weeks) | 78 (26 weeks) | B (I) | B (II) |
| 4 | INH, RIF, EMB | 7 days/week for 56 doses (8 weeks) OR 5 days/week for 40 doses (8 weeks) ^d | 4a | INH/RIF | 7 days/week for 217 doses (31 weeks) OR 5 days/week for 155 doses (31 weeks) ^d | 273–195 (39 weeks) | C (I) | C (II) |
| | | | 4b | INH/RIF | Twice weekly for 62 doses (31 weeks) | 118–102 (39 weeks) | C (I) | C (II) |

EMB, ethambutol; INH, isoniazid; PZA, pyrazinamide; RIF, rifampin; RPT, rifapentine.

^aDefinitions of evidence ratings: A = preferred; B = acceptable alternative; C = offer when A and B cannot be given; E = should never be given.

^bDefinitions of evidence ratings: I = randomized clinical trial; II = data from clinical trials that were not randomized or were conducted in other populations; III = expert opinion.

^cPatients with cavitation on initial chest radiograph and positive cultures at completion of 2 months of therapy should receive a 7-month continuation phase (31-week; either 217 doses [daily] or 62 doses [twice weekly]).

^dFive-day-a-week administration is always given by directly observed therapy (DOT). Rating for 5 day/week regimens is A (III).

^eOptions 1c and 2b should be used only in HIV-negative patients who have negative sputum smears at the time of completion of 2 months of therapy and who do not have cavitation on the initial chest radiograph.

^fNot recommended for HIV-infected patients with CD4+ cell counts <100 cells/mL. From reference 61, with permission.

persons with suspected or confirmed infectious TB be placed in respiratory isolation until they are determined not to have TB, they are discharged from the hospital, or they are confirmed to be noninfectious.⁴² Based on M.W.'s subjective and objective findings, she should be placed in respiratory isolation. M.W.'s symptoms of TB should abate within the first 4 weeks. She would be considered to be noninfectious when she is receiving effective drug therapy, is improving clinically, and has had negative results for three consecutive sputum AFB smears collected on different days.⁴² Patients who have responded clinically may be discharged to home despite positive smears if their household contacts have already been exposed and these contacts are not at increased risk of TB (e.g., infants, HIV-positive and immunosuppressed persons). In addition, patients discharged to home with positive smears must agree not to have contact with other susceptible persons.⁴²

Fluoroquinolones as Initial Therapy

Interest in the fluoroquinolones for the treatment of TB dates back >20 years with a report describing the use of ofloxacin in 19 patients with chronic, drug-resistant disease.⁶⁴ In a more recent study from India, 92% to 98% of patients with newly diagnosed pulmonary TB had negative sputum cultures after

2 months of ofloxacin-containing regimens.⁶⁵ This study, however, did not have a standard control for comparison.

Several fluoroquinolones have in vitro activity against *M. tuberculosis*. The most potent activity has been reported with moxifloxacin and gatifloxacin; minimum inhibitory concentrations (MICs) for these agents are 4 to 8 times lower than for levofloxacin.⁶⁶ In murine models of TB, moxifloxacin, in combination with rifampin and pyrazinamide, has been shown to reduce the time to negative lung cultures by up to 2 months and produce stable cure compared with isoniazid, rifampin, and pyrazinamide.^{67,68} In mice treated for 4 months, no relapses occurred in the moxifloxacin-containing regimen.⁶⁸

In a recent study, moxifloxacin was compared with ethambutol in the first 2 months of treatment in adults with smear-positive pulmonary TB.⁶⁹ Patients were randomized to receive moxifloxacin 400 mg daily or ethambutol (based on body weight), and all patients received INH, rifampin, and pyrazinamide. Patients receiving moxifloxacin were more likely to have negative sputum cultures at 4 weeks (37% vs. 26%, $p = 0.05$) and at 6 weeks (54% vs. 42%, $p = 0.06$), but the 2-month conversion rates were 71% in each group.⁶⁹ Relapse rates were not evaluated in this study. Nausea was reported more frequently in the moxifloxacin group (22% vs. 9%, $p = 0.002$), but similar proportions of patients in each group

Table 61-3 Drugs Used in the Treatment of Tuberculosis in Adults and Children

| <i>Drug</i> | <i>Dosing (Maximal Dose)</i> | <i>Primary Side Effects</i> | <i>Dose Adjustment in Renal Impairment</i> | <i>Comments</i> |
|---------------------------|--|--|--|--|
| First-Line Agents | | | | |
| Isoniazid | Adults: 5 mg/kg (300 mg) daily; 15 mg/kg (900 mg) once, twice, or thrice weekly. Children: 10–15 mg/kg (300 mg) daily; 20–30 mg/kg (900 mg) twice weekly | Increased aminotransferases (asymptomatic), clinical hepatitis, peripheral neuropathy, CNS effects, lupus-like syndrome, hypersensitivity reactions | No | Peripheral neuropathy preventable with pyridoxine 10–25 mg; increased serum level of phenytoin. Hepatitis more common in older patients and alcoholics |
| Rifampin | Adults: 10 mg/kg (600 mg) once daily, twice weekly, or thrice weekly. Children: 10–20 mg/kg (600 mg) once daily or twice weekly | Pruritis, rash, hepatotoxicity, GI (nausea, anorexia, abdominal pain), flu-like syndrome, thrombocytopenia, renal failure | No | Orange-red discoloration of body secretions (sweat, saliva, tears, urine). Drug interactions caused by induction of hepatic microsomal enzymes (warfarin, antiretroviral agents, corticosteroids, diazepam, lorazepam, triazolam, quinidine, oral contraceptives, methadone, sulfonyleureas) |
| Rifabutin | Adults: 5 mg/kg (300 mg) once daily, twice weekly, or thrice weekly. Children: unknown | Neutropenia, uveitis, GI symptoms, polyarthralgias, hepatotoxicity, rash | No | Orange-red discoloration of body secretions (sweat, saliva, tears, urine). Weaker inducer of hepatic microsomal enzymes than rifampin. |
| Rifapentine | Adults: 10 mg/kg (600 mg) once weekly during continuation phase. Children: not approved | Similar to rifampin | Unknown | Drug interactions caused by induction of hepatic microsomal enzymes (see rifampin). |
| Pyrazinamide | Adults: 20–25 mg/kg (2 g) daily; 40–55 kg: 2 g twice weekly or 1.5 g thrice weekly; 56–75 kg: 3 g twice weekly or 2.5 g thrice weekly; 76–90 kg: 4 g twice weekly or 3 g thrice weekly. Children: 15–30 mg/kg (2 g) daily; 50 mg/kg twice weekly (2 g) | Hepatotoxicity, nausea, anorexia, polyarthralgias, rash, hyperuricemia, dermatitis | No | Monitor aminotransferases monthly |
| Ethambutol | Adults: 15–20 mg/kg (1.6 g) daily; 40–55 kg: 2 g twice weekly or 1.2 g thrice weekly; 56–75 kg: 2.8 g twice weekly or 2 g thrice weekly; 76–90 kg: 4 g twice weekly or 2.4 g thrice weekly. Children: 15–20 mg/kg (1 g) daily; 50 mg/kg (2.5 g) twice weekly | Optic neuritis, skin rash, drug fever | Yes | Routine vision tests recommended; 50% excreted unchanged in urine |
| Second-Line Agents | | | | |
| Cycloserine | Adults: 10–15 mg/kg/day (1 g), usually 500–750 mg/day in two divided doses. Children: 10–15 mg/kg/day (1 g) | CNS toxicity (psychosis, seizures), headache, tremor, fever, skin rashes | Yes | May exacerbate seizure disorders or mental illness. Some toxicity preventable by pyridoxine (100–200 mg/day). Monitor serum concentrations (peak 20–35 mg/L desirable) |
| Ethionamide | Adults: 15–20 mg/kg/day (1 g), usually 500–750 mg/day in one daily dose or 2 divided doses. Children: 15–20 mg/kg/day (1 g) | GI effects (metallic taste, nausea, vomiting, anorexia, abdominal pain), hepatotoxicity, neurotoxicity, endocrine effects (alopecia, gynecomastia, impotence, hypothyroidism), difficulty in diabetes management | Yes | Must be given with meals and antacids. Monitor aminotransferases and thyroid-stimulating hormone monthly. |

Table 61-3 Drugs Used in the Treatment of Tuberculosis in Adults and Children (Continued)

| Drug | Dosing (Maximal Dose) | Primary Side Effects | Dose Adjustment in Renal Impairment | Comments |
|---------------------------------------|---|--|-------------------------------------|---|
| Second-Line Agents (Continued) | | | | |
| Streptomycin | Adults: 15 mg/kg/day (1 g); ≥ 60 years, 10 mg/kg/day (750 mg). Children: 20–40 mg/kg/day (1 g) | Vestibular and/or auditory dysfunction of eighth cranial nerve, renal dysfunction, skin rashes, neuromuscular blockade | Yes | Audiometric and neurologic examinations recommended; 60% to 80% excreted unchanged in urine. Monitor renal function |
| Amikacin | Adults: 15 mg/kg/day (1 g); ≥ 60 years, 10 mg/kg/day (750 mg). Children: 15–30 mg/kg/day (1 g) | Ototoxicity, nephrotoxicity | Yes | Less vestibular toxicity than streptomycin. Monitoring similar to streptomycin. |
| Capreomycin | Adults: 15 mg/kg/day (1 g); ≥ 60 years, 10 mg/kg/day (750 mg). Children: 15–30 mg/kg/day (1 g) as single dose or twice weekly dose | Nephrotoxicity, ototoxicity | Yes | Monitoring similar to streptomycin. |
| Para-aminosalicylic acid (PAS) | Adults: 8–12 g/day in two to three doses. Children: 200–300 mg/kg/day in two to four divided doses | GI intolerance, hepatotoxicity, malabsorption syndrome, hypothyroidism | Yes | Liver enzymes and thyroid function should be monitored. |
| Levofloxacin | Adults: 500–1,000 mg/day | Nausea, diarrhea, headache, dizziness | Yes | Do not give with divalent and/or trivalent cations (e.g., aluminum, magnesium, iron) |
| Moxifloxacin | Adults: 400 mg/day | Nausea, diarrhea, headache, dizziness | No | See levofloxacin |
| Gatifloxacin | Adults: 400 mg/day | Nausea, diarrhea, headache, headache | Yes | See levofloxacin |

CNS, central nervous system; GI, gastrointestinal.

completed study treatment.⁶⁹ Controlled studies of other fluoroquinolones have also found sputum conversion earlier in therapy, but no difference in negative cultures at 2 months.^{70,71} Lastly, fluoroquinolone resistance in *M. tuberculosis* has been described, occurring more commonly in multidrug-resistant isolates.⁷²

Susceptibility Testing

Drug susceptibility testing is essential and should be performed on all initial isolates of *M. tuberculosis*; however, these results may not be available for several weeks after treatment is initiated. The maximal turnaround time for susceptibility testing is ≥ 30 days from the date of specimen collection.⁷³ To expedite this process, rapid tests for the detection of drug resistance are being developed, but none of the tests are currently approved by the FDA.⁴⁶ Tests using molecular beacons utilize fluorescent-labeled, hairpin-shaped DNA probes in which a fluorophore is adjacent to a molecule which prevents fluorescence.⁴⁶ Using a real-time polymerase chain reaction (PCR) assay, fluorescence occurs if the amplified PCR products have the wild-type gene sequence, but fluorescence is not detected if mutations are present in the target sequence. These tests have high sensitivity (89%–98%) and specificity (99%–100%) for rifampin resistance, but sensitivity is lower for detecting INH resistance.⁴⁶ Line probe assays and phage-based assays are commercially available, but more data are needed. One of the line probe assay

kits, INNO-LiPA Rif. TB, is highly sensitive ($>95\%$) and specific ($>99\%$) for detecting rifampin-resistant *M. tuberculosis* in culture, but more data are needed for application of the test to clinical specimens.⁴⁶

Contact Investigation

9. If M.W. is a risk to the community, does anyone need to know?

Yes! Each case of active TB disease must be reported to the local, state, or both public health departments.^{18,42,73} This not only ensures proper therapy by monitoring adherence to therapy, but it also ensures that contact and source case investigations will be performed. They will attempt to evaluate all people who have been in close contact to M.W. so they may be evaluated for latent TB infection or active disease as well. Reporting of cases also permits record-keeping and surveillance to determine if public health TB control efforts are achieving their goal of preventing the spread of TB.^{42,73}

Continuation Therapy

Regimens

10. Six weeks later, M.W.'s sputum cultures were positive for *M. tuberculosis*. Drug susceptibility tests demonstrated susceptibility to both INH and rifampin. What drug regimen should be

used for continued therapy of M.W.? How long should treatment be continued?

Successful treatment of uncomplicated TB can now be completed in 6 months (26 weeks) if INH, rifampin, pyrazinamide, and ethambutol are used for the first 2 months (8 weeks) and if patient adherence to the regimen and the organism susceptibility can be assured.⁶¹ Therefore, after 8 weeks of DOT with INH, rifampin, pyrazinamide, and ethambutol, M.W.'s regimen may be reduced to INH and rifampin daily (5 days or 7 days per week) or two to three times per week under continued DOT for an additional 18 weeks (Table 61-2). Because M.W. is HIV-negative and her chest radiograph did not reveal cavitory lesions, she may also be a candidate for once weekly administration of INH and rifapentine, as long as her sputum AFB smear is negative after completing the initial 8 weeks of therapy.⁶¹

One study of 160 patients with both pulmonary and extrapulmonary TB demonstrated the effectiveness of a primarily twice-weekly treatment regimen. It consisted of INH 300 mg, rifampin 600 mg, pyrazinamide 1.5 to 2.5 g, and streptomycin 750 to 1,000 mg intramuscularly (IM) daily for 2 weeks, followed by the same drugs twice weekly at higher doses (except rifampin) for an additional 6 weeks. The regimen was then reduced to INH and rifampin twice weekly for the remaining 16 weeks (4 months). All doses were administered by DOT. Three months after beginning therapy, 75% of all patients studied had negative sputum cultures, and all patients were culture negative at 20 weeks. A 1.6% relapse rate (two patients) and only minor adverse effects were reported. Another important feature of this regimen is that it is highly cost effective. Among the 6- and 9-month regimens, it is the second lowest in cost, primarily because of the least number of patient–health care worker encounters (62 directly observed doses).⁷⁴

If pyrazinamide cannot be included in the initial regimen, therapy should be initiated with INH, rifampin, and ethambutol for the first 8 weeks. Therapy should be continued with INH and rifampin for 31 weeks given either daily or twice weekly.⁶¹ If drugs other than INH and rifampin are used in the initial phase, treatment must be continued for 18 to 24 months.⁶²

Twice weekly administration of INH (900 mg) and rifampin (600 mg) is recommended for M.W. because this approach requires fewer doses and should result in substantial cost savings.^{61,74} In addition, the relapse rate for the twice- and thrice-weekly INH and rifampin continuation regimens is significantly lower than the once-weekly regimen of INH and rifapentine 600 mg.^{75,76} Five characteristics were identified to be independently associated with increased relapse risk in the INH and rifapentine group: sputum culture positive at 2 months; cavitation on chest radiograph; being underweight; bilateral pulmonary involvement; being a non-Hispanic white person.⁷⁶ A potential explanation for these results is the high protein binding of rifapentine (97%). A study evaluated the safety and tolerability of rifapentine 600 mg, 900 mg, and 1,200 mg once weekly (with INH 15 mg/kg) in 150 HIV-negative patients.⁷⁷ A trend toward more adverse events was observed in the 1,200 mg treatment arm ($p = 0.051$), but the 900-mg dose was well tolerated.⁷⁷ Relapse rates for the higher dose rifapentine regimens were not known, however. A subsequent study demonstrated that low plasma concentrations of INH were associated with failure or relapse with once-weekly INH and rifapentine.⁷⁸

Two patients who relapsed with *M. tuberculosis* mono-resistant to rifamycin had very low INH concentrations.⁷⁸ Rapid acetylation status was a risk factor in those patients who failed or relapsed.⁷⁸ Rifamycin pharmacokinetics did not influence patient outcomes, however.⁷⁸

Treatment with INH and rifampin should be continued for a minimum duration of 26 weeks. Recent recommendations suggest that a full course of therapy is determined more accurately by the total number of doses taken, not solely by the duration of therapy.⁶¹ Thus, 26 weeks is the minimum duration of treatment and accurately indicates the amount of time the drugs are given only if there are no interruptions in drug administration.⁶¹ Pyridoxine 10 to 25 mg/day should be continued throughout the treatment period. If M.W. is symptomatic or smear or culture is positive after 3 months of therapy, she should be re-evaluated for possible nonadherence with her therapy or infection with drug-resistant organisms. Evaluation should include a second culture and a second susceptibility test, consideration of DOT (if not already instituted), and consultation with experts in the treatment of TB.⁴²

Directly Observed Therapy

11. What exactly is DOT, and why is it important that it be used in M.W.?

Directly observed therapy is the practice of a health care provider or other responsible person observing as the patient ingests and swallows the TB medications. DOT is the preferred core management strategy for *all* patients with TB.^{42,46,61} The purpose of DOT is to ensure adherence to TB therapy. DOT not only ensures completion of therapy, but it may also reduce the risk of developing drug resistance. By improving these two factors, it also reduces the risk to the community. DOT can be administered with daily or two- to three-times-per-week regimens. It can be administered to patients in the office or clinic setting, or it be given at the patient's home, school, work, or other mutually agreed on place.^{61,62} Often, enablers or incentives, such as food, clothing, or transportation, are used to improve adherence to DOT. A comprehensive review of DOT-related articles by a consensus panel of public health experts found that the completion rate of TB therapy exceeds 90% when DOT, as recommended by the CDC, is used along with enablers.^{46,79} A study from San Francisco, California found that culture-positive patients treated for active pulmonary TB with DOT had significantly higher cure rates (97.8% vs. 88.6%, $p < 0.002$) and lower TB-related mortality (0% vs. 5.5%, $p = 0.002$) compared with patients treated using self-administered therapy.⁸⁰ Rates of treatment failure and relapse were similar between the two groups.⁸⁰ Although DOT is recommended for all patients, public health departments may not provide it for cost reasons. A study reported the cost-to-benefit analysis of DOT versus self-administered therapy. Although the initial cost of DOT is greater, when the costs of relapse and failure were included in the model, DOT was significantly less expensive, with differences up to \$3,999.00 versus \$12,167.00.⁸¹ When drug resistance develops because DOT was not used, the cost of salvage therapy increases to \$180,000.00 per patient!⁸² It is therefore widely accepted that patients with TB should receive DOT.^{81,83}

Multiple Drug Therapy

12. Why is multiple drug therapy indicated for the treatment of active TB disease? What is the role of each drug in the treatment of TB?

The key to treating active TB disease is multiple drug therapy for a sufficient time to kill the organisms and to prevent development of resistant strains of *M. tuberculosis*. Most cavitory lesions contain 10^9 – 10^{12} organisms, and the frequency of mutations that confer resistance to a single drug is approximately 10^{-6} for INH and streptomycin, 10^{-8} for rifampin, and 10^{-5} for ethambutol.⁶¹ Considering the many organisms involved, patients with active TB disease likely harbor organisms with random mutations that confer drug resistance to a given drug. If a single drug is given, it would reduce the number of drug-susceptible organisms but leave the drug-resistant organisms to replicate. By using multiple drug therapy, the likelihood of encountering organisms with mutations to multiple drugs is reduced. For example, the frequency of concurrent mutations to INH and rifampin would be 10^{-14} (10^{-6} for INH and 10^{-8} for rifampin), making simultaneous resistance to both drugs an unlikely event in an untreated patient.⁶¹ Therefore, monotherapy has no place in the treatment of active TB disease.^{61,82}

Multiple drug therapy also serves to sterilize the sputum and lesions as quickly as possible. The drugs available for the treatment of TB vary in their ability to accomplish this task.⁶¹ Drugs effective against tubercle bacilli can be divided into first-line and second-line agents (Table 61-3). The foundation of treatment should be with first-line agents, such as INH, rifampin, pyrazinamide, and ethambutol. Of the various agents, INH has the most cidal activity versus rapidly multiplying *M. tuberculosis* during the initial phase of therapy (early bactericidal activity), followed by ethambutol, rifampin, and streptomycin.^{84–86} Drugs that have potent early bactericidal activity more rapidly decrease the infectiousness of the patient and reduce the likelihood of developing resistance within the bacillary population.⁶¹ Pyrazinamide has weak early bactericidal activity during the first 2 weeks of therapy and is less effective at preventing emergence of drug resistance than INH, rifampin, and ethambutol.^{61,84,87} Therefore, pyrazinamide should not be combined with only one other agent when treating active TB disease. Rifampin also has activity against intracellular organisms that are usually dormant but undergo periods of active growth. This ability to penetrate and destroy the persistent intracellular organisms makes rifampin extremely valuable in short-course chemotherapy regimens.⁸⁸

Pyrazinamide is most effective against tubercle bacilli in the acidic environment within the macrophage or areas of tissue necrosis. In addition, it is most effective in sterilizing lesions when used in the first 2 months of treatment, but it does not offer substantial sterilizing activity after 2 months. Pyrazinamide is an essential component of the short-course regimens and must be prescribed for regimens as short as 6 months to be effective.^{61,62}

Ethambutol is bacteriostatic at low doses and bactericidal at higher doses. It is moderately effective against the fast-growing bacilli. It has little sterilizing activity and is primarily used to prevent the emergence of drug-resistant organisms.⁶²

Streptomycin is bactericidal against the rapidly multiplying extracellular organisms and is effective when given daily for 2

months followed by two to three times weekly administration thereafter. In the past, streptomycin was administered by IM injection, but these IM injections were painful. Therefore, although it is not labeled for IV use, streptomycin may be given in 50 to 100 mL 5% dextrose in water or normal saline and infused over 30 to 60 minutes.⁸⁹ Also, as with all aminoglycosides, streptomycin can cause ototoxicity and nephrotoxicity.^{62,89}

The other drugs used in the treatment of TB (capreomycin, amikacin, cycloserine, ethionamide, para-aminosalicylic acid) are usually reserved for cases involving drug-resistant organisms, treatment failures, drug toxicity, or patient intolerance to the other agents. Their use is discussed later in the chapter (see Question 23).

Monitoring Drug Therapy

Subjective Symptoms

13. What subjective and objective findings should be followed to ensure therapeutic efficacy and minimize drug toxicity? Should M.W. be followed closely after completion of her treatment regimen?

M.W. should be questioned about the occurrence of adverse reactions secondary to the INH and rifampin (Table 61-3). Specifically, she should be asked about anorexia, nausea, vomiting, or abdominal pain, which may be an indication of possible hepatitis. Because she has diabetes and is at greater risk for the development of peripheral neuropathy, she should be questioned about numbness and tingling in her extremities. INH-induced peripheral neuropathy, however, should not be a problem in M.W. because she is also taking pyridoxine, which should prevent this adverse effect. M.W. also should be examined for, and questioned about, petechiae or bruises, because thrombocytopenia occasionally is seen with intermittent rifampin therapy. This effect purportedly occurs more frequently with intermittent rifampin therapy, but it is rare at the currently recommended intermittent rifampin dose of 10 mg/kg/day (~600 mg).⁶²

In a study comparing 6-month versus 9-month antituberculosis therapies of mostly INH and rifampin in 1,451 patients, the incidence of side effects was similar between the two groups. Adverse effects occurred in 7.7% of patients in the 6-month arm compared with 6.4% in the 9-month arm, a difference that was not statistically significant (95% CI, 0.0–4.6%).⁹⁰ Hepatic disturbances occurred in 1.6% of patients in the 6-month regimen, a nonsignificant difference from patients in the 9-month regimens (1.2%). Hematologic disturbances were rare at 0.2% and 0.0% in the 6-month and 9-month groups, respectively. Other reported effects, gastrointestinal (GI) problems, rash, and arthralgias, were minor and infrequent in both regimens.⁹⁰

Objective Signs

A pretreatment complete blood count, platelet count, blood urea nitrogen (BUN), hepatic enzymes (serum aminotransferases), bilirubin, and serum uric acid should be evaluated. Baseline visual examination should also be considered for patients receiving ethambutol. These tests are performed to detect any abnormality that may complicate or necessitate modification of the prescribed regimen. They should be repeated if the

patient experiences any evidence of drug toxicity or has abnormalities at baseline.^{61,62}

M.W. is >35 years of age and at increased risk for development of drug-induced hepatotoxicity. INH can cause asymptomatic increases in serum transaminases as well as clinical hepatitis.⁶¹ Pyrazinamide has also been associated with hepatotoxicity, but the incidence is less common at doses of 25 mg/kg/day. Transient asymptomatic hyperbilirubinemia and typically cholestatic hepatitis can occur in patients receiving rifampin.⁶¹ Therefore, it is important that that patient be instructed about possible symptoms of hepatotoxicity, primarily nausea, vomiting, abdominal pain, anorexia, and jaundice. Monthly serum liver function tests (LFT) are no longer recommended because they are costly, transient, asymptomatic elevations occur, and it may result in discontinuation of optimal therapy. The CDC recommends that medical personnel question the patient about symptoms once monthly.⁶²

Sputum cultures and smears for AFB should be ordered every 2 to 4 weeks initially and then monthly after the sputum cultures become negative. With appropriate therapy, sputum cultures should become negative in >85% of patients after 2 months. At this point, they will usually need only one more sputum smear and culture at the completion of therapy. Radiologic examination (chest radiographs) is not as important as sputum examination, but it may be useful at the completion of therapy to serve as a comparison for any future films.

Patients who are culture-positive at 2 months need to be carefully re-examined. Drug susceptibility testing should be performed to rule out acquired drug resistance, and special attention should be given to drug adherence (i.e., DOT should be used). If drug resistance is demonstrated, the regimen should be modified as needed (see MDR-TB, Question 23). Sputum cultures should also be obtained monthly until negativity is achieved.⁶²

As was the case for M.W., weight loss and nutritional depletion are common in patients with active TB disease. In a large TB treatment study, 7.1% of patients experienced relapse, with relapse greatest in patients who were underweight at diagnosis (19.1% vs. 4.8%, $p < 0.001$) or with a body mass index $< 18.5 \text{ kg/m}^2$ (19.5% vs. 5.8%, $p < 0.001$).⁹¹ In those patients underweight at diagnosis (defined as $\geq 10\%$ below ideal body weight), weight gain of 5% or less between diagnosis and completion of 2 months of therapy was independently associated with relapse (odds ratio 2.4, $p = 0.03$).⁹¹ In addition, the relapse rate was 50.5% in underweight patients with a cavitary lesion on chest radiograph, positive sputum cultures after 2 months of therapy, and $\leq 5\%$ weight gain in the first 2 months of therapy.⁹¹ Therefore, it may be prudent to monitor M.W.'s weight during the initial 2 months of therapy and M.W. may need to receive more intensive therapy or a longer duration of therapy.

Routine follow-up usually is not required after the successful completion of chemotherapy with INH and rifampin. It may be prudent, however to re-examine the patient 6 months after completion of therapy or at the first sign of any symptoms suggestive of active TB. This is especially important in patients who were slow to respond to therapy or who have significant radiologic findings at completion of therapy. These recommendations are only for those patients with organisms fully susceptible to the medications being used.⁶²

Patients who are culture negative but have radiographic abnormalities consistent with TB should have an induced sputum or bronchoscopy performed to establish a microbiologic diagnosis and monitored radiographically. Patients with extrapulmonary TB should be evaluated according to the site of involvement.^{61,62}

Treatment Failure

14. If M.W. does not respond to her current therapy, should one more drug be added to her regimen?

No! Adding a single drug to a failing regimen is the most common and devastating mistake in TB therapy today. This practice is essentially monotherapy because the assumption is that the organisms are resistant to the medications currently being used. Resistance to the new drug will eventually develop, further reducing the patient's chance of cure. At least two, and preferably three, new drugs to which susceptibility can be inferred should be added to lessen the probability of further acquired drug resistance. Empiric retreatment regimens may include a fluoroquinolone, an injectable agent (e.g., streptomycin, amikacin, or capreomycin), and an additional oral agent (e.g., para-aminosalicylic acid, cycloserine, or ethionamide).⁶¹ New susceptibilities should be obtained and treatment adjusted accordingly.^{1,61,82}

TREATMENT OF LATENT TB INFECTION

15. M.W.'s 38-year-old husband, S.W., is skin tested with 5-TU PPD to determine whether he is infected with *M. tuberculosis*. He has a 10 mm reaction to the tuberculin skin test, which is classified as positive. He does not have any clinical symptoms or radiographic findings suggestive of active TB at this time. Is he at risk of developing active disease? What are the current recommendations for drug therapy for persons with latent TB infection? Should S.W. be treated?

Because S.W. is a household contact of a person with active TB disease and has a positive tuberculin skin test, he is at great risk of becoming infected and developing active disease.^{33,34} During the first year after infection from the source case, a household contact's risk of developing active disease is 2% to 4%, with persons having a positive skin test at the greatest risk.⁶²

Treatment of latent TB infection is effective in preventing active TB disease in persons who have positive tuberculin skin tests and in those at risk for reactivation of active TB; therefore, it is strongly recommended.^{33,34,42} Treatment decreases the population of tubercle bacilli and reduces future morbidity from TB in the groups at high risk for developing active disease. In clinical studies, INH prevents TB in up to 93% of persons who receive the drug, depending on the duration of therapy and patient adherence to the prescribed regimen.³³ Although debate regarding the issue continues, the benefits of treating latent TB infection outweigh the risks of INH-induced hepatitis because all persons infected with TB is at risk for developing active disease throughout their lifetime.^{2,62}

S.W. is infected with *M. tuberculosis*, but he does not currently have active TB disease. In 2000, the CDC recommended four regimens for the treatment of latent TB infection, and daily

INH for 9 months was the preferred regimen.³³ Studies in HIV-negative persons indicated that 12 months of INH was more effective than 6 months; however, the maximal benefit on INH is likely achieved by 9 months. Daily INH for 6 months and twice weekly INH for 6 or 9 months are also recommended treatment options for latent TB infection.³³ In a population of 3,788 patients beginning INH treatment for latent TB, only 64% of patients completed at least 6 months of therapy.⁹² Higher completion rates were associated with younger age, Hispanic ethnicity, and non-U.S. country of birth.⁹² Lower completion rates were associated with homelessness, excess alcohol intake, and experiencing an adverse event.⁹² One or more adverse event, generally age related, was reported in 18% of patients. INH-associated liver injury was seen in only 0.3% of patients.⁹²

Because of concerns about INH toxicity and poor adherence secondary to the relatively long duration of therapy, shorter rifampin-based regimens were also recommended. Rifampin and pyrazinamide, daily for 2 months or twice weekly for 2 to 3 months, and daily rifampin monotherapy for 4 months were recommended alternatives to INH therapy.³³ In 2001, however, severe and fatal hepatitis was reported in two patients receiving rifampin and pyrazinamide for latent TB infection.⁹³ Both patients developed anorexia and malaise, and liver functions tests revealed an alanine aminotransferase and an aspartate aminotransferase (AST) greater than 20 times the upper limit of normal. The total bilirubin peaked at 17.8 mg/dL and 27.5 mg/dL in the first and second patient, respectively.⁹³ Later in the same year, the CDC reported an additional 21 cases of liver injury associated with the 2-month rifampin and pyrazinamide regimen.⁹⁴ Of these 21 cases, 16 patients recovered and 5 patients died of liver failure. The onset of liver injury occurred during the second month of the 2-month course in those who died.

To reduce the risk of liver injury associated with rifampin and pyrazinamide therapy, the American Thoracic Society and the CDC, with the endorsement of the Infectious Diseases Society of America, have published revised recommendations for the treatment of latent TB infection.⁹⁴ For persons not infected with HIV, daily INH therapy for 9 months remains the preferred regimen, and 4 months of daily rifampin is an acceptable alternative. The 2-month rifampin and pyrazinamide regimen should be used with caution, if at all, especially in patients receiving medications associated with liver injury or those with alcoholism. No more than a 2-week supply of INH and pyrazinamide should be dispensed at a time to facilitate periodic clinical assessments of the patient. Serum aminotransferases and bilirubin should be measured at baseline, and at 2, 4, and 6 weeks of treatment in patients receiving the rifampin and pyrazinamide regimen.⁹⁴

Daily rifampin for 4 months was compared with daily INH for 9 months to assess completion of therapy and costs in a relatively small study of patients with latent TB infection.⁹⁵ For the patients randomized to rifampin, 91% took 80% of the doses, and 86% took more than 90% of the doses at 20 weeks.⁹⁵ For the patients randomized to INH, 76% took 80% of the doses, and only 62% took more than 90% of the doses at 43 weeks.⁹⁵ Discontinuation of therapy because of adverse events was more common in the INH group (14%) versus the rifampin group (3%), and the total cost of therapy was significantly less in the rifampin group.⁹⁵ Rifampin for 4 months is an effective,

safe, and affordable strategy to consider when treating latent TB infection in selected populations of patients.^{95,96}

In a study of 399 household contacts of patients with newly diagnosed pulmonary TB with a positive PPD, TB rates, adverse events, and adherence to therapy were compared between weekly rifapentine and isoniazid for 12 weeks and daily rifampin and pyrazinamide for 8 weeks.⁹⁷ Adherence to therapy was $\geq 95\%$ in both groups. Four patients developed active TB disease: three in the rifapentine and INH group and one in the rifampin and pyrazinamide group ($p = \text{NS}$).⁹⁷ Of patients in the rifapentine and INH group, 1% experienced hepatotoxicity compared with 10% in the rifampin and pyrazinamide group. Although more data are needed, weekly rifapentine and INH may be an alternative for treatment of latent TB infection.

S.W. should be placed on INH 300 mg/day for at least 6 months and preferably up to 9 months or rifampin for 4 months.^{33,94} Although at increased risk of developing INH-associated liver damage (2.3%) because of his age, S.W. also has a high risk for developing active TB. In this case, the benefits of treatment outweigh the possible risks of hepatitis. S.W. should be educated and questioned frequently about the clinical symptoms of hepatitis, such as GI complaints. Pretreatment serum aminotransferases and bilirubin should be assessed to rule out pre-existing liver disease. The American Thoracic Society and the CDC do not recommend routine monitoring of LFT unless symptoms suggest hepatotoxicity.⁶²

ADVERSE DRUG EFFECTS

Isoniazid

Hepatotoxicity

16. After 2 months of INH therapy, S.W. was found to have an AST of 130 U/L (normal, 7–40). Discuss the presentation, prognosis, and mechanism of INH-induced hepatitis. What are the risk factors for developing hepatitis? Should INH be discontinued to prevent further liver damage?

[SI unit: 130 U/L]

Approximately 10% to 20% of patients treated with INH alone for latent TB infection will develop elevated serum aminotransferases, which are generally transient and asymptomatic.^{61,98} Most patients with mild, subclinical hepatic damage do not progress to overt hepatitis and recover completely even while continuing INH. In contrast, continuation of INH in patients with symptoms of hepatitis increased the risk of mortality compared with immediate discontinuation.⁶¹ The risk of death from TB, however, is estimated to be 11 times higher than the risk of death from INH hepatotoxicity.⁹⁹

Isoniazid-induced hepatotoxicity generally occurs within weeks to months of initiating therapy; 60% of cases occur in the first 3 months and 80% occur in the first 6 months.⁹⁸ Constitutional symptoms may be seen early and may last from days to months. Nausea, vomiting, and abdominal pain are seen in 50% to 75% of patients with severe hepatotoxicity.⁹⁸ Jaundice, dark urine, and clay-colored stools may also be seen. Recovery may take weeks after discontinuing INH therapy. The development of INH hepatotoxicity has been linked to several factors, including acetylator phenotype, age, daily alcohol consumption, and concurrent rifampin use. Additionally, women may

be at higher risk of death, especially during the postpartum period.⁹⁹

The mechanisms responsible for INH hepatotoxicity remain unclear. Previously, it was thought that rapid acetylators had a greater risk for INH hepatotoxicity than slow acetylators. Rapid acetylators of INH form monoacetylhydrazine, a compound that can cause liver damage, more rapidly than slow acetylators.¹⁰⁰ Rapid acetylators also would eliminate monoacetylhydrazine at a faster rate, however, and this should equalize the risk of toxicity between slow and fast acetylators.¹⁰¹ One study demonstrated a different incidence of hepatitis between Asian males and females. Because both groups were fast acetylators, this study suggests that hepatitis is associated with factors other than acetylator phenotype.¹⁰² Acetylator status alone does not explain the development of INH hepatotoxicity. Some evidence supports the theory that INH-induced hepatitis is a hypersensitivity reaction; however, many patients tolerate INH on rechallenge, discounting this theory.^{103,104}

Age and concurrent daily alcohol ingestion are the most consistent risk factors for INH hepatitis.⁶² Progressive liver damage is rare in persons <20 years of age. It occurs in approximately 0.3% of persons between the ages of 20 and 34 years, 1.2% of those between the ages of 35 and 49 years, and 2.3% of persons >50 years of age.⁶² One prospective cohort study, however, demonstrated a low incidence of INH hepatitis. Of 11,141 patients receiving INH alone for the treatment of latent TB infection, only 11 (0.1% of those starting and 0.15% of those completing therapy) developed clinical hepatitis.¹⁰⁵ Previous studies suggested a higher incidence of clinical hepatitis in patients receiving INH alone, and a meta-analysis of six studies estimated the rate to be 0.6%.⁶¹

High-risk patients should be followed with routine monitoring of LFT. These patients include those who consume alcohol daily, persons >35 years of age, those taking other hepatotoxic drugs, those with pre-existing liver disease, IV drug abusers, black and Hispanic women, and all postpartum women. In these high-risk patients, INH should be discontinued if the AST level exceeds three to five times the upper limit of the normal value.⁶² Because S.W.'s AST is three times the upper range of the normal value and he is >35 years of age, INH should be discontinued temporarily until the AST returns to normal. At that time, INH should be resumed, and his LFT rechecked. If the AST increases again, the drug should be discontinued and S.W. should be followed frequently for development of active TB.

17. C.M., a 50-kg, 35-year-old woman, is being treated for active TB disease with INH 1,200 mg and rifampin 600 mg twice weekly. Is 1,200 mg of INH twice weekly an appropriate dose for a 50-kg patient? What INH side effects, other than hepatotoxicity, should be anticipated?

The usual twice-weekly INH dose is 15 mg/kg, with a maximal dose of 900 mg; therefore, C.M. should be receiving no more than 900 mg rather than 1,200 mg of INH. Although high doses or increased serum concentrations have not been linked with hepatitis, elevated serum INH concentrations have been associated with increased central nervous system (CNS) effects, ranging from somnolence to psychosis and seizure. GI complaints are also more commonly observed at doses >20 mg/kg.

Peripheral Neuropathy

Although uncommon at both the recommended daily and intermittent doses, INH can cause a peripheral neuropathy by interfering with pyridoxine (vitamin B₆) metabolism.^{33,61} As many as 20% of patients may experience this problem with INH doses >6 mg/kg/day. Numbness or tingling in the feet or hands is the most common neuropathic symptom. In patients with medical conditions where neuropathy is common, such as diabetes mellitus, alcoholism, HIV infection, malnutrition, and renal failure, supplemental pyridoxine 25 mg/day should be given with INH.^{33,61} Women who are pregnant or breastfeeding and persons with seizure disorders should also receive supplemental pyridoxine with INH.³³

Allergic Reactions

Allergic reactions consisting of arthralgias, skin rash, swelling of the tongue, and fever have also occurred. INH has been associated with arthritic symptoms and systemic lupus erythematosus; approximately 20% of patients receiving INH develop antinuclear antibodies.⁶¹

Other Reactions

Other reactions that might occur with INH are dry mouth, epigastric distress, CNS stimulation and depression, psychoses, hemolytic anemia, pyridoxine-responsive anemia, and agranulocytosis.¹⁰³

Drug Interactions

In addition to the previously mentioned adverse reactions, INH is a relatively potent inhibitor of several cytochrome P450 isoenzymes (CYP2C9, CYP2C19, CYP2E1), but has minimal effects on CYP3A.⁶¹ INH inhibits the hepatic metabolism of phenytoin and carbamazepine, resulting in increased plasma concentrations of these drugs. Patients receiving either of these two drugs with INH should be observed for signs of phenytoin or carbamazepine toxicity, such as nystagmus, ataxia, headache, nausea, or drowsiness. Plasma phenytoin and carbamazepine concentrations should be monitored periodically so that the doses can be adjusted if necessary. Carbamazepine also may induce INH hepatitis by inducing its metabolism to toxic metabolites.¹⁰⁶ In addition, INH inhibits the metabolism of diazepam and triazolam. It is important to note that rifampin has the exact opposite effect on hepatic metabolism. Rifampin is a stronger inducer than INH is an inhibitor as documented by the fact that INH-rifampin combination therapy induces the metabolism of diazepam, phenytoin, and other agents metabolized by the cytochrome P450 system.¹⁰⁷

Rifampin

Flu-like Syndrome

18. One month after beginning her twice-weekly DOT regimen, C.M. developed symptoms of myalgias, malaise, and anorexia. Laboratory data were normal except for a slightly decreased platelet count. Could C.M.'s symptoms be related to her drug therapy? What adverse reactions other than hepatotoxicity should be anticipated in a patient receiving rifampin?

A flu-like syndrome has been reported in about 1% of patients receiving intermittent rifampin administration. This

syndrome is rarely seen with usual doses of 600 mg twice weekly, but the incidence increases with twice-weekly doses >900 mg. The incidence also increases if the dosage interval is increased to 1 week or longer.^{108,109} Unless the symptoms are severe, discontinuation of the drug is unnecessary. Because C.M. is receiving rifampin 900 mg twice weekly, her dose should be reduced to 600 mg and administered daily until the symptoms subside. The temporary administration of a nonsteroidal anti-inflammatory drug (NSAID) has been used to alleviate the flu-like symptoms. Twice-weekly therapy may then be resumed as long as the dose of rifampin does not exceed 600 mg.

Hepatotoxicity

Rifampin (rifapentine) is associated with a <1% rate of hepatotoxicity. Therefore, the risk of drug-induced hepatotoxicity is greater with INH than with rifampin. On occasion, rifampin can cause hepatocellular injury and potentiate hepatotoxicity of other antituberculosis drugs.⁹⁸ Although elevations of liver enzymes are seen on occasion, rifampin is more likely to produce cholestasis, as manifested by increases in alkaline phosphatase and hyperbilirubinemia without hepatocellular injury.⁹⁸ Elevations of all liver function tests may be seen transiently during the first month of rifampin therapy, but they are usually benign.⁶¹

Thrombocytopenia

Thrombocytopenia is more frequently associated with intermittent or interrupted rifampin administration, likely caused by production of IgG and IgM antibodies to rifampin. These antibodies likely fix complement onto the platelets, resulting in platelet destruction. Hypothetically, intermittent or interrupted rifampin therapy results in increased antibody production resulting in destruction of platelets. Once thrombocytopenia occurs with rifampin, its subsequent use is contraindicated because the problem will likely recur.^{110,111}

Miscellaneous Reactions

In addition to the side effects associated with high-dose, intermittent therapy, 3% to 4% of patients taking normal doses of rifampin may experience adverse reactions.¹¹⁰ The most common of these are nausea, vomiting, fever, and rash. Other reactions to rifampin include the hepatorenal syndrome, hemolysis, leukopenia, anemia, and arthralgias as part of a suspected drug-induced lupus syndrome.^{61,112} The development of these latter reactions would require discontinuation of the drug.

Acute Renal Failure

Acute renal failure has also occurred rarely with rifampin.⁶¹ This hypersensitivity reaction may occur with both intermittent and daily administration and may last as long as 12 months.¹⁰⁸ Rifampin should be discontinued, and other drugs (e.g., pyrazinamide and ethambutol) should be given. The dose of ethambutol should be adjusted for renal dysfunction. Both rifampin and INH may, however, be given in normal dosages to patients with pre-existing renal failure.^{113,114}

Another important characteristic of rifampin relates to its chemical makeup. It is an orange-red crystalline powder that is distributed widely in body fluids. As a result, it can discolor saliva, tears, urine, and sweat.⁶¹ Patients using rifampin should be warned of this effect and cautioned not to use soft contact lenses because of possible discoloration. This effect may also be used to monitor adherence to rifampin therapy.

Drug Interactions

Rifampin is a potent inducer of cytochrome P450 isoenzymes, especially CYP3A4.⁶¹ The rifamycins differ in their ability to induce cytochrome P450 isoenzymes, in which rifampin is the most potent, rifapentine is intermediate, and rifabutin is the least potent enzyme inducer.⁶¹ Rifampin increases the metabolism of protease inhibitors, nonnucleoside reverse transcriptase inhibitors, macrolide antibiotics, azole antifungal agents, corticosteroids, oral contraceptives, warfarin, cyclosporine, tacrolimus, theophylline, phenytoin, quinidine, diazepam, propranolol, metoprolol, sulfonyleureas, verapamil, nifedipine, diltiazem, enalapril, and simvastatin.^{61,107} While the patient is receiving rifampin, it may be necessary to monitor serum concentrations of the aforementioned drugs, where appropriate, or increase their dosages. Also, women who are taking rifampin and oral contraceptives should use an alternative method of birth control. When treating any patient with rifampin, the health care professional should carefully evaluate all concomitant medications for the possibility of drug–drug interactions.

INH-Rifampin

Hepatotoxicity

19. Does the combination of INH and rifampin cause hepatotoxicity more frequently than either drug alone?

Some initial evidence suggested that the use of INH and rifampin together was associated with a greater incidence of hepatotoxicity. The mechanism was thought to be owing to rifampin induction of the metabolism of INH to either monoacetylhydrazine or to other hepatotoxic products of hydrolysis. Steele et al.¹⁰⁴ performed a meta-analysis reviewing the incidence of hepatitis between 1966 and 1989 using regimens that contained INH without rifampin, rifampin without INH, and regimens containing both drugs. They found the incidence of clinical hepatitis was greater in regimens containing both INH and rifampin (2.7%) versus regimens of INH alone (1.6%), but this effect was additive, not synergistic, and therefore expected.¹⁰⁴ The use of the two drugs together, therefore, is not contraindicated. Caution should be used in high-risk groups such as the elderly, alcoholics, those receiving concomitant hepatotoxic agents, and those with pre-existing liver disease.⁹⁸

Ethambutol

Optic Neuritis

20. S.E., a 65-year-old woman, was placed on INH 300 mg/day, rifampin 600 mg/day, pyrazinamide 900 mg/day, and ethambutol 1,200 mg/day for initial treatment of active pulmonary TB.

Two months after the initiation of therapy, she began to complain of blurred vision. A routine eye examination and visual field tests yielded a diagnosis of optic neuritis. No evidence was seen of glaucoma, cataracts, or retinal damage. Laboratory tests were within normal limits except for an elevated serum uric acid (9.7 mg/dL; normal, 2–8 mg/dL) and a slightly elevated serum creatinine (SrCr) (1.6 mg/dL; normal, 0.6–1.4 mg/dL). No symptoms of joint pain were associated with the elevated serum uric acid, and there was no history of gout. Her calculated creatinine clearance (ClCr) based on her weight of 65 kg was 35 mL/minute. Could the visual problem and increased uric acid levels be related to her medications?

[SI units: uric acid, 576.96 mol/L; SrCr, 123.76 mol/L; ClCr, 0.83 mL/sec]

S.E.'s decrease in visual acuity is compatible with ethambutol-induced optic neuritis. This condition is characterized by central scotomas, loss of red-green color vision, or less commonly, a peripheral vision defect. The intensity of these ocular effects is related to the duration of continued therapy after decreased visual acuity is first noted. The optic neuritis is dose and duration related. The optic neuritis is rare at doses of 15 mg/kg.^{115–117} The incidence is estimated to be 6% for doses of 25 mg/kg and increases to 15% for doses >35 mg/kg. Recovery, which may take many months, is usually, but not always, complete when the drug is discontinued.

The optic neuritis manifested in S.E. is probably caused by the use of an increased ethambutol dose (18.5 mg/kg) in a patient with impaired renal function (estimated ClCr 35 mL/minute). Because ethambutol adds no additional benefit to the INH and rifampin regimen after the first 2 months unless drug-resistant organisms are suspected, it can be discontinued. Because ethambutol is excreted by the kidney (50%–80%), her ethambutol dosage interval (or dosage) for ethambutol should have been increased based on the decline in creatinine clearance.¹¹³ Her visual acuity should be monitored closely through periodic eye examinations, and she should be instructed to contact her physician immediately if she experiences any further visual changes.

S.E.'s elevated serum uric acid also may be attributed to her ethambutol as well as a decline in her renal function, but it is more likely caused by pyrazinamide, which decreases the tubular secretion of urate.⁹⁰ Asymptomatic hyperuricemia secondary to drugs usually does not require treatment.

SPECIAL TREATMENT CONSIDERATIONS

The Elderly

Incidence

21. G.H., a 75-year-old, 80 kg man who resides in a nursing home, becomes disoriented, refuses to eat, and has a productive cough. Physical examination reveals a thin man who is having slight difficulty breathing. Laboratory findings are essentially normal with the exception of a slightly elevated BUN of 25 mg/dL (normal, 10 to 20 mg/dL) and SrCr of 1.3 mg/dL (normal, 0.6–1.3 mg/dL). A chest radiograph reveals infiltrates in the right lower lobe; he has a history of congestive heart failure, which is well controlled. Blood, urine, and sputum samples are sent for culture and susceptibility testing; the initial Gram stain is negative. Because the nursing home has recently had two cases of active

TB, a PPD skin test and sputum smear for AFB are ordered. The PPD skin test induration is 16 mm, and the sputum smear is positive for AFB. G.H.'s admission skin test several months ago was negative. Discuss the presentation of TB in the elderly, and the appropriate treatment of active disease in G.H. Is the incidence of drug side effects higher in the elderly? Should other patients in close contact with G.H. receive INH therapy?

[SI units: BUN, 8.93 mmol/L of urea (normal, 3.57–7.14); SrCr, 114.92 mol/L (normal, 53.04–88.4)]

The case rate of TB in adults ≥ 65 years is increased over all other age groups (7.7 per 100,000 population).¹³ In 2005, 2.4% of TB cases were reported in residents of long-term care facilities,¹³ and the case rate for nursing home residents is 1.8 times higher than that for elderly persons living in the community.¹¹⁸ Active TB disease in the elderly has been attributed to a decrease in the immune system followed by reactivation of an earlier infection, but active disease is a common, endemic infection in nursing home patients with no previous immunity (negative skin test) to *M. tuberculosis*.^{118,119} The incidence of positive skin tests increases after patients have been in the nursing home >1 month. Therefore, all patients entering a nursing home should be tested with 5-TU PPD. If the initial test is negative and a source case is present in the nursing home (as illustrated by this case), this test should be repeated in 1 month. The rate of tuberculin skin test conversion (from negative to positive tests) in this population is approximately 5%. If these recent converters are not treated with INH, approximately 17% will develop progressive pulmonary TB.¹²⁰

Diagnosis

The diagnosis of active TB in elderly patients is difficult because the classic symptoms of TB (cough, fever, night sweats, weight loss) are often absent, and elderly patients may describe their symptoms poorly. The chest radiograph and PPD skin test may be the only signs of TB infection.^{118,120} Frequently, the chest radiograph is atypical, resembling pneumonia or worsening heart failure. Chest radiographs in the elderly are less likely to have upper lobe infiltration, but more commonly have extensive infiltration of both lungs.¹²¹ If the patient's clinical disease is caused by granuloma breakdown (reactivation), the chest radiograph often shows apical infiltrates or nodules. If the disease is progressing from an initial infection, as in the case of G.H., lower lobe infiltrates may be present.¹¹⁸ TB in this population may present clinically with changes in activities of daily living, chronic fatigue, cognitive impairment, anorexia, or unexplained low-grade fever. Nonspecific signs and symptoms that range in severity from subacute to chronic and that persist for weeks to months must alert clinicians to the possibility that unrecognized TB is present.¹²² Sputum examination for *M. tuberculosis*, and AFB smear and culture should be performed in all patients, including the elderly.

Treatment of Active Disease in the Elderly

The principles of TB treatment are the same for the elderly as for any other age group.^{61,118} Because G.H. has clinical symptoms of a respiratory infection, positive sputum smears for AFB, and a positive tuberculin skin test, he should be treated with a four-drug regimen for active TB disease. Most TB cases in elderly patients are caused by drug-susceptible strains of *M. tuberculosis*; however, notable exceptions would be older

patients who are from a country or region where the prevalence of drug-resistant strains is high, persons who have been inadequately treated in the past, or persons who acquired the infection from a recent contact known to be infected with drug-resistant *M. tuberculosis*.¹²² G.H.'s drug regimen likely would include INH 300 mg, rifampin 600 mg, pyrazinamide 20 to 25 mg/kg daily, and ethambutol 15 to 20 mg/kg daily for 8 weeks followed by INH and rifampin daily or 2 to 3 times a week for 16 weeks (DOT). Another option might be INH, rifampin, pyrazinamide, and ethambutol daily for 2 weeks, followed by twice weekly for 6 weeks, then INH and rifampin twice weekly for 16 weeks.¹²² Some clinicians prefer treating the elderly with 9-month regimens of INH and rifampin. G.H. should also receive pyridoxine 10 to 50 mg with each dose.⁶²

Adverse Drug Effects

Although INH hepatitis is more common in elderly patients, both INH and rifampin are generally well tolerated within this age group, with major hematologic or hepatic side effects occurring in 3% to 4% of patients.¹²³ Therefore, serum aminotransferases should be assessed at baseline, and G.H. should be observed monthly for clinical signs of hepatitis. As discussed, routine monitoring of LFT remains controversial because transient, asymptomatic rises do occur among the elderly.¹²³

Although uncommon at 600 mg, rifampin given twice weekly may cause a greater incidence of flu-like symptoms. Because potential drug interactions with INH and rifampin are possible, any medication added to the patient's regimen should be carefully evaluated. Considering that G.H. has age-related decreased renal function, signs of ethambutol-induced visual dysfunction should be monitored carefully.

Treatment of Latent Infection in the Elderly

Treatment of elderly patients with positive tuberculin skin tests but no active TB disease with INH 300 mg daily for 6 to 9 months is essential if a source case is present in the nursing home. Stead et al.¹²⁰ reported only one case of active disease in patients receiving therapy for latent TB infection compared with 69 cases in untreated patients. In patients with recently converted skin tests, one patient in the group receiving INH therapy developed active disease compared with 45 who received no treatment.¹²⁰ Rifampin for 4 months is also an acceptable regimen in the elderly.¹¹⁸

Multidrug-Resistant Organisms

Definition and Etiology

22. M.S., an ill-appearing 22-year-old Asian man, is admitted to the hospital with signs and symptoms of pneumonia. He is coughing and his chest radiograph indicates bilateral infiltrates. He is placed in respiratory isolation pending the results of sputum testing for *M. tuberculosis*. He states that he was diagnosed with TB 3 months ago and started on a regimen of INH, rifampin, pyrazinamide, and ethambutol. He stopped taking his medication after 1 month, and an HIV test from 3 months ago was negative. What is the likelihood of acquired drug resistance?

Drug-resistant *M. tuberculosis* became increasingly prevalent in the United States in the late 1980s to early 1990s, although this has decreased in more recent years.^{3,4,13,124,125} In 2005, the incidence of INH resistance in the United States

was 7.3%, and the incidence of resistance to both INH and rifampin (multidrug-resistance) was 1.0%.¹³ These resistance rates have remained stable for the past 10 years.¹³ Resistance to *M. tuberculosis* is either primary or acquired. Primary drug resistance occurs when a patient harbors a resistant strain before any drugs have been administered. Acquired drug resistance occurs when resistant subpopulations are selected by inappropriate therapy.⁸² The World Health Organization (WHO) conducted a global survey of drug resistance in *M. tuberculosis*, which showed that resistance to at least one antituberculosis drug occurs in a median of 9.9% of strains in patients never having received treatment (primary) and in 36.0% of strains in patients who received treatment for at least 1 month (acquired). Based on these results, acquired drug resistance is a larger problem.¹²⁵

Acquired drug resistance may be the result of treatment errors, such as addition of a single drug to a failing regimen, inadequate primary regimen, failure to recognize resistance, and, most importantly, nonadherence to the prescribed regimen. Sporadic ingestion, inadequate dosages, or malabsorption of medications can cause susceptible *M. tuberculosis* strains to become resistant to multiple drugs within a few months.^{76,126,127} These resistant organisms can then be transmitted to persons who have never received treatment and lead to primary resistance in these patients. Patients with MDR-TB are twice as likely to have cavitory lesions on chest radiography ($p < 0.001$) and seven times more likely to have reported prior treatment for TB ($p < 0.001$).¹²⁸

Patterns and prevalence of drug-resistance vary throughout the world, and the highest rates of MDR-TB are in countries of the former Soviet Union and China. As mentioned, the incidence of MDR-TB in the United States has declined from 2.5% in 1993 and has remained stable at 1.0% over the past 10 years.¹³ Nonetheless, it is important to note that certain populations are at risk for infections caused by MDR-TB. These include HIV-infected persons and those in groups or institutional settings, such as hospitals, prisons, nursing homes, and homeless shelters.¹²⁹

M.S. is Asian and, therefore, may have primary resistance from his country of origin, making a detailed exposure history essential for the treatment of his infection. M.S. is also an example of the problem of treatment failure caused by nonadherence and the potential development of drug-resistant organisms. Homelessness and lack of awareness of the severity of TB have been shown to be significantly associated with interruptions in TB therapy.¹³⁰ Therefore, educational efforts to improve a patient's understanding of TB disease is critical for appropriate treatment of the disease.

Treatment

23. Can M.S. be cured, and how should he be treated?

Many factors can affect the outcome of therapy for MDR-TB. These include HIV status, treatment adherence, the number of drugs to which the tubercle bacilli are still susceptible, and the time since the first diagnosis of TB.¹³¹⁻¹³³ In a recent study, all 11 patients who were HIV-positive died during observation.¹³² In another study, 77% of patients with MDR-TB had sputum cultures convert to negative in a median time of 60 days (range, 4-462 days), but 23% of patients never

converted to negative cultures.¹³³ Of the patients who converted, 60% converted after 4 months of therapy.¹³³ Predictors of a longer time for sputum culture conversion were high initial sputum colony counts, bilateral cavitation on chest radiograph, previous treatment of MDR-TB, and the number of drugs the initial isolate was resistant to at the beginning of therapy.¹³³

Because his recent HIV test was negative, M.S. has a high probability of treatment success. In HIV-negative patients, 32 (97%) of 33 patients with MDR-TB were cured, and these patients received an average of five second-line drugs.¹³² Only one relapse occurred 5 years after treatment.¹³² Therefore, M.S.'s current regimen should be re-evaluated, drug susceptibility testing should be determined, and the patient should be referred to a specialist or consultation at a specialized treatment center.⁶¹ Current drug susceptibility testing in most institutions takes several weeks; however, this can be decreased to 3 weeks with the use of the BACTEC system. When initiating or revising therapy, at least three previously unused drugs to which there is in vitro susceptibility should be employed, and one of these agents should be injectable.⁶¹ A new regimen should contain at least four drugs, possibly more, depending on the severity of the disease and the resistance pattern. If resistance to INH and rifampin is suspected, M.S. should be started on a regimen of pyrazinamide, ethambutol, a fluoroquinolone (levofloxacin, ciprofloxacin, or moxifloxacin), and an injectable agent (streptomycin, amikacin, capreomycin), pending the results of susceptibility testing.⁶¹ Treatment should be given by DOT and continued for 18 to 24 months.^{61,131}

The fluoroquinolone antibiotics, ciprofloxacin, levofloxacin, and moxifloxacin are active against mycobacteria, including *M. tuberculosis*, and they penetrate rapidly into macrophages and exhibit intracellular mycobactericidal activity.¹³¹ Fluoroquinolones inhibit DNA gyrase in *M. tuberculosis*, but the other molecular target of these agents, topoisomerase IV, is absent.¹³¹ Older studies did not demonstrate cross-resistance between fluoroquinolones and other antimycobacterial drugs^{134,135}; however, a recent study found that 76% of ciprofloxacin-resistant strains were resistant to INH and rifampin.⁷² Ciprofloxacin, ofloxacin, and levofloxacin have been used long term for the treatment of mycobacterial infections and were well tolerated with few serious adverse effects.^{135,136} Of the commercially available fluoroquinolones against *M. tuberculosis*, moxifloxacin is the most potent agent.⁶⁶ Limited data suggest that moxifloxacin is an acceptable option in the treatment of MDR-TB.¹³⁷ Selection of fluoroquinolone resistance has been observed in vivo, and complete cross-resistance within the class is the accepted rule.¹³¹ Other medications used for MDR-TB include para-aminosalicylic acid, cycloserine, ethionamide, and capreomycin. These are all associated with numerous side effects and should not be prescribed without the guidance of an expert in the treatment of MDR-TB (Table 61-3).

HIV

Treatment of Latent Infection with MDR-TB

24. L.W., the 26-year-old roommate of M.S., was recently found to be HIV-positive. Currently, he does not have symptoms of active TB. His PPD skin test is 6 mm. What is the possibility that M.S. has

infected L.W. with drug-resistant *M. tuberculosis*? How should he be managed?

The risk that L.W. is infected with drug-resistant *M. tuberculosis* is high. HIV-infected persons are much more likely to become infected than persons who are immunocompetent. Because L.W. is at high risk of infection with multidrug-resistant organisms, he should be started on two drugs for treatment of latent TB infection.³³ He could be started on pyrazinamide 20 to 25 mg/kg/day and ethambutol 15 to 20 mg/kg/day for 12 months. Another possible regimen would be pyrazinamide and a fluoroquinolone (levofloxacin, moxifloxacin, or ciprofloxacin). The specific regimen for L.W. should also take into consideration the drug susceptibility results of his roommate, M.S.

25. Because he is HIV-positive, what is L.W.'s prognosis?

Mortality in patients with HIV who are infected with MDR-TB remains significantly higher than in HIV-negative patients.¹³² If L.W. develops active MDR-TB disease and had acquired immunodeficiency syndrome (AIDS), his risk of death would be >70% even with aggressive multidrug treatment.

26. F.R., a 32-year-old man diagnosed with AIDS 6 months ago, is experiencing mild pleuritic chest pain with a productive cough. He also has experienced weight loss, fatigue, and night sweats over the past 2 weeks. A chest radiograph revealed bilateral infiltrates. Sputum samples are ordered for AFB smear and culture, and a PPD skin test is placed. The AFB smear is positive, and the induration from the PPD is 6 mm. His CD4(+) count is 150/mm³. He is currently receiving zidovudine, lamivudine, lopinavir, and ritonavir for his HIV disease with no complaints. How does TB present and what is its frequency in a patient with AIDS? How effective is skin testing in the diagnosis of latent TB infection? How should F.R. be treated?

Human immunodeficiency virus infects CD4(+) T cells, leading to a decrease in cell-mediated immunity. This absence of immunity allows the rapid development of active TB disease in a person who is infected with *M. tuberculosis*.^{23,49,63,138-140} The lungs are most frequently affected (74%–79% of cases); however, extrapulmonary disease also occurs much more frequently in patients with HIV infection than in patients without HIV infection (45%–72% vs. 17.5%).^{138,140} Patients with AIDS have a much greater chance of extrapulmonary disease when compared with an asymptomatic HIV-infected person. Infection with *M. tuberculosis* may be difficult to distinguish from other HIV-related pulmonary opportunistic infections (*Pneumocystis jirovecii*, *M. avium* complex). TB often precedes other opportunistic pulmonary infections and should be ruled out in any patient with HIV infection.¹³⁸ Several studies have identified predictors of poor survival in HIV-infected patients. These include low CD4(+) cell counts, MDR-TB, no DOT, and a history of IV drug abuse.¹⁴¹ New therapies, such as the fluoroquinolones and immunomodulating agents, may improve the outcome in these patients, but more clinical research is needed to assess their value.¹⁴²

PPD and Treatment of Active Disease

A PPD skin test should be applied to HIV-infected patients. Nevertheless, only about 30% to 50% of patients with AIDS

and TB will respond to a PPD skin test with an induration >10 mm. Therefore, an induration ≥ 5 mm is considered to be a positive reaction in this population.^{33,62,143} F.R.'s reaction to PPD (6 mm) should be considered positive. Based on his symptoms and positive AFB smear, he should be started on multiple-drug therapy for treatment of active TB disease. Recommendations for the treatment of TB in HIV-infected adults are the same as those for HIV-uninfected persons, with a few important exceptions (Table 61-2).⁶¹ These exceptions include the potential for drug–drug interactions between rifamycins and antiretroviral agents and the potential for the development of acquired rifamycin resistance with intermittent therapy.^{61,144,145} Antiretroviral therapy should not be withheld simply because the patient is being treated for TB, and a rifamycin should not be excluded for the treatment regimen for fear of interactions with certain antiretroviral agents.^{61,146} Exclusion of a rifamycin will likely delay sputum conversion, prolong the duration of therapy, and possibly result in a poor outcome.

Treatment of active TB in patients with HIV may be complicated by the occurrence of immune reconstitution inflammatory syndrome, which occurs in 30% of patients who begin therapy for both infections in close temporal proximity.¹⁴⁶ This syndrome reflects reconstituted immunity to *M. tuberculosis* and usually occurs in the first 4 to 8 weeks after initiation of antiretroviral therapy.¹⁴⁶ Symptoms include fever, malaise, and local reactions in organs, depending on the location of the mycobacterial infection (e.g., lungs). Immune reconstitution syndrome reactions are best managed with anti-inflammatory agents, including corticosteroids.¹⁴⁶

As noted earlier, rifampin is a potent inducer of cytochrome P450 isoenzymes (especially CYP3A4), rifapentine is intermediate, and rifabutin is the least potent inducer.^{46,61} Rifabutin is highly active against *M. tuberculosis*, so it has been recommended in place of rifampin for the treatment of active TB in HIV-infected patients receiving certain protease inhibitors or nonnucleoside reverse transcriptase inhibitors.⁶¹ Data from clinical trials also suggest that rifabutin- and rifampin-based regimens are equally efficacious.⁶¹ Protease inhibitors and nonnucleoside reverse transcriptase inhibitors may, however, either induce or inhibit cytochrome P450 isoenzymes, depending on the specific drug. As a result, these drugs may alter the serum concentrations of rifabutin.^{61,147}

The CDC has published guidelines for the use of rifampin for treatment of TB in HIV-infected patients receiving protease inhibitors and nonnucleoside reverse transcriptase inhibitors.¹⁴⁸ Based on these guidelines, rifampin can be used in the following situations: (a) a patient whose antiretroviral regimen includes the nonnucleoside reverse transcriptase inhibitor efavirenz and two nucleoside reverse transcriptase inhibitors; (b) a patient whose antiretroviral regimen includes the protease inhibitor ritonavir and one or more reverse transcriptase inhibitors; or (c) a patient whose antiretroviral regimen includes the combination of two protease inhibitors.¹⁴⁸ Because F.R. is receiving lopinavir and ritonavir, a potent cytochrome P450 3A4 inhibitor, he could be started on rifampin 600 mg, INH 300 mg, pyrazinamide 20 to 25 mg/kg, and ethambutol 15 to 20 mg/kg daily for the first 8 weeks of therapy. If rifabutin is started in place of rifampin, the dose of rifabutin must be decreased to reduce the likelihood of clinical toxicity associated with increased concentrations of rifabutin (leukopenia, uveitis,

arthralgias, skin discoloration).¹⁴⁷ Acquired rifamycin resistance is more common in patients with very low CD4(+) cell counts or who received intermittent dosing in the first 2 months of therapy.^{144,145} Therefore, daily administration is necessary during the intensive phase of treatment.

After this initial period, if no drug resistance is evident on susceptibility testing, F.R. can be treated with INH and rifampin (or rifabutin) daily or two to three times a week for a minimum of 26 weeks. Because he is receiving ritonavir, the rifabutin dose for intermittent therapy should be 300 mg.¹⁴⁷ Although not applicable to F.R. because his CD4(+) count is 150 cells/mL, it should be noted that twice weekly continuation therapy with INH and rifampin or INH and rifabutin is not recommended for HIV-infected patients with CD4(+) cell counts <100 cells/mL because of an increased frequency of acquired rifamycin resistance.^{61,147,149} In addition, the once weekly continuation regimen of INH and rifapentine is contraindicated in HIV-infected patients because of a high rate of relapse with organisms that have acquired resistance to the rifamycins.⁶¹ Because the margin of error is less in HIV-infected patients, special care to ensure adherence is required. In other words, DOT is highly recommended in this population. Furthermore, if the patient is slow to respond, prolonged therapy (>6 months) should also be considered. In addition to the antituberculosis medications, pyridoxine should be given to prevent peripheral neuropathy.

Drug Interactions

27. Are there any interactions between TB and antiretroviral agents to consider in F.R.'s therapy?

Yes, many! Since 1995, the FDA has approved several products in the protease inhibitor class of antiretroviral drugs: ritonavir (Norvir), saquinavir hard-gel capsule (Invirase), saquinavir soft-gel capsule (Fortovase), indinavir (Crixivan), nelfinavir (Viracept), amprenavir (Agenerase), and lopinavir + ritonavir (Kaletra). These products are the most potent antiretroviral agents available to treat HIV-infected patients, but they have many drug–drug interactions that are important to consider. First, all of the protease inhibitors are cytochrome P450 3A4 inhibitors, and ritonavir is the most potent inhibitor in the class. As a result, drugs affected by this interaction, such as rifabutin, will have elevated concentrations. In addition to their effect on other drugs, the protease inhibitors are affected by other drugs that affect the cytochrome P450 system, such as by rifampin, which is a potent inducer of the cytochrome P450 system. The protease inhibitor concentrations are reduced by 35% to 80% with concomitant rifampin administration. This reduction is somewhat less with rifabutin.^{150–152}

The nonnucleoside reverse transcriptase inhibitors, nevirapine (Viramune), delavirdine (Rescriptor), and efavirenz (Sustiva), are metabolized by cytochrome P450, but they affect other drugs metabolized by cytochrome P450 3A4 to varying degrees. Nevirapine is an inducer of CYP 3A4 isoenzymes, delavirdine is an inhibitor of CYP 3A4 isoenzymes, and efavirenz is a mixed inducer–inhibitor. Therefore, their interactions cannot be summarized as a class. The nucleoside reverse transcriptase inhibitors, such as zidovudine and lamivudine, are not metabolized by the cytochrome P450 system, making drug interactions unlikely.¹⁵²

Malabsorption

As mentioned, inadequate therapy of TB is one of the main reasons for treatment failure and development of acquired drug resistance. This can occur in many ways, such as non-adherence to therapy or malabsorption of the TB medications. Malabsorption of TB medications has been documented in HIV-infected patients. In one study, 19 of 20 patients had subtherapeutic serum rifampin concentrations. This phenomenon is particularly common with rifampin and ethambutol and explains, in part, the slow response in HIV-infected patients with TB.^{127,153–155} Therefore, serum concentrations of rifampin (or rifabutin) and ethambutol should be monitored in E.R.^{127,153–155}

Therapy of Latent Infection in HIV

28. Why should N.M., an HIV-infected person with a positive PPD skin test and no clinical symptoms, receive treatment for his latent TB infection?

The risk of N.M. developing active TB disease is substantial. Pape et al.¹⁵⁶ conducted a randomized, placebo-controlled trial of INH therapy in HIV-infected patients. They found that patients receiving placebo were six times more likely to develop active TB than those receiving INH. The patients receiving INH were also less likely to develop AIDS.¹⁵⁶ INH 300 mg daily for 9 months is, therefore, recommended for N.M.³³ Some clinicians suggest that these patients receive INH for life because eventual failure of the immune system will allow infection to progress to active disease.¹³⁸ (Therapy for MDR-TB is addressed in Question 24.) Therapy should also be considered in nonanergic, HIV-infected, PPD-negative patients who have been in recent contact with an infectious TB patient. The effectiveness of INH therapy in anergic, HIV-infected patients has not been established.⁵¹

Pregnancy

29. E.F. is a 25-year-old Hispanic woman who is being treated with INH 900 mg and rifampin 600 mg twice a week for pulmonary tuberculosis. She completed 2 months of therapy with INH, rifampin, pyrazinamide, and ethambutol, and began the new regimen 2 months ago. She recently became pregnant, and her obstetrician is concerned about the possible teratogenic effects of INH. What are the risks of TB and its treatment to the mother and the fetus? Are these drugs teratogenic?

Risks, Teratogenicity, and Treatment

Although concerns regarding the use of any medication during pregnancy always exist, it is now recognized that untreated TB represents a far greater risk to a pregnant woman and her fetus than does the treatment.^{61,62} INH, rifampin, pyrazinamide, and ethambutol are not teratogenic in humans, and the WHO recommends their use in women who are pregnant.^{157,158} In the United States, pyrazinamide is not recommended for use during pregnancy because of insufficient safety data.⁶¹ If pyrazinamide is not included in the initial treatment regimen, the minimal duration of therapy is 9 months.⁶¹ All pregnant women

receiving INH also should receive pyridoxine 25 mg/day because of the possibility of CNS toxicity.

Streptomycin should not be used during pregnancy except as a last alternative because it has been associated with mild-to-severe ototoxicity in the infant. This ototoxicity can occur throughout the gestational period and is not confined to the first trimester. With the exception of streptomycin ototoxicity, the occurrence of birth defects in women being treated for TB with the above agents is no greater than that of healthy pregnant women.^{159,160} Therefore, administration of antituberculosis drugs is not an indication for termination of pregnancy.⁶¹ Because E.F. likely became pregnant after completing the first 2 months of therapy, she should continue her current regimen for a total of 6 months because she received pyrazinamide as part of the initial regimen.

MDR-TB in Pregnancy

Little is known about the efficacy and safety of second-line drugs used to treat MDR-TB during pregnancy. Two reports with small numbers of patients have suggested that treatment is effective with no adverse effects to mother or child.^{161,162} In a study of seven women treated for MDR-TB during pregnancy, no obstetrical complications or perinatal transmission of MDR-TB was observed.¹⁶¹ Five women were cured, one experienced treatment failure, and one stopped therapy prematurely.¹⁶¹ No evidence of drug toxicity was seen among their children exposed to second-line drugs in utero, although one child was diagnosed with MDR-TB.¹⁶² Clearly, more data are needed, but pregnancy should not be a limitation to the treatment of MDR-TB.

Lactation

When the baby is born, E.F. may breast-feed while continuing her medication. Drug concentrations are minimal and do not provide sufficient quantities for the treatment or prevention of TB in the nursing infant.^{61,62,158}

Pediatrics

30. A.M., a 3-year-old black boy, is suspected of having TB. His father has been receiving treatment for TB for the last 2 months. A.M. has a productive cough, fever, and general malaise. His sputum is positive for AFB, and his PPD skin test is positive (10 mm). What is the incidence of TB in children? How should A.M. be treated?

The incidence of TB in children <15 years of age has declined from 1,663 cases (2.9 per 100,000 population) in 1993 to 863 cases (1.4 per 100,000 population) in 2005.¹³ Children commonly develop active TB disease as a complication of the initial infection with *M. tuberculosis*, and the disease is characterized by intrathoracic adenopathy, mid and lower lung infiltrates, and the absence of cavitation on chest radiography.^{61,163} Because of the high risk of disseminated TB in infants and children, treatment should be started as soon as the diagnosis of TB is suspected. In general, the regimens recommended for adults are also the regimens of choice for infants, children, and adolescents, with the exception that ethambutol is not used routinely in children.⁶¹ Although it is no more toxic,

ethambutol is often avoided because it is difficult to assess visual acuity in children. A.M. should be started on INH 10 to 15 mg/kg/day, rifampin 10 to 20 mg/kg/day, and pyrazinamide 15 to 30 mg/kg/day.^{61,62,163} Many experts prefer to treat children with three drugs (rather than four) in the initial phase because the bacillary population is usually lower than in an adult and it may be difficult for an infant or child to ingest four drugs. If resistance is suspected, ethambutol 15 to 20 mg/kg/day or streptomycin 20 to 40 mg/kg/day should be added to the regimen until susceptibility of the organism to INH, rifampin, and pyrazinamide is known. Pyridoxine is recommended for infants, children, and adolescents who are receiving INH.⁶¹

If resistance is not suspected in A.M. and susceptibility is confirmed by testing, he should receive the INH, rifampin, and pyrazinamide daily for 8 weeks. He can then continue to take the INH and rifampin daily or two to three times a week (DOT) for an additional 4 months. The dosage for INH and rifampin in a two to three times a week regimen would be 20 to 30 mg/kg per dose and 10 to 20 mg/kg per dose, respectively (Table 61-3).

A.M. should be examined routinely for signs and symptoms of hepatitis. Although antituberculosis medications are generally well-tolerated in children, LFT two to three times normal are common. These are often benign and transient; however, the incidence of hepatitis in children from INH with rifampin may be four to six times more common than in children receiving INH alone. Most hepatitis occurs within the first 3 months of therapy and generally is associated with more than recommended doses of INH or rifampin.^{104,164}

The last guidelines for targeted tuberculin skin testing and treatment of latent TB in children and adolescents were published in 2004.¹⁶⁴ Children and adolescents should be screened for risk factors for TB using a questionnaire, and they should be skin tested with 5 TU PPD if one or more risk factors are present.¹⁶⁴ Insufficient data are available to recommend use of whole blood interferon- γ assays in children. INH for 9 months is recommended for treatment of latent TB in this population.¹⁶⁴ Daily rifampin for 6 months is an acceptable alternative, especially in children who cannot tolerate INH or those exposed to a source case whose isolate was INH-resistant.¹⁶⁵

Extrapulmonary Tuberculosis and Tuberculous Meningitis

31. R.U. is a 64-year-old man who is brought to the emergency department following a 4-day period during which he became progressively disoriented, febrile to 40.5°C, and obtunded. He also had severe headaches during this time. Physical examination revealed some nuchal rigidity and a positive Brudzinski sign (neck resistant to flexion). An initial diagnosis of possible meningitis was made, and a lumbar puncture ordered. The cerebrospinal fluid (CSF) appeared turbid, and laboratory analysis revealed an elevated protein concentration of 200 mg/dL, a decreased glucose concentration of 30 mg/dL, and a white blood cell (WBC) count of 500/mm³ (85% lymphocytes). A Gram stain of the spinal fluid and a sputum smear for AFB were negative; other laboratory tests were within normal limits. A diagnosis of tuberculous meningitis was presumed. Discuss the presentation and prognosis of tuberculous meningitis. How should R.U. be treated?

[SI units: WBC count, 500 10⁹/L (0.85 lymphocytes)]

Tuberculous meningitis is only one of the extrapulmonary complications of infection with *M. tuberculosis*. Successful treatment of extrapulmonary TB can usually be accomplished in 6 to 9 months with an acceptable relapse rate.^{61,62,166} Some forms, such as bone or joint TB, miliary TB, or tuberculous meningitis may require 9 to 12 months of therapy.⁶¹ Because specimens for culture and susceptibility testing may be difficult or impossible to obtain from a site, response to treatment must be based on clinical and radiographic improvement.

Tuberculous meningitis in older persons usually is caused by hematogenous dissemination of the tubercle bacilli from a primary site, usually the lungs. In its early stages, tuberculous meningitis often is confused with aseptic meningitis because the Gram stain is negative. The most common symptoms of tuberculous meningitis are headache, fever, restlessness, irritability, nausea, and vomiting. A positive Brudzinski sign and neck stiffness may be present. As illustrated by R.U., the CSF is usually turbid with increased protein and decreased glucose concentrations. There is an increase in the CSF WBC count with a predominance of lymphocytes. Culture of the CSF for *M. tuberculosis* may not be helpful because rates of positivity for clinically diagnosed cases range from 25% to 70%.¹⁶⁷ Early recognition and treatment is essential for a favorable outcome. Thus, empirical treatment before receipt of confirmatory culture and susceptibility results is common in suspected tuberculous meningitis. Multiple-drug therapy should be used because irreversible brain damage or death can occur as soon as 2 weeks after the onset of infection (not clinical symptoms).¹⁶⁷

Treatment

Treatment should be initiated in R.U. with daily administration of INH 300 mg, rifampin 600 mg, pyrazinamide 20 to 25 mg/kg, and ethambutol 15 to 20 mg/kg for the first 2 months.⁶¹ After this initial phase of treatment, R.U. should receive daily INH and rifampin treatment for an additional 7 to 10 months, although the optimal duration of therapy is unknown.⁶¹ In addition, because R.U. is older, pyridoxine 10 to 50 mg/day should be given to prevent the occurrence of peripheral neuropathy from INH. It also should be remembered that rifampin may impart a red to orange color to the CSF.

Isoniazid readily penetrates into the CSF, with CSF concentrations reaching up to 100% of those in the serum. Rifampin is often included in tuberculous meningitis regimens and may be associated with reduced morbidity and mortality; however even with inflammation, its CSF concentrations are only 6% to 30% of those found in the serum. Ethambutol should be used in the highest dosage to achieve bactericidal concentrations in the CSF because its CSF concentrations are only 10% to 54% of those in the serum. Streptomycin penetrates into the CSF poorly even with inflamed meninges.^{168,169}

Corticosteroids

Corticosteroids in moderate to severe tuberculous meningitis appear to reduce sequelae and prolong survival.¹⁷⁰ The mechanism for this benefit is likely owing to reduction of intracranial pressure. Dexamethasone 8 to 12 mg/day (or prednisone equivalent) for 6 to 8 weeks should be used and then tapered slowly after symptoms subside.¹⁷⁰ Corticosteroids are likely indicated for R.U.

Solid Organ Transplant Recipients

32. M. S. is 66-year-old man with a history of TB as child. He recently underwent a renal transplant. Will he develop TB, and if so, are there any pharmacologic concerns to address in him?

The risk of developing TB is 36 to 74 times greater among solid-organ transplant recipients than in the general population. The overall mortality rate in this population is 29%. The increased risk of developing TB is largely caused by the immunosuppressive therapy given to prevent transplant rejection. Although some patients may acquire the TB nosocomially,

most, including possibly M.S., will develop it as reactivation of dormant TB. More than half of the patients will develop pulmonary disease. Many, however, will also develop disseminated or extrapulmonary disease, which is difficult to diagnose and therefore may cause a delay in diagnosis.¹⁷¹ Patients should be treated with a standard TB regimen.^{61,62} Attention should be paid to potential interactions with rifampin, which may increase the metabolism of cyclosporine, tacrolimus, and other medications. In addition, transplant recipients, in particular liver transplant recipients, may be at an increased risk of developing INH hepatitis. It is recommended that all transplant recipients receive a tuberculin skin test and that chemoprophylaxis be offered to all high-risk patients.¹⁷¹

Infectious diarrhea is caused by the ingestion of food or water contaminated with pathogenic microorganisms or their toxins. The spectrum of infection caused by enteropathogens includes asymptomatic carriage to life-threatening illnesses requiring urgent medical attention. This chapter focuses on the diagnosis and management of the common microbial causes of acute infectious diarrhea.

DEFINITIONS

Diarrhea is often defined as three or more episodes of loose stool or any loose stool with blood during a 24-hour period.¹

The duration of illness is often classified as acute diarrhea if the illness is <2 weeks' duration, persistent diarrhea if the illness lasts >14 days, and chronic diarrhea if the illness lasts >30 days.

The classification of infectious diarrheas as either a noninflammatory or inflammatory diarrheal illness is often used to predict the most likely enteropathogen causing the illness and to guide the overall treatment of this infection. Noninflammatory diarrheas are generally a less severe illness in which patients present with nonbloody, watery stools; patients are afebrile and without significant abdominal pain.¹ Examination of stool specimens does not reveal the presence of fecal white

blood cells (WBC) or occult blood. Noninflammatory diarrheas are typically caused by rotaviruses, noroviruses, *Staphylococcus aureus*, *Bacillus cereus*, *Clostridium perfringens*, *Cryptosporidium parvum*, and *Giardia lamblia*.² Most patients with noninflammatory diarrheal illnesses require only supportive therapies.

In contrast, inflammatory diarrheas are generally a more severe illness in which patients present with bloody diarrhea, severe abdominal pain, and fever,² and examination of stool specimens reveals the presence of large numbers of fecal leukocytes. Inflammatory diarrheas are caused by invasive pathogens including *Campylobacter jejuni*, *Shigella* species, *Salmonella* species, *Clostridium difficile*, *Shiga toxin-producing Escherichia coli* (STEC), and *Entamoeba histolytica*.² Selected persons with inflammatory diarrheal illnesses may benefit from antimicrobial therapy directed at the causative pathogen.

PREVALENCE

During the 1990s, worldwide, more than 3 million deaths were attributed to infectious diarrhea, with most deaths occurring in developing countries.¹ The morbidity and mortality from diarrheal illnesses are largely attributed to dehydration,² with the very young, the elderly, and the immunocompromised at highest risk for this complication.^{2,3} In developing countries, infectious diarrhea is mainly attributed to inadequate disposal of sewage, leading to unsafe drinking water. In developed countries persons at risk for infectious diarrhea include international travelers to underdeveloped countries; and persons in institutional settings where maintenance of good hygiene is often difficult (e.g., day care centers, hospitals, and extended care facilities). Our increasing reliance on foreign food supplies is another means by which exposure to foodborne infections may occur.¹ Finally, the increasing numbers of immunocompromised hosts including human immunodeficiency virus (HIV)-infected persons and organ transplant recipients comprise a population that is more susceptible to intestinal infections.³

ETIOLOGY

Microbial causes of infectious diarrhea include bacteria, viruses, protozoa, or fungi (Table 62-1). In developing countries, rotavirus is thought to be responsible for 60% of all diarrheal illnesses,⁴ whereas the most common bacterial pathogens include the pathogenic *E. coli*, *Campylobacter*, *Salmonella*, *Shigella*, and *Vibrio* species.⁴ In the United States, the Food-Net Surveillance Network also identified these pathogens as the most common causes of bacterial diarrheal illnesses, adding *Cryptosporidium* as a cause of parasitic diarrheal illnesses.⁴ Rotavirus infection, which is commonly associated with the hospitalization of children with diarrheal illnesses, is likely to be the causative agent in many cases of community-acquired diarrhea.⁴

PATHOGENESIS

Bacterial Virulence Factors

Enteropathogens possess a number of virulence factors, including toxins, adhesions, and invasive properties that contribute to the organism's pathogenicity.¹ Enterotoxins target

the small bowel, causing net movement of fluid into the gut lumen leading to voluminous quantities of watery stools and potentially life-threatening dehydration. Watery diarrhea can also be caused by an alteration in the absorptive function of the villus tip, as seen with rotaviruses and noroviruses.⁵ Cytotoxins target the colon, causing direct mucosal damage leading to fever and bloody diarrhea.

The invasive properties identified in *Shigella* species and invasive strains of *E. coli* allow these bacteria to invade and destroy epithelial cells causing bloody or mucoid stools.⁵ Some enteropathogens induce a vigorous host response (e.g., release of proinflammatory cytokines from intestinal epithelial cells) that can lead to diarrhea.⁵ Adhesions allow enteropathogens to attach to and colonize the gastrointestinal (GI) mucosa, facilitating invasion, dissemination, toxin delivery, or host cell lysis.

Host Defenses

The human gastrointestinal tract possesses numerous defense mechanisms to protect against enteric infection. For example, because many bacteria cannot survive in an acidic environment, the normal gastric acidity of the stomach prevents viable pathogens from passing from the stomach into the small intestine. Intestinal peristalsis moves bacteria and their toxins along and out of the GI tract. Gastrointestinal mucus and mucosal tissue integrity provide physical barriers against infection. Intestinal immunity, including the local production of antibody, contributes to the host's ability to resist enteric infection. Finally, the normal bacterial flora compete for space and nutrients with potentially pathogenic organisms, or produce substances that may be inhibitory to enteropathogens.⁵

Predisposing Factors

Predisposing factors to infectious diarrhea include travel history, compromised immune status, exposure to outbreaks of foodborne or waterborne illnesses, poor personal hygiene, and the use of pharmacologic agents. These predisposing factors also provide clues to the most likely microbes causing the diarrheal illness. For example, a diarrheal illness in the setting of recent travel to a developing country suggests travelers' diarrhea caused by the pathogens endemic to that area. HIV-infected persons are susceptible to infectious diarrhea caused by *Salmonella*, *Cryptosporidium*, and numerous other enteropathogens.³ Outbreaks of diarrheal illnesses should raise suspicions of illness caused by *S. aureus*, *B. cereus*, *C. perfringens*, *Shigella*, *Salmonella*, *Campylobacter*, or noncholera *Vibrio*.³ In the day care setting, agents spread by the fecal-oral route, such as *Shigella*, *G. lamblia*, and *Cryptosporidium*, should be considered.³ Diarrhea in the setting of hospitalization or recent exposure to antibiotics increases the likelihood of *C. difficile* colitis.¹ Drugs that increase gastric pH, such as H₂-receptor antagonists, proton pump inhibitors, or antacids increase the risk for infection with *Salmonella* because these bacteria do not survive well in the normally acidic stomach (Table 62-2).

CLINICAL PRESENTATION

Details of the patient's clinical presentation, such as the specific symptoms, the severity and duration of symptoms, and the

Table 62-1 Predisposing Factors, Symptoms, and Therapy of Gastrointestinal Infections

| Pathogen | Predisposing Factors | Symptoms | Diagnostic Evaluations | Drug of Choice | Alternatives |
|---|---|--|---|---|---|
| <i>Salmonella</i> (nontyphoidal) | Ingestion of contaminated poultry, raw milk, custards, and cream fillings; foreign travel | Nausea, vomiting, diarrhea, cramps, fever, tenesmus Incubation: 6–72 hrs | Fecal leukocytes, stool culture | Fluoroquinolone, third-generation cephalosporins | Ampicillin, amoxicillin, TMP-SMX, chloramphenicol, azithromycin |
| <i>Salmonella</i> (typhoidal) | Ingestion of contaminated food, foreign travel | High fever, abdominal pain, headache, dry cough | Fecal leukocytes, stool culture, blood culture | Fluoroquinolone, third-generation cephalosporins | Chloramphenicol, TMP-SMX, ampicillin, amoxicillin, azithromycin |
| <i>Shigella</i> | Ingestion of contaminated food, foreign travel. | Fever, dysentery, cramps, tenesmus Incubation: 12–24 hrs | Fecal leukocytes | Fluoroquinolone | Azithromycin, TMP-SMX, ampicillin, ceftriaxone |
| <i>Campylobacter</i> | Contaminated eggs, raw milk, or poultry; foreign travel | Mild to severe diarrhea; fever, systemic malaise Incubation: 24–72 hrs | Fecal leukocytes, stool culture | Erythromycin, azithromycin | Fluoroquinolone, tetracycline, gentamicin |
| <i>Clostridium difficile</i> | Antibiotics, antineoplastics | Mild to severe diarrhea, cramps | <i>C. difficile</i> toxin, <i>C. difficile</i> culture, colonoscopy | Metronidazole | Vancomycin |
| Staphylococcal food poisoning | Custard-filled bakery products, canned food, processed meat, ice cream | Nausea, vomiting, salivation, cramps, diarrhea; usually resolves in 8 hrs Incubation: 2–6 hrs | — | Supportive therapy only | — |
| Travelers' diarrhea (<i>Escherichia coli</i>) | Contaminated food (vegetables and cheese), water, foreign travel | Nausea, vomiting, mild to severe diarrhea, cramps | Stool culture | See Table 62-3 | — |
| Shiga toxin-producing <i>Escherichia coli</i> (<i>E. coli</i> O157:H7) | Beef, raw milk, water | Diarrhea, headache, bloody stools Incubation: 48–96 hrs | Stool cultures on MacConkey's sorbitol | Supportive therapy only | — |
| Cryptosporidiosis | Immunosuppression, day care centers, contaminated water, animal handlers | Mild to severe diarrhea (chronic or self-limited); large fluid volume | Stool screening for oocytes, PCR, ELISA | See Chapter 71, Opportunistic Infections in HIV-Infected Patients | — |
| Viral gastroenteritis | Community-wide outbreaks, contaminated food | Nausea, diarrhea (self-limited), cramps Incubation: 16–48 hrs | Special viral studies | Supportive therapy only | — |

ELISA, enzyme-linked immunosorbent assay; HAART, highly active antiretroviral therapy; PCR, polymerase chain reaction; TMP-SMX, trimethoprim-sulfamethoxazole.

^aSee text for doses and duration of therapy.

^bNot all cases require antibiotic therapy. See text for details.

From Hines J et al. Effective use of the clinical microbiology laboratory for diagnosing diarrheal diseases. *Clin Infect Dis* 1996;23:1292, with permission.

Table 62-2 Pharmacologic Agents That May Promote Gastrointestinal Infection

| Drug | Mechanism |
|--|--|
| Antacids, H ₂ -receptor antagonists, proton pump inhibitors | Increased gastric pH; viable pathogens passed to lower gut |
| Antibiotics | Eradication of normal (anaerobic) flora |
| Antidiarrheals | Decreased gut motility; bacterial growth |
| Immunosuppressives | Inhibition of gut immune defenses |

onset of the illness also help to predict the most likely microbial cause of the diarrheal illness. For example, watery diarrhea associated with nausea and vomiting occurring within hours of exposure to a contaminated food source suggests the ingestion of preformed toxins such as those produced by *S. aureus* or *B. cereus*.³ Abdominal cramps and diarrhea occurring within 8–16 hours after consumption of contaminated meats and gravies suggests infection with *C. perfringens*.

Bloody diarrhea and fever should raise suspicion of infection with invasive pathogens, such as *Salmonella*, *Shigella*, and *Campylobacter*. Some invasive enteropathogens, such as *Campylobacter*, *Aeromonas*, *Shigella*, and *Vibrio parahaemolyticus*, may, however, initially cause watery diarrhea, which is then followed by bloody diarrhea.¹ In the United States, STEC is the most common cause of bloody diarrhea, and should be suspected, especially if fever is absent.⁶

Persistent diarrhea in travelers is associated with parasites such as *G. lamblia*, *Cryptosporidium*, or *Isospora belli*; and bacteria such as enteropathogenic *E. coli*, enterotoxigenic *E. coli*, STEC, *Shigella*, *C. jejuni*, and *Aeromonas*.⁴

Complications of infectious diarrhea most commonly include dehydration and electrolyte losses. Metabolic alkalosis can result from the severe vomiting associated with staphylococcal food poisoning, or from gastroenteritis caused by rotaviruses or noroviruses. Other complications associated with specific enteropathogens include toxic megacolon and intestinal perforation following *Shigella*, STEC, and *C. difficile* infection; hemolytic uremic syndrome following STEC and *Shigella* infection; a reactive arthritis following *Shigella*, *Salmonella*, and *Campylobacter* infection; and metastatic infection following *Salmonella* infection.⁴

TREATMENT OF PATIENTS WITH INFECTIOUS DIARRHEA

Infectious diarrhea is generally a self-limiting illness, and most patients never seek medical attention. In many cases, replacement of fluids and electrolytes is all that is required. Medical evaluation is warranted for patients with profuse watery diarrhea with dehydration, six or more unformed stools within a 24-hour period, bloody stools, temperature >101.3°F, or illness of >48 hours' duration. Other persons requiring medical evaluation for a diarrheal illness include patients >50 years of age with severe abdominal pain, patients ≥70 years of age, and immunocompromised patients (e.g., acquired immunodeficiency syndrome [AIDS], organ transplant recipient, or patients have cancer chemotherapy).³ The evaluation of any diarrheal illness should also consider the possibility of a noninfectious cause for

the illness, such as medications, inflammatory bowel disease, radiation colitis, or malabsorption syndromes.⁷

Rehydration Therapy

Depending on the degree of dehydration and ongoing losses, fluids and electrolytes may be replaced intravenously or orally. The degree of dehydration is assessed by careful physical examination and measurement of vital signs. Severe dehydration is characterized by lethargy and inadequate oral intake; very sunken and dry eyes and a very dry tongue and mouth; and a very fast, weak or nonplapable pulse.^{8,9} Other characteristics of dehydration include poor urine output and low blood pressure. Intravenous replacement therapies are warranted for severely dehydrated persons, or persons with intestinal ileus or who are unable to drink on their own.⁸

Mild to moderate dehydration can be treated primarily with oral replacement therapies.^{8,9} For adults able to drink normally, beverages containing glucose (e.g., lemonades, sweet sodas, or fruit juices) or soups rich in electrolytes are recommended.¹⁰ In developing countries, oral replacement therapy solutions containing optimal concentrations of glucose, sodium, potassium, chloride, and bicarbonate are responsible for the significant reduction in mortality attributed to dehydration.⁹ These oral replacement solutions are effective because sodium absorption is accelerated in the presence of glucose.⁹

Laboratory Tests

Inflammatory diarrheal illnesses are characterized by stool specimens containing large numbers of fecal leukocytes (e.g., more than three leukocytes per high-power microscopic field in four or more fields, or markers of fecal leukocytes such as lactoferrin) or the presence of occult blood.^{2,11} Pathogens commonly cultured from these patients include *Shigella*, *Salmonella*, *Campylobacter*, *Aeromonas*, *Yersinia*, noncholera *Vibrio*, and *C. difficile*.³ The absence of leukocytes in a stool specimen, however, does not rule out an inflammatory diarrhea.¹¹ The mean sensitivity of fecal leukocytes for the prototypical inflammatory diarrheal disease agent *Shigella*, averages 73% (range, 49%–100%).¹¹ The absence of fecal WBC suggests a noninflammatory diarrhea.

A microbiologic diagnosis of infectious diarrhea from a stool sample is made by culture of the pathogen or isolation of toxins (e.g., *C. difficile*) produced by the organism. Careful selection of patients in whom stool cultures are performed should maximize the cost-effectiveness of performing this test.¹¹ Stool cultures are recommended for patients with one of the following: severe diarrhea; bloody stools; or stools containing leukocytes, lactoferrin, or occult blood; or an oral temperature ≥101.3°F. Cultures are also recommended in patients with persistent diarrhea who have not been given empiric antimicrobials.³ Identification of parasitic causes of infectious diarrhea is made by microscopic examination of a stool specimen for ova and parasites. More sensitive tests to diagnose parasitic infections include direct immunofluorescence assay (DFA) to detect *G. lamblia* and *Cryptosporidium*, and enzyme immunoassay (EIA) to detect *G. lamblia* and *Cryptosporidium* antigen.¹¹

Enteropathogens may also be isolated from extraintestinal sites such as the blood and bone marrow, or other sites to which infection has spread.

Drug Therapy

Bismuth Subsalicylate

Bismuth subsalicylate is an antidiarrheal agent with antibacterial properties.¹² Adverse effects of bismuth subsalicylate include darkening of the tongue and stools,⁴ tinnitus,¹³ and encephalopathy when high doses are used.⁴ Bismuth subsalicylate can interfere with the absorption of other medications such as doxycycline used in malaria prophylaxis, and fluoroquinolones used in the management of travelers diarrhea.

Loperamide and Diphenoxylate/Atropine

The antimotility agents loperamide and the combination product diphenoxylate/atropine provide symptomatic relief by slowing intestinal transit time.¹⁰ Loperamide is preferred over diphenoxylate/atropine because of its better efficacy, lower potential for adverse effects, and availability as an over-the-counter preparation.¹⁰ Diphenoxylate/atropine can cause drowsiness, dizziness, dry mouth, and urinary retention. Although controversial,¹³ experts do not recommend the use of antimotility drugs in persons with fever or bloody diarrhea¹⁴ or when invasive pathogens are suspected, because of concerns that prolonging the clearance of pathogens from the intestinal tract could worsen the severity of illness.¹³

Probiotics

Probiotics are live microbial mixtures of bacteria and yeasts used to restore the normal intestinal flora, thereby reducing intestinal colonization with pathogenic organisms.¹⁵ Probiotics can also produce pathogen-inhibiting substances, inhibit pathogen adhesion to the GI tract, inhibit the action of microbial toxins, and stimulate immune defense mechanisms.¹⁶ Interest in probiotics stems in part from their potential to decrease the use of antibiotics.

Disadvantages of probiotics include the lack of both well-controlled trials supporting their efficacy and quality controls on the manufacturing of these products, and the risk for systemic infection, particularly in the immunocompromised host.¹⁶ Some evidence supports the use of probiotics for the treatment of rotavirus diarrhea in children and as an adjunct for the treatment of recurrent *C. difficile* colitis.¹⁶

Antimicrobials

Because infectious diarrhea is generally a self-limiting illness, the routine use of antimicrobials is not necessary.¹ In selected individuals antimicrobials are beneficial, however, because they decrease the duration and the severity of illness, prevent invasive infection, and prevent person-to-person transmission of pathogens.⁷ In general, antimicrobials are recommended for patients with severe illness, patients with conditions that compromise normal enteric defenses, or for immunocompromised patients. Antibiotics are also necessary to treat extraintestinal complications of enteric infection, such as bacteremia and osteomyelitis.

Trimethoprim-sulfamethoxazole (TMP-SMX), the aminopenicillins, tetracyclines, and nalidixic acid have been used extensively for the treatment of enteric infections because of their ease of administration, relative safety, and low cost. The emergence of enteric pathogens resistant to one or all of these agents is limiting their usefulness for both domestically and internationally acquired infectious diarrhea.⁷ Depending on the

microbial cause of diarrhea, alternatives to these agents include the fluoroquinolones, selected third-generation cephalosporins (e.g., ceftriaxone, cefotaxime, cefixime), azithromycin, and rifaximin. Because fluoroquinolones have been widely used in humans, and in agriculture and veterinary medicine, increasing resistance to this class of antimicrobials among common bacterial enteropathogens, such as *Salmonella*, *Shigella* and *Campylobacter* species, is not uncommon.

Besides increasing resistance of enteropathogens to fluoroquinolones, another issue with these agents is that they are not approved for use in children because lesions on cartilage tissue have been reported in juvenile animals.¹⁷ Nevertheless, because of the emergence of multidrug-resistant enteropathogens in some geographic areas, clinical trials using fluoroquinolones in children have been performed, and the available data suggest that a short course of these agents is safe.^{17,18}

Prevention

Measures to prevent the spread of enteropathogens include good personal hygiene; and proper handling, cooking, and storage of foods. Persons traveling to areas with inadequate sewage and water systems should follow the rule, “boil it, cook it, peel it, or forget it.” Vaccines to prevent typhoid fever are available.

TREATMENT OVERVIEW

1. B.K. is a 78-year-old man presenting to his physician with a diarrheal illness of 1 day’s duration. His illness began with vomiting, followed by abdominal pain, nausea, and watery diarrhea without blood. He denies any fever. B.K.’s history of present illness is significant for dining with friends at a seafood restaurant 2 nights ago. They all shared an appetizer of raw oysters, and he has since learned his friends are experiencing a similar illness. B.K. has no significant medical history. He denies recent hospitalization, contact with small children, recent travel, or recent use of antimicrobials. On physical examination B.K. is alert and oriented, and is not “toxic” appearing. The remainder of his examination is only significant for decreased skin turgor and dry mucous membranes. What is your general approach to the management of B.K.’s diarrheal illness?

The most common complication of any diarrheal illness is loss of fluids and electrolytes, which in extreme cases can lead to hypovolemia, shock, and death. Once replacement of fluid and electrolyte losses have been addressed, patients are evaluated to determine the need for further medical evaluation and the need for drug therapy to provide symptomatic relief or specific antimicrobial therapy directed at the causative pathogen.

2. What specific plan for rehydration would you recommend for B.K.? Would evaluation of a stool sample for the presence of WBC or blood provide useful information to assist in treating his illness?

B.K.’s clinical presentation is that of a nontoxic-appearing elderly man with signs and symptoms of mild to moderate volume depletion (decreased skin turgor and dry mucous membranes). An oral rehydration solution containing 45 to 90 mEq/L of sodium can be used to manage his fluid and electrolyte losses.³

Further medical evaluation to determine if B.K.'s illness is consistent with an inflammatory or noninflammatory diarrheal illness will assist in assessing the role of specific drug therapies. Patients with an inflammatory diarrheal illness may benefit from antimicrobial therapy directed at the causative pathogen, whereas those with a noninflammatory diarrheal illness can generally be treated by fluids and electrolyte replacement. A stool specimen should be sent to the laboratory and examined for the presence of WBC and blood.

VIRAL GASTROENTERITIS

Clinical Presentation and Treatment

3. B.K.'s stool is negative for WBC and blood. In the meantime, because of B.K.'s history of dining with friends with a similar illness, the physician calls the Board of Health to ask about other reports of person with a similar illness, and is told of an outbreak of *Norovirus* (previously called Norwalk-like virus) gastroenteritis associated with food served at the restaurant where B.K. had dined. Why are B.K.'s history of present illness and clinical presentation consistent with the presumptive diagnosis of gastroenteritis caused by noroviruses?

Noroviruses are estimated to be responsible for more than two-thirds of pathogen-confirmed, foodborne illnesses.¹⁹ Of the common viral causes of gastroenteritis, B.K.'s history and clinical presentation suggest a *Norovirus* as the likely pathogen. Noroviruses are responsible for major outbreaks of foodborne viral illnesses in both adults and children, usually in association with restaurants, schools, and day care centers.¹⁹ These viruses are spread by (a) the consumption of fecally contaminated water or foods, such as inadequately cooked clams and oysters harvested from contaminated waters, (b) person-to-person contact, or (c) exposure to recreational waters.¹⁹ Illness typically begins within 12–48 hours after exposure to the virus and generally lasts 1–3 days. The gastrointestinal illness is generally mild, with patients reporting nausea, vomiting, diarrhea, abdominal cramps, myalgias, headache, and chills. Fever occurs in one-third to one-half of cases. Prevention of illness is aimed at proper food handling practices.¹⁹

Rotaviruses and astroviruses are important causes of infectious diarrhea in children, with rotaviruses responsible for 30%–60% of all cases of severe watery diarrhea in this population.²⁰ Following an incubation period of 1–3 days, patients present with fever, vomiting, and watery but nonbloody diarrhea. In normal hosts, this illness lasts for 5–7 days.²⁰ Because rotavirus is spread by the fecal–oral route, preventive measures include proper handwashing and disposal of contaminated items. A recently U.S. Food and Drug Administration (FDA)-approved rotavirus vaccine (RotaTeq) is indicated for the prevention of rotavirus gastroenteritis in infants and children caused by selected serotypes. A three-dose series is administered between the ages of 6–32 weeks.²¹

The morbidity and mortality of viral gastroenteritis primarily is caused by fluid and electrolyte losses. Thus, supportive measures to correct these deficits and replace ongoing losses are the mainstay of treatment for viral gastroenteritis. Probiotics have been found to decrease the duration of diarrhea caused by the rotavirus. In young children hospitalized with acute diarrhea primarily caused by rotavirus, a randomized,

double-blind placebo-controlled trial demonstrated that a mixture of lactobacillus strains administered early (<60 hours) in the course of illness decreased the duration of the diarrheal illness from 130 hours–80 hours ($p = 0.003$). The lactobacillus strains used in this study were selected for their potential probiotic characteristics.²²

VIBRIO SPECIES

Vibrio species are curved gram-negative rods whose natural habitats are the environmental waters. Toxigenic *V. cholerae* 01 and 0139 cause epidemic cholera in humans,²³ whereas the noncholerae *Vibrio* species, such as *V. parahaemolyticus*, generally cause gastroenteritis and extraintestinal infection.²⁴

Vibrio cholerae

Clinical Presentation

4. M.M., a 50-year-old previously healthy man, is brought to the emergency department (ED) by his family because of severe watery diarrhea, vomiting, and altered mental status. His history of present illness is significant for return 1 day ago from Latin America where he visited with relatives, several of whom were recovering from infection caused by *V. cholerae*. Approximately 24 hours before admission, he noted the onset of watery diarrhea and began drinking the oral rehydrating solution left over from his trip to Latin America. Over the past several hours he has been unable to drink on his own, however, and his family noticed “white flecks” in his stools.

In the ED, M.M.'s vital signs are as follows: temperature 101°F, blood pressure is 70/40 mmHg, and heart rate is 130 beats/minute. His weight is 61 kg, which is 8 kg below his normal weight. Physical examination reveals a critically ill man with sunken eyes, poor skin turgor, and dry mucous membranes. The physician's assessment is severe dehydration, most likely secondary to infection from *V. cholerae*. What are the signs and symptoms suggestive of severe dehydration, and how should M.M.'s dehydration be treated?

M.M. shows signs of severe dehydration as manifested by his altered mental status, sunken eyes, poor skin turgor, dry mucous membranes, low blood pressure, increased heart rate, and weight loss of >10% of his normal body weight.⁸ Other complications of severe fluid and electrolyte losses associated with cholera infection include acidosis as a result of bicarbonate losses through stool along with lactic acidosis from shock, and renal failure secondary to hypovolemia.⁸

Fluid and electrolyte replacement is the mainstay of treatment for patients with cholera. The watery stools of patients with cholera contain high concentrations of sodium, potassium, and bicarbonate.⁸ In the United States, Ringer's lactate solution is the only readily available intravenous (IV) solution with the electrolyte composition required to treat cholera.⁸ Vigorous IV hydration to restore his intravascular volume should be instituted. Monitoring of blood pressure and normalization of heart rate are mandatory. Once M.M. is able to drink fluids, oral rehydration can be started even while rehydration with IV fluids is ongoing. When replacing fluids in patients with cholera, the use of oral replacement solutions containing <75 mEq/L of sodium is inappropriate because of the large amounts of sodium lost through cholera stools.⁸

5. Why is M.M.'s history of present illness and clinical presentation consistent with a severe diarrheal illness caused by toxin-producing *V. cholerae*?

The incubation period of *V. cholerae* is typically 1–3 days, but ranges from a few hours to 5 days. The spectrum of illness caused by *V. cholerae* includes asymptomatic carriage (most persons), mild to moderate watery diarrhea, and life-threatening dehydration.⁸ M.M. is one of the few (2%–5%) persons with severe dehydration which, within hours, could evolve into hypovolemic shock and death. The watery and colorless stools with “white flecks” of mucus are referred to as *rice-water stools*. Patients can lose up to 1 L/hour of fluid during the first 24 hours and may lose up to 10% of their body weight. The watery diarrhea is caused by the cholera toxin, which promotes the secretion of fluids and electrolytes by the small intestine. Cholera epidemics are caused by toxin-producing strains of *V. cholerae* 01 or 0139.²⁴ Hypoglycemia can occur in severe cholera, especially in children.⁸

In developing countries with inadequate sanitation facilities, cholera infection is primarily spread by the consumption of contaminated water and foods. Foods that are often contaminated with *V. cholera* include improperly preserved fish, raw oysters, and undercooked shellfish, such as crabs.⁸ In the United States and other developed nations, cholera has been virtually eliminated because of modern sewage and water treatment systems. Nevertheless, cases of cholera are still seen in the United States, particularly in persons traveling to parts of Latin America, Africa, or Asia where epidemics of cholera still occur, or in travelers bringing contaminated seafood back to the United States. Domestic cases of cholera arise from the consumption of undercooked seafood harvested from contaminated waters off the Gulf Coast.²³

Treatment

6. Would M.M. benefit from the administration of antibiotics?

Antimicrobials are beneficial in the treatment of patients with cholera because they decrease the volume of diarrheal losses and shorten illness duration.²⁵ In areas of the world with limited health care resources, shortening the duration of an illness with the use of relatively inexpensive antimicrobials is a means of conserving health care resources because of the shortened hospital stay and less need for intravenous fluids.²⁵ Because antimicrobial resistance patterns of *V. cholerae* vary in different regions of the world, as well as change over time with antimicrobial resistant strains reverting back to susceptible strains, selection of a specific antimicrobial regimen should consider the susceptibility pattern of the circulating strain.²⁵ Both single-dose and multiple-dose regimens are clinically effective for the treatment of *V. cholerae* infection caused by susceptible strains; single-dose regimens are preferred because of their ease of administration.²⁵

Effective single-dose oral regimens in adults infected with susceptible strains of *V. cholerae* include 300 mg of doxycycline,²⁵ 1 g of ciprofloxacin,²⁶ or 1 g of azithromycin.²⁷ One study illustrated the importance of the need for ongoing surveillance of antimicrobial susceptibility patterns of *V. cholerae* in order to increase the likelihood of clinical success.²⁷ Although a prior study demonstrated the efficacy of ciprofloxacin for the treatment cholera caused by *V. cholerae*, a more recent study reported that, because resis-

tance to ciprofloxacin had since emerged, a single 1-g dose of ciprofloxacin was less effective than a single 1-g dose of azithromycin.²⁷

Effective single-dose, oral regimens for the treatment of cholera in children include ciprofloxacin 20 mg/kg (maximum, 750 mg)²⁸ or azithromycin 20 mg/kg (maximum, 1 g).²⁹ These regimens were as effective as the standard treatment with erythromycin 12.5 mg/kg/dose (maximum, 500 mg/dose) Q 6 hr for 3 days. In these studies, single-dose regimens were better tolerated than the multiple-dose regimen using erythromycin. Compared with children treated with erythromycin, children treated with a single dose of ciprofloxacin experienced less vomiting and fewer stools,²⁸ and those treated with azithromycin also experienced less vomiting.²⁹

Effective multiple-dose regimens for cholera include tetracycline (500 mg orally Q 6 hr for 48–72 hours),²⁵ erythromycin 250 mg orally four times daily for 3 days,⁸ and TMP-SMX (adults, 160 mg TMP, 800 mg SMX twice daily for 3 days; children, 5 mg/kg TMP, 25 mg/kg SMX twice daily for 3 days).⁸ Although resistance to TMS-SMX had previously been problematic, more recent strains of *V. cholerae* O139 causing infection in Bangladesh are now susceptible to trimethoprim and sulfamethoxazole.³⁰

Vibrio parahaemolyticus

Clinical Presentation

7. C.T. is a 45-year-old man presenting to his family physician with a 1-day history of nonbloody, watery diarrhea. His history is significant for return 2 days ago from the coastal areas of Florida. On the evening before leaving Florida, he and his wife dined at a seafood restaurant where they shared the same meal, with the exception of an appetizer of raw oysters that only C.T. had consumed. His wife is not ill. C.T. has no significant medical history. His physical examination reveals no signs or symptoms of dehydration. Why is C.T.'s history of present illness and clinical presentation consistent with non-cholerae *Vibrio* gastroenteritis?

A key piece of information from C.T.'s history of present illness, which is consistent with the presumptive diagnosis of non-cholerae *Vibrio* gastroenteritis, is consumption of raw oysters harvested from areas where *V. parahaemolyticus* species have been identified. In a survey of *V. parahaemolyticus* infection in the United States, gastroenteritis accounted for 59% of infections, wound infection accounted for 34% of infections, and septicemia accounted for 5% of infections.²⁴ Following a median incubation period of 17 hours (range, 4–90 hours),³¹ clinical manifestations of gastroenteritis include diarrhea, abdominal cramps, nausea, vomiting, and fever. Bloody diarrhea occurs in 9%–29% of cases.^{24,31} In Japan, *V. parahaemolyticus* is a frequent cause of watery diarrhea because of the consumption of raw fish and shellfish.²

Treatment

8. Should a course of antibiotics be prescribed for C.T.?

In healthy adults, *V. parahaemolyticus* gastroenteritis is usually a mild, self-limiting illness lasting a median of 2.4–6 days.³² Antibiotics have not been shown to shorten the course of uncomplicated infection,³² but they may be helpful in patients with severe diarrhea.²⁴ Antimicrobials are also used to

treat wound infections and septicemia.²⁴ When indicated, cefazidime with doxycycline, or doxycycline with ciprofloxacin or an aminoglycoside is recommended.³¹ Individuals with liver disease or alcoholism are at risk for severe *Vibrio* infections, including septicemia.²⁴ The risk for infection can be reduced by avoiding the consumption of raw or undercooked shellfish; and avoiding the exposure of wounds to seawater, especially during the warmer months when water temperatures favor the multiplication of *Vibrio*.³¹

STAPHYLOCOCCUS AUREUS, BACILLUS CEREUS, AND CLOSTRIDIUM PERFRINGENS

Clinical Presentation and Treatment

Staphylococcus aureus, *B. cereus*, and *C. perfringens* are important causes of toxin-mediated foodborne illnesses. Gastrointestinal symptoms typically begin within 24 hours of ingestion of contaminated foods, which is in contrast to the longer incubation periods for illnesses caused by *Salmonella*, *Shigella*, and *Campylobacter*. *B. cereus* causes two different intestinal syndromes: the short-incubation disease characterized by vomiting (emetic syndrome) and the long-incubation disease characterized by a diarrheal illness (diarrheal syndrome).²⁰

9. T.N., a 30-year-old woman, presents to her family physician with an acute onset of nausea and vomiting. Her history is significant for attending a Chinese buffet 3 hours ago with friends who are experiencing a similar illness. The buffet included a variety of beef, fish, and chicken dishes; fried rice; and desserts, including cream-filled pastries. T.N. is alert and oriented, and her physical examination is normal. Why are T.N.'s history of present illness and clinical presentation consistent with food poisoning caused by *S. aureus*, or short-incubation disease caused by *B. cereus*? Should empiric antibiotics be prescribed?

Foodborne illnesses are often grouped by their usual incubation period: <6 hours, 8–16 hours, and >16 hours. The rapid onset (within 6 hours) of T.N.'s GI symptoms after eating suggests the illness is caused by preformed toxins produced by *S. aureus* or *B. cereus* (short-incubation disease, emetic syndrome). Diarrhea and abdominal cramps may also occur. Although cooking kills the toxin-producing bacteria, it does not destroy toxin that has already been produced. Foods implicated in staphylococcal food poisoning include salads, cream-filled pastries, and meats,²⁰ whereas foods implicated in *B. cereus* food poisoning include fried rice, dried foods, and dairy products.²⁰

In contrast, the features of T.N.'s illness are not consistent with signs and symptoms of toxin-mediated illness caused by *C. perfringens* or *B. cereus* (long-incubation disease, diarrheal syndrome). These bacteria are associated with the onset of diarrhea and abdominal cramps within 8–16 hours after the ingestion of contaminated foods, and vomiting is not a prominent symptom in these illnesses. *C. perfringens* or *B. cereus* causing the long-incubation disease produces heat-labile toxins in vivo after the ingestion of contaminated foods, thus, explaining the longer incubation period compared with illness caused by the ingestion of preformed toxins. Foods implicated in *C. perfringens* food poisoning include improperly stored beef, fish, poultry dishes, pasta salads, and dairy products, whereas foods

implicated in long-incubation *B. cereus* food poisoning include meats, vanilla sauce, cream-filled baked goods, and salads.²⁰

Illnesses caused by these toxin-producing bacteria usually resolve within 24 hours. Antibiotic therapy is not indicated.²⁰

SHIGELLA

Shigella species are gram-negative bacilli that are frequent causes of the dysentery syndrome. Dysentery is a severe manifestation of inflammatory diarrhea characterized by bloody or mucoid stools, abdominal cramps, and tenesmus (painful straining when passing stools). Of the four *Shigella* species, severe dysentery is most likely to be caused by *S. dysenteriae* followed by *S. flexneri*, whereas a milder illness characterized by watery diarrhea with or without blood is generally caused by *S. sonnei* and *S. boydii*.^{33,34} In addition to the greater propensity for dysentery to be caused by *S. dysenteriae*, differentiating between the various *Shigella* species (i.e., *S. dysenteriae* versus other *Shigella* species) has implications in terms of the clinical response to the prescribed antimicrobial regimen.

Shigella dysenteriae

Clinical Presentation

10. M.T. is a 60-year-old, ill-appearing man presenting to the hospital because of worsening bloody diarrhea and fever. Two days before admission, he noted the onset of fever, abdominal cramps, and six to seven nonbloody, watery stools. His diarrhea has since worsened to 10–12 small-volume stools with blood and mucus, and he now complains of painful straining while passing his stools. His history of present illness is significant for return 2 days ago from a business trip to Bangladesh. During the business portion of his trip, M.T. remained at the hotel where the meeting was being held and where all of his meals were prepared by the hotel staff. On the day of his departure, however, he decided to consume meals prepared by local street vendors. M.T. lives alone in Florida. He has no significant medical history, has no known drug allergies, and takes no medications. On admission, his temperature is 101°F. Physical examination reveals an acutely ill man with severe abdominal tenderness, and with signs and symptoms of mild dehydration. Why are his history of present illness and clinical presentation consistent with the diagnosis of dysentery, most likely caused by *Shigella dysenteriae*?

A key piece of information from M.T.'s history of present illness that is consistent with his presumptive diagnosis of shigellosis is his recent travel to Bangladesh, where shigellosis is endemic because of the lack of adequate systems for sewage disposal. Epidemics or outbreaks of *S. dysenteriae* have been reported in other areas of the world, including South Asia, India, and Sri Lanka.³⁴ M.T. probably acquired his infection following the consumption of contaminated foods prepared by local street vendors. Because as few as 10–100 *Shigella* organisms can cause infection in healthy hosts,³⁴ shigellosis is easily spread by symptomatic persons with diarrhea, by person-to-person contact, by consumption of contaminated food and water, or by asymptomatic persons who continue to excrete shigellae from their stool.³⁵ Good hygiene and access to clean water and foods are essential to prevent the spread of shigellosis.

As in M.T., symptoms of dysentery begin within 24–48 hours following ingestion of *Shigella* bacteria and include fever, fatigue, malaise, and anorexia.³⁵ Watery diarrhea generally precedes dysentery, and frequently is the only manifestation of mild infection.³⁵ Progression to dysentery may follow within hours to days and is characterized by frequent small volume, bloody, and mucoid stools; abdominal cramps; and tenesmus.³⁵ Of the four *Shigella* species, severe dysentery is most likely to be caused by *S. dysenteriae*.^{33,34} Complications of shigellosis include seizures, hemolytic uremic syndrome (HUS), and toxic megacolon.³⁵

Treatment

11. Would M.T. benefit from antibiotics to treat his presumed diagnosis of shigellosis?

Effective antimicrobial therapy for shigellosis has several benefits. First, effective therapy reduces the average duration of illness from 5–7 days to about 3 days.³⁵ Within 48 hours of starting treatment, patients can expect to experience decreases in stool frequency, the volume of bloody stools, and fever, and an improved appetite.³³ Second, effective antimicrobial therapy reduces the risk of death and serious complications associated with shigellosis.³³ Third, effective antimicrobial therapy quickly reduces the carriage and excretion of *Shigella* species, which serves to limit the spread of infection.³⁶

Despite the aforementioned benefits of antimicrobial therapy in patients with *S. dysenteriae* type 1 infection, prior case-control studies suggest an association between the development of HUS and antimicrobial use.³⁷ In contrast, a recent study reported that early administration of effective antimicrobials is associated with a low risk for developing HUS. These authors speculated that the prior association between HUS and antimicrobial use may have been observed because effective antibiotics were given later in the course of the illness. Reasons for the delay in administration of antimicrobials were possibly related to patient's delay in seeking medical care, or because the *Shigella* species were subsequently found to be resistant to the empiric antimicrobials prescribed.³⁷

12. What empiric antimicrobial regimens are available for the treatment of shigellosis?

Shigella species are well known for rapidly becoming resistant to antimicrobials following exposure to these drugs.³⁵ At one time, effective empiric treatments for shigellosis included the following older agents administered orally: TMP-SMX¹⁸ ampicillin (but not amoxicillin),^{18,38} or nalidixic acid.¹⁸

During the 1990s, as multidrug-resistant *Shigella* species (e.g., resistance to ampicillin, TMP-SMX, and chloramphenicol) became more common, fluoroquinolones became the antimicrobials of choice for the empiric treatment of shigellosis.³⁹ Clinical trials enrolling primarily adults found norfloxacin 400 mg twice daily for 5 days⁴⁰ or ciprofloxacin 500 mg twice daily for 3–5 days^{39,41} were as effective as the standard therapies used for the treatment of shigellosis. Subsequently, a single dose of ciprofloxacin 1 g⁴² or norfloxacin 800 mg⁴³ were also found to be as effective as longer treatment courses for patients with mild to moderate disease. Although the benefits of the single-dose fluoroquinolone treatments include greater adherence to therapy and less cost, single dose regimens are less effective than the standard 5-day treatment

courses in patients with more severe illness⁴² and in patients with *S. dysenteriae* type 1 infection.⁴²

Since the introduction of fluoroquinolones as the drugs of choice for the empiric treatment of shigellosis, *Shigella* species with reduced susceptibility to ciprofloxacin (i.e., higher ciprofloxacin minimal inhibitory concentrations (MIC) in the range of 0.25–1 mcg/mL) have been identified in England and Wales,⁴⁴ and *Shigella* species with even higher MIC to ciprofloxacin (MIC of 8 minimal inhibitory concentration to 32 mcg/mL) have been identified in India.⁴⁵ Current alternatives to fluoroquinolones for the empiric treatment of shigellosis include ceftriaxone,²⁵ and azithromycin,^{33,46} although there is no national guideline for in vitro azithromycin susceptibility testing for *Shigella* species.⁴⁶

Besides emerging resistance, also of issue with fluoroquinolones are data citing lesions on cartilage tissue in juvenile animals given these agents.¹⁷ Although fluoroquinolones are not approved for use in children, the emergence of multidrug-resistant enteropathogens in some geographic areas led to clinical trials of the short-term use of fluoroquinolones in children; and the available data suggest that a short course of these agents is safe.^{17,47} The World Health Organization's guideline for the control of shigellosis, an infection which is so common in developing countries, note that the risk of fluoroquinolone toxicity in children is outweighed by the benefit of effective therapy.³³ The guideline is intended to assist public health authorities and health care providers with the management of cases shigellosis, and it recommends ciprofloxacin for the treatment of shigellosis in both children (15 mg/kg orally twice daily for 3 days) and adults (500 mg orally twice daily for 3 days).³³

Azithromycin has been successfully used in the treatment of shigellosis. In adults with moderate to severe shigellosis caused by multidrug-resistant *Shigella* species (e.g., variable resistance to TMP-SMX, ampicillin, and nalidixic acid), clinical success was similar for subjects treated with oral azithromycin (500 mg on day 1, then 250 mg daily for 4 days) or oral ciprofloxacin (500 mg Q 12 hr for 5 days) 89% versus 82%, respectively; $p > 0.2$.⁴⁸ Despite in vitro susceptibility to these study antibiotics, both azithromycin and ciprofloxacin, however, were less effective in the subset of patients infected with *S. dysenteriae* type 1 (failure rate of 29% and 17%, respectively) compared with patients infected with other *Shigella* species (failure rate of 6% for either antibiotic).⁴⁸

In the setting of epidemic dysentery caused by *S. dysenteriae* type 1 in which nearly all of the isolates were resistant to ampicillin and TMP-SMX, similar clinical outcomes were observed in adults treated with a single 1-g oral dose of azithromycin or multiple doses of ciprofloxacin 500 mg orally twice daily for 3 days. In this study, the mean number of days until resolution of symptoms after starting therapy was 2.5 days for azithromycin versus 2.3 days of ciprofloxacin.⁴⁹

Ceftriaxone and cefotaxime, which are parenteral third-generation cephalosporins with excellent in vitro activity against *Shigella* species, have been used alone³⁹ or with amikacin⁴⁵ for the treatment of shigellosis in patients failing ciprofloxacin therapy. Of concern are reports of ceftriaxone-resistant *S. dysenteriae* and other *Shigella* species from India, Korea, Taiwan, Argentina, and Turkey. Ceftriaxone resistance in these *Shigella* strains is attributed to the production of extended-spectrum β -lactamases.⁵⁰

Cefixime, an oral third-generation cephalosporin, is unreliable for the treatment of shigellosis with clinical and bacteriologic failures reported in 11%–47% and 22%–60% of patients, respectively.⁴⁶ The higher treatment failure rate with cefixime is from a study of adults with illness primarily caused by *S. flexneri* and *S. dysenteriae* type 1, the *Shigella* species that typically cause a more severe illness.⁵¹ When cefixime was compared with azithromycin, a trend toward better clinical outcome and eradication was observed with azithromycin.⁵²

13. Should loperamide be started in patients with dysentery?

The use of loperamide in dysentery is controversial.¹³ Because of concerns that prolonging the clearance of pathogens from the intestinal tract could worsen the severity of illness, experts do not recommend the use of antimotility drugs in persons with fever or bloody diarrhea¹⁴ or when invasive pathogens are suspected.¹³ In adults with bacillary dysentery primarily caused by *Shigella* species but who were not critically ill, however, the combination of ciprofloxacin and loperamide did not prolong fever. Rather, the combination decreased the number of unformed stools and shortened the duration of diarrhea.

14. What would be an appropriate antimicrobial regimen to treat M.T.'s presumed case of shigellosis, likely caused by *S. dysenteriae*?

For persons with mild-to-moderate shigellosis, many authorities recommend treatment with one or two doses of a fluoroquinolone. For more severe shigellosis, such as that displayed by M.T., or for the treatment of proven *S. dysenteriae* type 1 infection, 3–5 days of therapy is recommended.^{33,35} Alternatives to fluoroquinolones include ceftriaxone or azithromycin, and, if susceptible, TMP-SMX or ampicillin.

Shigella species other than *S. dysenteriae*

Clinical Presentation

15. F.F., a 30-year-old, previously healthy female, presents to her physician with nonbloody, watery diarrhea of 3 days' duration. Her history of present illness is significant for close contact with her 2-year-old nephew who is recovering from shigellosis caused by *S. sonnei*, which he acquired from the day care center he attends. F.F. lives in California and has no significant medical history. Overall, she feels better compared with the previous day. F.F. is afebrile, and her physical examination is completely normal. How does F.F.'s clinical presentation of shigellosis differ from that of M.T. in the previous question?

Unlike the more severe clinical presentation characteristic of shigellosis caused by *S. dysenteriae*, *S. sonnei* generally causes a mild and self-limited illness for which antimicrobials are not generally required, but are often prescribed to shorten the duration of illness and reduce the infectious period.⁵³ In industrialized countries, *S. sonnei* is the most common cause of shigellosis, accounting for 90% of infections caused by *Shigella* species.⁵⁴

Treatment

16. Should F.F. receive a course of antibiotics to treat her presumed case of shigellosis?

If prescribed, the antimicrobial choices for F.F. are similar to those discussed in the previous case. Until recently, in the United States multidrug-resistant *Shigellae* had not been particularly problematic, and therefore TMP-SMX had been recommended for the empiric treatment of shigellosis.⁵⁵ In 1995, however, more than 50% of *Shigella* species isolated from persons living in Oregon were reportedly resistant to TMP-SMX or ampicillin.⁵⁵ In 2005, outbreaks of shigellosis in United States day care centers reported that 89% of *S. sonnei* was resistant to both ampicillin and TMP-SMX.⁵³ The origin of multidrug-resistant *Shigella* species in the United States may be related to migrant workers traveling to areas such as Latin American and Mexico where multidrug-resistant *Shigella* species is common.⁵⁵

Because fluoroquinolones are not FDA approved for use in children, in this population, alternatives for the treatment of multidrug-resistant *Shigella* species include azithromycin⁴⁶ and ceftriaxone.³³

SALMONELLA

Salmonellae are often referred to as either nontyphoidal (e.g., *S. typhimurium*, *S. enteritidis*, *S. choleraesuis*, and many others) or typhoidal (*S. typhi* and *S. paratyphi*) salmonellae. These enteric gram-negative bacilli are important causes of foodborne illness in humans, causing the clinical syndromes of gastroenteritis, bacteremia, localized infection,⁵⁶ typhoid fever (enteric fever) and the chronic carrier state.⁵⁷ The role of antimicrobial therapy in the treatment of salmonellosis is based on the severity of the patient's illness, presenting clinical syndrome, and underlying health problems.

Nontyphoidal Salmonellosis

Uncomplicated Gastroenteritis in the Immunocompetent Host CLINICAL PRESENTATION

17. B.B., a 35-year-old, previously healthy man, presents to his physician with a 1-day history of abdominal pain, nausea, vomiting, and nonbloody stools. One day before the onset of his symptoms, he ate a turkey dinner at the local diner, and was later informed of an outbreak of *Salmonella* gastroenteritis attributed to food served at the restaurant. B.B. has no significant medical history. On physical examination, he is not ill appearing, but is febrile. The rest of his examination is normal. B.B. is given the presumptive diagnosis of mild, uncomplicated nontyphoidal *Salmonella* gastroenteritis. Why is B.B.'s history of present illness and clinical presentation consistent with this diagnosis?

A key piece of information from B.B.'s history of present illness that is consistent with the presumptive diagnosis of foodborne *Salmonella* gastroenteritis is his consumption of foods associated with an outbreak of *Salmonella* gastroenteritis. Salmonellae are widely found in nature, colonizing animal hosts, including mammals, reptiles, and birds. Worldwide, nontyphoidal salmonellae are major causes of foodborne illnesses related to the consumption of contaminated beverages or foods such as poultry (chickens, turkeys, ducks) or poultry products (eggs), and dairy products.⁵⁶

As in B.B., symptoms of *Salmonella* gastroenteritis usually begin 6–72 hours after ingestion of contaminated foods. B.B. displays some of the typical clinical manifestations

of *Salmonella* gastroenteritis, including the acute onset of fever, diarrhea, and abdominal cramping. Other manifestations of *Salmonella* gastroenteritis include bloody diarrhea and dehydration.⁵⁴

TREATMENT

18. Should B.B. receive a course of antibiotics to treat his presumed diagnosis of uncomplicated nontyphoidal *Salmonella* gastroenteritis?

In otherwise healthy individuals such as B.B. presenting with a mild episode of uncomplicated gastroenteritis secondary to nontyphoidal *Salmonella* species, antibiotics are not routinely recommended because this is typically a self-limiting illness lasting for 2–5 days. In most instances, persons with uncomplicated nontyphoidal *Salmonella* gastroenteritis require only replacement of fluid and electrolyte losses. When antimicrobials have been prescribed in this setting, they have not reduced the duration or severity of illness.⁵⁴ In addition, unnecessary use of antimicrobials may prolong asymptomatic carriage of these organisms,⁵⁴ place patients at risk for adverse drug reactions, and promote the emergence of antimicrobial-resistant bacteria.⁵⁴ A recent study in children confirmed that antimicrobials are still not mandatory even when nontyphoidal salmonellosis (manifesting primarily with GI symptoms and limited signs of systemic inflammation) is caused by antimicrobial-resistant *Salmonellae*.⁵⁴

Antimicrobials should be reserved for persons who are severely ill⁵⁶ or for persons with risk factors for developing extraintestinal *Salmonella* infection. Antimicrobials can also be used when rapid interruption of fecal excretion of organisms is needed to control outbreaks of salmonellosis in institutionalized persons.⁵⁶

19. Following resolution of B.B.'s acute episode of *Salmonella* gastroenteritis, he is inadvertently found to be still excreting *Salmonella* bacteria from his stool, despite remaining asymptomatic. Should antimicrobials be prescribed to eliminate B.B.'s intestinal carriage of nontyphoidal *Salmonella*?

Antimicrobials provide no benefit to persons such as B.B. who are asymptomatic carriers of nontyphoidal *Salmonella* and, therefore, they are not recommended to eliminate intestinal carriage of these organisms.⁵⁸ In healthy, asymptomatic adults living in an area where nontyphoidal salmonellae are endemic, a randomized, double-blind trial concluded that neither norfloxacin nor azithromycin was any better than placebo in eradicating intestinal carriage of these organisms.⁵⁸ Although antimicrobials can rapidly convert stool cultures to negative immediately after therapy, a longer follow-up reveals usually no difference in the time to final clearance of *Salmonella* in persons given antimicrobials versus those given placebo.⁵⁶ The median duration of fecal shedding of nontyphoidal *Salmonella* is about 1 month in adults and 7 weeks in children <5 years of age.⁵⁶

Adverse consequences of using antimicrobials to eliminate intestinal carriage is the emergence of *Salmonellae* that are resistant to the antibiotics used,⁵⁸ and adverse effects to the antimicrobial.

Gastroenteritis in Patients at Risk for Extraintestinal *Salmonella* Infection

CLINICAL PRESENTATION

20. W.M., a 75-year-old moderately ill-appearing man, presents to his clinic physician with signs and symptoms of *Salmonella* gastroenteritis. His history of present illness is significant for eating the same turkey dinner as B.B. (Question 17). In contrast to B.B., W.M.'s medical history is significant for recently diagnosed leukemia. Would antimicrobial therapy benefit W.M.?

Overall, <5% of patients with nontyphoidal *Salmonella* gastroenteritis become bacteremic, although infections with *S. choleraesuis* and *S. dublin* are more likely to cause bacteremia.⁵⁹ Host factors that compromise the body's ability to contain infections increase the risk for extraintestinal *Salmonella* infection. These host factors include a very young age; persons with HIV infection, diabetes, malignancy, rheumatologic disorders, and low gastric pH (e.g., as in infancy, pernicious anemia, or induced by medications); and persons receiving immunosuppressive therapies.⁵⁶ Bloodstream infection with *Salmonella* can lead to hematogenous seeding of any body site.⁵⁶

Antimicrobial therapy (usually 3–7 days is reasonable) is recommended for persons such as W.M. who are severely ill, or who have host factors that increase their risk for extraintestinal spread of infection.⁵⁶ Additionally, a short course (duration of 48–72 hours or until the patient is afebrile) of antimicrobials is also commonly recommended for persons >50 years of age who may have atherosclerotic lesions which, if bacteremia were to occur, could become hematogenously seeded.⁵⁶ Other extraintestinal infections seen in persons with *Salmonella* bacteremia include osteomyelitis, septic arthritis, meningitis, and infectious endarteritis.⁵⁹

TREATMENT

21. What antimicrobials are available for the treatment of nontyphoidal *Salmonella* infection? What empiric antibiotic would be appropriate for W.M.?

Before the 1980s, the drugs of choice for the treatment of nontyphoidal salmonellosis included ampicillin, TMP-SMX, and chloramphenicol.⁵⁹ Because it is not uncommon to find that more than 50% of nontyphoidal *Salmonella* are resistant to these antimicrobials, fluoroquinolones are now widely used for the empiric treatment of salmonella infection.⁵⁹

In the 1990s, reports of suboptimal clinical responses in persons with nontyphoidal salmonellosis treated with fluoroquinolones raised questions about the effectiveness of this class of antimicrobials for the treatment of salmonellosis.⁶⁰ Microbiologic tests revealed these *Salmonella* strains were resistant to nalidixic acid, a drug which is the prototype for the quinolone group of antimicrobials.⁶⁰ Nalidixic acid-resistant salmonellae generally have higher MIC to ciprofloxacin (MIC range of 0.12–0.5 mcg/mL) compared with nalidixic acid-susceptible strains (MIC <0.03 mcg/mL).⁶⁰ In the United States, nalidixic acid-resistant, nontyphoidal *Salmonella* species increased from 0.4% in 1996 to 2.3% in 2003.⁶¹

Infection with antimicrobial-resistant *Salmonella* is associated with suboptimal clinical outcomes. Some evidence suggests that standard, long-course (7–10 days) fluoroquinolone

regimens are less effective for the treatment of infection caused by nalidixic acid-resistant *Salmonellae*.⁶⁰ In addition, persons with bloodstream infection caused by antimicrobial-resistant nontyphoidal *Salmonella* are more likely to have bloodstream infection and to be hospitalized versus persons with infection caused by pansusceptible *Salmonella*.⁶²

With concerns over fluoroquinolone resistance in *Salmonella* species, alternative antimicrobials include the expanded spectrum cephalosporins (cefotaxime or ceftriaxone) and imipenem.⁵⁹ Azithromycin has also been used in a limited number of cases of nontyphoidal salmonellosis.⁵⁶ Since 1991, however, nontyphoidal *Salmonella* species resistant to extended-spectrum cephalosporins are increasingly being identified in many areas of the world.⁵⁹ *Salmonella* resistance to the expanded spectrum cephalosporins is primarily attributed to the production of extended spectrum β -lactamases,⁵⁹ and these strains may also exhibit decreased susceptibility to ciprofloxacin.⁶³ Imipenem has been successfully used for the treatment of invasive infection caused *S. enterica serotype choleraesuis* resistant to both ceftriaxone and ciprofloxacin.⁶⁴

Invasive Nontyphoidal *Salmonella* Infection

22. B.T., a severely ill-appearing, 70-year-old man, presents to the ED with complaints of severe abdominal pain, bloody diarrhea, new-onset right hip pain, and a temperature of 102°F. His history of present illness is significant for eating the same turkey dinner as B.B. (Question 17) and W.M. (Question 18). His past history is significant for a right hip prosthesis. Would B.T. benefit from antibiotic therapy?

CLINICAL PRESENTATION AND TREATMENT

B.T. is presenting with signs and symptoms of *Salmonella* gastroenteritis, and probable bloodstream infection complicated by localized infection to his prosthetic hip (i.e., new onset right hip pain). Treatment of *Salmonella* bacteremia without other infectious complications is generally successful following 10–14 days of antimicrobial therapy. A longer duration of treatment and surgery may be required for metastatic infections such as osteomyelitis.⁵⁶

Regarding empiric antimicrobial treatment for B.T., the widespread resistance to older agents (e.g., ampicillin and TMP-SMX) makes these agents unsuitable options until susceptibility data are available. Instead, empiric therapy with antimicrobials, such as selected third-generation cephalosporins (cefotaxime or ceftriaxone), or a fluoroquinolone can be used, keeping in mind the possibility of resistance to fluoroquinolones. Selection of a specific antimicrobial should also consider the specific extraintestinal site of infection.

Typhoidal Salmonellosis—Typhoid Fever (Enteric Fever)

Enteric fever is an acute systemic illness caused by typhoidal *Salmonellae*, most commonly *S. typhi*. Enteric fever caused by *S. typhi* is referred to as “typhoid fever,” whereas enteric fever caused by *S. paratyphi* is referred to as “paratyphoid fever.”

Clinical Presentation

23. B.C., a 49-year-old obese woman, presents to the ED with a 1-week history of fever, abdominal pain, headache, anorexia, and

diarrhea. One day before admission, she noted a new red rash on her chest. Her history of present illness is significant for return 10 days ago from travel to the Indian subcontinent where she stayed with relatives, some of whom were recovering from typhoid fever. B.C.’s medical history is significant for gallstones. She lives in California with her husband. On admission, she is alert and oriented and moderately ill appearing. Vital signs are as follows: temperature is 101 °F and heart rate is 60 beats/minute, blood pressure is stable. Physical examination is significant for splenomegaly and hepatomegaly. Laboratory tests include the following: WBC is $3.0 \times 10^6/\text{mm}^3$; liver function tests are mildly elevated and the results of two sets of blood cultures are pending. Why is her history of present illness, clinical presentation, and laboratory findings consistent with the presumed diagnosis of typhoid fever?

B.C.’s recent travel history to the Indian subcontinent and exposure to relatives recovering from typhoid fever are key pieces of information supporting her diagnosis of typhoid fever. Most cases of typhoid fever occur in developing areas of the world, including the Indian subcontinent, Southeast Asia, Africa, and Latin America where the disease is endemic.⁵⁷ In developed countries, enteric fever is a sporadic disease occurring mainly in travelers returning from areas where the disease is endemic. In the United States, 74% of cases of typhoid fever are diagnosed in persons reporting recent travel.⁵⁷ It is likely that B.C. acquired her infection following the consumption of contaminated foods during her trip to the Indian subcontinent.

B.C.’s clinical presentation includes the classic signs and symptoms of enteric fever, such as high fever for > 1 week associated with abdominal pain, anorexia, diarrhea or constipation; headache, dry cough, splenomegaly, and hepatomegaly.⁵⁷ Other manifestations of severe typhoid fever include GI bleeding, encephalopathy and shock.⁵⁷ Laboratory abnormalities consistent with typhoid fever include B.C.’s low WBC count and mildly elevated liver function tests.⁵⁷

The incubation period of B.C.’s illness is consistent with the usual 7–14 days seen in persons with typhoid fever.⁵⁷ During the incubation period, *Salmonellae* multiply within macrophages and monocytes, and systemic manifestations of typhoid fever appear when bacteria are released into the bloodstream.

Treatment

24. Would B.C. benefit from a course of antimicrobials to treat her presumptive diagnosis of typhoid fever? If so, what options are available?

Effective antimicrobials for typhoid fever have several benefits. First, effective therapy reduces fever and other symptoms within 3–5 days, with acceptable regimens clearing all symptoms within 7–10 days.⁶⁵ Second, effective antimicrobial therapy decreases mortality—<1%⁵⁷ from the 5%–10% mortality rate reported in untreated patients.⁶⁵ Third, effective therapy prevents relapse of infection, which generally occurs in 5%–10% of patients, and usually within 2–3 weeks after resolution of fever.⁶⁶ Finally, effective therapy eradicates fecal shedding of *S. typhi*, which limits the spread of infection.⁶⁵

Until the late 1980s, the standard treatment for typhoid fever was 14–21 days of chloramphenicol, TMP-SMX, or ampicillin.⁶⁶ The subsequent availability of newer, but more costly antimicrobials, including ceftriaxone and azithromycin, provided alternatives for the treatment of typhoid fever. In

adults and children with enteric fever caused by *S. typhi* or *S. paratyphi* remaining susceptible to ampicillin, chloramphenicol, and TMP-SMX, clinical cure was achieved in 91% of persons treated with parenteral ceftriaxone (3–4 g/day for 3–7 days), which was similar to the 94% cure rate in persons treated with chloramphenicol.⁶⁷ In children and adolescents with uncomplicated typhoid fever caused primarily by antimicrobial-susceptible strains (>90% susceptible to ampicillin, TMP-SMX, chloramphenicol, ciprofloxacin, and ceftriaxone) once daily administration of oral azithromycin (20 mg/kg/day, maximum, 1,000 mg/day for 5 days) or parenteral ceftriaxone (75 mg/kg/day, maximum, 2.5 g/day for 5 days) produced similar clinical cure rates of 94% and 97%, respectively. In this study, although bacteremia was present longer in the azithromycin-treated patients, relapse of infection at day 30 was higher in the ceftriaxone-treated patients versus the azithromycin-treated patients, 6 (19%) versus 0%, respectively. This rate of relapse with the short course of ceftriaxone is consistent with the 5%–15% reported by other investigators.⁶⁸

During the early 1990s, multidrug-resistant (i.e., simultaneous resistance to chloramphenicol, ampicillin, and TMP-SMX) *S. typhi* caused outbreaks of typhoid fever in India, Pakistan, Bangladesh, Vietnam, the Middle East, and Africa, thus, limiting the usefulness of these older antimicrobials for the empiric treatment of typhoid fever.⁶⁶ Consequently, the availability of fluoroquinolones, which retained activity against these multidrug-resistant strains,^{69,70} and which could be administered orally, made the fluoroquinolones the preferred treatments for enteric fever in both adults and children. In children with uncomplicated typhoid fever in which 86% of isolates were multidrug resistant (i.e., resistant to chloramphenicol, TMP-SMX, ampicillin, and tetracycline), ofloxacin (7.5 mg/kg twice daily for 2–3 days) achieved cure rates of >89%.⁷⁰ Likewise, in adults with enteric fever, 63% of whom were infected with multidrug-resistant *S. typhi*, oral ofloxacin (200 mg Q 12 hr for 5 days) was superior to a 5-day course of ceftriaxone (3 g/day) with clinical cure achieved in 22 (100%) versus 18 (75%) patients treated with these respective regimens. In this study, all *S. typhi* isolates were susceptible to the study antimicrobials, and the ceftriaxone failures were successfully treated with ofloxacin.⁶⁹

Azithromycin also has proved to be effective for the treatment of typhoid fever caused by multidrug-resistant strains. In adults (approximately one-third of whom were infected with *Salmonella* resistant to at least two of the following: chloramphenicol, ampicillin, or TMP-SMX, but susceptible to azithromycin and ciprofloxacin), oral azithromycin (1 g on day 1, then 500 mg daily on days 2–6) was as effective as oral ciprofloxacin 500 mg twice daily for 7 days (100% cure rate for both treatment groups).⁷¹ A 7-day course of azithromycin in children (10 mg/kg/day orally once a day; maximum, 500 mg daily) and adults proved effective for the treatment of infection caused by multidrug-resistant and nalidixic acid-resistant *S. typhi*.⁷² Finally, in children with typhoid fever, oral azithromycin given once daily (10 mg/kg/day for 7 days; maximum, 500 mg/day) was as effective as ceftriaxone (75 mg/kg/day for 7 days; maximum, 2.5 g/day), with clinical response rates of 91% and 97%, respectively. Despite in vitro susceptibility, relapse of infection was higher in the ceftriaxone versus azithromycin-treated patients, 14% versus 0%, respectively.⁷³ When a longer course (14 days) of ceftriaxone

was used in children with multidrug-resistant *S. typhi* (resistance to ampicillin, chloramphenicol, and TMP-SMX), however, no child experienced a relapse, whereas 14% of children treated with only 7 days of ceftriaxone experienced a relapse.⁷⁴ Although ceftriaxone remains very active against *S. typhi*, isolates with high-level resistance to ceftriaxone have been indentified.⁶⁶

Because the fluoroquinolones have been widely used for the treatment of typhoid fever, increasingly reported are clinical treatment failures when these antimicrobials were used to treat this infection. Microbiologic examination of the strains associated with fluoroquinolone treatment failure reveals these isolates have higher MIC to ciprofloxacin compared with earlier strains. *Salmonella* that are fully susceptible to ciprofloxacin by disc testing generally have a ciprofloxacin MIC of <0.03 mcg/mL and are usually susceptible to nalidixic acid, the prototype drug for the quinolone group of antimicrobials.⁶⁵ In contrast, strains with low level ciprofloxacin resistance (intermediate MIC of 0.125–1 mcg/mL) are usually resistant to nalidixic acid, and these strains are associated with unsatisfactory treatment responses to fluoroquinolones (see below).⁶⁵ Ciprofloxacin-resistant *S. typhi* have ciprofloxacin MIC >1 mcg/mL and are resistant to nalidixic acid.⁶⁴ Fully fluoroquinolone-resistant isolates have been detected in India.⁶⁵

In some regions of the world, clinical failure rates in patients with enteric fever following treatment with fluoroquinolones increased from 9%–35%, in 1997 and 1999, respectively.⁷⁵ Following 12–14 days of ciprofloxacin for the treatment of typhoid fever, the overall condition of 32 patients did not improve, and all cases were eventually successfully treated with ceftriaxone.⁷⁶ In this report, the ciprofloxacin MIC of *S. typhi* isolates ranged from 0.0625–0.5 mcg/mL, and ceftriaxone MIC were <0.0625 mcg/mL. A retrospective review of persons with infection caused by nalidixic acid-susceptible or nalidixic acid-resistant *S. typhi* and who were treated with a short course of ofloxacin reported more treatment failures in patients infected with the resistant strains versus the susceptible strains, 50% versus <5%, respectively.⁷⁷ Short courses of fluoroquinolones are not recommended for the treatment of infections caused by nalidixic acid-resistant *S. typhi*.⁶⁵ Recent in vitro data show that the newer fluoroquinolones (gemifloxacin and moxifloxacin) may be the best drugs in this class for the treatment of multidrug-resistant and nalidixic acid-resistant isolates.⁷⁸

Cefixime, an oral third-generation cephalosporin, has been used for the treatment of typhoid fever, although with variable success. In one study, cefixime administered for 12–14 days was effective treatment for typhoid fever; however, when a shorter, 7-day course of cefixime was used, cefixime was less effective than 5 days of ofloxacin.⁷⁹ Recent reports from Nepal have shown that cefixime is not an acceptable alternative.⁷⁸

Optimal treatment for fluoroquinolone-resistant isolates has not been determined. Azithromycin, ceftriaxone, or maximal recommended doses of fluoroquinolones for 10–14 days have been recommended.⁶⁶

25. What specific empiric antibiotic regimen would you recommend be initiated for the empiric treatment of B.C.'s typhoid fever?

Uncomplicated cases of typhoid fever can be treated with oral antibiotics, whereas severe cases are treated with parenteral therapy.⁶⁶ For the empiric treatment of typhoid fever, ceftriaxone or a fluoroquinolone can be used.⁸⁰ Azithromycin is also an alternative agent. When susceptibility data are known, fully susceptible isolates can be treated with a fluoroquinolone for 5–7 days, or with TMP-SMX, ampicillin, or chloramphenicol for 10–14 days.⁶⁶ Finally, the re-emergence of *S. typhi* susceptible to TMP-SMX⁸¹ and chloramphenicol⁶⁶ may mean these older agents may again be useful and inexpensive alternatives for the treatment of *S. typhi* infection.

Adjunctive Treatment

26. Besides the administration of antibiotics, are there adjunctive therapies from which B.C. could benefit?

For persons with severe typhoid fever (with altered mental status or shock), mortality is decreased to 10% when chloramphenicol is combined with dexamethasone (3 mg/kg IV followed by 1 mg/kg Q 6 hr IV for eight doses) compared with chloramphenicol alone (56% mortality).⁸² The benefit of steroids when the more potent fluoroquinolones are used is unknown, however.⁸³

Chronic Typhoid Carriers CLINICAL PRESENTATION

27. Fourteen months following discharge from the hospital, B.C.'s stool is still positive for *S. typhi*. During this time, her husband has had two episodes of typhoid fever. Why is B.C.'s clinical syndrome consistent with the chronic carrier state?

Although most patients excrete *S. typhi* in their stools for 3–4 weeks following recovery from their illness, 1%–3% excrete *Salmonella* from stool or urine for >1 year after infection; and these individuals are referred to as “chronic carriers.” B.C.'s risk factor for becoming a chronic carrier is her history of gallstones, which allows the sequestration of organisms in her diseased biliary tract. Although B.C. remains asymptomatic, she serves as a reservoir for spreading infection to others.

TREATMENT

28. What therapeutic options are available to cure B.C.'s chronic carrier state?

Treatment options for chronic *S. typhi* carriers such as B.C. include a prolonged course of antibiotics, cholecystectomy, or suppressive antimicrobial therapy.⁶⁶ Of chronic carriers, 50%–90% may be cured following prolonged courses of antibiotics,^{84–87} although efficacy may be lessened when anatomic abnormalities (e.g., cholelithiasis) are present.⁸⁴ Relapse is usually detected within the first several months after completing antimicrobial therapy,⁸⁸ but can occur up to 24 months after completing therapy.⁸⁴ If *S. typhi* are susceptible, antimicrobial regimens proved effective in curing chronic carriers include amoxicillin 2 g three times daily for 28 days,⁸⁶ ampicillin 1 g four times daily for 90 days,⁸⁵ ampicillin 1.5 g four times daily plus probenecid for 6 weeks,⁸⁴ TMP-SMX 160/800 mg twice a day for 3 months,⁸⁷ ciprofloxacin 500–750 mg twice a day for 3–4 weeks,^{88–90} or norfloxacin 400 mg twice daily for 4 weeks.⁹¹ Patient follow-up in these studies ranged from 10–12 months following completion of therapy.

Prevention

29. B.C.'s sister is planning a trip to the Indian subcontinent and is concerned about developing typhoid fever. What can she do to reduce her risk for developing typhoid fever?

In the United States, an intramuscular vaccine that is 51%–77% effective in preventing typhoid fever can be administered to persons >2 years of age. Adverse effects with the parenteral vaccine include local pain and swelling, fever, headache, and malaise.⁶⁶ The Ty21a oral vaccine affords a protective efficacy rate ranging from 42%–96%.⁶⁶ This oral vaccine is well tolerated and can be administered to persons >6 years of age. B.C.'s sister should consult with her physician regarding the need for typhoid vaccination. She should also be informed that, because the vaccine may not be fully protective, good hygiene and avoiding foods with a high risk for contamination are still necessary to minimize her risk for acquiring typhoid fever.

ESCHERICHIA COLI O157:H7

Epidemiology

30. P.J., a 3-year-old girl, is brought to the ED because of “stomach pains” and nonbloody diarrhea that has progressed to bloody diarrhea over the past 48 hours. Five days before the onset of diarrhea, the family celebrated the Fourth of July at a fast-food restaurant; P.J.'s parents ate fish sandwiches and P.J. ate a hamburger. P.J.'s mother noted that, unlike previous hamburgers eaten at the restaurant, this hamburger was not thoroughly cooked because the juices from the hamburger were still pinkish. P.J. has no significant medical history. During the week, she attends a day care center.

On physical examination P.J. is afebrile, with signs of mild to moderate dehydration. A stool sample is negative for fecal leukocytes. The physician assesses her illness as bloody diarrhea, possibly caused by STEC. The plan is to admit P.J. to the hospital for hydration, observation, and further workup. What clinical and laboratory findings and epidemiologic history are consistent with the diagnosis of STEC as the cause of P.J.'s illness?

Escherichia coli O157:H7 is a strain of *E. coli* that produces Shiga toxins as one of its mechanisms of causing GI illness. A second virulence factor of STEC strains is their ability to attach to and damage the intestinal mucosa.⁹² These *E. coli* bacteria cause a spectrum of infection, including asymptomatic carriage, mild and nonbloody diarrhea, bloody diarrhea (hemorrhagic colitis), HUS, and thrombotic thrombocytopenia purpura.⁹³

Escherichia coli O157:H7 should be suspected in the setting of abdominal cramps with nonbloody diarrhea that progresses to bloody diarrhea over 1–2 days.⁹² Unlike bloody diarrhea associated with *Shigella* species or *Campylobacter* species, fever is often absent or of low grade because this pathogen is not invasive.⁹⁴ Patients with severe illness are more likely to have fever, however.⁹⁵

Shiga toxin-producing Escherichia coli is most commonly spread by consumption of undercooked beef products that are contaminated with *E. coli* O157:H7, although other modes of acquiring this infection have been reported (see Question 32). The incubation period for this infection is usually

3–4 days, which is consistent with P.J.'s recent history of eating undercooked hamburger. In most instances, the illness resolves in 5–7 days.⁹² Fecal leukocytes may or may not be found in stool samples.⁹⁶

Laboratory Diagnosis

31. How can the diagnosis of *E. coli* O157:H7 infection be confirmed?

In the United States, *E. coli* O157:H7 is the most common STEC serotype identified as causing this infection.⁹⁶ Unlike other *E. coli*, O157:H7 does not rapidly ferment sorbitol, thus allowing the use of special culture media (Sorbitol-MacConkey) to help in identifying this organism. Because of sorbitol-fermenting organisms and non-O157 STEC, further testing for Shiga toxins or the genes encoding them is increasingly performed.^{92,93,96}

Hemolytic Uremic Syndrome

32. Forty-eight hours after admission to the hospital, P.J. is pale and has developed several “bruises” on her extremities. The nurse recorded only a minimal output of darkened urine during the past 24 hours. New laboratory tests reveal blood urea nitrogen (BUN), 150 mg/dL (normal, 5–25); serum creatinine (SrCr), 6 mg/dL (normal, 0.3–0.7); serum potassium (K), 6.8 mEq/L (normal, 3.5–5.5); WBC count, 20,000 cells/mm³ (normal, 5,000–15,000); hemoglobin (Hgb), 5 g/dL (normal, 11–13); platelets, 50,000 cells/mm³ (normal, 150,000–350,000); and urinalysis is positive for blood and protein. The stool specimen sent on admission is positive for *E. coli* O157:H7. What complication of *E. coli* O157:H7 infection does P.J. now display?

[SI units: BUN, 53.55 mmol/L of urea (normal, 1.79–8.93); SrCr, 530.4 μmol/L (normal, 26.52–62.88); K, 6.8 mmol/L (normal, 3.5–5.5); WBC count, 20 × 10⁹/L (normal, 5–15); Hgb, 50 g/L (normal, 110–130); platelets, 50 × 10⁹/L (normal, 150–350)]

The new clinical and laboratory findings support the diagnosis of HUS, a well-known complication of STEC infection. HUS is characterized by the triad of thrombocytopenia, microangiopathic hemolytic anemia, and acute renal failure with oliguria.⁹⁷ On physical examination, P.J.'s “bruises” on her extremities are consistent with thrombocytopenia, which is confirmed by the low platelet count. Her pale appearance is consistent with anemia and is confirmed by the low Hgb; the dark urine is caused by the color imparted from bilirubin because of red cell lysis (hemolytic anemia). Finally, P.J.'s decreased urine output and increased serum creatinine and BUN concentrations are consistent with renal failure.⁹⁸

P.J. has several risk factors for HUS: her age (i.e., children aged <5–15 years, median age 4–8 years), fever, increased peripheral WBC count, and the season of the year (i.e., summer).^{95,97,99–102} Although not present in this case, another possible risk factor for developing HUS is treatment with antimotility or antidiarrheal agents,¹⁰³ although this has not been universally confirmed.^{95,100} In addition to young age, age >65 years appears to be a risk factor for HUS.⁹⁵ The progression of *E. coli* O157:H7 gastroenteritis to HUS typically becomes

apparent about 1 week after the onset of diarrhea.^{95,97,99} Of children, 3%–7%¹⁰⁴ may develop HUS, with a mortality rate ranging from 3%–5%. In adults, *E. coli* O157:H7 infection progresses to HUS in as many as 27% of patients, with a higher rate in patients >65 years of age.⁹⁵ HUS-related mortality has reached 42% in patients >15 years of age⁹⁵; elderly nursing home patients have a mortality rate of up to 88%.¹⁰⁵

Treatment

33. Would P.J. benefit from drug therapy, including antimicrobial, antimotility, or antidiarrheal agents?

Other than supportive measures to manage the complications associated with illness caused by *E. coli* O157:H7, no specific drug therapy for this infection exists.⁹² In retrospective and prospective studies, antibiotics have not influenced the severity of illness, or the duration of diarrhea or other GI symptoms.^{106,107} When TMP-SMX was started a mean of 7 days after the onset of diarrhea, the duration of *E. coli* O157:H7 excretion was not altered.¹⁰⁶

The effect of antibiotic administration on the risk of *E. coli* O157:H7 complications (e.g., HUS) remains controversial. A prospective cohort study of 71 children with diarrhea caused by *E. coli* O157:H7 found that antibiotic treatment increased the risk of progression to HUS.¹⁰⁰ Previous publications have supported these findings,^{104,106,107} whereas others have reported that antibiotics do not increase the risk of progression to HUS.^{95,103} A meta-analysis of these and other studies revealed no association between antibiotic administration and development of HUS.¹⁰⁸ Antibiotic selection, timing of administration, STEC strain, and patient selection vary in the selected studies and complicate the analysis. Thus, the role of antibiotics in the treatment of *E. coli* O157:H7 infection remains controversial. Currently, clinicians do not recommend antibiotic treatment for STEC. Clinicians must carefully weigh empiric antibiotic treatment before the organism has been identified.¹⁰⁹

Antimotility drugs are not recommended for patients with *E. coli* O157:H7 infection because they have been variably associated with an increased risk of progression to HUS,^{103,104} although other studies have failed to find an association.^{95,100} Although the explanation for the increased risk is unknown, the reduction of bowel motility may decrease the clearance of organisms from the GI tract, thereby increasing the absorption of toxins. Administration of antimotility drugs within the first 3 days of illness has been associated with a longer duration of bloody diarrhea.¹¹⁰

Prevention

34. P.J.'s family members want to know what they could have done to prevent this infection. On discharge from the hospital, is it safe for P.J. to return to her day care center?

Shiga toxin-producing Escherichia coli is often spread to humans by consumption of contaminated beef products that are not thoroughly cooked.⁹³ Because thorough cooking kills this organism, meat should be well cooked (i.e., juices from meat should be clear, not pink). In addition, this infection can

be acquired by consuming other contaminated foods, including water, unpasteurized milk, apple cider, lettuce, and sprouts.^{92,93}

An experimental *E. coli* O157 O-polysaccharide conjugate vaccine is currently under study by the National Institutes of Health.¹¹¹ In a phase II trial, the vaccine was effective in inducing an immune response in the target population of young children and demonstrated no untoward effects.

Finally, because contact with infected persons commonly results in transmission of this infection to others,^{104,105,107} P.J. should have two consecutive stool cultures that are negative for *E. coli* O157:H7 before returning to day care.¹¹²

CAMPYLOBACTER JEJUNI

Campylobacter species are gram-negative bacilli that have a curved or spiral shape. Of the various *Campylobacter* species, *C. jejuni* and *C. fetus* are associated with human illness, with *C. jejuni* accounting for most of *Campylobacter* species isolated.¹¹³

Clinical Presentation

35. M.U. is a 20-year-old, previously healthy woman presenting to the Student Health Center with the following complaints for the past 24 hours: malaise, fever, diarrhea, abdominal pain, and bloody diarrhea. One day before the onset of her symptoms, she had dinner at a restaurant near campus where she ordered a chicken sandwich, but ate only a portion of it because the chicken was not thoroughly cooked. She has no significant medical history and no recent travel history. On physical examination, M.U. is not ill appearing. The physician tells her that over the past week, several students with gastrointestinal symptoms similar to hers have been diagnosed with *C. jejuni* gastroenteritis, and all had recently eaten at the same restaurant. Why are M.U.'s history of present illness and clinical presentation consistent with *Campylobacter* gastroenteritis?

A key piece of information from M.U.'s history of present illness, which is consistent with her presumptive diagnosis of *Campylobacter* gastroenteritis, is her consumption of undercooked chicken at a restaurant with an ongoing outbreak of *Campylobacter* gastroenteritis. In industrialized nations, the most important risk factor for acquiring *Campylobacter* infection is the consumption of improperly cooked foods such as unpasteurized foods, and contaminated water. Prevention of *Campylobacter* infection involves careful food preparation and cooking practices.¹¹⁴ Person-to-person transmission is not a major means of spreading this infection.

Symptoms of *Campylobacter* gastroenteritis begin 24–72 hours following exposure to contaminated foods. Clinical manifestations of gastroenteritis include diarrhea and fever (90%), abdominal cramps, and either loose and watery or bloody stools.¹¹³ M.U. does not exhibit signs or symptoms of complications associated with *Campylobacter* infection, such as meningitis, cholecystitis, pancreatitis, peritonitis, gastrointestinal hemorrhage, a reactive arthritis, and bacteremia. Bacteremia occurs in <1% of cases and most commonly in immunosuppressed persons, the very young, or the elderly. Guillain-Barré syndrome is an important but uncommon (<1/1,000 cases of infections) postinfectious complication of *C. jejuni* gastroenteritis.¹¹³

Treatment

36. Would M.U. benefit from antimicrobial therapy to treat her *Campylobacter* gastroenteritis?

Because *C. jejuni* gastroenteritis is an acute, self-limiting illness that typically resolves within 1 week,¹¹³ antibiotic therapy is usually not necessary.¹¹⁵ On the other hand, antibiotics are recommended for the treatment of *Campylobacter* infection in patients having symptoms lasting >1 week, high fevers, bloody stools, pregnant women, or immunocompromised hosts.¹¹³ Based on M.U.'s clinical presentation, including fever with bloody stools, antimicrobial therapy is warranted.

When administered early in the course of the illness (i.e., before determining the cause of the diarrhea), antimicrobial therapy shortens the duration and the severity of illness and the duration of fecal excretion of pathogens.¹¹⁴ In contrast, when antimicrobials are initiated later during the course of the illness (i.e., after determining the cause of the diarrhea), antimicrobials do not alter the clinical course of *Campylobacter* gastroenteritis.¹¹⁶

37. What empiric antimicrobial therapies could be initiated to treat M.U.'s presumed case of *C. jejuni* enteritis?

Fluoroquinolones were once considered the drugs of choice for *Campylobacter* infection.¹¹³ Fluoroquinolone-resistance in *Campylobacter* species, however, is no longer an uncommon finding. For example, fluoroquinolone-resistant *Campylobacter* in Sweden, the United Kingdom, and The Netherlands ranges from 18%–29%, and is even higher (72%–84%) in Thailand and Spain.¹¹³ In the United States, fluoroquinolone-resistant *Campylobacter* species causing human illness in Minnesota increased from 1.3% in 1992 to 10.2% in 1998, whereas resistance to erythromycin remained low at 2%.¹¹⁴ This widespread fluoroquinolone resistance is largely attributed to the frequent use of these antimicrobials in veterinary medicine and food animals (e.g., poultry).

In the clinical setting, patients with fluoroquinolone- or erythromycin-resistant *Campylobacter* infection are at increased risk for invasive illness or death.¹¹⁵ In travelers with *Campylobacter* gastroenteritis, a trend is seen toward a longer duration of illness in patients treated with ciprofloxacin versus azithromycin (52 hours vs. 40 hours, respectively); which may be related to the finding that 50% of the *Campylobacter* isolates were resistant to ciprofloxacin, whereas all isolates were susceptible to azithromycin.¹¹⁷

The drug of choice for *C. jejuni* gastroenteritis is erythromycin (adults, 250 mg four times daily; or children, 30–50 mg/kg in divided doses) for 5–7 days¹¹⁸; clarithromycin or azithromycin are also effective.^{113,117} Based on M.U.'s medical history and clinical presentation, empiric therapy with oral erythromycin can be started.

TRAVELERS' DIARRHEA

Of the more than 50 million persons traveling from industrialized countries to developing countries where individuals are at risk for acquiring travelers' diarrhea (TD), about 40% of travelers will experience a diarrheal illness.¹² Of these travelers, between 5% and 10% will continue to have enteric symptoms

for 6 months after the episode of TD, a condition referred to as the *postinfectious irritable bowel syndrome*.¹²

Etiology and Clinical Presentation

38. E.J. and B.R. are healthy 23-year-old women planning a 2-week vacation to Mexico. Before leaving on vacation, they discussed with their physician ways to avoid acquiring travelers' diarrhea. Contrary to their physician's recommendations, on the day of their arrival in Mexico they both began eating fresh fruits and vegetables from street vendors and drinking unbottled water. On the second day of their vacation, B.R. noted the passing of one to two watery stools without blood and without other GI symptoms. In contrast, E.J. felt "feverish" and passed six to seven loose, bloody stools. Neither traveler felt dizzy or thirsty, and both continued drinking adequate amounts of fluids to avoid becoming dehydrated. Why is the history of present illness and clinical presentation of their illnesses consistent with the diagnosis of TD? What risk factors do they have for acquiring TD?

Travelers' diarrhea is defined as three or more loose, unformed stools per day plus at least one symptom of enteric infection, such as abdominal cramps, nausea, vomiting, fever, fecal urgency, tenesmus, or the passage of bloody or mucoid stools.¹¹⁹ Clinical manifestations of TD typically begin within 24–48 hours after consuming fecally contaminated foods. Of travelers, 40% developing diarrhea have a mild, self-limiting illness of 1–2 days' duration.

The major risk factors these women have for acquiring TD are their destination to a developing country with suboptimal sanitation facilities to manage the disposal of sewage and the consumption of food items with a high likelihood of being contaminated with enteropathogens. These high-risk food items include unbottled water, ice cubes, raw milk, unpeeled fruits and vegetables, uncooked foods, moist foods (e.g., salads served at room temperature), and food from street vendors.¹²

Infectious agents are the major cause of TD, with bacteria representing 80% of the cases in which a pathogen is identified.¹² Overall, *Enterotoxigenic E. coli* (ETEC) and *enteroaggregative E. coli* (EAEC) are the etiologic pathogens identified in 50%–60% of TD cases,¹² and invasive pathogens, such as *Shigella*, *Campylobacter*, and *Salmonella* species, are responsible for an additional 10%–15% of episodes of TD.¹²

General Management

39. What general approach should B.R. and E.J. take to manage their illnesses?

The general approach to the management of TD includes replenishing fluid and electrolyte losses, avoiding continued ingestion of foods at high risk for being contaminated with enteropathogens, considering the use of specific drug therapy, or seeking medical attention. Neither traveler shows signs and symptoms of dehydration, including thirst, dizziness, and altered mental status, and both are drinking normally. They should continue to drink fluids, such as tea, broth, carbonated beverages, and fruit juices. For travelers able to drink fluids *ad libitum*, a modified World Health Organization oral rehydration solution has not been shown to provide additional benefit over the administration of loperamide alone.¹²⁰ Electrolytes

can be replaced by eating salted crackers or similar sources of sodium chloride.¹²⁰

Travelers should eat well-cooked foods that are served steaming hot and drink boiled or commercially bottled beverages.¹² Depending on the severity of their illness, travelers can consider the use of antimotility agents alone or in combination with antimicrobials. Self-treatment for TD can be particularly important for persons who become ill in areas where reliable medical care is not available.¹² Of travelers receiving pretravel instructions for the self-medication of TD, 80% report their self-treatment was effective.¹²¹ For severe symptoms, travelers should seek medical attention.

40. What drug therapies could B.R. and E.J. consider using to reduce the duration and severity of travelers' diarrhea?

Bismuth Preparations and Loperamide

Both bismuth subsalicylate and loperamide decrease the number of unformed stools in persons with TD. Concurrent administration of bismuth preparations and fluoroquinolones (antimicrobials commonly used in persons with TD) should be avoided because the chelation of fluoroquinolones by bivalent cations will reduce the bioavailability of these agents.^{122,123} Compared with bismuth subsalicylate, loperamide acts more rapidly by exerting an antimotility effect.¹³

Antimicrobials

Effective antimicrobial therapy shortens the duration and severity of TD. Previously effective antimicrobials for the treatment of TD included tetracycline and TMP-SMX, but widespread resistance of enteropathogens to these agents renders them unsuitable for the empiric treatment of this infection. Depending on the most likely pathogen(s) causing TD, the recommended antimicrobial options for the empiric treatment of this infection include the fluoroquinolones, azithromycin, and rifaximin.¹³

Clues to the likely pathogen causing TD include the area of travel and the clinical presentation of the illness. For example, noninvasive pathogens, such as ETEC, are more common causes of TD in Latin America and Africa,¹³ and the diarrheal illness caused by these enteropathogens is characterized by a less severe illness in which patients are afebrile, with nonbloody, watery stools, and are without significant abdominal pain.¹ In studies performed in travelers to Mexico^{119,124,125} or Kenya,¹²⁴ a single dose of an antimicrobial (ciprofloxacin 500 mg,¹²⁶ azithromycin 1 g,¹¹⁹ or levofloxacin 500 mg¹¹⁹) decreased the median time to passage of the last unformed stool to 22–33 hours,^{119,124} compared with 54–66 hours in travelers given placebo.¹¹⁹ In some,¹²⁷ but not all studies,¹²⁸ when ETEC was the most common pathogen identified, the diarrheal illness was shorter in travelers taking loperamide plus an antimicrobial. Specifically, fewer travelers taking ofloxacin plus loperamide passed their last unformed stool at 24 hours compared with travelers treated with ofloxacin alone, 62% versus 91% respectively.¹²⁹ A recent study in military personnel stationed in Turkey reported the median time to the passage of the last unformed stool was shortened to as little as 3 hours in recruits given levofloxacin (single 500-mg dose) plus loperamide (4 mg initially, then 2 mg as needed; maximum 16 mg/day); a finding that did not differ significantly from the

13 hours observed in recruits randomized to treatment with azithromycin (single 1-g dose) plus loperamide, $p = 0.2$.¹³⁰

Rifaximin is a poorly absorbed rifamycin derivative that is FDA approved for the treatment of TD caused by noninvasive strains of *E. coli*. In travelers to Mexico and India, oral rifaximin 200 mg three times daily or ciprofloxacin 500 mg twice daily for 3 days significantly reduced the median time to passage of the last unformed stool to 32 hours and 29 hours, respectively, versus 66 hours for travelers given placebo.¹³¹ In this study, rifaximin was as effective as ciprofloxacin against noninvasive bacterial enteropathogens, but was less effective than ciprofloxacin when invasive pathogens were identified. Rifaximin should not be used in patients with diarrhea complicated by fever and bloody stools, or diarrhea caused by pathogens other than *E. coli*.¹³²

Invasive pathogens, such as *Shigella*, *Campylobacter*, and *Salmonella* species, are more common causes of TD in Asia,¹² and the diarrheal illness caused by these pathogens is characterized by a more severe illness in which patients are febrile, with bloody diarrhea, and severe abdominal pain.² A recent study enrolling military personnel developing TD while in Thailand reported that most were infected with *Campylobacter* species, of which 50% were resistant to levofloxacin, whereas resistance to azithromycin was not detected. In this study, the cure rate was highest following a single dose of azithromycin 1 g (96%), compared with the cure rates following 3 days of azithromycin 500 mg daily (85%) or levofloxacin 500 mg daily (71%), $p = 0.03$.¹³³ Levofloxacin was inferior to azithromycin, except when patients were infected with levofloxacin-susceptible *Campylobacter*, or when no pathogen was identified. The highest rate of nausea during the 30 minutes after receiving the first antimicrobial dose was seen in persons given 1 g of azithromycin (14% vs. <6%, respectively, for the other regimens, $p = 0.06$). A prior trial in Thailand also reported a trend toward a shorter duration of illness with azithromycin (40 hours) versus ciprofloxacin (52 hours), which could be related to the slower response in persons infected with ciprofloxacin-resistant strains.¹¹⁷

41. Based on the severity of their illnesses, what specific drug therapies could B.R and E.J. consider taking?

Treatment of TD with specific drug therapy is partly based on the severity of the individual's illness and likely enteropathogen. Travelers such as B.R. with a mild diarrheal illness (one to two stools/24 hours) with mild or absent symptoms may forgo specific drug therapy or elect to use bismuth subsalicylate. Patients with a mild to moderate diarrheal illness (more than three stools/24 hours) with no distressing symptoms can consider the use of loperamide or bismuth subsalicylate (Table 62-3), although persons on a short and critical trip (e.g., business) might also consider the addition of an antibiotic. For patients with distressing frequency or symptoms, loperamide plus a fluoroquinolone, azithromycin or rifaximin can be used; they should be reassessed after 24 hours.¹³

For travelers such as E.J., with severe diarrhea or diarrhea with fever or bloody stools, a full 3 days of a fluoroquinolone or azithromycin is recommended. Azithromycin can be considered a first-line agent for TD in areas where fluoroquinolone-resistant *Campylobacter* species is common.¹³ Loperamide can

Table 62-3 Therapy for Travelers' Diarrhea in Adults

| Drug | Treatment |
|---------------|-------------------------------------|
| Ciprofloxacin | 500 mg twice daily for 1–3 days |
| Ofloxacin | 400 mg twice daily for 1–3 days |
| Levofloxacin | 500 mg daily for 1–3 days |
| Azithromycin | 500 mg daily for 1–3 days |
| Rifaximin | 200 mg three times daily for 3 days |

Adapted from DuPont HL. Travelers' diarrhea: contemporary approaches to therapy and prevention. *Drugs* 2006;66:303; and Castelli F, et al. Prevention and treatment of traveler's diarrhea. *Digestion* 2006;73(Suppl 1):109, with permission.

be added for severe cramps or fluid losses, although the use of loperamide in patients with dysentery is controversial.¹³

Some experts recommend that travelers to high-risk areas for acquiring TD be provided with medications and instructions for the self-treatment of TD, which is particularly important to travelers who become ill in remote areas where reliable medical care is not available.¹² One recommendation is to provide travelers with nine 200-mg tablets of rifaximin for the treatment of nondysenteric illness, and three 500-mg tablets of azithromycin for use in case they develop febrile dysentery.¹²

Prophylaxis

42. On hearing of the travels of B.R. and E.J., classmates J.G. and T.M. begin planning their vacation to Mexico, but want to prevent any diarrheal illness that could interfere with their travel plans. Neither student has any significant medical history. Besides avoiding the consumption of food items with a high likelihood of being contaminated with enteropathogens, what drug therapies can be used to minimize their likelihood of developing TD?

Antimicrobials

A single daily dose of a fluoroquinolone provides a protection rate of 80% against TD.¹² Significantly fewer diarrheal illnesses are reported in patients given norfloxacin 400 mg daily or ciprofloxacin 500 mg daily for 7–15 days (26%–64%) versus travelers given placebo (2%–7%).¹²⁷

Rifaximin provided a protective efficacy of 72%–77% against TD in students traveling from the United States to Mexico. Because ETEC was the main enteropathogen identified in this study, another study is needed to determine if rifaximin can prevent diarrhea caused by invasive bacterial pathogens.¹³⁴ Rifaximin is not approved for the prophylaxis of TD.¹³²

Miscellaneous Agents

Bismuth subsalicylate, two tablets (524 mg/dose) four times daily for a maximum of 3 weeks, has a protective efficacy of 65% against TD.¹² Probiotics have been studied on the basis of their ability to prevent enteropathogen colonization. To date, the effectiveness of probiotics is conflicting, and the data are not sufficiently strong to recommend their use as the only prophylactic agent for TD.¹³

43. What specific drug therapies would be reasonable for T.M. and J.G. to take as prophylaxis against travelers' diarrhea?

Despite their efficacy in preventing TD, for several reasons many experts^{14,135} do not recommend universal antimicrobial

prophylaxis against TD. First, most persons will experience a self-limiting illness. Second, if TD should occur effective antimicrobial therapies can reduce the duration of illness to as little as a few hours.¹³⁵ Instead, antimicrobials should be reserved for situations where the benefit of preventing illness outweighs the downside of their use, including adverse drug reactions, increased bacterial resistance, and expense.¹³ Candidates for prophylactic antimicrobials include travelers in whom a bout of diarrhea would not be well tolerated (e.g., persons with autoimmune disorders, diabetes or chronic cardiac conditions, impaired gastric acid secretion, inflammatory bowel disease, HIV infection or those who are immunosuppressed; or in travelers on short-term critical trips such as diplomats and athletes).¹³

CLOSTRIDIUM DIFFICILE-ASSOCIATED DIARRHEA

Mild to Moderate Infection

Clinical Presentation and Diagnosis

44. B.W., a 35-year-old woman, is admitted to a 10-bed medical ward for the treatment of *Streptococcus pneumoniae* meningitis. On arrival, she is started on ceftriaxone (Rocephin) 2 g IV Q 12 hr and improves over the next few days. On day 7 of antibiotic therapy, she complained of feeling warm, with cramping abdominal pain and diarrhea. She began passing mucoid, greenish, foul-smelling watery stools, and had a temperature of 101°F. Microscopic examination of a stool sample was positive for fecal leukocytes. The physician's assessment of B.W.'s clinical and laboratory findings is antibiotic-associated diarrhea (AAD), most likely caused by *C. difficile*. What is the most likely mechanism for this patient's AAD?

Antibiotic-associated diarrhea is a common complication of antimicrobial therapy.¹³⁶ The mechanisms by which antibiotics cause diarrhea include allergic and toxic effects on intestinal mucosa, and alterations of GI motility (e.g., erythromycin), and of normal intestinal flora. Changes in the normal bowel flora can lead to changes in carbohydrate or bile acid metabolism by intestinal bacteria or to overgrowth of pathogenic bacteria, either of which may be followed by diarrhea.¹³⁷ Bacteria known to be associated with AAD include *C. perfringens*, *S. aureus*, *Klebsiella oxytoca*, *Candida* species, and *C. difficile*.¹³⁷ *C. difficile* infection is most clinically relevant and is the focus of this section.

A spore-forming, gram-positive anaerobic bacillus, *C. difficile* can cause a wide spectrum of syndromes, including asymptomatic carriage, diarrhea of varying severity, colitis with or without formation of pseudomembranes, toxic megacolon, colonic perforation, and death.¹³⁶

The pathogenesis of *C. difficile* infection involves disruption of the normal colonic flora, most commonly by antibiotics; however, antineoplastic drugs¹³⁸ and tacrolimus¹³⁹ have been implicated as well (Table 62-4). Alteration of the colonic microflora is followed by overgrowth of toxin-producing strains of *C. difficile*.¹³⁷ These toxins are responsible for causing colonic inflammation and the clinical manifestations of this infection.^{136,139}

45. Why is B.W.'s history and presentation consistent with AAD caused by *C. difficile*?

Table 62-4 Medications Implicated in Clostridium difficile-Associated Diarrhea

| Commonly Implicated | Rarely Implicated |
|-------------------------------|-----------------------|
| Cephalosporins | Aminoglycosides |
| Clindamycin | Rifampin |
| Ampicillin | Tetracycline |
| Fluoroquinolones | Chloramphenicol |
| | Vancomycin |
| Less Commonly Implicated | Metronidazole |
| Erythromycin | Antineoplastic agents |
| Clarithromycin | |
| Azithromycin | |
| Other penicillins | |
| Trimethoprim-sulfamethoxazole | |

From Fekety R. Guidelines for the diagnosis and treatment of *Clostridium difficile*-associated diarrhea and colitis. *Am J Gastroenterol* 1997;92:739; Johnson S, et al. *Clostridium difficile*-associated diarrhea. *Clin Infect Dis* 1998;26:1027; and Pepin J, et al. Emergence of fluoroquinolones as the predominant risk factor for *Clostridium difficile*-associated diarrhea: a cohort study during an epidemic in Quebec. *Clin Infect Dis* 2005;41:1254, with permission.

B.W.'s major risk factor for acquiring *C. difficile*-associated diarrhea (CDAD) is owing to her having received an antibiotic within the last 2 weeks. *C. difficile* is a common cause of nosocomial diarrhea. The clinical and laboratory findings consistent with CDAD include mucoid, greenish, foul-smelling watery stools and crampy abdominal pain. Patients usually present with low-grade fevers, but temperature may be >104°F.¹³⁶ Peripheral leukocytosis is common, with CDAD a common cause of WBC >30,000 cells/mm³.^{140,141} Fecal leukocytes are variably present in CDAD and are not clinically useful for diagnosis.¹⁴²

The onset of symptoms of CDAD varies widely from a few days after the start of antibiotic therapy to 8 weeks after the agent is discontinued.¹³⁶ Other risk factors for acquiring CDAD are admission to a hospital in which *C. difficile* is endemic or in which there is an ongoing outbreak of *C. difficile* infection.

46. How can the diagnosis of CDAD be confirmed?

Several tests are available to make the diagnosis of *C. difficile* infection. The rapid tests latex agglutination and EIA are commonly used in clinical laboratories. The latex agglutination test detects antigens to *C. difficile*; EIA detects toxins A and B produced by *C. difficile*.¹³⁶ Limitations of the latex agglutination test are that it also detects antigens to other intestinal bacteria, and it does not differentiate toxin-producing strains from non-toxin-producing strains.¹³⁶ Of the *C. difficile* strains isolated from various populations, 5%–25% do not produce toxins (nontoxicogenic) and do not cause colitis or diarrhea.¹⁴³

Colonoscopy with biopsy is used to make the diagnosis of *C. difficile* colitis rapidly. The characteristic colonic changes are raised, yellowish nodules or plaquelike pseudomembranes, often with skip areas of normal mucosa.¹³⁶ Because the characteristic pseudomembranes may be scattered throughout the colon, the diagnosis of pseudomembranous colitis can be missed with colonoscopy.

47. How can B.W.'s CDAD be differentiated from enigmatic AAD?

Only 10%–20% of cases of AAD are positive for toxigenic *C. difficile*; the remaining cases have an unknown cause and are referred to as simple, benign, or “nuisance” diarrhea.^{136,140} The clinical presentation of benign diarrhea is similar to many cases of CDAD in that it is a self-limited illness that resolves with nonspecific supportive measures and discontinuation of antibiotics.¹³⁶ Despite these similarities, these clinical entities can be differentiated from one another by several objective measures. In hospitalized patients, watery diarrhea, low functional capacity, acid suppression, low albumin, and a WBC >13,000 cells/mm³ were significant predictors of CDAD.¹⁴⁴ Other clinical features that suggest CDAD rather than enigmatic diarrhea are constitutional symptoms, no antibiotic dose relationship to the illness, and hospital-wide epidemics of diarrhea.¹⁴⁰

Treatment**48. B.W.'s stool sample is positive for *C. difficile* toxin. What is the general plan for treat B.W.'s CDAD?**

After replacement of fluids and electrolytes, there are three options to manage B.W.'s diarrhea. The first is to discontinue the offending drug (if possible), which in B.W.'s case is probably the antibiotic ceftriaxone. In approximately 25% of cases, discontinuation of the offending agent with concomitant fluid and electrolyte replacement leads to resolution of symptoms within 48–72 hours.¹⁴⁵ Thus, patients with mild diarrhea may not require any treatment other than discontinuation of the offending agent.^{136,143}

Because B.W. is being treated for bacterial meningitis, a life-threatening infection, discontinuing antibiotics is not an option. A second option is to change her antimicrobial therapy to an agent less likely to cause CDAD. B.W. is taking a cephalosporin, which, as with ampicillin, amoxicillin, and clindamycin, is frequently implicated as a cause of *C. difficile* diarrhea (Table 62-4). In contrast, antibiotics, such as TMP-SMX, and aminoglycosides, are less commonly associated with *C. difficile* infection.^{136,143,146} None of these antimicrobials, however, is a suitable alternative for treating *S. pneumoniae* meningitis.

The third and most reasonable option for B.W. is to receive therapy directed against *C. difficile* while continuing to take ceftriaxone for the treatment of her bacterial meningitis.

METRONIDAZOLE AND VANCOMYCIN**49. What antibiotics could be prescribed to treat B.W.'s CDAD?**

The oral agents most commonly used to treat CDAD are metronidazole and vancomycin. In a randomized trial that enrolled patients with CDAD and colitis, no significant difference was found in the efficacy of these drugs after 10 days of treatment.¹⁴⁷ Overall, >95% of patients treated for a first episode of CDAD with oral metronidazole or vancomycin is expected to respond to therapy.^{147,148} Recent reports have shown increases in *C. difficile* resistance to metronidazole and vancomycin, but the clinical significance in treatment selection is unknown.¹⁴⁹ Antibiotic sensitivities, therefore, are not routinely performed on *C. difficile*.

Metronidazole is well absorbed after oral administration and is excreted through the biliary tract before reaching the

colon. Common adverse reactions include nausea, vomiting, diarrhea, dizziness, confusion, and an unpleasant metallic taste.¹³⁶ A disulfiramlike reaction can occur when alcohol or alcohol-containing medications are taken concurrently with metronidazole.¹⁵⁰ Because metronidazole is a carcinogen and, in some animal species, a mutagen, it should be used in pregnancy only if clearly needed. Similarly, metronidazole's safety in children has not been proved, and many prefer not to use it in this population if other options exist.¹³⁶

Oral vancomycin produces fecal concentrations that are several hundred times the concentration needed to inhibit toxin-producing strains of *C. difficile*.¹⁴⁸ A 7- to 10-day course of oral vancomycin (125–500 mg orally four times daily) is recommended for the treatment of CDAD, with all dosing regimens equally effective.^{136,148,151,152} Because of equal efficacy and high concentrations in the colon with all doses, 125 mg is the most commonly prescribed dose. Although oral vancomycin is not well absorbed, measurable serum concentrations have been found in patients with both normal and compromised renal function.^{153–155}

Oral vancomycin is recommended when patients (a) fail to respond to metronidazole; (b) are infected with *C. difficile* resistant to metronidazole; (c) cannot tolerate metronidazole (e.g., allergy, or concurrent use of ethanol-containing products); (d) are pregnant or <10 years of age; (e) are critically ill because of *C. difficile* infection; or (f) have evidence of diarrhea caused by *S. aureus*.^{136,156}

50. What antibiotic regimen would you recommend for treatment of B.W.'s CDAD?

When antibiotic therapy is required for patients who are not critically ill as a result of their *C. difficile* infection, metronidazole (250–500 mg orally four times daily or 500–750 mg orally three times daily) for 7–10 days is recommended as first-line treatment.^{136,157} Oral metronidazole and oral vancomycin are equally efficacious,¹⁴⁷ but vancomycin use should be limited to prevent emergence of vancomycin-resistant organisms.¹⁵⁷ In addition, oral vancomycin is significantly more expensive than a course of oral metronidazole. Some of this cost differential can be offset by using the IV vancomycin preparation to prepare an oral solution (Table 62-5).

Once therapy directed against *C. difficile* is initiated, diarrhea or cramping should subside within 2–4 days. If B.W.'s symptoms have not resolved, vancomycin can be tried.¹⁴⁰

51. Following resolution of B.W.'s CDAD, is it necessary to send a follow-up stool sample to determine whether it is negative for *C. difficile* toxin?

After resolution of diarrhea, obtaining a follow-up stool sample to determine whether it is negative for *C. difficile* toxin is not recommended as part of routine practice because most patients with positive tests will not develop a recurrence of their diarrhea.¹³⁶ In addition, approximately 5% of healthy adults carry small numbers of *C. difficile* in their feces, whereas colonization rates are much higher (30%–50%) in hospitalized patients and newborns.^{136,143}

BACITRACIN**52. What other oral therapies have been used to treat CDAD?**

In a randomized, double-blind trial, oral bacitracin (80,000–25,000 U/day) was as effective as oral vancomycin

Table 62-5 Costs of Oral Drug Therapy for *Clostridium difficile*-Associated Diarrhea

| Drug | Regimen | Cost ^a |
|--|----------------------|-------------------|
| Metronidazole tablets (generic) | 500 mg TID × 10 days | \$21.84/10 days |
| Vancomycin capsules (Vancocin) | 125 mg QID × 10 days | \$646.40/10 days |
| Vancomycin solution ^b (generic) | 125 mg QID × 10 days | \$37.80/10 days |
| Nitazoxanide (Alinia) | 125 mg BID × 10 days | \$251.60/10 days |

^aAWP Red Book 2006.

^bPrepared from intravenous formulation.

(500–2,000 mg/day) in resolving symptoms of CDAD. Although the difference was not statistically significant, however, was a trend was seen toward a slower clinical response with bacitracin. Compared with vancomycin, the clinical response to bacitracin is slower and less certain, possibly because of resistance to bacitracin.¹³⁶ The recurrence rate is similar for both antibiotics.^{158, 159}

NITAZOXANIDE

Nitazoxanide is an oral nitrothiazolide currently FDA approved for the treatment of cryptosporidia and giardia. Nitazoxanide has in vitro activity against *C. difficile* and has been shown to be as effective as metronidazole in the initial treatment of CDAD in a small comparative trial.¹⁶⁰

RAMOPLANIN

Ramoplanin is a nonabsorbed, investigational, oral glycolipopeptide currently being studied in clinical trials for the treatment of CDAD.¹⁶¹ Phase II trials have shown similar response rates when compared with vancomycin. In animal models, ramoplanin has been shown to more effectively kill *C. difficile* spores, a potentially important factor in relapse of infection.¹⁶²

TOXIN BINDERS

Anion-binding resins (e.g., cholestyramine, colestipol) are not as reliable or as rapidly effective as oral metronidazole or vancomycin.¹³⁶ If prescribed, they are recommended only for mild CDAD.^{136, 163} The rationale for using exchange resins for CDAD is their ability to bind to toxin B produced by *C. difficile*¹⁶³; however, resins have a limited binding capacity for toxins that is probably inadequate for severe cases.¹³⁶ Other limitations of exchange resins include their inability to eradicate the pathogenic organisms responsible for toxin production and their ability to bind to vancomycin, which may reduce the efficacy of the antibiotic.¹³⁶ Severe constipation is a side effect of exchange resins.¹³⁶

Tolvamer is an investigational anionic polymer that binds *C. difficile* toxins A and B. In a phase II trial, tolvamer (6 g/d) alone was shown to be as effective as vancomycin for mild to moderate CDAD, and trended toward lower recurrence rates.¹⁶⁴ Further studies of variable doses are ongoing. Toxin binding may also be useful as adjunctive therapy with other antibacterials.

PROBIOTICS

Probiotic microorganisms are introduced into the normal flora to counteract disturbances and reduce the colonization with pathogenic species.¹⁵ Although orally administered *Lac-*

tobacillus species and the yeast *Saccharomyces boulardii* have been used to treat CDAD, no data support the use of probiotics alone to treat CDAD. Adjunctive use, however, has been suggested to prevent CDAD and its recurrences. Reports of isolated adverse effects, including fungemia, with ingestion of viable *S. boulardii* have been reported.¹⁶⁵

ANTI-DIARRHEALS

53. What is the role of antidiarrheal agents in patients with CDAD?

Opiates and other antiperistaltic agents should be avoided in patients with CDAD. Although these types of drugs may relieve diarrheal symptoms, they may also delay toxin removal from the GI tract. Patients with antibiotic-associated pseudomembranous colitis have deteriorated during therapy with antimotility medications.¹⁶⁶

Transmission

54. H.T., a 76-year-old man with multiple medical conditions, is admitted to the same 10-bed ward as B.W. His medical history is significant for a stroke that has left him bedridden in a nursing home. His only medications are those used to manage his hypertension. On day 4 of his hospitalization, H.T. complained of severe abdominal pain and watery, loose stools with blood. Physical examination revealed a toxic-appearing man with a temperature of 101°F. A stool specimen is positive for *C. difficile* toxin, and colonoscopy reveals pseudomembranes and colitis. A surgical consultant recommends an emergent colectomy because of impending bowel perforation secondary to the *C. difficile* infection. What are H.T.'s risk factors for acquiring *C. difficile*-associated pseudomembranous colitis during his hospitalization?

H.T.'s risk factors for acquiring *C. difficile* infection include his advanced age, bedridden status,¹⁶⁷ underlying diseases,¹⁶⁸ and admission to the hospital. *C. difficile* infection is spread when hospital personnel or equipment contaminated with *C. difficile* spores come into contact with susceptible patients. Physical proximity to an infected patient has been associated with an increased risk of CDAD.¹⁶⁹ Therefore, measures to prevent the spread of *C. difficile* infection include proper hand-washing before and after contact with infected patients, and the use of gloves and enteric isolation precautions when in contact with infected patients with diarrhea. Contaminated equipment should be properly disinfected.¹³⁶

Although *C. difficile* is often thought of as a nosocomial pathogen, it is being increasingly isolated in outpatient settings.^{170, 171} A European study found that up to 28% of all cases occurred without previous hospitalization.¹⁷⁰

New Epidemic Strain

55. Could there be a strain difference causing the severe CDAD in H.T.?

A highly pathogenic strain of *C. difficile* has recently been described in outbreaks in the United States.¹⁷² This strain, labeled BI/NAP1, causes more severe disease. Among its increased virulence factors are an increased production of both toxins A and B and a binary toxin. These strains are also newly resistant to fluoroquinolones, which may increase the frequency of disease.¹⁴⁶ No current clinical tests exist to distinguish BI/NAP1 from other strains. There are no specific treatment recommendations for this strain.

56. Over the next few days, all 10 patients on the ward with B.W. and H.T. are found to have *C. difficile* toxin in their stools. Five patients have diarrhea and the other five are asymptomatic. What is the role of antibiotic therapy directed at *C. difficile* in controlling this outbreak?

Neither oral metronidazole nor vancomycin is reliably effective in eradicating the carrier state (i.e., asymptomatic, fecal excretion), and neither is recommended for use in this situation.¹⁷³ The lack of efficacy of these drugs is probably related because, unlike the vegetative forms of *C. difficile*, the spores of *C. difficile* are resistant to the action of antibiotics.¹³⁶ Furthermore, compared with placebo, vancomycin administration is associated with a significantly higher rate of *C. difficile* carriage 2 months after treatment.¹⁷³ Restricting the use of clindamycin can be an effective component in efforts to control nosocomial epidemics of CDAD.¹⁶⁷ With the emergence of the BI/NAP1 strain, control of all antibiotic use, including fluoroquinolones, may be important in outbreak control.¹⁷⁴

57. What effect will the current CDAD outbreak have on the outcomes of the infected patients and on health care costs?

In a prospective study, hospitalized patients who developed CDAD had a 3.6-day increase in length of stay.¹⁷⁵ This increase was accompanied by a doubling of hospital costs. Although 3-month mortality rates were higher in patients with CDAD (48% vs. 22%), no significant differences were observed when adjustments were made for severity of underlying illness. The current outbreak is likely to increase both hospital costs and individual lengths of stay.

Severe *C. difficile* Infection

58. What treatment is recommended for patients such as H.T. who are critically ill from a *C. difficile* infection? What criteria are used to characterize patients as “critically ill”?

Of patients with antibiotic-associated pseudomembranous colitis who require surgical intervention (colectomy), up to 57% die.¹⁷⁶ Although the precise definition of “critically ill” is not clear, it has included patients with pseudomembrane formation, fever >104°F, marked abdominal tenderness, and marked leukocytosis.¹⁵⁷ Limited evidence suggests that vancomycin may be more effective than metronidazole in patients with predefined severe disease, including those admitted to

the intensive care unit.¹⁵⁶ H.T. meets these criteria for being critically ill.

Nonoral Treatment

59. Three days after oral vancomycin is initiated, H.T. develops an ileus and cannot take anything by mouth. What therapeutic options are available to treat H.T.’s pseudomembranous colitis?

Adequate antibiotic levels in the colon are necessary to treat *C. difficile*-associated pseudomembranous colitis. If the oral route is not feasible (e.g., patients with an ileus or bowel obstruction), the clinician must choose an agent that is either secreted or excreted into the GI tract in its active form. IV vancomycin is not the most desirable agent in this situation because it is not secreted into the GI tract. In contrast, metronidazole is eliminated by both renal and hepatic routes; bactericidal concentrations are achieved in both serum and bile.¹⁷⁷

The literature contains few reports of successful attempts to treat CDAD or pseudomembranous colitis with IV metronidazole (500 mg Q 6–8 hr).^{178–180} Likewise, unsuccessful attempts to treat CDAD with IV metronidazole have been reported.^{178,181} When oral therapy is not feasible in patients with CDAD, some experts recommend IV metronidazole 500–750 mg three or four times daily with concurrent use of enteral vancomycin.¹³⁶ The clinical response of *C. difficile* infection to IV vancomycin in a patient who did not survive was difficult to ascertain.¹⁴⁸

In adults, enteral vancomycin 500 mg four times daily can be given through an ileostomy or colostomy (if present). Several reports of successful outcomes using intercolonic vancomycin (as an adjunct to oral or IV antibiotics) in patients with CDAD have been documented. Rectal doses of vancomycin have varied from 500 mg Q 4–8 hr to 1,000 mg/L Q 8 hr.¹⁸² Because patients with CDAD are at risk for colonic perforation, enteral vancomycin should be administered cautiously.

Relapse

60. One week after discharge from the hospital, B.W. once again developed abdominal pain and diarrhea. Her clinic physician assumed these symptoms could not be related to a relapse of her CDAD because she had responded so well to metronidazole. What is the likelihood that CDAD has recurred?

Regardless of the antibiotic regimen prescribed for CDAD, symptomatic relapse occurs in 5%–30% of patients who respond to their initial treatment regimen.^{136,143} Relapses occur 2 weeks to 2 months (median of 7 days) after treatment has been discontinued.¹⁸³

In most instances, relapses are caused by germination of dormant spores that are intrinsically resistant to antibiotics. Reinfection with *C. difficile* from external sources, however, may account for up to half of all second episodes.¹⁸⁴ In rare instances, either vancomycin¹⁸⁵ or metronidazole¹⁸⁶ may have caused CDAD.

Risk factors for recurrent CDAD include increasing age, low quality-of-health score,¹⁸³ use of additional antibiotics, spring onset, and multiple prior episodes of *C. difficile*

infection.¹⁸⁷ Of patients experiencing their first episode of CDAD, 24% experience a relapse, and 65% of patients with a prior history of CDAD relapse.¹⁸⁸

Data suggest that patients with a poor immune response to *C. difficile* toxin A are more likely to have a relapse of CDAD.¹⁸⁹ It is not clinically helpful in the case of B.W., because no standard tests are currently available for this immune response. The influence of the immune system, however, has led to the usage of IV immune globulin in refractory or severe cases of CDAD.^{190,191} The utility of the usage of immune globulins has been debated in small single institution reviews. Immune globulins would not be considered the next line of therapy for B.W.

61. How should patients such as B.W. who relapse after therapy for CDAD be treated?

Most infections resulting from relapse are not related to bacterial resistance and they respond to retreatment with the same antibiotic used for initial treatment of the *C. difficile* infection.^{143,192} Thus, an appropriate approach for B.W. is to administer another 7- to 10-day course of oral metronidazole.

For patients with multiple recurrences of CDAD, the optimal management plan is unresolved.¹³⁶ Different approaches have been tried, including (a) high-dose vancomycin (2,000 mg/day)¹⁹³; (b) a 4- to 6-week course with vancomycin, after which the dose is tapered over a 1- to 2-month period^{193,194}; (c) exchange resins^{163,195}; (d) “pulse” dosing every 2–3 days¹⁹³; or (e) a combination of vancomycin and rifampin (600 mg orally twice daily).¹⁹⁶ Tapered and pulse therapy with vancomycin were shown to be most effective in a clinical trial comparing multiple strategies.¹⁹³ When combined with standard antibiotic therapy, a clinical trial with the probiotic *S. boulardii* for cases of relapsing CDAD noted a 65% response rate versus a 36% response rate for combination therapy with placebo.¹⁸⁸ The relapse rate was reduced to 17% when *S. boulardii* was combined with high-dose vancomycin.¹⁹⁷

Nitazoxanide had a 74% initial response rate in patients who had previously failed metronidazole therapy.¹⁹⁸ Recurrent relapse was successfully treated with a second course of nitazoxanide in a limited number of individuals, representing an overall 66% response rate in a small difficult-to-treat population.

Following treatment with vancomycin, a 2-week “chaser” course of rifaximin, a poorly absorbed rifamycin derivative, was successful in a case series for seven of eight patients with multiple relapses.¹⁹⁹ Although obviously a small sample, concern must be raised that the single failure occurred in concert with emerging rifaximin resistance.

Cryptosporidium Parvum

Cryptosporidia are intracellular parasites that infect cells of the GI tract, leading to a watery diarrheal illness. Of the various species, *C. parvum* is the most common cause of human illness. Although *C. parvum* causes an intestinal illness in both healthy and immunocompromised persons; the clinical presentations, the role of antiparasitic agents, and the clinical response to antiparasitic agents differ between these populations.

Clinical Presentation

62. C.K., a 35-year-old, previously healthy man, presents to his family physician with complaints of 15 days of watery diarrhea and a 5-lb weight loss. He heard an announcement by the Board of Health of a community-wide outbreak of cryptosporidiosis from contaminated water supplies, and is concerned that he has this illness. Why are C.K.’s history of present illness and clinical presentation consistent with cryptosporidiosis? Should antiparasitic agents be prescribed to treat cryptosporidiosis in otherwise healthy persons such as C.K.?

A key piece of information from C.K.’s history of present illness that is consistent with the diagnosis of cryptosporidiosis is his exposure to water supplies known to be contaminated with cryptosporidium oocysts, because this is the most important mode of acquiring this infection.²⁰⁰ Other means of spreading cryptosporidiosis include animal contact (cattle and sheep), and person-to-person contact (e.g., health care workers, day care personnel).²⁰⁰

C.K. is presenting with persistent diarrhea, which is defined as diarrhea lasting > 14 days. Common microbial causes of persistent watery diarrhea include parasites, such as *Isospora belli*, *Microsporidia*, *G. lamblia*, and *C. parvum*. The spectrum of infection with *C. parvum* ranges from asymptomatic carriage to a persistent, noninflammatory diarrheal illness.²⁰⁰ Other manifestations of cryptosporidiosis include nausea, vomiting, abdominal cramps, weight loss, and fever.²⁰⁰ In immunocompetent patients such as C.K., cryptosporidiosis is generally a self-limiting illness lasting approximately 2 weeks.²⁰⁰ In contrast, in immunocompromised patients, cryptosporidiosis can be a chronic, debilitating, diarrheal illness associated with malabsorption and significant weight loss.

Treatment

In immunocompetent hosts with a diarrheal illness attributed to *C. parvum* or in asymptomatic persons, other than replacement of fluids and electrolytes, no specific therapy directed at this parasite is generally required.²⁰¹ If needed, a 3-day course of nitazoxanide given with food (≥ 12 years, 500 mg Q 12 hr; 4–11 years, 200 mg Q 12 hr; and 1–3 years, 100 mg Q 12 hr) is approved for the treatment of diarrhea caused by *C. parvum* in persons > 1 year of age.²⁰² A randomized, double-blind, placebo-controlled trial in immunocompetent adults and children found that diarrhea resolved in 80% of those treated with nitazoxanide versus 41% of patients given placebo, $p < 0.0001$; oocyst shedding was also significantly reduced. In this study, diarrhea usually resolved within 3–4 days of starting treatment.²⁰³

In contrast, for immunocompromised persons, a meta-analysis of treatments for cryptosporidiosis found no evidence to support the role of chemotherapeutic agents for the management of cryptosporidiosis in this population.²⁰¹ These findings are consistent with a randomized trial that found a 3-day course of nitazoxanide did not provide any benefit to children who were HIV positive, whereas in children who were HIV negative, nitazoxanide treatment significantly improved the resolution of diarrhea and decreased mortality.²⁰⁴ In persons who are HIV positive, reconstitution of the immune system is the mainstay of treatment for cryptosporidiosis.²⁰¹

INTRODUCTION

Despite the introduction of new antimicrobial agents and improvements in diagnostic and surgical techniques, the treatment of intra-abdominal infections remains a therapeutic challenge. Improvements in radiographic techniques with improved localization of abscesses and early drainage, improved nutritional management, and the selection of appropriate antimicrobial agents all have contributed to a decrease in mortality associated with intra-abdominal infections.

Intra-abdominal infections are those contained within the peritoneal cavity, which extends from the undersurface of the diaphragm to the floor of the pelvis or the retroperitoneal space. Intra-abdominal infections can present as localized infections, a diffuse inflammation throughout the peritoneum, or infections in visceral organs such as the liver, biliary tract, spleen, pancreas, or female pelvic organs. Abscesses can form anywhere within the abdomen, between bowel loops, or in solid organs. If adequate source control is delayed, subsequent bacteremia and multiple organ failure are more likely to occur.

Although antimicrobial therapy should be selected on the basis of the suspected pathogens, judicious use of antimicrobial agents is warranted owing to increasing rates of resistant pathogens.

Normal Gastrointestinal Flora

The stomach of fasting individuals contains very few bacteria (i.e., <100 colony-forming units [CFU]/mL) because of the combined effects of gastric motility and the bactericidal activity of normal gastric fluid, which has a pH of 1 to 2.¹ The bacterial population of the stomach can be altered by drugs or diseases that increase gastric pH or decrease gastric motility.

Thus, patients with bleeding or obstructing duodenal ulcers, gastric ulcers, or gastric carcinomas have an increased number of oral anaerobes and facultative gram-negative bacteria colonizing the stomach.

The upper small intestine (duodenum and jejunum) usually contains relatively few bacteria and harbors mainly oral flora. The lower small intestine serves as a transitional zone between the sparsely populated stomach and the abundant microbial flora of the colon.² The biliary tree is generally sterile, although colonization with aerobic gram-negative bacilli (particularly *Escherichia coli* and *Klebsiella* spp) is more likely in patients with biliary tract stones, surgical biliary interventions, and in the elderly patient population.³

In the ileum, facultative gram-negative and gram-positive species, as well as obligate anaerobes, are encountered. As the distal ileum is approached, the quantity and variety of bacteria increase. Substantial numbers of anaerobic bacteria are present, including *Bacteroides* spp., *E. coli*, and *Enterococcus* are the most commonly encountered gram-negative and gram-positive organisms, respectively.^{1,2}

In the large bowel, anaerobic bacteria, particularly *Bacteroides* species, predominate. In the distal colon, bacterial counts average 10¹⁰ CFU/mL of feces, with anaerobes outnumbering other organisms by a ratio of 1,000 to 10,000:1.² Although large numbers of *Clostridia* spp., anaerobic gram-positive cocci, and non-spore-forming anaerobic rods are present, the most prevalent anaerobes are *Bacteroides* species. Among the facultative aerobes, *E. coli* is the most frequently isolated species.^{1,2} Given these differences in regional microflora populations, it is not surprising that trauma to the colon carries a much higher risk of intra-abdominal infection than it does to the stomach or jejunum⁴ (Fig. 63-1).

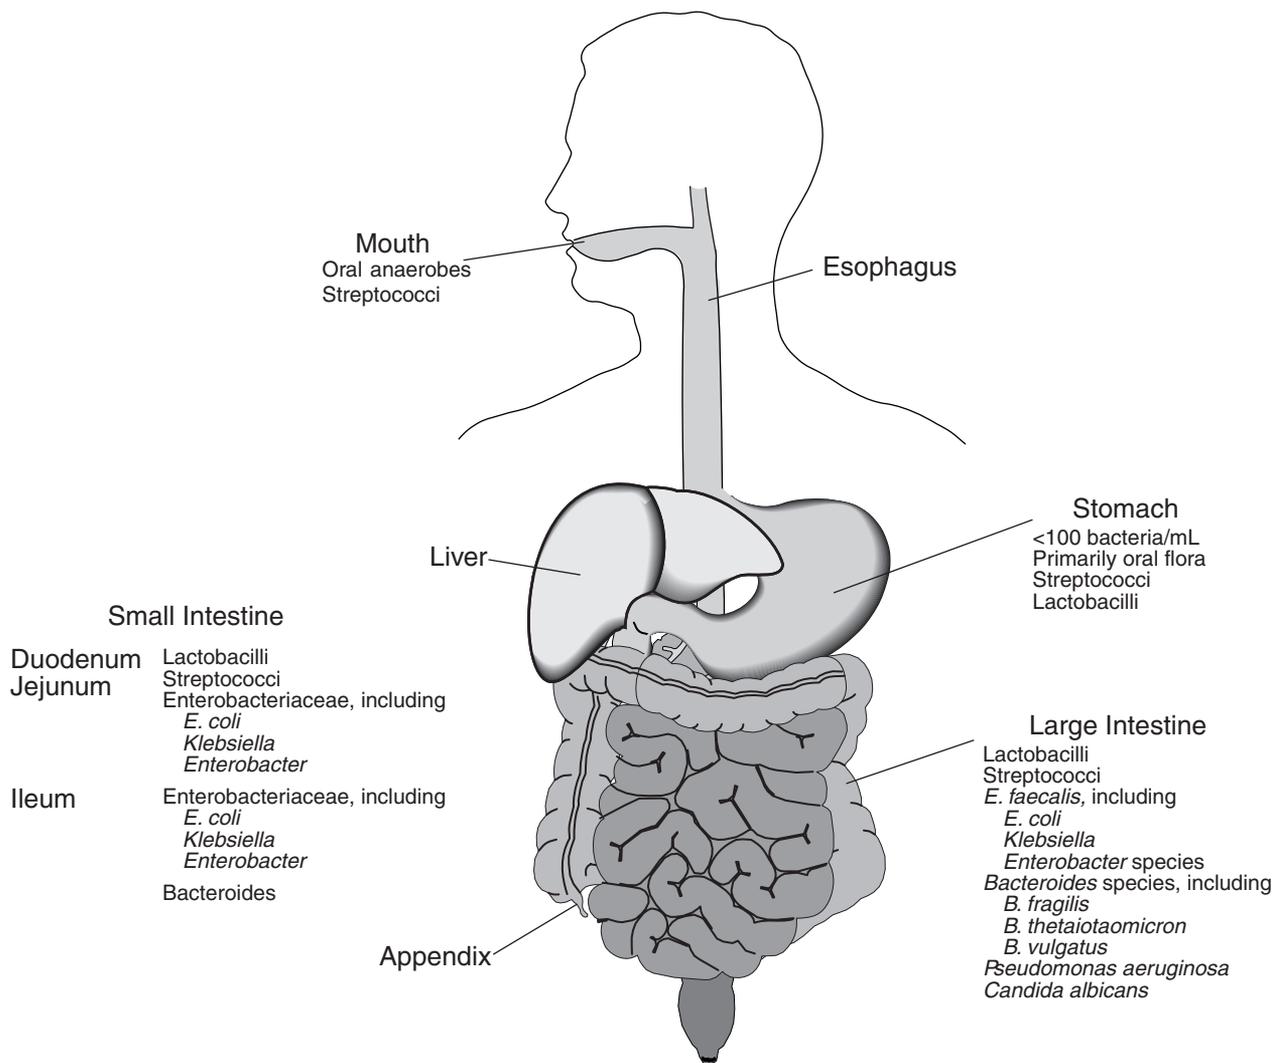

FIGURE 63-1 Microflora of the gastrointestinal tract.

INFECTIONS OF THE BILIARY TRACT

Cholecystitis and Cholangitis

Cholecystitis and cholangitis are intra-abdominal infections that originate as inflammatory conditions of the biliary tract, most commonly as a result of obstruction in the gallbladder or common bile duct. The obstruction is typically caused by the presence of cholelithiasis. The biliary tract is sterile under normal conditions and the flow of bile, along with its bacteriostatic properties, function to maintain the sterility. Infection typically occurs as a secondary event to obstruction.^{3,4}

Acute cholecystitis is the acute inflammation of the gallbladder. The presence of gallstones in >90% of cases prevents the outflow of gallbladder drainage by obstructing the neck of the gallbladder, Hartmann's pouch, or the cystic duct.³ The obstruction causes an increase in intraluminal pressure, gallbladder distention, and edema, which triggers an acute inflammatory response. The potential consequences of this obstruction and inflammation include infection, ischemia, perforation, and necrosis.^{3,5} The reduction in gallbladder outflow leads to biliary stasis, which provides an ideal environment for bacterial proliferation and subsequent infection (Fig. 63-2).

Acute cholangitis is an acute inflammation of the common bile duct. The most common cause of cholangitis in the United States is common bile duct obstruction as a consequence of cholelithiasis. Less common causes include neoplastic obstruction, postoperative obstruction following biliary intervention, benign strictures, and primary sclerosing cholangitis.³ Acute cholangitis characteristically involves the presence of organisms and increased biliary pressure. The decrease in biliary outflow results in biliary stasis and bacterial proliferation. The obstruction of the biliary tree results in increased biliary pressure, which facilitates the spread of bacteria into lymphatics and potentially the bloodstream via alterations in membrane permeability.^{3,6}

Clinical Presentation and Diagnosis

1. D.S., a 42-year-old man, presents to the hospital with a 2-day history of abdominal pain and tenderness, localized to the right upper quadrant, fever to 38.9°C, and chills. He complains of nausea, with three episodes of emesis occurring in the past 24 hours. D.S. appears jaundiced and reports dark-colored urine. His laboratory values are white blood cell (WBC) count, $15 \times 10^3/\text{mm}^3$

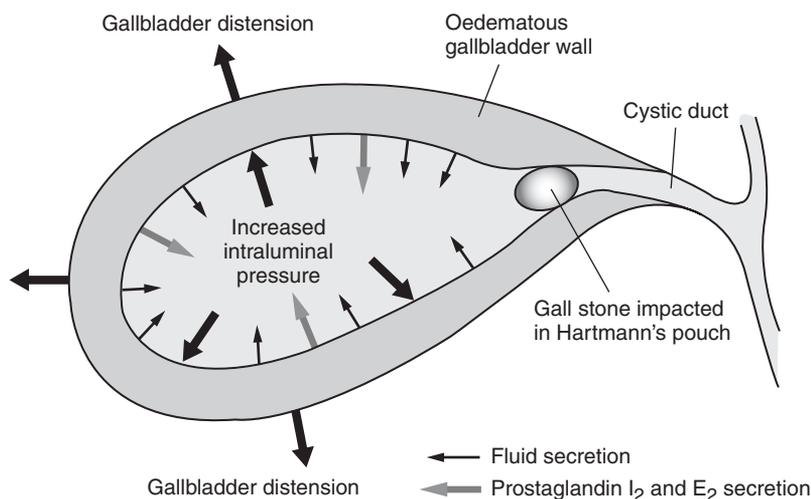

FIGURE 63-2 Pathogenesis of acute cholecystitis.

(normal, 3.2–9.8); serum creatinine (SrCr), 1.2 mg/dL (normal, 0.6–1.2); total bilirubin, 4 mg/dL (normal, 0.1–1); and alkaline phosphatase, 220 U/L (normal, 30–120). What evidence of cholangitis exists in D.S.? How does the presentation of cholecystitis differ from cholangitis?

[SI units: WBC count, 15×10^9 /L (normal, 3.2–9.8); SrCr, 106.08 $\mu\text{mol/L}$ (normal, 50–110); total bilirubin, 68.4 $\mu\text{mol/L}$ (normal, 2–18)]

The clinical manifestations of acute cholangitis vary, but the classic presentation involves Charcot's triad, which consists of fever, jaundice, and right upper quadrant abdominal pain. Fever is present in 90% of cases, and jaundice and abdominal pain occur in 60% to 70% of cases.³ A smaller percentage of patients may present with changes in mental status and hypotension.³ Laboratory findings of acute cholangitis include leukocytosis, elevated bilirubin and alkaline phosphatase, and mildly elevated liver transaminases.^{3,6} The clinical signs and symptoms of cholangitis, as exemplified by D.S., include high fevers (38.9°C), chills, jaundice, and right upper quadrant abdominal pain. Laboratory evidence supportive of cholangitis includes leukocytosis with WBC of $15 \times 10^3/\text{mm}^3$, increased bilirubin of 4 mg/dL, and elevated alkaline phosphatase of 220 U/L.

The clinical presentation of acute cholecystitis involves fever, nausea, vomiting, and a prolonged constant abdominal pain that is typically localized to the right upper quadrant. On physical examination, patients with cholecystitis often have tenderness in the right upper quadrant, which is evident by Murphy's sign (inspiration is inhibited by pain on palpation).^{3,5} Laboratory findings include leukocytosis with increased neutrophils (left shift) and mild elevations in transaminases. Patients with cholecystitis may also present with mild jaundice (bilirubin <60 $\mu\text{mol/L}$) in comparison to cholangitis.^{3,5}

Diagnostic imaging for cholecystitis typically involves ultrasonography, which may reveal pericholecystic fluid, distention of the gallbladder, edema of the gallbladder wall, stones, and a sonographic Murphy's sign.³ Ultrasound is less sensitive for choledocholithiasis, but may depict the presence of biliary dilation with cholelithiasis to infer cholangitis. Computed tomography (CT) imaging is also commonly utilized for the diagnosis of cholangitis and may be superior in determining

the extent of biliary obstruction.³ Biliary scintigraphy and endoscopic retrograde cholangiopancreatography (ERCP) are alternative modes of imaging for cholecystitis and cholangitis, respectively.^{3,6}

Etiology

2. What are the most likely organisms causing infection in D.S.? What clinical specimens are helpful to identify the causative pathogen(s)?

The most common pathogens associated with cholangitis include *E. coli*, *Klebsiella* spp., *Enterococcus* spp., and *Enterobacter* spp. However, *Pseudomonas aeruginosa*, skin flora (*Staphylococcus* spp., *Streptococcus* spp.), and oropharynx bacteria may be cultured. Anaerobic organisms are associated with ~15% of infections, particularly in elderly patients undergoing biliary tract surgery.^{3,7} The etiology of cholecystitis typically involves *E. coli*, *Klebsiella* spp., and *Enterococcus* spp. Anaerobes are less commonly isolated^{3,5} (Table 63-1).

As described above, the stasis of bile flow allows bacteria to proliferate within the gallbladder or common bile duct. Acute cholangitis results in increased pressure within the common bile duct with dissemination of bacteria from the biliary tree to the bloodstream. Blood cultures may be positive in up to 40% of patients with symptomatic acute cholangitis.³ Acute cholecystitis may reveal positive bile cultures in 20% to 75% of patients with symptomatic disease, but the utility of bile cultures has yet to be determined.² In contrast to cholangitis, bacteremia is unlikely with cholecystitis. The choice of antibacterial agents is largely empiric covering the aforementioned common causative pathogens.

Treatment

Definitive therapy for both cholangitis and cholecystitis must involve the removal of the obstruction and infected contents, using surgery, percutaneous drainage, or endoscopic intervention. Empiric antibacterial therapy should be added owing to the likelihood of secondary infection and to prevent complications. Supportive measures include fluid and electrolyte supplementation and analgesia.^{3–6}

Table 63-1 Common Pathogens in Intra-Abdominal Infection

| Disease | Pathogens | Comments |
|--|--|--|
| Primary peritonitis | <i>Escherichia coli</i> , <i>Klebsiella pneumoniae</i> , <i>Streptococcus pneumoniae</i> , <i>Streptococcus</i> spp., occasional anaerobes | Predominately in spontaneous bacterial peritonitis in cirrhotics. Anaerobes less likely than aerobes. |
| Secondary peritonitis | <i>E. coli</i> , <i>Bacteroides fragilis</i> , other aerobic gram-negative rods and anaerobes, <i>Enterococcus</i> | Generally polymicrobial with both aerobic and anaerobic pathogens. <i>Enterococcus</i> spp. are associated with nosocomial infections and chronic surgical infections, particularly in patients receiving broad-spectrum antimicrobials. |
| Chronic ambulatory peritoneal dialysis | <i>S. epidermidis</i> , <i>Staphylococcus aureus</i> , diphtheroids, gram-negative rods | Dwell time of exchange with intraperitoneal antibiotics must be a minimum of 6 hours. |
| Cholecystitis, cholangitis | <i>E. coli</i> , <i>K. pneumoniae</i> , anaerobes, other gram-negative rods, <i>Enterococcus</i> | Necessity for antimicrobials that achieve high biliary concentrations is unknown. |

To decompress or drain the biliary ductal system in cholangitis ERCP is used, with a success rate of >90% in the treatment of cholangitis.³ Alternatively, percutaneous transhepatic biliary drainage (PTBD) or endoscopic sphincterotomy (ES) can be utilized to drain the contents. Open surgery is a less favored option to decompress the biliary tree, owing to increased mortality.³ Acute symptomatic cholecystitis requires removal of the gallbladder (cholecystectomy). The procedure of choice is laparoscopic cholecystectomy within 48 to 72 hours of onset of symptoms. Early intervention is associated with decreased morbidity and length of hospital stay compared with delayed surgical intervention.^{3,5} In high-risk patients, where the risks outweigh the benefits of early surgery, percutaneous cholecystostomy can be performed to drain the contents of the gallbladder. The procedure improves the clinical symptoms in 75% to 90% of patients who cannot undergo surgery. Cholecystectomy, however, should take place once the patient is stable for surgery.³

Antimicrobial Therapy

3. Based on the most likely causative pathogen(s), what empiric antimicrobial therapy is recommended for D.S., given a diagnosis of cholangitis?

Empiric antimicrobial therapy for cholangitis and cholecystitis should be initiated after blood cultures have been collected. The empiric choice of therapy should cover enteric gram-negative pathogens, particularly *E. coli*. The addition of anaerobic coverage is generally recommended, particularly for patients with cholangitis and elderly patients with previous biliary tract interventions.³ *Enterococcus* spp. are less commonly encountered pathogens and empiric coverage is typically not necessary in community-acquired intra-abdominal infections.

Antimicrobial therapy must be guided by drug pharmacokinetics and pharmacodynamics, local resistance patterns, and patient factors, such as drug allergies, renal or hepatic dysfunction, and cost. Examples of appropriate empiric regimens include combination therapy with an extended spectrum cephalosporin (ceftriaxone, cefotaxime, or cefepime) or an aminoglycoside, plus metronidazole, or a fluoroquinolone (ciprofloxacin or levofloxacin) plus metronidazole.⁸ Utilization of aminoglycosides in uncomplicated, community-acquired infections is not routinely recommended because of the need for therapeutic drug monitoring and potential nephrotoxicity and

ototoxicity.⁸ Furthermore, the risk of renal toxicity has been suggested to be greater in patients with obstructive jaundice.⁹ Therapy with ciprofloxacin or levofloxacin is appropriate in combination with metronidazole owing to the relatively poor anaerobic activity of the fluoroquinolones. Other fluoroquinolones, such as moxifloxacin and garenoxacin, with increased anaerobic activity may represent a potential monotherapy option in the future.¹⁰ Monotherapy with a β -lactam- β -lactamase inhibitor combination (ampicillin-sulbactam, ticarcillin-clavulanate, and piperacillin-tazobactam) or a carbapenem (imipenem-cilastatin, meropenem, and ertapenem) would also be appropriate therapy given the broad spectrum of gram-positive, gram-negative, and anaerobic activity.^{8,11} Considering their activity versus multidrug-resistant gram-negative bacilli, the carbapenems generally should be reserved for infection caused by these pathogens.

An appropriate regimen for D.S. is ampicillin-sulbactam 3 g IVPB every 6 hours as monotherapy. Aminoglycoside therapy can be considered in D.S., but given the recent onset of signs and symptoms and the likelihood of community-acquired organisms, other treatment options are available. The presence of hyperbilirubinemia may also place D.S. at higher risk for the development of aminoglycoside-induced nephrotoxicity.

Biliary Concentrations

4. The physician caring for D.S. questions the need for an antibiotic that concentrates in the bile. Is there a benefit to using an antibiotic that is extensively excreted into bile?

Common bile duct obstruction is a factor that can prevent the entry of antibiotics into the bile, but the need for high biliary concentrations of antibiotics in the treatment of cholangitis has often been questioned.¹² Nagar et al.¹³ reviewed the biliary excretion of several antibiotics and concluded that a number of antibiotics with excellent in vitro susceptibility are poorly excreted into bile but are still clinically effective. Biliary antibacterial concentrations have not been correlated with an improved outcome.³ Highly biliary excreted versus moderately biliary excreted antibiotics have been compared.¹² The investigators concluded that serum concentrations were more important than biliary levels in reducing the septic complications of biliary tract surgery. These authors concluded that biliary excretion of any antibiotic is minimal in the presence of obstruction.¹²

The treatment of D.S.'s biliary tract infection must include biliary drainage. Ampicillin–sulbactam should be continued for 5 to 7 days.

PRIMARY PERITONITIS

Peritonitis is inflammation of the peritoneum as a result of infectious or chemical inflammation within the peritoneal cavity.^{2,14} Infectious peritonitis can be classified as primary, secondary, or tertiary. Primary peritonitis involves the development of infection in the peritoneal cavity in the absence of intra-abdominal abnormality.^{14,15} Secondary peritonitis classically results from contamination of the peritoneum with gastrointestinal (GI) or genitourinary microorganisms as a result of loss of mucosal barrier integrity. Tertiary peritonitis describes clinical peritonitis along with signs of sepsis and multiorgan dysfunction that persist or recur following the treatment of secondary peritonitis.^{2,14}

Primary peritonitis is also known as *spontaneous bacterial peritonitis* (SBP) and is most frequently identified in adults with cirrhosis and ascites. Nearly 10% to 30% of hospitalized patients with cirrhosis and ascites have SBP.^{2,15,16} Primary peritonitis can also be associated with postnecrotic cirrhosis, chronic acute hepatitis, acute viral hepatitis, congestive heart failure, metastatic malignancy, or systemic lupus erythematosus.^{2,14}

Spontaneous Bacterial Peritonitis in Cirrhotic Patients

Clinical Manifestations and Diagnosis

Patients with SBP may present with fever, signs of peritoneal irritation with abdominal pain, changes in GI motility, nausea, vomiting, diarrhea, or ileus.¹⁶ Fever is the most common sign, occurring in 50% to 80% of patients with SBP.² Patients may potentially have an atypical presentation or even lack symptoms.¹⁶ The diagnosis of SBP is made on clinical presentation and examination of the peritoneal fluid via paracentesis. The ascitic fluid is tested for cell counts with WBC differential and the presence of microorganisms based on Gram stain and culture. Ascitic fluid with an elevated polymorphonuclear (PMN) count ($\geq 250/\text{mm}^3$) is diagnostic of SBP.¹⁶

Etiology and Pathogenesis

5. M.W., a 51-year-old man with alcoholic cirrhosis and significant abdominal ascites, presents with a 4-day history of fever to 38.4°C and abdominal pain. Ascitic fluid obtained by paracentesis was cloudy. Culture of the ascitic fluid is pending. Laboratory values are ascitic fluid PMN count, 450/mm³, serum WBC count, 12.2 × 10³/mm³ (normal, 3.2–9.8), and total bilirubin, 4.4 mg/dL (normal, 0.1–1). What organisms are likely to be cultured from M.W.'s ascitic fluid?

[SI units: WBC count, 12.2 × 10⁹/L (normal, 3.2–9.8); total bilirubin, 75.2 μmol/L (normal, 2–18)]

An estimated 70% of cases of SBP are caused by aerobic enteric organisms considered normal flora of the GI tract.¹⁶ *E. coli* is the most commonly cultured organism, followed by *Klebsiella pneumoniae*.² Other common causes of SBP include *Streptococcus pneumoniae* and other *Streptococcus* spp., accounting for 20% of cases. *Enterococcus* spp. are isolated in ~5% of cases.¹⁶ *Staphylococcus* spp., anaerobes, and

microaerophilic organisms are rarely reported in community-acquired SBP. SBP is largely a monomicrobial infection.

One of the main mechanisms of pathogenesis associated with the development of SBP is bacterial translocation, which is the migration of microorganisms through the GI wall to mesenteric lymph nodes and other structures outside the intestine, including the bloodstream. Bacteria will then infect the ascitic fluid by hematogenous or lymphogenous spread.^{16,17} Certain characteristics of cirrhotic patients may facilitate the pathogenesis of SBP, including bacterial overgrowth, decreased motility, structural intestinal damage, and decreased host defense mechanisms that function to eliminate microorganisms. Bacterial overgrowth in the face of decreased motility and increased gut wall permeability, secondary to structural damage, facilitates subsequent systemic infection. Reduced opsonic activity and phagocytosis allows the microorganisms to escape the hosts' defenses and subsequently infect the ascitic fluid.¹⁷

Spontaneous bacterial peritonitis with underlying cirrhosis was previously associated with a >90% mortality rate, but with the advances in antibacterial therapy, the rate has reduced to ~20% to 40%.^{2,16} Patient characteristics associated with increased mortality include renal insufficiency, hypothermia, hyperbilirubinemia, and hypoalbuminemia. Gram-negative infections are also associated with a high mortality rate in SBP compared with gram-positive infections.² Early diagnosis and effective antibacterial treatment of SBP have been associated with reduced rates of mortality.¹⁸

Antimicrobial Therapy

6. What empiric antimicrobial therapy is recommended for M.W. pending ascitic fluid culture results? What is an appropriate duration of therapy, and how should the response to therapy be monitored?

Although a positive Gram stain and culture will provide guidance for antibacterial therapy, nearly 60% of patients with signs and symptoms of SBP have negative cultures.¹⁹ Initial antibacterial therapy for patients with a diagnosis of SBP is typically empiric and targeted toward the most likely pathogens as described above. Ampicillin plus an aminoglycoside traditionally was used as empiric therapy; however, third-generation cephalosporins (cefotaxime and ceftriaxone) or β-lactam–β-lactamase inhibitor combinations (ampicillin–sulbactam) as monotherapy represent safer, possibly more effective options.^{19,20} An oral fluoroquinolone (ofloxacin or ciprofloxacin) has been recommended in uncomplicated SBP in the absence of renal dysfunction or encephalopathy.¹⁶ The lack of streptococcal activity of these agents suggests, however, they should not be used first line. The treatment of choice for community-acquired SBP is typically a third-generation cephalosporin. As described, aminoglycosides are not recommended in cirrhotic SBP therapy because of the risk of nephrotoxicity.¹⁶ As with all infections, antibacterial therapy should be adjusted on the availability of culture and sensitivity data.

Antibiotic therapy is recommended until the PMN count from the ascitic fluid falls below 250 cells/mm³, which normally occurs within 5 days.¹⁸ Franca et al.²¹ concluded that a 5-day course of cefotaxime for the treatment of SBP was as effective as a 10-day course.

M.W. should receive empiric therapy with an antimicrobial agent effective against *E. coli* and other common pathogens such as *Klebsiella* spp. and *S. pneumoniae*. Any of the above-mentioned options would be reasonable empirical choices.

Prophylaxis

7. After treatment is completed, should prophylactic antimicrobial therapy be initiated in M.W.?

Recurrence rates for primary peritonitis are high. Cirrhotic patients who survive an episode of SBP have a 1-year recurrence rate of nearly 70%. Two other types of cirrhotic patients are also considered high risk for the development of SBP: patients with low ascitic protein (<1.0 g/dL) or elevated serum bilirubin (>2.5 mg/dL) and patients presenting with GI hemorrhage.¹⁶ Prophylactic antimicrobial therapy has been shown to be of some benefit in cirrhotic patients at risk for the development of SBP (primary prophylaxis) and those with a high risk for the recurrence (secondary prophylaxis) of SBP: the risks and benefits must be carefully evaluated, however.

Secondary prophylaxis in cirrhotic patients is typically initiated with an antibacterial agent to provide selective decontamination of the GI tract. The goal of this therapy is to reduce the burden of bacteria and subsequently prevent bacterial translocation and therefore infection.¹⁶ Prospective, randomized studies in cirrhotic subjects with ascites provide support for the use of oral antibacterial agents to reduce the rate of recurrence. The agents studied include oral norfloxacin,²² ciprofloxacin,²³ and trimethoprim-sulfamethoxazole.²⁴ Long-term secondary prophylaxis is recommended based on the significant reduction in rates of recurrence in clinical trials.

Long-term primary prophylaxis in patients with low ascitic proteins, elevated bilirubin, or both may also be beneficial but is not associated with decreased overall infection or mortality and, therefore, not uniformly recommended.^{16,17,22–24} Primary prophylaxis is recommended, however, in all cirrhotic patients presenting with a GI hemorrhage.¹⁶ Clinical trials have provided evidence to support the use of short course therapy (7 days) of norfloxacin or ceftriaxone in patients presenting with GI hemorrhage.^{17,25} Prophylactic therapy prevents bacterial infection and reduces the risk of rebleeding.¹⁷ Several cost analyses have been performed demonstrating that prophylactic therapy in high risk groups of cirrhotic patients is cost-effective.¹⁷

Concerns have been raised regarding the rapid emergence of bacterial resistance in cirrhotic patients receiving norfloxacin prophylaxis. In one study evaluating the influence of prophylactic norfloxacin (400 mg/day) on fecal flora, fluoroquinolone-resistant isolates developed during treatment. Rates of fluoroquinolone-resistant and trimethoprim-sulfamethoxazole-resistant gram-negative bacilli have become more prevalent in patients who receive long-term prophylactic therapy.²⁶ Because of an increase both in resistance and in gram-positive causative organisms, the utilization of long-term prophylaxis must be considered when initiating antibacterial therapy for the treatment of new infections in this patient population.²⁷

M.W. has cirrhosis, a previous episode of SBP, and a high total bilirubin; thus, he is at high risk for recurrence. Prophylactic antimicrobial therapy should be considered and may be a cost-effective measure. Any of the aforementioned prophylac-

tic regimens would be appropriate for M.W. A specific choice for prophylactic therapy for M.W. would depend on institutional resistance patterns.

Penetration of Antimicrobial Agents Into Peritoneal Fluid

8. The physician asks if the agents chosen for treatment and prophylaxis of peritonitis in M.W. will penetrate across the peritoneum. What properties determine the penetration of antibiotics into the peritoneal fluid?

The penetration of antimicrobial agents into tissues or abscess cavities depends on the serum-to-tissue fluid concentration gradient; the binding of the antimicrobial to serum and tissue proteins; the diffusibility of the drug, based on its molecular size and acid dissociation constant (pKa); and lipid solubility.²⁸ In general, the β -lactam antimicrobials have been shown to achieve peritoneal fluid concentrations that exceed typical minimum inhibitory concentrations (MIC) for most commonly encountered facultative gram-negative and anaerobic bacteria.^{28,29}

Continuous Ambulatory Peritoneal Dialysis-Associated Peritonitis

9. H.M., a 43-year-old woman with diabetes mellitus and end-stage renal disease, has undergone continuous ambulatory peritoneal dialysis (CAPD) daily for the past year. She presents with abdominal pain and a cloudy dialysate fluid. H.M. has negligible residual urine output. What are the most common causative organisms related to CAPD-associated peritonitis? What empiric antimicrobial therapy should be initiated? How should antimicrobial agents be administered?

Pathogenesis and Clinical Presentation

Peritonitis continues to remain a major complication of peritoneal dialysis. An estimated 45% of patients undergoing continuous ambulatory peritoneal dialysis will experience at least one episode of peritonitis in the first 6 months of dialysis. Approximately 60% to 70% of patients develop peritonitis during the first year of dialysis, and recurrent infection occurs in 20% to 30% of patients.² CAPD-related peritonitis is theorized to originate from contamination of the catheter by organisms of the normal skin flora, contamination of the peritoneum from an exit-site or subcutaneous-tunnel infection, contamination of the dialysate fluid, or bacterial translocation.² Alterations in host defenses of the peritoneum may also have a role in the development of CAPD-associated peritonitis.²

Clinical manifestations of CAPD-peritonitis include abdominal pain and tenderness, which is observed in 60% to 80% of patients. Nausea and vomiting occur in approximately 30% of patients, whereas 10% will have diarrhea, and 10% to 20% will present with fever. The diagnosis of peritonitis is made based on clinical signs and symptoms along with examination of the dialysate fluid for cell counts, Gram stain, and culture. Characteristically, the dialysate fluid will be cloudy and have a WBC count >100 cells/mm³ with a neutrophilic predominance (at least 50%).³⁰ The Gram stain may be negative in 5% to 10% of cases and blood cultures are typically negative.² In most cases, peritonitis is commonly caused by a single organism.³¹

Etiology

The most common causative organisms are gram-positive bacteria, accounting for 60% to 80% of isolates. Coagulase-negative *Staphylococcus* spp. (*S. epidermidis*) are the most common causative organisms, followed by *Staphylococcus aureus* and *Streptococcus* spp., Gram-negative bacilli are isolated in approximately 15% to 30% of cases, with *E. coli* being the most common. Other common gram-negative organisms include *Klebsiella* spp., *Enterobacter* spp., *Proteus* spp., and *P. aeruginosa*. Anaerobes, fungi, and mycobacteria constitute the less commonly encountered pathogens.²

Antimicrobial Therapy

In general, empiric antibiotic therapy should be directed against the most common causative organisms, both gram-positive and gram-negative, until cultures of peritoneal fluid are available. Intraperitoneal (IP) delivery of antibacterial agents is the preferred route of administration for the treatment of CAPD-associated peritonitis. The IP route provides very high local concentrations of antibacterial agents as well as the ability to avoid a venipuncture and allow the patient to self-administer therapy at home.³⁰

Treatment guidelines for CAPD-associated peritonitis provide a systematic approach for antimicrobial selection, dosing guidelines, and duration of therapy. Initial therapy recommendations include vancomycin or a first-generation cephalosporin for gram-positive coverage with an appropriate antibacterial agent for gram-negative coverage.³⁰ Because of the increasing rates of methicillin resistant *S. aureus* (MRSA) and *S. epidermidis* (MRSE), vancomycin may be the most appropriate initial therapy for gram-positive organisms, although ceftazidime remains effective in certain geographical areas.^{31–33} Gram-negative therapy options include an aminoglycoside, ceftazidime, cefepime, or a carbapenem.^{30,34} Local resistance patterns must govern the decision for initial therapy for both gram-positive and gram-negative causative organisms.³⁰ Oral treatment with fluoroquinolones represents an option in certain cases of CAPD-peritonitis given the extent of distribution into the peritoneal cavity. An increasing prevalence of fluoroquinolone-resistant gram-negative organisms, particularly *E. coli*, however, exists in many areas and must be considered.^{35,36}

When culture and susceptibility results are available, antibacterial therapy should be adjusted as necessary. Antibiotic therapy is recommended for at least 2 weeks and even longer in severe cases. Duration may be determined based on clinical response. When *S. aureus* is isolated from culture, therapy will be determined by susceptibility and may include the removal of the dialysis catheter. Vancomycin plus or minus rifampin is recommended for MRSA, although monotherapy with vancomycin is adequate, particularly if the infected catheter is removed. Conversely, ceftazidime alone is adequate for MSSA. Coagulase-negative *Staphylococcus* spp. generally require vancomycin owing to the high rate of methicillin resistance. *Enterococcus* spp. or *Streptococcus* spp. should be treated with ampicillin if susceptible. The addition of synergistic doses of gentamicin may be considered, although clear benefit has not been established in the treatment of enterococcal peritonitis. Furthermore, patients with CAPD do not eliminate gentamicin well and may be at additional risk of aminoglycoside ototoxicity. Vancomycin should be used for

ampicillin-resistant enterococcus; however, vancomycin resistant *Enterococcus* spp. (VRE), requires treatment with linezolid, quinupristin–dalfopristin, or daptomycin. In the case of culture-negative peritonitis and clinical improvement after 3 days of empiric coverage, a single agent directed toward gram-positive organisms may be continued for a total of 2 weeks.³⁰

When a single gram-negative organism is cultured (e.g., *E. coli*, *Klebsiella* spp., or *Proteus* spp.), therapy can be narrowed based on susceptibility. Isolation of *P. aeruginosa* most often indicates a severe infection which may also involve the dialysis catheter. Two antibacterial agents can be considered for 2 weeks. Monotherapy, however, appears to be as efficacious. Therapy options include an antipseudomonal β -lactam such as ceftazidime, cefepime, or imipenem–cilastatin with or without an oral fluoroquinolone or an aminoglycoside. Aztreonam can be used in the case of severe IgE-mediated penicillin allergy. Polymicrobial peritonitis is uncommon, and may indicate a more complicated intra-abdominal process. Therapy should include activity for anaerobes with metronidazole, in combination with gram-positive, gram-negative coverage according to culture and susceptibility data. Table 63-2 lists antimicrobial dosing guidelines for the treatment of peritonitis associated with CAPD.³⁰

An example of an appropriate regimen for H.M. may include vancomycin plus cefepime or an aminoglycoside given intraperitoneally. The clinician should follow culture and sensitivity results to adjust therapy based on guidelines, local sensitivity patterns, and therapeutic response.

Fungal CAPD-Associated Peritonitis

10. Two years later, H.M. presents with abdominal pain and cloudy dialysate fluid. *Candida albicans* is cultured from the dialysate fluid. No other organisms are present. How should H.M. be treated?

Fungal peritonitis is a rare complication of CAPD that is associated with significant morbidity and mortality. The rate of mortality in fungal peritonitis is approximately 25%.³⁰ It is recommended to remove the dialysis catheter in patients with evidence of fungal peritonitis because of the high rates of failure associated with maintaining the catheter.³⁰ Patients who have received prolonged or multiple courses of antibiotics are at increased risk for fungal peritonitis owing to a shift in normal flora.³⁷ Most cases are caused by *Candida* spp., most commonly *C. albicans*. An increase in nonalbicans species has emerged in many areas.³⁷ Antifungal therapy options include amphotericin B and flucytosine, caspofungin, fluconazole, or voriconazole. Amphotericin B may be administered intravenously (IV) or IP, but when given IP it is very irritating to the peritoneum.³⁰ The azole antifungal agents can be administered orally, IV, or IP. Fluconazole is active against *C. albicans* but has decreased activity against certain types of nonalbicans species, such as *C. glabrata*. In general, fluconazole would be appropriate, safe therapy for *C. albicans*, however, other options, such as a polyene or echinocandin, would be needed for *C. glabrata*. Initial therapy is commonly amphotericin B plus flucytosine until the culture results are obtained. Therapy should continue for a minimum of 2 weeks after catheter removal and total duration may be based on severity and clinical response.³⁰

Table 63-2 Intraoperative Antibiotic Dosing Recommendations for CAPD Patients. (Dosing of Drugs With Renal Clearance in Patients with Residual Renal Function (Defined as > 100 mL/day Urine Output): Dose Should Be Empirically Increased by 25%)

| Drug | Intermittent (per exchange, once daily) | Continuous (mg/L, all exchanges) |
|---------------------------|---|----------------------------------|
| Aminoglycosides | | |
| Amikacin | 2 mg/kg | LD 25, MD 12 |
| Gentamicin | 0.6 mg/kg | LD 8, MD 4 |
| Tobramycin | 0.6 mg/kg | LD 8, MD 4 |
| Cephalosporins | | |
| Cefazolin | 15 mg/kg | LD 500, MD 125 |
| Cefepime | 1 g | LD 500, MD 125 |
| Cephalothin | 15 mg/kg | LD 500, MD 125 |
| Ceftazidime | 1,000–1,500 mg | LD 500, MD 125 |
| Ceftizoxime | 1,000 mg | LD 250, MD 125 |
| Penicillins | | |
| Ampicillin | ND | MD 125 |
| Oxacillin | ND | MD 125 |
| Nafcillin | ND | MD 125 |
| Amoxicillin | ND | LD 250–500, MD 50 |
| Penicillin G | ND | LD 50,000 units, MD 25,000 units |
| Quinolones | | |
| Ciprofloxacin | ND | LD 50, MD 25 |
| Others | | |
| Vancomycin | 15–30 mg/kg every 5–7 days | LD 1,000, MD 25 |
| Aztreonam | ND | LD 1,000, MD 250 |
| Antifungals | | |
| Amphotericin | NA | 1.5 |
| Combinations | | |
| Ampicillin–sulbactam | 2 g every 12 hours | LD 1,000, MD 100 |
| Imipenem–cilastatin | 1 g BID | LD 500, MD 200 |
| Quinupristin–dalfopristin | 25 mg/L in alternate bags ^a | |

^aGiven in conjunction with 500 mg intravenous twice daily. BID, twice daily; CAPD, continuous ambulatory peritoneal dialysis; LD, loading dose, in mg; MD, maintenance dose, in mg; NA, not applicable; ND, no data. From reference 30, with permission.

H.M.'s treatment should include temporary catheter removal and administration of antifungal agents. Antifungal therapy with fluconazole 200 mg orally everyday should be continued for at least 14 days.

SECONDARY PERITONITIS

Pathogenesis and Epidemiology

Secondary peritonitis usually occurs after fecal contamination of the peritoneal cavity or its surrounding structures.^{1,8} Infections most often occur after perforation of the GI tract (e.g., appendicitis, diverticulitis, perforated ulcer, abdominal trauma, bowel neoplasm). Secondary peritonitis most commonly occurs after penetrating or blunt abdominal trauma.

Localization of infection without eradication of bacteria results in intraperitoneal or visceral abscesses. Intraperitoneal

abscesses occur most often in the right lower quadrant in association with appendicitis or a perforated peptic ulcer. Other causes can include diverticulitis, pancreatitis, inflammatory bowel disease, trauma, and abdominal surgery. Visceral abscesses generally are found in the pancreas but also occur in the liver, spleen, or kidney.²

11. A.H., a 52-year-old man, presents with severe abdominal pain and nausea. Colonoscopy reveals a perforated colon. Vital signs include temperature of 102°F and tachycardia (pulse, 110 beats/minute). Bowel sounds are absent. Laboratory values are WBC count, $19 \times 10^3/\text{mm}^3$ (normal, 3.2–9.8), and blood urea nitrogen (BUN), 34 mg/dL (normal, 8–18). What signs and symptoms of secondary peritonitis does A.H. display?

[SI units: WBC count, $19 \times 10^9/\text{L}$ (normal, 3.2–9.8); BUN, 11 mmol/L (normal, 3–6.5)]

Clinical Presentation and Diagnosis

Making the diagnosis of a localized intra-abdominal infection may be difficult, despite the presence of signs and symptoms typical of severe infection. The patient may experience pain and voluntary guarding of the abdomen. Generalized abdominal pain usually is followed by a rigid, “boardlike” tensing of the abdominal muscles.² Inflammation around the intestines and peritoneal cavity results in local paralysis and reflex rigidity of the abdominal wall muscles and the diaphragm, causing rapid and shallow respirations.² Bowel sounds may be faint or absent with concomitant abdominal distention, nausea, and vomiting. Fever usually is present with tachycardia and decreased urine output secondary to fluid loss into the peritoneum. These signs usually are accompanied by an elevated WBC count with a predominance of neutrophils (left shift). The hematocrit (Hct) and BUN may be elevated as a result of dehydration. Initially, patients are usually alkalotic as a result of vomiting and hyperventilation, but in the later stages of peritonitis, acidosis usually occurs. Untreated peritonitis can result in generalized sepsis and hypovolemic shock.^{1,2}

Gram stain and culture should be performed immediately on infected material before the initiation of antimicrobial therapy. The presence of pleomorphic gram-negative bacilli, a strong odor, or tissue gas is strongly suggestive of infection with anaerobes, particularly *Bacteroides fragilis*.

12. Given these findings, what are the most likely pathogens for A.H.'s secondary peritonitis?

Etiology

Because secondary peritonitis can result from perforation of the intestinal tract, the normal flora consistent with the perforated segment determines the most likely pathogens. Studies consistently document a mixed culture of aerobes and anaerobes. The presence of anaerobic bacteria in the culture is indicative of a polymicrobial infection with a predictable group of pathogens.^{1,2}

The most commonly isolated facultative bacterium is *E. coli*, which is found in approximately 60% of cultures. A variety of other gram-negative bacteria also are isolated, including *Klebsiella* spp., *Proteus* spp, *Enterobacter* spp., and *P. aeruginosa* (Table 63-3).^{1,38–40} Highly antibiotic-resistant strains of

Table 63-3 Bacteriology of Intra-Abdominal Infections^{1,38-40}

| Bacteria | Patients (%) |
|--|--------------|
| Facultative and Aerobic | |
| <i>Escherichia coli</i> | 42-64 |
| <i>Proteus</i> sp. | 4-20 |
| <i>Klebsiella</i> or <i>Enterobacter</i> sp. | 6-23 |
| Streptococci (including enterococci) | 3-27 |
| Staphylococci | 3-10 |
| <i>Pseudomonas aeruginosa</i> | 4-15 |
| Anaerobes | |
| <i>Bacteroides fragilis</i> | 30-50 |
| Other <i>Bacteroides</i> sp. | 9-16 |
| Peptostreptococci | 10 |
| <i>Clostridium</i> sp. | 2-20 |
| <i>Fusobacterium</i> sp. | 10 |

Candida, *P. aeruginosa*, *Serratia*, *Acinetobacter*, *Enterobacter* spp., and *Enterococcus* often are isolated from patients who develop secondary peritonitis while hospitalized.^{2,8} *B. fragilis* is recovered from intra-abdominal sites because of its particular virulence factors and is the most frequently isolated anaerobe following perforation of the colon.^{2,41} Anaerobic cocci (*Peptostreptococcus*) and facultative gram-positive cocci, such as *Enterococcus*, are also isolated.^{2,8,39,41} *B. fragilis* and *E. coli* are the most common pathogens found in blood culture samples after bacteremia associated with an intra-abdominal infection.²

In summary, A.H. is likely to have an intra-abdominal infection caused by mixed flora, containing both aerobic and anaerobic bacteria. His current clinical status, highlighted by an elevated temperature, is probably secondary to the presence of facultative gram-negative bacteria, such as *E. coli*, *Proteus*, *Klebsiella*, or *Enterobacter*. *P. aeruginosa*, *Candida* spp., or other resistant bacteria are more likely with prolonged hospitalization or receipt of broad-spectrum antimicrobial agents.

Antimicrobial Therapy

Empiric Therapy

13. How should A.H. be treated? Based on clinical studies, what empiric antimicrobial therapy is appropriate for A.H. at this time?

Therapy for secondary peritonitis should include early administration of antimicrobial agents directed at gram-negative bacteria and anaerobes, fluid therapy, and support of vital organ function, as well as source control measures. *Source control* is a term used to involve all physical measures needed to eradicate an infection, such as debridement of necrotic tissue or drainage of an abscess or fluid collections. Surgical debridement and drainage, in conjunction with appropriate antimicrobial therapy, decrease the morbidity and mortality associated with this disease.^{1,2,42} Therapy with an agent with activity against *P. aeruginosa* is desirable if the infectious process develops while the patient is hospitalized or has received broad-spectrum antimicrobials. This is not necessary in A.H.

In general, when an intra-abdominal infection is present, antimicrobial agents should be started immediately after ap-

Table 63-4 Treatment of Intra-Abdominal Infections

| Regimen | Dosage |
|---|--|
| <i>Combination Therapy</i> | |
| 1. Metronidazole Plus Aminoglycoside | 500 mg IV every 8 hr 5-7 mg/kg/day (normal renal function) |
| 2. Metronidazole Plus Aztreonam | 500 mg IV every 8 hr 1-2 g IV every 8 hr |
| 3. Metronidazole Plus Ceftriaxone Or Cefotaxime Or Cefepime | 500 mg IV every 8 hr 1-2 g IV every 24 hr 1-2 g IV every 8 hr 1-2 g IV every 8 hr |
| 4. Metronidazole Plus Ciprofloxacin | 500 mg IV every 8 hr 400 mg IV every 12 hr |
| <i>Monotherapy</i> | |
| Ampicillin-sulbactam | 3 g IV every 6 hr |
| Cefoxitin | 1-2 g IV every 6 hr |
| Ertapenem | 1 g IV every 24 hr |
| Imipenem-cilastatin | 500 mg IV every 6 hr |
| Meropenem | 1 g IV every 8 hr |
| Piperacillin-tazobactam | 3.375-4.5 g IV every 6 hr |
| Ticarcillin-clavulanic acid | 3.1 g IV every 6 hr |

IV, intravenous.

propriate specimens (e.g., blood, peritoneal fluid, abscess drainage) are obtained for culture and sensitivity and before any surgical procedures are performed.^{1,2,8,43} The parenteral route should be used to ensure adequate systemic and tissue concentrations, especially in patients in whom shock or poor perfusion of the muscles or GI tract precludes the use of oral or intramuscular (IM) routes of administration. Therefore, antimicrobial therapy is generally empiric, based on the expected pathogens at the site of infection. Table 63-4 outlines dosing recommendations for antibiotics commonly used in the treatment of intra-abdominal infections.

Early clinical trials of clindamycin combined with gentamicin are efficacious.² Increasing resistance rates, the potential for oto- and nephrotoxicity secondary to aminoglycosides, and clindamycin-associated enterocolitis have resulted, however, in many other options.^{38,44-49} For mild to moderate community-acquired infections, monotherapy with a β -lactam- β -lactamase inhibitor is recommended. Combination therapy with either a cephalosporin or a fluoroquinolone plus metronidazole is also reasonable.^{8,44} A third- or fourth-generation cephalosporin, ciprofloxacin, aztreonam, or an aminoglycoside in combination with metronidazole represent alternative options for severe infections.^{9,45} Meropenem, or imipenem-cilastatin^{8,44} should be reserved for presumed or documented multidrug-resistant pathogens or in sepsis. Although meropenem and imipenem should be reserved as last-line agents, ertapenem may have a role in mild to moderate intra-abdominal infection. In comparative trials of ertapenem versus piperacillin-tazobactam, the two agents were shown to

be similar in efficacy and safety.^{45–47} Moxifloxacin with mixed aerobic and anaerobic coverage may be a monotherapy option; however, resistance to *E. coli* and anaerobes may limit its utility.³⁹ Because monotherapy has been shown to be efficacious in numerous trials, combination therapy is now rarely used.

Meropenem and imipenem–cilastatin, because of their broad spectrum of activity, should be reserved for the treatment of more resistant gram-negative organisms associated with nosocomial infections. Although piperacillin–tazobactam, ticarcillin–clavulanic acid, and ampicillin–sulbactam may have utility in complicated intra-abdominal infections, ampicillin–sulbactam has inferior activity against nosocomial gram-negative organisms and should not be used in patients with long-term hospitalization or extensive antibiotic history.

A.H. should receive antimicrobial therapy with activity against facultative gram-negative bacteria and anaerobes, including *B. fragilis*. IV ertapenem 1 g every 24 hours would be an appropriate treatment for A.H.’s mild to moderate infection.

Duration of Antimicrobial Therapy

14. For how long should A.H. receive antimicrobial therapy?

Recommendations for the duration of therapy for intra-abdominal infection vary from 5 to 7 days and depend primarily on the patient’s clinical response to therapy and need for surgical drainage.^{8,44} In general, antimicrobial therapy should be continued until resolution of signs of infection takes place, including return of WBC count to normal and elimination of fever.

Enterococcal Infection

15. S.S. is a 66-year-old, nonobese man with a strangulating bowel obstruction. One day after undergoing surgical resection of the duodenum, he develops a fever of 101°F, shaking chills, and abdominal pain. Laboratory values are WBC count, $18.4 \times 10^3/\text{mm}^3$ (normal, 3.2–9.8), and creatinine, 1.2 mg/dL (normal, 0.6–1.2). S.S.’s peritoneal fluid cultures grow *E. coli*, *B. fragilis*, *C. albicans*, and *Enterococcus*. Blood cultures are negative. Should he receive additional antimicrobial therapy active against *Enterococcus*?

Although *Enterococcus* is commonly cultured in patients with secondary peritonitis, its pathogenicity has been questioned. *Enterococcus* can cause serious infections (e.g., endocarditis, urinary tract infections), but is less virulent in the setting of polymicrobial infections such as intra-abdominal infections.

An important issue is whether empiric treatment should have included antibiotics directed specifically against *Enterococcus*. Some investigators believe that *Enterococcus* spp. are commensal organisms that need not be treated in most clinical settings. They point to clinical studies in which antibiotic regimens lacking in vitro activity against *Enterococcus* have been successful. The pathogenicity of *Enterococcus* lies in its ability to enhance the formation of abscesses.^{1,2}

In general, coverage is warranted if *Enterococcus* is present in blood cultures, is the sole organism on culture, or is the predominant organism on Gram stain.^{2,44} Antienterococcal therapy may also be recommended in patients with nosocomial or health care-associated infections.⁴⁴ Because S.S.’s blood cul-

tures are negative and ascitic culture has demonstrated mixed pathogens, *Enterococcus* coverage is not necessary. S.S. should be treated with an antimicrobial regimen that has activity against gram-negative pathogens and anaerobes.

Antifungal Therapy: Treatment of *Candida*

16. Should S.S.’s antimicrobial therapy include an agent with antifungal activity?

The need to treat *Candida* species as a solitary isolate or as part of a polymicrobial infection is controversial. Certainly, *Candida* has the potential to cause peritonitis, IP abscesses, and subsequent candidemia. Parenteral administration of amphotericin B is an option for fungal peritonitis.^{14,44} Concern over the toxicity of amphotericin is warranted, however, and the risk-to-benefit ratio must be assessed carefully for each patient. To date, no clinical trials have assessed the efficacy and safety of lipid-based amphotericin B, voriconazole, or caspofungin in the treatment of intra-abdominal fungal infections. The use of antifungal agents, such as fluconazole, may offer decreased toxicity in these patients. The potential risk of the development of resistance must, however, be addressed in clinical trials. Fluconazole is considered an appropriate drug of choice for *C. albicans*.⁴⁴ For *Candida glabrata* or other fluconazole-resistant species, an echinocandin or an amphotericin product is an appropriate option.⁸

Therapy with an antifungal agent is not warranted at this time unless positive blood cultures for *Candida* are isolated or S.S. fails to respond to appropriate antimicrobial therapy.

Antimicrobial Irrigations

17. S.S.’s physician wishes to irrigate the peritoneum with aminoglycosides to achieve high local concentrations. Is irrigation with antimicrobial agents rational or effective in the treatment of intra-abdominal infections?

Hypothetic concerns regarding irrigation of the peritoneal cavity include spread of local infection, damage to the mesothelium, dilution of opsonins, or suspension of bacteria in a fluid medium where they are less amenable to phagocytosis. Gravity and the movement of the diaphragm during respiration, however, spread bacteria throughout the peritoneal cavity even in the absence of irrigation. In addition, free circulation of fluids within the peritoneal cavity facilitates lymphatic clearance of microorganisms and toxins.⁵⁰

Although data are limited, systemic antibiotic therapy and antibiotic irrigations appear to be efficacious for both the prevention and treatment of postoperative infections.^{51,52} The clinician, however, must recognize the potential for systemic toxicity resulting from systemic absorption of antimicrobial agents from the peritoneal cavity. Most antimicrobials are readily absorbed from mucosal surfaces, especially when they are inflamed. When large volumes of irrigating solution containing antibiotics are used (especially in combination with IV doses), systemic drug concentrations can markedly exceed the therapeutic range. Neuromuscular blockade, renal failure, and ototoxicity have been reported after absorption of aminoglycosides from mucosal surfaces. Although a greater margin of safety exists for many of the penicillins and cephalosporins, the potential for toxicity is still of concern.⁵³

Few data support the superiority of antibiotic-containing irrigating solutions over systemic therapy. Given the potential for systemic toxicity secondary to absorption of antimicrobial agents from the peritoneum, the paucity of controlled trials documenting the efficacy of this method of administration, and the proved efficacy of systemic therapy, it seems prudent to use systemic therapy alone for the treatment of intra-abdominal infections.^{51,52}

Anaerobic Bacteria

18. The surgical resident initiated S.S. on piperacillin-tazobactam for the treatment of his intra-abdominal infection. Should culture and sensitivity results be used to monitor for anaerobic activity?

With the introduction of broad-spectrum antimicrobial agents with in vitro activity against *B. fragilis* and a significant problem of increasing resistance, the choice of a specific anaerobic agent has become more complex. Multiple mechanisms of resistance are encountered, and resistance rates differ among various geographic areas of the United States. Although *Bacteroides* resistance to metronidazole is rare,^{14,54} resistance to clindamycin has increased.¹⁴ Although the carbapenems and the β -lactamase inhibitor combinations are exquisitely active against *Bacteroides*, resistance has been reported.

The Clinical and Laboratory Standards Institute (CLSI), formerly known as the National Committee for Clinical Laboratory Standards (NCCLS), has suggested that susceptibility testing be performed to determine patterns of anaerobic susceptibility to new antimicrobial agents and to monitor susceptibility patterns periodically on a geographic and local basis.⁵⁵

Because most anaerobes are cultured in the setting of mixed flora, isolation of individual components of a complex mixture can be time-consuming. In addition, most anaerobes are very slow growing, and it may take days to weeks for a definitive culture and sensitivity report. If specimens are not collected and transported in optimal media or in a timely manner, inaccurate or misleading results may be reported. The methods for susceptibility testing of anaerobic bacteria are not well standardized, and many hospital laboratories do not have resources to perform extensive culture and sensitivity testing. It has been argued that routine cultures may be unnecessary because few routine cultures affect the choice of antibiotic regimen, and empiric therapy usually determines outcome.⁵⁶ Therefore, empiric therapy must be aimed at the most likely pathogens, and the clinician must be aware of the usual sensitivity patterns at the institution, if anaerobic testing takes place. Routine susceptibility testing for patient-specific cases is not recommended because of the prolonged time needed to achieve results.

Intra-Abdominal Abscess

19. F.S. is a 32-year-old man who has undergone abdominal surgery. Two weeks postoperatively, he develops abdominal pain and purulent material begins to drain from his abdominal wound. An intra-abdominal abscess is visualized by plain films. How did this abscess develop? What considerations should be taken into account in the selection of appropriate antimicrobial agents?

Abscesses are collections of necrotic tissue, bacteria, and WBC that form over a period of days to years. They generally

result from chronic inflammation and the body's attempt to localize organisms and toxic substances by formation of an avascular fibrous wall. This isolates bacteria and the liquid core from opsonins and antimicrobial agents.

Microbiology

Although pathogens encountered in abscesses are similar to those encountered in other intra-abdominal infections, abscesses pose a therapeutic challenge because they typically contain large bacterial inocula that are likely to include subpopulations of resistant bacteria.⁴² Furthermore, the rate of penetration of antibiotics into abscesses is hindered by the low surface-to-volume ratio, low pH, and decreased permeability.

Although surgical debridement and drainage of F.S.'s abscess is crucial, adjunctive therapy with antimicrobial agents is warranted. The optimal antimicrobial agent should penetrate into the abscess in adequate concentrations with adequate spectrum of activity.^{14,42} F.S. should be placed on an antimicrobial regimen that covers gram-negative bacteria and anaerobes, such as piperacillin-tazobactam 3.375 g IV every 6 hours.

INFECTIONS AFTER ABDOMINAL TRAUMA AND POSTOPERATIVE COMPLICATIONS

Risk factors for infection after penetrating abdominal trauma include the number, type, and location of injuries; the presence of hypotension; large transfusion requirements; prolonged operation; advanced age; and the mechanism of injury.⁵⁷

Most investigators stress the importance of instituting antimicrobial therapy as close to the time of trauma as possible. Bozorgzadeh et al.⁵⁸ demonstrated a significant reduction in the incidence of postoperative infections when antibiotics were administered before surgical repair of the penetrating abdominal trauma.

Antimicrobial Therapy

Penetrating Trauma

20. M.S., a 23-year-old man, is admitted to the emergency department within 1 hour after sustaining a penetrating knife wound to the stomach and colon. He is to undergo emergency laparotomy. What antimicrobial therapy is appropriate at this time?

As with other types of intra-abdominal infections, antibiotics active against both aerobic and anaerobic pathogens should be used.

Anti-infective therapy has been studied in patients who have sustained penetrating trauma to the abdomen (usually from knife or gunshot wounds). In several comparative trials, single-drug therapy with cefoxitin was as effective as the combination of clindamycin or metronidazole plus an aminoglycoside.⁵⁹ In evaluating these studies, however, it is important to note that most patients did not sustain injuries to the colon, where the risk of infection is highest. Although the age of this patient suggests he would tolerate aminoglycoside therapy, monotherapy with cefoxitin or one of the β -lactamase inhibitor combinations would be appropriate.

21. How long should antibiotic therapy be administered to M.S.?

Consensus guidelines regarding the duration of therapy were published by the Eastern Association for the Surgery of Trauma (EAST) Practice Management Group. These investigators reviewed all literature from 1976 to 1997 regarding the duration of antimicrobial use following penetrating abdominal trauma. They concluded that antimicrobial use should not exceed 24 hours in this patient population.⁵⁷

The shortest duration of therapy that has been shown to be effective has been 12 hours with the possibility that a short course (<48 hours) of antimicrobial therapy is as efficacious as 5- to 7-day courses of therapy if antimicrobial therapy is promptly instituted.⁴⁴ Several other trials have confirmed no additional benefit exist in providing a longer treatment duration.^{44,56,57,60–62}

Because antimicrobial therapy carries a risk of adverse reactions, the development of resistance and unnecessary cost, short-term therapy seems warranted as long as it is instituted soon after the injury.^{57,63} If the initial dose of antibiotic is administered >3 to 4 hours after injury, therapy should be continued for 3 to 7 days because the incidence of infection in this circumstance is high.

Antimicrobial therapy was instituted soon after M.S. sustained the colonic injury; therefore, a short course of antimicrobial therapy is appropriate. Therapy should be continued for 24 hours.

Appendectomy

22. B.B. is a 17-year-old girl with a 2-day history of periumbilical pain migrating to the right lower quadrant, abdominal distention, fever of 101.6°F, diarrhea, and decreased bowel sounds. Her WBC count is $16 \times 10^3/\text{mm}^3$ (normal, 3.2–9.8). A presumptive diagnosis of acute appendicitis is made. What antimicrobial therapy is indicated, and for how long should it be continued?

[SI unit: WBC count, $16.1 \times 10^9/\text{L}$ (normal, 3.2–9.8)]

Clinical manifestations commonly encountered with acute appendicitis include right lower quadrant abdominal pain, rebound tenderness, and low-grade fever complicated by nausea, vomiting, and anorexia.²

A variety of antimicrobial agents are effective in the treatment of peritoneal contamination associated with acute appendicitis.^{64–68} Most studies, however, have included patients without gangrenous or perforated appendices, which are associated with the highest risk of infection. In several well-designed, randomized, placebo-controlled trials, the combination of clindamycin or metronidazole plus an aminoglycoside has been compared with imipenem–cilastatin, β -lactams, and β -lactamase inhibitor combinations. These single agents were found to be as efficacious as combination therapy.^{21,65,67} Patients with gangrenous or perforated appendices who were afebrile for 48 hours have been treated for durations ranging from a single dose⁶⁸ to 3 or more days.⁶⁶

Overall, the studies justify the use of single-agent therapy with a β -lactam or β -lactamase inhibitor combination active against both gram-negative aerobes and anaerobes. In patients with uncomplicated appendicitis, single-dose therapy is sufficient; however, patients with gangrenous or perforated appendicitis should be treated for 3 or more days.

B.B. should receive a preoperative dose of any of the aforementioned β -lactam antimicrobials with activity against facultative gram-negative and anaerobic bacteria, such as cefotaxime (1 g IV \times 1). Cost, potential side effects, and ease of administration can be used to guide selection of a specific agent. If a gangrenous or perforated appendix is found during surgery, antimicrobial therapy should be continued for a minimum of 3 days or until B.B. has been afebrile for 48 hours.

INTRODUCTION

This chapter begins with a brief review of urinary tract infections (UTI), but focuses on the treatment of patients with UTI. For a more detailed discussion of the etiology, pathophysiology, and diagnosis of UTI, the reader is referred to some excellent texts and review articles.¹⁻⁹ Additionally, a glossary of associated terms is supplied at the end of this chapter.

Epidemiology

Urinary tract infections occur frequently in both community and hospital environments and are the most common bacterial infections in humans.¹ UTI encompass a spectrum of clinical entities ranging in severity from asymptomatic infection to acute pyelonephritis with sepsis.^{1,6} Approximately 7 million cases of acute cystitis and 250,000 cases of acute pyelonephritis occur annually in the United States, resulting in more than 100,000 hospitalizations.^{4,10} Direct costs associated with the diagnosis and treatment of UTI have been estimated at more than \$2.5 billion annually in the United States.^{8,10} After 1 year

of age until about age 50, UTI is predominantly a disease of females. From ages 5 through 14, the incidence of bacteriuria is 1.2% among girls and 0.03% among boys. Of women between the ages of 15 and 24 years, 1% to 5% have bacteriuria; the incidence increases 1% to 2% for each decade of life until approximately 10% of women are bacteriuric after age 70.^{1,7,11} Approximately 25% to 40% of all women will experience a UTI during their lifetime.⁴ Women have more UTI than men, probably because of anatomic and physiologic differences. The female urethra is relatively short and allows bacteria easy access to the bladder. In contrast, males are partly protected because the urethra is longer and antimicrobial substances are secreted by the prostate.^{1,7}

The incidence of UTI in neonates is about 1% and is most frequent among male neonates, many of whom prove to have congenital structural abnormalities.¹² The mortality rate among newborns with UTI was earlier reported to be as high as 10%¹²; more recently, this rate has decreased because of an increased awareness of the high frequency of UTI in children, improved diagnostic techniques, and more effective management.¹²

Urinary tract infections again become a problem for males after the age of 50, when prostatic obstruction, urethral instrumentation, and surgery influence the infection rate. Infection in younger men is rare and requires careful evaluation for urinary tract pathology.^{13,14}

In general, 5% to 20% of the elderly living at home have bacteriuria. This increases to 20% to 50% in extended care facilities and 30% in hospitals.^{11,15,16} The frequency of infection also rises with increasing age for those 65 years or older. Most UTI in these patients are asymptomatic, but are still important because they often result in symptomatic infection.^{11,15,16} Whether bacteriuria in old age is associated with decreased survival is controversial^{17,18}; however, the presence of asymptomatic bacteriuria is associated with decreased functional ability of institutionalized persons.^{11,15} Reasons for higher UTI rates in elderly persons include the high prevalence of prostatic hypertrophy in men, incomplete bladder emptying caused by underlying diseases or medications, dementia, and urinary and fecal incontinence.^{7,15,16}

Etiology

Community-Acquired Infections

Most UTI are caused by gram-negative aerobic bacilli from the intestinal tract. *Escherichia coli* cause 75% to 90% of community-acquired, uncomplicated UTI.^{1,2,19} Coagulase-negative staphylococci (i.e., *Staphylococcus saprophyticus*) account for another 5% to 20% of UTI in younger women.^{1,2,4} Other Enterobacteriaceae (*Proteus mirabilis*, *Klebsiella*) and *Enterococcus faecalis* also are common pathogens.^{1,2,19} Uncomplicated infections are nearly always caused by only a single organism.

Hospital-Acquired Infections

Urinary tract infections occur in up to 10% of hospitalized patients and represent 30% to 40% of all nosocomial infections.²⁰ *E. coli* remains the most common pathogen in hospital-acquired or other complicated UTI, but it is responsible for only 15% to 20% of these infections. Other gram-negative organisms such as *Pseudomonas aeruginosa*, *Proteus*, *Enterobacter*, *Serratia*, and *Acinetobacter* cause significantly more infections (up to 25%) than in community-acquired infections.^{4,21,22} *Enterococcus* is also a common pathogen in hospital-acquired infections and causes approximately 25% of infections.^{21,22} UTI caused by *Staphylococcus aureus* are usually the result of hematogenous spread, although this pathogen is also associated with urinary catheterization.^{1,23,24} Finally, *Candida albicans* is a common pathogen in hospital-acquired infections and may be involved in 20% to 30% of cases.^{20,22} In contrast to uncomplicated infections that are usually monomicrobial, hospital-acquired UTI associated with structural abnormalities or indwelling urinary catheters are often caused by multiple organisms.^{1,20,21,23,24}

Pathogenesis

The usual pathway for the spread of bacteria to the urinary tract is the ascending route. A UTI usually begins with heavy and persistent colonization of the introitus (i.e., vaginal vestibule and urethral mucosa) with intestinal bacteria, especially in

women with recurrent UTI. Once introital colonization has occurred, colonization of the urethra leads to retrograde infection of the bladder.^{3,25}

The bladder has additional defense mechanisms that prevent spread of the infection after urethral colonization occurs. Urination washes bacteria out of the bladder and is effective if urine flows freely and the bladder is emptied completely. Substances in the urine, including organic acids (which contribute to a low pH) and urea (which contributes to a high osmolality), are antibacterial. The bladder mucosa also has antibacterial properties.^{1,2} Lastly, other substances, including IgA and glycoproteins (e.g., Tamm-Horsfall protein), are actively secreted into the urine and act to prevent adherence of bacteria to uroendothelial cells.^{3,25}

Focal renal involvement may result from the spread of bacteria via the ureters and may be facilitated by vesicoureteral reflux or decreased ureteral peristalsis. Reflux can be produced by cystitis alone or by anatomic defects. Ureteral peristalsis is decreased by pregnancy, ureteral obstruction, or gram-negative bacterial endotoxins.^{1,3,25}

Predisposing Factors

Extremes of age, female gender, sexual activity, use of contraception, pregnancy, instrumentation, urinary tract obstruction, neurologic dysfunction, renal disease, previous antimicrobial use, and expression of A, B, and H blood group oligosaccharides on the surface of epithelial cells are among the many predisposing factors for the development of UTI.^{1,3,5,26}

The overall likelihood of developing a UTI is approximately 30 times higher in women than in men.² The incidence of bacteriuria in pregnant women is 2% to 10%, which is approximately twice that of similarly aged nonpregnant women.^{1,11,27} The incidence of acute symptomatic pyelonephritis in pregnant women with untreated bacteriuria also is high. Many factors contribute to the increased susceptibility of the pregnant female to infection; these include hormonal changes, anatomic changes, progressive urinary stasis, and glucose in the urine.²⁷

Instrumentation of the urinary tract (i.e., urethral and ureteral catheterization) is an important predisposing factor for hospital-acquired UTI in particular. As many as 67% of nosocomial UTI are preceded by urinary tract instrumentation.^{20,24} Other urologic procedures, such as cystoscopy, transurethral surgery, prostate biopsy, and upper urinary tract endoscopy, are much less likely to result in infection unless there is pre-existing bacteriuria or other contaminated sites (e.g., prostate, renal stones).

Any obstruction to the free flow of urine (e.g., urethral stenosis, stones, tumor) or mechanical difficulty in evacuating the bladder (e.g., prostatic hypertrophy, urethral stricture) predisposes patients to UTI. Furthermore, infections associated with urethral or renal pelvic obstruction can lead to rapid destruction of the kidney and sepsis.¹

Renal disease increases the susceptibility of the kidney to infection.¹ The incidence of UTI among renal transplant recipients has been reported to range from 35% to 80%.²⁸

Patients with spinal cord injuries, stroke, atherosclerosis, or diabetes may have neurologic dysfunction that can cause UTI. The neurologic dysfunction can cause urinary retention, which

may lead to catheterization. Furthermore, prolonged immobilization facilitates hypercalciuria and stone formation in some of these patients.^{1,3,4}

Previous antimicrobial use (within the previous 15–28 days) has been shown to increase the relative risk for UTI in women by approximately three- to sixfold.⁵ This increased infection risk applies to prior antimicrobial use for treatment of UTI as well as other infections. The proposed mechanism for increased risk is alteration of normal flora of the urogenital tract and predisposition to colonization with pathogenic bacterial strains.⁵

Diabetes mellitus has often been associated with an increased risk for UTI because of glucose in the urine, which both promotes bacterial growth and impairs leukocyte function. Diabetes is also often associated with anatomic, neurologic, and immunologic abnormalities of the urinary tract that increase risk of infection, often because of increased need for urinary tract instrumentation.^{29,30} Several studies have documented a two- to threefold increase in UTI in diabetic women compared with nondiabetic women; rates of complications, such as pyelonephritis, are also increased.^{29,31} Patients with diabetes who have no neurologic complications resulting in bladder dysfunction and who have not had instrumentation are apparently not at increased risk compared with nondiabetic patients.³ With autonomic neuropathy affecting the bladder (i.e., cystopathy) or following instrumentation, UTI in diabetic patients are both more frequent and more severe.^{3,30}

Studies also have supported an association between sexual intercourse and UTI among otherwise healthy women.^{3,26,32} Specific contraceptive practices, particularly the use of spermicides, have also been associated with increased risk for UTI. The use of a diaphragm, cervical cap, or condom in combination with spermicidal jelly has been shown to increase the risk of UTI compared with the use of the barrier method alone.^{26,33} Although the greatest risk has been associated with the spermicide nonoxynol-9, the use of other types of spermicidal jellies has also been associated with a significantly higher risk for UTI.³⁴ Oral contraceptive use has also been associated with increased risk of UTI.²⁶ The exact mechanisms of infection related to sexual intercourse and contraceptive methods are unclear but appear to be related to alterations in vaginal flora that allow for bacterial overgrowth and subsequent infection.^{35,36}

Clinical Presentation

Symptoms commonly associated with lower UTI (e.g., cystitis) include burning on urination (dysuria), frequent urination, suprapubic pain, blood in the urine (hematuria), and back pain. Patients with upper tract infection (e.g., acute pyelonephritis) also may present with loin pain, costovertebral angle (CVA) tenderness, fever, chills, nausea, and vomiting.^{1,2,4,6}

Clinical signs and symptoms correlate poorly with either the presence or the extent of the infection. Symptoms common to lower UTI often are the only positive findings in upper UTI (i.e., subclinical pyelonephritis).^{1,6} The probability of true infection in women who present with one or more symptoms of UTI is only about 50%.³⁷ The presence of dysuria, back pain, pyuria, hematuria, bacteriuria, and a history of previous UTI enhance the probability of true infection; the absence of dysuria or back pain and history of vaginal discharge or irritation significantly decrease the likelihood of infection.³⁷ It has also been deter-

mined that the combination of dysuria and frequency in the absence of vaginal discharge or irritation increases the probability of true infection to >90%.³⁷ Fever, chills, flank pain, nausea and vomiting, or CVA tenderness are highly suggestive of acute pyelonephritis rather than cystitis.^{4,6} Many elderly patients with UTI are asymptomatic without pyuria. Additionally, because many patients have frequency and dysuria, it is difficult to distinguish between noninfectious and infectious causes based on symptoms.¹ Nonspecific symptoms, such as failure to thrive and fever, may be the only manifestations of UTI in neonates and children <2 years of age.¹

Laboratory Diagnosis

The urinalysis (UA) is a series of laboratory tests commonly performed in patients suspected of having a UTI.³⁸ A technician first performs a macroscopic analysis by describing the color of the urine; measuring its specific gravity; and estimating the pH and glucose, protein, ketone, blood, and bilirubin contents using a rapid “dipstick” method. Then the urine sediment, obtained by centrifugation, is examined under a microscope for the presence and quantity of leukocytes, erythrocytes, epithelial cells, crystals, casts, and bacteria.

Microscopic examination of urine sediment in patients with documented UTI reveals many bacteria (usually >20 per high-power field [HPF]). Gram staining of uncentrifuged (“unspun”) urine shows at least one organism per immersion oil field and usually correlates with a positive urine culture. Pyuria (i.e., ≥ 8 white blood cells [WBC] per mm^3 of unspun urine or 2–5 WBC/HPF of centrifuged urine) frequently is seen in patients with UTI. WBC casts in the urine strongly suggest acute pyelonephritis.¹

A rapid diagnostic dipstick test for the detection of bacteriuria, the nitrite test, detects nitrite formation from the reduction of nitrates by bacteria. This test is widely available and easily performed; however, at least 10^5 bacteria/ mm^3 are necessary to form sufficient nitrite for the reaction to occur. Although a positive nitrite reading is useful, false-negative results do occur. Dipstick testing can also be used to perform the leukocyte esterase test, which detects the esterase activity of leukocytes in the urine. A positive test correlates well with significant pyuria³⁹; however, both false-negative and false-positive findings can occur with the leukocyte esterase panel. Nitrite and leukocyte esterase tests are useful in ruling out the presence of infection if results of both tests are negative, whereas positive results of both tests in combination are highly suggestive of the presence of infection. Confirmatory tests (e.g. urine culture) should be performed, however, if one or both dipstick test finding is positive owing to the possibility of false-positive test results.³⁹

The major criterion for the diagnosis of UTI is the urine culture. Proper interpretation of these cultures depends on appropriate urine collection techniques. Urinating into a sterile collection cup using the midstream clean-catch technique is the most practical method of urine collection. This method of urine specimen collection is especially useful for male patients, but is less useful in female patients because contamination is extremely difficult to avoid.¹ The external urethral area must first be thoroughly cleaned and rinsed, then the urine specimen collected after initiation of the urine stream (hence “midstream”).

Suprapubic bladder aspiration, although unpleasant from a patient's point of view, generally is not painful and is quite reliable. It is not practical for routine office or clinic practice, but may be useful when voided urine samples repeatedly yield questionable results or when patients have voiding problems. Because contamination is negligible, any number of bacteria found by this method reflects infection.¹

Urinary catheterization for a urine culture sample yields fairly reliable results if performed carefully. Infections can result from the procedure itself because organisms might be introduced into the bladder at the time of catheterization.

Urine must be plated on culture media within 20 minutes of collection to avoid erroneously high colony counts from bacterial growth in urine at room temperature. Otherwise, urine should be promptly refrigerated until it can be cultured. Colony counts are also affected by the concentration of bladder urine; bacterial counts are higher in first-voided morning urines compared with those obtained from the same patient later in the day.

Urine cultures in the bacteriology laboratory usually are evaluated by the pour-plate or streak-plate method. Greater than 10^5 colonies of bacteria/mm³ cultured from a midstream urine specimen confirms a UTI. A single, carefully collected urine specimen provides 80% reliability, and two consecutive cultures of the same organism are virtually diagnostic.^{1,2}

It is important to understand that the classic definition of UTI as $\geq 10^5$ bacteria/mm³ is fairly insensitive in accurately diagnosing patients with UTI. Approximately 30% to 50% of actual cases of acute cystitis have $< 10^5$ bacteria/mm³.^{4,11} Particularly in a symptomatic patient, using a definition of $\geq 10^2$ bacteria/mm³ is much more sensitive and avoids failure to diagnose infection in many patients.⁴

Diagnosis of UTI in men also requires different interpretation of laboratory data. Contamination of urinary specimens is much less likely to occur in men compared with women, and numbers of bacterial colonies in specimens are therefore much lower. Greater than 10^3 bacteria/mm³ is thus highly suggestive of UTI in men.^{13,14,40} In addition, although a positive nitrite test in a symptomatic man is highly indicative of the presence of an acute UTI, a negative nitrite test does not necessarily exclude infection and should be confirmed with a urine culture.⁴¹

Diagnosis of UTI in children is particularly problematic because of the difficulties and high contamination rates associated with commonly used methods of urine specimen collection. Suprapubic aspiration is the most accurate method in children, followed by urinary bladder catheterization.⁹ Although clean-catch and bag methods (i.e., collecting urine into a bag placed around the urogenital area) are most susceptible to contamination and inaccurate results, they are also the most preferred methods for parents and health care personnel because they are simple and noninvasive. The choice of diagnostic tests for children will therefore be based on the experience, skill, and preferences of those involved with the child, and no one technique will be ideal in every setting.⁹

Simplified culture methods such as the filter-paper method (e.g., Testuria-R), dip-slide method (e.g., Uricult), and pad-culture method (Microstix) are as reliable as traditional laboratory methods for bacterial identification and quantification. The filter-paper method is relatively inexpensive but does not differentiate between gram-positive and gram-negative organisms. The dip-slide and pad-culture methods are accurate, differentiate between gram-positive and gram-negative organ-

isms, and are similar in cost. The dip-slide method has the added advantages of ease of storage and a nitrite indicator pad.

LOWER URINARY TRACT INFECTION

Initiation of Therapy

1. V.Q., a 20-year-old woman (married, no children) with no previous history of UTI, complains of burning on urination, frequent urination of a small amount, and bladder pain. She has no fever or CVA tenderness. A clean-catch midstream urine sample shows gram-negative rods on Gram stain. A culture and sensitivity (C&S) test is ordered, and the results of a STAT UA are as follows: appearance, straw-colored (normal, straw); specific gravity, 1.015 (normal, 1.001–1.035); pH, 8.0 (normal, 4.5–7.5); and protein, glucose, ketones, bilirubin, and blood are all negative (normal, all negative); WBC, 10 to 15 cells/mm³ (normal, 0–2 cells/mm³); red blood cells (RBC), 0 to 1 cells/mm³ (normal, 0–2 cells/mm³); bacteria, many (normal, 0 to rare); epithelial cells, 3 to 5 cells/mm³ (normal, 0 to few cells/mm³). Based on these findings, V.Q. is presumed to have a lower UTI. What should be the goals of therapy and treatment plan at this time?

Drug treatment of a lower UTI often is started before C&S results are known because the most probable infecting organism and its sensitivity to antibiotics can be predicted (Table 64-1). Approximately 75% to 90% of community-acquired infections are caused by Enterobacteriaceae (especially *E. coli*). Although these organisms may be sensitive to ampicillin, amoxicillin, and the sulfonamides such as trimethoprim-sulfamethoxazole (TMP-SMX), resistance to these agents is common.^{42,43} Ampicillin resistance has been reported in as many as 25% to 70% of community-acquired isolates; resistance nationwide is currently about 30% to 40%.^{1,4,19,42,44} TMP-SMX has been a traditional agent of choice for many years; however, TMP-SMX resistance has significantly increased in recent years and may be as high as 20% to 30% among community-acquired *E. coli* isolates.^{19,42,45} Although traditionally associated with hospital-acquired infections, resistance among *E. coli* and *Klebsiella* caused by production of extended-spectrum β -lactamase (ESBL) enzymes which confer resistance to penicillins and cephalosporins has also been increasing among community-acquired pathogens.⁴⁶ Another relatively common organism is *S. saprophyticus*. Most strains are susceptible to sulfonamides, TMP-SMX, penicillins, and cephalosporins. Alternative medications and doses are shown in Table 64-2.

The goals of therapy for treatment of acute cystitis are to effectively eradicate the infection and prevent associated complications, while minimizing adverse effects and costs associated with drug therapy. To accomplish these goals, selection of a specific antimicrobial agent should be made after considering several factors: (a) pathogens likely to be causing the infection, (b) resistance rates to various antimicrobials within the specific geographic area, (c) desired duration of therapy, (d) clinical efficacy and toxicity profiles of various agents, and (e) costs of specific agents. Because resistance rates among various pathogens vary considerably among geographic areas, clinicians involved in the treatment of patients with UTI must be familiar with resistance rates prevalent within the specific area within which they practice.^{19,42,43}

Table 64-1 Urinary Tract Infections

| Organisms Commonly Found | Antibacterial of Choice |
|--------------------------------------|---|
| Uncomplicated UTI | |
| <i>Escherichia coli</i> | TMP-SMX ^c |
| <i>Proteus mirabilis</i> | TMP-SMX ^c |
| <i>Klebsiella pneumoniae</i> | TMP-SMX ^c |
| <i>Enterococcus faecalis</i> | Amoxicillin |
| <i>Staphylococcus saprophyticus</i> | First-generation cephalosporin or TMP-SMX |
| Complicated UTI^{a,b} | |
| <i>Escherichia coli</i> | First-, second-, or third-generation cephalosporin; TMP-SMX ^c |
| <i>Proteus mirabilis</i> | First-, second-, or third-generation cephalosporin |
| <i>Klebsiella pneumoniae</i> | First-generation cephalosporin; fluoroquinolone |
| <i>Enterococcus faecalis</i> | Ampicillin or vancomycin ± aminoglycoside |
| <i>Pseudomonas aeruginosa</i> | Antipseudomonal penicillin ± aminoglycoside; ceftazidime; cefepime; fluoroquinolone; carbapenem |
| <i>Enterobacter</i> | Fluoroquinolone; TMP-SMX; carbapenem |
| Indole-positive <i>Proteus</i> | Third-generation cephalosporin; fluoroquinolone |
| <i>Serratia</i> | Third-generation cephalosporin; fluoroquinolone |
| <i>Acinetobacter</i> | Carbapenem; TMP-SMX |
| <i>Staphylococcus aureus</i> | Penicillinase-resistant penicillin; vancomycin |

TMP-SMX, trimethoprim-sulfamethoxazole; UTI, urinary tract infection.

^a Oral therapy when appropriate.

^b Drug selection based on culture and susceptibility testing when possible.

^c Caution in communities with increased resistance (>10%–20%). Fluoroquinolone, nitrofurantoin, or cephalosporins should be used in areas with increased TMP-SMX resistance.

cause of the relatively high incidence of *E. coli* resistance to ampicillin and amoxicillin, some experts do not recommend these agents for initial, empiric use.^{2,4,42–44,48,49} Although TMP-SMX is still recommended as the preferred agent for acute, uncomplicated UTI, this agent also may not be a suitable choice for empiric therapy in certain geographic areas because of increasing resistance. Use of trimethoprim or TMP-SMX has been discouraged in geographic areas where the incidence of *E. coli* resistance exceeds 15% to 20%.^{42,43,45,48,51,52} The fluoroquinolones have become favored agents in many geographic areas with high rates of resistance to ampicillin, TMP-SMX, and trimethoprim because of excellent activity against common urinary pathogens and the ability to use short 3-day courses of therapy. The choice of a specific agent should be based on geographic susceptibilities as well as any patient allergies and the relative cost of the drugs.

Even a single dose of an antibiotic may be effective. Bacteria disappear from the urine within hours after antibacterial therapy has been initiated.⁴⁸ This, coupled with the urinary bladder's ability to defend itself through micturition, acidification, and inherent antibacterial activity, gives theoretic support to the clinical evidence that a large single dose of an antibiotic can eradicate a UTI.

Single-Dose Therapy

3. Would a 3-day course of therapy or single-dose therapy be preferred for V.Q.?

A single antibiotic dose is reasonably effective in treating acute, lower UTI in young adult females.^{4,7,48} Commonly used regimens are TMP-SMX (two or three double-strength tablets), trimethoprim 400 mg, amoxicillin-clavulanate 500 mg, amoxicillin 3 g, ampicillin 3.5 g, nitrofurantoin 200 mg, ciprofloxacin 500 mg, and norfloxacin 400 mg.^{1,48,49} Again, choice of a specific agent should be based on local susceptibility patterns, patient allergies, and relative drug costs. Female patients with history or clinical presentation suggestive of complicated infection (e.g., systemic manifestations of infection, renal disease, anatomic abnormalities of the urinary tract, diabetes mellitus, pregnancy), a history of antibiotic resistance, or a history of relapse after single-dose therapy should not receive single-dose regimens. Single-dose therapy is also not appropriate for male patients with UTI. Because V.Q. does not have any of these contraindications, she could potentially receive single-dose therapy with an appropriate agent.

The advantages of single-dose treatment of UTI include improved compliance, cost savings, proved efficacy in a defined population of patients (i.e., young women with acute, uncomplicated lower UTI), minimal side effects, and a potentially decreased incidence of bacterial resistance associated with antibiotic overuse. Furthermore, failure to eradicate the organism with a single dose of an antibiotic may help identify patients who have subclinical pyelonephritis and require more intensive evaluation of their urinary tract.

Some concerns also exist about single-dose therapy.^{4,7,48,49} First, sample sizes in most of the comparative studies to date have been relatively small. Consequently, it is difficult to determine whether differences in effectiveness or incidence of side effects between single-dose and multiple-dose therapy are clinically significant. Meta-analysis of studies comparing

Duration of Therapy

2. What treatment duration options are available for V.Q.?

Outpatients with acute, uncomplicated UTI can be treated successfully with a 7- to 14-day course of oral medications, a 3-day course of therapy, or by single-dose therapy.^{1,4,47} A urine C&S may be obtained before antibacterial therapy and repeated 2 to 3 weeks after the completion of therapy,^{1,2,4} although this practice is seldom necessary in young adult females with a lower UTI.^{1,4}

The duration of therapy for UTI has been extensively studied and progressively shortened. The traditional 7- to 14-day course of antibiotic therapy now is considered excessive for most patients with uncomplicated infections.^{1,2,4,43,47,48} A 3-day antibiotic treatment regimen is just as effective as a 10-day regimen in achieving clinical cures and eradicating urinary tract organisms, although this is somewhat antibiotic class-specific.^{1,2,4,43,47,48} TMP-SMX and the fluoroquinolones are recommended as the preferred agents for 3-day treatment regimens. β -Lactam antibiotics and nitrofurantoin are more appropriately reserved for longer treatment courses of 7 to 14 days^{4,49}; however, a recent study has shown that a 5-day course of nitrofurantoin is as effective as a 3-day course of TMP-SMX.⁵⁰ Longer treatment courses are also used in cases of treatment failure following regimens of shorter duration. Be-

Table 64-2 Commonly Used Oral Antimicrobial Agents for Acute Urinary Tract Infections^{1,2,4,27,48,49,96}

| Drug | Usual Dose | | Pregnancy ^a | Breast Milk ^a | Comments ^b |
|-------------------------------------|--|---|---|---|---|
| | Adult | Pediatric | | | |
| Amoxicillin | 250 mg Q 8 hr or 3 g single dose | 20–40 mg/kg/day in three doses | Crosses placenta (<i>cord</i>) = 30% (maternal) ^c | Small amount present | Watch for resistant organisms. |
| Amoxicillin + potassium clavulanate | 500 + 125 mg Q 12 hr | 20 mg/kg/day (amoxicillin content) in three doses | Unknown | Unknown | |
| Ampicillin | 250–500 mg Q 6 hr | 50–100 mg/kg/day in four doses | Crosses placenta | Variable amount (<i>milk</i>) = 1%–30% (serum) ^c | Watch for resistant organisms. Should be taken on an empty stomach. |
| Cefadroxil | 0.5–1 g Q 12 hr | 15–30 mg/kg/day in four doses | Crosses placenta | Enters breast milk (<i>milk</i>) = 20% (serum) ^c | Alternate choices for patients allergic to penicillins, although cross-hypersensitivity can occur. May be associated with high failure rates. |
| Cephalexin | 250–500 mg Q 6 hr | 15–30 mg/kg/day in four doses | Crosses placenta | | |
| Cephradine | 250–500 mg Q 6 hr | 15–30 mg/kg/day in four doses | Crosses placenta (<i>cord</i>) = 10% (maternal) ^c | | |
| Norfloxacin ^d | 400 mg Q 12 hr | Avoid | Arthropathy in immature animals | Unknown | Useful for pseudomonal infection. <i>Avoid antacids and divalent cations and sucral-fate. May cause dizziness.</i> |
| Ciprofloxacin ^d | 250–500 mg Q 12 hr | Avoid | Arthropathy in immature animals | Unknown | Alternate choices for patients allergic to β -lactams |
| Levofloxacin | 250 mg Q 24 hr | Avoid | Arthropathy in immature animals | (<i>milk</i>) = 100% (serum) ^c | |
| Nitrofurantoin | 50–100 mg Q 6 hr | 5–7 mg/kg/day in four doses | Hemolytic anemia in newborn | Variable amounts; not detectable to 30%; may cause hemolysis in G6PD-deficient baby | Alternate choice. <i>To be taken with food or milk. May cause brown or rust-yellow discoloration of urine. See Questions 47–49.</i> |
| Sulfisoxazole | 0.5–1 g Q 6 hr | 50–100 mg/kg/day in four doses | Crosses placenta; hemolysis in newborn with G6PD deficiency; displacement of bilirubin may lead to hyperbilirubinemia and kernicterus; teratogenic in some animal studies | Enters breast milk; displacement of bilirubin may lead to neonatal jaundice; may cause hemolysis in G6PD deficient baby | Alters bowel flora to favor resistant organisms. <i>To be taken on an empty stomach with a full glass of water. Photosensitivity may occur.</i> |
| Sulfamethoxazole (SMX) | 1 g Q 12 hr | 60 mg/kg/day in two doses | | | |
| Trimethoprim (TMP) | 100 mg Q 12 hr | | Crosses placenta (<i>cord</i>) = 60%; (maternal) folate antagonism; teratogenic in rats | (<i>milk</i>) > 1 (serum) ^c | Alternate choice. |
| TMP-SMX | 160 + 800 mg Q 12 hr or 0.48 + 2.4 g single dose | 10 mg/kg/day (TMP component in two doses) | Crosses placenta (<i>cord</i>) = 60%; (maternal) folate antagonism; teratogenic in rats | (<i>milk</i>) > 1 (serum) ^c | <i>To be taken on an empty stomach with a full glass of water. Photosensitivity may occur. Monitor HIV-infected patients closely for development of adverse hematologic reactions</i> First-line agent for prostatitis |

^a Also see Chapter 46, Obstetric Drug Therapy.^b Includes unique patient consultation information in italics.^c Denotes drug concentration.^d May increase theophylline concentrations when given concurrently. Carefully monitor theophylline serum concentrations during quinolone use.

TMP = SMX, trimethoprim-sulfamethoxazole.

either single-dose or 3-day regimens with multiple-dose TMP-SMX therapy has demonstrated that single-dose therapy is significantly less effective in eradicating bacteriuria than regimens of either ≥ 5 days (83% vs. 93%, respectively, $p < 0.001$) or ≥ 7 days in duration (87% vs. 94%, respectively; $p = 0.014$).^{47,48} Although side effects were more common with longer courses of therapy (11%–13% with single-dose versus 19%–28% with longer regimens), they were mild and well tolerated.^{47,48} Although fewer studies have directly compared single-dose versus 3-day therapies, numerous studies have shown that 3-day courses are as effective as courses of longer duration.^{47,48} A 3-day course of therapy is therefore currently recommended for uncomplicated cystitis.

A second area of concern relates to recurrences in patients treated with single-dose therapy. Recurrent infections may represent either a relapse caused by incomplete eradication of more deep-seated kidney infection or a true reinfection in a high-risk patient. If it is assumed that patients who receive single-dose therapy are selected properly, then reinfection is a more likely explanation. It has also been suggested, however, that relapse following single-dose therapy actually suggests subclinical upper urinary tract infection.⁴ In either case, single-dose therapies have been associated with higher rates of recurrence compared with therapies of longer duration. Finally, the safety of single-dose therapy in patients with subclinical pyelonephritis needs further evaluation, and these regimens are not currently recommended in this setting.

Based on the preceding information, a 3-day antibiotic course is reasonable in V.Q. and would be the recommended treatment for her infection. Although single-dose regimens are considered appropriate for some carefully selected patients with acute, uncomplicated lower tract infection, 3-day courses are generally preferred for most patients.⁴

When using short-course (i.e., 1- or 3-day) regimens, it is important to counsel the patient that the clinical signs and symptoms of infection may often not be completely resolved for 2 to 3 days following initiation of therapy. Therefore, symptoms that persist after beginning therapy (or actually completing therapy, in the case of single-dose regimens) are not necessarily indicative of treatment failure.

Trimethoprim-Sulfamethoxazole

4. TMP-SMX, one double-strength tablet twice daily (BID) for 3 days is prescribed for V.Q. Is this appropriate therapy?

Yes. TMP-SMX (Co-trimoxazole, Bactrim, Septra) has been shown to be effective for single- and multiple-dose therapy of uncomplicated cystitis.^{1,2,48} Gram-positive and gram-negative organisms, with the notable exceptions of *P. aeruginosa*, *Enterococcus*, and anaerobes, generally are susceptible to TMP-SMX.⁵³ Although TMP-SMX may appear active against enterococci in vitro, clinical efficacy against this pathogen is variable and does not always correlate well with in vitro susceptibilities. The efficacy of TMP-SMX largely depends on the sensitivity of the organism to trimethoprim, although *Neisseria gonorrhoeae* is relatively more susceptible to the sulfonamide component. Individually, trimethoprim and sulfamethoxazole are bacteriostatic, but in combination they are bactericidal against most urinary pathogens.⁵³ Furthermore, this combination is almost uniformly successful in the treatment of un-

complicated UTI, even against organisms that originally were resistant to either agent alone. Although rates of trimethoprim resistance have increased over the past several years,^{19,45,45,54} resistance rates remain relatively low in many geographic areas and trimethoprim alone would be effective in managing many simple UTI.

The ratio of trimethoprim to sulfamethoxazole in the available tablet products is 1:5 (e.g., 80 mg trimethoprim and 400 mg sulfamethoxazole). This combination has been chosen to achieve peak serum concentrations of the two drugs that approximate a 1:20 ratio. This ratio is optimal for synergistic activity against most microorganisms, although the drugs remain synergistic and bactericidal in ratios ranging from 1:5 to 1:40 in vitro.^{53,55} Urinary concentrations of trimethoprim and sulfamethoxazole far exceed the minimum inhibitory concentrations (MIC) for most susceptible urinary pathogens. Therefore, good in vitro activity, excellent clinical success, relatively low resistance rates among common pathogens in many geographic areas, and low cost make TMP-SMX a reasonable choice in V.Q. Many consider TMP-SMX the initial agent of choice in the treatment of acute, uncomplicated lower UTI in geographic areas where the incidence of TMP-SMX resistance among *E. coli* is $< 20\%$.^{4,42,43,48,51,52}

Interpretation of Culture and Sensitivity

5. C&S studies in V.Q. show a few *Klebsiella* and $> 10^5$ bacteria per milliliter of *P. mirabilis*, which are sensitive to ampicillin, amoxicillin-clavulanate, cephalosporins, TMP-SMX, and gentamicin. The *Proteus* is intermediately sensitive to nitrofurantoin, and is resistant to ciprofloxacin. Based on V.Q.'s clinical presentation and recent culture reports, did she have a true UTI?

Yes. Most women with either lower or upper UTI have $> 100,000$ bacterial colonies/mm³ of urine. As previously mentioned, a major revision in the diagnostic criteria for symptomatic UTI has been the abandonment of the absolute requirement for growth of at least 10^5 bacterial colonies/mm³ of urine. The criterion of ≥ 100 bacteria/mm³ appears to provide excellent sensitivity and specificity for the purpose of correctly diagnosing and treating women with symptomatic infection.¹¹ This same criterion should also be applied to lower UTI when *S. saprophyticus* is isolated, because UTI caused by this pathogen often are associated with low urine bacterial colony counts, suboptimal growth on commonly used media, and negative findings on nitrite screening.

Mixed flora (more than two organisms) is rare except in severely debilitated persons and other complicated infections. Thus, mixed flora in the setting of uncomplicated infection frequently suggests contamination, and a repeat specimen should be obtained.

6. What is the correlation between sensitivity of the organism to a particular drug and treatment outcome in acute cystitis?

Bacterial susceptibility to different antimicrobial drugs usually is tested by placing discs impregnated with antibacterial agents on an agar surface that has been seeded with the infecting organism. Bacterial susceptibility is indicated by a zone of inhibited growth around the disc containing the drug. Most discs are impregnated with a quantity of drug that correlates with achievable serum concentrations. Drugs useful in

the treatment of UTI are excreted primarily by the kidney, however, and urine concentrations of these drugs may be 20 to 100 times greater than serum concentrations. Therefore, an organism that is only intermediately sensitive, or even “resistant” to the concentration of antibacterial drug in the testing disc, might be sensitive to the high concentration of drug present in the urine.

Although in vitro susceptibility testing is not always predictive of patient response to therapy, studies clearly show that patients infected with a resistant pathogen are at increased risk of treatment failure.^{52,56–58} Several studies reported clinical response to infection in only 24% to 61% of patients with organisms resistant to TMP-SMX compared with 83% to 92% of patients infected with susceptible organisms.^{52,56,57,59} Another study found that patients infected with TMP-SMX-resistant pathogens were 17 times more likely to fail therapy compared with patients with susceptible strains.⁶⁰ Patients treated with TMP-SMX who were infected with drug-resistant organisms were also found to have longer median times to symptom resolution (14 vs. 7 days, $p = 0.0002$), more frequent return clinic visits within 1 week (36% vs. 6%, $p < 0.0001$), more frequent need for subsequent antibiotic therapy (36% vs. 4%, $p < 0.0001$), and higher rates of significant bacteriuria after 1 month (42% vs. 20%, $p = 0.04$).⁵⁷ Although 50% to 60% of patients with resistant organisms may experience failure of TMP-SMX therapy, antimicrobial therapy is usually chosen empirically without the benefit of C&S testing results. Appropriateness of antibiotic therapy is thus usually judged according to subsequent clinical response. If the infecting organism is sensitive, the urine will usually be sterile in 24 to 48 hours. If a urine specimen collected 48 hours after initiation of therapy is not sterile and the patient has been taking the medication properly, the antibiotic may be inappropriate or the focus of infection may be deeper (e.g., pyelonephritis, abscess, obstruction). If the urine specimen is sterile and the patient is symptomatically improved, the appropriate antimicrobial is being used (regardless of sensitivity studies) and the full course of therapy should be completed.

7. Was it necessary to order a pretreatment urine C&S for V.Q.?

Some investigators question the value of pretreatment urine cultures.^{1,4} Women with lower UTI usually have pyuria on urinalysis and respond rapidly to antimicrobial treatment. Pyuria appears to be a better predictor of treatable infection than the colony count obtained on urine culture. Furthermore, the urine culture accounts for a large portion of the cost of treating a patient with a UTI. Consequently, in patients with uncomplicated, acute, lower UTI, it is more cost-effective to order a urinalysis and, if pyuria is present, to forego a urine culture. Instead, the patient should be empirically treated with a conventional 3- to 7-day course of antibiotic therapy. If V.Q. remains symptomatic 48 hours later, a C&S test can be ordered.

Fluoroquinolone Therapy

8. I.B., a 48-year-old woman, presents with a community-acquired UTI. She has experienced a rash with TMP-SMX and has a type I hypersensitivity reaction to penicillins. What is the

role of fluoroquinolones in the treatment of I.B.’s community-acquired UTI?

Several fluoroquinolones are indicated for the treatment of uncomplicated or complicated UTI; these include norfloxacin, ciprofloxacin, and levofloxacin. The fluoroquinolones are usually administered orally in the treatment of UTI and have excellent in vitro activity against most gram-negative organisms, including *P. aeruginosa*.⁶¹ They are also active in vitro against many gram-positive organisms including *S. saprophyticus*.⁶¹ Resistance to fluoroquinolones among organisms causing acute uncomplicated UTI is usually <1% to 2%.¹⁹ Fluoroquinolone resistance may, however, be more frequent in some geographic areas (5%–10%) and in complicated infections^{44,54}; these quinolone-resistant strains also tend to be resistant to multiple other antimicrobials.⁶² The activity of many fluoroquinolones in vitro is antagonized by urine (acidic pH, divalent cations); however, this is unlikely to be clinically significant because urine concentrations are several hundred-fold greater than serum levels.⁶¹

Although the fluoroquinolones are as effective as TMP-SMX in the treatment of uncomplicated UTI, they are not recommended as first-line therapy because they are more expensive and provide no additional treatment benefits.^{4,7,42,43,48,61} Concerns also exist regarding the overuse of fluoroquinolones and the promotion of drug resistance among community-acquired pathogens. These agents are appropriate alternatives for patients with allergies to first-line agents or for patients infected with organisms resistant to multiple antibiotics, such as *P. aeruginosa*. Fluoroquinolones are also recommended as first-line agents in geographic areas with >20% resistance of *E. coli* to TMP-SMX.^{42,43,48,51} Finally, the fluoroquinolones are effective in treating patients with structural or functional abnormalities of the urinary tract and other types of complicated infections.^{61,63,64}

A fluoroquinolone is appropriate for I.B. because it will be effective and because she has experienced previous adverse reactions to penicillins and sulfas. The fluoroquinolones are considered similar in efficacy in this setting^{63,64}; choice of a specific agent should be based on comparative costs and compliance considerations. The duration of fluoroquinolone therapy in I.B. would be 3 days.

Drug Interactions

9. I.B. also is taking Maalox for a duodenal ulcer. What is the likelihood that this antacid will affect the action of the fluoroquinolones?

It is imperative that clinicians question patients such as I.B. regarding other medications (both prescription and nonprescription) that they may be taking. Products containing divalent and trivalent cations (Mg^{2+} , Ca^{2+} , Zn^{2+} , Al^{3+} , Fe^{2+}) invariably cause significantly decreased fluoroquinolone absorption (20%–70% decrease in area under the concentration curve [AUC]), and this may result in therapeutic failures. Although this interaction can be avoided by taking the antacids or other products at least 2 hours before or 4 to 6 hours after the fluoroquinolone dose, this is complicated and inconvenient for the patient.⁶⁵ Patients simply should avoid these products while taking fluoroquinolones. Interactions of the fluoroquinolones with H_2 -receptor antagonists and proton pump inhibitors are

usually not clinically significant, and these agents can be used for patients with gastrointestinal (GI) ulcers.⁶⁵

Some older fluoroquinolones also interfere with theophylline metabolism, especially ciprofloxacin (20%–90% increase in AUC). Norfloxacin increases the theophylline AUC by approximately 15%.⁶⁶ Therefore, theophylline levels should be monitored closely in patients receiving these quinolones and theophylline together. Levofloxacin does not significantly alter methylxanthine metabolism.⁶⁵ Whereas ciprofloxacin interferes with the metabolism of caffeine, levofloxacin does not.⁶⁵ Although the clinical significance of the interaction between caffeine and most fluoroquinolones is minimal, patients should be monitored carefully for signs and symptoms of caffeine toxicity. This is especially important for patients ingesting large quantities of caffeine and in older patients.

There have been isolated reports of a clinical interaction between certain quinolones (e.g., ciprofloxacin) and warfarin. Although there seems to be no truly relevant pharmacokinetic or pharmacodynamic interactions, patients receiving both warfarin and quinolone therapy should nevertheless be carefully monitored for changes in their anticoagulation.⁶⁵ Isolated cases have also been reported of increased toxicity with coadministration of quinolones and nonsteroidal anti-inflammatory drugs (NSAID), phenytoin, and cyclosporine; whether these interactions truly exist is unknown.⁶⁵

HOSPITAL-ACQUIRED ACUTE URINARY TRACT INFECTION

10. P.M., an alert, 70-year-old woman with chest pain, was hospitalized to rule out acute myocardial infarction. This is her third hospitalization for chest pain in the past 6 months. A urinary catheter was temporarily placed as part of her routine medical care. Two days after admission, she complained of burning on urination and bladder pain. TMP-SMX double strength, one tablet BID was ordered after microscopic examination of the urine indicated a UTI. Why was this empiric therapy appropriate?

Hospital-acquired (or nosocomial) UTI occur in about one-half million patients per year and most are associated with the use of indwelling bladder catheters. Approximately 10% to 30% of catheterized patients develop infection.²⁴ Complications of catheter-associated UTI are significant. Nosocomial UTI are the source of up to 15% of all nosocomial bloodstream infections, occurring in about 4% of all catheterized patients⁶⁷; the associated mortality rate is approximately 15%.²⁴ Nosocomial UTI also prolong hospitalization by an average of 2.5 days and cost an additional \$600 to \$700.^{21,24,67} Prevention is the best way to manage nosocomial UTI, but antibiotic treatment is usually initiated in hospitalized patients who develop UTI symptoms.

The susceptibility of hospital-acquired pathogens to antimicrobial agents differs from community-acquired bacteria, and these susceptibilities frequently vary from one hospital to another. Therefore, the microbiology department of a particular hospital should be consulted to determine current trends in the antibiotic susceptibility of bacteria acquired in that setting. In general, *E. coli* is still the predominant urinary tract pathogen. An increased proportion of infections is caused, however, by other gram-negative bacteria such as *Proteus* and

Pseudomonas, gram-positive pathogens such as *Staphylococcus* and *Enterococcus*, and yeast (e.g., *Candida*).^{20,22,24}

Repeated courses of antibiotic therapy, anatomic defects of the urinary tract, old age, increased hospital length of stay, and repeated hospital admissions are associated with a higher incidence of infection with antibiotic-resistant organisms.^{20,24,68,69} *Pseudomonas*, *Proteus*, *Providencia*, *Morganella*, *Klebsiella*, *Enterobacter*, *Citrobacter*, and *Serratia* are particularly difficult to eradicate because they usually are less susceptible to commonly used antimicrobial agents.

P.M. is elderly, hospitalized, and has been repeatedly exposed to potentially resistant organisms during her previous hospitalizations. Because prompt treatment is deemed necessary, oral TMP-SMX is a reasonable first choice because *E. coli* still is the most likely causative agent, and P.M. is only mildly ill with signs and symptoms of lower UTI. Oral fluoroquinolones are more commonly used in this setting, however, because of the high potential for infection with resistant pathogens.^{20,70,71} Cultures of P.M.'s urine should be performed and, once C&S test results are known, therapy promptly changed according to susceptibility reports. To achieve the most cost-effective therapy, oral agents should be administered to all patients capable of taking medications by mouth unless the isolated pathogens are resistant to oral medications or underlying GI dysfunction makes adequate absorption of oral antibiotics questionable.^{70,71}

11. If P.M. had additional symptoms of fever, chills, flank pain, and vomiting, how would her treatment differ?

In seriously ill patients with possible sepsis, broad-spectrum parenteral antibiotics with activity against *P. aeruginosa* are usually preferred as initial therapy (Table 64-3). Suitable antibiotic choices include antipseudomonal cephalosporins (e.g., ceftazidime, cefepime), extended-spectrum penicillins (e.g., piperacillin-tazobactam, ticarcillin-clavulanate), carbapenems (imipenem-cilastatin, meropenem), intravenous (IV) fluoroquinolones (ciprofloxacin), and aztreonam. These antibiotics appear to be at least as effective as the aminoglycosides and lack the ototoxic and nephrotoxic potential. These newer agents are more costly, however, and may be associated with the emergence of resistant organisms and superinfection with organisms such as *Enterococcus* and *Candida*.

In general, antipseudomonal β -lactam antibiotics remain the drugs of choice for nosocomial urologic sepsis.⁷¹ The combination of a β -lactam plus an aminoglycoside may be advantageous in neutropenic patients. Once the susceptibility pattern of the infecting organism is known, therapy should be altered to single-agent therapy whenever possible to decrease both the risks of drug toxicity and the drug costs.⁷¹

ACUTE PYELONEPHRITIS

Signs and Symptoms

12. L.B., a 45-year-old woman with diabetes, comes to the emergency department (ED) complaining of frequent urination, fever, shaking chills, and flank pain. She takes 20 U of NPH insulin subcutaneously (SC) every morning. Positive physical findings include a temperature of 103°F, a pulse of 110 beats/minute, blood pressure (BP) of 90/60 mmHg, and CVA tenderness. A Gram stain

Table 64-3 Parenteral Antimicrobial Agents Commonly Used in the Treatment of Urinary Tract Infections

| Class | Drug | Average Adult Daily Dose | | Usual Dosage Interval ^a | Comments |
|----------------------------------|-------------------------|--------------------------|------------|------------------------------------|--|
| | | UTI | Sepsis | | |
| Penicillins | Ampicillin | 2–4 g | 8 g | Q 4–6 hr | Use should be based on local susceptibility patterns. |
| | Ampicillin-sulbactam | 6 g | 12 g | Q 6 hr | |
| Extended-spectrum penicillin | Ticarcillin-clavulanate | 9–12 g | 18 g | Q 4–6 hr | |
| | Piperacillin-tazobactam | 9 g | 18 g | Q 4–6 hr | |
| First-generation cephalosporins | Cefazolin | 1.5–3 g | 6 g | Q 8–12 hr | More effective than second- or third-generation cephalosporins against gram-positive organisms. |
| Second-generation cephalosporins | Cefoxitin | 3–4 g | 8 g | Q 4–8 hr | Intermediate between first- and third-generation cephalosporins against gram-negative organisms. |
| | Cefuroxime | 2.25 g | 4.5 g | Q 8 hr | |
| Third-generation cephalosporins | Cefotetan | 1–4 g | 6 g | Q 12 hr | Better coverage than first- and second-generation cephalosporins against gram-negative organisms. Ceftazidime and cefepime are most effective against <i>Pseudomonas</i> . All generations of cephalosporins are ineffective against <i>Enterococcus faecalis</i> and methicillin-resistant staphylococci. |
| | Cefotaxime | 3–4 g | 8 g | Q 6–8 hr | |
| | Ceftizoxime | 2–3 g | 8 g | Q 8–12 hr | |
| | Ceftriaxone | 1 g | 2 g | Q 12–24 hr | |
| | Ceftazidime | 1.5–3 g | 6 g | Q 8–12 hr | |
| Fourth-generation cephalosporins | Cefepime | 1–2 g | 4 g | Q 12 hr | |
| Carbapenems | Imipenem-cilastatin | 1 g | 2 g | Q 6 hr | The most broad-spectrum coverage of any antibiotics listed. Ertapenem not active against <i>Pseudomonas</i> . Resistance may develop especially with <i>Pseudomonas</i> . Toxic in some pregnant animals |
| | Meropenem | 1.5–3 g | 3 g | Q 8 hr | |
| | Doripenem | 0.5 g | 0.5g | Q 8 hr | |
| | Ertapenem | 0.5–1 g | 1 g | Q 24 hr | |
| Monobactam | Aztreonam | 1–2 g | 6–8 g | Q 8–12 hr | Active against gram-negative aerobic pathogens, including <i>Pseudomonas</i> sp. |
| Aminoglycosides | Gentamicin | 3 mg/kg | 5 mg/kg | Q 8 hr | Potent against gram-negative bacteria including <i>Pseudomonas</i> . Associated with possible eighth nerve toxicity in the fetus. Amikacin should be reserved for multiresistant bacteria. |
| | Tobramycin | 3 mg/kg | 5 mg/kg | Q 8 hr | |
| | Amikacin | 7.5 mg/kg | 15 mg/kg | Q 12 hr | |
| Quinolones | Ciprofloxacin | 400–800 mg | 800 mg | Q 12 hr | Use for resistant organisms. Change to oral therapy when indicated |
| | Levofloxacin | 250–500 mg | 500–750 mg | Q 24 hr | |

^a Assuming normal renal function.

of L.B.'s urine reveals gram-negative rods, and a STAT UA demonstrates glucosuria, macroscopic hematuria, 20 to 25 WBC/mm³, numerous bacteria, and WBC casts. She also has a blood sugar level of 400 mg/dL (normal, 70–105 mg/dL). L.B. is admitted to the hospital with a diagnosis of acute bacterial pyelonephritis, and routine laboratory tests including a blood chemistry profile, complete blood count (CBC) with differential, and specimens of urine and blood for C&S are ordered. L.B. is started on IV normal saline, ampicillin 1 g IV every 6 hours, and a sliding-scale schedule of regular insulin based on every 6-hour blood sugars. Which signs and symptoms in L.B. are consistent with a kidney infection?

[SI units: blood sugar, 22.20 mmol/L (normal, 3.88–5.82)]

It is not always possible to differentiate clinically between upper and lower urinary tract infections. Symptoms common in lower UTI often are the only positive findings in upper UTI (i.e., subclinical pyelonephritis).^{1,4,6,72} L.B., however, does manifest signs and symptoms of systemic infection consistent with acute bacterial pyelonephritis, including tachycardia, hypotension, fever, shaking chills, flank pain, CVA tenderness, hematuria, and WBC casts. In addition, her diabetes may predispose her to various renal infections, including pyelonephritis, possi-

bly because diabetic patients have altered antibacterial defense mechanisms.^{6,72,73}

Treatment

Triage for Hospitalization

13. Why was L.B. hospitalized?

Most patients with clinical pyelonephritis have relatively mild infection and usually can be treated as outpatients. The need for hospitalization often is determined by the patient's social situation and ability to maintain an adequate fluid intake and tolerate oral medications.^{6,7,72} Patients such as L.B. with evidence of bacteremia (e.g., fever, shaking chills) or sepsis (e.g., hypotension) should be hospitalized and treated with parenteral antibiotics.^{6,7,72} L.B. should be hospitalized because her acute pyelonephritis may predispose her to diabetic ketoacidosis.

Although blood cultures are usually obtained in patients with moderate-to-severe pyelonephritis, one study found that blood cultures were of low yield in the setting of acute uncomplicated pyelonephritis; they rarely provided any additional information not already obtained from the urine culture and were

not helpful in the clinical management of such cases.⁷⁴ Blood cultures may be positive in up to 25% of patients with severe or complicated pyelonephritis, however, and they are still recommended for patients such as L.B.^{6,72}

Antimicrobial Choice

14. Was ampicillin appropriate treatment for L.B.?

Ampicillin is not an appropriate choice for L.B. because diabetic patients (and patients treated with corticosteroids) are susceptible to colonization with unusual or more resistant organisms. As with lower tract UTI, pyelonephritis is often classified as uncomplicated or complicated. L.B.'s infection would be classified as a complicated infection because of her underlying diabetes.^{6,72} *E. coli* remains the predominant pathogen in complicated pyelonephritis, but other gram-negative organisms (e.g., *Klebsiella*, *Proteus*, *Pseudomonas*) are found relatively more frequently.^{6,72} Because L.B. is acutely ill and has gram-negative organisms in her urine, she should be treated with an antibiotic that has a better spectrum of activity against gram-negative organisms. Broad-spectrum antibiotics appropriate for initial therapy would include parenteral third-generation cephalosporins (e.g., ceftriaxone), IV fluoroquinolones (e.g., ciprofloxacin, levofloxacin), and piperacillin-tazobactam; aminoglycosides are also sometimes recommended as monotherapy.^{6,7,75} Aztreonam may also be considered for treatment of patients with severe β -lactam allergies. It is not always necessary to initially treat patients with antipseudomonal therapy; thus, agents such as ceftriaxone with relatively less activity against *Pseudomonas* are often appropriate as initial therapy in patients such as L.B.^{6,7,72,75} Because most hospital laboratories can report C&S results within 48 hours, these antibiotics can be replaced with more specific ones if appropriate.

Serum versus Urine Concentrations

15. Is it necessary to achieve bactericidal concentrations of antimicrobials in the serum, or are high urinary concentrations adequate for L.B.? How long should she be treated? How should therapeutic success be determined?

In patients with pyelonephritis and infection of the renal parenchyma, adequate tissue concentrations of antimicrobial agents are needed. Therefore, antibiotics that achieve bactericidal concentrations in serum and kidney tissues should be selected.⁷⁰ Patients requiring hospitalization should be treated with parenteral antibiotics until fluids can be taken orally and the patient is symptomatically improved and afebrile for 24 to 48 hours. This should be followed with a course of oral antibiotics for a total duration of antimicrobial therapy of 14 to 21 days; less severe infections not requiring hospitalization are usually treated with 7- to 14-day courses. Although it is customary to observe the patient in the hospital for 24 hours after switching from parenteral to oral antibiotics before discharge, this is probably of limited benefit.^{6,7,72,75} Specimens for C&S should be obtained on the second day of therapy (to rule out treatment failure), 2 to 3 weeks after the completion of therapy, and again at 3 months.^{1,6}

For patients who have relapsed after 14 days, retreatment for 6 weeks usually is curative. There have been reports of

successful therapy with 5 days of treatment⁷⁴; however, longer courses are recommended.^{7,72,75}

Oral Therapy

16. When should oral therapy be recommended for the initial treatment of acute pyelonephritis?

Patients with mild, acute pyelonephritis (no nausea, vomiting, or signs of sepsis) can be treated with oral antibiotics such as TMP-SMX for 14 days.^{6,72,75} This regimen is as effective as 6 weeks of TMP-SMX and significantly better than 6 weeks of ampicillin. The fluoroquinolones may be useful for patients infected with resistant organisms because of their excellent in vitro activity against gram-negative organisms and high kidney tissue concentrations (two- to tenfold greater than serum).⁶¹ Agents, such as amoxicillin-clavulanate, cefixime, or cefuroxime, also can be used in this setting.

SYMPTOMATIC ABACTERIURIA

Clinical Presentation

17. R.D., a 22-year-old woman, complains of urinary frequency and painful urination, which have developed over the past 4 to 5 days. UA reveals 10 to 15 WBC/mm³ (normal, 0–2 WBC/mm³), but no bacteria are seen on a Gram stain of the urine. Phenazopyridine 200 mg three times daily (TID) is prescribed. What is a reasonable assessment of R.D.'s clinical presentation?

Acute urethral syndrome is defined as symptoms consistent with lower UTI but with no organisms evident on Gram stain or culture. The lack of detectable pathogens may mean that the urine specimen is sterile or that the concentration of the organism in the urine sample is small. Patients with these findings still may have a UTI even though the voided urine is sterile or contains $<10^5$ microorganisms per milliliter.⁷⁶ The causative organisms and the pathogenesis of infection in these cases are the same as for lower UTI. Other organisms that can cause urethritis in this setting are *Chlamydia trachomatis*, *N. gonorrhoeae*, and *Trichomonas vaginalis*.⁷⁶

Most cases of UTI with low bacterial counts are associated with bacteriuria or *C. trachomatis* and also demonstrate pyuria (>8 WBC/mm³).⁷⁶ Conversely, pathogens are seldom present in patients with the acute urethral syndrome when pyuria is absent. Because R.D. is symptomatic, has 10 to 15 WBC/mm³ in her urine, and no bacteria on Gram stain, infection with *C. trachomatis* or some other more atypical pathogen is likely.

Interstitial cystitis is a chronic clinical syndrome characterized by bladder or pelvic pain and urinary frequency or urgency.⁷⁷ Although the exact cause of interstitial cystitis is not known, it is not an infection-related disorder and does not respond to antibiotic therapy. The clinical presentation of interstitial cystitis is very similar to that of symptomatic abacteriuria, but absence of pyuria is a key difference. Interstitial cystitis should be suspected in patients with clinical findings suggestive of lower UTI but who do not manifest pyuria and who have not responded to previous empiric antibiotic therapy; no antibiotics should be administered without further diagnostic evaluation.⁷⁷

Antibiotic Treatment

18. Should R.D. be treated with antibiotics?

Yes. A double-blind, placebo-controlled study evaluated the use of doxycycline 100 mg BID in patients with UTI and low bacterial counts. Clinical cure of bacteriuria and pyuria was significantly greater in the doxycycline-treated group, but doxycycline did not alter symptoms in patients without pyuria.⁷⁶ Because *E. coli*, other gram-negative bacteria, and *C. trachomatis* are the usual causes of acute urethral syndrome, an antibiotic such as doxycycline with activity against *Chlamydia* is reasonable initial treatment for patients such as R.D. presenting with urinary tract symptoms (without bacteriuria) if pyuria also is present. All tetracyclines and sulfonamides, with or without trimethoprim, also are likely to be effective in such patients, but doxycycline has been best studied to date. Of the fluoroquinolones, newer agents, such as levofloxacin, offer promise as alternatives to doxycycline but have not been well studied in this setting.⁷⁶ Azithromycin as a single dose also has a major role in treating chlamydial infections (see Chapter 65, Sexually Transmitted Diseases).

Prolonged therapy of 2 to 4 weeks in duration and treatment of sexual partners may be required to prevent reinfection through intercourse. Prolonged therapy is appropriate if the patient has a history consistent with *Chlamydia* urethritis; a sexual partner with recent urethritis; a recent new sexual partner; a gradual, rather than abrupt, onset of symptoms that has occurred over a period of days (as in R.D.); and no hematuria. Patients without such a history can be treated with a short course of antibiotics as any other patient with a lower UTI.

Phenazopyridine

19. Was phenazopyridine appropriate for R.D.?

Phenazopyridine, a urinary tract analgesic, often is prescribed alone or along with an antibacterial agent for the symptomatic relief of dysuria. Although 200 mg orally TID may relieve dysuria, it is ineffective in the actual eradication of true UTI. Phenazopyridine plus an antibiotic is not any better than an antibiotic alone; therefore, the drug is not likely to be of significant value in R.D. and should seldom be prescribed for such patients.

Although most patients have resolution of symptoms within 24 to 48 hours after beginning therapy, some patients with severe dysuria or delayed response to antibiotic therapy may benefit symptomatically from a short trial (1–2 days) of phenazopyridine.⁴ The need for, and duration of, analgesic therapy must be individualized.

Side Effects

20. What side effects have been associated with phenazopyridine?

Phenazopyridine is an azo dye and may discolor the urine to an orange-red, orange-brown, or red color that can stain clothes. Other adverse effects of phenazopyridine occur following acute overdose, or as a result of accumulation in older patients or in patients with decreased renal function who take the drug chronically. In vivo, about 50% of phenazopyridine is metabolized to aniline, which can cause methemoglobinemia and hemolytic

anemia. The hemolytic anemia associated with phenazopyridine occurs primarily in patients with glucose-6-phosphate dehydrogenase (G6PD) deficiency.⁷⁸ Cases of reversible acute renal failure and allergic hepatitis have also been rarely reported following brief exposure to phenazopyridine.⁷⁸

ASYMPTOMATIC BACTERIURIA

Antibiotic Treatment

21. A.K., an asymptomatic 6-year-old girl, is found to have significant bacteriuria on routine screening. Should she be treated with an antimicrobial agent?

The treatment of patients with asymptomatic bacteriuria depends on the clinical setting in which it is found. Asymptomatic bacteriuria occurs in a heterogeneous group of patients with different prognoses and risks. Therefore, recommendations for treatment of asymptomatic patients with significant bacteriuria (two consecutive voided urine specimens showing $\geq 10^5$ bacteria per milliliter of urine in women, or a single clean-catch voided specimen in men) are based on specific age, sex, and clinical characteristics.^{1,11,12,79} These recommendations are based on the risk for development of acute UTI and subsequent long-term complications. Generally, patients who appear to benefit most from antibiotic treatment are those with complicating factors such as urinary tract structural abnormalities, immunosuppressive therapy, and procedures requiring urinary tract instrumentation or manipulation.^{1,2,11} Short-course regimens (i.e., single-dose or 3-day) are usually recommended when treatment is desired,² although longer regimens have also been recommended.¹¹

Urinary tract infections in infants and preschool children (predominantly girls) occasionally are associated with renal tissue damage.⁸⁰ Asymptomatic bacteriuria of childhood also is important because it may be a manifestation of an anatomic or mechanical defect in the urinary tract. Therefore, it should be evaluated fully. Because most cases of renal scarring as a result of bacteriuria occur within the first 5 years of life, it is controversial whether treatment should be limited to infants and preschool children or whether all children should be treated regardless of age. Screening for bacteriuria in children and treating those with positive cultures, regardless of their clinical presentation, seems reasonable and is frequently recommended.⁸⁰ Treatment of A.K., although still controversial, seems prudent because renal damage resulting from asymptomatic bacteriuria generally occurs during childhood. Should the decision be made to treat, principles of therapy are similar to those for symptomatic infections.

Pregnant Patients, the Elderly, and Other Adult Populations

22. The decision to treat the asymptomatic bacteriuria of A.K. was based primarily on the increased probability of renal damage during childhood. What other population groups should be treated for asymptomatic bacteriuria?

Without urinary tract obstruction, UTI in adults rarely lead to progressive renal damage.^{2,4} Therefore, asymptomatic bacteriuria does not require treatment in most adult patients who have no evidence of mechanical obstruction or renal

insufficiency. Aggressive antimicrobial therapy is appropriate during pregnancy, however, because as many as 40% of pregnant women with asymptomatic bacteriuria later develop symptomatic UTI, particularly pyelonephritis.¹¹ In addition, studies have confirmed associations between acute pyelonephritis during pregnancy with increased rates of preterm labor, premature delivery, and lower birth-weight infants.²⁶ The treatment of asymptomatic bacteriuria in pregnancy is therefore justified to decrease the risk of associated complications.¹¹

Treatment should be based on in vitro susceptibility testing or by selecting the least expensive, least toxic agent. Sulfonamides should be avoided in late pregnancy because they can contribute to kernicterus in the neonate. Fluoroquinolones should be avoided during pregnancy because of the risk of arthropathies (see Question 37).

Bacteriuria in the elderly is common.^{15,16} Although bacteriuria in this population often leads to symptomatic infection, clinical studies, however, have consistently documented no beneficial outcomes in treated patients compared with untreated patients.^{11,15} Consequently, therapy is not recommended for the asymptomatic older patient because the expense, side effects, and potential complications of drug therapy appear to outweigh the benefits.^{11,15} Patients experiencing symptomatic infections should be treated as usual.

The treatment of asymptomatic bacteriuria in women with diabetes has recently been shown not to reduce complications and is not currently recommended.^{11,79} Similarly, because asymptomatic bacteriuria in patients with urinary catheters is very common (~25% with short-term catheterization and virtually 100% long-term) but is associated with few complications, antibiotic therapy is not recommended as long as the catheter remains in place. Antibiotic treatment may be considered in asymptomatic women who still have bacteriuria ≥48 hours after removal of the catheter.¹¹

RECURRENT URINARY TRACT INFECTIONS

Relapse versus Reinfection

23. T.W., a 28-year-old woman with a history of recurrent infections, recently was treated for an *E. coli* UTI with TMP-SMX for 10 days. A repeat UA was scheduled, but she canceled her appointment because she “felt fine.” Eight weeks later, she returned to the clinic with signs and symptoms of another UTI. The only other medication she has taken is an oral contraceptive. Why would C&S testing of a urine sample be especially useful at this time?

Recurrent infections develop in approximately 20% to 30% of women with acute cystitis.^{2,4,81,82} Repeat C&S data should help determine whether this infection represents a relapse or a reinfection. *Relapse* refers to a recurrence of bacteriuria caused by the same microorganism that was present before therapy initiation. Most relapses occur within 1 to 2 weeks after the completion of therapy and are caused by persistence of the organism in the urinary tract. Relapses often are associated with an inadequately treated upper UTI, structural abnormalities of the urinary tract, or chronic bacterial prostatitis.^{1,81,83}

Reinfection implies recurrence of bacteriuria with a different organism than was present before therapy. Reinfections can

occur at any time during or after the completion of treatment, but most appear several weeks to several months later. Approximately 80% of recurrences are caused by reinfection.¹ Reinfection is generally caused by introital colonization with *Enterobacteriaceae* from the lower intestinal tract¹; of these, *E. coli* is the most common. Certain *E. coli* strains have been shown to adhere to vaginal epithelial cells and, in women with recurrent UTI, adherence of these organisms to epithelial cells is increased.²⁵ That T.W. was symptom free for 8 weeks suggests that this is a reinfection.

Oral Contraceptives as a Risk Factor

24. Is there an association between T.W.’s use of oral contraceptives and her risk of contracting a UTI?

Information regarding the association between oral contraceptive use and UTI is controversial. The two most recent studies to examine this association disagree in their conclusions. A well-designed, prospective study examined 796 women and found the incidence of UTI to be exactly the same between oral contraceptive users and nonusers.³³ A subsequent case-control study in 229 women with recurrent UTI and 253 control subjects, however, found that oral contraceptive users were at significantly higher risk for recurrent infection.²⁶ The association between oral contraceptive use and risk of UTI remains unclear.

The association between diaphragm use and UTI is much stronger. Diaphragm users are approximately three times more likely to develop a UTI than women using other contraceptive methods, especially when the diaphragm is used in conjunction with spermicidal jelly.^{26,33} Possible explanations include urethral obstruction by the diaphragm together with increased vaginal colonization by coliform organisms caused by the spermicide. Use of a spermicide-coated condom also has been shown to increase the risk of UTI.^{26,84}

Treatment for Reinfection

25. Pending the C&S results, what therapy should be instituted in T.W.?

T.W. has a history of recurrent infections and now probably has a reinfection. Because reinfection is not caused by failure of previous therapy, TMP-SMX may be a reasonable choice once again. The probability that a resistant organism will be responsible for the infection increases when the interval between infectious episodes is short. If several months elapse between each episode of antimicrobial therapy, normal fecal bacterial flora become re-established and the risk of infection with resistant pathogens is reduced.

The alteration of fecal flora caused by the sulfonamides makes these drugs poor choices for repeated use in cases of frequent reinfection, especially when C&S results are unknown. The development of bacterial resistance also may limit the usefulness of these agents for chronic antimicrobial therapy.^{19,44,81,82}

26. If T.W. developed an adverse reaction to TMP-SMX, what are some other therapeutic alternatives?

Nitrofurantoin is effective against 80% to 90% of *E. coli* strains. It does not significantly alter the fecal or introital

flora, and the development of resistance in previously sensitive strains does not often occur.^{19,44,85} Therefore, it generally is a useful agent for the treatment of recurrent *E. coli*, *S. saprophyticus*, and *Enterococcus* infections. On the other hand, *Proteus*, *Enterobacter*, and *Klebsiella* tend to be somewhat resistant to this drug (susceptibility <60%).¹⁹

Nitrofurantoin is absorbed orally. Food substantially decreases the rate of absorption, but increases the total bioavailability of nitrofurantoin from both the macrocrystalline capsules and the microcrystalline tablets by about 40%. This effect lengthens the duration of therapeutic urine concentrations by about 2 hours.⁸⁶ Nitrofurantoin barely reaches detectable levels in the plasma because it is eliminated rapidly (half-life, 20 minutes) into the urine and bile; urine levels are 50 to 250 mg/L.⁸⁶ Thus, nitrofurantoin is used only for UTI. The Kirby-Bauer disc sensitivity test measures the sensitivity of an organism to the expected serum levels of most antibiotics, whereas in the case of nitrofurantoin, the test measures sensitivity to urinary levels.

The fluoroquinolones also are useful in this setting. Their widespread use should not be encouraged for reinfections as in T.W. in light of their high cost and selection of resistant organisms.⁴⁹ Cephalexin and trimethoprim also have been recommended as alternative agents in this setting.^{2,81,82}

Evaluation Procedures (Localization)

27. Greater than 10⁵ bacteria per milliliter of *P. mirabilis*, sensitive to ampicillin and TMP-SMX, are cultured in T.W.'s urine. One week after completing her second course of TMP-SMX therapy, signs and symptoms of a UTI again appear. How should T.W. be assessed at this time?

First, attempt to rule out common causes for relapse. Inadequate therapy resulting from patient noncompliance with the prescribed treatment, inappropriate antibiotic selection, or bacterial resistance to the prescribed agent should be considered if significant bacteriuria persists despite treatment. Next, consider renal infections (e.g., subclinical pyelonephritis), which cause many relapsing UTI.^{1,2,81,82} Finally, if these common causes are not present, radiologic tests should be performed to rule out surgically correctable structural abnormalities of the urinary tract (e.g., IV pyelogram). Infected kidney stones and unilateral atrophic kidneys are common but correctable abnormalities in females.

Radiologic tests are indicated when UTI start to recur in children, in men <50 years of age, and in patients with UTI associated with bacteremia, ureteral colic, or passage of stones. These populations are most likely to have surgically correctable lesions. In contrast, these procedures rarely are necessary in adult women and elderly men until the common causes of relapse in these populations have been eliminated.^{4,23,83} Chronic bacterial prostatitis should be considered as a frequent cause of recurrent infections in male patients.

Treatment of Relapse

Trimethoprim-Sulfamethoxazole

28. Pending C&S results, TMP-SMX is again prescribed. Is this still a reasonable medication for T.W. at this time?

Because the *P. mirabilis* cultured during the last recurrence was still susceptible to TMP-SMX, this agent would again be

a reasonable choice until C&S results are obtained. Alternatively, use of a different agent (e.g., fluoroquinolone) could be considered because the relapse occurred within 1 week of completing the previous treatment and resistance may have developed.⁴

29. How long should this therapy be continued?

The duration of therapy for relapsing infections usually is 14 days. In patients who relapse after a second 2-week course of therapy, treatment for 6 weeks should be instituted.^{1,2,83} If relapse occurs after a 6-week course, some experts recommend longer courses of 6 months to 1 year.^{1,2} These prolonged courses should be reserved for children, adults who have continuous symptoms, or adults who are at high risk for developing progressive renal damage. Asymptomatic adults without evidence of obstruction should not receive these longer courses. T.W. should be treated for at least 2 weeks and perhaps as long as 6 weeks.

Trimethoprim

30. T.W. was previously treated with TMP-SMX and experienced nausea and vomiting after taking the medication. Why would trimethoprim alone be an appropriate substitute?

Trimethoprim alone and in combination with sulfamethoxazole is active in vitro against many of the *Enterobacteriaceae* associated with UTI and is an effective alternative to TMP-SMX in the management of both chronic and acute UTI.^{1,2,4,83} It would be especially appropriate for T.W. because GI intolerance to TMP-SMX is most commonly attributed to the sulfamethoxazole component, and trimethoprim is associated with a lower incidence of side effects. Some concern exists for the potential development of resistant organisms, but studies using trimethoprim alone have failed to demonstrate a significant increase in bacterial resistance.⁸¹ Trimethoprim is used for the treatment of acute, uncomplicated UTI in a dosage of 200 mg/day.

Chronic Prophylaxis

31. T.W. was treated successfully with trimethoprim for 6 weeks. Is prophylactic antimicrobial therapy indicated? If so, how long should it be continued?

Cases of chronic UTI in adult patients may be managed by treating each recurrent infection with an appropriate antibacterial. A single dose or longer course may be used. Chronic UTI may also be managed by administering chronic, low-dose prophylactic therapy. The frequency of urinary infections probably is the main determinant of whether chronic suppressive therapy should be used, because data suggest that repeated treatment of recurrent infections eventually will result in a decreased incidence of subsequent infections.^{1,82,87} Long-term prophylactic therapy clearly reduces the frequency of symptomatic infections in nearly all patients.^{15,87}

From a cost-effectiveness standpoint, women having more than one episode of cystitis per year may benefit from antimicrobial prophylaxis.^{81,83} For women with three or more episodes of cystitis per year, prophylaxis clearly is more cost-effective than treating individual infections. Therefore, chronic antimicrobial prophylaxis should be considered in any adult patient with two or more episodes of UTI per year.^{82,83}

The duration of prophylactic therapy also is determined by the frequency of infection. Women with three or more UTI

in the 12 months before a 6-month course of antimicrobial prophylaxis have a significantly higher recurrence rate (75%) in the 6 months following prophylaxis than women who have had only two infections in the 12 months before prophylaxis (26% recurrence rate).⁸⁷ Therefore, prophylaxis should be continued for 6 months in patients with fewer than three UTI per year and for at least 12 months in adult patients with three or more UTI per year.

Before chronic antimicrobial suppressive therapy is initiated, active infections must be completely eradicated with a full course of appropriate antibiotic therapy. The low doses of antimicrobials used for chronic prophylaxis suppress bacterial growth but do not eliminate active infection. Furthermore, surgically correctable anatomic abnormalities that predispose the patient to recurrent infections (e.g., obstruction, stones) should be ruled out. Patients with urologic abnormalities respond poorly to prophylactic therapy.^{81,83} Age also should be considered when contemplating chronic antimicrobial therapy. An asymptomatic, elderly patient taking many other medications is usually not an ideal candidate for chronic prophylactic treatment because of problems of noncompliance, cost, and potential drug interactions or toxicities.^{81,83} Younger patients, however, are good candidates for long-term suppressive therapy.^{82,83}

Because T.W., a 28-year-old woman, has had at least three UTI in the past few months, has undergone extensive evaluation, and has just been successfully treated with a standard course of trimethoprim, a 12-month course of antimicrobial prophylaxis would seem reasonable. She also should be evaluated at regular intervals for recurrent UTI and for the development of resistant organisms.

Although the foregoing discussion applies to antimicrobial prophylaxis in adults, relatively few data are available concerning long-term prophylaxis of recurrent UTI in children. One recent study examined risk factors for recurrent UTI and associations with antimicrobial prophylaxis in a prospective cohort study involving nearly 75,000 children 6 years of age or younger.⁸⁸ Among the children in this study, antimicrobial prophylaxis was not associated with decreased risk of recurrent UTI; however, prophylaxis was associated with a 7.5 times increased risk of infection caused by resistant bacteria. Long-term antimicrobial prophylaxis, therefore, should not be routinely recommended for prevention of recurrent UTI

in children until such time as more favorable data become available.^{1,2,81,82}

32. What drugs can be used for long-term suppressive therapy?

Although numerous drugs are used for prophylaxis, TMP-SMX may be the drug of choice for chronic antimicrobial therapy owing to extensive experience, proved efficacy, infrequent toxicities, and low cost.^{82,83} TMP-SMX also has the effect of decreasing vaginal colonization with uropathogens.⁸² TMP-SMX one-half tablet daily is commonly prescribed for chronic UTI prophylaxis; TMP-SMX TID is also an effective, well-tolerated and convenient prophylactic regimen.^{82,83}

Successful prophylaxis, however, is significantly decreased in patients with urologic abnormalities or renal dysfunction. Also, infections that are not eradicated by a short-term therapeutic trial of TMP-SMX are not likely to respond to a long-term regimen.⁸¹ Finally, enterococci may colonize introitally in patients taking chronic TMP-SMX.⁸⁷

Fluoroquinolones are effective for chronic suppressive therapy but should be used only when antimicrobial resistance exists among cultured organisms or if the patient is intolerant to other recommended drugs. Cephalosporins also have been recommended as being appropriate for long-term prophylactic therapy, but are perhaps best reserved for patients intolerant to or failing prophylaxis with other agents.^{81,83}

When selecting a drug for chronic antimicrobial therapy, it is important to consider efficacy, the likelihood that resistant organisms will develop, long-term toxicity, convenience, and cost to the patient. The most commonly used agents are listed in Table 64-4.

Based on the available information, it appears that T.W. could be switched to TMP-SMX. Although she has a history of GI distress because of this drug, this may not be a problem with the lower doses used for prophylaxis. If it is, trimethoprim alone, nitrofurantoin, or a fluoroquinolone also should be effective.

Cranberries and probiotics have long been of interest for their potentially beneficial effects in preventing UTI. Cranberries contain two known compounds that prevent *E. coli* from adhering to uroepithelial cells in the urinary tract.⁸⁹ A number of clinical trials have examined the efficacy of cranberries in the prophylaxis of UTI, but the results are inconclusive

Table 64-4 Antimicrobial Agents Commonly Used for Chronic Prophylaxis Against Recurrent UTIs^{1,2,4,81-83,87}

| Agent | Adult Dose | Comments ^a |
|---|--------------------------------------|--|
| Nitrofurantoin | 50–100 mg nightly | Contraindicated in infant <1 month of age. <i>To be taken with food or milk. May cause brown or rust-yellow discoloration of urine.</i> |
| Trimethoprim | 100 mg nightly | Not recommended in children <12 years of age. |
| Trimethoprim 80 mg + Sulfamethoxazole 400 mg | 0.5–1 tablet nightly or 3/week | Not recommended for use in infants <2 months. <i>To be taken on an empty stomach with a full glass of water. Photosensitivity may occur.</i> |
| Norfloxacin | 200 mg/day | Avoid antacids; monitor theophylline levels. |
| Cephalexin | 125–250 mg/day | |
| Cefaclor | 250 mg/day | |
| Cephradine | 250 mg/day | |
| Sulfamethoxazole | 500 mg/day | |

^aIncludes unique patient consultation information in italics.

overall.^{89,90} Importantly, studies have used a wide variety of cranberry products (e.g., juice concentrate, juice cocktail, capsules, tablets) as well as different dosing regimens.^{89,90} Although two trials found that cranberry juice may decrease the number of symptomatic UTI over a 12-month period in younger women, it is not known whether it is effective for other groups such as children and elderly men and women.^{89,90} Probiotics (particularly *Lactobacillus* strains) have also been examined as a means of supplementing or re-establishing normal rectal or vaginal flora and thereby preventing colonization with pathogenic strains associated with UTI.⁹¹ Studies of probiotics for prophylaxis, however, are inconclusive at this time. Further research is required to clarify unanswered questions regarding the role of cranberries or probiotics in the prevention of UTI.^{89,91}

SPECIAL CASES

Prostatitis

Prostatitis is a common but poorly understood entity. The most prevalent forms include acute and chronic bacterial prostatitis, chronic calculus prostatitis, nonbacterial prostatitis, and prostatodynia.^{13,14}

Acute Bacterial Prostatitis

Acute bacterial prostatitis is characterized by the sudden onset of chills and fever; perineal and low back pain; urinary urgency and frequency; nocturia, dysuria, and generalized malaise; and prostration. Patients also may complain of myalgias, arthralgias, and symptoms of bladder outlet obstruction. Rectal examination usually discloses an exquisitely tender, swollen prostate that is firm and warm to the touch. The pathogens generally can be identified by culture of the voided urine and usually are similar to those causing UTI in women (Table 64-1). In patients with acute bacterial prostatitis, prostatic massage should be avoided because of patient discomfort and the risk of bacteremia.^{13,14}

Chronic Bacterial Prostatitis

Chronic bacterial prostatitis is one of the most common causes of recurrent UTI in men. Except in male patients with spinal cord injuries, infectious stones, or obstructive abnormalities of the urinary tract, recurrent infections are almost always relapses caused by persistence of bacteria in the prostate. Normally, men secrete a prostatic antibacterial factor; however, this substance is absent in men with chronic prostatitis. Simple UTI will often eventually involve the prostate gland, where bacteria are difficult to eradicate.

The clinical manifestations of chronic bacterial prostatitis are highly variable and, in many patients, are asymptomatic. The disease usually is suspected when a male patient treated for UTI relapses, and the diagnosis is confirmed by examination of expressed prostatic secretions.^{13,14} To ensure accurate localization (i.e., to distinguish prostatic from urethral bacteria), segmented urine samples are taken. The first 10 mL of voided urine represents the urethral sample, the midstream urine collected represents the bladder sample, and the first 10 mL voided immediately after prostatic massage represents the prostate sample. When the bladder sample is sterile or nearly so, bacterial prostatitis is diagnosed if the bacterial count in the prostate sample is at least one logarithm greater than that

in the urethral sample. The bacterial pathogens responsible for chronic prostatitis often are similar to those of acute prostatitis and UTI in general (Table 64-1).^{13,14}

Treatment

33. D.G., a 60-year-old man, experienced his first UTI at age 40, with symptoms of frequency, dysuria, nocturia, perineal pain, chills, and fever, but no flank pain. Acute prostatitis was diagnosed. *E. coli* was cultured from the urine, and treatment with a sulfonamide was successful. After 12 asymptomatic years, acute prostatitis caused by *E. coli* recurred and again responded to sulfonamide therapy. Two more *E. coli* infections that responded to sulfonamide therapy occurred over the next 8 years. Why were sulfonamides appropriate treatment for D.G.'s acute episodes of bacterial prostatitis?

Most antibacterial drugs appropriate for UTI, including sulfonamides, can be used to treat acute bacterial prostatitis because the diffuse, intense inflammation of the prostate gland allows many drugs to readily penetrate into the prostatic fluid and tissues. Antimicrobial therapy should be continued for at least 1 month to prevent the development of chronic prostatitis.^{13,14,92}

In addition to antibiotics, other supportive measures may provide symptomatic relief to patients with acute bacterial prostatitis. These measures include liberal hydration, NSAID for pain relief, sitz baths, and stool softeners.

In retrospect, sulfonamides were appropriate for D.G. because they effectively treated his infections.

34. Taking into account the pathophysiology of prostatitis, what would be a reasonable choice of therapy for D.G. should he have future recurrences of prostatitis?

Because inflammation is minimal in patients with chronic prostatitis, most antibiotics that are acidic do not readily cross the prostatic epithelium into the alkaline prostatic fluid. Theoretically, the high alkalinity of prostatic fluids should impair the diffusion of trimethoprim and enhance the diffusion of the tetracyclines, certain sulfonamides, and the macrolide antibiotics, such as erythromycin. Nevertheless, TMP-SMX historically has the best documented cure rates in the treatment of acute and chronic bacterial prostatitis. Long-term therapy of chronic bacterial prostatitis with TMP-SMX for 4 to 16 weeks is associated with a cure rate of 32% to 71%, which significantly exceeds the cure rate associated with short-term therapy of 2 or fewer weeks.^{13,14}

The fluoroquinolones have become well-accepted alternatives to TMP-SMX and are even considered by many to be the agents of choice for the treatment of prostatitis.⁹² A number of studies have documented bacteriologic cure in 80% to 90% of patients treated with norfloxacin, ciprofloxacin, or levofloxacin for 4 to 12 weeks, rates comparable to or substantially higher than those achieved with agents such as TMP-SMX.^{13,14} The fluoroquinolones have assumed an important role in the treatment of prostatitis owing to their bactericidal activity against common pathogens and excellent penetration into prostatic tissues and fluid. The fluoroquinolones are often used as initial empiric therapy of prostatitis and are also excellent alternatives to other agents in patients who are unresponsive or intolerant to conventional therapy, or in those infected with resistant organisms.^{13,14,92} Fluoroquinolones also have been used

for chronic suppressive therapy (one-half normal doses) in patients who relapse after conventional treatment.¹

D.G. should be treated with TMP-SMX for a minimum of 6 weeks; some authorities recommend a 2- to 3-month total course of therapy. If an adequate trial of TMP-SMX is unsuccessful, fluoroquinolone therapy can be used. Alternatively, a fluoroquinolone could be used as initial therapy.⁹²

If D.G. continues to develop recurrent infections following a trial of fluoroquinolone therapy, chronic low-dose treatment with TMP-SMX, fluoroquinolones, or nitrofurantoin can alleviate the symptoms of episodic bladder infection associated with chronic bacterial prostatitis. Infections eventually recur with greater frequency in most of these patients, although some become asymptomatic, even with chronic bacteriuria. Chronic, low-dose antibacterial therapy sterilizes the bladder, alleviates symptoms, confines bacteria to the prostate, and prevents infection of and damage to the rest of the urinary tract. Chronic bacterial prostatitis is one of the few indications for continuous antibiotic therapy.

Urinary Tract Infection and Sexual Intercourse

35. On routine screening, asymptomatic bacteriuria is noted in W.W., a 30-year-old pregnant woman in her first trimester. Five years ago, during her first pregnancy, she developed acute bacterial pyelonephritis, which required hospitalization and treatment with parenteral antibiotics. Since that time, she has had recurrent UTI, apparently related to sexual intercourse. These subsided when she began taking a single dose of nitrofurantoin after coitus, but she discontinued the practice before this pregnancy because she was afraid of the potential effects of this drug on the fetus. What is the association between sexual intercourse and the occurrence of UTI?

Studies strongly support an association between sexual intercourse and UTI.^{1,2,26,33,83} A direct relationship seems to exist between the number of days with intercourse within the previous week and the risk of developing a UTI.³³ One study found the relative risk of infection in women with 1, 4, and 7 days of intercourse within the previous week to be 1.4, 3.5, and 9.0, respectively, compared with women who were sexually inactive within the previous week. Another study found that the risk of UTI was doubled in women having intercourse more than four times per month compared with those women who did not.²⁶ Studies also indicate that introital colonization by fecal bacteria has a definite role in recurrent infections related to intercourse. The migration of these colonizing bacteria into the bladder appears to be facilitated during intercourse, but the exact mechanism remains unclear.^{1,2,33,83} Because UTI are uncommon in men, transmission of an infection from the man is unlikely. Occasionally, bacteria harbored under the foreskin of an uncircumcised man may be transmitted to his partner through intercourse.³

36. Was it rational to treat these infections with a single dose of an antibiotic after intercourse?

Postcoital antibiotic prophylaxis often is recommended when recurrent UTI are thought to result from sexual intercourse. Theoretically, a single dose of an antimicrobial agent produces bactericidal activity in the urine before bacteria have a chance to multiply, and the infection is averted. Patients should

be instructed to empty their bladder just after intercourse and before taking the medication to minimize the number of bacteria present in the bladder and to eliminate unnecessary dilution of the drug in the urine. Because most drugs effective for UTI are rapidly excreted by the kidney and reach high urinary concentrations, this regimen appears reasonable and does lower the incidence of postcoital infections.^{87,93} It has the same drawbacks as does any other type of antibiotic prophylaxis, however, and is not recommended in patients with structural abnormalities of the urinary tract or decreased renal function. It also is important to treat symptomatic infection before beginning prophylaxis.

Depending on the frequency of intercourse, postcoital prophylaxis may result in less antibiotic use compared with continuous prophylaxis. TMP-SMX or nitrofurantoin is the most commonly recommended agent; however, other agents such as fluoroquinolones and cephalexin may be used.^{81,83,93,94}

Urinary Tract Infection and Pregnancy

37. Because W.W.'s UTI is asymptomatic at this time, should treatment be withheld because of her pregnancy?

W.W. should be treated because acute symptomatic pyelonephritis may develop in pregnant women with untreated bacteriuria. In addition, evidence suggests that maternal UTI during pregnancy are associated with increased rates of preterm labor, premature delivery, and lower birth-weight infants.²⁶ Although a cause-and-effect relationship has not been definitely established, treatment with an appropriate antimicrobial agent is currently recommended for all pregnant patients with significant bacteriuria.^{11,27}

Nitrofurantoin is often recommended during pregnancy because teratogenic effects have not been observed clinically. In vitro investigations, however, suggest a slight mutagenic potential. Nitrofurantoin also could cause hemolytic anemia in a G6PD-deficient nursing infant; however, only small amounts have been detected in breast milk.^{95,96} The fluoroquinolones are contraindicated in pregnancy because of the arthropathy observed in immature animals.⁶⁸

The penicillins, cephalosporins, and aminoglycosides appear to be relatively safe for use during pregnancy, although caution with the aminoglycosides is warranted because of possible eighth nerve toxicity in the fetus. These drugs, along with the others listed in Tables 64-2 and 64-3, cross the placental barrier; thus, the risk of toxicity or teratogenicity to the fetus always must be considered before deciding to treat a pregnant patient with a UTI.^{95,96}

In this case, a cephalosporin or sulfisoxazole could be safely prescribed for treatment of W.W.'s UTI. Ampicillin or amoxicillin would also be reasonable choices if W.W. resided in a geographic area where rates of resistance to these agents were known to be low. W.W. was correct in discontinuing her nitrofurantoin before pregnancy because of the risk to the fetus, although small, tends to offset the advantage of antimicrobial prophylaxis. W.W. must receive proper follow-up care.

38. How long should W.W. be treated?

Few studies have compared single-dose and 3-day therapy with conventional 7-day therapy in pregnant patients. Initial

trials demonstrated, however, that cure rates of single-dose therapy were lower than 7- to 10-day therapy.²⁶ Although more recent trials have shown that single-dose therapy effectively eradicates bacteriuria in pregnancy, these studies were conducted in a small number of patients. Therefore, it is recommended that pregnant patients receive either a 3-day regimen or a 7- to 10-day regimen rather than single-dose therapy.^{11,26}

Irrespective of the duration of therapy, appropriate follow-up of patients is crucial. Clinicians must document elimination of pathogens 1 to 2 weeks after therapy and follow the patient monthly for the remainder of gestation. If bacteriuria recurs, therapy should be given for relapse or reinfection and the patient evaluated radiologically for structural abnormalities.^{1,26}

Urinary Catheters

Catheter-associated UTI, the most common type of hospital-acquired infection, occur in up to 30% of catheterized patients.²⁴ Catheterization and other forms of urologic instrumentation are involved in 65% to 95% of all hospital-acquired UTI.²⁰ These UTI also are a major cause of nosocomial gram-negative bacteremia.

Catheter infection can occur by bacterial entry from several routes. The urethral meatus and the distal third of the urethra normally are colonized by bacteria; therefore, initial catheter insertion can introduce bacteria into the bladder. Bacteria contaminating catheter junctions and the urine collection bag can migrate through the catheter lumen to the bladder, initiating infection.²⁴ The extraluminal space in the urethra also has been considered a potential route of contamination. The risk of infection is directly related to catheter insertion technique, care of the catheter, duration of catheterization, and the susceptibility of the patient. A diagnostic or single, short-term catheterization is associated with a much lower risk of infection than indwelling, long-term catheterization. Despite careful technique, the risk of contaminating a sterile bladder with urethral bacteria is always present. The incidence of infection following a single catheterization is 1% in healthy young women and 20% in debilitated patients. Each reinsertion of the catheter introduces a risk of infection.²⁴

Infections have been reduced dramatically by the closed, sterile drainage system, the most common type of catheter currently in use. With this system, the drainage tube leads from the catheter directly to a closed plastic collection bag. The overall incidence of infection from the closed system with careful insertion and maintenance is about 20%; the risk increases to 50% after 14 days of catheterization. If the system is disconnected or contaminated accidentally, the infection rate is similar to that of an open system.²⁴

Condom catheters appear to be associated with a lower incidence of bacteriuria than indwelling urethral catheters. These catheters avoid problems associated with insertion of a tube directly into the urinary tract; nevertheless, urine within the catheters may have high concentrations of organisms so that colonization of the urethra and subsequent cystitis may develop.²⁴

To prevent bacterial contamination of the bladder when the catheter is inserted, the periurethral area should be cleansed carefully with soap and water followed by some type of antiseptic solution. An iodophor solution often is recommended. Once the catheter is in place, proper maintenance and strict ad-

herence to good catheter care are imperative to minimize the incidence of infections. Thus, caregivers must be trained in the techniques of obtaining urine samples from closed systems. Application of antibacterial substances to the collection bag and the catheter-urethral interface do not appear to decrease the incidence of bacteriuria.^{24,97,98} The use of antimicrobial-coated catheters (e.g., silver, rifampin plus minocycline) have been shown in some studies to decreased rates of bacteriuria and UTI.^{97,98} The overall effects of these catheters on infection rates, patient outcomes, and antibiotic resistance are not known, however. The routine use of antibiotic-coated catheters is not currently recommended.^{95,97}

39. J.W., an 18-year-old man, was hospitalized following a diving accident that resulted in a spinal cord injury with paralysis. Included among several initial interventions was insertion of an indwelling catheter with a closed drainage system because of bladder incontinence. Two weeks after admission to the hospital, J.W. has developed asymptomatic bacteriuria. Should this be treated?

A systemic antibiotic selected specifically for the infecting organism will temporarily result in sterile urine. Reinfection, often by a resistant organism, occurs in 30% to 50% of these cases if closed drainage catheterization is continued during therapy.^{1,24} For this reason, it generally is recommended that systemic antimicrobial therapy be initiated after or just before catheter removal.^{1,24} Because long-term catheterization is necessary in many patients and because bacteriuria is an inevitable consequence, it is often recommended that asymptomatic patients (such as J.W.) be left untreated to avoid the complications of recolonization and potential infection with resistant organisms.^{1,11,24} Therapy must be started, however, if fever, flank pain, or other symptoms indicative of UTI develop.^{1,24}

40. Is systemic antimicrobial prophylaxis useful for J.W.?

The benefits of systemic antibiotics in preventing catheter-induced UTI are not clear. Studies using closed drainage systems with diligent catheter care indicate that systemic antibiotics decrease the daily and overall incidence of infection in patients with sterile urines before catheterization.^{97,98} The preventive effect of antimicrobials is greatest for short-term catheterizations or during the first 4 to 7 days of long-term catheterization.^{97,98} Thereafter, the rate of infection increases. Although the overall infection rate remains lower than in untreated patients, the emergence of resistant organisms is significant. Therefore, in deciding to use systemic antimicrobials, it is important to consider the patient's underlying diseases, risk factors, probable duration of catheterization, and potential complications of drug toxicity or resistant organisms that can result from the chronic use of antimicrobials. Because long-term catheterization is anticipated for J.W., antimicrobial prophylaxis for J.W. is not recommended.

41. C.A., a 60-year-old woman admitted for coronary bypass, is catheterized for urinary incontinence. Two days after removal of the catheter, she still has asymptomatic bacteriuria. How should she be treated?

Catheter-acquired bacteriuria that persists 48 hours after catheter removal may be treated with either a single large dose or a 3-day regimen of TMP-SMX, even if the patient is asymptomatic.^{11,24,92} Older women (>65 years) probably should be treated with a 10-day course; however, the optimal duration in this age group is unknown. Whether these

treatment regimens can be used in male patients requires further study.

Renal Failure

42. K.M., a 55-year-old man with a history of hypertension and chronic renal failure, develops a UTI. His creatinine clearance (ClCr), determined from a recent 24-hour urine collection, is 20 mL/minute. What antimicrobial agent should be prescribed?

[SI unit: SrCr, 0.33 mL/sec]

The major problem in treating UTI in patients with renal failure is how to achieve adequate urine concentrations of the drug without causing systemic toxicity. The ideal drug would be (a) inherently nontoxic, even at high serum concentrations, making dosage adjustments unnecessary; (b) excreted unchanged in the urine (i.e., not metabolized); and (c) eliminated by renal tubular secretion rather than glomerular filtration. Because renal tubular secretion remains active in all but the most severe cases of renal failure, antibiotics eliminated by this mechanism would reach adequate urinary levels; however, no such ideal drug exists.

Nitrofurantoin, doxycycline, and many sulfonamides are substantially metabolized by the liver and generally produce low urine levels in uremic patients. The aminoglycosides are eliminated almost exclusively by the kidneys, but uremic patients are at high risk of drug-induced toxicities and alternative agents are usually recommended. Penicillins, cephalosporins, and trimethoprim are partially metabolized by the liver but are also eliminated by the kidney to a significant extent. These agents are suitable for use in renal failure according to the criteria described above. Certain fluoroquinolones, specifically ciprofloxacin and levofloxacin, are highly excreted in the urine through a combination of filtration and tubular secretion and reach extremely high urinary concentrations. These agents are also considered safe and effective in the treatment of UTI in patients with renal failure.

ADVERSE DRUG REACTIONS AND DRUG INTERACTIONS

Trimethoprim-Sulfamethoxazole

Hemolytic Anemia

43. G.R., a 45-year-old black man with an 8-year history of congestive heart failure, was admitted to the hospital with increasing shortness of breath. His hematocrit (Hct) was stable at around 42% (normal in men, 40%–49%) and his total serum bilirubin was 0.8 mg/dL (normal, 0.2–1.1 mg/dL). Sixteen days after admission, an *E. coli* UTI was diagnosed and G.R. was treated with TMP-SMX 160 mg/800 mg twice daily. Four days after beginning TMP-SMX, the Hct suddenly dropped to 25% and the hemoglobin (Hgb) to 8.4 g/dL (normal in men, 14–18 g/dL). There were no signs of bleeding, but his sclerae became icteric. After 7 days of TMP-SMX therapy, the Hct was still 25%, but the reticulocyte count had risen to 6.6% (normal, 0.5%–1.5%) and the total serum bilirubin was 3.0 mg/dL. The TMP-SMX was discontinued, and over a period of 2 weeks the Hct steadily rose to 40%. What mechanism might explain G.R.'s sulfonamide-induced hemolytic anemia? Is his presentation typical? Are there any other drugs used to treat UTI that can cause a similar reaction?

[SI units: Hct, 0.39 to 0.43, 0.25, and 0.40, respectively (normal, 0.40–0.49); bilirubin, 13.7 and 51.3 μ mol/L, respectively (normal, 3.4–18.8); Hgb, 84 g/L (normal, 140–180 g/L); reticulocyte count, 0.066 (normal, 0.005–0.015)]

Hemolytic anemia is associated with sulfonamide administration and may be mediated by several mechanisms, including abnormally high blood levels, acquired hypersensitivity as reflected by the development of a positive Coombs' test, genetically determined abnormalities of red blood cell metabolism (e.g., G6PD deficiency), or an "unstable" hemoglobin in RBC (e.g., Hgb Zurich, Hgb Towns, Hgb H).^{91,92} Although the defect appears to be most common in Mediterranean male patients, one variant affects as many as 11% of American black men.⁹²

Acute hemolytic anemia induced by sulfonamides in G6PD-deficient patients does not appear to be dose related. It usually is abrupt in onset and occurs within the first week of therapy. Typical symptoms include nausea, fever, vertigo, jaundice, hepatosplenomegaly, and occasionally, hypotension. Hematocrit and hemoglobin values may fall precipitously and may be reduced to 30% to 50% of the normal values, as illustrated by G.R., Leukocytosis and reticulocytosis are common, and acute renal failure may result from the hypotension and hemoglobinuria. A mild hemolytic episode is characterized by reticulocytosis without a significant fall in hemoglobin or hematocrit. Nitrofurantoin has also been reported to induce G6PD-deficiency hemolysis.⁹⁹

Clinical illness, as well as drug administration, can precipitate hemolysis in patients with G6PD deficiency. Patients with chronic bacterial infections of the urinary or upper respiratory tract who receive chronic or repetitive courses of certain drugs are particularly predisposed to hemolysis.⁹⁹

Patients with enzyme deficiencies, especially those enzymes associated with the pentose-phosphate shunt (as is G6PD), can develop hemolytic reactions when taking drugs commonly used to treat UTI. Future use of sulfonamides or nitrofurantoin should be avoided in G.R.

Rash and Drug Fever

44. J.P., a 63-year-old diabetic woman taking glipizide 10 mg/day, developed an acute UTI for which TMP-SMX 160 mg/800 mg BID for 10 days was prescribed. Seven days later she presented to the ED with a pruritic maculopapular rash and fever. Are the rash and fever in J.P. typical of that caused by the sulfonamides?

Yes. Rash is one of the more common side effects associated with sulfonamide use and occurs in approximately 1% to 2% of patients treated with TMP-SMX. Various hypersensitivity skin and mucous membrane reactions have been reported, including morbilliform, scarlatiniform, urticarial, erysipeloid, pemphigoid, purpuric, and petechial rashes. Erythema nodosum, exfoliative dermatitis, photosensitivity reactions, and the Stevens-Johnson syndrome also are associated with sulfonamides. Skin eruptions usually appear after 1 week of treatment, although more rapid onset may occur in a sensitized person.⁵³ The hypersensitivity reactions that occurred in J.P. signify that an alternate drug should be used to treat future UTI.

Folate Deficiency

45. D.M., a 50-year-old epileptic woman, has been taking prophylactic TMP-SMX nightly for 3 months for chronic recurrent

UTI. She also takes phenytoin 300 mg/day, which effectively controls her seizures, and diazepam 2 mg TID. She smokes one pack of cigarettes/day and drinks 1 pint of gin/day. Routine CBC after a clinic visit shows a Hgb of 9 g/dL (normal in females, 13.5–16.7 g/dL), a Hct of 30% (normal in females, 40%–49%), a mean corpuscular volume (MCV) of 105 mm³ (normal, 80–100 mm³), and a mean corpuscular hemoglobin concentration (MCHC) of 32% (normal, 32%–36%). Could TMP-SMX account for D.M.'s megaloblastic anemia?

[SI units: Hgb, 90 g/L (normal, 135–167); Hct, 0.30 (normal, 0.40–0.49); MCV, 105 fL (normal, 80–100); MCHC, 0.32 (normal, 0.32–0.36)]

Megaloblastic anemia secondary to folate deficiency has been rarely associated with the use of TMP-SMX.⁵³ Sulfonamides inhibit folic acid synthesis in bacterial and protozoal cells but do not affect the human cell to a significant degree, except when given in high doses. It is especially a problem in patients with known or potentially deficient folate stores, such as pregnant women, older persons, patients with malabsorption or malnutrition, alcoholics, patients receiving anticonvulsants, or those with chronic hemolysis (e.g., sickle cell disease). Concomitant administration of folic acid reverses these effects without interfering with antimicrobial activity.⁵³ It is doubtful that significant folate deficiency occurs following short-term TMP-SMX therapy or in patients without the above risk factors.

In D.M., both phenytoin and alcohol undoubtedly contributed to folate deficiency anemia. Whether or not TMP-SMX was a significant factor may be questioned, but an alternate antibacterial may be preferable in a patient already at risk for folate deficiency.

Nitrofurantoin

Gastrointestinal Disturbance

46. J.R., a 45-year-old, 110-pound woman, is given nitrofurantoin 100 mg four times daily (QID) for 14 days for an acute UTI. She complains of nausea and GI upset after the ingestion of each dose of nitrofurantoin. How can this effect be minimized?

Nausea is a fairly common complication of nitrofurantoin therapy, and the patient's compliance with the prescribed regimen may be severely affected by this common side effect. It is not known whether the mechanism by which nitrofurantoin produces nausea is central or local. The following approaches can be used to decrease nitrofurantoin-induced nausea:

- *Take Each Dose With Food.* Nitrofurantoin should be taken with food or milk. If the nausea is a locally mediated effect, the food may serve as a buffer; if the nausea is centrally mediated, then food may slow the rate of absorption and lower the peak serum concentration of the drug. Food, however, may also increase the bioavailability of nitrofurantoin. Slowing of absorption is particularly beneficial in decreasing the incidence of nausea and vomiting associated with the microcrystalline product.⁹⁴
- *Change to a Macrocrystalline Product.* Use of the macrocrystalline preparation results in significantly fewer adverse effects without affecting clinical cure rates. The larger particle size of the macrocrystalline preparation results in slower rates of dissolution and absorption, and lower serum levels.

This may decrease the nausea and vomiting associated with the microcrystalline product.⁹⁴ A disadvantage of the macrocrystalline form is the cost, which may be 2 to 10 times that of the microcrystalline form, depending on the product source.

- *Lower the Dose.* Nausea and vomiting appear to be dose related and occur more frequently in small persons.⁹⁴ The minimal effective dose of nitrofurantoin generally is stated to be 5 mg/kg/day and the average dose is usually 7 mg/kg/day. At daily doses >7 mg/kg, the incidence of nausea appears to increase significantly, so the dose in this 110-pound (50 kg) patient could be decreased.

Pneumonitis

47. J.R. tolerated the macrocrystalline form taken with meals and continued her regimen. However, 10 days later she presented with dyspnea, tachypnea, coughing, and wheezing. Examination revealed a temperature of 38.4°C, pulse of 115 beats/minute, and soft inspiratory and expiratory rhonchi with a few bibasilar rales. Nitrofurantoin was stopped, and inhaled β_2 -agonists and steroids were administered. Symptoms gradually disappeared after a few days; however, rechallenge with a single 50-mg dose of nitrofurantoin caused a recurrence of the respiratory distress. What is the nature of the apparent nitrofurantoin-induced respiratory reaction that occurred in J.R.?

Several hundred cases of nitrofurantoin-induced pulmonary reactions have been reported.¹⁰⁰ Acute, subacute, and chronic reactions have been described. The acute form, illustrated by J.R., often manifests within several days of initiating the drug with a sudden flulike syndrome consisting of fever, dyspnea, and cough. The subacute form tends to occur after at least a month of exposure; symptoms include fever and dyspnea. The chronic form tends to be more insidious with milder dyspnea and low-grade fever. In all forms, rales are commonly heard and pulmonary infiltrates can be demonstrated on chest radiograph. Although eosinophilia frequently occurs with the acute form, it may be absent with the subacute and chronic forms. Antinuclear antibodies are elevated in the latter two forms. Discontinuation of nitrofurantoin results in complete symptomatic recovery after several weeks; however, permanent fibrotic changes may persist with the chronic pulmonary reaction. Although steroids are frequently administered when the adverse reaction is diagnosed, their efficacy has not been demonstrated. Rechallenge with oral nitrofurantoin results in rapid reappearance of pulmonary symptoms in those who have had an acute reaction.¹⁰⁰

Neurotoxicity

48. G.T., a 55-year-old woman, has been taking nitrofurantoin 100 mg QID for an acute UTI. Pertinent history includes hypertension and moderate renal failure. Medications include lisinopril, hydrochlorothiazide, and allopurinol. On the tenth day of therapy, she complains that both her hands and feet feel numb and weak. Physical examination shows significant sensory loss to the hands and feet as well as no ankle reflexes, although knee and arm reflexes are present. What are the characteristics of neuropathy associated with nitrofurantoin therapy?

Peripheral neuropathy usually is characterized by symmetric dysesthesia and paresthesia in the distal extremities, which progresses in a central and ascending fashion. It usually occurs

within the first 60 days of treatment, although neuropathy can be recognized up to 6 weeks after discontinuation of therapy in 16% of patients. Symptom severity is not dose related and is generally reversible, although more severe cases may require up to several months to resolve completely; a few patients may develop permanent neuropathy. Renal failure is a risk factor for toxicity, but neuropathy has also been reported in patients with normal renal function.^{86,94}

Nitrofurantoin excretion is impaired in renal failure; however, serum levels do not rise proportionately, suggesting that the drug might be sequestered in an extravascular space. It has been postulated that neurotoxicity is caused by accumulation of nitrofurantoin in neural tissue, or that toxic metabolites are involved.^{86,94} In view of the inability to achieve adequate urinary concentrations of nitrofurantoin, even in mild renal failure, G.T. should not be given this drug.

Fluoroquinolone Use in Pediatric Infections

49. C.S. is a 2-year old girl with a history of multiple recurrent UTI caused by congenital urinary tract abnormalities that have not been corrected. She has had at least nine UTI since birth and has received multiple courses of antibiotics, including ampicillin, amoxicillin, amoxicillin-clavulanate, and TMP-SMX. She has also been on chronic low-dose antibiotic prophylaxis with TMP-SMX. C.S. was brought to her pediatrician 48 hours ago with signs and symptoms consistent with a new UTI. Suprapubic aspiration was performed and urine samples sent for C&S testing at that time, and C.S. was empirically begun on amoxicillin-clavulanate pending laboratory test results. C&S results, however, are now available and show $>10^5$ colonies/mm³ of *P. mirabilis*. The organism is susceptible to ciprofloxacin, gentamicin, and ertapenem; and resistant to ampicillin, trimethoprim, TMP-SMX, cephalexin, cefaclor, cefpodoxime, tetracycline, nitrofurantoin, and erythromycin. C.S. has not clinically improved while receiving empiric amoxicillin-clavulanate. What antibiotic therapy would be most appropriate for continued management of this acute infection in C.S.?

This case illustrates the serious dilemmas caused by antibiotic resistance among uropathogens. The pathogen isolated from C.S. is resistant to all commonly used, orally administered antibiotics that have been proved effective in the treatment of UTI in pediatric patients. Although penicillins, cephalosporins, nitrofurantoin, and sulfonamides are frequently recommended for treatment of pediatric UTI, multiple past treatment regimens and chronic antibiotic prophylaxis have led to these agents being unsuitable for treatment of this new infection. Although in vitro susceptibility testing does not accurately predict clinical response to therapy in all cases, the risk of treatment failure and poor patient outcome is significantly increased when agents to which isolates are resistant are administered.^{42,43,51,52,56,57} Alternative treatment is required; however, few desirable options exist for C.S.

The recommended duration of antibiotic therapy in C.S. would be at least 2 weeks for the treatment of this complicated and recurrent infection. Although the organism isolated from C.S. is susceptible to gentamicin and this drug would be effective, parenteral (intramuscular or intravenous) administration would be required and the lengthy required treatment duration makes this far from ideal. Use of amino-

glycosides would also be less desirable because of toxicity concerns. Although ertapenem would also likely be effective, there is relatively little clinical experience with this agent in the pediatric population and ertapenem would also require parenteral administration for the duration of the treatment regimen.

Fluoroquinolones are contraindicated in children and adolescents <18 years of age because of concerns regarding potential musculoskeletal toxicities in juvenile populations. Although not approved for pediatric use, fluoroquinolones have been formally studied for febrile neutropenia, infectious gastroenteritis, otitis media, bacterial meningitis, and other uses.¹⁰¹⁻¹⁰³ In addition, the use of fluoroquinolones has been noted to be dramatically increasing in children and adolescents, most likely owing to resistance to other antimicrobials; approximately 520,000 prescriptions were written for patients <18 years of age during 2002, of which nearly 3,000 prescriptions were for children <2 years.¹⁰¹ Several recent reviews have summarized data related to the safety of fluoroquinolones in children; while tendinopathy or other musculoskeletal toxicities have been recorded, they were usually mild in severity, reversible, and occurred at rates comparable to that seen in adults.¹⁰¹⁻¹⁰³ Based on currently available information and in consideration of problems related to antimicrobial resistance, the American Academy of Pediatrics has published recommendations regarding the use of fluoroquinolones in children and adolescents.¹⁰¹ According to these recommendations, fluoroquinolones may be considered in special circumstances including (a) infections caused by multidrug-resistant pathogens for which there are no other safe and effective alternatives; and (b) parenteral therapy is not feasible and no other effective oral agent is available. Treatment of UTI caused by multidrug-resistant, gram-negative pathogens are specifically mentioned as a potentially appropriate use for fluoroquinolones in pediatric patients.¹⁰¹

Selection of a specific agent for the treatment of UTI in C.S. should be based on careful consideration of potential risks and benefits of available antibiotic options. The feasibility, risks, expenses, and inconvenience associated with prolonged (≥ 2 weeks) parenteral administration of an aminoglycoside or carbapenem may pose a difficult problem; however, the ease of oral fluoroquinolone administration must be carefully balanced against the possible risks of using these agents in this population. Clearly, no antibiotic of choice exists for treatment of C.S. and both the providers and the child's parents must be involved in development of an acceptable and well-informed treatment plan.

GLOSSARY

Acute pyelonephritis: Inflammation of the kidney, with flank pain and tenderness, bacteriuria (often bacteremia), pyuria, and fever.

Bacteriuria: Bacteria cultured from urine when it is obtained by either suprapubic aspiration, catheterization, or from a freshly voided specimen. Asymptomatic bacteriuria exists if colony counts exceed 10^5 /mL in a patient without UTI symptoms. Clinically significant bacteriuria probably exists if colony counts are $\geq 10^2$ /mL in patients with UTI symptoms.

Chronic pyelonephritis: A chronic, inflammatory condition of the kidney with associated calyceal dilation and overlying cortical scarring. A nonspecific pathologic appearance of the kidney seen with many disease entities, only one of which is bacterial infection of the kidney.

Complicated urinary tract infection: Infections associated with conditions that increase the risk for acquiring infection, the potential for serious outcomes, or the risk for therapy failure. Such conditions are often associated with abnormalities that may interfere with normal urine flow or the voiding mechanism. Infections in men, children, and pregnant women are considered complicated. Other examples of complicated infections include those associated with structural and neurologic abnormalities of the urinary tract, metabolic or hormonal abnormalities, impaired host responses, and those caused by unusual pathogens (e.g., yeasts, *Mycoplasma*).

Cystitis: An inflammation of the bladder and urethra with dysuria, frequency, urgency, pyuria, clinically significant bacteriuria, and suprapubic tenderness on examination.

Prostatitis: An inflammatory condition affecting the prostate. It can be acute or chronic. Frequently, specific bacterial organisms cannot be detected.

Pyuria: White blood cells in the urine. A WBC count of $\geq 8/\text{mm}^3$ of uncentrifuged urine or 2 to 5 per HPF in centrifuged urine sediment is consistent with a UTI.

Subclinical pyelonephritis: A kidney infection, but with lower UTI signs and symptoms only. Uncomplicated urinary tract infection: Infections occurring in otherwise healthy persons, usually women, who have none of the underlying risk factors known to increase the risk for treatment complications or failure (see Complicated UTI above).

Urethritis: An inflammation of the urethra with dysuria. The etiologic organisms most commonly implicated are *Neisseria gonorrhoeae*, *Ureaplasma urealyticum*, *Chlamydia trachomatis*, and herpes simplex virus.

Urinary tract infection: Microorganisms (bacteria, fungi, viruses) in the urinary tract, including the bladder, prostate, kidneys, and collecting duct. Although fungi and viruses are occasional etiologic agents, UTI are predominantly caused by bacteria.

Vaginitis: Inflammation of the vagina with dysuria, vaginal discharge, and vaginal odor. Common etiologic agents include *Candida albicans*, *Gardnerella vaginalis*, and trichomonads.

VACCINES 65-30

Although descriptions of sexually transmitted diseases (STDs) can be discerned in the earliest written records, only recently have the common STDs been differentiated from each other; unique STD syndromes continue to be described today. For example, of the common STDs, bacterial vaginosis (BV) was not described clearly as a syndrome (initially called *Haemophilus vaginalis* vaginitis) until the 1950s; herpes sim-

plex virus (HSV) type 2 (the cause of genital herpes) was not differentiated from HSV type 1 until the 1960s; the spectrum of genital chlamydial infections was not well worked out until the 1970s; and the human immunodeficiency virus (HIV) as an STD, was not recognized until the 1980s. Since 1980, eight additional sexually transmitted pathogens have been identified. They include the human papillomaviruses (HPV), human

T-lymphotropic virus (HTLV-I and II), *Mycoplasma genitalium*, *Mobiluncus* species, HIV-1 and -2, and the human herpes virus type 8 (associated with Kaposi sarcoma).¹

GONORRHEA

Gonorrhea is caused by *Neisseria gonorrhoeae*, a Gram-negative diplococcus. In 130 AD, Galen coined the term gonorrhea (Greek for “flow of seed”) for the syndrome associated with this infection because he believed the urethral exudate was semen. Although the role of the gonococcus in causing urethral discharge in men has been known for years, the manifestations of gonorrhea in women were determined later. In the 1930s, sulfonamides became the first form of effective antimicrobial therapy for gonorrhea until penicillins and tetracyclines became the mainstays of therapy. Considering the high levels of resistance to these two antimicrobial agents, neither are recommended in the treatment of this disease state.

In the United States, the incidence of gonorrhea rose steadily (15% per year) from the early 1960s through 1975, then fell 74% between 1975 and 1997. Since 1998, the rate has been stable, however, greater than the Centers for Disease Control and Prevention (CDC) goal of <100 cases per 100,000 people (Fig. 65-1).² Notably, the incidence of gonorrhea in heterosexuals rose sharply in 1985 for the first time in a decade. Since this time, the rate has declined, although only in whites and Asians. In contrast, the rate among African Americans was approximately 18 times higher than the rate among whites in 2005. The highest incidence of gonorrhea is in men aged 20 to 24 years and in females aged 15 to 19 years and aged 20 to 24 years.³ Additional risk factors for gonorrhea include low socioeconomic status, urban residence, unmarried marital status, illicit drug use, inconsistent condom use, new or multiple sex partners, prostitution, and a history of gonorrhea or other sexually transmitted infections.⁴⁻⁶ Although the risk of gonorrhea was greater in homosexual men than in heterosexual men in the past, the incidence dropped in homosexual men during the 1980s AIDS epidemic, in large part due to a reduction in sexual risk behaviors. Since 1988, the rate of gonococcal iso-

lates from homosexual men has increased from 4% to a high of 17% in 2001, then fell to 11% in 2005.^{3,7}

Uncomplicated Gonorrhea

Transmission

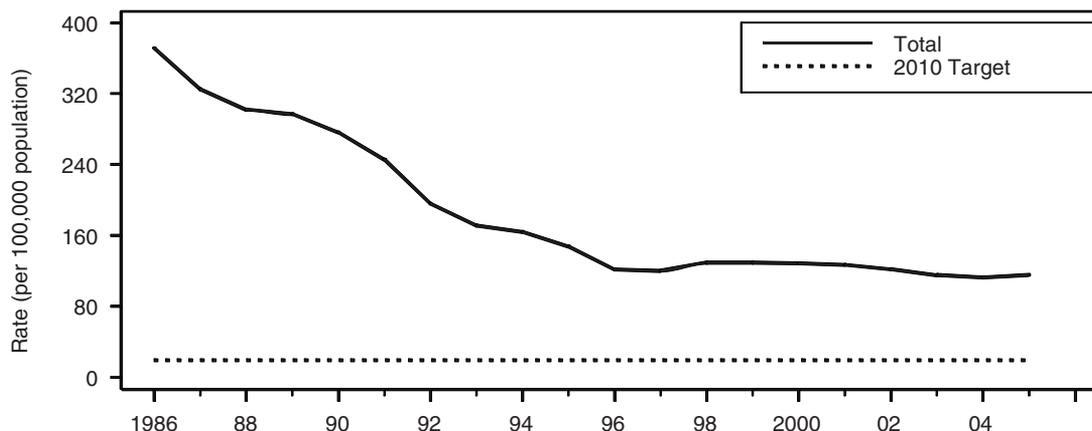

1. D.S., a 23-year-old male naval officer recently stationed in the Philippines, complains of dysuria, meatal pain, and a profuse yellow urethral discharge for 2 days. He admits to extramarital sex with a prostitute over the past week. He is accompanied by his pregnant wife, C.S., who is asymptomatic. D.S. engages in vaginal sex but there is no history of oral or anal sex with either partner. Assuming the prostitute has gonorrhea, what is the likelihood that D.S. and C.S. have been infected?

After one or two episodes of unprotected vaginal intercourse with an infected prostitute, a man has approximately a 50% risk of acquiring a urethral infection; the risk increases with repeated exposures and high prevalence among commercial sex workers.⁸ The prevalence of infection in women who are secondary sex contacts of infected men is as high as 80% to 90%.⁹ Therefore, the likelihood that D.S. and C.S. are infected is high. Because D.S. had sex with a prostitute, both D.S. and C.S. should also be tested for HIV infection.

Signs and Symptoms: Males

2. What signs and symptoms in D.S. are consistent with the diagnosis of gonorrhea? Describe D.S.'s anticipated clinical course if he remains untreated.

In males, gonorrhea usually becomes clinically apparent 1 to 7 days after contact with an infected source. A purulent discharge associated with dysuria is the first sign of infection; D.S. exhibits both. The discharge, which is presumably caused by chemotactic factors such as C5a released when antigonococcal antibody binds complement, may become more profuse and blood tinged as the infection progresses. Some strains of gonorrhea have a propensity to cause asymptomatic or minimally symptomatic infection with negative Gram stain, probably owing to different auxotypes.¹⁰

Note: The Healthy People 2010 (HP2010) objective for gonorrhea is 19.0 cases per 100,000 population.

FIGURE 65-1 Gonorrhea: reported rates in the United States, 1986 to 2005 and the *Healthy People 2010* Target. Gonococcal Isolate Surveillance Project (GISP). (From reference 2.)

Patients with asymptomatic or minimally symptomatic disease may serve as reservoirs for the infection, evading treatment for prolonged periods of time.¹¹ At one time, only females were thought to have asymptomatic gonorrhea, but now it is known that men may be asymptomatic carriers as well.¹²

In the pre-antimicrobial era, gonococci occasionally spread to the epididymis, causing unilateral epididymitis; the prevalence was 5% or more in patients in some studies. Now epididymitis occurs in <1% of men with gonorrhea. Urethral stricture after repeated attacks and sterility after epididymitis are rare complications of gonococcal infection owing to the effectiveness of antibiotics.

Diagnosis: Males

3. Intracellular Gram-negative diplococci were seen on the Gram stain of D.S.'s urethral exudate. Is any further diagnostic testing required?

Demonstration of intracellular Gram-negative diplococci in the Gram-stained exudate confirms the diagnosis in symptomatic men. Until recently, some experts recommended that cultures be reserved for individuals with negative Gram stain of urethral exudate. However, today cultures are recommended for all patients to permit isolation and testing of the bacteria for antibiotic susceptibility. Cultures usually are performed on Thayer–Martin medium, an enriched chocolate agar to which vancomycin, colistimethate, and nystatin have been added. Cultures from the throat should be obtained if D.S. was exposed by cunnilingus to the prostitute. In D.S.'s case, a urethral culture is indicated.

Signs and Symptoms: Females

4. C.S., D.S.'s wife, is asymptomatic. What symptoms would be consistent with gonorrhea in C.S.? Do the symptoms differ because she is pregnant? What is the natural course of gonorrhea in women if left untreated?

Because the endocervical canal is the primary site of urogenital gonococcal infection in women, the most common symptom is vaginal discharge. Many women infected with gonorrhea have abnormalities of the cervix, including purulent or mucopurulent endocervical discharge, erythema, friability, and edema of the zone of ectopy.⁹ The incubation period for urogenital gonorrhea in women is variable.¹³ Pelvic inflammatory disease (PID) is a serious complication in 10% to 20% of women with acute gonococcal infection and can lead to infertility and chronic pelvic pain.⁹ The assessment of signs and

symptoms in women with gonorrhea often is confounded by nonspecific signs and symptoms and a high prevalence of coexisting infection, especially with *Chlamydia trachomatis* or *Trichomonas vaginalis*.

Although lower genital tract symptoms in women may disappear, they remain carriers of *N. gonorrhoeae* and should be treated. Complications of urogenital gonorrhea in pregnancy include spontaneous abortion, premature rupture of the fetal membranes, premature delivery, and acute chorioamnionitis.^{14,15} Other complications include gonococcal arthritis (see Question 16) conjunctivitis, and ophthalmia neonatorum in the newborn.¹⁶ For these reasons, it is critical that C.S. be worked up thoroughly for gonorrhea.

Diagnosis: Females

5. How should gonorrhea be ruled out in C.S.?

C.S. should undergo an endocervical culture, which is positive in 80% of women with gonorrhea and is still considered the “gold standard.”¹⁷ This test should be a part of every pelvic examination of sexually active women. Nucleic acid amplification tests (NAATs), such as polymerase chain reaction (PCR), may yield sensitivities and specificities in the 90% to 100% range, but results must be confirmed with endocervical culture in low-prevalence communities (i.e., <4%).¹⁸ In C.S., anal cultures also could be performed because the rectum can serve as a reservoir for gonococci.

Treatment

6. Compare the various drug regimens used for uncomplicated gonorrhea.

The CDC recommendations are summarized in Table 65-1. Many strains of *N. gonorrhoeae* exhibit plasmid-mediated resistance to penicillin and tetracycline (penicillinase-producing *N. gonorrhoeae* [PPNG] and/or tetracycline-resistant *N. gonorrhoeae* [TRNG]; Fig. 65-2). In addition, significant levels of chromosomally mediated resistance to penicillin, tetracycline, and cefoxitin have been reported.² In 2005, all isolates in the Gonococcal Isolate Surveillance Project (GISP) were susceptible to ceftriaxone; therefore, a single dose of intramuscular (IM) ceftriaxone is preferred for the treatment of gonorrhea. Cefixime 400 mg orally as a single dose is also recommended by the CDC; however, tablets are currently unavailable from the manufacturer. Recently, the CDC withdrew recommendations for use of fluoroquinolones such as ciprofloxacin and ofloxacin because of unacceptably high levels of quinolone-resistant *N. gonorrhoeae* (QRNG).¹⁹

Table 65-1 CDC Recommendations for Treatment of Uncomplicated Gonorrhea

| Presentation | Drugs of Choice (% Cured) | Dosage | Alternative Regimens |
|---|--|----------------------------------|---|
| Urethritis, cervicitis, ^a rectal | Ceftriaxone (98.9) Cefixime (97.4) ^b | 125 mg IM once 400 mg PO once | Cephalosporin single dose regimens ^c |
| Pharyngeal | Ceftriaxone | 125 mg IM once | |

^aBecause a high percentage of patients with gonorrhea have coexisting *Chlamydia trachomatis* infections, many clinicians recommend treating all patients with gonorrhea with a 7-day course of doxycycline or single-dose azithromycin for treatment of Chlamydia.

^bIn July of 2002, Wyeth discontinued oral cefixime (Suprax); currently, only an oral suspension is available.

^cAdditional cephalosporin regimens include ceftizoxime 500 mg IM, cefoxitin 2 g IM (administered with probenecid 1 g PO), and cefotaxime 500 mg IM. Limited evidence suggests that cefpodoxime 200 mg and cefuroxime axetil 1 g might be oral alternatives.

Adapted from reference 6.

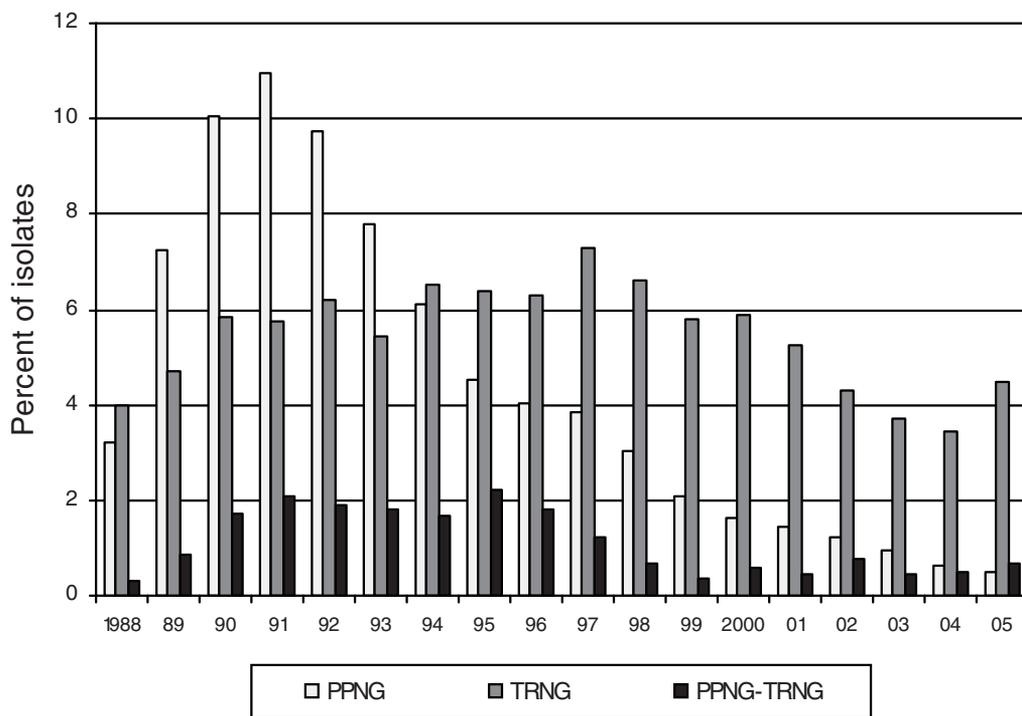

FIGURE 65-2 Plasmid-mediated resistance to penicillin and tetracycline among GISP isolates, 1988 to 2005: Gonococcal Isolate Surveillance Project (GISP). PPNG, penicillinase-producing *N. gonorrhoeae*; TRNG, tetracycline-resistant *N. gonorrhoeae*; PPNG-TRNG, resistant to both penicillin and tetracycline. (From reference 2.)

Because a high percentage of patients with gonorrhea are also coinfecting with *C. trachomatis*, a single dose of azithromycin or a 7-day course of doxycycline is recommended to be taken concurrently for a presumed infection (see Question 22).

IM spectinomycin, which traditionally had been used in individuals who could not tolerate either fluoroquinolones or cephalosporins, is also unavailable from the manufacturer. Spectinomycin was the recommended treatment option for gonorrhea in those with either penicillin or cephalosporin allergies.²⁰ Individuals who have either penicillin or cephalosporin allergies can be desensitized to cephalosporins before treatment begins.²¹

CEFTRIAXONE

Ceftriaxone, a third-generation cephalosporin, is given as a single, small-volume IM injection (e.g., 125 mg diluted with normal saline or 1% lidocaine solution). Ceftriaxone eradicates anal and pharyngeal gonorrhea and is also safe in pregnancy (U.S. Food and Drug Administration [FDA] pregnancy category B). Other injectable cephalosporins (notably ceftizoxime, cefoxitin, and cefotaxime) have been found to be safe and highly effective, although efficacy in pharyngeal infections is not as well-established. Considering the limited availability of cefixime tablets, other oral cephalosporins have been studied. Although not meeting the strict CDC definition of success, evidence suggests that the oral cephalosporins cefpodoxime and cefuroxime axetil are effective in the treatment of uncomplicated urogenital gonorrhea.⁶

Ceftriaxone is ineffective against *C. trachomatis* and in the prevention of postgonococcal urethritis, whereas ofloxacin and levofloxacin for 7 days have similar efficacy to doxycycline.⁶

FLUOROQUINOLONES

Fluoroquinolones have been routinely used since the 1990s for the treatment of gonorrhea; however, since 2002, the GISP has documented increasing rates of fluoroquinolone resistance in *N. gonorrhoeae* isolates (Fig. 65-3), which has necessitated changes in the CDC's Sexually Transmitted Treatment guidelines for 2006. Because of this increased resistance, the CDC no longer recommends ciprofloxacin, levofloxacin, ofloxacin, and other fluoroquinolones for the treatment of gonorrhea. This recommendation also extends to the treatment of gonorrhea-associated conditions such as PID.¹⁹

PRESCRIBING PATTERNS

The CDC's 2005 Sexually Transmitted Disease Surveillance Program observed that ceftriaxone 125 mg, followed by the fluoroquinolones ciprofloxacin and ofloxacin, were the most commonly prescribed agents (Fig. 65-4).² Cefixime is currently only available in a generic suspension (100 or 200 mg/5 mL) form.²² Cefixime 400 mg tablets were unavailable since 2002, but in 2008, they were re-introduced onto the market. Their use should increase as they are the CDC preferred agent for uncomplicated gonorrhea.

7. How should D.S.'s urethritis be treated? Because C.S. is totally asymptomatic and the results of her cultures are pending, should she be treated empirically? If so, what drug(s) would you recommend?

Because D.S. has gonococcal infection limited to the urethra (uncomplicated), a few treatment regimens are possible, as outlined in question 6. Either ceftriaxone or cefixime is the preferred treatment. With the current unavailability of cefixime

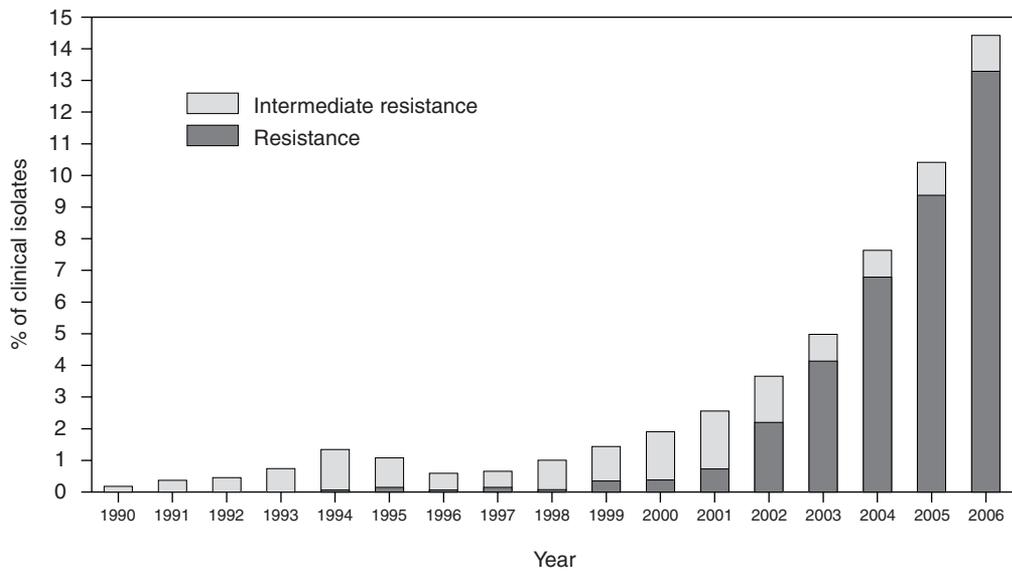

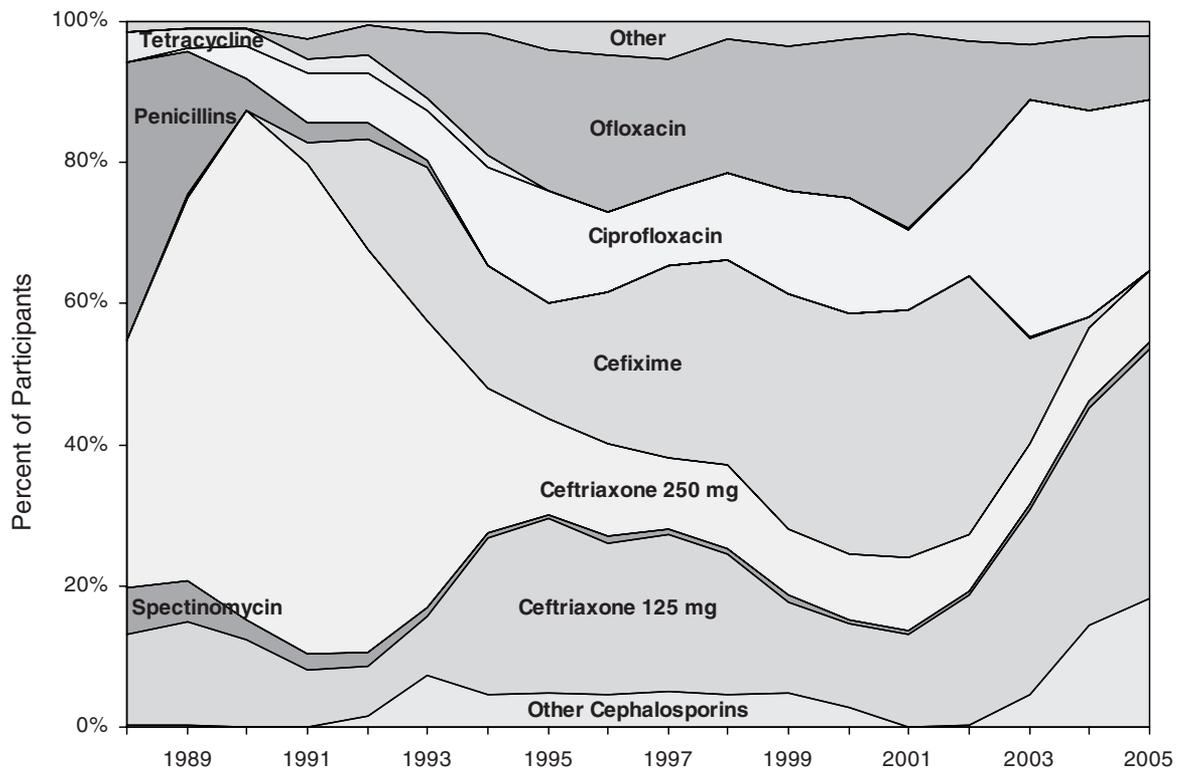

FIGURE 65-3 Percentage of *N. gonorrhoeae* isolates with intermediate resistance or resistance to ciprofloxacin, 1990 to 2006: Gonococcal Isolate Surveillance Project (GISP). Note: Resistant Isolates have ciprofloxacin MICs 1 mcg/ml or higher. Isolates with intermediate resistance have ciprofloxacin MICs of 0.125 to 0.5 mcg/ml. Susceptibility to ciprofloxacin was first measured in GISP in 1990. (From reference 2.)

tablets, alternative oral agents may need to be considered if ceftriaxone is not appropriate. Quinolones should be avoided because of increased resistance in *N. gonorrhoeae* and because D.S.'s infection was likely obtained in the Philippines, where quinolone resistance occurs in over half of all isolates.^{19,23}

Cefpodoxime 200 mg PO and cefuroxime axetil 1 g PO are active in vitro against PPNG, chromosomally mediated resistant *N. gonorrhoeae* (CMRNG), and TRNG, but have limited clinical evidence to support their use. They are, however, FDA approved to treat uncomplicated *N. gonorrhoea*.^{24–26} Because

Note: For 2005, "Other" includes no therapy (1.4%), azithromycin 2 g (0.1%), levofloxacin (0.4%), and other less frequently used drugs.

FIGURE 65-4 Drugs used to treat gonorrhea in GISP participants, 1988 to 2005. (From reference 2.)

no single-dose therapy for gonorrhea and chlamydia is highly effective, additional concurrent therapy needs to be administered. Azithromycin or doxycycline are effective for concomitant chlamydia coinfection. Single-dose azithromycin 2 g PO has been used to treat concurrent gonorrhea and chlamydia, but it is more expensive, poorly tolerated because of increased gastrointestinal (GI) side effects, and less effective than standard combination therapy.²⁷

SEXUAL PARTNERS

C.S. also should be treated even though she appears asymptomatic. All partners who have had sexual exposure to patients with gonorrhea within 60 days should be treated. If the patient has not been sexually active for 60 days, the most recent sexual partner should be treated. This is especially true when the partner is pregnant because gonorrhea during pregnancy is associated with chorioamnionitis and prematurity, as well as neonatal infection. Pregnant women can be treated safely with cephalosporins and azithromycin for gonorrhea and Chlamydia. Doxycycline should be avoided during pregnancy.

FOLLOW-UP

8. How does one determine whether the drug therapy of gonorrhea has been effective in D.S. and C.S.?

If recommended therapies are used for treatment of uncomplicated gonorrhea (see Table 65-1), a test of cure is not necessary for either C.S. or D.S. because cure rates are close to 100%.^{6,9} If symptoms persist in D.S., who was treated with ceftriaxone, cultures should be done to rule out other causes of urethritis.

ANTIBIOTIC-RESISTANT *NEISSERIA GONORRHOEAE*

9. D.S. states that he was treated with penicillin in the past for a gonococcal infection. Why are penicillins not prescribed routinely today?

Failure of penicillin to eradicate the gonococcus can be the result of plasmid (e.g., PPNG) or CMRNG antibiotic resistance. PPNG contain plasmids, which determine the production of lactamase, an enzyme that hydrolyzes the lactam ring of penicillin G or ampicillin. Chromosomally mediated resistance does not involve β -lactamase production and often is associated with increased resistance to other β -lactams. The clinical significance of CMRNG is questionable because serum levels of approved antibiotics are achieved far above the minimum inhibitory concentration, such that treatment failure is unlikely. However, to date, CMRNG remain largely susceptible to ceftriaxone. High-level tetracycline resistance is defined by gonococci that carry plasmid-encoded resistance to 16 g/mL or more of tetracycline. These strains are known as TRNG. Although not of major concern in the United States, development of resistance to alternative therapies is a continuing concern.

The first cases of PPNG infection were reported in the United States in 1976. PPNG are especially prevalent in Southeast Asia, the Far East, and West Africa, where the prevalence often exceeds 50%. In the United States, the percent of PPNG strains reached a peak of about 11% in 1991; since then, cases have steadily declined to 0.5% in 2005, according to the CDC's GISP² (Fig. 65-3). Strains of TRNG were first identified in 1985, but fortunately most TRNG isolates still are sensitive to β -lactam antibiotics. The use of tetracycline was officially

abandoned by the CDC in 1985 and penicillin was abandoned in 1987. In the late 1990s, the number of TRNG and PPNG plus TRNG cases plateaued at about 5% and 1%, respectively.

Because about 21% of gonococcal isolates are resistant to tetracycline and/or penicillin within the United States, it is still not acceptable to use these agents in the initial management of uncomplicated genital gonorrhea. Clinicians should obtain a travel history to identify patients in whom multiple drug resistance is endemic. In endemic areas such as the United States and in hyperendemic areas where PPNG accounts for 3% or greater of all gonococcal isolates, IM ceftriaxone is the drug of choice. Antibiotic susceptibility testing is recommended in cases of persistent infection after treatment.

Quinolone-resistant *N. gonorrhoeae* was first reported in 1990 and was reported to be 0.2% of isolates in the continental United States.^{2,6} As early as 1992 in Cleveland, Ohio,²⁸ and 1995 in Seattle, Washington,²⁹ outbreaks of QRNG were reported. In the 2005 GISP report, 19.3% of isolates from Hawaii were QRNG, whereas among California sites, 14.5% to 31.3% of isolates were QRNG.² In other geographic regions, strains exhibiting resistance to ciprofloxacin are as high as 63% in the Philippines and 48.8% in Hong Kong, with slightly lower rates reported in the rest of Asia.^{30,31} For this reason, quinolones have not been recommended for gonorrhea acquired in Hawaii, California, or Asia.³² However, more recently, *N. gonorrhoeae* resistance to quinolones has increased and has become widespread in the United States, resulting in the CDC recommending against using quinolones for the treatment of gonococcal or related conditions (e.g., PID) acquired in the United States. In 2006, 13.3% of all isolates collected by the GISP demonstrated resistance to ciprofloxacin.¹⁹ Resistance to fluoroquinolones is associated with mutations of GyrA and is commonly identified in strains that produce β -lactamase and strains exhibiting chromosomally mediated resistance to penicillin and tetracycline.³³ *N. gonorrhoeae* strains may therefore exhibit decreased susceptibility or complete resistance to the recommended dose of quinolones and the clinical importance of strains with decreased susceptibility is unknown.³⁴

D.S. was likely infected with *N. gonorrhoeae* in the Philippines; thus, an appropriate cephalosporin antibiotic (such as IM ceftriaxone or PO cefixime) should be recommended; QRNG is highly likely. If he had been initially treated with ceftriaxone, the expectation would be that he would be free of gonococcal infection within 3 days. To date, ceftriaxone-resistant strains of *N. gonorrhoeae* have not been reported.

Anorectal and Pharyngeal Gonorrhea

Epidemiology

10. M.B. is a 24-year-old, sexually active, homosexual male with a 2-month history of perianal itching, painful defecation, constipation, a bloody mucoid rectal discharge, and a sore throat. Sigmoidoscopy revealed rectal mucosal inflammation but no apparent ulcers or fissures. Stool examination for parasites was negative and a Venereal Disease Research Laboratory (VDRL) test was nonreactive. Both rectal and pharyngeal cultures revealed *N. gonorrhoeae*. How does gonorrhea in homosexual men compare with gonorrhea in heterosexual men?

The most prevalent bacterial STD among the homosexual male population is gonorrhea.³⁵ Rectal infection occurs rarely in strictly heterosexual men, whereas in the

male homosexual population, anorectal (25%) and pharyngeal (10%–25%) gonococcal infections occur more often.^{9,36} Because pharyngeal^{36,37} and anorectal gonococcal infections are often asymptomatic, a large reservoir of carriers in the homosexual male population may exist, diagnosed only with more sensitive DNA amplification techniques.³⁸ By comparison, very few urethral gonococcal infections are asymptomatic. In addition, recent data indicate that pharyngeal infections may be an important source of urethral gonorrhea in homosexual men, spread by fellatio.³⁶

Signs and Symptoms

11. Are M.B.'s signs and symptoms consistent with gonorrhea?

Rectal gonorrhea produces the syndrome of proctitis with anorectal pain, mucopurulent anorectal discharge, constipation, tenesmus, and anorectal bleeding. The differential diagnosis of proctitis in the homosexual male includes rectal infection with *N. gonorrhoeae*, *C. trachomatis*, HSV, and syphilis. Proctitis, limited to the distal rectum, should be differentiated from proctocolitis, which is often caused by *Shigella* species, *Campylobacter* species, or *Entamoeba histolytica* in homosexual men. The incidence of rectal gonorrhea and Chlamydia has dramatically risen since 1996.³⁹ Rectal Chlamydia is often asymptomatic and observed more often than gonorrhea, necessitating testing for both pathogens.⁴⁰

Treatment

12. How should M.B.'s diagnosis be managed?

The treatment of choice for patients such as M.B. with anorectal and/or pharyngeal gonorrhea is ceftriaxone 125 mg IM as a single dose (see Table 65-1). Azithromycin or doxycycline should be given to those with rectal gonorrhea to treat possible coexisting rectal chlamydial infection. Patients such as M.B. with either anorectal or pharyngeal gonorrhea should be advised to avoid further unprotected sexual activity and should be counseled and tested for infection with HIV.

13. What are alternative regimens for patients with isolated anal or pharyngeal gonorrhea?

Women with anorectal gonorrhea alone can be treated with either ceftriaxone or cefixime. Alternative regimens for isolated anorectal infection include a single-dose cephalosporin regimen such as with ceftizoxime. Because spectinomycin is unavailable, patients with anorectal gonorrhea who are allergic to penicillin or cephalosporins can be desensitized before treatment is initiated. Patients with gonococcal infections of the pharynx should be treated with ceftriaxone; however, infections of this nature are more difficult to eradicate than infections at anorectal sites. Chlamydial coinfection is uncommon in pharyngeal gonorrhea, but should be treated with either doxycycline or azithromycin.⁶

Prevention

14. What measures have been used to prevent the sexual transmission of infection?

Condoms, when used properly, seem to provide a high degree of protection against the acquisition and transmission of STDs.⁴¹ Previous studies indicated that the use of the spermicide nonoxynol-9 had activity against gonorrhea and Chlamydia, although more recent studies show no effect.^{42,43} In light

of recent evidence that suggests nonoxynol-9 might actually increase the chance of acquiring HIV, the CDC recommends that it should not be used for the prevention of any sexually transmitted infection.^{6,44} Thus, widespread use of this agent for the purpose of decreasing the risk of STDs cannot be recommended at this time. Topical antibacterial agents, urinating, and washing after intercourse are of little value in preventing the transmission of STDs. Douching may increase the risk of other STDs such as trichomoniasis.⁴⁵

The prophylactic administration of antibiotics immediately before or soon after sexual intercourse is not recommended owing to increased costs and antimicrobial resistance. Use of rapid, specific tests and empiric syndromic management should be used to enhance detection and treatment of gonorrhea.

PELVIC INFLAMMATORY DISEASE

The term *pelvic inflammatory disease (PID)* commonly refers to a variety of inflammatory disorders of the upper female reproductive tract. This term does not denote the primary infection site (the fallopian tubes) nor the causative microorganisms. PID also has been used to connote an infection that occurs acutely when either vaginal or cervical microorganisms traverse the sterile endometrium and ascend to the fallopian tubes. Acute salpingitis also may be used to describe an acute infection of the fallopian tubes. Therefore, the terms PID and salpingitis are used interchangeably in this discussion to denote an acute infection involving the fallopian tubes.

PID affects 1 million women annually in the United States.⁴⁶ However, since 1985, the rate of hospitalization owing to PID has decreased 68%.⁴⁷ Many cases of acute PID occur by sexual transmission, especially in young women 16 to 24 years who are more likely to have multiple sexual partners.⁴⁷ Not all PID is caused by Chlamydia or gonorrhea. Up to 70% of cases may be polymicrobial and include *M. genitalium* and BV.⁴⁸ Other risk markers and factors include unprotected sexual intercourse before age 15, douching, BV, sex while menstruating, and smoking.⁴⁹ It is unclear whether an intrauterine device (IUD) increases the risk of PID, but it may be prudent to avoid placement when the patient has chlamydial or gonococcal cervicitis.⁵⁰ Two-thirds of PID cases resulting in infertility are asymptomatic, and up to one-third are incorrectly diagnosed owing to low specificity of diagnostic techniques. In the United States, infertility occurs in about 12.1% of women after the first episode of PID.⁵¹ The estimated cost of direct medical expenditures for PID and its sequelae was estimated to be \$1.88 billion in 1998 with most of this cost associated with treatment of acute PID.⁵²

Etiology

Most cases of PID are caused by *C. trachomatis* and *N. gonorrhoeae*.⁶ Some microorganisms that comprise the vaginal flora are also associated with PID, including *Gardnerella vaginalis*, *H. influenzae*, and *Streptococcus agalactiae*.⁶ *Mycoplasma hominis*, *Ureaplasma urealyticum*, and *M. genitalium* have been associated with PID, but a causative role is unclear.⁵¹ Facultative enteric Gram-negative bacilli and a variety of anaerobic bacteria have also been isolated from the upper genital tract of up to 70% of women with acute PID.⁴⁸ Women diagnosed with acute PID should be tested for *C. trachomatis* and *N. gonorrhoeae* and screened for HIV.⁶

Signs and Symptoms

The onset of symptoms of abdominal pain attributable to PID caused by either gonococci or chlamydia often occurs soon after the menstrual period. Symptoms of PID, if present, are often nonspecific, which can create a delay in or failure of diagnosis. Vaginal discharge, menorrhagia, dysuria, and dyspareunia are commonly associated with PID. Signs include cervical motion tenderness, uterine tenderness, or adnexal tenderness. Temperatures above 101°F, abnormal cervical or vaginal mucopurulent discharge, white blood cells (WBC) on saline microscopy of vaginal secretions, elevated erythrocyte sedimentation rate, or an elevated C-reactive protein support a diagnosis of PID.⁶ Clinical diagnosis has sensitivity for PID of about 65% to 90%, whereas laparoscopy and a newer technique, transvaginal Doppler ultrasound, are about 100% specific, resulting in the combination of laparoscopy and clinical impression serving as the gold standard.^{6,53,54} Unfortunately, laparoscopy and Doppler ultrasound are costly and often not readily available for acute cases nor is it diagnostic for endometritis; thus, clinical impression is critical. A key to reducing the incidence of PID may be through active screening of *chlamydia* in young, sexually active women.^{55,56}

Clinical Sequelae

An abscess may form in the pelvic or abdominal cavity and in one or both fallopian tubes. Chronic abdominal pain develops in 18% of women with PID and may be the result of pelvic adhesions surrounding the tubes and ovaries. After a single episode of PID, tubal occlusion and fibrosis secondary to fallopian tube inflammation (salpingitis) result in 12% infertility, 25% infertility after two episodes, and 50% infertility after three or more episodes.⁵¹ Other sequelae include ectopic pregnancy (9%) and chronic pelvic pain (18%).⁵⁷ The risk of ectopic pregnancy is increased approximately eightfold after one or more episodes of PID.

Diagnosis and Treatment

15. H.C., a 19-year-old, sexually active woman, complains of mild dysuria, a purulent vaginal discharge, fever, and moderately severe, bilateral, lower abdominal pain of 3 days' duration. Examination confirms uterine and adnexal tenderness, a purulent cervical exudate, and a temperature of 39°C. Laboratory examinations show a nonreactive VDRL and negative urinalysis. A pregnancy test performed at this time was negative. The peripheral WBC count was mildly elevated (11,000/mm³) with 70% polymorphonuclear leukocytes. Does H.C. have PID? How should she be treated?

Although fever and leukocytosis are often absent in mild or subacute PID, these findings in a woman with uterine and adnexal tenderness with cervical exudate increases the likelihood of acute PID. Treatment should be initiated immediately after diagnosis of PID to prevent clinical sequelae; confirmation of the actual pathogen rarely takes place (Table 65-2). Patients such as H.C. with mild to moderate PID can be hospitalized and treated with parenteral antibiotics; however, clinical efficacy and overall outcomes are equal between parental and oral therapy, and H.C. could also be treated on an outpatient basis. For inpatient treatment, the 2006 CDC guidelines recommend

either intravenous (IV) cefotetan 2 g every 12 hours or IV ceftioxin 2 g every 6 hours for at least 24 hours beyond the first signs of clinical improvement. Once clinical improvement is noted, parenteral therapy may be discontinued and PO doxycycline 100 mg every 12 hours can continue to complete 14 days of therapy. For outpatient treatment, the CDC guidelines recommend either IM ceftriaxone 250 mg as a single dose or IM ceftioxin 2 g as single dose (with probenecid 1 g PO × 1) plus PO doxycycline 100 mg twice a day for 14 days with or without PO metronidazole 500 mg twice daily for 14 days. A tetracycline derivative or an alternative agent that is active against *C. trachomatis* should be included in the treatment of PID; however, monotherapy with a tetracycline is not recommended because of the lack of activity against Gram-negative aerobic and anaerobic organisms and *N. gonorrhoeae*. The addition of metronidazole, which covers anaerobic bacteria, should also be considered; anaerobes have been isolated from the upper reproductive tract of women with PID and may cause tubal and epithelial destruction.⁶ Metronidazole is widely used by clinicians, although its application is theoretical because the role of anaerobes in PID is not well understood. Quinolones (e.g., levofloxacin, ofloxacin) are no longer recommended for the treatment of PID because of the increase in prevalence of QRNG in the United States.¹⁹

Both oral and IV doxycycline have similar bioavailability; therefore, doxycycline should be given PO whenever possible because IV administration may be painful.⁶ Substantial clinical improvement is usually seen within 3 days after initiation of therapy. Clindamycin plus gentamicin can be used alternatively in penicillin-allergic and pregnant females.⁶ Because H.C. is sexually active, any sexual partners within the previous 60 days (or if >60 days, then the most recent sexual partner) should be empirically treated because of the risk of gonococcal or chlamydial urethritis as well as to reduce the risk of reinfection.⁶

COMPLICATED GONORRHEA

Disseminated Gonococcal Infection

Signs and Symptoms

16. S.P., a 28-year-old, sexually active woman, was seen for stiffness and pain of the right wrist and left ankle and fever (38°C). On physical examination, the knee and wrist joints were found to be hot, red, and swollen; papules and pustular lesions were observed on S.P.'s legs and forearms. A latex fixation test for rheumatoid factor was negative. A tap of the right knee yielded an effusion with a WBC count of 34,000/mm³ (80% polymorphonuclear leukocytes). Cultures of the skin lesions were negative, but *N. gonorrhoeae* was isolated from the throat, cervix, blood, and synovial fluid. A chest radiograph, echocardiogram, and electrocardiogram all were normal, and no murmur could be appreciated. Assess S.P.'s clinical presentation.

S.P.'s signs, symptoms, and laboratory findings are consistent with gonococcal bacteremia, which today occurs in less than 1% of women and men with gonorrhea. The most common manifestation of gonococcemia is the gonococcal arthritis–dermatitis syndrome or disseminated gonococcal infection (DGI) exhibited by S.P. Symptoms include fever, occasional chills, a mild tenosynovitis of the small joints,

Table 65-2 Antimicrobial Regimens Recommended by the CDC for Treatment of Acute Pelvic Inflammatory Disease

| <i>Treatment Setting, Drugs, Schedule</i> | <i>Advantage</i> | <i>Disadvantage</i> | <i>Clinical Considerations</i> |
|--|---|--|--|
| Inpatient | | | |
| Regimen A Cefotetan 2 g IV Q 12 hr or cefoxitin 2 g IV Q 6 hr plus doxycycline 100 mg IV or PO ^a Q 12 hr Continue doxycycline (100 mg PO BID) after discharge to complete 14 days of therapy | Optimal coverage of <i>N. gonorrhoeae</i> (including resistant strains) and <i>C. trachomatis</i> | Possible suboptimal anaerobic coverage | Penicillin-allergic patients also may be allergic to cephalosporins; doxycycline use in pregnant patients may cause reversible inhibition of skeletal growth in the fetus and discoloration of teeth in young children |
| Regimen B Clindamycin 900 mg IV Q 8 hr plus gentamicin loading dose IV or IM (2 mg/kg) followed by a maintenance dose of 1.5 mg/kg Q 8 hr ^b Continue clindamycin 450 mg PO QID or doxycycline 100 mg PO BID after discharge to complete 14 days of therapy | Optimal coverage of anaerobes and Gram-negative enteric rods | Possible suboptimal coverage of <i>N. gonorrhoeae</i> and <i>C. trachomatis</i> | Patients with decreased renal function may not be good candidates for aminoglycoside treatment or may need a dosage adjustment |
| Alternative regimen Ampicillins/sulbactam 3 g IV Q 6 hr plus doxycycline 100 mg PO or IV Q 12 hr | Optimal coverage of <i>N. gonorrhoeae</i> and <i>C. trachomatis</i> | Inadequate coverage of anaerobes necessitates use of metronidazole or ampicillin/sulbactam | Not appropriate in pregnancy or in young children |
| Outpatient | | | |
| Regimen A Ceftriaxone 250 mg IM in a single dose plus doxycycline 100 mg PO BID for 14 days with or without metronidazole 500 mg PO BID for 14 days or cefoxitin 2 g IM in a single dose and probenecid, 1 g PO administered concurrently in a single dose plus doxycycline 100 mg PO BID for 14 days with or without metronidazole 500 mg PO BID for 14 days or other parenteral third-generation cephalosporins (e.g., ceftizoxime or cefotaxime) plus doxycycline 100 mg PO BID for 14 days with or without metronidazole 500 mg PO BID for 14 days | Good to excellent coverage of <i>N. gonorrhoeae</i> and optimal coverage of <i>C. trachomatis</i> | Possible suboptimal anaerobic coverage necessitating the addition of metronidazole | Optimal cephalosporin is unclear; more complicated regimen requiring combination of parenteral and oral therapies |
| ^a Because of the pain involved with doxycycline infusions and the comparable PO/IV bioavailability, IV therapy should be replaced with PO as soon as possible. ^b Single daily dosing may be substituted. Adapted from reference 6. | | | |

and skin lesions; the latter primarily involving the distal extremities are petechial, papular, pustular, and hemorrhagic in appearance.⁵⁸

Diagnosis of DGI is made by Gram stain and culture. However, blood cultures are positive in only 33% of DGI cases, even when patients are cultured early in the course of the infection.⁵⁹ The low positive yield from blood cultures may be due to the low inoculum and/or intermittent bacteremic period. Routine culture of the urethra, cervix, pharynx, and rectum should be performed in any patient suspected of having DGI.

Treatment

17. How should S.P. be managed? How quickly will she respond to therapy?

Patients like S.P. with gonococcal arthritis and bacteremia should be hospitalized for treatment with ceftriaxone 1 g IV daily until clinical improvement, such as decreased fever and

pain, is sustained for 24 to 48 hours, at which time therapy may be switched to an appropriate oral agent. Unfortunately, owing to the increased incidence of QRNG in the United States, only oral cefixime 400 mg daily for 7 days is currently recommended (Table 65-3).^{6,19} Symptoms and signs of tenosynovitis should be improved markedly within 48 hours. Septic gonococcal arthritis with purulent synovial fluid may require repeated aspiration and resolves more slowly.

Treatment of Gonococcal Endocarditis and Meningitis

18. How should gonococcal endocarditis and meningitis be treated?

Gonococcal endocarditis and meningitis, occurring in only 1% to 3% of DGIs, require high-dose IV therapy such as ceftriaxone (1–2 g IV every 12 hours) for 10 days or more in the case of meningitis and for 4 weeks in the case of endocarditis.^{6,9}

Table 65-3 Treatment of Disseminated Gonococcal Infection^a**No Penicillin Allergy****Parenteral**

Ceftriaxone 1 g IV or IM Q 24 hr or cefotaxime 1 g IV Q 8 hr or ceftizoxime 1 g IV Q 8 hr and doxycycline 100 mg PO BID^b or erythromycin base 500 mg PO QID^b (if pregnant)

Oral

Cefixime 400 mg PO BID

Penicillin Allergy**Parenteral**

Spectinomycin 2 g IM Q 12 hr and doxycycline 100 mg PO BID^b or erythromycin base 500 mg PO QID^b (if pregnant)

^aDuration of treatment is 7 days.

^bFor possible concomitant chlamydial infection, treat for 7 days.

Adapted from reference 6.

Neonatal Disseminated Gonococcal Infection: Treatment**19. How should neonatal DGI and meningitis be managed?**

Neonatal DGI and meningitis can be treated with either ceftriaxone or cefotaxime for 7 days; however, if meningitis is documented, 10 to 14 days of treatment is required. Ceftriaxone is given at 25 to 50 mg/kg (IV or IM) Q 24 hr and cefotaxime is given at 25 mg/kg (IV or IM) Q 12 hr.

CHLAMYDIA TRACHOMATIS

C. trachomatis was first isolated from patients with lymphogranuloma venereum (LGV). However, laboratory diagnoses for this pathogen were not developed until the 1960s and 1970s.⁶⁰ From 1986 to 2005, the rate of reported Chlamydia infections in the United States rose from 35.2 to 332.5 cases per 100,000 individuals and was largely attributable to the increased development and use of more sensitive screening tests and improved national reporting efforts. Women are three times more likely than men to be infected with Chlamydia—496.5 cases versus 161.1 cases per 100,000 individuals, respectively, in 2005; however, from 2001 to 2005, the infection rate among men increased by 43.5% compared with 15.6% in

women over.⁶¹ In U.S. family planning clinics, the chlamydial test positivity, a proxy for prevalence, is 6.3% in 15- to 24-year-old women and probably much lower for men, although men are less frequently screened.⁶² If left untreated, chlamydial infection in women can lead to serious sequelae such as PID, ectopic pregnancy, and infertility. Asymptomatic infection is also observed in both men and women; however, routine screening is only recommended for sexually active women at least 25 years old and women with risk factors for infection (e.g., multiple sexual partners, new sexual partners). Screening sexually active men for *C. trachomatis* can be considered in settings with a high prevalence of the infection.⁶

C. trachomatis, an intracellular obligate organism, can be diagnosed either by culture, direct immunofluorescence assay (DFA), enzyme immunoassay (EIA), or NAATs of endocervical or male urethral swabs.⁶ However, *C. trachomatis* is a difficult organism to demonstrate in clinical specimens because cell culture techniques are not readily available to the practitioner. Because few practitioners have access to facilities for isolation of *C. trachomatis*, most chlamydial infections are diagnosed and treated based on clinical impression and laboratory techniques. Diagnostic tests, such as NAATs, DFA, and EIA, are generally sensitive methods for detecting *C. trachomatis*. Ligase chain reaction and PCR are two NAATs with wide commercial availability, are relatively simple to use, and are more sensitive than non-NAATs.¹⁶ A test of cure is not necessary unless patient compliance is questionable, symptoms persist, or reinfection is suspected. Repeat testing fewer than 3 weeks after initiation of treatment is not recommended because false-negative results may occur as a result of undetectable *C. trachomatis* organisms. Moreover, false positives may occur with repeat NAATs as the result of the continued excretion of dead organisms.⁶

The variety of clinical syndromes that are now known to be caused by *C. trachomatis* are cervicitis, urethritis, Bartholinitis, endometritis, salpingitis, and perihepatitis in women, and urethritis, epididymitis, prostatitis, proctitis, and Reiter syndrome in men.⁶³ It is interesting to note that the spectrum of chlamydial infections closely resembles those caused by the gonococcus, which is why many patients presenting with these syndromes are treated with drugs effective against both organisms (Table 65-4).

Table 65-4 Clinical Parallels Between Genital Infections Caused by *N. gonorrhoeae* and *C. trachomatis*: Resulting Clinical Syndromes

| Gender | Site of Infection | <i>N. gonorrhoeae</i> | <i>C. trachomatis</i> |
|---------------|-------------------|-------------------------|--|
| Male | Urethra | Urethritis | NGU, postgonococcal urethritis |
| | Epididymis | Epididymitis | Epididymitis |
| | Rectum | Proctitis | Proctitis |
| | Conjunctiva | Conjunctivitis | Conjunctivitis |
| | Systemic | DGI | Reiter syndrome |
| Female | Urethra | Acute urethral syndrome | Acute urethral syndrome |
| | Bartholin gland | Bartholinitis | Bartholinitis |
| | Cervix | Cervicitis | Cervicitis |
| | Fallopian tube | Salpingitis | Salpingitis |
| | Conjunctiva | Conjunctivitis | Conjunctivitis |
| | Systemic | DGI | Arthritis-dermatitis (Reiter syndrome) |

Adapted from Schachter J. Chlamydial infections. *N Engl J Med* 1978;298:428, 490, 540. Copyright 2008 Massachusetts Medical Society.

There is controversy in how *C. trachomatis* is cultured and what the in vitro results mean clinically, especially in the 10% to 15% of cases that fail treatment.⁶⁴ The CDC thus uses cure rates instead of microbial susceptibilities to make treatment recommendations. Only azithromycin and doxycycline have 97% and 98%, respectively, cure rates.⁶⁵ Agents mentioned as alternatives include erythromycin, ofloxacin, and levofloxacin, but not the penicillins, cephalosporins, aminoglycosides, clarithromycin, ciprofloxacin, or metronidazole.^{6,66,67}

Nongonococcal Urethritis

Etiology

20. T.K., a 26-year-old, sexually active man, complains of mild dysuria and a mucoidlike urethral discharge that started about 15 days after his last intercourse. He had no fever, lymphadenopathy, penile lesions, or hematuria. A Gram stain smear of an anterior urethral specimen showed 20 polymorphonuclear neutrophilic leukocytes (PMNs) per oil immersion (1,000) field and no Gram-negative diplococci. What pathogens are associated with nongonococcal urethritis (NGU)?

In the United States, NGU is the most common STD in men.^{63,68} Depending on the study design and diagnostic technique, causative organisms identified include *C. trachomatis* in 35% to 50%,⁶³ *U. urealyticum* in 9% to 42%,⁶⁹ *M. genitalium* in 15% to 25%,⁷⁰ *T. vaginalis* in 5% to 15%,⁷¹ and no identifiable cause in up to 20%.⁶⁹ The variety of pathogens and disparity among identification techniques require sound clinical judgment and an algorithmic laboratory testing approach to accurately identify and treat the cause. A NAAT, if available, should be performed to rule out the presence of *C. trachomatis*.

Signs and Symptoms

21. Describe the clinical presentation of a person with NGU. Is T.K.'s presentation consistent with NGU? How does one differentiate between NGU and gonococcal urethritis?

T.K.'s presentation is typical. Compared with gonococcal urethritis, NGU typically produces less severe and less frequent dysuria and less penile discharge. Chlamydial urethral infection is completely asymptomatic more often than gonococcal urethral infection. The incubation period for gonococcal urethritis is 2 to 7 days, whereas the incubation period for NGU is typically 2 to 3 weeks.

Nonetheless, NGU and gonococcal urethritis cannot be reliably differentiated solely on the basis of symptoms and signs. If there is objective evidence of a urethral discharge (expressed by milking the urethra), a Gram stain with fewer than 5 WBCs per oil immersion field in the urethral secretion, positive leukocyte esterase test demonstrating 10 WBCs per high-power field, the diagnosis of NGU is made by excluding the presence of *N. gonorrhoeae* by Gram stain and/or culture.

Treatment

22. How should T.K. be treated?

If *C. trachomatis* cannot be ruled out, therapy with azithromycin should be initiated to cover for both *M. genitalium* and Chlamydia.⁶ Doxycycline does not effectively eradicate *M. genitalium*.⁷² For NGU, doxycycline 100 mg PO BID for 7 days may also be prescribed. Both azithromycin and doxy-

cycline are considered equally effective against NGU.^{6,73–75} Doxycycline is less expensive and has been used more extensively than azithromycin. Erythromycin base 500 mg PO QID or erythromycin ethylsuccinate 800 mg PO QID for 7 days are alternative CDC-approved regimens. Additionally, ofloxacin 300 mg PO BID or levofloxacin 500 mg PO QD for 7 days are other alternatives, but they offer no significant advantages over the previously mentioned agents, may not treat *U. urealyticum* adequately, and are significantly more expensive.⁷⁶ Ciprofloxacin should be avoided because treatment failures have been reported.⁷⁷ Patient counseling should emphasize the need for abstinence from sexual intercourse at least until the prescribed course of therapy has been completed (or 7 days after single-dose therapy) by the patient and their sexual partner(s).⁶³ There is some indication that the proportion of NGU caused by *C. trachomatis* is declining, potentially being replaced by an increased proportion of *U. urealyticum*, which is variably cured at 2 weeks by azithromycin (73%) and doxycycline (65%).⁷³

RECURRENT INFECTION

23. T.K. was treated with doxycycline 100 mg BID for 7 days. He remained asymptomatic for 14 days after completion of his therapy, when he again noticed similar symptoms of dysuria and a mucoidlike urethral discharge. How should T.K.'s recurrent infection be treated?

The major problem encountered in the treatment of NGU is the high rate of recurrent infections. Approximately 20% to 60% of patients experience recurrent or persistent urethritis within 1 to 2 weeks after treatment.⁷⁰ The rate of recurrence is highest in patients with idiopathic urethritis, that is, those not infected with *C. trachomatis* or *U. urealyticum*. Recurrence suggests re-exposure to an untreated partner, whereas persistent urethritis (without improvement during therapy) suggests the presence of other organisms including *M. genitalium*, *U. urealyticum*, or *T. vaginalis*.⁶⁹ NGU that persists or recurs should be retreated with the initial regimen if the patient was not compliant or the sexual partner was not treated.⁶ For patients with persistent symptoms who were compliant with the initial regimen and were not re-exposed, the CDC recommends using either metronidazole or tinidazole 2 g PO as a single dose plus a single 1 g dose of azithromycin if not used for the initial episode.⁶

Men with acute epididymitis often have chlamydial or gonococcal infection, particularly if they are younger than 35 years of age or have a urethral discharge. Older men with epididymitis more often are infected with *Escherichia coli* or other urinary pathogens. If testicular tenderness is present with urethritis, and the clinical impression is consistent with epididymitis caused by chlamydia or gonorrhea, some experts recommend a single dose of ceftriaxone 250 mg IM plus doxycycline 100 mg PO twice for 10 days. For a nonsexually transmitted etiology of epididymitis, ofloxacin 300 mg PO BID or levofloxacin 500 mg PO once daily for 10 days may be used.⁶

Sexual Partners

24. A.C., T.K.'s girlfriend, comes into the clinic 3 weeks after T.K.'s last visit. She is worried that she may have a similar infection, although she has no signs or symptoms. What clinical

manifestations of chlamydial infections are seen in women? Should A.C. be treated for suspected chlamydial infection?

In the absence of cultures for Chlamydia, empirical treatment of women who are sexual partners of men with NGU is recommended. Routine partner referral for presumptive therapy is not indicated for nonchlamydial NGU.⁶⁹ Many partners are asymptomatic, but from 30% to 70% are culture positive if tested. A.C. should be examined carefully for mucopurulent cervicitis and salpingitis. Although many women with chlamydial infection of the cervix are asymptomatic, up to one-quarter have evidence of mucopurulent discharge.⁷⁸ A Gram stain of appropriately collected mucopurulent endocervical discharge from these patients shows many PMNs and an absence of gonococci.

Regardless of findings, treatment should be initiated with the same doxycycline regimen used for NGU. However, if A.C. is pregnant, tetracyclines and fluoroquinolones should be avoided. Azithromycin 1 g PO as a single dose or amoxicillin 500 mg PO TID for 7 days could be used instead. Alternatively, either erythromycin base 500 mg QID for 7 days, erythromycin base 250 mg PO for 14 days, erythromycin ethylsuccinate 800 mg PO QID for 7 days, or erythromycin ethylsuccinate 400 mg PO for 14 days can be used.⁶ Erythromycin estolate should be avoided in pregnancy because of the increased risk of hepatotoxicity. Azithromycin seems to be safe and effective during pregnancy.^{79,80} High rates of GI complaints limit the use of erythromycin. In pregnant women, a repeat NAAT is recommended 3 weeks after completion of therapy to ensure therapeutic cure.⁶ Coinfection with Chlamydia is common in heterosexual men and women with gonorrhea. Therefore, drug regimens effective against both organisms are recommended in patients with gonorrhea to prevent postgonococcal chlamydial morbidity (epididymitis, mucopurulent cervicitis, salpingitis) and to reduce the genital reservoir of *C. trachomatis*.

Lymphogranuloma Venereum

Etiology and Signs and Symptoms

25. S.F., a 32-year-old male student who recently arrived from Uganda, presents to the STD clinic with a chief complaint of pain and swelling in the groin. He reports the appearance of a small ulcer on his penis about 2 weeks ago, which resolved rapidly. Upon examination, he has a bubo (inflammatory swelling of one or more lymph nodes in the groin) with surrounding erythema on his right side. S.F. also has a fever (39°C). Laboratory findings are remarkable for a mild leukocytosis (WBC count, 12,000 cells/mm³). What organisms are responsible for LGV? Describe its clinical course. What subjective and objective manifestations in S.F. are consistent with LGV?

Lymphogranuloma venereum is rare in the United States, occurring mainly in Africa, India, Southeastern Asia, South America, and the Caribbean, but it may be on the rise in Europe and North America.^{81,82} The cause of LGV is usually *C. trachomatis* serovars L1, L2, or L3, which is different from those serovars responsible for chlamydia urethritis. Three stages of LGV infection are recognized in heterosexual men.⁸³ During stage I, a small genital papule or vesicle appears between 3 and 30 days after exposure. The patient usually is asymptomatic; the ulcer heals rapidly and leaves no scar. This primary lesion is

consistent with the penile ulcer reported by S.F. Many patients with LGV recall no primary lesion.

Stage II is characterized by acute, painful lymphadenitis with bubo formation (the inguinal syndrome); it often is accompanied by pain and fever, as illustrated by S.F. Without treatment, the buboes may rupture, forming numerous sinus tracts that drain chronically. Adenopathy above and below the inguinal ligament results in the “groove sign.” Healing occurs slowly, and most patients suffer no serious sequelae. Patients in this stage also may present with an anogenitoretal syndrome, which is accompanied by proctocolitis and hyperplasia of intestinal and perirectal lymphatic tissue. Late or tertiary manifestations include perirectal abscesses, rectovaginal fistulae (in women), rectal strictures, and genital elephantiasis.⁸³ Appropriate treatment of stage II LGV usually prevents these late complications.

An acute anorectal syndrome of LGV occurs in homosexual men who acquire the infection through rectal receptive intercourse. In these cases, a primary anal ulcer may be noted with associated inguinal adenopathy (anal lymphatics drain to inguinal nodes). Subsequently, acute hemorrhagic proctocolitis occurs with tenesmus, rectal pain, constipation, and a mucopurulent, bloody rectal discharge. Rectal biopsy may show granulomatous colitis, mimicking Crohn disease. Perirectal pelvic adenopathy also occurs.

Treatment

26. How should S.F. be treated?

Current CDC recommendations for LGV include doxycycline 100 mg PO BID or erythromycin base 500 mg PO QID for 21 days.⁶ Surgical intervention may be needed for later forms of the disease. Azithromycin 1 g weekly for 3 weeks may be effective, but clinical data on its use are lacking.⁶

SYPHILIS

Epidemiology

Syphilis is caused by the spirochete, *Treponema pallidum*. The rates of primary and secondary syphilis in the United States are thought to have increased in the late 1980s secondary to crack cocaine use (and associated unsafe sex practices), but from 1990 to 2000, rates have decreased to those reported in 1941 (when reporting began), representing a >86% decrease since 1990.^{84,85} However, the number of cases have steadily risen since 2000, reaching a high of 8,724 cases in 2005, primarily in men who have sex with men.⁸⁶ Another concern is that syphilis facilitates the transmission of HIV, and recent outbreaks of syphilis have been associated with HIV-positive men who have sex with men.^{86,87} From 1996 to 2005, rates of congenital syphilis decreased on average by 14.1% per year (Fig. 65-5). From 2004 to 2005, the overall rate of congenital syphilis decreased by 12.1% from 9.1 to 8 cases per 100,000 births.⁸⁶ The *Healthy People 2010* (HP) goal (0.2 cases per 100,000 people) is significantly lower than the *HP 2000* goal (4 cases per 100,000). Although we have met the *HP 2000* goal, we still have far to go to surpass the *HP 2010* goal (Fig. 65-6).

The clinical manifestations of syphilis have not changed appreciably since their first description. However, early diagnosis,

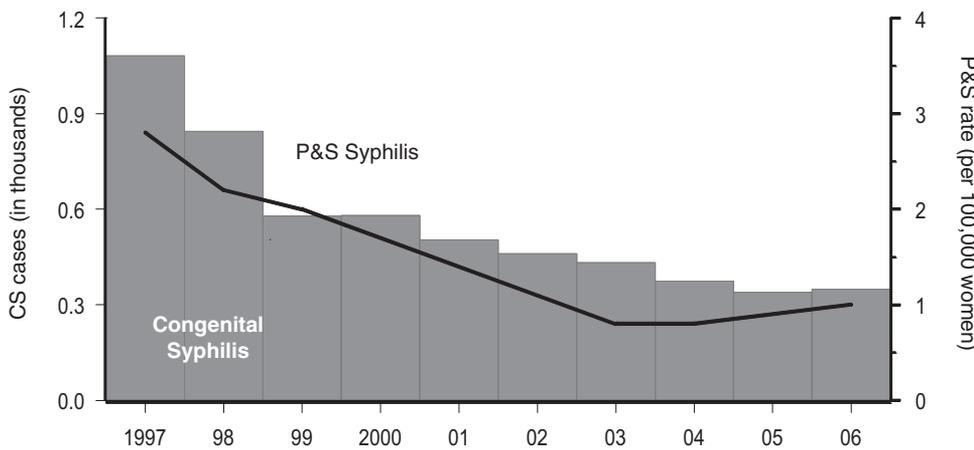

FIGURE 65-5 Congenital syphilis (CS). Reported cases for infants younger than 1 year of age and rates of primary and secondary syphilis among women, 1997 to 2006. (From reference 86.)

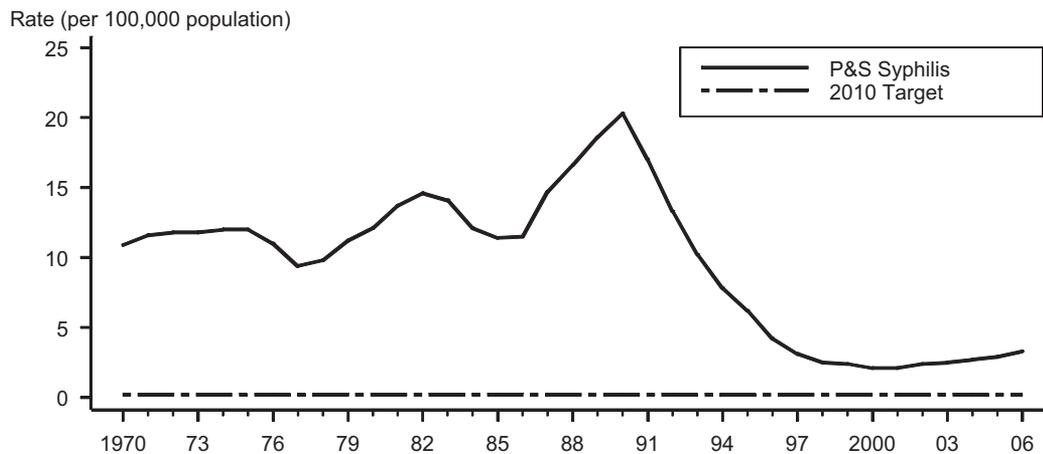

treatment, and greater physician/patient awareness of the disease have reduced the incidence of its severe forms. Penicillin continues to be the mainstay of therapy. Vaccine development, although premature, hopefully will advance as more is learned about the biology of *T. pallidum*.

Clinical Stages

27. D.M., a 27-year-old homosexual man, presents to the STD clinic with complaints of malaise, headache, and fever of 4 days' duration. He also reveals that he had a sore on his penis about 8 weeks ago, but it has since resolved. Upon examination, he is afebrile and has a widespread maculopapular skin rash that also involves the soles of his feet; general lymphadenopathy also is appreciated. Medical history is unremarkable except for one episode of gonorrhea 2 years ago that was treated with procaine penicillin. Laboratory findings include a normal peripheral WBC count, a negative serology for HIV antigen, and a positive rapid plasma reagin (RPR) test and fluorescent treponemal antibody absorption (FTA-Abs) test. Describe the clinical course of syphilis. Are D.M.'s symptoms consistent with this infection?

Primary Stage

The average incubation period for syphilis is 3 weeks and ranges from 10 to 90 days.⁸⁸ During this incubation period, *T. pallidum* can be demonstrated in the lymph and blood. The primary chancre develops at the site of inoculation as a painless papule that becomes ulcerated and indurated. The ulcer is nontender and filled with spirochetes. The chancre usually involves the penis in the heterosexual male; the penis or anus in the homosexual male; and the vulva, perineum, or cervix in the female. Occasionally, the lip or tongue is involved. Regional lymph nodes are enlarged, firm, and nontender. Unfortunately, the typical chancre described earlier often is missed, particularly in women or homosexual men.⁸⁹ Without treatment, the primary chancre resolves spontaneously, usually in 2 to 6 weeks. The differential diagnosis of genital ulcers also includes chancroid and genital herpes. Like chancroid, genital herpes produces painful, superficial, nonindurated ulcers with tender inguinal adenopathy. However, unlike chancroid, lesions of genital herpes characteristically proceed through a vesicular state and often are associated with urethritis, cervicitis, and constitutional symptoms, such as fever and chills.

Note: The Healthy People 2010 (HP2010) target for primary and secondary syphilis is 0.2 cases per 100,000 population.

FIGURE 65-6 Primary and secondary syphilis, reported rates, 1970 to 2006 and the Healthy People 2010 objective (0.2 CASES PER 100,000). (From reference 86.)

Syphilis can be differentiated from herpes by a nonpainful versus painful lesion, a papular versus vesicular appearance, and single versus multiple lesions. Chancroid is more difficult to differentiate from syphilis, although chancroid tends to have a more tender lesion, jagged border, and striking inguinal lymphadenopathy.⁹⁰

Secondary Stage

Approximately 6 weeks after a chancre first appears, the untreated patient begins to manifest signs and symptoms of the secondary stage of syphilis. This stage is currently illustrated by D.M. Skin lesions of secondary syphilis may erupt in a variety of patterns and are usually widespread in distribution. A macular lesion often is the earliest manifestation in this stage. The lesion is round or oval, occurs primarily on the trunk, and is rose or pink in color. As lesions mature, they become papular or nodular with scaling (the so-called papulosquamous rash). The differential diagnosis of diffuse papulosquamous rashes includes psoriasis, pityriasis rosea, and lichen planus. In syphilis, the palms and soles are characteristically involved, and oral lesions (mucous patches) may occur. Generalized lymphadenopathy usually is present, and patching alopecia may be seen. The most infectious lesion of secondary syphilis is condyloma latum. Condylomata lata are characteristically wet, indurated lesions occurring primarily in the perineum or around the anus as a result of direct spread from the primary lesion. Laboratory studies sometimes reveal anemia, leukocytosis, or an increased erythrocyte sedimentation rate. Other manifestations of secondary syphilis include mild hepatitis, aseptic meningitis, uveitis, neuropathies, and glomerulonephritis.⁹¹

Latent Stage

By definition, untreated, asymptomatic persons with serologic evidence for syphilis have latent syphilis. The latent stage is divided into two phases: the early latent (<1 year's duration) and late latent (>1 year's duration). In the Oslo study of patients with untreated syphilis, 25% experienced secondary relapses, usually within the first year.⁹² Patients who relapse to the secondary stage are infectious; those in the late latent stage are not infectious and are immune to reinfection with *T. pallidum*.

Tertiary Stage

Morbidity and mortality of syphilis in adults are due primarily to a variety of late manifestations involving the skin, bones, central nervous system, and cardiovascular system. Infectious granulomas (gummas), the characteristic lesions of tertiary syphilis, now are observed infrequently. Most gummas respond quickly to specific therapy, although if critical organs are involved (heart, brain, liver), they can be fatal.⁹³ The most common manifestations of syphilitic cardiovascular disease are aortic insufficiency and aortitis, with aneurysm of the ascending aorta.

Neurosyphilis may be classified as asymptomatic early or late, meningeal, parenchymatous, or gummatous. Although neurosyphilis has been a rare complication for more than 40 years because of the widespread use of penicillin, syphilitic meningitis, an early form of neurosyphilis, may be increasing among HIV-positive patients.^{94,95} Late neurosyphilis may be asymptomatic or accompanied by a variety of manifestations; the most common syndromes are meningovascular syphilis, general paresis, tabes dorsalis (locomotor ataxia), and

optic atrophy. In patients with asymptomatic neurosyphilis, examination of the cerebrospinal fluid (CSF) typically reveals mononuclear pleocytosis, an elevated protein concentration, and a positive VDRL reaction.

Patients with asymptomatic neurosyphilis are at increased risk for developing clinical neurologic disease. Meningovascular syphilis, now accounting for almost 38% of all cases of neurosyphilis, typically begins abruptly with hemiparesis or hemiplegia, aphasia, or seizures.⁹⁶ General paresis is characterized by extensive parenchymal damage and includes abnormalities associated with the mnemonic PARESIS (personality, affect, reflexes [hyperactive], eye [Argyll Robertson pupil], sensorium [hallucination, delusions, illusions], intellect [decreased recent memory, calculations, judgment], and speech). Tabes dorsalis occurs after demyelination of the spinal cord. Symptoms observed include an ataxic, wide-based gait and foot slap; paresthesias; bladder irregularities; impotence; areflexia; and loss of position, deep pain, and temperature sensation. The Argyll Robertson pupil, seen in both paresis and tabes dorsalis, is a small, irregular pupil that reacts to accommodation but not to light.

Laboratory Tests

28. Evaluate D.M.'s laboratory findings.

Dark-Field Examination

Exudate expressed from the chancre or from condyloma latum is examined with a dark-field microscope. The diagnosis of syphilis is made if spirochetes with characteristic corkscrew morphology and mobility are present. Dark-field examination is the most specific and sensitive method, but only when the microscopist is experienced in the diagnosis of syphilis.⁹⁷ Three dark-field examinations on consecutive days should be performed before considering the test negative in suspected primary syphilis.

Serologic Tests

Serologic tests become reactive during the primary stage, but as shown in Table 65-5, they may be negative at the time of presentation with primary syphilis. When the history or examination suggests primary syphilis, a VDRL should be sent to the laboratory, or an RPR test should be performed in the clinic (see discussion on nontreponemal tests, following). If initial serology and dark-field examinations are negative, the serology should be repeated in 1 to 4 weeks to exclude primary syphilis. If the dark-field examination is positive, an RPR

Table 65-5 False-Negative Results With VDRL and FTA-Abs Tests

| Stage of Syphilis | Percentage | |
|-------------------|------------|---------|
| | VDRL | FTA-Abs |
| Primary | 24 | 14 |
| Secondary | <0.1 | <0.1 |
| Early latent | 5 | 1 |
| Late latent | 28 | 5 |

FTA-Abs, fluorescent treponemal antibody absorption; VDRL, Venereal Disease Research Laboratory.

may still be ordered to establish a baseline for follow-up after treatment.

Serologic tests are essentially always positive during secondary syphilis.⁹⁰ Two types of tests are used for the serodiagnosis of syphilis: nontreponemal tests, which measure serum concentrations of reagin (antibody to cardiolipin), and treponemal tests, which detect the presence of antibodies specific for *T. pallidum*.

NONTREPONEMAL TESTS

Nontreponemal tests are not specific for *T. pallidum*, but can be quantified. They are inexpensive and useful for screening large numbers of people. The most widely used nontreponemal tests are the VDRL test and the RPR Card Test. The RPR test is the most widely used because it is simpler to perform than the VDRL. Results of the VDRL and RPR are not interchangeable; thus, the same test should be used throughout the post-treatment monitoring period.⁹⁸

The result reported in the quantitative VDRL test is the most dilute serum concentration with a positive reaction. This test may be used to follow the decline in VDRL titer after effective therapy (see Question 31). In some individuals, a serofast reaction occurs in which nontreponemal antibodies may remain at a low titer for a long time and even their entire lives. When false-positive tests occur (Table 65-6), the titer usually is low (e.g., VDRL or RPR titer = 1:8).⁹⁹ In secondary syphilis, sensitivity of the RPR and VDRL approach 100% owing to the high antibody concentrations.¹⁰⁰

TREPONEMAL TESTS

Specific treponemal tests are most useful to confirm a positive nontreponemal test. The FTA-Abs test is the most commonly used treponemal test. Because the FTA-Abs test requires fluorescence microscopy, it is relatively difficult and expensive to perform and not appropriate for screening.

The *T. pallidum* immobilization (TPI) test, the microhemagglutination (MHA-TP) test, and the hemagglutination test for syphilis (HATTS) are three other treponemal tests. The TPI test is used rarely because of its cost and complexity. The MHA-TP and HATTS tests are both easier to perform and less expensive than the FTA-Abs test, but they are less sensitive in primary syphilis. Treponemal tests should not be used to assess treat-

ment response because antibody titers correlate poorly with disease progression. A newer test is the *T. pallidum* latex agglutination test, which, in one study, was 100% sensitive and specific for nearly all stages of syphilis and took only 10 minutes to complete.^{98,101} This test, however, is not in widespread use.

Treatment

29. How should D.M. be treated?

Penicillin G is the drug of choice for the treatment for all stages of syphilis (Table 65-7).⁶ Every effort should be made to rule out penicillin allergy before choosing other antimicrobials that have been studied much less extensively than penicillin in the treatment of syphilis. Considering that penicillin-resistant *T. pallidum* has never been observed, treatment regimens for syphilis have changed relatively little over the years.

As shown in Table 65-7, recommended therapy for primary, secondary, or latent syphilis (with negative findings in the CSF) of <1 year's duration is a single, IM 2.4 MU dose of benzathine penicillin G. If penicillin is contraindicated, tetracycline (500 mg PO QID) or doxycycline (100 mg PO BID) for 2 weeks are the main alternatives.⁶ If the patient is allergic to penicillin, not pregnant, and is contraindicated or cannot tolerate tetracycline or doxycycline, a 14-day regimen of azithromycin (500 mg PO QD) or ceftriaxone (500 mg IM QD) may be used (Table 65-7).¹⁰² The CDC lists an alternative regimen of azithromycin 2 g in one dose or ceftriaxone 1 g IM or IV for 8 to 10 days.⁶ The use of erythromycin as an alternative is no longer recommended by the CDC because of its poor efficacy. The optimal dose, duration, and efficacy of these alternative regimens are not well-defined, necessitating close follow-up of patients. Skin testing should be performed for individuals who claim allergy to penicillin. If the patient is truly allergic, he or she should be desensitized with oral penicillin in incrementally greater doses over a 4-hour period, after which a full course of penicillin may be given.⁶ Latent syphilis (>1 year's duration) and cardiovascular syphilis are treated with IM benzathine penicillin G weekly (2.4 MU) for a total of 3 weeks. The alternative regimen is doxycycline (100 mg PO BID) or tetracycline (500 mg PO QID) for 28 days with close serologic and clinical follow-up. CSF examination is recommended if alternatives to penicillin are being considered.

Neurosyphilis

30. Would D.M.'s treatment differ if his CSF had tested positive for syphilis?

Neurosyphilis can present at any stage of syphilis. When conventional IM doses of benzathine penicillin G are administered, measurable levels of penicillin are not obtainable in the CSF. However, this does not mean that penicillin does not concentrate in meningeal tissue.¹⁰² Treatment failures, as well as late clinical progression to neurosyphilis, can occur after treatment with the recommended IM regimen. After one dose, benzathine penicillin reaches peak plasma concentration slower (13–24 hours) but with more prolonged treponemal plasma concentrations (7–10 days) than procaine penicillin (1–4 hours to peak; 12- to 24-hour treponemal plasma concentrations).¹⁰² Because of reports of benzathine penicillin

Table 65-7 Treatment Guidelines for Syphilis

| Stage | Recommended Regimen | Alternative Regimen |
|--|--|--|
| Early (primary, secondary, or early latent) ^a | Benzathine penicillin G 2.4 MU single dose IM | Doxycycline 100 mg PO BID for 14 days <i>or</i> Tetracycline 500 mg PO QID for 14 days <i>or</i> Ceftriaxone 1 g IM/IV QD for 8 to 10 days <i>or</i> Azithromycin 2 g PO × 1 dose |
| Late latent or latent syphilis of unknown duration | Lumbar puncture If CSF normal: Benzathine penicillin G 2.4 MU/wk × 3 wk IM | Lumbar puncture If CSF normal: Doxycycline 100 mg PO BID for 28 days <i>or</i> Tetracycline 500 mg PO QID for 28 days |
| Neurosyphilis ^b (asymptomatic or symptomatic) | If CSF abnormal: Treat as neurosyphilis Aqueous penicillin G 18–24 MU IV QD × 10–14 days ^c | If CSF abnormal: Treat as neurosyphilis Procaine penicillin 2.4 MU IM QD plus probenecid 500 mg PO QID, both for 10–14 days |
| Congenital | Aqueous penicillin G 100,000–150,000 U/kg/d, administered as 50,000 U/kg/dose IV Q 12 hr during the first 7 days of life, and Q 8 hr thereafter for a total of 10 days ^d <i>or</i> Procaine penicillin G 50,000 U/kg/dose IM a day in a single dose for 10 days | If CSF normal: benzathine penicillin G 50,000 U/kg/dose IM in a single dose |
| Syphilis in pregnancy | According to stage | According to stage |

^aSome experts recommend repeating this regimen after 7 days for HIV-infected patients.

^bBecause of the shorter duration of therapy as compared with latent syphilis, some experts recommend giving benzathine penicillin G, 2.4 MU/wk for up to 3 weeks, after the completion of these neurosyphilis regimens to provide a comparable total duration of therapy.

^cAdministered as 3–4 MU IV every 4 hours or continuous infusion.

^dAll infants born to women treated during pregnancy with erythromycin must be treated with penicillin at birth.

Adapted from reference 6.

failures in the 1970s, the CDC guideline recommends treatment of neurosyphilis with aqueous penicillin G, 3 to 4 MU IV every 4 hours, or 18 to 24 MU/d continuous infusion, for 10 to 14 days.⁶ Alternatively, neurosyphilis can be treated with procaine penicillin (2.4 MU IM/d) plus probenecid (500 mg PO every 6 hours) for 10 to 14 days. Some experts add benzathine penicillin G (2.4 MU IM once a week for up to 3 weeks) after the completion of aqueous penicillin G or procaine penicillin in the hope of providing persistent treponemicidal blood/tissue/CSF levels; the duration of therapy is the same as that for late-stage syphilis. Penicillin-allergic patients should be skin tested to confirm allergy and, if confirmed, the patient should be desensitized and treated with an appropriate penicillin regimen. The World Health Organization also recommends penicillin-allergic nonpregnant patients receive either doxycycline 200 mg PO BID or tetracycline 500 mg PO QID for 30 days.¹⁰³

Follow-Up

31. D.M. was treated with a single IM dose of benzathine penicillin (2.4 MU). How should his response to therapy be monitored?

Physical examination and a quantitative VDRL or RPR test for primary and secondary syphilis should be repeated at least 6 and 12 months after therapy.⁶ Retreatment should be considered when the RPR or VDRL titer does not decline by fourfold in 6 months. Patients who also are infected with HIV should have serologic testing every 3 months for 1 year and then a follow-up at 2 years.⁹⁰ Patients with latent syphilis should be retested 6, 12, and 24 months after treatment. Close nontreponemal serologic test monitoring is necessary if antibiotics other than penicillin are used; CSF examination should be per-

formed in these patients at their last follow-up visit. Patients with neurosyphilis should be monitored serologically every 6 months; CSF examinations should be repeated at 6-month intervals until normal. If still abnormal at 2 years, retreatment should be considered. Return of lesions, a fourfold increase in titer, or a titer of 1:8 that does not fall at least fourfold within 12 months indicates the need for retreatment because of relapse or reinfection. Suspected treatment failures, especially if there is an abnormal CSF, should be treated as described for neurosyphilis. However, false-positive serologic results should be ruled out (Table 65-6).

Within 2 years, most patients with early syphilis become seronegative. However, if the disease is treated during the late stages, complete seroreversal may not occur. Patients treated with oral doxycycline or erythromycin are less likely to become seronegative.¹⁰⁴ Therapy is considered adequate in patients who never become seronegative if the titer decreases fourfold. Although the disease process may be halted in patients with tertiary syphilis, existing damage to the cardiovascular or nervous systems cannot be reversed.

Pregnancy

32. N.W., a 27-year-old woman in her 19th week of gestation, has a positive VDRL and FTA-Abs. How should N.W. be managed? How would management be altered in the face of penicillin allergy?

Although pregnancy has been a reported cause of false-positive nontreponemal tests,⁹¹ the presence of both a positive treponemal test and a nontreponemal test virtually excludes a false-positive reaction.⁹⁷ The next step is to determine whether

N.W. already has been treated adequately. If she has previously received adequate treatment and follow-up and shows no evidence of persistence or recurrence of syphilis, then she requires no further therapy. Pregnancy has no known effect on the clinical course of syphilis.¹⁰⁵ However, her infant should be observed carefully. If N.W. has not been treated previously for syphilis, then she should be treated with penicillin in the same doses recommended for nonpregnant women; some experts recommend a second dose 1 week later of 2.4 MU of benzathine penicillin.⁶

The goal of therapy should be to treat the mother with syphilis as soon as possible. Syphilis transmission can occur transplacentally as early as 9 to 10 weeks' gestation and by direct contact with lesions in the birth canal.^{105,106} If the mother is left untreated, 70% to 100% of fetuses born to mothers with primary or 40% with secondary syphilis may be aborted, stillborn, or born with congenital syphilis (see Question 34).^{107,108}

There is no completely satisfactory alternative for the pregnant woman allergic to penicillin. Tetracycline, as well as doxycycline, should be avoided during pregnancy, especially during the second or third trimester, because of tetracycline's known effects on the fetus (tooth staining and inhibition of bone growth).¹⁰⁹

Erythromycin has been used to treat pregnant patients with syphilis. However, the mean transplacental transfer rate (ratio of the concentration between maternal and fetal blood levels) of erythromycin is only 3%.¹¹⁰ This may explain why some patients treated with erythromycin aborted or had stillborn infants. Therefore, erythromycin is no longer recommended as therapy for syphilis in the pregnant patient.⁶ A woman with a history of allergy to penicillin should be skin tested; if allergy is confirmed, she should be desensitized and treated with penicillin.⁶ It is possible that the newer cephalosporins and azithromycin may ultimately prove to be more acceptable alternatives to penicillin G in the pregnant woman with syphilis who is allergic to penicillin, but data are insufficient at this time to recommend their use. Even with adequate detection and treatment, fetal infection may still occur; however, more recent evidence suggests that adequate treatment with the appropriate penicillin dose can prevent up to 98% of fetal infections.^{111,112} During pregnancy, the patient should be followed up with monthly quantitative VDRL titers to evaluate the effectiveness of therapy; thereafter, she should be followed up as any other patient with syphilis.

Jarisch-Herxheimer Reaction

33. N.W. was treated with an IM injection of 2.4 MU of benzathine penicillin G. Six hours later, she complained of diffuse myalgias, chills, headache, and an exacerbation of her rash. She was tachypneic, but normotensive. What has happened? How should N.W. be managed?

N.W. has developed the Jarisch-Herxheimer reaction (JHR), a benign, self-limited complication of antitreponemal antibiotic therapy that develops in a high proportion of patients within a few hours after treatment of secondary syphilis and less often after primary. The cause of JHR is not well understood, but is probably related to release of cytokines.¹¹³ Clinical manifestations include fever, chills, myalgias, headache, tachycardia, and hypotension. The pathogenesis of the syndrome is uncertain, but the reaction is not an allergic reaction

to penicillin. It typically begins 1 to 2 hours after antibiotic administration and normally subsides spontaneously even while antibiotics are continued.¹¹⁴ Notably, JHR can occur after administration of many antimicrobials and is not exclusive to penicillins, nor is it exclusive to syphilis treatment, occurring in other spirochetal diseases such as Lyme disease and relapsing fever.¹¹⁵ Usually self-limiting in nonpregnant patients, the primary risk of this reaction in pregnant women is miscarriage, premature labor, or fetal distress.¹¹⁶ Pregnant women should seek medical attention if contractions or a change in fetal movements are noted. Close monitoring of JHR should be observed for patients with ophthalmic or neurologic syphilis. For these patients, prednisolone 10 to 20 mg three times a day for 3 days given 24 hours before syphilis treatment may prevent fever, but will not control local inflammation.¹⁰² Tumor necrosis factor- α has been demonstrated to have some success in the prevention of JHR in spirochete disease.¹¹⁷ Although there is no proven effective preventive therapy, some experts still recommend antipyretics, hydration, and patient education; antibiotic therapy should not be discontinued.

Neonatal Syphilis

34. How should N.W.'s baby be treated if a diagnosis of congenital syphilis is confirmed?

Infants born to mothers who have been treated for syphilis during pregnancy should be carefully examined at birth, at 1 month, every 2 to 3 months for 15 months, and then every 6 months until the VDRL is negative or stable at a low titer. Newborn serology is difficult to interpret because of transplacental transfer of nontreponemal and treponemal immunoglobulin G to the infant. Treatment decisions are largely based on evidence of syphilis in the mother, adequacy of maternal treatment, comparison of maternal and neonate nontreponemal serology, and/or presence of clinical or laboratory evidence of syphilis in the neonate. Aqueous penicillin G 50,000 U/kg per dose IV every 12 hours should be used during the first 7 days of life and every 8 hours thereafter for a total of 10 days. Procaine penicillin G 50,000 U/kg per dose IM daily for at least 10 days is an alternative regimen.⁶ If more than 1 day of therapy is missed, the CDC recommends restarting the entire course. In addition, infants should be treated at birth, even if they are asymptomatic, when maternal treatment is unknown or inadequate, or when infant follow-up cannot be guaranteed. In most cases, a CSF examination should be performed before treatment is begun to rule out neurosyphilis. Although benzathine penicillin (50,000 U/kg IM) as a single dose is recommended by some clinicians to treat infants who may not be followed up on, data on the efficacy of this treatment regimen are lacking and any abnormalities in the infant's examination (e.g., abnormal or uninterpretable CSF, long-bone radiographs, complete blood count, and platelets) should preclude its use.⁶

CHANCROID

Chancroid or soft chancre is a painful genital ulcer disease that often is associated with tender inguinal adenopathy. It is caused by *Haemophilus ducreyi*, a Gram-negative bacillus. Chancroid is endemic in developing countries and some areas of the United States, but its incidence in the United States has steadily declined from nearly 5,000 cases in 1987 to 17 cases in

2005.³ Chancroid and other genital ulcers have been implicated in the transmission of HIV. In the United States, up to 18% of people with genital ulcers were also HIV seropositive.¹¹⁸

Signs and Symptoms

35. T.G., a 31-year-old uncircumcised man, presents to the STD clinic with complaints of tender lesions on the penis and inguinal regions. He noticed the penile lesions on the external surface of the prepuce (foreskin) 2 days before his visit. The lesions were sharply demarcated, but were not indurated; the base of the penile ulcer was covered by a yellow-gray purulent exudate. Right inguinal adenitis was present and extremely painful on palpation. A dark-field examination of the purulent exudate was negative. Gram stain revealed a mixture of Gram-positive and Gram-negative flora. T.G. claims to have no drug allergies. What is the natural course of chancroid? Does T.G. have signs or symptoms consistent with chancroid? What diagnostic procedures are necessary?

Uncircumcised males may have an increased risk of chancroid infection and may not respond to therapy as well as circumcised males.^{6,119} A painful genital ulcer appears 3 to 10 days after exposure and begins as a tender, red papule that becomes pustular and ulcerates within 2 days. As illustrated by T.G., the ulcer may be covered by a grayish or yellow exudate. Multiple ulcers and tender inguinal lymph nodes, which may become fluctuant, are seen in about 50% of cases.¹²⁰ Aspiration of fluctuant nodes may be necessary to prevent rupture. A Gram stain can be misleading because of the polymicrobial nature of the ulcer and culture and because isolation of *H. ducreyi* is difficult, requiring specialized specimen collection and growth media.^{6,121}

Treatment

36. How should T.G.'s chancroid be treated?

Most strains of *H. ducreyi* produce a TEM-type β -lactamase, and many strains are resistant to the antimicrobials that traditionally were used to treat chancroid, such as sulfonamides and tetracycline.^{122,123} Currently recommended treatment regimens include azithromycin 1 g PO for 1 dose, ceftriaxone 250 mg IM once, ciprofloxacin 500 mg PO BID for 3 days, or erythromycin base 500 mg PO TID for 7 days.⁶ Ciprofloxacin is contraindicated in pregnant and lactating women and children 17 years of age or younger. Because T.G. does not have a history of penicillin hypersensitivity, ceftriaxone as a single dose is the preferred treatment regimen. Treatment may not be as effective for patients who are coinfecting with HIV or who are uncircumcised.^{6,119} Follow-up should occur 3 to 7 days after treatment is initiated. Depending on the size of the ulcer, the time required until complete recovery will vary; larger ulcers may require longer than 2 weeks.⁶

VAGINITIS

Vaginitis is one of the most common reasons why women seek gynecologic care. Approximately 10 million physician office visits are made annually in the United States for women seeking evaluation and treatment of their symptoms.¹²⁴ The term *vaginitis* refers to such nonspecific vaginal symptoms as itching, burning, irritation, and abnormal discharge that may be

caused by infection or other medical conditions. The most common vaginal infections are BV (22%–50% of cases), vulvovaginal candidiasis (VVC; 17%–39% of cases), and trichomoniasis (4%–35% of cases). However, between 7% and 72% of cases of vaginitis may remain undiagnosed.¹²⁵

BACTERIAL VAGINOSIS

Bacterial vaginosis (formerly called nonspecific vaginitis, leukorrhea, *G. vaginalis*, or *H. vaginalis*) is associated with an increased, malodorous vaginal discharge. The normal vaginal lactobacillus flora is replaced by *Mobiluncus* species, *Prevotella* species, *M. hominis*, and increased numbers of *G. vaginalis*.

The prevalence of BV varies widely owing to differing diagnostic criteria, demographics, and lack of a national reporting system, but it probably represents the most common cause of vaginal discharge.¹²⁶ Many sexually active women are infected with *G. vaginalis* at any one time, yet fewer than 50% are symptomatic or have signs of abnormal vaginal discharge.¹²⁷ The evidence for definitive risk factors in BV is inconclusive. Multiple sexual partners,⁶ a new sexual partner,⁶ IUDs,¹²⁸ and douching¹²⁹ have been associated with BV, whereas smoking, abnormal Pap smears, and timing in relation to menstrual cycle have not.¹²⁹ There is conflicting information on the role of heterosexual transmission; some nonsexually active postpubertal women had BV,¹³⁰ whereas longitudinal cohort studies showed increased incidence of BV after single and multiple sexual experiences.^{131,132} A study among sexually active lesbians showed strong evidence for sexual transmission.¹³³ The routine treatment of sexual partners is not recommended because clinical trials have shown that a women's response to therapy or her likelihood of relapse or recurrence is not affected by the treatment of her sexual partner(s).⁶

Signs, Symptoms, and Diagnosis

37. H.H. is a 24-year-old, sexually active woman with a 1-week history of moderate vaginal discharge that has a "fishy" odor, most notable after coitus. She has no complaints of vaginal pruritus or burning. On examination, the discharge appears thin, white, homogeneous, and notably malodorous. A wet mount of the vaginal secretion revealed few leukocytes and numerous "clue cells." The vaginal pH was 4.8, and a characteristic fishy odor was noted when the discharge was mixed with 10% potassium hydroxide (KOH). Does H.H. have signs and symptoms consistent with BV? What diagnostic tests are required?

H.H.'s signs and symptoms are typical of BV. The clinical diagnosis can be confirmed by a vaginal Gram stain that shows overgrowth of the vagina with *G. vaginalis* and other organisms as noted earlier.

A 10% KOH solution mixed with the vaginal secretions yields a transient "fishy" odor because of the increased production of biogenic diamines (positive amine test). A wet preparation of the specimen reveals "clue cells" (exfoliated vaginal epithelial cells with adherent coccobacillary pathogens), pH >4.5, and the characteristic KOH "whiff" test.¹³⁴ If there are many white cells, other infections (e.g., *T. vaginalis*) should be suspected. Self-diagnosis is correct only about 3% to 4% of the time because most women attribute symptoms to poor hygiene.¹³⁵

Treatment

38. How should H.H. be treated?

Nonpregnant women with symptomatic disease require treatment. Oral metronidazole 500 mg twice a day for 7 days is the most effective treatment of BV. Initially, up to 95% of women respond to this regimen, although only 82% still report cure after 4 weeks, indicating the need for follow-up if symptoms persist or recur.^{126,136} The FDA has approved metronidazole extended release 750 mg once daily for 7 days and a single dose of clindamycin intravaginal cream for the treatment of BV; however, the CDC reports that limited data have been published evaluating these regimens to other established therapies.⁶ Metronidazole 2 g as single-dose therapy is no longer recommended for treatment because this regimen has the lowest efficacy against BV.⁶ Ampicillin is no longer considered an alternative treatment because approximately 50% of women develop recurrent symptoms within 6 weeks.^{126,137} Clindamycin cream 2%, one full applicator (5 g) intravaginally at bedtime for 7 days or metronidazole 0.75% gel, one full applicator (5 g) intravaginally, once daily for 5 days are CDC-approved topical recommendations.^{6,138} Patients should be instructed to avoid consuming alcohol during treatment with metronidazole and for 24 hours afterward. Additionally, clindamycin cream is oil based and may weaken latex condoms or diaphragms. Alternatively, the CDC recommends clindamycin 300 mg PO two times a day for 7 days or clindamycin ovules 100 mg intravaginally once daily at bedtime for 3 days.

BV has been associated with pregnancy complications such as preterm labor and premature delivery. If the decision is made to treat BV during pregnancy, the CDC recommends metronidazole 250 mg PO three times daily for 7 days or 500 mg PO twice a day for 7 days or clindamycin 300 mg PO twice daily for 7 days. Recent teratogenic data suggest that metronidazole is not harmful to the fetus but the use of intravaginal clindamycin cream has been associated with preterm delivery.^{6,139}

VULVOVAGINAL CANDIDIASIS

Candida albicans is the causative organism of VVC in 80% to 92% of cases, with *C. glabrata* and *C. tropicalis* accounting for most of the remaining cases.^{140,141} The latter organisms have been identified increasingly as the causative agents of VVC over the past two decades. Approximately 75% of women will experience at least one episode of VVC, and 40% to 45% will have two or more episodes within their lifetime.⁶ Approximately 5% of women who have VVC have recurrent candidal episodes (defined as four or more episodes of VVC in 1 year).⁶ Vulvovaginal candidiasis is not usually described as an STD because celibate women can develop VVC; however, the incidence of VVC increases when women become sexually active.¹⁴¹ Because of this, VVC is often diagnosed during evaluation for a suspected STD when women present with vaginal symptoms.⁶

Assessing Self-Treatment

39. L.L., a 23-year-old woman, purchases an over-the-counter (OTC) antifungal agent to relieve vaginal symptoms that she believes are caused by a vaginal yeast infection. L.L. asks the pharmacist for assistance in the selection of an antifungal agent. What

Table 65-8 Questions to Gain Information About Possible *Candida* Vulvovaginitis^a

What symptoms are you experiencing currently?
Have you previously been diagnosed by a physician as having a vaginal yeast infection?
What symptoms did you experience with that previous yeast infection?
Are the symptoms you are experiencing now the same or similar to those you had with that previous infection?
If you were treated previously for a vaginal infection, what antifungal agent did you use? For how long did you use it? Was it effective?
Did you experience any adverse effects associated with use of the antifungal agent?
Are you pregnant?
Do you have any medical problems?
Are you taking any medications?
Do you have allergies?
Do you use any vaginal preparations (e.g., feminine hygiene sprays or douches)?
If you have sexual intercourse, what contraceptive method do you use?
Does your sexual partner use a condom?
You could also ask questions about tight-fitting clothes, nylon undergarments, swimming, etc.

^a A questionnaire form might also be helpful in collecting information from the patient.

information should be obtained from L.L. before a medication is recommended?

The pharmacist should ask L.L. if this is her first episode of vaginitis or whether she has experienced similar symptoms previously that have been diagnosed as a vaginal yeast infection and treated by a physician. The nonprescription antifungal agents are indicated for the treatment of VVC in women who previously were diagnosed and treated by their physician. She should be referred to her physician if (a) this is her first episode of VVC; (b) she has had two episodes of VVC within the past 6 months; (c) she is pregnant; (d) she is younger than 16 or older than 60 years of age; (e) she currently has abnormal vaginal bleeding or lower abdominal pain; (f) she has been exposed to a STD; or (g) she has a malodorous vaginal discharge (Table 65-8).

Signs and Symptoms

40. L.L. has experienced two episodes of vaginal yeast infections, with the most recent case occurring approximately 1 year ago. On both occasions she was diagnosed as having VVC by her physician and responded to antifungal therapy. L.L. currently describes vaginal and vulvar itching, vaginal soreness, and vulvar burning accompanied by a thick, white vaginal discharge that has the consistency of cottage cheese. She has been unable to have sexual intercourse because of pain. These symptoms are similar to those she experienced with her previous vaginal yeast infections. L.L. has no underlying major health problems. Her current medications include oral tetracycline for acne and Ortho Tri-Cyclen for birth control. She has regular menstrual cycles and her last menstrual period ended 4 days ago. What clinical manifestations does L.L. exhibit that are consistent with VVC? What are other common manifestations?

L.L. exhibits signs and symptoms associated with VVC (i.e., vulvar and vaginal pruritus, vaginal soreness, vulvar

burning, dyspareunia, and a thick, white vaginal discharge that appears to be “curdlike”).⁶ Although vulvar pruritus occurs in most symptomatic patients, many affected women have little or no vaginal discharge.¹⁴⁰ Typically, the vaginal discharge associated with VVC is a nonodorous, highly viscous, white discharge that may vary in consistency from curdlike to watery.¹⁴⁰ Symptoms may be worse before menses and may diminish with the onset of menses.¹⁴⁰

Differential Diagnosis

41. How can VVC be differentiated from other vaginal infections?

VVC should be differentiated from other vaginal infections (e.g., BV) because a nonprescription antifungal agent could delay the appropriate treatment of other vaginal infections. The physical appearance of the vaginal discharge may be useful in predicting VVC if it is a viscous, nonodorous, white, curdlike discharge and the patient has a normal vaginal pH (pH < 4.5).⁶ The quantity of the discharge may be scanty to profuse. Some women with VVC exhibit only vaginal erythema with minimal discharge or an increased amount of normal vaginal secretion. Table 65-9 characterizes the vaginal discharges associated with VVC, BV, and vaginal trichomoniasis. The vaginal discharge from a woman with signs and symptoms of VVC should be examined for the microscopic presence of *Candida* using a wet mount preparation with 10% KOH or a Gram stain of the vaginal discharge. The use of KOH improves the visualization of yeast or pseudohyphae that are seen in approximately 70% of women diagnosed with VVC.⁶ If the wet mount is negative, the patient’s vaginal discharge should be cultured for *Candida* in an appropriate growth medium. The identification of *Candida* in the absence of signs and symptoms is not diagnostic for VVC and therefore treatment should not be initiated because *Candida* and other species of yeast represent part of the normal flora in approximately 10% to 20% of women.⁶ It is the proliferation of *C. albicans* or other yeasts that lead to vulvovaginitis symptoms.

PHYSIOLOGICAL VAGINAL DISCHARGE AND SYMPTOMATIC NORMAL pH VULVOVAGINITIS

42. Do women such as L.L., who have an increased vaginal discharge and symptoms consistent with VVC, necessarily have a vaginal infection?

Although the possibility of vaginal infection must be addressed when a woman presents with an increased vaginal discharge with or without symptoms, other conditions are as-

Table 65-10 Modified Amsel’s Criteria for the Diagnosis of Bacterial Vaginosis

At least three of the following signs must be present for diagnosis:

- Homogeneous discharge
- Fishy amine odor when 10% KOH is added (sniff test)
- Clue cells (i.e., >20% on wet mount)
- Vaginal pH > 4.5
- No lactobacilli on wet mount
- KOH, potassium hydroxide.

From reference 236.

sociated with an increased discharge. First, a physiological vaginal discharge must be distinguished from a pathological discharge. Physiological discharges (Table 65-9) characteristically are nonodorous, white or clear, highly viscous or floccular, and acidic (pH ~4.5). Physiological discharges may become more profuse at midcycle secondary to increased cervical mucus or vaginal epithelial cells. Other conditions resulting in excessive vaginal discharge with or without VVC-like symptoms include retention of foreign bodies (e.g., tampons) and allergic reactions or contact dermatitis secondary to the use of vaginal spermicidal agents, soaps, deodorants, douches, vaginal lubricants, and condoms. Episodes of vulvovaginitis-like symptoms can be secondary to the frequent use of hot tubs, Jacuzzis, or swimming pools that contain chemically treated water (e.g., high levels of chlorine).¹⁴²

Susceptibility to Vulvovaginal Candidiasis

43. What specific groups of women are most susceptible to VVC? Does L.L. fit into any group at high risk for VVC?

Women are most susceptible to VVC during their child-bearing years. Approximately 50% of U.S. college women report having an episode of VVC between menarche and age 25.¹⁴¹ *Candida albicans* colonization and symptomatic VVC increase during pregnancy and when high estrogen-containing oral contraceptives are used. This increase has been attributed to estrogen enhancement of the binding affinity of vaginal epithelial cells to *C. albicans*.¹⁴³ Women with high glycogen concentrations (e.g., uncontrolled or poorly controlled diabetes mellitus); women with depressed cell-mediated immunity secondary to disease (e.g., cancer, HIV infection); and women taking broad-spectrum antibiotics or immunosuppressive drugs (e.g., cytotoxic agents, corticosteroids) may have increased susceptibility to VVC.^{141,143} Individual cases of VVC,

Table 65-9 Characteristics of Vaginal Discharge

| Characteristics | Normal | Candidiasis | Trichomoniasis | Bacterial Vaginosis |
|-----------------------|----------------|-----------------|----------------|---------------------|
| Color | White or clear | White | Yellow-green | White to gray |
| Odor | Nonodorous | Nonodorous | Malodorous | Fishy smell |
| Consistency | Floccular | Floccular | Homogeneous | Homogeneous |
| Viscosity | High | High | Low | Low |
| pH | ~4.5 | 4–4.5 | 5–6.0 | >4.5 |
| Other characteristics | | Thick, curdlike | Frothy | Thin |

From references 140, 141, and 143.

although not related to intercourse, may be related to orogenital sex.

L.L. is taking tetracycline, which may heighten her risk of developing VVC. Antibacterials (e.g., tetracycline, ampicillin, cephalosporins) increase the risk for *C. albicans* overgrowth by suppressing the normal vaginal flora (e.g., lactobacilli), which normally protect against *C. albicans*. L.L. is also taking a low-estrogen-containing oral contraceptive; however, low-dose oral contraceptives have not been consistently associated with an increased risk of VVC.^{144,145} The use of diaphragms, vaginal sponges, and IUDs also may be risk factors for VVC.¹⁴⁶

Stress-induced VVC and an increased incidence of VVC before menstruation have been described.¹⁴³ The cause of both is currently unknown. Although various dietary factors have been postulated as a cause of vaginal yeast overgrowth, the role of diet in the development of VVC remains inconclusive.¹⁴³

Treatment of Vulvovaginal Candidiasis VAGINALLY ADMINISTERED AZOLES

44. What vaginally administered therapy might be effective for L.L.'s VVC?

L.L. is an appropriate candidate for OTC therapy (Table 65-11) because she had previous vaginal yeast infections with symptoms similar to those she currently is experiencing, and her VVC is uncomplicated (defined as sporadic disease with mild to moderate symptoms in a immunocompetent host).⁶ When a patient's VVC appears complicated (defined as recurrent infections, severe symptoms, non-*albicans* candidiasis, presence of uncontrolled diabetes, debilitation, immunosuppression, or pregnancy), she should be referred to her medical practitioner.⁶ L.L. should respond to short-term topical azole therapy. In addition, L.L. should ask her physician whether she

Table 65-11 Products Available for the Treatment of *Candida* Vulvovaginitis

| Drug | Availability | Trade Names | Dosing Regimens |
|----------------------------------|--|---|--|
| OTC Products | | | |
| Butoconazole | 2% vaginal cream ^a | Femstat 3 | <i>Nonpregnant women:</i> Administer 1 applicatorful intravaginally QHS for 3 consecutive days <i>Pregnant women during second and third trimesters:</i> Administer 1 applicatorful intravaginally QHS for 7 consecutive days |
| Clotrimazole | 1% vaginal cream ^a | Gyne-Lotrimin 7; Mycelex-7; Sweet'n Fresh Clotrimazole 7; various generics | Administer 1 applicatorful intravaginally QHS for 7 consecutive days |
| Miconazole | 2% cream ^a | Monistat 7; Femizol-M; various generics | Administer 1 applicatorful intravaginally QHS for 7 consecutive days |
| | 100-mg vaginal suppositories ^a | Monistat 7 | Insert 1 suppository intravaginally QHS for 7 consecutive days |
| | 200-mg vaginal suppositories ^a | Monistat 3 | Insert 1 suppository intravaginally QHS for 3 consecutive days |
| Tioconazole | 1200-mg vaginal suppositories ^a | Monistat 1 Daytime Ovule | Insert 1 suppository intravaginally HS for 1 dose only |
| | 6.5% vaginal ointment | Vagistat-1, generics | Administer 1 applicatorful intravaginally at HS for 1 dose only |
| Prescription Products | | | |
| Butoconazole (sustained release) | 2% vaginal cream ^a | Gynazole 1 | <i>Nonpregnant women:</i> Administer 1 applicatorful HS for 1 dose only |
| Clotrimazole | 100-mg vaginal tablets | Gyne-Lotrimin; Mycelex-7; Sweet'n Fresh Clotrimazole 7; various generics | Insert 1 tablet intravaginally QHS for 7 consecutive days |
| | 100-mg vaginal tablets | Gyne-Lotrimin; Mycelex-7; Sweet'n Fresh Clotrimazole 7; various generics | Insert 2 tablets intravaginally QHS for 3 consecutive days |
| Fluconazole | 150-mg oral tablet | Diflucan tablet | Take 1 tablet PO for 1 dose only |
| Nystatin | 100,000 U vaginal tablet | Mycostatin; Nystatin; various generics | Insert 1 tablet intravaginally QHS for 14 consecutive days |
| Terconazole | 0.4% vaginal cream ^a | Terazol 7 | Administer 1 applicatorful intravaginally QHS for 7 consecutive days |
| | 0.8% vaginal cream ^a | Terazol 3 | Administer 1 applicatorful intravaginally QHS for 3 consecutive days |
| | 80-mg vaginal suppositories ^a | Terazol 3 | Insert 1 suppository intravaginally QHS for 3 consecutive days |

^aThe CDC states that the use of vaginally administered oil-based preparations may weaken latex products such as condoms and diaphragms. OTC, over-the-counter; QHS, at bed time. From reference 6.

should continue with oral tetracycline or be prescribed another oral antibiotic instead. If L.L. had been evaluated by her physician, single-dose oral fluconazole or 3-day intravaginal therapy might have been prescribed.

The available azole antifungals are equally effective in treating VVC with cure rates between 80% and 90% when a full course of therapy is completed.^{6,147} All the azole antifungal products listed in Table 65-11 are superior to nystatin. The medication used to treat L.L.'s VVC should be selected based on response or failure to previous therapy, convenience, ease of use, length of therapy, dosage form, and cost. L.L. should select a non-oil-based product if a latex condom or a diaphragm is used for contraception (Table 65-11).

OTHER TREATMENTS FOR ACUTE VULVOVAGINAL CANDIDIASIS

Oral lactobacillus and lactobacillus-containing yogurt have long been advocated for the treatment of VVC; however, evidence in support of this treatment is inconclusive.¹⁴⁸ Boric acid (600-mg capsules) inserted high in the vagina at bedtime for 14 days is effective for the treatment of VVC, but vaginal burning and irritation occur in approximately 4% of women and boric acid is poisonous if inadvertently ingested.¹⁴⁸ The primary indication for these extemporaneously prepared boric acid capsules primarily has been in the treatment of fluconazole-resistant *Candida* infection, especially that due to *C. glabrata*. Gentian violet preparations also have limited use in the treatment of candidiasis because they stain clothing and bed linens and cause local irritation and edema. It is important to note that these alternative regimens for the treatment of acute VVC are not currently recommended by the CDC.

ORAL AZOLES

45. How effective are orally administered azoles in the treatment of an acute VVC infection such as the one L.L. is experiencing?

Fluconazole (Diflucan), administered as a single 150-mg oral dose, is the only oral antifungal agent currently recommended by the CDC for the treatment of acute VVC (Table 65-11).⁶ In two clinical studies, a single 150-mg oral dose of fluconazole was as effective as 3- to 6-day regimens of intravaginal clotrimazole.^{149,150} Although some women may prefer an orally administered drug to one that is administered intravaginally, their use for mild to moderate VVC is of some concern because of the possibility for systemic adverse effects.

Adverse Effects Associated With Azoles

46. What adverse effects might L.L. experience from intravaginally or orally administered azoles?

When used intravaginally, azoles are associated with minimal adverse reactions, many of which are similar to the symptoms women report from candidiasis infections. Thus, it can be difficult to differentiate disease symptoms from adverse drug reactions. If the vaginal symptoms seem to worsen after therapy is started, the patient should contact her health care provider. In addition, if symptoms have not improved within 3 days after initiation of therapy, the patient should contact her physician to rule out more severe disease, treatment of the wrong disease, or drug-related adverse effects. Vulvovaginal irritation, itching, burning, and pelvic cramps are commonly associated with vaginal administration of azoles (3%–4%).¹⁵¹

Miconazole has also been associated with headaches, allergic contact dermatitis, and skin rashes; clotrimazole with vulvovaginal pruritus, dyspareunia, and bloating; butaconazole with vulvovaginal pruritus (0.9%), burning (2.3%), soreness, discharge, and swelling; terconazole with headaches (21%–30%), dysmenorrhea (6%), genital pain (4.2%), and pruritus (2.3%–5%); and tioconazole with burning (6%) and itching (5%). Oral fluconazole has been associated with headache (13%), nausea (7%), abdominal pain (6%), diarrhea, dyspepsia, dizziness, taste perversion, angioedema, and rare cases of anaphylactic reactions.¹⁵¹

Patient Counseling

47. How should L.L. be counseled about the use of a nonprescription (OTC) vaginal antifungal product?

The details of intravaginal administration should be reviewed with L.L., including instructions on how to clean the applicator (if one is used for drug administration) after each use. To minimize leakage and annoyance, L.L. should apply the product at bedtime to increase retention in the vagina. She should be advised that the OTC vaginal antifungal creams and suppositories are oil based and thus may weaken condoms or diaphragms, thereby reducing their effectiveness.

L.L. should be informed about the importance of completing a full course of therapy even if her symptoms subside beforehand and to continue her antifungal treatment through her menstrual period should it occur. In addition, L.L. should be instructed to see her physician if her symptoms persist, if she experiences symptoms that signal a more serious problem (e.g., abdominal pain, fever, a foul-smelling or bloody vaginal discharge), or if another yeast infection occurs within 2 months.

L.L. also should be advised to avoid wearing tight-fitting, unventilated underwear (e.g., nylon panties or panty hose) and tight-fitting jeans because a warm, moist environment can facilitate fungal growth. However, a study addressing risk factors for VVC found no relation between type of underwear and the incidence of VVC.¹⁴⁶ L.L. also could be alerted to the possible relation between candidiasis and swimming in a heavily chlorinated pool or frequent use of a Jacuzzi or hot tub.

Complicated Vulvovaginal Candidiasis

48. How would management of L.L.'s VVC differ if she had poorly controlled diabetes?

VVC in a woman with uncontrolled diabetes is usually considered to be complicated VVC. A diagnosis of complicated VVC is also warranted when the VVC is severe, recurrent (as defined), caused by non-*albicans* species of *Candida*, or when VVC occurs in an immunosuppressed, debilitated, or pregnant woman. Approximately 10% to 20% of VVC cases can be classified as complicated.⁶ The treatment of complicated VVC varies depending on the underlying cause of complication. Severe VVC (extensive vulvar erythema, edema, excoriation, and fissures) should be treated with a 7- to 14-day course of topical azoles or two oral doses of fluconazole 150 mg given 72 hours apart.⁶ Infection with non-*albicans Candida* should be treated with a 7- to 14-day course of an oral or intravaginal azole.⁶ Oral fluconazole has poor activity against non-*albicans Candida* and should not be used; however, a 7-day regimen of terconazole 0.4% cream has been shown to eradicate

non-*albicans* *Candida* in 56% of affected patients.^{6,152} Boric acid 600-mg capsules administered intravaginally once daily for 14 days can be used if this regimen is not effective in eradicating the infection.⁶

Recurrent Vulvovaginal Candidiasis

49. L.L. develops another case of VVC 1 month later. Does she have recurrent VVC? How should she be treated?

Most women have only occasional episodes of VVC, but approximately 5% experience recurrent VVC infections defined as four or more episodes per year.⁶ To determine whether L.L. has recurrent VVC, a diagnosis of *Candida* needs to be confirmed by vaginal cultures. Then, underlying risk factors for VVC, such as uncontrolled diabetes mellitus, consumption of excess sugars, IUD placement, and use of antibiotics, must be ruled out.¹⁵³ Based on the timing of L.L.'s episodes and the absence of risk factors, L.L. does not meet the definition for recurrent VVC. If a patient meets the criteria for recurrent VVC, an underlying cause of the problem may not be determined. In addition, the role of sexual transmission is not currently well understood.¹⁴¹ In most patients, the pathogenesis of recurrent VVC cannot be determined.

Treatment of recurrent *C. albicans* vulvovaginitis should focus on a prolonged (7- to 14-day) course of topical therapy or a three dose regimen of oral fluconazole (100, 150, or 200 mg) administered every 3 days to eliminate symptoms and induce remission.⁶ A 6-month maintenance regimen should be initiated after remission has been achieved. See Table 65-12 for a list of maintenance regimens. Despite the efficacy of these regimens, discontinuation of therapy after 6 months can result in relapse in up to 50% of women.^{6,153} Azole-resistant strains of *C. albicans* are rare; therefore, culture and sensitivity testing is not usually performed to help guide treatment before initiation.

Vulvovaginal Candidiasis During Pregnancy

50. What teratogenic risks are associated with the use of azole preparations?

Vaginal colonization with *Candida* and symptomatic VVC are common during pregnancy.¹⁵⁴ Asymptomatic colonization is not associated with increased maternal or fetal risks and need not be treated.¹⁵⁵ However, symptomatic VVC should be treated. Although doses of oral fluconazole used to treat VVC have not been associated with increased fetal defects, higher doses may be teratogenic. Therefore, topical antifungal agents

are preferred for treatment of VVC in pregnant women. The CDC currently recommends a 7-day course of topical antifungal therapy for VVC during pregnancy; however, a 3-day regimen with appropriate follow-up to assess efficacy has been shown to be effective in mild to moderate cases.^{6,155} Although nystatin is classified as a category B drug during pregnancy, it is not commonly used bits inferior efficacy rate. Clotrimazole is also classified as a category B drug for fetal risk, and the remaining vaginally administered azoles are designated as category C.¹⁵⁵

TRICHOMONIASIS

Signs and Symptoms

51. N.B. is a 31-year-old woman with a recent history of diffuse vaginal discharge with vaginal irritation. A wet-mount examination of vaginal secretions revealed numerous trichomonads. Examination confirms the presence of an increased, yellow-green vaginal discharge. What subjective and objective clinical data support a diagnosis of trichomoniasis?

Trichomoniasis is an STD caused by the protozoan *T. vaginalis*. The prevalence in women ranges from 5% to 10% and up to 60% in commercial sex workers.¹⁵⁶ Trichomoniasis in women is asymptomatic about 20% to 50% of the time.¹⁵⁷ In men, *T. vaginalis* presumably infects the urethra, although the site of infection (urethra versus prostate) is uncertain. Men with *T. vaginalis* infection usually are asymptomatic. Classic symptoms of trichomoniasis in women include a diffuse, yellow-green discharge with pruritus, dysuria, and a “strawberry” cervix (cervical microhemorrhages). The latter are typically only seen in 2% to 25% of cases.¹⁵⁸ In almost all cases of trichomoniasis, a vaginal pH higher than 5 or 6 is observed.¹⁵⁹ The Pap smear was reported to have a 48.4% error in diagnosis when used alone.¹⁵⁸ Direct microscopic observation of trichomoniasis using a wet mount suffers from low sensitivity, but is up to 99% specific.¹⁶⁰ Broth culture is considered to be the gold standard for identification of trichomoniasis, but it requires up to a 7-day incubation period and the culture system is not widely available.¹⁵⁸ The best approach to diagnosis requires clinical and laboratory confirmation.

Treatment

Metronidazole and Tinidazole

52. How should N.B.'s trichomoniasis be treated?

The only class of drugs that are effective for the treatment of trichomoniasis are the nitroimidazoles. In the United States, metronidazole and tinidazole are the only available nitroimidazoles. Both are CDC-recommended first-line treatments given as a single 2-g oral dose.⁶ In addition, sexual partners should be simultaneously treated. Metronidazole cure rates are reported to be 90% to 95%, whereas tinidazole cure rates are reported to be 86% to 100%; concurrently treating sexual partners might increase these rates.^{6,161} Clinical trials seem to suggest that tinidazole is equivalent or superior to metronidazole in achieving cure and resolution of symptoms.¹⁶² Approximately 2% to 5% of *T. vaginalis* isolates exhibit resistance to metronidazole therapy, necessitating a dose increase or a change in therapy to tinidazole.⁶ If the 2-g metronidazole dose fails and reinfection

Table 65-12 Maintenance Regimens for Recurrent Vulvovaginal Candidiasis

| | Dose | Frequency |
|------------------------------------|---------------------|--------------|
| Topical agents | | |
| Clotrimazole | 200 mg | Twice weekly |
| Clotrimazole vaginal suppositories | 500 mg | Weekly |
| Oral agents | | |
| Fluconazole tablets | 100, 150, or 200 mg | Weekly |

From reference 6.

is excluded, either metronidazole 500 mg PO twice daily for 7 days or tinidazole 2 g PO as a single dose can be used. If either of these regimens fail, either metronidazole or tinidazole 2 g PO daily for 5 days may be used. In the case of allergy to nitroimidazole compounds, patients can be desensitized and subsequently treated with metronidazole.¹⁴⁴

ADVERSE EFFECTS

53. N.B. was treated with metronidazole 500 mg twice a day for 7 days. On the fourth day of therapy while attending a party, N.B. developed a severe headache, followed by nausea, sweating, and dizziness. Could N.B.'s symptoms be caused by metronidazole?

Minor side effects associated with metronidazole therapy include nausea, vomiting (especially with single-dose therapy), headache, skin rashes, and alcohol intolerance. The alcohol intolerance may be due to a metronidazole-induced inhibition of aldehyde dehydrogenase, which results in the buildup of high serum acetaldehyde levels, although this mechanism is questionable.¹⁶³ Severe "antabuse reactions" are uncommon, but according to the manufacturer, patients still should be warned about the possibility of nausea, vomiting, flushing, and respiratory distress after alcohol consumption, although reliable evidence is lacking.¹⁴⁶ As a general rule, patients should avoid alcohol ingestion during treatment and for 24 hours after metronidazole therapy and for 72 hours after tinidazole therapy.⁶

Pregnancy

54. S.G., a 31-year-old woman, is in her first trimester of pregnancy and has a history of recurrent trichomoniasis. She now complains of a diffuse, yellow vaginal discharge. The preliminary diagnosis of trichomoniasis is confirmed by a wet-mount examination of vaginal secretions that revealed numerous trichomonads. S.G. has read much of the lay press on metronidazole and is concerned about her own safety as well as that of her fetus. Can metronidazole be used for S.G.?

During pregnancy, trichomoniasis is associated with premature rupture of the membranes, preterm delivery, and low birth weight.⁶ In a recent meta-analysis, an association between metronidazole use and teratogenicity or mutagenicity in infants could not be shown.¹⁶⁴ However, caution should still be exercised if metronidazole must be administered within the first trimester. Metronidazole is mutagenic in facultative bacteria and contains a nitro-reductase enzyme. Long-term, high-dose metronidazole in laboratory mice is associated with the development of pulmonary and hepatic tumors. Midline facial defects have been documented in humans, but two literature reviews indicate that metronidazole is not a teratogen.^{165,166} In contrast, the use of metronidazole in asymptomatic women has not been shown to decrease rates of preterm labor despite eliminating the organism from its host.¹⁶⁷

TREATMENT

55. How should S.G. be treated?

All symptomatic women should be treated with metronidazole 2 g PO as a single dose.⁶ Metronidazole is classified as pregnancy category B. Tinidazole 2 g PO as a single dose could be suggested as an alternative regimen; however, it is classified as pregnancy category C.

GENITAL HERPES

The word *herpes* is of Greek origin and means "to creep." HSV is a DNA-containing virus that consists of two antigenic distinct serotypes: HSV-1 and HSV-2. The primary cause of herpes labialis (cold sores), herpes keratitis, and herpetic encephalitis is HSV-1. Genital herpes and neonatal herpes primarily are the result of HSV-2 infections. However, up to 50% of all reported cases of primary genital herpes are due to HSV-1 infections acquired through oral sex.^{168,169}

Etiology

Most infants are exposed to HSV-1 early in life with over half being positive for HSV-1 antibodies before 18 years and more than 90% of the population positive by 70 years of age.¹⁷⁰ The infection often is asymptomatic and generally is acquired through primary infection of the respiratory tract. The initial, primary disease is a gingivostomatitis characterized by vesicles in the oral cavity and occasionally an elevated temperature; life-threatening encephalitis or keratitis may appear during this interval. Usually after primary exposure, HSV-1 enters cells of the trigeminal ganglion, where it may remain latent for the lifetime of the host.¹⁷¹

Initial HSV-2 infections usually follow puberty and coincide with the onset of sexual activity, although transfer to a neonate from an infected mother can occur. After primary infection, the virus enters a state of latency in the sacral dorsal root ganglia in many infected individuals; a high percentage of infected persons may never manifest the disease clinically.^{171,172}

In both HSV-1 and HSV-2 infections, the latent virus can reactivate. Recurrent disease may occur even when circulating antibody and sensitized lymphocytes are present. Clinically, the lesions periodically erupt usually at the same location, and the interval between episodes varies widely between individuals.

Epidemiology

Although herpes was recognized several thousand years ago, genital herpes was not described formally until the 18th century. The seroprevalence of genital herpes has increased dramatically in the United States—from 16.4% in the late 1970s to 21.9% in the early 1990s—making it the most common STD with over 45 million people infected in the United States.¹⁷³ In 2001, U.S. physicians saw more than 150,000 new patients presenting with herpes simplex.³

The prevalence of antibody to genital herpes is greater among women (26%) than men (18%) and among blacks (45.9%) than whites (17.6%).^{170,173} Demographic characteristics obtained at the University of Washington indicate that the mean number of lifetime sexual partners before acquisition of the disease was 8.8 in women compared with 32.8 in men, with the overall chance of acquiring HSV-2 of 5 per 1,000 sex contacts.¹⁷⁴ The mean time from the last sexual exposure to the onset of disease was 5.8 days.¹⁷²

Signs and Symptoms

56. B.J., a 28-year-old, sexually active man, complains of painful penile lesions and tender inguinal adenopathy. The lesions are vesicular and limited to the scrotum, glands, and shaft of the

penis. The onset of the lesions was preceded by a 1-week period of fever, malaise, headache, and itching. Viral culture of the lesions was positive for HSV infection. Describe the typical course and clinical presentation of herpes genitalis in men and women. What subjective and objective clinical data in B.J. are compatible with herpes genitalis?

Most initial episodes of genital herpes, especially in the male, are symptomatic. As illustrated by B.J., the symptoms usually start about 1 week after the initial exposure with prodromal signs of tingling, itching, paresthesia, and/or genital burning.¹⁷⁵ The prodromal stage, which can last from a few hours to several days, is followed by the appearance of numerous vesicles. The vesicles eventually erupt, resulting in painful genital ulcers. The pain and edema associated with genital herpetic lesions, especially if they are infected secondarily, can be severe enough to result in dysuria and urinary retention. Bilaterally distributed lesions of the external genitalia are characteristic. The lesions usually are limited to the glands, corona prepuce, and shaft of the penis in males and to the vulva and vagina in females. However, lesions can occur on the buttocks, thighs, and urethra.¹⁷² Asymptomatic or mucopurulent cervicitis occurs in about 15% to 20% of women with primary HSV-2 infections.¹⁷⁶ Rectal and perianal HSV-2 infections increasingly are being recognized. Herpes simplex virus proctitis usually is seen in homosexual men and heterosexual men who engage in anorectal intercourse. Symptoms include anorectal pain and discharge, tenesmus, and constipation.

Prior infection with HSV-1 seems to ameliorate the severity of the first episode of genital herpes, but does not appear to affect the rate of recurrence.¹⁷⁷ In primary infections, the local symptoms of pain, itching, and urethral or vaginal discharge last from 11 to 14 days, with a complete disappearance of lesions in 3 to 6 weeks.^{172,177} The clinical course of primary herpes is presented in Figure 65-7. Most patients, however, have minor symptoms or are asymptomatic and unaware of their disease; they are most infectious within the first year of acquisition of the virus.¹⁷⁸

Recurrence

57. Is B.J.'s infection likely to recur?

Most patients experience a recurrence of their initial infection. The rate of recurrent infections varies among individual patients. In one study, 38% experienced at least six episodes, and 20% had more than ten recurrences.¹⁷⁷ Natural infection with HSV-2 induces type-specific immunity against exogenous reinfection, but does not affect recurrences.¹⁷⁹ The severity of the primary episode as well as the host's immune response to the disease seem to influence the subsequent recurrence rate.¹⁷⁷ Recurrent infections usually appear at or near the site of the initial infection, and prodromal symptoms are reported by about 50% of persons with recurrent infection. Men seem to have slightly more frequent recurrences. In contrast with primary infections, there are fewer lesions and they are often unilateral.¹⁷² Constitutional symptoms such as lymphadenopathy, fever, and malaise generally are milder. Recurrent infections are shorter in duration (average, 1 week); local symptoms such as pain and itching last 4 to 5 days and the lesions themselves last 7 to 10 days.¹⁷² By about 5 years after the initial infection, recurrence rates tend to decrease.¹⁸⁰ Genital infections with HSV-1, however, recur infrequently and decrease by 50% between 1 and 2 years after infection.¹⁸¹

Transmission

58. B.J. states that this is the first time he has had such lesions and that he has had only one sexual partner for the last 14 months. His sexually active female partner has no history of herpes genitalis or any other STD. The couple is very curious as to how B.J. acquired his infection. How is HSV transmitted?

Transmission of HSV occurs by direct contact with active lesions or from a symptomatic or asymptomatic person shedding virus at a peripheral site, mucosal surface, or secretion.¹⁸² Genital HSV-2 infections usually are acquired through sexual (vaginal or anorectal) intercourse, whereas genital HSV-1 infections are acquired via oral-genital sexual practices. Because

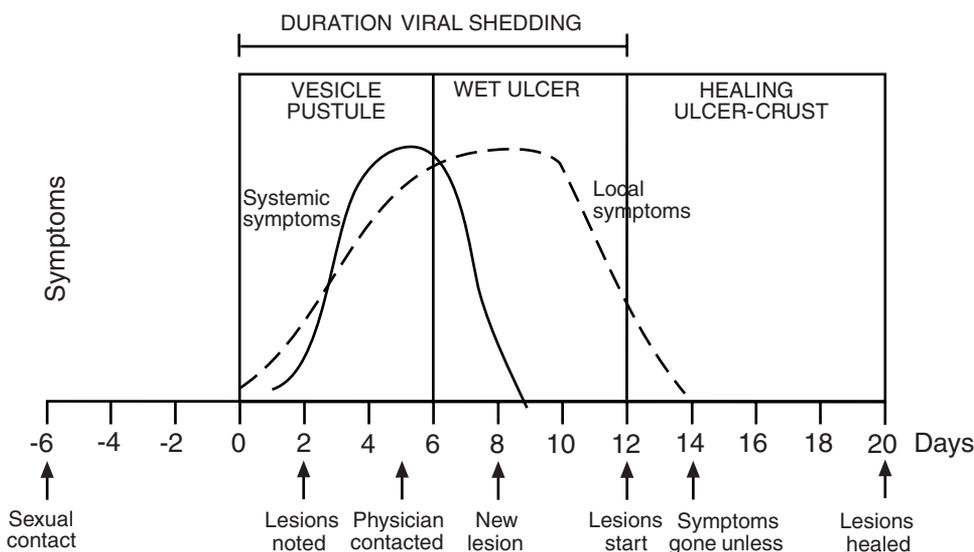

FIGURE 65-7 The clinical time course of primary genital herpes infections. (Reprinted with permission from reference 172.)

HSV is inactivated readily by drying and exposure to room temperature, aerosol and fomite spread are unusual means of transmission.¹⁸³ Condoms may act as an effective barrier to viral transmission in women, but this method does not offer complete protection for men.^{184,185} Recent evidence suggests that the frequency of condom use is directly proportional to protection against acquisition of HSV-2.¹⁸⁶

A patient with genital herpes is contagious only when he or she is shedding the virus. The patient begins to shed virus during the prodromal phase, which may be several hours to days before the actual lesions first appear. Subclinical or asymptomatic viral shedding is the most common means of sexual transmission and important from a public health standpoint.^{187,188} Lesions are most contagious during the ulcerative phase. The median duration of viral shedding as defined from onset to the last positive culture is about 12 days.¹⁷² The mean time from the onset of vesicles to the appearance of the crust stage (~10.5 days) correlates well with the duration of viral shedding. However, there is considerable overlap between the duration of viral shedding and the duration of crusting. Therefore, patients should be advised to refrain from sexual activity until the lesions have completely healed. Women seem to require a longer total lesion healing time than men, 19.5 and 16.5 days, respectively.¹⁷² The mean duration of viral shedding from the cervix is 11.4 days.

A genital herpes infection may be acquired from an individual who has never had symptomatic genital lesions. States of asymptomatic or subclinical viral shedding occur in the majority of women with recurrent genital herpes as a result of reactivation of latent infection. These recurrent infections can have a primary disease presentation, causing the patient to blame the most proximate sexual partner when in actuality, the exposure could have occurred in the distant past.¹⁸⁹ Serologic and virologic typing can be used to determine whether this is a true primary infection. Using sensitive detection techniques such as PCR, women with recurrent HSV infections demonstrated viral shedding up to 28% of the time, but the relationship between a PCR-positive HSV test and true communicability has yet to be determined.¹⁹⁰ A recent study of men and women seropositive for HSV-2, but with no previous history of symptomatic genital herpes, demonstrated viral shedding in the genital tract at a rate similar to those who reported symptomatic infection.¹⁹¹ Seropositive HSV patients also should be counseled to practice safer sex, using male or female condoms, at all times, not just during symptomatic episodes.

Diagnostic Tests

59. An HSV antibody test (Western blot) of B.J.'s serum taken on day 1 of the illness was negative. However, 20 days later, the HSV-2 antibody was positive. Viral cultures of B.J.'s genital lesions grew HSV-2. A genital Pap smear and serologic antibody detection tests were negative in B.J.'s asymptomatic sexual partner. How are these laboratory tests to be interpreted?

The accuracy with which herpes genitalis can be diagnosed without the aid of laboratory tests generally is quite good, especially if the infection is recurrent in nature. However, because of the potentially severe psychological and physiological ramifications of such a diagnosis, either virologic and/or serologic confirmation of the diagnosis may be obtained.

The laboratory diagnosis of HSV-1 or HSV-2 infection depends on isolation of virus from tissue culture; detection of viral particles by electron microscopy; visibility of giant cells or intranuclear inclusions by Papanicolaou or Giemsa staining (which are insensitive and nonspecific); direct detection of HSV nucleic acid in cells, blood, or CSF by PCR; or serologic methods using Western blot or EIA.¹⁷⁵ Tissue culture currently is the most sensitive method for detecting mucocutaneous herpes simplex infection. Tests that measure serologic response (as in B.J.'s partner) are valuable in documenting primary infection, but they are not very usefully in recurrent infections. It is possible to differentiate between antibody to HSV-1 and HSV-2 by means of the Western blot assay. Point-of-care devices using HSV-1- and HSV-2-specific antibody testing kits offer ease, reduced time, differentiation between HSV-1 and HSV-2, and high sensitivities and specificities.^{6,192,193}

Primary HSV infections are characterized by a fourfold or greater rise in the HSV antibody titer as seen in B.J.'s case. Fewer than 10% of patients with recurrent episodes of disease experience a serologic rise in antibody titer between acute and convalescent sera.¹⁹⁴

B.J.'s partner's results need to be interpreted cautiously. The negative Pap smear is not completely diagnostic. A nonreactive serology (absence of HSV antibodies) implies the absence of a primary infection, although false-negative reactions have occurred. Absence of antibody to HSV-2 by Western blot would be good evidence against asymptomatic carriage.

Treatment

60. How should B.J.'s lesions be managed? Because the likelihood of recurrence of genital herpes is high, what treatment and prevention measures are recommended currently?

The great anxiety commonly associated with the diagnosis of genital herpes is because there is presently no cure available for the condition. Therapies ranging from antiviral agents and photoinactivation to investigational vaccines have been tried. Currently, only acyclovir (ACV), famciclovir (FCV), and valacyclovir (VCV) are used to treat and prevent genital herpes outbreaks.

The ideal anti-HSV agent should (a) prevent infection, (b) shorten the clinical course, (c) prevent the development of latency, (d) prevent recurrence in patients with established latency, (e) decrease transmission of disease, and (f) eradicate established latent infection.¹⁷² To date, no agent has been successful in achieving all of these goals.

All three agents, ACV, FCV, and VCV, are effective for the short-term treatment of some HSV infections. In general, ACV has been in clinical use longer than FCV or VCV and thus has more data to support its role in the treatment and suppression of mucocutaneous and visceral HSV infections. ACV, a nucleoside analog, is a substrate for HSV-specific thymidine kinase. Through a series of phosphorylation steps, ACV is transformed to ACV-triphosphate, a competitive inhibitor of viral DNA polymerase. ACV has potent in vitro activity against both HSV-1 and HSV-2 and is least active against varicella-zoster and cytomegalovirus.¹⁹⁵ FCV, a prodrug of penciclovir, has increased oral bioavailability. Once converted in the intestine and liver to the active form, penciclovir, it is quickly phosphorylated in HSV in a similar manner as ACV. VCV is the

L-valyl ester prodrug of ACV. The oral bioavailability of VCV is significantly better than ACV, producing plasma levels of ACV comparable to those attained with IV administered ACV, often eliminating the need for parenteral therapy with ACV.¹⁹⁶ All three antiviral drugs seem to have good clinical benefit for genital herpes infections.

In studies of severe, primary genital herpes, IV ACV (5 mg/kg Q 8 hr) significantly reduced the duration of viral shedding, decreased the duration of signs and symptoms of disease by a mean of 5 days, and hastened the time to healing of lesions by a mean of 6 to 12 days over placebo-treated patients.^{6,197} Similar findings have been shown in the immunocompromised patient population.¹⁹⁸ IV and oral ACV or VCV also prevent HSV reactivation in seropositive immunocompromised patients who are undergoing bone marrow transplantation.¹⁹⁹ For patients with HIV, ACV 400 mg PO three times daily, FCV 500 mg twice daily, or VCV 500 mg twice daily for 5 to 10 days have been used for recurrent episodes.⁶ Currently, IV therapy is recommended only for patients with severe genital or disseminated infections who cannot take oral medication.

Topical therapy with ACV ointment (5% in polyethylene glycol) has minimal effect on the duration of viral shedding, symptoms, and lesion healing in first-episode primary genital herpes and has no effect on the recurrence rate.¹⁹⁷ Currently, topical ACV is not recommended for primary genital herpes. Penciclovir 1% cream is applied every 2 hours while awake and has been shown to be effective for treatment of herpes simplex labialis,²⁰⁰ but insufficient data exist to recommend its use for genital herpes infections.

The introduction of oral agents (Table 65-13) has replaced the use of topical ACV and thus are indicated for B.J. Oral antivirals speed the healing and resolution of symptoms of

first and recurrent episodes of genital HSV-2 infections.²⁰¹ Treatment of primary infection after the first week of infection does not seem to change the natural history of recurrent outbreaks; thus, patients should be educated about risk of sexual transmission and prompt recognition of signs and symptoms and the early use of antivirals.²⁰² The frequency of recurrence decreases with time in most patients. Recurrent episodes of genital HSV-2 infection can be treated with any of the three available oral antivirals (Table 65-13). Rather than having to go into clinic, patients with recurrent infection should have a supply of their antiviral drug with them to allow early initiation of therapy, which may abort or reduce symptoms by 1 to 2 days.^{203,204}

Daily suppressive therapy with ACV, FCV, or VCV reduces the frequency of recurrent episodes up to 70% among patients with frequent (more than six episodes per year) genital herpes.^{6,205–207} Recurrent outbreaks diminish over time; thus, after each year of continuous suppressive therapy, an effort should be made to discuss discontinuing therapy with the patient.⁶ The use of suppressive therapy does not completely eliminate viral transmission. However, a recent randomized, controlled clinical trial of serodiscordant HSV-2–positive couples demonstrated a statistically significant decrease in the rate of transmission to uninfected partners when infected partners took 500 mg/day of VCV.²⁰⁸ This 8-month study was restricted to heterosexual partners with fewer than ten recurrences per year. The CDC recommends various dosing regimens for VCV, but the 500-mg once-daily dose appears to be less effective than the 1-g once-daily dose in patients with frequent recurrent episodes (i.e., > 10 episodes per year).⁶ Immunocompromised patients may require higher doses or more frequent intervals for suppression.²⁰⁹ An increased frequency of resistant strains has been reported in immunocompromised hosts who

Table 65-13 Antiviral Chemotherapy of Genital HSV-2 Infections

| | <i>Acyclovir</i> | <i>Valacyclovir</i> | <i>Famciclovir</i> | <i>Duration</i> | <i>Comments</i> |
|------------------------------|---|---|--------------------|-----------------|---|
| First clinical episode | 400 mg PO TID <i>or</i> 200 mg PO 5 per day | 1 g PO BID | 250 mg PO TID | 7–10 days | May extend treatment duration if healing is incomplete |
| Episodic recurrent infection | 400 mg PO TID <i>or</i> 200 mg PO 5 per day <i>or</i> 800 mg PO BID | 500 mg PO BID <i>or</i> 1 g QD | 125 mg PO BID | 5 days | Most effective if initiated within the first 24 hr of onset of lesions or during the prodrome |
| Daily suppressive therapy | 400 mg PO BID ^a | 500 mg PO QD ^b <i>or</i> 1 g PO QD | 250 mg PO BID | Daily | Reduces the frequency of genital herpes recurrences by ≥75% among patients who have frequent recurrences (i.e., ≥6 recurrences per year); use should be reevaluated at 1 yr |
| Severe disseminated | 5–10 mg/kg IV Q 8 hr | Not indicated | Not indicated | Variable | Hospitalize and treat until clinical resolution of symptoms Follow-up IV therapy with PO ACV to complete 10 days |
| HIV-infected: episodic | 400 mg PO TID <i>or</i> 200 mg 5 per day | 1 g PO BID ^c | 500 mg PO BID | 5–10 days | Treat until clinical resolution of lesions |
| HIV-infected: suppressive | 400–800 mg PO BID <i>or</i> TID | 500 mg PO BID ^d | 500 mg PO BID | | |

Note: Regimen recommendations derived from 2002 CDC Recommendations.⁶

^aSafety and efficacy up to 6 years have been documented with the use of acyclovir.

^bValacyclovir 500 mg QD seems less effective in patients with >10 episodes per year. Thus, 1 g QD should be used in these patients.

^cDosages up to 8 g/day have been used, but an association with a syndrome resembling either hemolytic uremic syndrome or thrombotic thrombocytopenic purpura was observed.

^dEffective in decreasing both the rate of recurrences and the rate of subclinical shedding among HIV-infected patients.

have used long-term therapy.²¹⁰ All ACV-resistant strains are also resistant to VCV, and most are resistant to FCV as well. Foscarnet 40 mg/kg IV every 8 hours may be used for severe ACV-resistant genital HSV infections.⁶ Cidofovir 1% gel (not commercially available in the United States, but has been compounded by pharmacists) applied once daily for 5 days may be an alternative to IV foscarnet, but more studies are needed.^{6,211}

B.J. is not yet a candidate for daily suppressive ACV therapy. A summary of the indications for ACV, FCV, and VCV is outlined in Table 65-13.

ADVERSE EFFECTS

61. What adverse effects secondary to ACV, FCV, or VCV should be anticipated?

Overall, all forms of ACV, including VCV and FCV, are associated with relatively few adverse reactions largely because of the drugs' affinity for viral thymidine kinase over cellular kinase.

Hematuria and an increase in blood urea nitrogen and serum creatinine may occur, primarily in patients with underlying renal disease or those receiving concomitant nephrotoxic agents. Transient elevations in serum creatinine are associated more frequently with IV than with oral administration. In addition, severe local reactions are possible with IV administration. In immunocompromised patients, VCV at a dosage of 8 g/day was associated with symptoms resembling a hemolytic uremic syndrome or thrombotic thrombocytopenic purpura, but in normal therapeutic doses, this has not occurred according to the manufacturer. When given intravenously in high doses or when significant dehydration exists, ACV has been shown to crystallize in the renal collecting tubules of animals, leading to renal insufficiency.²¹² ACV should not be rapidly infused or administered at concentrations >10 mg/mL. If oral ACV or VCV is administered to produce plasma levels equivalent to IV doses, similar changes in renal function may be observed. Dose adjustment is necessary for all three antiviral agents in patients with decreased renal function.

Although neurotoxicity is a rare side effect, case reports of coma and delirium have been reported in patients with renal failure and renally adjusted ACV dosages.^{213,214}

Intravenous ACV occasionally has been associated with cutaneous irritation and phlebitis, reversible leukopenia,²¹⁵ and transient elevations of liver transaminases. Oral ACV and VCV are relatively safe and do not produce any serious side effects at normal doses. Patients receiving oral ACV, VCV, or FCV may complain of nausea, dizziness, diarrhea, and headaches.

Patient Education and Counseling

62. What are the roles for education and counseling in patients with genital herpes? Are other forms of local or symptomatic care useful?

Most genital herpes infections are benign, and lesions heal spontaneously unless the patient is immunocompromised or the lesions have become infected secondarily. The patient should be instructed to keep the involved areas clean and dry. To prevent autoinoculation, the patient should be told not to touch the lesions and to wash his hands immediately afterward if he comes in contact inadvertently. Local anesthetics provide relief from the pain of genital lesions, but they should be avoided if possible because they counteract efforts to keep

the lesions dry. Local corticosteroid therapy is contraindicated because it may predispose the patient to secondary bacterial infections.

Patient counseling is an important facet in the therapy of genital herpes and should include the source contact and any future partner. Health care practitioners should attempt to relieve patients' feelings of guilt and anxiety; discussion of long-term consequences should take place after the acute symptoms of the infection have resolved.

For individuals with frequent recurrences, efforts should be made to identify and avoid stimulatory factors such as sunlight, trauma, or emotional stress. The limitations of therapy and the decreased severity and frequency of recurrences with time should be explained to the patient. The periods of infectivity and the need to avoid sexual activity during these times also should be emphasized, although subclinical or asymptomatic shedding does occur, indicating the need for continuous barrier protection. Women with herpes genitalis should be scheduled for routine Pap smears and should be instructed to discuss the problem with their physicians if they become pregnant.

Currently, there is no completely effective way to prevent the transmission of HSV-2 infection. Barrier forms of contraception, in particular condoms, may reduce the transmission of HSV, but this may be limited only to male-to-female transmission owing to the large area that herpes lesions may occupy on the female.¹⁸⁴ However, recent evidence suggests that a higher frequency of use by males of condoms can increase protection and thus condoms should be recommended routinely to prevent HSV infections in males and females.¹⁸⁶ Nonoxynol-9, a spermicide that has in vitro anti-HSV activity, is ineffective in the treatment of established genital HSV infection and may actually increase the risk of transmission of HSV by causing genital ulceration.²¹⁶

Complications

63. M.F. is a 23-year-old, sexually active female student with a history of frequent and severe recurrences of genital herpes since her initial infection 3 years ago. M.F. has tried numerous therapies, including suppressive and episodic antivirals. None of these therapies has provided M.F. with any relief of her symptoms, nor have they decreased the frequency of her recurrences. M.F. has read much in the lay press about herpes and is concerned about the possible complications of the disease, especially cervical cancer. What are the potential complications of herpes genitalis?

Previous research suggested that HSV-2 might be an oncogenic agent responsible for carcinoma of the cervix. The theoretical association between HSV-2 and carcinoma of the cervix was most likely biased by cross-sectionally designed studies, misclassification, confounding with HPV, now known to cause cervical cancer, and lack of power. A large longitudinal nested case-control study using nearly 20 years of seroepidemiologic and epidemiologic data combined with a meta-analysis concluded that it is very unlikely that HSV-2 is associated with the development of invasive cervical carcinoma.²¹⁷

Pregnancy

64. A.P., a 26-year-old woman in her 32nd week of gestation, was hospitalized with complaints of painful genital lesions, headache, fever, increased vaginal discharge, and dysuria of 1 week's

duration. Multiple ulcerative lesions consistent with genital herpes were present on the cervix, vulva, labia minora, and thighs. How should A.P. be treated?

Herpes genitalis seropositivity in pregnant women occurs more frequently than in nonpregnant women, with 30% to 60% of all pregnant women having serologic evidence of HSV-2 infection.¹⁷² Unfortunately, a large proportion of those infections occurring during pregnancy are limited to the cervix and are totally asymptomatic, often eluding diagnosis.

Pregnant patients with a history of recurrent genital herpes should be examined carefully when they present in labor for evidence of active disease. The safety of systemic ACV and VCV in pregnant women has not been established in controlled trials and therefore is not clearly indicated for A.P. Some small studies suggest ACV administered for several weeks before delivery may decrease recurrent outbreaks and lessen the need for herpes-related cesarean section,²¹⁸ whereas a larger randomized clinical trial did not show a benefit on reducing the need for a cesarean delivery with primary infection.²¹⁹ In general, it does seem that patients with symptomatic genital herpes benefit from caesarian section.²²⁰ The manufacturer of Zovirax (ACV) maintains an extensive database of fetal complications related to ACV use. To date, no link between ACV and birth defects has been established.²²¹ The decision to treat HSV with ACV during pregnancy should depend on the clinical severity of infection. Fetal exposure data to FCV or VCV are limited. If the mother has an active herpes genitalis infection at the time of delivery (either active genital lesions or asymptomatic HSV-2 cervicitis), the baby should be delivered by cesarean section within 4 hours after the membranes have ruptured to prevent exposure of the neonate to the virus.¹⁷² However, if no genital lesions are present at the time of labor, vaginal delivery may be recommended.⁶ There is evidence that up to 70% of neonatal herpes cases occur in asymptomatic women and the use of ACV or VCV after 36 weeks gestation may decrease clinical disease and viral shedding to the fetus.²²²

Neonatal herpes is a devastating systemic infection of the newborn, associated with high morbidity and mortality. In 1994, assuming an average incidence of 265 cases of neonatal HSV per year, the estimated annual cost to the health care system was \$10.5 million.¹ HSV-2 usually is transmitted to the newborn during passage through an infected birth canal, although ascending infections in newborns delivered by cesarean section 6 hours after the membranes have ruptured have been known to occur.²²³ The risk of transmission to the newborn is greatest in mothers who acquire an initial infection late in the third trimester and lower in mothers with recurrent infection or those who acquire herpes in the first trimester.⁶ A primary episode of clinically apparent HSV-2 results in neonatal HSV-2 infection 50% of the time; 33% of the time in asymptomatic primary infection; 4% if lesions are due to recurrent infection; and 0.04% in nonprimary asymptomatic infection.²²⁴

GENITAL WARTS

65. S.L., a 19-year-old woman, presents to the women's health clinic for her annual pelvic examination. One week later, her Pap smear is read as showing koilocytosis. A colposcopy is subsequently performed, revealing changes consistent with cervical flat warts. What is the cause of S.L.'s infection? How should she be managed?

HPV, primarily types 6 and 11, are the cause of genital warts, or condylomata acuminata. In the United States, the overall prevalence of HPV infection in women 14 to 59 years is 26.8%, with most occurring among 14- to 24-year-olds.²²⁵ Other types of HPV, including 16 and 18, are strongly associated with cervical cancer.²²⁶ These cause Pap smear changes, including koilocytosis and cervical dysplasia. A common cervical cancer grading system, cervical intraepithelial neoplasia (CIN), uses histologic changes to classify specimens in three categories, CIN1, -2, and -3. The higher the CIN, the greater the chance of progressing to invasive cervical cancer. Most new cases of HPV infection spontaneously regress, but with progressive histologic changes, the chance of spontaneously regressing diminishes (CIN1, 60%; CIN2, 30%; CIN3, 10%).²²⁷ Types of HPV are also classified as high risk, or those likely to cause cancer, and low risk, those less likely to cause cancer. HPV types 16 and 18 are considered high risk and types 6 and 11 are low risk, mostly resulting genital warts. In women, visible warts occur on the labia, introitus, and vagina. Subclinical lesions also commonly occur on these sites and on the cervix, as in S.L.'s case. They are visible only by colposcopy after applying acetic acid. Men can sexually transmit HPV infections to women as well as develop genital warts, and anal and penile cancer associated with oncogenic HPV types, especially type 16.²²⁸

The goal of HPV therapy is the removal of symptomatic warts. Several therapeutic options are available and include patient-administered treatments to visible warts such as podofilox 0.5% solution or gel and imiquimod 5% cream and provider-administered products such as topical treatments (podophyllin 10%–25%, trichloroacetic acid 80%–90%, and cryotherapy), surgery (laser or scalpel), and intralesional interferon.⁶ None of these treatments has been shown to eradicate HPV infection or alter the natural history of HPV. It is important to individualize therapy, considering location and number of warts, patient preference, cost, and convenience.

Podophyllin, compounded as a 10% to 25% solution in tincture of benzoin, is applied by the health care provider to visible warts. After application, it is washed off 3 to 4 hours later and then reapplied once or twice a week until the warts have disappeared. Podofilox 0.5% solution or gel, the active component of podophyllin resin, may be applied by the patient with a cotton swab, or podofilox gel with a finger, to visible genital warts twice a day for 3 days, followed by 4 days of no therapy. A total of four cycles, 0.5 mL/day, or application of an area larger than 10 cm² should not be exceeded. Podofilox solution is not suitable for use with perianal warts; the gel is more practical for this region. Podophyllin is potentially neurotoxic if absorbed in large amounts. Podofilox has the advantage over podophyllin resin in that it has a longer shelf life, does not need to be washed off, and has less systemic toxicity.²²⁹ Therefore, it should be applied in limited doses and should also be avoided in pregnancy. The rate of wart recurrence after podophyllin therapy is extremely high, probably 50%. With the high cost of clinic care and the high recurrence rate, home treatment of HPV with podofilox solution may be more cost effective and equally efficacious.²³⁰

Imiquimod induces cytokines and activates the cell-mediated immune system. In initial trials, complete clearance of warts took place in 37% to 50% of immunocompetent patients, but up to 20% experienced recurrence.²³¹ A 5% cream may be applied with a finger at bedtime three times per week

for up to 16 weeks. It is usually left on for 6 to 10 hours before it is washed off with soap and water. Imiquimod may take as long as 8 weeks before warts are cleared. Mild to moderate local irritation occurs in more than half of the patients who use it, especially when used daily instead of three times weekly.²³²

Cryotherapy by application of liquid nitrogen can be more effective than podophyllin, but requires special equipment and highly trained personnel to avoid over- or undertreating warts. Pain and skin blistering after treatment is not unusual. Cryotherapy is associated with little systemic toxicity and is useful against oral, anal, urethral, and vaginal warts.

Trichloroacetic acid (80%–90%) is used topically in the treatment of some genital warts, but its efficacy is uncertain. To date, interferons are not recommended because of expense, frequent occurrence of toxicity when given systemically, and limited efficacy for intralesional administration. Cases refractory to topical drug therapy should be considered for surgical treatment.

Prevention

In 2006, the first vaccine to prevent HPV types 6, 11, 16, and 18 was approved in the United States. This quadrivalent vaccine was tested in women from 15 to 26 years of age with 98% to 100% protection against HPV types contained in the

vaccine.^{233,234} This three-dose series can be given as early as 9 years of age, but is CDC recommended at 11 to 12 years as part of a routine adolescent health care visit and ideally before commencement of sexual activity.²³⁵ Because there are more than 30 types of HPV associated with anogenital disease, a previous HPV infection is not a contraindication to vaccination. It is also important to note that receipt of the HPV vaccine does not change the recommendation for Pap smears. It is also not a therapeutic vaccine; it has no effect on clearing a current HPV infection.²³⁶

VACCINES

Prevention and control of STDs have largely revolved around education and antimicrobials. Immunization, however, holds the promise of protecting large numbers of people before they are at risk for STDs as well as targeting those who already have the infection. Hepatitis B is an example of an STD with a highly effective vaccine that is now mandatory for school-aged children. The quadrivalent HPV vaccine is gaining momentum and a bivalent (HPV 16 and 18) is awaiting review and approval by the FDA. Herpes simplex vaccines have been extensively studied, but no candidate vaccine has been submitted for approval.

Osteomyelitis is an inflammation of the bone marrow and surrounding bone caused by an infecting organism. Any bone can be involved. Serious morbidity often occurs even with early diagnosis and treatment. Despite the continued refinement of diagnostic procedures (e.g., radionuclide imaging, magnetic resonance imaging), advances in antimicrobial therapy, and the use of prophylactic antibiotics before orthopedic procedures, osteomyelitis continues to be a serious problem because the infection is not always cured.

Previously, osteomyelitis was more common in children and the elderly, and the causative microorganisms were usually Gram-positive cocci such as streptococci and staphylococci. Although *Staphylococcus aureus* remains the most common causative organism, the prevalence of infection caused by Gram-negative and anaerobic bacilli is increasing. Osteomyelitis can affect all age groups.¹

Bone can be infected by three routes: hematogenous spread of bacteria from a distant infection site, direct infection of bone from an adjacent or contiguous source of infection, and infection of bone because of vascular insufficiency. Table 66-1 summarizes important characteristics of these types of osteomyelitis.^{1,2} Patients with recurrent osteomyelitis are considered to have chronic osteomyelitis.

BONE ANATOMY AND PHYSIOLOGY

Understanding the pathophysiology of osteomyelitis requires a basic understanding of bone anatomy and physiology. Figure 66-1 is a graphic representation of a long bone. The bone is divided into three sections: the epiphysis, located at the end

of the bone; the metaphysis; and the diaphysis. The epiphysis and metaphysis are separated by the epiphyseal growth plate. This is the rapidly growing area of the bone, supported by many blood vessels. Surrounding most of the bone is a fibrous and cellular envelope. The external portion of this envelope is called the *periosteum*, and the internal portion is referred to as the *endosteum*.

The blood vessels that supply bone tissue are located predominantly in the bone's epiphysis and metaphysis. The nutrient arteries enter the bone at the metaphyseal side of the epiphyseal growth plate and lead to capillaries that form sharp loops within the growth plate. These capillaries lead to large sinusoidal veins that eventually exit the metaphysis of the bone through a nutrient vein. Within the sinusoidal veins, blood flow is slowed considerably, and infection can begin if bacteria settle here.

Variations exist in the vasculature of bone in different age groups, leading to different forms of osteomyelitis. In neonates and adults, vascular communications are present between the epiphysis and metaphysis, which can allow infection to spread from bone to the adjacent joint. During childhood, however, this area often is protected from infection because the epiphyseal plate separates the vascular supply for these two regions.

HEMATOGENOUS OSTEOMYELITIS

Hematogenous osteomyelitis classically has been a disease of children, although the number of cases reported in adults is increasing. Osteomyelitis in children tends to be acute and hematogenous and is often responsive to antibiotic therapy

Table 66-1 Features of Osteomyelitis

| Feature | Hematogenous | Adjacent Site of Infection | Vascular Insufficiency |
|-------------------------|--|--|---|
| Usual age of onset (yr) | <20; >50 | >40 | >40 |
| Sites of infection | Long bones, vertebrae | Femur, tibia, skull, mandible | Feet |
| Risk factors | Bacteremia | Surgery, trauma, cellulitis; joint prosthesis | Diabetes, peripheral vascular disease |
| Common bacteria | <i>Staphylococcus aureus</i> , Gram-negative bacilli; usually one organism | <i>S. aureus</i> , Gram-negative bacilli; anaerobic organisms; often mixed infection | <i>S. aureus</i> , coagulase-negative staphylococci, streptococci, Gram-negative and anaerobic organisms; usually mixed infection |
| Clinical findings | | | |
| Initial episode | Fever, chills, local tenderness, swelling; limitation of motion | Fever, warmth, swelling; unstable joint | Pain, swelling, drainage, ulcer formation |
| Recurrent episode | Drainage | Drainage, sinus tract | As above |

alone. In comparison, osteomyelitis in adults tends to be subacute or chronic and commonly results from trauma, prosthetic devices, or other insult. As a result, surgical débridement often is needed in addition to antibiotics when treating osteomyelitis in adults.

Infection in children develops primarily in the metaphysis of the rapidly growing long bones of the body, probably because the slow blood flow in these areas allows bacteria to settle and multiply. The acute infectious process (e.g., edema, inflammation, small vessel thrombosis) causes a rise in pressure within the bone that compromises blood flow and eventually leads to necrosis. Released cytokines alter bone integrity by promoting osteoclast activity. Eventually, the elevated pressure and necrosis might cause devitalized bone to fragment from healthy bone (sequestra). With continued spread of the infection into the outer layers of the bone and soft tissue, abscess and draining sinus tracts form.^{1,2}

In children, hematogenous infection most commonly occurs in the long bones, as a single focus in the femur and tibia.¹ In adults, the vertebrae are more commonly involved,

and infection usually occurs in the fifth and sixth decades of life.³ In neonates, hematogenous osteomyelitis is an especially serious disease that often involves multiple bones, especially the long bones. Rapid spread across the epiphyseal plate can involve the adjacent joint, making immediate, aggressive treatment crucial.

The most common organism causing hematogenous osteomyelitis in children is *S. aureus*, which is caused partly by the proclivity of this bacterial species to settle and adhere to bone and cartilage. In adults, *S. aureus* is also the most common causative pathogen. Gram-negative bacilli (*Escherichia coli*, *Klebsiella*, *Proteus*, *Salmonella*, and *Pseudomonas*), however, are responsible for an increasing number of cases of osteomyelitis. Intravenous (IV) drug abuse often leads to infection with *Pseudomonas aeruginosa*, whereas *Salmonella* species is a common cause in patients with sickle cell anemia.^{1,2}

The clinical features of hematogenous osteomyelitis vary, depending on the patient's age and the infection site. In children, infection usually is characterized by an abrupt onset of high fever and chills, localized pain, tenderness, and swelling. Systemic symptoms often are absent in neonates, delaying the diagnosis. A diagnosis, therefore, must be made on the basis of localized symptoms such as edema and restricted limb movement. Systemic symptoms are also less common in adults. Patients with vertebral osteomyelitis can present with the insidious onset of localized back pain and tenderness.^{1,3}

ACUTE OSTEOMYELITIS

Usual Clinical Presentation

1. T.S., a 9-year-old boy, is unable to go to school today because of fever and increasing leg pain. Three to four days ago, he says his upper left leg started to hurt and he began limping last night. There is no history of trauma to the area. His only past medical history is two episodes of otitis media at ages 4 and 6. In the pediatrician's office today, maximal tenderness is focally localized over the left distal femur without knee joint effusion. No visible signs of swelling, warmth, or trauma are seen. His white blood cell (WBC) count is 7,000 cells/mm³ (normal, 5,000–10,000), with a normal WBC differential. Plain radiographic studies of the left leg are normal, but the erythrocyte sedimentation rate (ESR) is 62 mm/hour (normal, 0–15). Two blood cultures are obtained, and T.S. is sent home with directions for bed rest and use of

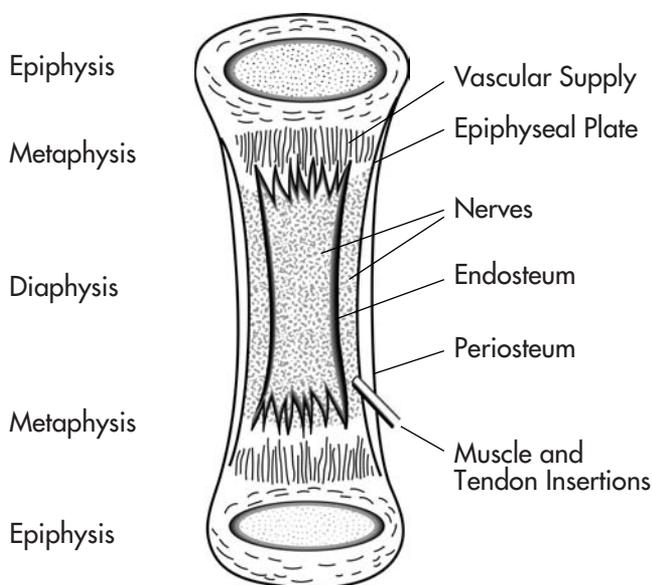

FIGURE 66-1 Long bone anatomy. Source: Adapted from Triffitt JT. Organic matrix of bone tissue. In: Urist MR, ed. *Fundamental and Clinical Bone Physiology*. Philadelphia, Pa.: JB Lippincott; 1980:46.

acetaminophen as needed for fever. However, 2 days later, he is admitted to the hospital because of severe pain and tenderness in his left leg and a fever of 38.8°C. The blood cultures obtained 2 days ago are positive for *S. aureus*, sensitive to oxacillin (OSSA), and the C-reactive protein (CRP) is 14 mg/dL (normal, <2.0). Another x-ray study is again normal, but a magnetic resonance imaging (MRI) scan is positive for inflammation in the left distal femur. What findings in T.S. are consistent with hematogenous osteomyelitis?

[SI units: WBC, $7,000 \times 10^9/L$ (normal, 5,000–10,000); ESR, 62 mm/hour (normal, 0–15); CRP, 14 mg/dL (normal, <2.0)]

T.S. displays the usual signs and symptoms of acute hematogenous osteomyelitis in children. He is a previously healthy child who developed acute localized pain and tenderness of the left distal femur, abrupt onset of high fever, and an elevated ESR. The plain radiographic study was normal on two occasions before hospitalization; however, plain radiographs of bone are usually normal during the first 2 weeks of infection. MRI scans usually can detect bone changes earlier in the course of disease, and T.S.'s MRI scan on hospitalization detected inflammation in the left distal femur.² Although T.S. did not have a bone biopsy sent for culture, his clinical picture, a positive MRI scan, and blood cultures positive for *S. aureus* establish the diagnosis of osteomyelitis.^{2,4} As in many cases of osteomyelitis, the specific event that caused bacteremia with bacterial dissemination to bone is unknown.

Several laboratory tests should be obtained in every child suspected of having osteomyelitis. Although these tests are not specific for the diagnosis of osteomyelitis, they help confirm the clinical diagnosis. A complete blood count (CBC) and an ESR are routinely obtained. The serum CRP, when elevated, is a measure of systemic inflammation.

An increased WBC count is consistent with osteomyelitis, but significant leukocytosis is absent in many children with osteomyelitis at the initial examination. Thus, T.S.'s WBC count of 7,000/mm³ is not unusual. In adults, leukocytosis does occur, but it is more commonly associated with an acute infection than with recurrent disease. When leukocytosis is present, the WBC count rarely exceeds 15,000/mm³.^{2,5}

Although the ESR and the CRP are relatively nonspecific, most patients with osteomyelitis have ESR values >20 mm/hour and a CRP >2.0 mg/dL.² Therefore, the increased ESR and CRP in T.S. are consistent with osteomyelitis. Destructive changes of bone can be seen in plain radiographs, although these do not appear for at least 10 to 14 days after the onset of infection.² MRI scans can detect inflammation of bone more quickly than plain radiographs.⁶ Hence, a normal plain film does not rule out acute osteomyelitis if obtained within the first 2 weeks of infection. The MRI scan in T.S. was extremely helpful because acute osteomyelitis was detected before the appearance of osteomyelitis on plain x-ray film.

Predisposing factors for hematogenous osteomyelitis include any risk factors that promote bacteremia (e.g., indwelling catheters, hemodialysis shunts, central venous catheters used for chemotherapy or parenteral nutrition). A distant focus in the gastrointestinal or urinary tract can lead to bacteremia and predispose a patient to the development of osteomyelitis. Intravenous (IV) drug abuse leading to bacteremia can be a predisposing factor for osteomyelitis. None of these factors seem to have predisposed T.S. to the development of osteomyelitis. In

children such as T.S. who have no history of fractures or penetrating injury, the most common cause for acute hematogenous osteomyelitis is *S. aureus*, including methicillin-resistant strains.^{1,2,4,7}

Patient Workup

2. What additional patient and diagnostic information should be obtained before T.S. receives his first dose of antibiotics?

Before T.S. receives antibiotic therapy, he should be assessed for drug allergies, especially penicillin allergy. Patient interviews, discussions with his parents, and a comprehensive review of his medical record are necessary, especially if a history of allergy is reported. Details of an allergic reaction, including symptoms, onset of the reaction, probable causative agent, treatment, and exposure to related compounds, should be sought.

Cultures of blood and bone aspirate material are the best ways to identify the specific bacterial cause for osteomyelitis and are often part of the initial workup. Cultures taken after antibiotics are started often are negative, however, thereby necessitating the use of empiric broad-spectrum antibiotic therapy for several weeks. As a result, both the cost of therapy and the risk of toxicity increase.

In T.S.'s case, the positive blood culture and MRI scan establish the diagnosis of osteomyelitis without the need for a bone culture. If the blood cultures had been negative, however, a bone aspirate for culture to identify the pathogen would be recommended.^{1,2} Once material has been obtained for culture, initial empiric therapy should start as soon as possible.

Treatment

Empiric Antibiotic Therapy

3. T.S. has no history of drug allergies; he took amoxicillin for the previous episodes of acute otitis media without incident. What antibiotic treatment should be started? What is the relevance of bone concentrations or protein binding of antibiotics in the selection of therapy for osteomyelitis?

For initial antimicrobial treatment of hematogenous osteomyelitis, the agent chosen should be administered IV at high dosages to achieve adequate levels in the infected bone. It is important to initiate treatment as soon as possible to improve the chances for complete eradication of infection and to avoid the need for surgery. Thus, empiric antibiotic therapy often is instituted before culture and sensitivity results are known.

Based on the epidemiology of T.S.'s infection and the results of the blood culture, he should be treated for *S. aureus* osteomyelitis. In both children and adults, approximately one-third of cases of acute osteomyelitis are currently caused by oxacillin-resistant strains (ORSA).^{7–9} Hence, initial, empiric treatment should be with IV vancomycin until susceptibility results indicate the isolate is oxacillin- (or nafcillin-) susceptible. In the absence of susceptibility results or if the isolate is oxacillin-resistant, therapy would continue with vancomycin. Recurrent infection rates with vancomycin therapy are concerning, however; thus, it is crucial that appropriate biopsy and culture results are obtained whenever possible so that patients receive β -lactam-based therapy for

Table 66-2 Empiric Intravenous Antibiotics for Acute Osteomyelitis in Children

| Host | Likely Etiologies | Antibiotics | Dosage | |
|--------------------------------------|---|--|--------------|-------------|
| | | | (mg/kg/day) | (doses/day) |
| Neonate | <i>Staphylococcus aureus</i> | Oxacillin (or nafcillin) + | 100 | 4 |
| | Group B streptococci | cefotaxime <i>or</i> | 150 | 3 |
| | Gram-negative bacilli | Oxacillin (or nafcillin) + gentamicin | 100 5–7.5 | 4 3 |
| <3 yr | <i>S. aureus</i> | Vancomycin <i>or</i> | 45 | 4 |
| | <i>Haemophilus influenzae</i> type b | Cefuroxime <i>or</i> | 50 | 2 |
| | | Oxacillin (or nafcillin) + cefotaxime | 150 100 | 4 4 |
| ≥3 yr | <i>S. aureus</i> | Vancomycin <i>or</i> | 45 | 4 |
| | | Oxacillin (or nafcillin) <i>or</i> | 150 | 4 |
| | | Cefazolin <i>or</i> | 100 | 3 |
| | | Clindamycin | 30–40 | 3 |
| After puncture wound through shoe | <i>P. aeruginosa</i> | Ceftazidime | 150 | 3 |
| Child with sickle cell disease | <i>Salmonella</i> sp. <i>S. aureus</i> | Oxacillin (or nafcillin) + | 150 | 4 |
| | | cefotaxime <i>or</i> | 100 | 4 |
| | | Vancomycin + | 45 | 4 |
| | | cefotaxime | 100 | 4 |

oxacillin-susceptible isolates.^{10,11} Because of less experience in treating ORSA osteomyelitis, clindamycin or linezolid should be used only in patients who are vancomycin intolerant. Other organisms that can cause osteomyelitis include *Staphylococcus epidermidis*, *Streptococcus pyogenes*, *Streptococcus pneumoniae*, *Haemophilus influenzae*, and *P. aeruginosa*. In the neonate with osteomyelitis, *S. aureus* and *Streptococcus* species are commonly responsible.¹ T.S.'s blood culture grew OSSA and he is not allergic to penicillin. He is placed on IV oxacillin therapy at 150 mg/kg/day Q 6 hr. He could have been started on IV nafcillin instead of oxacillin because these two drugs are therapeutically equivalent, and are given in similar dosage. His prior exposure to amoxicillin is irrelevant except to establish the absence of a penicillin allergy.

Under circumstances of negative cultures or while blood or bone cultures are pending, the age of the child with acute osteomyelitis is important in the selection of appropriate empiric antibiotics. Table 66-2 summarizes recommended drugs and dosages in children with acute osteomyelitis.^{1,4,12}

Antibiotic Bone Penetration and Protein Binding

The importance of selecting an antibiotic that penetrates into bone when treating osteomyelitis is unclear, nor does a clear relationship exist between bone concentrations and outcome of therapy.^{1,2,13} Theoretically, drug protein binding could influence clinical efficacy because it is believed that the free drug, rather than the protein-bound drug, diffuses from plasma into bone tissue. Studies evaluating the penetration of highly protein-bound drugs, such as cefazolin (90% protein bound), show high cefazolin bone levels after a single 1-g IV dose, exceeding levels achieved with cephalothin, a drug with only 20% protein binding. In addition, cefazolin and ceftriaxone, two highly protein-bound drugs, usually are effective in treating osteomyelitis, provided high dosages are given for an ex-

tended period, and the responsible pathogen is susceptible. In summary, antibiotic bone concentrations and protein binding of antibiotics (when appropriate dosages are used) are not significant factors in the selection of appropriate therapy for osteomyelitis.^{1,2}

Duration of Therapy

4. The *S. aureus* grown from T.S.'s blood culture is OSSA. Is oxacillin the best antibiotic choice, or would other antibiotics, given less frequently, also be adequate therapy?

Continuing to treat T.S. with IV oxacillin (or nafcillin) every 6 hours follows treatment recommendations for OSSA osteomyelitis. Antistaphylococcal penicillins achieve high levels in bone and usually provide effective therapy when the treatment regimen is followed with frequent doses for an adequate duration. Changing T.S. to cefazolin would allow slightly less frequent dosing (Q 8 hr), a potential advantage for home treatment. Vancomycin use should be discouraged in T.S.'s case because cultures grew an oxacillin-sensitive organism, and vancomycin is associated with higher rates of treatment failure.^{10,11} While the logistics of outpatient therapy in T.S. are being investigated, he should remain on oxacillin while in the hospital.

5. Both of T.S.'s parents are employed, and their work schedules would prevent them from leaving their jobs to transport him to an outpatient antibiotic treatment center. Is T.S. a candidate for outpatient IV antibiotic therapy at home, or could oral antibiotic treatment be considered at this time? Must T.S. remain in the hospital to receive his oxacillin?

Initially, all patients should receive IV antibiotics because early, aggressive therapy offers the best chance to cure the infection. T.S., however, does not necessarily need to stay in

the hospital to complete therapy. A peripheral central catheter (PICC) can be inserted for treatment, with antibiotic administered via continuous infusion pump.^{1,2,4} Whether T.S. should go home on IV antibiotics must be decided in concert with his parents. If they do not have the resources or are unwilling to oversee IV treatment at home, T.S. should remain hospitalized to assess the first week of treatment. In any case, expecting a 9-year-old boy such as T.S. to complete several weeks of IV therapy at home is overly optimistic. Furthermore, catheter complications (e.g., dislodgment, infection, or occlusion) are concerns. As discussed in Question 6, T.S. may be able to complete most of his course of treatment with oral antibiotics. Oral antibiotics, however, should not be given to T.S. until the effectiveness of the first week of IV therapy can be assessed. The total duration of IV and oral therapy for T.S. should be at least 4 weeks, or until the ESR has returned to the normal range.^{1,2,12}

Use of Oral Antibiotics

6. After 1 week of IV oxacillin, T.S. is afebrile and the pain and tenderness in his left leg are significantly reduced. The ESR is 40 mm/hour, and CRP is 6.0 mg/dL. The plan is to switch T.S. to oral antibiotics to complete a 4-week course of treatment at home. What is an appropriate dosing regimen, and how often should he return to the clinic for evaluation?

[SI units: ESR, 40 mm/hour; CRP, 6.0 mg/dL]

Because IV therapy for several weeks is inconvenient and expensive, even at home, patients such as T.S. who have responded to IV antibiotics can be switched to oral therapy. Again, this decision must be made in concert with T.S.'s parents, who must understand the vital importance of frequent antibiotic doses in these circumstances. Oral antibiotics are appropriate only if a clear clinical response to IV therapy has occurred over 7 to 10 days, and the patient can swallow and tolerate oral therapy in adequate dosage.^{1,4}

Thus, T.S. is a candidate for oral therapy, assuming his parents agree to supervise treatment once he leaves the hospital. T.S. has responded promptly to the IV therapy: his fever, leg pain, and tenderness have resolved, the ESR and CRP are reduced. The CRP changes more quickly in response to adequate antimicrobial therapy than does the ESR.¹⁴ Oral therapy, however, will be effective only if T.S. is compliant. Therefore, assurances must be in place to guarantee that all doses will be taken. T.S.'s parents have made arrangements with his fourth-grade teacher to help him take his oral antibiotic during the day.

T.S. can complete his 4-week course of antibiotics with oral dosing of cephalexin capsules or suspension, which seems to taste better (and hence is usually better tolerated) than dicloxacillin suspension. Cephalexin dosage should begin at 37.5 mg/kg Q 6 hr. Close follow-up of T.S. (weekly) is required under these circumstances to monitor compliance and clinical response to therapy. Parenteral therapy should be reinitiated promptly if T.S.'s compliance is not perfect, or symptoms (or increased ESR or CRP) recur.^{4,12,15} Initial oral therapy with a quinolone is not appropriate for T.S. primarily because staphylococci resistance to ciprofloxacin has emerged, and secondarily because quinolone use is relatively contraindicated in children. Dosages of oral antibiotics for children with osteomyelitis are summarized in Table 66-3.¹²

Table 66-3 Oral Antibiotic Doses for the Treatment of Osteomyelitis in Children

| Drug | Dosage(mg/kg/day) | Interval between Doses (hr) |
|---------------|-------------------|-----------------------------|
| Penicillin V | 125 | 4 |
| Dicloxacillin | 100 | 6 |
| Amoxicillin | 100 | 6 |
| Cephalexin | 150 | 6 |
| Cefaclor | 150 | 6 |
| Clindamycin | 40 | 8 |

Duration of Follow-Up for Recurrent Infection

7. T.S. has completed 4 weeks of treatment for his acute staphylococcal osteomyelitis. Clinical evidence shows that the osteomyelitis is completely resolved, and the ESR and CRP are normal. For how long should T.S. be followed for possible recurrence of his infection?

Relapses of osteomyelitis can occur years after the initial acute episode.^{1,2} In T.S.'s case of uncomplicated acute osteomyelitis, he should be evaluated for recurrence at least every 3 months for at least 2 years.

SECONDARY OSTEOMYELITIS

Osteomyelitis Secondary to a Contiguous Source Infection

8. R.W., a 56-year-old man, suffered an open right tibial fracture 4 weeks ago in a motorcycle accident. His fracture was set by open reduction and external fixation. Cefazolin, given as surgical prophylaxis, was continued for 24 hours. Antibiotics were then switched to IV ampicillin/sulbactam for 1 week, followed by oral amoxicillin/clavulanic acid, which he is still taking today. The postoperative course was unremarkable until yesterday, when he developed right leg pain and spontaneous drainage from the surgical wound. On presentation, his right shin is tender, warm, swollen, and erythematous, but he is afebrile. Other physical findings are within normal limits. Laboratory data, including WBC count, serum creatinine, and blood urea nitrogen (BUN), are normal, but the ESR is 38 mm/hour, and CRP is 8 mg/dL. Plain bone films and bone MRI show inflammation and nonhealing of the tibial fracture. What findings in R.W. are characteristic of secondary osteomyelitis?

Few of the systemic signs and symptoms usually associated with acute osteomyelitis are seen in secondary osteomyelitis. The objective findings usually present in hematogenous disease, such as fever, leukocytosis, and an elevated ESR, can be absent. The most common subjective complaint in acute contiguous osteomyelitis is pain in the area of infection, which often is accompanied by localized tenderness, swelling, erythema, and drainage. Because several weeks might pass before the patient becomes symptomatic, radiographic studies at the time of diagnosis might reveal abnormalities consistent with bone deterioration.^{1,2}

Clinical Presentation

R.W.'s case is consistent with osteomyelitis secondary to a contiguous focus of infection. Probable infection has arisen

in his right leg at the site of surgical repair of a fracture of his right tibia. R.W.'s localized symptoms, along with the absence of fever and leukocytosis, are characteristic of secondary osteomyelitis. In these cases, bone becomes infected from an exogenous source, or through spread of an infection from adjacent tissue to bone. Infection can result from any trauma followed by an orthopedic procedure to fix a bone fracture. The bones most commonly involved are the hip, tibia, femur, and fibula.^{1,2}

Other associated situations are caused by contiguous spread of an infection. These include any penetrating injury, such as a gunshot wound or a nail puncture, or soft tissue infections, such as pressure sores or those involving the fingers and toes.

Unlike hematogenous osteomyelitis, which occurs mostly in children, acute contiguous infection occurs more often in adults. This is explained by the higher incidence of precipitating factors within this age group, such as hip fractures, orthopedic procedures, oral cancers, sternotomy incisions for cardiac surgery, and craniotomies.^{1,2}

Common Pathogens

Whereas hematogenous osteomyelitis usually involves a single pathogen, coinfection with several organisms is common in contiguous-spread osteomyelitis. Thus, although *S. aureus* is the most common pathogen, it is often part of a mixed infection. Other organisms responsible for infection include *Pseudomonas*, *Proteus*, *Streptococcus*, and *Klebsiella* species, *E. coli*, and *S. epidermidis*. Most cases of osteomyelitis involving the mandible, pelvis, and small bones (e.g., those of the hands and feet) are caused by Gram-negative organisms. *Pseudomonas* often is isolated from infections after puncture wounds of the foot.^{1,2}

Anaerobes also are associated with contiguous-spread osteomyelitis. The anaerobic organisms most commonly isolated are *Bacteroides* species and anaerobic cocci. Possible predisposing factors include previous fractures or injuries resulting from human bites. Adjacent soft tissue infections can also lead to anaerobic bone infections, as in the case of sacral osteomyelitis secondary to severe decubitus ulcers.

To establish the pathogenic organisms, R.W. should have surgical re-evaluation and a biopsy of involved bone at the probable site of infection.^{1,2} The bone films and MRI scan will help localize the possible infectious process to direct the surgical biopsy.

Initial Treatment

9. R.W. returns to the operating room for surgical exploration, and bone tissue is obtained for culture. He has no drug allergies. The initial postoperative antibiotic order is for vancomycin, 1 g IV Q 12 hr. Is this adequate antibiotic treatment for R.W.?

R.W. has had surgery to obtain bone material for culture because cultures of adjacent wound or sinus tract material are not predictive of the bacteria actually infecting the bone.¹⁶ Broad antibiotic coverage is necessary now because *S. aureus* and polymicrobial Gram-negative aerobic bacilli most likely are causing this infection.¹ R.W. already has been started on vancomycin to cover for *S. aureus*; however, a third- or fourth-generation cephalosporin (cefotaxime, ceftriaxone, ceftazidime, or cefepime) or a quinolone (ciprofloxacin) should be added for Gram-negative coverage. Cefepime (2 g

IV Q 12 hr) or meropenem (1 g IV Q 8 hr) is suggested in cases involving *P. aeruginosa*, although other antipseudomonal drugs (e.g., ceftazidime, aztreonam, imipenem) would also be appropriate.² Vancomycin usually is adequate for effective treatment of ORSA infection, although optimal trough concentrations are not defined; some authors suggest trough concentrations should be in the 15 to 20 mcg/mL range.^{17,18} Third-generation cephalosporins or quinolones should not be used to treat serious staphylococcal infection; therefore, combined therapy with antistaphylococcal penicillins (if OSSA) or vancomycin is necessary.¹ Oxacillin and vancomycin have activity against Gram-positive anaerobes, but not against an important Gram-negative anaerobe, *Bacteroides fragilis*. If *B. fragilis* is cultured from bone, additional therapy with metronidazole is indicated. Alternatively, combined, broad aerobic (including *Pseudomonas*) and anaerobic Gram-negative coverage could be provided by β -lactam/ β -lactamase inhibitor combination therapy with piperacillin/tazobactam. While cultures are pending for R.W., his antibiotic regimen is changed to vancomycin 1.5 g IV Q 12 hr and ciprofloxacin 400 mg IV Q 12 hr.

OSTEOMYELITIS CAUSED BY PSEUDOMONAS

10. The bone biopsy from R.W. grows *P. aeruginosa*, which is sensitive to piperacillin, ceftazidime, imipenem, gentamicin, tobramycin, and ciprofloxacin. His leg pain is no worse than it was 2 days ago, and he remains afebrile. How should R.W. now be treated? Is he a candidate for oral therapy?

Traditional aggressive therapy for R.W. would include gentamicin or tobramycin plus a second agent active against *Pseudomonas*, such as piperacillin, ceftazidime, or ciprofloxacin. More recently, antipseudomonal therapy with a β -lactam plus ciprofloxacin combination has been used with increasing frequency to avoid the complications of aminoglycosides. Thus, vancomycin should be discontinued. There is reasonable experience treating *Pseudomonas* osteomyelitis with an antipseudomonal β -lactam, with an aminoglycoside added (both depending on sensitivities), to complete a 4-week course of therapy.¹ R.W. can receive cefipime (2 g IV Q 12 hr) plus gentamicin as initial therapy. To facilitate antibiotic therapy at home, R.W. is a candidate for once-daily dosing of gentamicin.¹ Because his renal function is normal, a single daily dose of 5 to 7 mg/kg can be administered. Although only a few reports exist of extended-dose aminoglycoside use in osteomyelitis, for other Gram-negative infections considerable evidence indicates that once-a-day therapy is as effective and possibly less toxic as multiple daily doses.^{19,20} At home, R.W. should have serum creatinine and trough gentamicin concentrations measured weekly. Desired trough levels are <1 mcg/mL.

In an effort to avoid aminoglycoside toxicity, some investigators have administered cephalosporins or ciprofloxacin alone for 4 to 6 weeks to treat osteomyelitis caused by *Pseudomonas*. These studies are inadequate, however, because they involved small case series without control groups or their follow-up time was too short (6 months).²¹⁻²³ Furthermore, studies do not yet support the use of oral quinolones (ciprofloxacin) alone in these cases.²⁴ To provide the best chance of cure, R.W. should receive cefipime and gentamicin for the entire 4-week course of therapy. The relative effectiveness of cefipime plus ciprofloxacin

is unknown. R.W.'s antibiotic therapy can be reasonably accomplished at home. If gentamicin nephrotoxicity occurs or if he develops an allergic reaction to cefipime, oral ciprofloxacin (750 mg PO Q 12 hr) can be used to complete the full 4-week course of therapy. He should be followed closely thereafter for at least 2 years to detect recurrent infection.

OSTEOMYELITIS ASSOCIATED WITH VASCULAR INSUFFICIENCY

11. P.G., a 60-year-old man, presents to the diabetes clinic with an ulcer on the inferior surface of his left big toe. This lesion began as a red spot about 6 months ago, but is now an ulcer approximately 2 cm wide × 1 cm deep. He has not paid much attention to it because it has not been very painful. The ulcer is not foul smelling. P.G. has had type 2 diabetes mellitus for 20 years and is currently treated with oral glipizide and metformin. Otherwise, he has no other complaints, but notes that his toe sore began after he started using a new pair of shoes about 7 months ago. Laboratory data obtained earlier today show a normal WBC count and differential, and normal electrolytes, BUN, and creatinine. His fasting blood glucose, however, is 240 mg/dL (normal, 65–110), and the ESR is 45 mm/hour (normal, 0–15). What findings in P.G. are consistent with secondary osteomyelitis?

[SI units: fasting plasma glucose, 13.3 mmol/L (normal, 3.6–6.1); ESR, 45 mm/hour (normal, 0–15)]

P.G. has chronic lower extremity vascular insufficiency as a result of type 2 diabetes. Patients such as P.G. with impaired blood flow usually develop osteomyelitis in the toes or small bones of the feet. Infection often first presents as cellulitis, as in P.G.'s case, which commonly progresses to deep ulcers. Finally, the infection spreads to the underlying bone. In many cases of osteomyelitis associated with vascular insufficiency, multiple pathogens can be cultured from surgical specimens or the wound. The most commonly isolated pathogens are *S. aureus*; however, Gram-negative and anaerobic bacteria also are often recovered.

Similar to contiguous-spread osteomyelitis, systemic signs of infection (e.g., fever and leukocytosis) are often absent in patients who develop bone infection secondary to vascular insufficiency. Local symptoms, such as pain, swelling, and erythema, usually dominate the picture.^{1,2,25}

P.G. may have a bone infection that underlies a chronic, cutaneous ulcer on the bottom of his left big toe. Because of likely diabetic neuropathy, the skin lesion may not be very painful, and poor blood supply to the site likely contributed to the development of a chronic infection and possibly secondary osteomyelitis. Clinically, osteomyelitis is suggested by his elevated ESR and fasting glucose (consistent with infection). In addition, diabetic foot ulcers that are >2 cm wide and >2 cm deep, or that penetrate to bone, are often predictive for underlying osteomyelitis.^{25,26}

Antibiotic Selection

12. P.G.'s wound is débrided, and material obtained from a deep wound swab is sent to the microbiology laboratory for cultures. He is hospitalized to receive wound care and to begin antibiotics. He

has no drug allergies, and he is started on vancomycin (1 g IV Q 12 hr) and oral ciprofloxacin (750 mg Q 12 hr). Is this appropriate initial therapy?

The antibiotic treatment selected for P.G. should be active against both Gram-positive and Gram-negative aerobic bacteria. Because anaerobic, Gram-negative bacteria are cultured from bone in diabetic patients with osteomyelitis ≤15% of the time, empiric anaerobic coverage may not be necessary at this stage of treatment.^{27,28} Because of the emergence of community-associated ORSA infection, vancomycin plus a third-generation cephalosporin (ceftriaxone, ceftazidime) or a quinolone (ciprofloxacin, levofloxacin) for Gram-negative coverage is a frequently used empiric regimen. If anaerobic bacteria are believed to be clinically involved (e.g., foul-smelling wound), metronidazole (Flagyl) should be added to the regimen. Hence, the initial regimen of vancomycin and ciprofloxacin for P.G. is rational. Further antibiotic refinement should occur after the results of the deep wound swab culture are available. The duration of IV therapy for diabetic foot osteomyelitis is not defined.^{26,28} Emerging evidence indicates the effectiveness of oral linezolid (600 mg Q 12 hr) to treat osteomyelitis caused by ORSA in diabetic patients.^{29,30} Other useful oral drugs for staphylococcal infections, depending on susceptibilities and patient tolerance, are clindamycin (300 Q 8 hr), trimethoprim-sulfamethoxazole (two DS Q 12 hr), and amoxicillin/clavulanate (Augmentin, 850 mg or Q 12 hr). The overall duration of combination therapy can range from 6 weeks to 10 months or more, depending on the healing rate of the ulcer.²⁸

P.G. should also be made aware that osteomyelitis associated with diabetic foot ulcers is difficult to treat because poor circulation can impair antibiotic delivery to the infection site. Despite surgical débridement of the infection followed by appropriate treatment with long-term IV and oral antibiotic therapy, cure rates are low. Even minor amputations (one or two toes) are unsuccessful in eradicating infection. Radical surgical approaches, such as transmetatarsal, below-the-knee, or above-the-knee amputations, often are necessary to cure these infections.^{1,2,26,31}

CHRONIC OSTEOMYELITIS

Clinical Presentation

13. F.B., a 48-year-old man, sustained a fracture of the left humerus in an automobile accident 6 years ago. That fracture clinically healed without any immediate consequences. However, 1 year ago, a draining sinus tract developed at the site of the previous fracture without any antecedent events. He has taken various oral antibiotics over this last year, including cephalexin and ciprofloxacin, which he stopped taking 2 months ago. One month ago, he noted increased sinus drainage, pain, swelling, and erythema of his left upper arm, and ciprofloxacin was restarted. A swab culture of the sinus drainage grew *S. epidermidis*, *E. coli*, *Peptostreptococcus micros*, and *Bacteroides* species. Two days ago, while off of antibiotics for a week, surgical débridement of bone and tissue was performed because of a further increase in drainage and poor appearance of the wound. Gentamicin-impregnated polymethylmethacrylate (PMMA) beads were placed in the tissue adjacent to the débrided

bone during surgery. Bone cultures grew *Proteus mirabilis*, *P. micros*, and *B. fragilis*. The *Proteus* was resistant to ampicillin, ceftazidime, ticarcillin, and ciprofloxacin, but sensitive to ceftaxime, ceftriaxone, imipenem, gentamicin, and trimethoprim-sulfamethoxazole. Antibiotic sensitivities for the *Bacteroides* were not tested. What aspects of F.B.'s case are characteristic of chronic osteomyelitis?

Inadequate treatment of an acute episode of osteomyelitis can lead to formation of necrotic, infected bone and recurrent symptoms consistent with chronic disease. Even with appropriate initial therapy, osteomyelitis can reactivate, even with different organisms from the initial episode. Some propose that previously infected bone might be a focus of reduced resistance to infection, and then at risk for reinfection.³² Persistent symptoms or signs lasting longer than 10 days correlate with chronic osteomyelitis and the development of necrotic bone.¹ Draining sinus tracts often develop from the bone to the skin in cases of chronic osteomyelitis.³³

F.B. probably developed a chronic bone infection after the automobile accident. The reappearance of sinus tract drainage in his left upper arm indicates an indolent infection of bone that was periodically suppressed, but not treated by oral antibiotics. Cultures of sinus drainage now grow multiple organisms, and components of the topical normal bacterial flora are found. These cultures usually do not correlate with the organisms actually causing bone infection.¹⁶ F.B.'s recurrent course of bone involvement with drainage and local symptoms, and lack of any remarkable systemic symptoms, is classic for chronic osteomyelitis.³³

Surgery and Oral Antibiotics

14. Oral ciprofloxacin (750 mg BID) was restarted 1 month ago when F.B.'s left arm became more painful and drainage increased. Was his poor response to therapy unexpected? How should his case have been managed?

F.B.'s poor response should have been expected for at least two reasons. Antibiotic therapy was started before surgical débridement of avascular tissue, and he was given an antibiotic that is ineffective because of resistance against the cultured organisms from bone.

Surgery plays an important role in the treatment of chronic osteomyelitis. Bone necrosis will progress if decompression and drainage of the infected area is not carried out as soon as possible. Furthermore, without initial surgical removal of necrotic bone and other poorly vascularized, infected material, even IV antibiotics are likely to fail.

After surgery, it is important to achieve high levels of antibiotics that have been selected based on culture results from specimens obtained by deep aspiration or bone biopsy. Antibiotics should not be selected based on culture results from sinus tract drainage because these cultures do not correlate with the actual causative organisms. F.B. should be treated initially with IV antibiotics because of relatively poor blood flow at the infection site. Although the optimal duration of therapy for chronic osteomyelitis is not well studied,^{1,2,34} parenteral therapy is generally recommended for 6 to 8 weeks, followed by 3 to 12 months of oral antibiotic therapy, depending on the healing rate.²

Finally, F.B. should continue to be evaluated by an orthopedic surgeon because he may require further surgical treatment to eradicate chronically infected bone.

Intravenous Antibiotics

15. What would be reasonable antibiotic therapy for F.B.?

On the basis of the bone culture and sensitivity results, F.B. needs high-dose therapy directed at *P. mirabilis* and *B. fragilis*. For convenience and possible future home therapy, ceftriaxone (2 g IV Q 24 hr) could be started for coverage of *Proteus*. The anaerobic activity of ceftriaxone is inadequate for infections caused by *Bacteroides*. Therefore, metronidazole (500 mg IV Q 8 hr) also should be started. Because of excellent oral bioavailability, the metronidazole can be rapidly converted to oral therapy at the same dose before discharge. Piperacillin/tazobactam (Zosyn) or ertapenem (Invanz) could be an alternative choice for home IV therapy circumstances, assuming it is documented that the *Proteus* isolate is sensitive to either agent. Both of these drugs would also provide excellent activity against anaerobic bacteria. Ertapenem is convenient for home therapy because it can be given once daily (1 g IV Q 24 hr).

After 6 to 8 weeks of parenteral therapy (which can be completed at home), F.B. should be closely evaluated for response. If symptoms have been reduced, then treatment with oral antibiotics (trimethoprim-sulfamethoxazole and metronidazole) should continue for at least 6 to 8 weeks, but treatment can be continued for several additional months based on resolution of the sinus tract drainage, pain, and tenderness in F.B.'s arm. Under these circumstances, F.B. should be monitored closely for possible adverse effects of these drugs given chronically (hepatitis, cytopenias, neuropathy). If the sinus tract does not heal or if F.B.'s arm remains painful, surgical exploration and bone cultures must be repeated.

Local Antibiotics

16. What are the rationale for and effectiveness of local antibiotic administration (the PMMA beads) inserted during F.B.'s orthopedic surgery?

To deliver high concentrations of antibiotics to poorly vascularized bone infection sites, various materials containing antibiotics have been placed at the infection site during surgery. Plaster pellets, fibrin, collagen, hydroxyapatite, and PMMA impregnated with antibiotic, usually an aminoglycoside or vancomycin, have been used. The dosage form is designed for the slow release of antibiotics from the material. The most commonly reported experience with local antibiotic delivery has been with antibiotic-impregnated PMMA cement or beads inserted during joint arthroplasty. Recurrent infection rates have been comparable in patients treated with local antibiotic insertion and those treated with systemic antibiotics. Thus, no evidence suggests that the PMMA beads will improve F.B.'s outcome when added to systemic therapy. Local delivery of antibiotics should never replace systemic antibiotics in the treatment of chronic osteomyelitis.³⁵

OSTEOMYELITIS ASSOCIATED WITH PROSTHETIC MATERIAL

Usual Clinical Presentation

17. S.M., a 73-year-old woman, had right hip replacement 8 years ago for chronic osteoarthritis. She is seen today in the orthopedic clinic because of increasing right hip pain for the last 3 months. The hip is painful and warm, but her temperature is 37.5°C. Aspiration of fluid from the hip reveals a total nucleated cell count of 80,000/mm³ with 90% neutrophils. A Gram stain of this fluid shows 4+ polymorphonuclear leukocytes (PMN) and 1+ Gram-positive cocci. Her peripheral WBC count is 8,800 cells/mm³. She is started on antibiotic therapy with vancomycin and piperacillin/tazobactam pending culture results, and she is scheduled for operative evaluation and possible removal of her prosthetic joint. Does S.M. have a prosthetic joint infection?

[SI unit: WBC, 8,800 × 10⁹ cells/L]

Joint replacement surgery has become a common orthopedic procedure for patients with significant joint destruction as a result of rheumatoid arthritis (RA) and other disabling diseases. Prosthetic knee, shoulder, elbow, or hip devices made of metallic alloys are cemented to adjacent bone to re-establish joint function. Infection of these foreign bodies can occur because of hematogenous dissemination of bacteria or by contiguous spread from a topical wound. *Staphylococcus* species are most commonly involved in prosthetic joint infections, followed by *Streptococcus* species, Gram-negative bacilli, and anaerobes. Bacteria infect bone adjacent to the joint prosthesis, including the bone–cement interface, which results in a loosened and less functional prosthesis.³⁶

Chronic pain, swelling, erythema, and tenderness over a prosthetic joint are typical findings associated with prosthetic joint infection. S.M. has a relatively lengthy duration of symptoms associated with her right hip, which also could be caused by joint loosening, but the cell count and differential from the joint aspirate suggest joint infection. Also, the predominance of neutrophils in her joint fluid and Gram-positive cocci on a Gram stain are consistent with an infected prosthesis. As is often the case, she has no obvious source of infection on her skin or other site from which bacteria could disseminate. Occasionally, sources of infection with hematogenous dissemination to the prosthetic joint are identified, such as dental infections, cellulitis, or urinary tract infections. Given the Gram stain result, S.M. should be covered for *Staphylococcus* and *Streptococcus* species with vancomycin, pending the results of cultures and sensitivities. *Staphylococcus* species, including coagulase-negative species such as *S. epidermidis*, are the most commonly isolated bacteria responsible for prosthetic infection. These coagulase-negative *Staphylococci* are especially adherent to prosthetic material and, although coagulase-negative *Staphylococci* are usually considered a contaminant in culture, and when a prosthesis is in place, it should be considered a likely pathogen. Coagulase-negative *Staphylococci* are often resistant to oxacillin, but are susceptible to vancomycin. Because Gram-negative bacteria also can infect these joints, it is reasonable to add Gram-negative coverage to S.M.'s regimen until the results of joint fluid cultures are available.

Surgery

18. Does S.M. need surgery and antibiotics to cure her infection?

Yes. Surgery to remove S.M.'s hip prosthesis and chronic antibiotics for 6 weeks are the current recommendations for optimal eradication of prosthetic joint infection.^{1,36} A two-stage orthopedic procedure is involved: removal of the infected prosthesis, placement of an antibiotic-filled spacer or block, joint immobilization, and antibiotics for 6 weeks. If the joint space remains culture negative, a new joint prosthesis is reinserted. Because avascular bone cement and prosthetic material can become seeded with bacteria, complete removal of this material is necessary to have the greatest chance of curing the infection. Six weeks of systemic antibiotic therapy in combination with orthopedic surgery results in restoration of joint function in 85% to 95% of cases. High rates of treatment failure (~70%) occur if the joint prosthesis is not removed and chronic suppressive antibiotics are not given.^{36,37}

Antibiotics

19. Because the pelvic portion of S.M.'s hip prosthesis is so firmly attached to bone, the surgeon decides not to remove this portion of the prosthesis because doing so would require a pelvic fracture. Instead, her hip is débrided and the acetabular lining material is replaced. Purulent material is sent for culture. The removed lining material and three swabs of the right hip prosthesis grow OSSA. How should S.M. be treated?

To prevent recurrence of infection, S.M. will need to take antibiotics indefinitely, perhaps for the rest of her life if the original prosthesis remains in place. Lifelong therapy is impractical, expensive, and likely to provoke adverse effects. S.M. should be treated initially with oxacillin (2 g IV Q 4 hr) for at least 2 weeks, although the optimal duration of this initial parenteral therapy is unknown. Thereafter, she should be treated with oral antibiotics. Limited success has been reported with the use of ciprofloxacin plus rifampin, both given orally, in patients with prosthetic joint infections caused by *Staphylococcus* species in which the implant was not removed. In 18 patients with a short duration of symptoms (<21 days), oral ciprofloxacin (750 mg BID daily) and oral rifampin (450 mg BID daily) were given for 3 months. Twelve patients who completed the protocol had no evidence of infection at 24 months of follow-up.³⁸ S.M.'s symptoms have lasted 3 months, suggesting that her infection may not respond to therapy as well as that reported. Nevertheless, a prolonged course of ciprofloxacin and rifampin could be tried for at least 3 months.³⁸ Because S.M. grew OSSA (and assuming the isolate is also rifampin-sensitive), she could be treated chronically with dicloxacillin plus rifampin. Rifampin should be used when possible for prosthetic joint infection caused by staphylococci.³⁶ An important consideration before using rifampin is to make sure the patient is not taking other agents (e.g., warfarin, anticonvulsants) where a detrimental rifampin-induced drug interaction could occur.³⁹ A third option for oral therapy is linezolid (Zyvox). Limited data exist on the use of linezolid for prosthetic joint infection, however, and chronic use is associated with thrombocytopenia. If linezolid is used for >2 weeks, S.M.'s platelet count should be followed weekly.^{29,40}

20. S.F. is a 48-year-old man with hemophilia A and chronic bilateral knee hemarthroses. He has been human immunodeficiency virus (HIV) seropositive for 12 years; his last CD4 count 1 month ago was 480 cells/mm³ (normal, >800). One week ago, he had uncomplicated bilateral knee arthroplasty. Cefazolin prophylaxis was administered before surgery and for 24 hours postoperatively. Soon after surgery, he noted intermittent chills and sweats accompanied by documented fevers. Two blood cultures drawn 3 days postoperatively were negative, and he was started on ampicillin/sulbactam (Unasyn) and gentamicin. Two more blood cultures drawn 3 days later are positive for *P. aeruginosa*, sensitive to ceftazidime, piperacillin, imipenem, ciprofloxacin, and gentamicin. The surgical sites are unremarkable. His antiretroviral medications are zidovudine and lamivudine (Combivir) and efavirenz (Sustiva). What is a rational antibiotic therapy plan for S.F.?

Antibiotic treatment for S.F. should be designed to treat his *Pseudomonas* bacteremia and also to eradicate and then suppress *Pseudomonas* that may have seeded his prosthetic joints. Without symptoms related to his knees (pain, swelling, redness, tenderness), it will be impossible to tell whether the joint has become infected without removing the prosthesis. The conservative approach is to treat S.F. with combined antipseudomonal antibiotics, such as ceftazidime (2 g IV Q 8 hr) and once-daily gentamicin for 6 weeks, followed by chronic suppressive therapy with oral ciprofloxacin for the rest of his life.³⁶ No evidence indicates that adjunctive rifampin improves outcomes in Gram-negative infections. Also, rifampin would interact significantly with S.F.'s antiretroviral therapy, particularly efavirenz.³⁹

SEPTIC ARTHRITIS

Nongonococcal Arthritis

21. M.T., a 65-year-old man, is referred to the rheumatology clinic for left knee swelling. One week ago, his left knee became painful and swollen and he was unable to flex the joint. He also noted a temperature of 100.5°F to 102°F for at least 5 days. In clinic, a joint effusion is noted, and fluid is aspirated for cell count, a Gram stain, and culture. His medical history is unremarkable except for an episode of hives after receiving cephalexin for cellulitis 2 years ago. M.T.'s WBC count is 14,000 cells/mm³, and his ESR is 40 mm/hour. The synovial fluid from his right knee contains 50,000 WBCs/mm³ with 94% neutrophils, and the Gram stain shows Gram-positive cocci in clusters. Culture results are pending. His temperature is 38.5°C. What findings in M.T. are consistent with septic arthritis?

[SI units: WBC count, 12,000 and 80,000 × 10⁹ cells/L, respectively; neutrophils, 0.94; ESR, 40 mm/hour]

Usual Clinical Presentation

Septic arthritis or infectious arthritis usually is acquired hematogenously. The highly vascular synovium of the joint allows easy passage of bacteria from blood into the synovial space. Bacteremia, secondary to *Neisseria gonorrhoeae* or *S. aureus* in particular, often is associated with the development of joint infections. Septic arthritis also can develop secondary to the spread of osteomyelitis into the joint. This is especially a problem in children <1 year of age who still have capillaries perforating the epiphyseal growth plate.^{2,4}

Several factors predispose patients to the development of infectious arthritis. Trauma can directly inoculate the synovium or allow infecting organisms to penetrate it more easily. Patients with certain systemic disorders, such as diabetes mellitus, RA, osteoarthritis, chronic granulomatous disease, cancer, or chronic liver disease, are more susceptible to the development of infection. Endocrine factors can predispose pregnant or menstruating women to the development of gonococcal arthritis. In the menstruating patient, this can be explained partially by the increased endocervical shedding of *N. gonorrhoeae*.^{41,42}

M.T. has had an acute onset of monoarticular joint pain and swelling, with reduced range of motion and fever. These findings are classic for septic, nongonococcal arthritis. The tap of his joint effusion with a predominance of neutrophils in the joint fluid confirms the diagnosis. In these circumstances, M.T.'s knee has been infected hematogenously from a distant, usually unrecognized, source of infection. The knee is involved most commonly, and *S. aureus* is the usual causative organism. If M.T. had a urinary tract infection, however, Gram-negative bacilli would more commonly be responsible for joint infection. Occasionally, a predisposing factor is present in the involved joint, such as pre-existing arthritis (i.e., RA) or trauma.^{41,42}

A single joint is involved in 90% of bacterial arthritis cases. As in M.T.'s case, the joint most commonly involved is the knee. Other potential sites of infectious arthritis in adults include the hip, shoulder, sternoclavicular and sacroiliac joints; the ankle and elbow are common sites of infection in children. The wrist and interphalangeal joints of the hand also may be involved, but in these cases, the infectious pathogens are most often *N. gonorrhoeae* and *Mycobacterium tuberculosis*.⁴¹ The most common systemic indication of infectious arthritis is fever. Localized symptoms include pain, decreased mobility of the involved joint, and swelling.

As illustrated by M.T., most patients also have joint effusion on physical examination. When evaluating a patient who may have a joint infection, any purulent joint effusion should be considered septic until a thorough workup proves otherwise. Alternatively, noninfectious conditions may be present, such as single joint involvement with synovial effusions (e.g., acute RA, gout, chondrocalcinosis).⁴¹

Aspirated joint fluid should be cultured because isolation of bacteria is the only definitive diagnostic test for bacterial arthritis. M.T.'s joint fluid picture also is typical. The leukocyte count in the synovial fluid usually is significantly elevated, with counts ranging from 50,000 to 200,000 cells/mm³. Leukocyte counts of <20,000 rarely are seen during infection, except in early cases of bacterial arthritis or in patients with disseminated gonococcal infection (DGI). Synovial fluid from an infected joint also may have a decreased glucose concentration, but this is seen in only about 50% of cases.⁴¹

Another laboratory finding in M.T. that is consistent with infectious arthritis is the elevated ESR. Although this value is higher in bacterial infection, viral or fungal arthritis also can be associated with this finding. Increased WBC counts in serum are common in younger patients, but rare in adults. Anemia also can be associated with infection, especially in patients with chronic involvement or in cases where predisposing factors such as RA are present.⁴²

When attempting to determine the most likely pathogen, the patient's age must be taken into consideration. In adults >30 years of age such as M.T., and in children >2 years of

age, *S. aureus* is the most common cause of bacterial arthritis. In adults <30 years of age, *N. gonorrhoeae* is more likely to be the causative agent. *Streptococci*, such as group A β -hemolytic *Streptococci*, can cause infection in children and adults. Other organisms, such as group B *Streptococci*, anaerobic *Streptococci*, and Gram-negative bacteria, can cause infection. Gram-negative bacilli are responsible for approximately 15% of cases and often infect multiple joints. Infections with these organisms usually are associated with predisposing factors, such as RA, osteoarthritis, or heroin use. The organism most commonly isolated from patients with bacterial arthritis who have a history of IV drug abuse is *P. aeruginosa*.^{41,42}

Initial Antimicrobial Therapy: Treatment in β -Lactam Allergic Patients

22. M.T. describes his reaction to cephalexin as intense pruritic skin lesions over his trunk and upper extremities that appeared acutely (several hours) after he had received several doses. He did not experience wheezing or shortness of breath, and his reaction was treated symptomatically with diphenhydramine and discontinuation of the cephalexin. He had received several types of oral antibiotics before this episode of pruritus without difficulty, but has not taken antibiotics since then. How should M.T. be treated?

Treatment of nongonococcal arthritis includes drainage of purulent joint fluid (by needle aspiration or surgery) and appropriate antibiotic therapy. Because *S. aureus* is most likely involved, initial empiric therapy with a penicillinase-resistant penicillin, a cephalosporin, or vancomycin should be initiated. M.T.'s reaction to cephalexin is worrisome, however, because readministration of a penicillin or cephalosporin could cause allergic symptoms. An alternative, effective non- β -lactam treatment is available, however. Because M.T.'s septic arthritis is probably caused by *S. aureus* and, perhaps, streptococci, vancomycin (1 g IV Q 12 hr), which covers both organisms, should be started as soon as possible. In patients who are not allergic to penicillin, oxacillin or nafcillin (2 g IV Q 4 hr) is recommended for OSSA infections. β -lactams and vancomycin penetrate joint effusions adequately for Gram-positive infections. If M.T. acquired his infection in the hospital, vancomycin also would be initially indicated because of the possibility that ORSA is involved. In a nonallergic patient, therapy then can be changed on the basis of sensitivity testing to oxacillin if the organism is susceptible.^{41,42}

Duration of Therapy

23. How long should M.T. be treated? How should the efficacy of treatment be monitored?

Although few studies have been carried out to determine the optimal duration of therapy for bacterial arthritis, the current recommendation is 2 to 3 weeks; some investigators recommend that treatment be extended to 4 weeks for infectious arthritis caused by *S. aureus* or Gram-negative bacilli.^{41,42}

M.T. should be treated for at least 3 weeks.^{42,43} His response to therapy should be monitored clinically (resolution of symptoms, fever, and falling ESR, CRP, or both) as well as by periodic evaluation of joint fluid. Frequent aspirations of joint fluid, initially on a daily basis, should be done, with evaluation of cell count and fluid culture. Effective therapy results

in a diminishing WBC count in the joint fluid and negative cultures, usually within 3 to 4 days of treatment. A poorer outcome (permanent joint dysfunction) can result if joint fluid cultures are still positive after 6 days of treatment for Gram-positive infection. If fluid cultures are persistently positive, more aggressive surgical management is necessary to preserve joint function.^{41,42}

Most joint fluid cultures become negative after 7 days of treatment with IV antibiotics. Joint inflammation and other symptoms also should diminish by this time. The duration of articular symptoms before antibiotic therapy is begun correlates with the subsequent time required to sterilize the synovial fluid. Therefore, delay in initiating antibiotic treatment may necessitate a longer course of therapy.

As in hematogenous osteomyelitis, oral antibiotics have been used in septic arthritis to complete a course of treatment if the initial response to IV therapy is adequate. Oral therapy should not be considered until the patient is afebrile, joint fluid cultures are negative, the ESR or CRP is normal, and there is decreased joint pain and increased joint mobility.⁴² There are case series with generally positive results, but adequately controlled, randomized clinical trials comparing IV and oral therapy are not available.⁴³ Because of M.T.'s allergy to cephalexin, the choice of adequate oral therapy to complete at least 3 weeks of treatment is difficult. Because of the continuing emergence of resistance among Gram-positive organisms to ciprofloxacin, use of this agent is not recommended. Oral clindamycin could be used, but published experience in adults is minimal and there would be concern about the possible development of antibiotic-associated colitis. Use of linezolid (Zyvox) in septic arthritis is also not extensively reported in the literature. If the *S. aureus* isolated from M.T. is sensitive to trimethoprim-sulfamethoxazole, this agent may be an alternative to clindamycin for oral treatment. Published experience with this mode of treatment also is lacking. M.T. should be advised that parenteral treatment with vancomycin, which can be accomplished at home, would be the most effective mode of treatment. Finally, injections of antibiotics into the joint space are of no value. Most antibiotics readily penetrate the joint space and enter the synovial fluid.^{41,42}

Gonococcal Arthritis

24. J.E., a 21-year-old woman, presents to the walk-in clinic with right knee and right shoulder pain, nausea, and vomiting. On physical examination, her right knee is swollen and she has decreased range of motion of her right shoulder. Several erythematous, papular skin lesions are noted on both hands. She also has a vaginal discharge. Her temperature is 38.2°C, and her WBC count is 15,000 cells/mm³. She gives a history of having two recent sexual partners. Cultures of blood, joint fluid, and vaginal discharge are obtained; a joint fluid Gram stain shows 4+ PMNs, but no organisms are seen. Why is J.E. considered to have gonococcal arthritis?

[SI unit: WBC, 15,000 \times 10⁹ cells/L]

Usual Clinical Presentation

Polyarticular arthritis in a young, sexually active adult, as is the case with J.E., is caused most commonly by *N. gonorrhoeae*. Arthritis in multiple joints is one of the most common features

of disseminated gonococcal infection (DGI). Unlike nongonococcal arthritis, which is almost exclusively monoarticular, gonococcal arthritis involves multiple joints in approximately 50% of cases. Clinically, patients present initially with a migratory polyarthralgia and later with fever, dermatitis, and tenosynovitis. Skin lesions are an important clue to the diagnosis of DGI and often begin as tiny erythematous papules and develop into larger vesicles. Other symptoms, such as purulent and swollen joints, are present in only 30% to 40% of patients. As in hematogenously acquired nongonococcal arthritis, the synovial fluid leukocyte count usually is elevated, but to a lesser degree. *N. gonorrhoeae* is recovered in <50% of purulent joint effusions, however, but blood cultures often are positive for this organism and, coupled with the patient's clinical presentation, can be used to make a definitive diagnosis.^{41,44}

J.E. has systemic signs of infection, skin lesions, and multiple joint involvement, which are classic for DGI. Her history of recent sexual activity and the presence of a vaginal discharge are consistent with gonococcal infection, although evidence of mucosal infection with *N. gonorrhoeae* is not necessary for disseminated infection to occur.^{41,44}

Patient Workup and Treatment in the Clinic

25. What additional workup should be done in J.E.? Can she be treated immediately in the clinic?

J.E. should be evaluated for other sexually transmitted diseases, specifically syphilis and HIV infection. Serologic testing for syphilis (rapid plasma reagent [RPR] or venereal disease research laboratory [VDRL] testing) and for antibody to HIV should be obtained. In addition, she should have a pregnancy test because some of the antibiotics that may be used in J.E. are contraindicated during pregnancy, including doxycycline.

Because of possible penicillinase production by *N. gonorrhoeae*, recommended therapy is with ceftriaxone (1 g intramuscularly or IV Q 24 hr) initially. J.E. should receive her first dose of ceftriaxone in the clinic today. Parenteral treatment should continue for 1 to 2 days after improvement begins; at that point, oral cephalosporin therapy (cefixime 400 mg BID or cefpodoxime 400 mg BID) can be started. Quinolone-resistant *N. gonorrhoeae* are prevalent throughout the United States, so the use of ciprofloxacin or levofloxacin as treatment is no longer recommended by the Centers for Disease Control and Prevention (CDC). The duration of antibiotic treatment is 7 to 14 days.^{42,45}

J.E.'s sexual partners should also be evaluated and treated for relevant sexually transmitted diseases.

Full Course of Therapy

26. Results of RPR and pregnancy testing in J.E. are negative. How should she complete her course of therapy?

J.E.'s DGI should be treated for at least 7 days. J.E. also should begin treatment with azithromycin (1 g orally once) or doxycycline (100 mg orally BID for 7 days) for the possibility of concomitant chlamydial infection. J.E. can complete her course of treatment for DGI orally, although parenteral therapy is recommended until signs and symptoms resolve. This usually takes 2 to 4 days.⁴⁴ She will have to return to the clinic for daily ceftriaxone administration unless other arrangements for parenteral therapy can be made. Current recommendations from the CDC are that oral treatment should be with either cefixime (400 mg BID) or cefpodoxime (400 mg BID).⁴⁵ Treatment guidelines for DGI are included in the gonorrhea section of the chapter on sexually transmitted diseases.

Skin and soft tissue infections refer to infections involving any or all layers of the skin (epidermis, dermis), subcutaneous fat, fascia, or muscle. Many terms or classifications are used to describe various skin and soft tissue infections, and these often are based on the site of infection and causative organism(s). The terms or classifications, however, add little to the understanding and treatment of these infections. In fact, confusion in terminology may be detrimental if treatment is delayed until a causative organism is identified.

Although mild skin and soft tissue infections often are self-limiting, moderate to severe infections can progress to complicated infections, such as septic arthritis, osteomyelitis, or systemic infections (bacteremia), if not treated appropriately. Soft tissue infections in diabetic patients can lead to gangrene and loss of limb, whereas necrotizing soft tissue infections, even with appropriate treatment, are fatal in 30% to 50% of patients.¹

This chapter focuses on skin and soft tissue infections that are primarily the result of a break in the skin following an abrasion, skin puncture, ulceration, surgical wound, intentional or unintentional insertion of a foreign body, or blunt soft tissue contusion. Not discussed are superficial skin infections, such as impetigo; infections that originate within the hair follicle (e.g., folliculitis, furuncles, carbuncles) or sweat pores; styes, acne, diaper rash, and skin infestations.

Treatment of traumatic skin and soft tissue infections often is empiric and based on the severity and site of infection, the patient's underlying immunocompetence, and the triggering event (e.g., abrasion, bite, insertion of a foreign object) because attempts to isolate the causative organism often are futile.^{2,3}

The organisms that should be considered when empirically treating patients with a traumatic skin or soft tissue infection are outlined in Table 67-1.

CELLULITIS

Definition and Causative Organisms

1. T.E., age 25 years, presents to her family doctor with a 2- to 3-day history of worsening pain, redness, and swelling on her left leg following an abrasion that occurred sliding into second base during a softball tournament. The area is warm to the touch with a defined erythematous border. Over the past 24 to 36 hours, the leg has become increasingly painful and "tight." Mild lymphadenopathy is present, and T.E. has a temperature of 38.2°C. The presumptive diagnosis is a moderate cellulitis, and cloxacillin (Tegopen, Cloxapen) is prescribed. Why is cloxacillin appropriate empiric treatment for T.E.?

Cellulitis (an acute inflammation of the skin and subcutaneous fat) is characterized by local tenderness, pain, swelling, warmth, and erythema with or without a definite entry point. Cellulitis is usually secondary to trauma or an underlying skin lesion that allows bacterial penetration into the skin and underlying tissues. Local treatment (i.e., cleaning or irrigation of the site with soap and water) is all that is required for mild cellulitis in patients with no evidence of a systemic infection. In T.E., however, her elevated temperature, increasing pain, and lymphadenopathy suggest a more serious infection. Antibiotics, in addition to local wound care, should be prescribed

X, organisms that should be covered empirically with appropriate antibiotic therapy.

for T.E. Cellulitis most often is caused by group A β -hemolytic streptococci (*Streptococcus pyogenes*) and, less often, *Staphylococcus aureus* (Table 67-1).^{2,3} In fact, unless there is an abscess or penetrating trauma *S. aureus* rarely causes cellulitis.⁴ Wound cultures often are negative, however, and fail to identify the causative organism.^{2,3} Other organisms (*Escherichia coli*, *Pseudomonas aeruginosa*, *Klebsiella pneumoniae*) also can cause cellulites, but should be suspected only in immunocompromised patients or in patients who fail to respond to antibiotics that have activity limited to gram-positive organisms. Recently the incidence of community acquired methicillin-resistant *S. aureus* (CA-MRSA) has been increasing.⁵

Empiric Antibiotic Therapy for Moderate Cellulitis

Oral cloxacillin (Tegopen, Cloxapen) is appropriate empiric therapy for cellulitis in an otherwise healthy individual such as T.E. Cloxacillin has good activity against staphylococcal and streptococcal organisms and is better tolerated than erythromycin (E-Mycin) or clindamycin (Cleocin). Dicloxacillin (Dynapen), another antistaphylococcal penicillin, produces slightly higher total serum concentrations than cloxacillin but is more highly protein bound, resulting in slightly lower free-serum concentrations.⁶ Flucloxacillin (Floxapen; not available in the United States) provides similar total serum concentrations to dicloxacillin (Dynapen) but is less protein bound and produces higher free concentrations than either cloxacillin or dicloxacillin.⁶ These small differences in pharmacokinetics do not affect clinical outcome, and the choice between these agents should be based on cost. If the cellulitis is well demarcated and there are no pockets of pus or evidence of vein thrombosis, penicillin (V-Cillin K, Pen-Vee K) alone can be appropriate because the causative organism is likely to be streptococcal. Many other available antibiotics that have activity against staphylococcal and streptococcal organisms have been evaluated for effectiveness in skin and soft tissue infections. In a surveillance study in the United States, all 405 isolates of *S. pyogenes* isolated from skin and soft tissue infections were sensitive to penicillin. *S. pyogenes* was also 100% susceptible to ceftriaxone, vancomycin, levofloxacin, and moxifloxacin; 6% of the organisms were resistant to azithromycin.⁷ Although many antibiotics are effective for the treatment of cellulitis, none is more effective than cloxacillin or dicloxacillin. Cephalexin (Keflex) is probably as effective and as well tolerated as cloxacillin or dicloxacillin and is comparable in cost. Cephalexin has been shown to be just as effective as more expensive agents (ofloxacin).⁸ The gram-negative activity of

cephalexin (not seen with cloxacillin or dicloxacillin) is not required for most cases of cellulitis in otherwise healthy patients. In many emergency departments (ED), a single dose of a long-acting parenterally administered cephalosporin (e.g., ceftriaxone), followed by oral therapy with one of the agents mentioned above, is often the preferred treatment regimen. This regimen is not more effective than oral therapy alone, and ceftriaxone (Rocephin) adds to the cost of treatment.

In this case, antibiotic treatment is required, and T.E. should receive the least expensive of cloxacillin, dicloxacillin, or cephalexin. Although some of the macrolides and quinolones are effective in treating cellulitis, they do not provide any therapeutic advantage over older and less expensive agents.⁴

However, in areas where the incidence of CA-MRSA has become clinically important (10–15% resistance) and especially if there are additional risk factors (Children, competitive athletes, prisoners, soldiers, selected ethnic populations, Native Americans/Alaska Natives, Pacific Islanders, intravenous drug users, men who have sex with men) empiric treatment should be with antibiotics that have activity against CA-MRSA.⁹ At present, most CA-MRSA are still susceptible to trimethoprim-sulfamethoxazole, clindamycin and tetracyclines but clinical trials of these agents for CA-MRSA infections are lacking.^{4,10} If these agents are used, a reasonable suggestion would be to re-evaluate (by the patient if they are competent) within 24 to 48 hours to verify that an improvement is occurring. Some clinicians are avoiding the use of clindamycin because of concerns of inducible resistance and in areas with a clinically important incidence of CA-MRSA, laboratories should likely be testing for inducible clindamycin resistance.

In addition to systemic therapy, T.E. should be instructed to keep the area clean with soap and water (if an open wound is present) and to protect the area.

Treatment for the Penicillin-Allergic Patient

2. What agents could be chosen if T.E. were allergic to penicillin?

Oral erythromycin (E-mycin) or clindamycin (Cleocin) could be chosen for patients with a documented history of penicillin or cephalosporin allergy. However, there has been an increase in certain regions of macrolide resistance group A streptococci and if this was the case for TE, then erythromycin may not be a reasonable alternative and oral quinolones such as moxifloxacin or levofloxacin could be considered⁴ and local sensitivities should direct the choice. Erythromycin causes

nausea, vomiting, diarrhea, and cramps in 30% to 40% of patients, but this can be decreased by taking it with food. Clindamycin causes diarrhea in 20% of patients and can cause serious toxicity secondary to antibiotic-associated colitis. Erythromycin is much less expensive than clindamycin, and unless a patient has documented gastrointestinal (GI) intolerance to erythromycin, it is preferred over clindamycin. Trimethoprim-sulfamethoxazole (Bactrim, Septra) has good activity against *S. aureus*; its activity against *S. pyogenes* is weak, however, and therefore, if a streptococcal organism cannot be ruled out, it should likely not be used as empiric therapy. In addition to the above mentioned agents, moxifloxacin could also be considered as an alternative in the penicillin allergic patient.

Dosages of Antibiotics

3. What dose should be prescribed for T.E.?

The recommended dosages in the literature for cloxacillin (Tegopen, Cloxapen) and dicloxacillin (Dynapen) are 250 to 500 mg orally Q 6 hr and 125 to 250 mg orally Q 6 hr, respectively. Although lower dosages of dicloxacillin can be used, cloxacillin and dicloxacillin produce relatively similar free serum concentrations and should be prescribed at similar dosages. The dosage for mild to moderate infections should be 250 mg orally Q 6 hr; for moderate to severe infections, it should be 500 mg orally Q 6 hr. Dosages up to 1,000 mg orally Q 6 hr have been used, but GI intolerance (usually diarrhea) can occur. These dosages also apply to cephalexin and erythromycin. The dosage for Pen-V is 250 to 500 mg orally Q 6 hr; for oral clindamycin, the dosage is 150 to 450 mg orally Q 6 hr. Because cloxacillin is the drug chosen for T.E., a dosage of 250 mg orally Q 6 hr should be sufficient. If she were more severely ill, however, the higher dosage of 500 mg orally Q 6 hr could be chosen. The dose for doxycycline is 100 mg orally Q 12 hr and the dose for trimethoprim-sulfamethoxazole is one double-strength tablet orally Q12 h. The recommended dose for moxifloxacin is 400 mg orally Q24 hr and 500 mg orally Q24 hr for levofloxacin.

Treatment Duration

4. For how long should T.E. be treated?

While the usual recommended duration of therapy for cellulitis is 10 days, 5 days of antibiotics has been shown to be as good as 10 days for uncomplicated cellulites.¹¹ An instruction to the patient to continue oral antibiotics for 2 to 3 days after the patient has become afebrile and has improved clinically seems reasonable. T.E. should be counseled to expect a response within 1 to 2 days after therapy begins (although erythema may persist longer). In addition, she should be instructed to return for re-evaluation if the condition does not improve or worsens over the next few days.

Evaluation of Therapy

5. What further diagnostic evaluation should be undertaken for T.E.?

In otherwise healthy individuals, identification of the causative organism in cases of cellulitis is unnecessary. Needle aspiration, fine-needle aspiration biopsy, and punch biopsy

have isolated the causative organism in only about 15% to 25% of patients.^{2,3} Appropriate empiric treatment is effective in most patients, and an attempt to isolate the organism does not contribute to the success of treatment and adds significantly to the cost of care. Although organisms often are not cultured, attempts to identify the organism are recommended if initial treatment fails and when treating immunocompromised patients, patients with potential joint or tendon damage, and patients with life-threatening infections requiring hospitalization. In these cases, a swab of the primary wound and a needle aspiration or punch biopsy of the leading edge of the cellulitis should be obtained for Gram stain and culture before initiating antimicrobial therapy. Blood for cultures should be drawn in addition to wound cultures in these patients. Anaerobic cultures need to be drawn only when the wound contains necrotic tissue, the wound is foul smelling, or crepitus is present. Even if wound and blood cultures are obtained, many infections will be culture negative (74%).² Blood culture results are positive in less than 5% of cases.¹² Culture information, in conjunction with clinical course, can be used to modify subsequent treatment. Because T.E. has only a moderate cellulitis, cultures are not required and therapy can be given empirically.

Role of Topical Antibiotics

6. What role do topical antibiotics play in treating T.E.'s cellulitis?

The value of topical antibiotics in treating skin infections is questionable. Most topical antibiotics have not been evaluated in appropriately designed trials. Although mupirocin produced positive bacteriologic results over placebo in treating some types of wound infections,^{13,14} most studies have found no important clinical differences.¹⁴ Mupirocin has been compared favorably with erythromycin and cloxacillin in the treatment of patients with impetigo, minor wound infections, and mild cellulitis; however, most cases of mild cellulitis will improve with only local wound care (e.g., cleansing or irrigation of the area). In patients with moderate to severe infections, mupirocin or any topical antibiotics (neomycin, bacitracin, polymyxin B) should not be used to replace or augment systemic antibiotics. Topical antibiotics likely do little but add to the cost of therapy, and they occasionally cause a contact dermatitis.¹⁴ Therefore, T.E. should not be treated with topical antibiotics because her moderate cellulitis should be managed adequately by her systemic antimicrobial therapy.

Empiric Antibiotic Therapy for Moderate to Severe Cellulitis

7. J.M., age 34 years, presents to the ED with a 3- to 4-day history of increasing pain around his left hip, secondary to an injury he received falling on the sidewalk. In addition, he has a fever and feels weak, lethargic, and nauseated. Examination reveals a swollen, warm, and extremely tender hip. J.M. has a temperature of 39.8°C and appears quite ill. A diagnosis of moderate to severe cellulitis is made, and J.M. is hospitalized because of the severity of the infection. J.M. has no other underlying medical problems. What empiric antibiotic regimen would be reasonable for J.M.?

In moderate to severely ill patients, when hospitalization is required, antibiotics should be administered parenterally. The

parenteral agent of choice is nafcillin (Nafcil; cloxacillin in Canada). Some clinicians add penicillin G (2 million units Q 6 hr) to nafcillin to ensure coverage against streptococcal organisms because the minimum inhibitory concentrations for penicillin against streptococci are lower than those with nafcillin. However, this “double coverage” is unnecessary if high-dose nafcillin (2 g intravenously [IV] Q 6 hr) is used. Cefazolin (2 g IV Q 8 hr) would be an appropriate alternative if it is less expensive than nafcillin. Second- and third-generation cephalosporins (cefuroxime [Zinacef], cefoxitin [Mefoxin], ceftriaxone [Rocephin], cefotaxime [Claforan]) and some quinolones may be as effective as nafcillin but provide no clinical advantages and are more expensive. Linezolid is also effective for the treatment of complicated skin and soft tissue infections, but it is no more effective than cloxacillin.¹⁵ In a large study (1,080 subjects) of complicated soft tissue infections linezolid produced similar cure rates to vancomycin overall (92% vs. 89%) but in a subset-analysis of subjects with MRSA, linezolid was associated with a better outcome rate (89% vs. 67%).¹⁶ Newer agents like daptomycin and tigecycline have also been shown to be effective in serious soft tissue infections but at present they don't appear to offer any advantages over other agents unless other agents have been shown to be ineffective or are not tolerated.

Therefore, J.M. should receive either nafcillin or cefazolin, whichever is less expensive. Once J.M. has become afebrile and has clinically improved for 2 days, the parenteral antibiotic should be discontinued and appropriate oral therapy (cloxacillin) initiated to complete at least a 10-day course (2 weeks if the patient responds slowly). In settings where 10% to 15% of community isolates of *S. aureus* are methicillin resistant or in severe infections (sepsis, necrotizing fasciitis, etc) or if the patient has the risk factors outlined in question 1, empiric treatment with vancomycin, linezolid or daptomycin should be considered until the results of cultures and sensitivities are known.

Penicillin Allergy

8. Two days after starting therapy, J.M. develops a maculopapular skin rash. What alternative therapy should be chosen?

Regardless of when during the course of therapy a drug rash occurs (early or late), the precipitant drug should be discontinued because there is a chance, although small, that the reaction could worsen. In patients who develop a penicillin allergy and who still require parenteral therapy, clindamycin, erythromycin, vancomycin (Vancocin), or linezolid (Zyvox in the United States; Zyvoxam in Canada) moxifloxacin or levofloxacin could be chosen. Because all of these agents are equally effective, the decision on which drug to use in J.M. should be based on cost and dosing convenience (clindamycin 600 mg IV Q 8 hr, erythromycin 500 mg IV Q 6 hr, vancomycin 1,000 mg IV Q 12 hr, and linezolid 600 mg IV Q 12 hr, moxifloxacin 400 mg IV Q24 hr and levofloxacin 500 mg IV Q24 hr). The administration of IV erythromycin is inconvenient because of its significant local irritative properties, and vancomycin, clindamycin, or linezolid, moxifloxacin or levofloxacin is preferred for J.M. The choice between these agents should be based on cost.

Culture and Sensitivity Results

9. After 48 hours of therapy, culture and sensitivity results are available. What changes, if any, should be made in J.M.'s treatment?

If cultures show only streptococcal organisms, in a patient who is not allergic to penicillin, therapy should be switched to penicillin G because it is effective, well tolerated, and less expensive than nafcillin (Nafcil). If cultures show staphylococcal species (*S. aureus*) that are sensitive to methicillin, the initial empiric therapy should be continued. If the organisms are resistant to methicillin, therapy should be switched to vancomycin 15 mg/kg IV Q 12 hr or linezolid 600 mg IV Q 12 hr. The choice between these two agents should be based on oral bioavailability, side effect profile, and cost. Because J.M. has developed a presumed penicillin allergy, he should continue with his existing therapy of either clindamycin or vancomycin.

Switching to Oral Therapy

10. After 72 hours of therapy, J.M. has improved considerably and has been afebrile for 24 hours. Can he be switched to oral therapy?

Once J.M. has been afebrile for at least 24 hours and is virtually asymptomatic, other than some continuing tenderness around the site of the infection, oral therapy can replace IV therapy, assuming J.M. can tolerate oral medications. Although clinicians often switch to an oral version of the drug that was given parenterally, this may not always provide the patient with the most convenient and cost-effective therapy. Clinicians should select the oral agent on the basis of culture results, convenience, and cost.

Intravenous Drug User

11. M.C., age 22 years, presents to the ED with a 3- to 4-day history of pain in her left forearm. On examination, she has a swollen and erythematous area of approximately 8 × 12 cm in the antecubital fossa of the left arm. The area is warm and tender to the touch. M.C. has a temperature of 39.2°C. She admits to injecting heroin daily; track marks are present on both arms. She states that she uses “filtered tap water” as a diluent for her narcotics and that her arm “has only been hurting for the last 3 days.” No signs of lymphangitis or thrombophlebitis are seen. What tests are needed to confirm the diagnosis?

M.C. has all the cardinal signs of cellulitis (i.e., induration, edema, erythema, and tenderness to touch). Given her history of an injury (injection), her presentation is compatible with cellulitis. No additional tests are required unless, on clinical examination, there is a suspicion of additional injury beyond the injection site or of a deeper infection (e.g., osteomyelitis). Obtaining a specimen from the infection site (by aspiration) to identify the organism(s) is unnecessary unless the patient has a concurrent condition that could impair her immunologic response.³ The sensitivity of needle aspiration at the edge of the wound or at the site of greatest inflammation in identifying the infecting organism is only about 10%.² Therefore, aspiration of the wound is not warranted. The sensitivity of needle aspiration increases to 25% in patients with underlying

immunologic dysfunction (e.g., diabetes, malignancy, poor peripheral circulation) and may be beneficial in identifying the infecting organism(s) in these patients.³ M.C. possesses risk factor (intravenous drug use) for CA-MRSA.¹⁷ She should be closely examined for any sign of abscess at the infected site, and drained if present. Cultures should be sent of any abscess fluid, but routine cultures for CA-MRSA in cellulitis is not required unless this is a repeat presentation or is part of monitoring for a community outbreak.¹⁷ For patients such as M.C. with signs and symptoms (e.g., fever) where the injury is a significant risk for bacteremia and potentially for endocarditis, blood cultures are warranted. Blood cultures should be drawn before antibiotics are started to assess the presence of bacteria. If the blood cultures return positive, further assessment for potential endocarditis is warranted.

Causative Organisms

12. Are the suspected organisms in this patient population similar to those found in other patients with cellulitis?

A wide range of organisms can cause cellulitis in an IV drug user because of the potential for direct inoculation of any organism with the drug of abuse. Despite the efforts of an IV drug user to make as sterile an IV product as possible, the IV drug user commonly is injecting a contaminated solution. Although almost any organism can be found, the infecting bacteria causing cellulitis in an IV drug user are similar to those found in normal hosts.¹⁸ β -Hemolytic group A streptococci and staphylococci, particularly *S. aureus*, are the most common infecting organisms.^{19,20} Intravenous drug use has been identified as a risk factor for infection with CA-MRSA and should be particularly considered if the patient has had recurrent infections or has failed to respond to antibiotic therapy.¹⁷ *Staphylococcus epidermidis* and gram-negative organisms, including *P. aeruginosa*, are rarely the causative organisms unless the IV drug user has taken oral cephalosporins concurrent with his or her injections, which is common in IV drug users.¹⁹ In areas with a high prevalence of methicillin-resistant *S. aureus*, a similar resistance pattern may be seen in IV drug users with cellulitis.²¹ Some investigators report a high incidence of anaerobic bacteria in cellulitis of IV drug users and hypothesize that these result from the transfer of oral flora.²²

Empiric Antibiotic Therapy

Antibiotic therapy directed at eradicating all possible infecting organisms is not required. Because streptococci and staphylococci account for >94% of all infecting organisms in IV drug users with soft tissue infections,¹⁹ therapy need cover only the sensitivity patterns of these organisms in the treatment area. Cloxacillin, dicloxacillin, or nafcillin is appropriate therapy (see Question 1). Oral therapy is appropriate for mild cases of cellulitis. Infections that involve a large area or that are associated with lymphangitis should be treated with parenteral antibiotics. Likewise, infections involving the hand should be treated parenterally.²² Since M.C. may be at risk for CA-MRSA, if this organism is common in her local community, initial therapy of cotrimoxazole (1 double strength tablet bid) or doxycycline (if confirmed not pregnant) would be appropriate. If treatment does not result in some resolution of inflammation within 48 hours, antimicrobial coverage should be expanded to cover gram-negative organisms.

The anaerobic organisms found in IV drug users with cellulitis usually respond to treatment with penicillins or cephalosporins.²¹

For patients not responding to initial therapy and for patients with signs or symptoms of a systemic response (e.g., rigors, hypotension), parenteral therapy that covers CA-MRSA is required, such as vancomycin, linezolid, daptomycin or tigecycline.¹⁷ Antibiotic therapy that provides coverage against the other common organisms causing cellulitis (i.e., *E. coli*, and *K. pneumoniae*) in the IVDU population should be added, based on the sensitivity patterns in your local area. This may include the use of a parenteral cephalosporin, quinolone, or aminoglycoside. Although some clinicians suggest that a third-generation cephalosporin or a quinolone be chosen over an aminoglycoside because of concerns about toxicity, an aminoglycoside is effective, safe, and inexpensive when used for a short period (5–7 days).²³ However, in patients with poor renal function (estimated creatinine clearance <60mL/minute) the aminoglycoside should be avoided.

Treatment of cellulitis in an IV drug user should include rest, immobilization and elevation of the infected arm, antibiotics, and surgical drainage or débridement as required. If any sign of pus collection in the wound is noted, the wound must be surgically explored and drained. If no area of pus collection can be seen or palpated, immobilization and elevation, combined with systemic antibiotic therapy, is appropriate treatment. The wound should be assessed daily for local tenderness, pain, erythema, swelling, ulceration, necrosis, and wound drainage until it shows signs of resolution to ensure that subsequent surgical treatment is not required.²²

SOFT TISSUE INFECTIONS IN DIABETIC PATIENTS

Skin and soft tissue infections are common in patients with diabetes mellitus. Approximately 25% of diabetic patients report a history of skin and soft tissue infections,²⁴ and 5% to 15% of diabetic patients may undergo limb amputation.²⁵ In addition to the cost associated with treating skin and soft tissue infections, functional disability can occur, which can significantly decrease the patient's quality of life.

Predisposing Factors

Diabetic patients are at particular risk for foot problems, primarily because of the neuropathies and peripheral vascular diseases associated with longstanding diabetes. The decreased pain sensation allows the patient to continue to bear weight in the presence of skin damage, thereby promoting the formation of an ulcer. In addition, minor trauma (e.g., cuts, foreign body insertion) can go unnoticed and, when left untreated, can become infected and extensive. Although these infections are common, preventive measures can reduce the frequency of amputations.²⁵

Causative Organisms

13. P.U., a 67-year-old man with diabetes, presents to his general practitioner for a routine checkup and has no specific complaints. P.U. has a 15-year history of poorly controlled type 2 diabetes and a 3-year history of recurrent foot ulcers. On examination, the physician sees that one ulcer on the underside of the foot, which had

previously healed over, is open and inflamed; purulent fluid can be expressed from the wound. P.U. reports no pain around the area and was unaware that the ulcer had worsened. His temperature is normal, and he shows no other signs of a systemic infection. Does P.U. have an active infection, and is antibiotic therapy required?

All open wounds, in diabetic and nondiabetic patients, will become colonized with bacteria, but only infected wounds should be treated with antibiotic therapy.²⁶ Often it is difficult to determine whether an open wound is infected, but signs and symptoms (e.g., purulent drainage, erythema, pain, and swelling around the area) are suggestive of infection. Based on his symptoms, P.U. should be considered to have an infection that requires treatment.

Empiric Antibiotic Therapy

14. What treatment should P.U. receive?

Mild infections can be treated empirically as are other soft tissue infections²⁶ because these are commonly caused by aerobic gram-positive cocci. A penicillinase-resistant penicillin (e.g., cloxacillin, nafcillin) or cephalexin will be effective in most cases. A culture of either the drainage or the infected site should be obtained, however, to help guide future treatment. The choice between these agents should be based on allergy status and cost. If anaerobes are suspected, metronidazole or clindamycin should be added to the regimen. In addition, for all diabetic patients with soft tissue infections, osteomyelitis must be ruled out. In patients with significant vascular compromise, crepitus, or gangrene, a radiograph should be taken to identify any bone involvement.

In moderate to severe infections, antibiotic coverage should be expanded because multiple organisms may be responsible for the infection. An average of two to six organisms are cultured from foot ulcers in patients with diabetes. The following organisms (in no particular order) are found in >20% of wounds in patients with diabetes: *S. aureus*, *S. epidermidis*, *Enterococcus faecalis*, other streptococci, *Proteus* species, *E. coli*, *Klebsiella* species, *Peptococcus* species, *Peptostreptococcus* species, and *Bacteroides* species.²⁶ These infections are often polymicrobial, but treatment can be effective even if not all cultured pathogens are covered.²⁶ To determine the pathogens most accurately, a specimen of infected tissue should be obtained that is not directly communicating with an ulcer. If this is not possible, cultures of purulent exudate or curettage should be obtained, versus superficial swab, to determine the true pathogens in the wound.²⁷ Although antibiotics are important, drainage and surgical débridement to remove all the infected or necrotic tissue are essential and are considered by some to be the mainstay of treatment.²⁶

Cultures of the affected areas may not be that useful unless bone involvement is suggested. Although anaerobic organisms often are difficult to culture, anaerobic organisms must be considered if an abscess or devitalized, necrotic, foul-smelling tissue is present or the wound is a result of abdominal surgery. Empiric coverage for *E. faecalis* is required only for severe (necrotizing) infections. Even if enterococci are found in the wound, enterococcal coverage probably is needed only if it is the predominant organism.

No “best” regimens exist to treat diabetic soft tissue infections.²⁸ Clindamycin 600 mg IV Q 8 hr with ciprofloxacin

400 mg or a third-generation cephalosporin is a very effective combination that will provide coverage against most potential pathogens (gram-positive, gram-negative, and anaerobes), with the exception of *E. faecalis*. Clindamycin, however, can cause *Clostridium difficile*-associated diarrhea, and the parenteral formulation is expensive. Aminoglycosides are associated with serious toxicity if used for an extended period and should probably be avoided in diabetic patients with pre-existing renal impairment. A β -lactam– β -lactamase inhibitor combination, such as piperacillin and tazobactam (Tazocin), ticarcillin and clavulanic acid, or ampicillin and sulbactam, provides similar coverage but also adds coverage against enterococci and could be chosen over other combinations if it is less expensive.

Other single-agent therapies could include the use of a carbapenem (imipenem or meropenem), but the increased cost and broad spectrum of activity of these agents should limit use to patients unresponsive to other therapies.

In many cases, diabetic foot infections are difficult to treat, but aggressive treatment can prevent extension of the infection, development of osteomyelitis, and on occasion loss of limb. Treatment should be continued for 3 to 4 days after all signs of infection are absent. Oral therapy should be considered once the infection has begun to abate. Because P.U. is an elderly diabetic patient and does not appear to be severely ill, the least expensive of ciprofloxacin–clindamycin or piperacillin–tazobactam, cefoxitin, or ceftizoxime, should be chosen as empiric therapy. In addition, ampicillin and sulbactam (Unasyn) or ticarcillin and clavulanate (Timentin) could be chosen if either is less expensive than the aforementioned agents or if local sensitivity patterns suggest that organisms typically found in these types of infections are routinely resistant to the other less expensive agents. The broad spectrum of carbapenems (e.g., imipenem, meropenem) may appear desirable, but frequent use contributes to isolation in individual patients and patient populations of more resistant pathogens, such as *Stenotrophomonas* organisms. Their use should be limited when possible. In areas where CA-MRSA is an issue, treatment should include antibiotics with activity against this organism. (see Questions 1–3)

Postamputation Antibiotic Treatment

15. Despite aggressive antibiotic therapy and débridement, P.U.’s infection spreads and an amputation is required. How long should antibiotics be prescribed for P.U. following surgery?

The best option for uncontrollable, life-threatening infections often is amputation to remove the infected area. Once the infected area has been removed, antibiotic therapy is no longer required. If it were impossible to remove all of the infected tissue, treatment should be continued as just described.

Prevention

16. What could have been done to prevent this complication in P.U.?

Many of the foot problems associated with diabetes can be prevented with proper foot care (Table 67-2),²⁵ and these preventive measures must be stressed. Diabetic patients with

Table 67-2 Foot Care for the Diabetic Patient

Inspect feet daily for cuts, blisters, or scratches. Pay particular attention to the area between the toes and use a mirror to examine the bottom of the foot.

Wash feet daily in tepid water and dry thoroughly.

Apply lotion to feet to prevent calluses and cracking.

Ensure that shoes fit properly (not too tight or too loose), and inspect them daily.

Trim nails regularly, making sure to cut straight across the nail.

Do not use chemical agents to remove corns or calluses.

neuropathies or those who are elderly should take care of their feet regularly (every 1–2 days).

NECROTIZING SOFT TISSUE INFECTIONS

Definitions, Terminology, and Causative Organisms

Skin and soft tissue infections are described as *necrotizing* when the inflammation is rapidly progressing and necrosis of the skin or underlying tissue is present. The following clinical signs are associated with necrotizing infections, but not with simple cellulitis: edema beyond the area of erythema, skin blisters or bullae, localized pallor or discoloration, gas in the subcutaneous tissues (crepitus), and the absence of lymphangitis and lymphadenitis. Pain out of proportion to the apparent extent of the infection or the hard wood feel of the infected area may be the only clues of necrotizing infection.⁴ Necrotizing soft tissue infections can progress rapidly to cause additional local effects (i.e., necrosis and loss of skin sensation) and severe systemic effects (e.g., hypotension, shock).²⁹

Group A β -hemolytic streptococci, *Pseudomonas* species, other gram-negative organisms, *Clostridium perfringens*, peptostreptococci, *B. fragilis*, and *Vibrio* species can cause necrotizing infections.²⁹

Necrotizing cellulitis involves the skin and subcutaneous tissues. Necrotizing fasciitis involves both superficial and deep fascia, and necrotizing infections involving the muscle are termed *myonecrosis*. These terms can be used to describe all three of these processes. Gas gangrene is myonecrosis caused by a *Clostridium* subspecies, most commonly *C. perfringens* (70%).²⁹ Gas in a wound is not necessarily indicative of gas gangrene caused by *C. perfringens*. Gram-negative organisms (e.g., *E. coli*, *Proteus Species*, *Klebsiella Species*), or anaerobic streptococci can produce gas in a wound. Air also could have been introduced at the time of the injury. Gas gangrene is characterized by acute onset of worsening pain that is usually out of proportion to the degree of injury.

Clostridial myonecrosis (true gas gangrene), streptococcal gangrene (caused by group A β -hemolytic streptococci), and synergistic bacterial gangrene (caused by anaerobic and aerobic bacteria, usually gram-negative) are other terms used to describe necrotizing skin and soft tissue infections. Fournier's gangrene (a type of synergistic bacterial gangrene of the scrotum), nonclostridial crepitant gangrene (nonclostridial gas gangrene), and necrotizing fasciitis (all necrotizing soft tissue infections other than clostridial myonecrosis, or sometimes just streptococcal gangrene) are other commonly used terms.²⁹

Empiric Antibiotic Therapy

17. M.T., a 45-year-old alcoholic man who lives on the streets of the city, presents to the ED with a broken nose and facial lacerations, which he received after a fight outside one of the local taverns. On examination, in addition to the facial wounds, an area of severe inflammation, erythema, and necrosis is found on his left calf. The area is very painful, crepitation is felt over the area, and a purulent discharge is present. M.T. states this is secondary to a knife wound he suffered approximately 1 week ago. What treatment should be provided?

In addition to setting the broken nose and suturing the facial lacerations, the clinician should evaluate the infection on M.T.'s calf. A Gram stain and culture of the purulent discharge should be evaluated before initiating antimicrobial therapy. Because crepitus is present, the area should be incised and a specimen of the infected tissue should be obtained for Gram staining and culture.¹

The primary treatment for necrotizing soft tissue infections involves extensive débridement of the area to remove all necrotic tissue and drain the area. Thus, a surgical consultation will be required for M.T. In addition, IV antibiotics are required. In this case, gas in the tissues could be caused by many organisms, and empiric antibiotic therapy should be broad spectrum and should include coverage against gram-positive organisms, the Enterobacteriaceae, and *B. fragilis*. Initial therapy should have a broad spectrum until microbiological verification of the pathogen is obtained. Initial therapy with piperacillin/tazobactam plus clindamycin or ampicillin/sulbactam plus clindamycin would be appropriate.⁴ If the Enterobacteriaceae in the local community have a high incidence of resistance to these agents, adding ciprofloxacin is recommended.⁴ Alternatively, therapy with a carbapenem could be used, with the addition of clindamycin if group A β -hemolytic streptococci is suspected. If the Gram stain of the discharge shows only gram-positive rods (which would likely be clostridial subspecies), the therapy could be streamlined to high-dose penicillin.

Flesh-eating disease is usually a necrotizing fasciitis caused by virulent strains of group A streptococci. High-dose penicillin G (3 million units Q 4 hr) plus clindamycin (900 mg IV Q 8 hr) are the drugs of choice for this condition.^{4,30,31} Although only experimental model data exist, the addition of clindamycin to penicillin is more effective in fulminant streptococcal infections than beta-lactam alone, potentially because it inhibits protein synthesis which may reduce toxin expression by the bacteria, and cytokine response by the host.⁴ Clindamycin may have adjunctive activities that contribute to reduced morbidity from gram-positive pathogens. In vitro evidence suggests that clindamycin suppresses toxin production by *S. aureus* isolates.³¹

Adjunctive therapy for streptococcal necrotizing skin infections could include IV immunoglobulin G (IVIG) 2 g/kg as a single dose or 0.4 mg/kg daily for 2 days.³² IVIG is thought to work by binding to the superantigens released by the streptococcal bacteria that are involved in the systemic effects of the infection. The optimal dosage and duration of IVIG therapy are unknown, as is the response to the variability between commercial lots of IVIG products.⁴

Therapy for necrotizing fasciitis should be altered based on the patient's clinical response and culture results.

ERYSIPELAS

Signs, Symptoms, and Causative Organisms

18. D.D., a 70-year-old man, presents to the ED with a red, swollen face. He describes the area as “a swollen red spot” that has appeared over the past 2 days. He also describes feeling unwell for the previous 3 days and having a fever. On examination, D.D. has a bright red, shiny, edematous lesion on his right cheek that is 0.4 cm wide. It is a continuous lesion with a clearly demarcated border. What signs and symptoms support the diagnosis of erysipelas in D.D.?

Erysipelas is a superficial skin infection caused by streptococci, predominantly group A, although groups C or G (and group B in children) also may cause the infection.³³ Erysipelas is diagnosed based on characteristics of the skin lesion and concurrent systemic symptoms.³³ Patients with erysipelas have associated systemic symptoms of high fever, chills, frequent history of rigors, and general malaise. This constellation of systemic symptoms differentiates erysipelas from other local skin disorders. The lesion is a continuous, indurated, edematous area. Early in the course, the lesion is bright red, but it may turn to brown as the lesion ages or grows. The lesion spreads peripherally with no islands of unaffected tissue. The initial lesion results from a small break in the skin that becomes infected, although signs of the initial wound often are not evident.

D.D. has the classic signs and symptoms of erysipelas: a well-demarcated, edematous, red lesion with associated systemic signs. No further diagnostic tests are required because aspiration of the lesion or a superficial swab is not useful in detecting the offending organism.³³

Empiric Antibiotic Therapy

19. What antibiotic therapy should be initiated for D.D.?

Erysipelas will respond promptly to antibiotics with activity against group A streptococci.³⁴ Oral penicillin V 250 to 300 mg (depending on available dosage form) Q 6 hr or parenteral penicillin G (1 million units IV Q 6 hr) should reduce the systemic symptoms (e.g., fever, malaise) within 24 to 48 hours.³⁴ It will take several more days for the skin lesion to resolve. If D.D. does not feel better within 72 hours after initiation of antibiotics, he should be instructed to return for reassessment. If D.D. has an allergy to penicillins, clindamycin or oral quinolone, such as moxifloxacin are alternatives. If your community has increased macrolide resistance to group A streptococci these agents should not be part of empiric therapy.³⁵ Antibiotic therapy should be continued for 10 days even if signs and symptoms resolve quickly to avoid a relapse, which could lead to chronic infection or scarring.

ACUTE TRAUMATIC WOUNDS

20. J.K., a 25-year-old construction worker, presents to the ED with a deep cut on his left forearm suffered when he accidentally

put his hand through a plate glass window. Fourteen stitches are required to close the wound. Is oral antibiotic therapy required for J.K.?

Although almost all traumatic wounds are contaminated with bacteria,³⁶ routine oral antibiotic therapy is not indicated unless there is evidence of an infection. Contaminated wounds do become infected more often than noncontaminated wounds, but prophylactic antibiotic therapy does not appear to decrease the chance of infection.³⁶ For all traumatic wounds, aggressive wound care (e.g., irrigation, removal of foreign objects) is required. A meta-analysis of randomized trials of prophylactic antibiotics in patients presenting to an ED for nonbite wounds found no evidence that oral antibiotics would protect against infection.³⁷ A course of antibiotic therapy should be given only to immunocompromised patients (e.g., those with diabetes mellitus, peripheral vascular disease, human immunodeficiency virus [HIV] or acquired immunodeficiency syndrome [AIDS], chronic corticosteroid use, leukopenia). Other potential candidates for antibiotic therapy include wounds with pus, contamination by feces, and delays in cleansing (>3 hours) of the wound.³⁸ Antibiotic therapy would be similar to that given for cellulitis (see Question 1). Patients with risk factors for the development of infective endocarditis (i.e., mitral valve prolapse with regurgitation, an indwelling non-native cardiac valve, a previous history of endocarditis, a history of congenital heart malformations, surgically constructed systemic-pulmonary shunts, and cardiomyopathy) should receive prophylactic amoxicillin (Amoxil) 3 g orally followed by 1.5 g in 6 hours or erythromycin 1,000 mg orally followed by 500 mg orally in 6 hours if the patient is penicillin allergic.³⁹ Because J.K. has no risk factors, all that is required is removal of any glass fragments, irrigation, and suturing of the area.

21. K.M., a 7-year-old boy, presents 30 minutes after falling and scraping his elbow on the pavement. The father requests an antibiotic ointment for the wound. You look at his elbow and notice a mildly abraded, 1-inch square area. What treatment would you recommend?

All minor injuries, such as scratches, cuts, and abrasions, should be thoroughly cleaned with soap and water. The evidence on the use of a topical antibiotic as a preventive measure is contradictory.³⁴ Placebo was compared with povidone ointment and a topical antibiotic combination (cetrimide–bacitracin–polymyxin) in children with minor dermatologic injuries.³⁴ The incidence of clinical infection was significantly different in placebo (12.5%) versus the topical antibiotic group (1.6%). No difference was seen in the incidence of clinical infection between povidone and the topical antibiotic group. In addition, no significant difference was noted between any of the preparations in the incidence of microbiologic infections. A randomized, double-blind, prospective trial comparing white petrolatum with bacitracin ointment in wound care following dermatologic surgery showed no difference between the groups in the incidence of wound infection.⁴⁰ Some patients can develop skin sensitivities to topical antibiotics. K.M.'s wound should be thoroughly washed and inspected, but a topical antibiotic ointment would not be required.

ANIMAL BITE WOUNDS

Evaluation of Dog and Cat Bites

22. P.J., a 14-year-old boy, presents to the ED 3 hours after being bitten on the leg by a neighbor's dog. He has a laceration, 14 cm long, on his medial calf. Four distinct puncture marks, suggestive of teeth marks, also are present on the calf. There is no suggestion of bone injury. P.J. was healthy before the attack and has no chronic illness. Should P.J. receive any treatment other than suturing of his laceration?

Any wound caused by an animal that results in the skin being cut or punctured should be examined to ensure no underlying tissue damage has occurred. This is especially true in patients with bites of the hand or around other joints. The wound should be washed with clean water as soon as possible after the bite.⁴² Irrigation of the wound, including puncture sites, should be extensive to reduce the risk of infection. Obtaining specimens for cultures is not required and wound irrigation should begin as soon as possible.⁴¹

P.J.'s wound should be evaluated for deep tissue injury, devascularization of any tissue, and bone injury.⁴² Loose suturing or closure with adhesive strips is appropriate for lacerations following irrigation.⁴¹ Although the safety of closure of bite wounds has been debated, a good therapeutic response has been obtained following the closure of wounds.⁴² P.J. should be instructed to keep his leg elevated and immobilized until signs of any infection have resolved.⁴³

The need for antibiotics is controversial and guided by wound characteristics. The patient should receive a course of antibiotics⁴⁴ if the wound involves the hand or is near joints⁴¹; if it involves deep punctures or is difficult to irrigate; if the patient is immunocompromised (e.g., diabetes, splenectomy); or if the wound is not well perfused. Antibiotics are not required for dog bites in which no deep tissue injury is present and the wound can be well irrigated, particularly if the wound is on the lower extremities in healthy adults or children.⁴⁵

Prophylaxis for rabies is required only if the animal is from an area with endemic rabies or if the bite was the result of an unprovoked attack by a wild animal.⁴⁶ Contact the local health board to determine the recent rabies risk in the area. If P.J. has not received a tetanus toxoid booster within the past 5 years, a booster should be administered. If P.J. has never been immunized for tetanus, tetanus immune globulin should be administered in addition to the tetanus toxoid (see Question 26).⁴⁶

Causative Organisms and Empiric Antibiotic Therapy

23. Because P.J. has several punctures that are difficult to irrigate, he is a candidate for antibiotic therapy. Which antibiotic(s) should he receive?

The selection of the appropriate antibiotic is based on the most likely pathogens from the specific animal bite. Animals have different oral flora, which alters the potential pathogens associated with bites. The most common pathogens in dog bites are β -hemolytic streptococci, *S. aureus*, *Pasteurella multocida*, anaerobic bacteria (particularly *Bacteroides* species), and *Fusobacterium* species.⁴⁶ Although *P. multocida* often

is considered the primary pathogen of dog bites, antibiotic coverage also must address the other common pathogens.⁴⁶ Monotherapy with amoxicillin/clavulante 500/875 orally Q12 hr is recommended.⁴ If the patient is allergic to penicillin, tetracycline or doxycycline provides adequate coverage. Doxycycline is preferred over tetracycline because it is more convenient to administer (twice daily for doxycycline vs. four times a day for tetracycline); it can be used in patients with decreased renal function, may be taken with food, and is only a little more expensive (in the generic form) than tetracycline.

If the penicillin-allergic patient cannot take doxycycline, a fluoroquinolone, such as moxifloxacin 400mg PO daily, could be used. In all cases, patients should be instructed to watch for a positive response; if the wound does not heal or it worsens within 48 hours, the patient needs to be re-evaluated.

Antibiotic treatment should not extend beyond 5 days unless signs of an infection remain.⁴¹ Appropriate therapy for P.J. would be penicillin V and a penicillinase-resistant penicillin (e.g., dicloxacillin or cloxacillin) orally.

For cat bites, the role of *P. multocida* appears more significant because this organism can be found in the oral flora of up to 75% of cats. Although antibiotic treatment is not required for some dog bites, reports of a >50% incidence of infection after cat bites⁴³ suggest that all patients with cat bites should receive antibiotics. Because *P. multocida* often is resistant to penicillinase-resistant penicillins and first-generation cephalosporins, use of these agents in cat bites should be avoided. Therapies discussed above for dog bites would be appropriate for treating cat bites.

If the patient presents with an established infection, parenteral therapy is warranted if the infection is over a joint, has lymphatic spread, or involves the hand or head. If the patient has not responded to oral therapy, parenteral second-generation cephalosporins, such as cefoxitin 1 g IV Q 6 hr or ceftizoxime 1 g IV Q 8 hr, have activity against *P. multocida*, streptococci, staphylococci, and anaerobes.⁴³ The value of parenteral administration of clindamycin or erythromycin is limited by poor activity against *P. multocida*.^{2,43} The poor activity of quinolones against anaerobes has limited their use, despite good activity against *P. multocida*.⁴⁷ Parenteral therapy should be continued until resolution of the wound is evident, and therapy should then be continued with oral antibiotics. Alternate, but more expensive, therapies would include β -lactam/ β -lactamase combinations or carbapenems. There is no evidence that these agents are superior to second or third generation cephalosporins. If anaerobic infection is considered, the addition of metronidazole to the cephalosporin therapy may be warranted.⁵ Treatment should continue for at least 7 days or until all clinical signs of the infection have resolved.

HUMAN BITE WOUNDS

Evaluation of Human Bites

24. E.D., a 40-year-old man, presents with a sore arm 24 hours after receiving a bite to his left forearm by his neighbor in a "discussion over property boundaries." E.D. was previously healthy and has no chronic diseases. A 6 × 8-cm area of his left forearm is swollen and erythematous and includes several distinct puncture marks consistent with a human bite. No joint deformity or bone

abnormality is detected on clinical examination. How should E.D. be treated?

Treating a human bite is similar to any other laceration, including cleansing, irrigating, exploring, débriding, draining, excising, and suturing, as required.^{46,48} All human bites should be cleansed as soon as possible, and any lacerations or punctures irrigated copiously. Surgical exploration with débridement, drainage, or excision should be undertaken if deeper tissues may have been injured or if pus collection could have occurred. Exploration for damage to subcutaneous nerves, tendons, joints, or vascularity is particularly important in bites to the hand, especially the knuckles, because subsequent infections could seriously affect hand function. Because E.D. presents 24 hours after the injury, thorough exploration and irrigation of all lacerations or punctures is required. With evidence of pus accumulation in his wound, the area should be explored and drained. E.D. also should receive systemic antibiotic therapy to eradicate potential infecting organisms. Tetanus toxoid booster should be administered if E.D. has not received a booster in the past 10 years.

Empiric Antibiotic Therapy and Causative Organisms**25. Which antibiotic should be prescribed for E.D.?**

If E.D. had been seen within 12 hours of the injury, the wound could likely have been treated adequately with simple irrigation. This is especially true if the human bite does not involve the hand.⁴⁶ If the hand has been bitten or the patient is immunocompromised, a course of antibiotics using oral agents is appropriate.

If the wound is severe (i.e., involves subcutaneous tissues, a joint, or a large area) or if the patient is unlikely to be compliant with oral antibiotics, parenteral administration of antibiotics is required.⁴⁹ The most common pathogens in human bites are β -hemolytic streptococci, *S. aureus*, *Eikenella corrodens*, and *Corynebacterium* subspecies.⁴⁶ Anaerobic bacteria also are commonly involved.⁴⁶ Treatment with a combination of penicillin G and a penicillinase-resistant penicillin is appropriate.⁴⁶ Therapy with a penicillinase-resistant penicillin or a first-generation cephalosporin alone is not appropriate because *E. corrodens* commonly is resistant to these antibiotics.^{43,47} If the anaerobic flora of the patient's community is often resistant to penicillin, alternative anaerobic coverage with amoxicillin-clavulanate may be required.⁴⁶ If parenteral therapy is required, a second-generation cephalosporin with antianaerobic activity (e.g., cefoxitin, ceftizoxime) is appropriate.⁴⁶ Cefuroxime should not be used as single-agent therapy because it lacks activity against anaerobes and *E. corrodens*.⁴³ Third-generation cephalosporins and quinolones have good activity against *E. corrodens*, but they cannot be recommended because of their inferior activity against anaerobic organisms.⁴³ Fluoroquinolones, such as levofloxacin or moxifloxacin, have good activity against the organisms of bite infections, with the exception of poor activity against *Fusobacterium* species.⁵⁰ Azithromycin is the macrolide with the best activity against bite organisms.⁵¹ Alternate, but more expensive, parenteral therapy would include β -lactam/ β -lactamase inhibitor combinations or carbapenems. Oral regimens for penicillin-allergic

patients would include combinations of cotrimoxazole plus metronidazole, or a fluoroquinolone plus clindamycin.⁴

TETANUS PROPHYLAXIS

26. G.T., a 48-year-old woman, presents to the ED 1 hour after receiving a 2-cm laceration to her foot from stepping on a nail while walking around her neighborhood. Examination of the wound found it to be clean, with no subcutaneous extension. The wound was closed with superficial sutures, and no antibiotics, systemic or topical, were prescribed. Should G.T. receive tetanus prophylaxis?

Tetanus is a preventable disease through primary prophylaxis and appropriate wound management. Every child should receive primary prophylaxis of three separate doses of tetanus toxoid. This provides adequate coverage for at least 10 years.⁵² Tetanus can develop in patients who have not been immunized or who have not received a booster dose within the past 10 years. If G.T. has received her primary tetanus immunization and had a booster dose within the previous 10 years, no additional tetanus prophylaxis is required for her wound (Table 67-3). If her primary immunization status is unknown or >10 years has elapsed since her last dose, a single 0.5-mL subcutaneous tetanus toxoid dose should be administered. If primary immunization is unknown or incomplete, G.T. should receive the initial 0.5-mL dose immediately and should be scheduled to complete the primary immunization over the next 2 months. For adults, the combination product of tetanus and diphtheria toxoid is the recommended treatment because this will enhance protection against diphtheria.

If G.T. had presented with a dirty wound (contaminated with dirt, feces, soil, or saliva) or if the wound had resulted from a burn, frostbite, missile (bullet), crush, or avulsion, she should receive passive tetanus immunization with tetanus immune globulin in addition to the tetanus toxoid described above. A single 250-U intramuscular dose of tetanus immune globulin will provide passive immunization in addition to the active immunization produced from exposure to the tetanus toxoid (Table 67-3).

Table 67-3 Tetanus Prophylaxis in Routine Wound Management: Adults

| History of Adsorbed Tetanus Toxoid | Clean, Minor Wounds | | All Other Wounds ^a | |
|------------------------------------|---------------------|-----|-------------------------------|-----|
| | Td ^b | TIG | Td ^b | TIG |
| Unknown or <3 doses | Yes | No | Yes | Yes |
| ≥3 doses | No ^c | No | Yes ^d | No |

^aIncluding, but not limited to, wounds contaminated with dirt, feces, soil, and saliva; puncture wounds, avulsions, and wounds resulting from missiles; crushing, burns, frostbite.

^bFor children <7 years of age, diphtheria-tetanus-pertussis (DTP) is preferred to tetanus toxoid alone. For persons ≥7 years of age, Td is preferred to tetanus toxoid alone.

^cYes, if >10 years since last dose.

^dYes, if >5 years since last dose. (More frequent boosters are not needed and can accentuate the side effects.)

Td, tetanus and diphtheria toxoid; TIG, tetanus immune globulin.

Many patients with malignancy have had their lives prolonged through therapeutic advances in chemotherapy, immunotherapy, and bone marrow transplantation. Despite such advances, infectious complications continue to be a major cause of morbidity and mortality in these patients, often replacing the primary disease as the leading cause of death.¹ Although newer broad-spectrum antimicrobial agents and chemotherapeutic agents have altered the frequency and types of infectious complications in patients with both solid and hematologic malignancies, the management of infections in immunocompromised hosts remains a major challenge to health care professionals.

This chapter focuses on the prevention, diagnosis, and management of infectious complications in patients with neutropenia secondary to cancer chemotherapy. The following topics are addressed: principles of prophylactic antimicrobials, em-

piric antibiotic selection in the febrile patient, modification and duration of therapy, monotherapy versus combination regimens, empiric antifungal and antiviral use, and the use of hematopoietic growth factors.

RISK FACTORS FOR INFECTION

Patients are rendered “immunocompromised” when there is a significant disruption or deficiency of one or more of the host defenses as a result of the underlying disease or chemotherapy. These risk factors include neutropenia, iatrogenic damage to skin and mucosal barriers, and impairment in both humoral (antibody and complement) and cell-mediated immune defenses. Bacteria, fungi, viruses, and protozoa may infect various sites, depending on the specific immunodeficiency (Table 68-1).

Table 68-1 Most Common Pathogens Causing Infections in Neutropenic Cancer Patients

| Immunologic Defect | Underlying Condition(s) | Pathogen(s) | | | |
|--|---|--|--|--|---|
| | | Bacteria | Fungi | Parasites | Viruses |
| Neutropenia | Cancer chemotherapy, acute leukemia | <i>S. aureus</i> , coagulase-negative staphylococci, enterococci, <i>E. coli</i> , <i>K. pneumoniae</i> , <i>P. aeruginosa</i> | <i>Candida</i> spp., <i>Aspergillus</i> spp., <i>Fusarium</i> | — | — |
| T-helper lymphocyte (cell-mediated immunity) | Immunosuppressive therapy, Hodgkin disease, transplantation | <i>Listeria monocytogenes</i> , <i>Nocardia asteroides</i> , <i>Legionella</i> , <i>Salmonella</i> , mycobacteria | <i>Cryptococcus</i> , <i>Aspergillus</i> , <i>Candida</i> , <i>H. capsulatum</i> , <i>Mucoraceae</i> | <i>Pneumocystis jirovecii</i> , <i>Toxoplasma gondii</i> | <i>Herpes simplex</i> , varicella-zoster, cytomegalovirus |
| Gamma-globulin (humoral immunity) | Splenectomy, chronic lymphocytic leukemia, hypogammaglobulinemia, bone marrow transplantation | <i>S. pneumoniae</i> , <i>H. influenzae</i> , <i>N. meningitidis</i> | — | <i>Pneumocystis jirovecii</i> , <i>Babesia</i> spp. | — |
| Damage to physical barriers | Surgical procedures | <i>S. aureus</i> ; coagulase-negative staphylococci, <i>S. pyogenes</i> ; Enterobacteriaceae; <i>P. aeruginosa</i> , <i>Bacteroides</i> spp. | <i>Candida</i> spp. | — | — |
| | Indwelling catheters, venipuncture | <i>S. aureus</i> , coagulase-negative staphylococci, <i>Corynebacterium</i> | <i>Candida</i> spp. | — | — |
| | Chemotherapy, endoscopy, radiation | <i>S. aureus</i> , coagulase-negative staphylococci, streptococci, Enterobacteriaceae, <i>P. aeruginosa</i> , <i>Bacteroides</i> | <i>Candida</i> spp. | — | <i>Herpes simplex</i> |
| Microbial colonization | Chemotherapy, antibiotics, hospitalization | <i>S. aureus</i> , coagulase-negative staphylococci, Enterobacteriaceae, <i>P. aeruginosa</i> , <i>Legionella</i> | <i>Candida</i> spp., <i>Aspergillus</i> | — | — |
| Transplantation | Bone marrow | — | <i>Candida</i> spp. | <i>Toxoplasma gondii</i> , <i>P. carinii</i> | Cytomegalovirus, hepatitis B and C, Epstein-Barr virus |

Neutropenia

Granulocytes, or granular leukocytes, represent an important defense against bacterial and fungal infections. *Neutropenia* (a reduction in the number of circulating granulocytes or neutrophils) predisposes the host to infections. The terms *granulocytopenia* and *neutropenia* are often used interchangeably. The degree of neutropenia is expressed in terms of the absolute neutrophil count (ANC) or the total number of granulocytes (polymorphonuclear leukocytes and band forms) present in the circulating pool of white blood cells (WBCs).

The quantitative relationship between neutropenia and outcome of infections was established more than 40 years ago.² It was discovered that the risk of infection in the neutropenic patient is proportional to both the severity and duration of neutropenia. In general, the risk of infection is low when the ANC exceeds 1,000 cells/mm³, with the frequency and severity of infection inversely proportional to the ANC.^{2,3} As the ANC drops to <500 cells/mm³, the risk of infection rapidly

increases. The risk of developing infection is further increased as the ANC drops to <100 cells/mm³.² Conversely, recovery of the ANC is the most important factor determining the outcome of infectious complications in the neutropenic patient. Febrile patients with short durations of neutropenia (<1 week) or in whom neutropenia is not severe (<100 cells/mm³) generally respond to empiric antibiotics and less frequently develop serious, life-threatening infections.² In contrast, patients rendered neutropenic for >1 week (e.g., those receiving more intensive chemotherapy regimens) and/or are severely neutropenic are more vulnerable to serious infection.²

Damage to Physical Barriers

The intact skin and mucosal surfaces of the body constitute the host's primary physical defense against microbial invasion. The integrity of this physical barrier may be disrupted by tumor, treatment (e.g., surgery, radiation), or various medical procedures (e.g., insertion of intravenous [IV] or urinary catheters,

venipuncture, measurement of rectal temperature).⁴ Device-related infections, including those associated with central IV catheters, are commonly caused by migration of skin flora (e.g., staphylococci) through the cutaneous insertion site.⁴ Infections secondary to damaged mucosal lining of the gastrointestinal (GI) tract are usually caused by enteric bacteria and fungi such as *Candida* spp.⁴

Alterations in the Immune System

Patients with immunoglobulin deficiencies (e.g., hypogammaglobulinemia, chronic lymphocytic leukemia, or splenectomy) are at increased risk for infections with encapsulated bacteria that must undergo antibody opsonization for efficient phagocytosis. Such bacteria include *Neisseria meningitidis*, *Haemophilus influenzae*, and *Streptococcus pneumoniae*.^{1,4} Hodgkin disease, organ transplantation, and HIV disease can disrupt the cellular immune system, increasing the risk for infections with obligate and facultative intracellular organisms such as mycobacteria, *Listeria*, *Toxoplasma*, viruses, and fungi.^{1,4}

Some chemotherapeutic regimens have profound effects on both cellular and humoral defenses. Corticosteroids exert their immunosuppressive effects on the cellular immune system, particularly at the T-lymphocyte and macrophage level. Therefore, patients receiving corticosteroids have increased susceptibility to infections with viral, bacterial, protozoal, and fungal infections.⁵ Infectious complications secondary to glucocorticoid use appear to be dose dependent. The risk of infection increases with daily doses > 10 mg or cumulative doses > 700 mg of prednisone or its equivalent.⁵ Thus, patients receiving corticosteroids in either high doses or for prolonged periods are at increased risk for a wide spectrum of infections caused by bacteria, fungi, and other opportunistic pathogens.⁵

Colonization

Microbial colonization can be a prerequisite to infection in neutropenic patients. *Colonization* may be defined as the recovery of an organism from any particular site (e.g., stool, nasopharynx) without clinical signs of infection. Most infections in neutropenic patients are caused by the host's endogenous microflora or hospital-acquired pathogens that have colonized the alimentary tract, upper respiratory tract, and/or skin.^{3,6}

Hematopoietic Stem Cell Transplantation

Transplantation of bone marrow predisposes patients to the development of opportunistic infections secondary to both intensive immunosuppressive therapy and transmission.^{7,8} These infections may be acquired from blood products or may represent reactivation of latent host infection.^{7,8} The types of infections are detailed in other chapters (see Chapters 35 and 92). The introduction of new therapeutic approaches for treatment of the underlying malignancy (including nucleoside analogs and monoclonal antibodies to CD20 and CD52), along with use of unrelated stem cell donors, has increased the potential for infections in these patients, particularly among allogeneic hematopoietic stem cell transplant (HSCT) recipients.

Radiation Therapy

Side effects associated with the use of radiation therapy for the treatment of malignancy (e.g., mucositis, skin breakdown, or reduction in blood counts) may also predispose a patient with neutropenia to infection.

MOST COMMON PATHOGENS

1. B.C., a 41-year-old woman, was admitted to the cancer center for placement of a central IV catheter for administration of chemotherapy to treat acute nonlymphocytic leukemia in relapse. She was diagnosed 2 years ago and was treated with cytarabine plus daunorubicin, which resulted in a complete remission for 33 months. This admission, she will be treated with high-dose cytarabine plus mitoxantrone for reinduction. What are the most likely pathogens to cause infection in patients like B.C. during periods of chemotherapy-induced neutropenia?

Bacteria are the primary pathogens associated with infection in febrile neutropenic patients, especially those occurring early (Table 68-1).⁹ Bacteremia is most often caused by aerobic Gram-negative bacilli (especially *Pseudomonas aeruginosa*, *Escherichia coli*, and *Klebsiella pneumoniae*) or aerobic Gram-positive cocci (i.e., coagulase-negative staphylococci, *Staphylococcus aureus*, enterococci, viridans streptococci).^{10,11} Since the mid-1990s, the proportion of Gram-negative infections has decreased with a proportional increase in Gram-positive infections.¹⁰⁻¹⁴ Gram-positive bacteria now account for approximately 60% to 70% of microbiologically-documented infections in neutropenic cancer patients.^{12,13} This is believed to be due (in part) to the frequent use of indwelling intravascular catheters, use of more intensive chemotherapy regimens, and widespread use of broad-spectrum antibiotics for prophylactic and therapeutic use. These factors can contribute to the development of infection in patients such as B.C.

S. aureus (including methicillin-resistant *S. aureus* [MRSA]) and *Staphylococcus epidermidis*, streptococci (including *S. pneumoniae* and viridans streptococci), and *Corynebacterium* species have become important pathogens in some cancer centers.¹⁰⁻¹³ Moreover, enterococcal infections (including vancomycin-resistant enterococci [VRE]) are increasing in frequency because of the routine use of broad-spectrum antibiotics.¹² Meningitis caused by the intracellular organism *Listeria monocytogenes* can be observed in patients with defective cellular immunity caused by disease or prolonged corticosteroid use. In general, anaerobic bacteria are an infrequent cause of infection in granulocytopenic patients with hematologic malignancies.¹⁵ However, they may occur more frequently in patients with GI malignancies or with significant disruption of the GI tract secondary to chemotherapy.¹⁵

Invasive fungal infections are a major cause of morbidity and mortality among neutropenic cancer patients and patients undergoing bone marrow transplantation.¹⁶ They tend to occur later in the illness. Patients with prolonged neutropenia (>7 days), allogeneic HSCT recipients, and those undergoing therapy for graft-versus-host disease (GVHD) are at increased risk of developing systemic fungal infections. In one report, approximately 50% of patients who die during prolonged periods of neutropenia had evidence of deep-seated mycoses at

autopsy.¹⁶ Prior to the use of fluconazole prophylaxis in selected populations, *Candida* spp. were responsible for most invasive fungal infections. Today, invasive infections due to *Aspergillus* spp. and other moulds are a major cause of invasive fungal infection (IFI)-related death (particularly those with prolonged neutropenia and GVHD).¹⁶

Viral infections are generally a reactivation of latent infection. These may include herpes simplex virus and varicella-zoster virus.^{3,10} Other viruses, such as cytomegalovirus (CMV), can be acquired during hematopoietic stem cell transplantation.⁷³ Respiratory viruses (e.g., respiratory syncytial virus [RSV], influenza, parainfluenza) and other seasonal viruses may occasionally cause infection in this population.

PROPHYLAXIS AGAINST INFECTION

Infection Control

Exogenous contamination can be prevented by strict protective isolation of patients in specially designed rooms that maintain a sterile environment. These laminar airflow rooms are ventilated with air that is passed through a high-efficiency particulate air (HEPA) filter, which removes >99% of all particles larger than 3 microns. Total protective isolation is accomplished by strict isolation in conjunction with the administration of sterile food and water, local skin care, and intensive microbial surveillance.⁸ However, this regimen is burdensome to the patient and health care personnel, difficult to accomplish and maintain, and expensive. Thus, it continues to be used in only a few treatment centers. However, close adherence to adequate handwashing procedures is essential. In addition, contact isolation is advocated in circumstances in which the patient may be colonized or infected with resistant organisms. Finally, isolating the patients from caregivers with potentially contagious respiratory viral illnesses is advocated.

Antimicrobial Prophylaxis

2. What is the role of oral antimicrobial prophylaxis during the neutropenic period?

Studies have demonstrated that the early administration of oral antibiotics (both antibacterials and antifungals) during the afebrile, neutropenic period in select “high-risk” patients can result in a reduction in the number of febrile episodes and subsequent risk of infection.¹⁷ The goals of such prophylactic antibiotic regimens have been aimed at reducing potentially pathogenic endogenous microflora or preventing the acquisition of new micro-organisms in the neutropenic patient.¹⁷ Potential benefits must outweigh the risks of antibiotic-related adverse effects, the development of resistance, and the potential for superinfection. Therefore, prophylaxis is generally considered only in select “high-risk” patients with neutropenia expected to be severe (<100 cells/mm³) or prolonged (<7 days).¹⁰

Nonabsorbable Antibacterials

The alimentary tract is recognized as an important reservoir of potential pathogens. Therefore, gut decontamination with and without total protective isolation has been investigated. The rationale behind the use of selective decontamination regimens is based on animal studies that demonstrated that selective elim-

ination of aerobic GI flora, although maintaining anaerobic flora, prevented colonization with potentially pathogenic aerobic Gram-negative bacteria. Early studies focused on the use of nonabsorbable antimicrobials such as gentamicin, polymyxin B, and colistin to eradicate selected bowel flora while reducing the potential for systemic toxicity.

Oral, nonabsorbable antibacterial regimens have not shown consistent efficacy in preventing infection in the neutropenic cancer patient.¹⁷ A major problem with these regimens has been poor patient compliance and tolerance, often because of their unpleasant taste. Of additional concern is the development of aminoglycoside resistance from the nonabsorbable aminoglycoside-containing regimens. Finally, colistin use has recently been identified as a risk factor for staphylococcal infections.¹² Therefore, use of nonabsorbable antibacterial agents have largely been supplanted by oral, absorbable antibiotics.^{10,17}

Trimethoprim-Sulfamethoxazole

Several studies have demonstrated the benefit of trimethoprim-sulfamethoxazole (TMP-SMX) in reducing bacterial infections when compared to placebo in febrile neutropenic patients.^{18–20} Its benefit in reducing mortality, however, is less clear. In contrast, its role in preventing *Pneumocystis jirovecii* (formerly known as *Pneumocystis carinii* or PCP) pneumonia has been established in many immunocompromised patient populations, independent of the presence of neutropenia.^{8,10,19} The potential benefits of TMP-SMX prophylaxis must be carefully balanced against the potential for drug-induced bone marrow suppression, hypersensitivity reactions, the emergence of resistant organisms (e.g., *E. coli*), and the development of superinfections. Patients at high risk for developing *P. jirovecii* pneumonia (i.e., patients with acute lymphocytic leukemia receiving intensive chemotherapy, AIDS, allogeneic HSCT recipients) should be strongly considered for TMP-SMX prophylaxis.^{3,10} Recipients of T-cell-depleting agents (e.g., fludarabine or cladribine), cancer patients receiving prolonged corticosteroids (>20 mg prednisone or its equivalent daily), and autologous HSCT recipients should also be considered for prophylaxis with TMP-SMX.³ In the absence of these risk factors, routine use of TMP-SMX as primary prophylaxis for neutropenia is not currently recommended.^{3,10} In patients requiring PCP prophylaxis but unable to tolerate TMP-SMX, patients should be considered for either TMP-SMX desensitization, atovaquone, dapsone, or aerosolized pentamidine as alternate strategies.³

Fluoroquinolones

Fluoroquinolones (e.g., ciprofloxacin, norfloxacin, ofloxacin, levofloxacin) are used by some centers as prophylaxis for patients at high risk of infection. Data regarding their use for preventing infection in neutropenic cancer patients have been summarized elsewhere.^{21–24} Of concern, however, is the increasing frequency of Gram-positive infections (including viridans streptococci) observed in patients receiving fluoroquinolone prophylaxis,^{25,26} combined with the emergence of resistant Gram-negative bacilli (especially *E. coli*)²⁷ caused by the widespread use of these agents. Recent meta-analyses report reductions in mortality in high-risk patients receiving prophylaxis with fluoroquinolones.²⁴ Because the benefits of fluoroquinolone prophylaxis may be offset by the emergence

of resistant organisms, routine prophylactic use in neutropenic patients should be avoided.³ However, those at highest risk of bacterial infections (i.e., those patients with an ANC <100 neutrophils/mm³ for >10 days) should be considered for fluoroquinolone prophylaxis until either the onset of fever or resolution of severe neutropenia (>100 neutrophils/mm³).³

Antifungals

3. What is the role of antifungal prophylaxis in neutropenic patients?

Routine antifungal prophylaxis is not indicated in all patients with neutropenia. However, select patients (i.e., those with acute leukemic patients with prolonged neutropenia [>7 days], allogeneic HSCT recipients, and patients receiving systemic corticosteroids for treatment of GVHD) are at increased risk of developing systemic fungal infections.¹⁶ Because of the frequency with which such infections are encountered, difficulties in establishing a diagnosis, and poor response rates in patients with serious invasive infection who are immunocompromised, effective prophylactic strategies are necessary in these high-risk patients.

NONABSORBABLE ANTIFUNGALS

Various nonabsorbable antifungal agents have been studied for use in fungal prophylaxis in neutropenic patients. Topical agents, such as oral nystatin,^{28,29} clotrimazole,³⁰ and oral amphotericin B,³¹ have been studied. Of these agents, only oral amphotericin B and clotrimazole have been successful in reducing the frequency of oropharyngeal candidiasis. None of the antifungals have a role as primary prophylaxis of invasive fungal infections.^{3,10}

SYSTEMIC ANTIFUNGALS

The use of systemic antifungals for prophylaxis has been extensively studied. Early trials with the imidazoles miconazole and ketoconazole met with limited success. The toxicities associated with these agents and the availability of newer, less toxic antifungals currently limit their clinical utility in this setting.

In addition to its *in vitro* activity against many *Candida* spp. (e.g., *C. albicans*), itraconazole is active *in vitro* against *Aspergillus* species. Randomized, placebo-controlled trials^{32,33} as well as comparisons with amphotericin B³⁴ have demonstrated its efficacy in reducing systemic *Candida* infections in this patient population. A previous limitation to the potential efficacy of itraconazole was the availability of a capsule formulation whose bioavailability following oral administration was significantly dependent on gastric acidity. The oral solution demonstrates improved bioavailability over the capsule. In addition, an IV formulation has also been introduced for use in patients unable to tolerate oral therapy.

Studies have demonstrated that fluconazole prophylaxis has decreased the frequency of both superficial (e.g., oropharyngeal candidiasis) and systemic fungal infections in bone marrow transplant patients^{35,36} but not in patients with leukemia.^{37,38} When fluconazole 400 mg/day was compared with placebo for fungal prophylaxis in bone marrow transplant recipients, it significantly reduced the incidence of invasive candidiasis and delayed the initiation of empiric amphotericin B from day 17 to day 21.³⁶ It is unknown, however,

if such patients who currently may experience a reduction in the degree and duration of neutropenia due to the administration of colony-stimulating growth factors would also benefit. In contrast, in a study of patients with acute leukemia undergoing chemotherapy, fluconazole prophylaxis was not associated with a reduction in invasive fungal infections or need for empiric amphotericin B.³⁸ Despite its potential role, concern over its lack of reliable *in vitro* activity against moulds limits its expanded use in high-risk patients. An increased frequency of isolation of non-*albicans Candida* (e.g., *C. krusei*, *C. glabrata*, *C. parapsilosis*) has also been noted in some institutions.³⁹ Fluconazole may not have a significant impact in reducing mortality in these patients.⁴⁰

Fluconazole is available as both oral and IV formulations, and its oral bioavailability is not significantly influenced by changes in gastric acidity. Like itraconazole, the IV formulation enables fluconazole to be administered to critically ill patients or patients who have difficulty swallowing. However, unlike itraconazole, it is not contraindicated in patients with significant renal impairment. Despite such potential advantages, the efficacy of fluconazole in preventing invasive fungal infections was inferior to that of itraconazole in a randomized, comparative trial performed in 140 patients receiving allogeneic hematopoietic stem cell transplants.⁴¹ In this trial, proven invasive fungal infections occurred in 6 of 71 (9%) itraconazole recipients and 17 of 61 (28%) fluconazole-treated patients. Although overall mortality was not different, fewer fungal deaths were reported in the itraconazole-treated patients (9% vs. 18%), but this difference was not statistically different ($P = 0.13$). In another randomized, comparative trial in allogeneic HSCT patients, fluconazole was compared with itraconazole.⁴² Although itraconazole demonstrated superiority during treatment and against mould infections, no differences in invasive fungal infections or mortality were observed between treatments during the entire study period. Treatment-related hepatotoxicity and drug discontinuation because of side effects (predominantly GI intolerance) were more frequent in the group receiving itraconazole (36% vs. 16%, $P < 0.001$).

The prophylactic role of IV amphotericin B has also been investigated.^{40,43} In one such evaluation, amphotericin B 0.5 mg/kg given three times weekly was compared with fluconazole 400 mg/day in 90 patients with acute leukemia.⁴³ Although efficacy against fungal infections was similar in both groups, more side effects (i.e., infusion-related reactions, nephrotoxicity, and electrolyte disturbances) were observed with the amphotericin B regimen. Therefore, the use of amphotericin B deoxycholate for primary prophylaxis is generally discouraged given existing options. There are limited published data on the efficacy of lipid-based formulations of amphotericin B (e.g., amphotericin B lipid complex, liposomal amphotericin B) for prophylaxis. One study compared liposomal amphotericin B versus a combination with fluconazole and itraconazole.⁴⁴ No significant differences were detected in terms of efficacy, but toxicity was noted more frequently in the patients receiving liposomal amphotericin B. Lipid-based amphotericin B preparations are generally reserved for patients with underlying renal dysfunction for which alternative strategies would be inappropriate.

The recent introduction of the echinocandin class of antifungals has expanded the number of agents evaluated as a

prophylactic strategy in high-risk patients. Micafungin was compared to fluconazole in a randomized, double-blind study conducted in autologous and allogeneic HSCT recipients.⁴⁵ Based on a composite endpoint (which included absence of breakthrough fungal infection and absence of empiric modifications to the antifungal regimen due to neutropenic fever), micafungin was found to be superior. Although breakthrough candidemia, survival, and adverse events were similar in both groups, a trend toward a reduction in invasive aspergillosis in the allogeneic HSCT population was noted in the micafungin group. Micafungin is currently U.S. Food and Drug Administration (FDA)-approved for the prevention of *Candida* infections in HSCT patients.

In addition to the echinocandins, extended-spectrum triazoles (posaconazole and voriconazole) have been evaluated. Posaconazole demonstrated improved survival, a reduction in proven or probable IFI, and a reduction in invasive aspergillosis when compared to standard prophylaxis (either itraconazole or fluconazole) for the prevention of fungal infection in patients undergoing chemotherapy for acute myelogenous leukemia or myelodysplastic syndrome.⁴⁶ Posaconazole has also proven to be an effective prophylaxis in allogeneic HSCT recipients undergoing therapy for GVHD.⁴⁷ Posaconazole is currently available only as an oral formulation, which may limit its use in patients unable to take oral therapy. Although the efficacy of voriconazole in the treatment of invasive aspergillosis has been well documented, published data to support its use as prophylaxis in this patient population is currently lacking. Side effects (most notably hepatotoxicity) and the increased potential (relative to fluconazole and the echinocandins) for drug interactions with voriconazole may limit its use in this setting to patients at highest risk of mould infections. Although use of voriconazole has also been implicated in the emergence of pathogens such as zygomycosis in this patient population, a definitive cause-and-effect relationship is lacking.

Primary antifungal prophylaxis should generally be reserved for high-risk patients with neutropenia (e.g., allogeneic HSCT recipients).³ Autologous HSCT recipients receiving agents causing significant mucositis, patients undergoing therapy for acute leukemia and those receiving corticosteroids for treatment of GVHD should also be considered for prophylaxis.³ Although fluconazole has demonstrated efficacy when compared to placebo, select agents (i.e., echinocandins, voriconazole, itraconazole, posaconazole, amphotericin B) might be preferred in patients at increased risk of mold infections. Prophylaxis is generally continued until day 75 after transplant or through induction therapy for patients with leukemia.³ Patients with a history of documented *Aspergillus* infection undergoing intensive chemotherapy should be considered for voriconazole. Although the addition of a second prophylaxis (e.g., caspofungin) may be considered, the benefits of combination therapy for secondary prophylaxis require further study. Other secondary prophylactic regimens can be used in patients with a history of IFIs, based on the infection.

Patients receiving cytotoxic chemotherapy for solid tumors have lower rates of invasive fungal infections compared with patients with hematologic malignancies and those receiving allogeneic bone marrow transplantation. This is primarily because of the differences in the duration of neutropenia. In patients receiving cytotoxic chemotherapy for solid tumors,

antifungal prophylaxis may not be beneficial and may actually increase the potential for superinfection with resistant fungi. Such patients should be managed with empiric antifungal therapy if they develop persistent fever and neutropenia.

Antivirals

The use of antiviral prophylaxis varies with patient population. High-risk patients (e.g., those receiving allogeneic HSCT, those with acute leukemia undergoing induction or reinduction therapy, those with a past history of infection during neutropenia or patients receiving T-cell-depleting agents such as fludarabine) and those who are seropositive for *herpes simplex* virus (HSV) should be considered for antiviral prophylaxis for the first month after transplant or (for acute leukemias) during periods of neutropenia.^{3,8,10} Both acyclovir and valacyclovir may be useful in such settings. Published data for famciclovir for this indication is lacking. Allogeneic HSCT patients who are seropositive for varicella-zoster virus (VZV) should also be considered for acyclovir prophylaxis until the patients have discontinued immunosuppression.^{3,8,10} In addition, bone marrow transplant recipients at increased risk of CMV infection (e.g., CMV-seropositive patients and CMV-seronegative recipients with a CMV-seropositive donor) should be considered for either ganciclovir prophylaxis or pre-emptive therapy if early evidence of infection is observed.^{7,9} The role of valganciclovir as a prophylactic strategy in this population requires further evaluation. Patients experiencing HSV reactivation during treatment should also receive prophylaxis during subsequent periods of neutropenia.³

Respiratory tract infections due to RSV, influenza, and parainfluenza are less commonly observed in patients with neutropenia. Although response to influenza virus vaccine may be attenuated, cancer patients should receive annual vaccinations with inactivated influenza vaccine.³ In contrast, immunocompromised patients should not receive the intranasal live virus vaccine.³

Hematopoietic Growth Factors

Updated guidelines have recently been published to readdress the use of granulocyte colony-stimulating factor (G-CSF; filgrastim), granulocyte-macrophage colony-stimulating factor (GM-CSF; sargramostim), or pegylated G-CSF (pegfilgrastim) for use in the prophylaxis of infection in the neutropenic patient.^{48,49} These guidelines advocated the use as primary prophylaxis in patients at high risk (>20%) of fever and neutropenia based on risk factors of age (i.e., younger than 65 years), medical history (including prior history of febrile neutropenic episodes, nutritional status, unstable comorbidities, and presence of active infections), disease characteristics (especially those involving bone marrow resulting in cytopenias), and myelotoxicity of the regimen (including both chemotherapy and radiation) used to treat the underlying malignancy. Secondary prophylaxis should be considered for patients who had experienced neutropenic complication from prior cycles of chemotherapy (especially if primary prophylaxis was not administered), or for whom reductions in chemotherapy dose to avoid neutropenia may compromise treatment outcome and disease-free or overall survival.

INFECTIONS IN NEUTROPENIC CANCER PATIENTS

Clinical Signs and Symptoms

4. Seven days after completing chemotherapy, B.C. developed a fever of 102°F (orally). Vital signs are blood pressure (BP), 109/70 mmHg; pulse, 102 beats/minute; and respirations, 25 breaths/minute. Physical examination demonstrates a clear oropharynx without exudates or plaques. Chest and cardiac examination are normal. The exit site for the Hickman catheter is clean and nontender without signs of erythema or induration. The perineum and rectum are nontender, and no masses are noted.

Laboratory data are hematocrit (Hct), 20% (normal, 33%–43%); hemoglobin (Hgb), 7 g/dL (normal, 14–18); WBC count, 1,400 cells/mm³ (normal, 3,200–9,800), with 3% polymorphonuclear leukocytes (PMNs; normal, 54–62), 1% band forms (normal, 3–5), 70% lymphocytes (normal, 25–33), and 22% monocytes (normal, 3–7); platelet count, 17,000 cells/L (normal, 130,000–400,000); blood glucose, 160 mg/dL (normal, 70–110); serum creatinine (SrCr), 1.1 mg/dL (normal, 0.6–1.2); blood urea nitrogen (BUN), 24 mg/dL (normal, 8–18).

What are the signs and symptoms of infection in B.C.? What are the most common sites and sources of infection in patients such as B.C.?

[SI units: Hct, 0.2 (normal, 0.33–0.43); Hgb, 70 g/L (normal, 140–180); WBC count, $1.4 \times 10^{10}/L$ (normal, 3.2–9.8) with 0.03 PMNs (normal, 0.54–0.62), 0.01 band forms (normal, 0.03–0.05), 0.7 lymphocytes (normal, 0.25–0.33), and 0.22 monocytes (normal, 0.03–0.07); platelets, $17 - 10^{10}/L$ (normal, 130–400); glucose, 8.88 mmol/L (normal, 3.89–6.11); SrCr, 97.24 mmol/L (normal, 53.04–106.08); BUN, 8.57 mmol/L urea (normal, 2.86–6.43)]

Neutropenia is usually defined as an ANC <500 cells/mm³, or <1,000 cells/mm³, and expected to decline to <500 cells/mm³ within 2 days.³ B.C. has an ANC of 48 cells/mm³ (1,400 WBC/mm³ \times [0.03 PMN + 0.01 bands]) and is therefore at high risk for infection. Fever in neutropenic patients is defined as a single oral temperature of $\geq 38.3^{\circ}\text{C}$ (101°F) or a temperature of $\geq 38.0^{\circ}\text{C}$ (100.4°F) for >1 hour in the absence of an obvious cause.^{10,50} As her case illustrates, fever is the earliest (and often the only) sign of infection in neutropenic patients because typical signs can be modified or absent in this patient population.^{9,47,48} In contrast, other signs and symptoms consistent with a diagnosis of infection without fever should be considered to be infection in the neutropenic host.

In patients with documented infections, the most common sites are skin, mouth/throat, esophagus, sinuses, abdomen/rectum/liver, vascular access, lungs, and urinary tract.³ Although the lung is the most common site of serious infection in neutropenic cancer patients, fever and dry cough are often the only presenting signs of pneumonia.⁵¹ The impaired inflammatory response in these patients often makes sputum production scant, and sputum Gram stains often contain few polymorphonuclear cells. Radiologic evidence of a pulmonary infection can be minimal or absent, and the chest examination is frequently nondiagnostic. Pneumonia has a high mortality rate in neutropenic patients, especially if it occurs in conjunction with bacteremia.¹⁰ In the presence of shock, a mortality rate of approximately 80% has been observed in these patients.⁵²

Invasive procedures such as venipuncture, central IV catheter placement (e.g., Hickman catheter), and skin biopsies are associated with cellulitis and systemic infections. However,

detecting skin and soft tissue infections is also difficult because the typical signs and symptoms of infection (e.g., pain, heat, erythema, swelling) are often absent.⁵¹ This phenomenon exists due to the lack of adequate numbers of granulocytes, as well as the suppression or absence of other components of the inflammatory response.² Colonization of these lesions may result in local infection and the potential for systemic dissemination of bacteria and fungi. Bacteremia occurs primarily from entry of bacteria through the skin or through unrecognized ulcerations in the GI and perirectal areas.¹⁰

Confirmation of Infection

5. How can an infection be confirmed in patients such as B.C.?

Noninfectious sources of fever in the neutropenic cancer patient include inflammation, tumor progression, tumor lysis, adverse drug reactions, and transfusion reactions. Because of the frequent lack of physical signs and symptoms of infection, the clinician must obtain an accurate history (including the cancer type and treatment regimen) and conduct a careful physical examination at the first sign of fever.^{51,53} A detailed search for subtle signs and symptoms of inflammation at the most common sites, such as the oropharynx, bone marrow aspiration sites, lung, periodontium, skin, vascular catheter access sites, nail beds, and perineum (including the anus) is necessary. Before antibiotics are initiated, two sets of blood cultures (with each set consisting of two culture bottles) should be obtained.³ Additional cultures (e.g., stool, urine, IV site, viral) should be obtained if such infections are suspected.³ Any indwelling urinary or IV catheter should be considered as a potential focus of infection and, if possible, should be removed and cultured.¹⁰ Chest radiographs and oximetry should be obtained if signs and symptoms point to the respiratory tract as a potential infection site.¹⁰ A complete blood count, serum electrolytes, and assessment of organ function (e.g., liver and kidney function) should be obtained to assist in drug dosing and monitoring for treatment-related toxicities.¹⁰

An infectious cause for fever can be documented either clinically or microbiologically in up to 60% of neutropenic cancer patients.⁹ Forty percent of these febrile episodes have a documented microbiological origin; the remaining 20% are attributed to infection based on clinical findings alone.⁹

Significance of Colonization

6. Routine surveillance cultures of swabs taken from B.C.'s axillae, nasopharynx, and rectum grew *C. jeikeium* (axillae), *S. aureus* (axillae and nasopharynx), and *Enterococcus faecium* (rectum). What is the significance of these culture results? Should routine, serial surveillance cultures be performed in patients such as B.C.?

Several factors influence the colonization and subsequent infection by micro-organisms in cancer patients such as B.C. Organisms isolated from infected patients can be found in endogenous flora or acquired during hospitalization.⁶ The sources of and factors contributing to colonization are numerous and include staff-to-staff and patient-to-patient transmission (e.g., lack of frequent and adequate hand hygiene), direct transmission from the environment (e.g., inadequately disinfected

bathbubs, sinks, toilet bowls), foods (e.g., raw fruits and vegetables), inhalation from contaminated fomites (e.g., respirators, ventilating systems), and IV access devices.

In addition to immunosuppression, the underlying malignancy and chemotherapy diminish the cancer patient's resistance to colonization and infection. For example, chemotherapy induces changes in the microbial binding receptors on epithelial cells in the oropharynx. This allows Gram-negative bacilli to adhere to these surfaces, changing the composition of the oropharyngeal flora from a mixture of Gram-positive aerobes and anaerobes to Gram-negative aerobic bacteria.⁵⁴ Colonization with resistant organisms is enhanced by prior antibiotic administration, which may suppress the growth of normal anaerobic flora in the GI tract. This anaerobic suppression may promote the overgrowth of resistant micro-organisms.⁵⁴ For example, *P. aeruginosa* and *K. pneumoniae* are not commonly found in the stools of normal healthy adults, but they are recovered from the stools of hospitalized cancer patients.

Organisms that colonize cancer patients differ in their invasiveness and propensity to cause infection.^{6,55} Colonization with *P. aeruginosa* is more likely to result in infection than is colonization with less virulent organisms such as *E. coli* or *S. epidermidis*.⁵⁶ However, if the host is profoundly impaired, organisms generally considered to be less virulent may become pathogenic.

The acquisition of and subsequent colonization by potentially pathogenic microbes may be detected by serial "surveillance" cultures of specimens obtained from various body sites such as the nasopharynx, axilla, urine, and rectum. Such surveillance cultures can provide information about the dynamic changes in microflora during hospitalization that may be useful for infection control purposes. However, little clinically useful information is gained when infection is absent.⁵⁷ Therefore, surveillance cultures are generally restricted to select patients for infection control purposes. In such cases, culture of the anterior nares (for MRSA) or rectal samples (for VRE or multidrug-resistant Gram-negative bacilli) may be performed.

In summary, B.C.'s surveillance culture results indicate that she is colonized with several potential pathogens associated with infection in the immunocompromised host, but these results are probably not useful in selecting empiric antibiotics for her fever.

EMPIRIC ANTIBIOTIC THERAPY

Rationale

7. Should B.C. be started on antibiotic therapy immediately? Is this rational in view of the fact that neither the source of her fever nor the pathogen has been established?

All febrile patients with either an ANC of <500 cells/mm³ or $<1,000$ and expected to decline to <500 cells/mm³ within 2 days should be considered to have a potentially life-threatening infection.^{3,10} In addition, afebrile neutropenic patients with signs or symptoms of infection should also receive antibiotic therapy. Once blood cultures and cultures from suspected sources of infection are obtained, these patients should be promptly started on broad-spectrum antibacterials.^{3,10} Early studies in the 1950s and 1960s documented the poor prognosis of neutropenic patients whose Gram-negative infections

were untreated during the first 24 to 48 hours following the onset of fever. Crude mortality rates secondary to *P. aeruginosa* bacteremia approached 91%.⁵⁶ This finding was confirmed in the 1970s when it was demonstrated that withholding antibiotics until a pathogen was isolated resulted in an unacceptably high mortality rate in neutropenic patients. Prompt use of empiric, broad-spectrum antibiotics since the mid-1980s has contributed to significant reductions in infectious mortality rates to $<30\%$, depending on the causative organism.⁵⁸ These observations emphasize the need for rapid institution of empiric antibiotic therapy to prevent early morbidity and mortality.

Optimal Antibacterial Spectrum

8. What pathogen- and patient-specific factors should be considered when initiating empiric therapy for B.C.?

Despite advances in the development in antibacterials since the 1960s, the empiric management of febrile neutropenic patients continues to be complicated by the changing spectrum of bacterial pathogens and their antimicrobial susceptibilities. Empiric antibiotic regimens should provide broad-spectrum coverage against the potential Gram-negative bacilli most commonly isolated from neutropenic cancer patients (e.g., *E. coli*, *K. pneumoniae*, *P. aeruginosa*), staphylococcal and viridans streptococci.^{3,10} Because mortality from untreated bacteremia caused by *P. aeruginosa* was high in early studies,⁵⁶ empiric regimens have traditionally included antimicrobials with antipseudomonal activity.

Selecting an initial empiric regimen for a given patient should take into account likely pathogens, their frequency of isolation, infection-specific antibiotic efficacy and institutional susceptibility patterns. Patient-related considerations should include medical stability, allergies, prior and concomitant antimicrobials, and organ dysfunction (e.g., renal or hepatic). Attempts should be made to identify low-risk patients for whom oral antimicrobial therapy may be an option.^{3,10} Finally, dosing schedules, acquisition costs, and the potential for significant toxicities should be considered.

In addition to broad-spectrum activity, antibacterial regimens should ideally have bactericidal activity against the infecting pathogen. However, no adequately controlled comparative trials of bacteriostatic versus bactericidal antibiotics have been conducted in humans.

In summary, many organisms, including those recovered from surveillance cultures, may be pathogens in B.C. Those associated with a high mortality rate during the first 48 hours should be empirically treated pending culture and sensitivity results. Therefore, an empiric regimen with optimal activity against commonly isolated Gram-negative bacilli (including *P. aeruginosa*) should be promptly administered to B.C.

Initial Empiric Antibiotic Regimens

9. What would be a reasonable initial empiric antibiotic regimen for B.C.?

Practice guidelines prepared by the National Comprehensive Cancer Network³ and the Infectious Diseases Society of America (IDSA)¹⁰ identify antimicrobial options for the treatment of fever in the neutropenic cancer patient. The ideal antibiotic regimen for empiric management in this setting

remains controversial. Various antibiotics, alone and in combination, have been studied extensively.¹⁰ Monotherapy regimens commonly include a third-generation cephalosporin (e.g., ceftazidime), a fourth-generation cephalosporin (e.g., cefepime), or a carbapenem (e.g., imipenem-cilastatin or meropenem). The combination regimens most frequently recommended (excluding those containing vancomycin) are an aminoglycoside (e.g., gentamicin, tobramycin, or amikacin) plus an antipseudomonal ureidopenicillin with or without a β -lactamase inhibitor (e.g., piperacillin, piperacillin-tazobactam), an aminoglycoside with an antipseudomonal cephalosporin (e.g., ceftazidime, cefepime), or an aminoglycoside in combination with a carbapenem (e.g., imipenem-cilastatin or meropenem).^{3,10} Although recommended by some sources,³ combination β -lactam antibiotics are less frequently used. Comparisons of efficacy rates between studies are complicated by differences in the definitions of neutropenia, the incidence of documented infections, criteria used to assess clinical response, and statistical methodology.⁵⁰ Guidelines have been proposed to establish standards for evaluating antimicrobial therapy in this population.⁵⁰ Despite such limitations, no striking differences regarding efficacy have been observed between these empiric approaches.¹⁰

Oral Antibiotics

Carefully selected (“low-risk”) adult febrile neutropenic patients may be candidates for oral antibiotic therapy, either as initial therapy or as follow-up to IV antibiotics (“sequential therapy”).^{10,59,60} This would EXCLUDE patients with any of the following: serious comorbidities, inpatient acquisition of infection, uncontrolled malignancy, pneumonia, recent HSCT, dehydration, hypotension, chronic lung disease, abnormal liver ($>3\times$ upper limits of normal) or renal function (serum creatinine >2 mg/dL), ANC <100 cells/mm³, or signs/symptoms lasting longer than 7 days.³ Patients must be without microbiological or clinical evidence of infection (other than fever), clinically stable, and closely observed. An international collaborative study established and validated a risk scoring system in adults that incorporated these principles to identify low-risk patients for whom oral therapy may be an option.⁶¹

Trials have confirmed the value of oral ciprofloxacin in combination with amoxicillin-clavulanate in low-risk adult patients with febrile neutropenia. Oral ciprofloxacin (30 mg/kg/day in three divided doses) combined with amoxicillin-clavulanate (40 mg/kg/day in three divided doses) has been compared to IV ceftazidime.⁶² Treatment was equally successful in both groups, but the ceftazidime group required significantly more modifications in the initial regimen compared with the oral group. Conversely, more patients receiving ciprofloxacin with amoxicillin-clavulanate were unable to tolerate the oral regimen. Similarly, the efficacy of oral ciprofloxacin (750 mg twice daily) in combination with amoxicillin-clavulanate (625 mg three times daily) versus IV ceftazidime and amikacin has been studied.⁶³ As with the previous trial, the oral regimen was found to be as effective as IV antibiotics. Therefore, ciprofloxacin plus amoxicillin-clavulanate is most frequently used. Clindamycin may be used in place of amoxicillin-clavulanate if the patient is allergic to β -lactam antibiotics.^{3,10} Cefixime has been used effectively as an alternative regimen in low-risk pediatric patients initially receiving IV therapy,⁶⁴ but there is not adequate experience with cefixime as an initial therapy.¹⁰

Patients receiving fluoroquinolone prophylaxis would generally be excluded from receiving oral therapy due to the increased risk of infection with resistant organisms. Low-risk patients with adequate home support (e.g., access to emergency facilities, phone access) and the desire for home treatment may be treated as an outpatient (with either IV or oral therapy). Monitoring in the outpatient setting should include either home nursing or office visits daily for 3 days to review progress and to screen for problems (e.g., progression of infection or drug intolerance).³ Patients who are stable and responding after the initial observation period may continue to receive monitoring by phone contact.³

Intravenous Monotherapy

10. Can any of the more potent, extended spectrum β -lactams be used as monotherapy in febrile neutropenic patients?

CEPHALOSPORINS

The antipseudomonal third-generation cephalosporin ceftazidime and the fourth-generation agent cefepime have been extensively studied as monotherapy for empiric therapy in febrile neutropenic patients. In general, these agents are safe and have potent broad-spectrum activity in vitro against many Gram-negative and some Gram-positive pathogens.

Numerous comparative clinical studies in both adults and children have been performed to evaluate the efficacy of ceftazidime as initial empiric monotherapy in febrile neutropenic cancer patients.^{65–79} Overall, ceftazidime was as effective as the standard regimen in patients with documented infections and unexplained fever. In some of these trials, the efficacy of ceftazidime in patients with documented staphylococcal infections was suboptimal. Select clinical trials have empirically added antistaphylococcal coverage with a glycopeptide (e.g., vancomycin) and have shown improved outcomes in these patients.^{80,81} In addition, pathogens (particularly Gram-negative pathogens) that produce either type 1 β -lactamase or extended spectrum β -lactamase (e.g., *K. pneumoniae*) are not likely to respond to ceftazidime monotherapy.^{82,83} These may be seen more frequently in patients with prolonged hospitalization or those who have received prior antimicrobial therapy.⁸² Therefore, local in vitro susceptibilities of common Gram-negative pathogens should be examined prior to the routine use of ceftazidime as monotherapy.

Cefepime is a fourth-generation cephalosporin with an FDA-approved indication for monotherapy for empiric management of infection in patients with febrile neutropenia. The potential advantage of this agent over third-generation cephalosporins is its low affinity for major chromosomally mediated β -lactamases.^{84,85} Compared with ceftazidime, cefepime has more potent activity in vitro against select Gram-positive bacteria (methicillin-susceptible *Staphylococcus* species, viridans streptococci, and *S. pneumoniae*).⁸⁵ Randomized, comparative studies have evaluated the role of cefepime as monotherapy in both adults and children with febrile neutropenia.^{66,67,69,71,72,86–93} The improved Gram-positive activity (relative to ceftazidime) may decrease the empiric need for vancomycin in some patients. However, this advantage is less likely in institutions with a high rate of MRSA because cefepime and other cephalosporins are inactive against this pathogen.

CARBAPENEMS

The carbapenems are a unique class of antibiotics with broad-spectrum activity against numerous Gram-positive and Gram-negative bacteria, including anaerobes. Imipenem (in combination with the dehydropeptidase inhibitor cilastatin) and meropenem are two currently available agents in this class. Both imipenem-cilastatin^{75,77,79,86,94–103} and meropenem^{68,70,74,76,102,104–108} have been studied as monotherapy for febrile, neutropenic patients. The third member of this class available in the United States, ertapenem, possesses microbiological activity similar to that of the other carbapenems, although it lacks *in vitro* activity against *Acinetobacter* species and *Pseudomonas*, including *P. aeruginosa*.¹⁰⁹ Considering this lack of activity, ertapenem would not be appropriate as empiric therapy for febrile neutropenic patients and has not been evaluated in this setting. Agents with increased anaerobic activity (e.g., carbapenems) might be used as empiric therapy in cases where an intra-abdominal infection is suspected.

Clinical outcomes with imipenem-cilastatin monotherapy have been comparable with those of the β -lactam plus aminoglycoside combinations,^{79,94,98,101} as well as combination of two β -lactams.⁹⁶ Although proven to be effective, imipenem-cilastatin has generally been associated with a higher incidence of nausea and vomiting compared with ceftazidime or meropenem.^{77,110} The GI side effects are generally dose related (3–4 g/day) and associated with the rate of IV administration.⁹⁷ Therefore, dosages of 2 g/day (divided Q 6 hr) are generally given to patients with normal renal function.¹¹¹

Meropenem has a broad spectrum of activity (similar to that of imipenem-cilastatin) but is generally associated with fewer GI side effects. Meropenem monotherapy for febrile neutropenia has been evaluated in both adults and children,^{68,70,74,76,102,104–108} and the results have supported the value of meropenem as empiric monotherapy for use in febrile neutropenic patients.

In summary, several studies have demonstrated that monotherapy with cefepime, ceftazidime, or a carbapenem (imipenem-cilastatin or meropenem) is appropriate as initial empiric antibiotic therapy in febrile neutropenic patients. There are no convincing data to support one choice over the others as empiric monotherapy. However, routine carbapenem use may be associated with increased drug acquisition cost (relative to cephalosporins) and increased potential for development of carbapenem resistance. Therefore, many institutions have elected to reserve the carbapenems for patients who have failed to respond to prior empiric therapy, have a history of infections with pathogens resistant to third- and fourth-generation cephalosporins, are clinically unstable, or have need for expanded anaerobic coverage.

ALTERNATIVE INTRAVENOUS MONOTHERAPY REGIMENS

Monobactams, fluoroquinolones, and β -lactam/ β -lactamase inhibitor combinations have shown efficacy in the management of febrile neutropenic patients. Monobactams and fluoroquinolones have been particularly useful as empiric alternatives in patients with β -lactam allergies.

Monobactams

Aztreonam, the only available monobactam, demonstrates *in vitro* activity only against Gram-negative aerobic bacilli.¹¹² Although its *in vitro* potency against Gram-negative bacteria

is comparable to that of ceftazidime, aztreonam lacks activity against Gram-positive bacteria or anaerobes.¹¹² Considering the lack of Gram-positive activity, aztreonam should not be used as monotherapy in this patient population. Empiric use with aztreonam has been evaluated in combination with either a β -lactam (piperacillin)¹¹³ or vancomycin.¹¹⁴

Fluoroquinolones

Select fluoroquinolones offer an approach to the empiric management of febrile neutropenic patients. Most agents in this class are bactericidal against many Gram-negative bacilli. However, they demonstrate variable potency *in vitro* against certain Gram-positive bacteria, such as *S. pneumoniae*, *S. aureus*, and *E. faecalis*. Of the currently available fluoroquinolones, ciprofloxacin is generally considered the most active *in vitro* against *P. aeruginosa*. However, surveys published within the past several years have demonstrated only approximately 60% of *P. aeruginosa* isolates are susceptible to ciprofloxacin.^{115,116}

Ciprofloxacin has been studied as both monotherapy^{117–121} and as part of combination regimens^{122–125} as initial empiric therapy in febrile neutropenic patients. However, monotherapy with ciprofloxacin has met with mixed success. A European Organization for Research and Treatment of Cancer (EORTC) trial comparing ciprofloxacin 400 to 600 mg/day versus piperacillin plus amikacin was terminated prematurely because of significantly poorer response rates in the patients treated with ciprofloxacin (65%) compared with the combination group (91%; $P < 0.002$).¹²⁰ This finding may be due in part to the suboptimal ciprofloxacin dosage used and the impact of fluoroquinolone prophylaxis on the institution's nosocomial flora. An additional study demonstrated more favorable results with ciprofloxacin monotherapy.¹²¹ However, the consensus is that the fluoroquinolones should not be used as monotherapy.^{3,10}

β -Lactam/ β -Lactamase Inhibitor Combinations

Randomized trials have compared piperacillin-tazobactam monotherapy to various antibiotics.^{87,100,126–130} Recently published trials have documented that piperacillin-tazobactam is noninferior to cefepime in this patient population.^{131,132} Although the results look promising, experience with this agent as monotherapy is limited relative to the carbapenems and antipseudomonal cephalosporins. In addition, piperacillin-tazobactam may interfere with the galactomannan assay used in the diagnosis of select IFIs, including aspergillosis.

Antimicrobial Combinations

11. B.L., a 13-year-old boy, presented with a 3-week history of “always being tired” and a persistent sore throat. Initial evaluation revealed anemia, thrombocytopenia, and a WBC count of 130,000 cells/L (normal, 3,200–9,800 cells/mm³), with a predominance of immature lymphoblasts. Further evaluation demonstrated that B.L. had “high-risk” acute lymphocytic leukemia. Remission induction treatment was initiated with teniposide plus cytarabine followed by prednisone, vincristine, and L-asparaginase. Seven days after induction chemotherapy, B.L. developed a fever (102° F) and chills. The ANC was 48 cells/mm³. SrCr and BUN were 1.0 mg/dL (normal, 0.6–1.2 mg/dL) and 15 mg/dL (normal, 8–18 mg/dL), respectively. The physician wants to empirically start B.L. on ceftazidime plus gentamicin combination regimen. What is the role of this combination in the empiric management of febrile

neutropenia? Are there any differences in efficacy between these combinations?

[SI units: SrCr, 88.4 mmol/L (normal, 53.04–106.08); BUN, 5.36 mmol/L urea (2.8–6.43)]

RATIONALE FOR USE

Prior to the introduction of third- and fourth-generation cephalosporins and carbapenems, the empiric use of antibacterial combinations in febrile neutropenic cancer patients was favored because these regimens offered a broader spectrum of activity against bacteria commonly infecting cancer patients. In addition, these combinations offered the potential, in select circumstances, to provide an additive or synergistic effect. Finally, they offered the potential to minimize the development of bacterial resistance. However, infections in neutropenic patients have shifted from Gram-negative to Gram-positive pathogens, against which traditional combination regimens (selected primarily for their activity against Gram-negative pathogens) have limited efficacy. Despite this concern, some clinicians continue to favor antibiotic combinations, especially in patients who are clinically unstable.

Synergy

Antibiotic *synergy* is defined as an interaction between antimicrobial agents in which the effect produced by the combination is greater than the sum of their individual activity. Various *in vitro* methods may be used to test for synergistic activity between antibacterials, and these methods may result in differing conclusions between similar combinations.

Studies published more than two decades ago reported that the outcome in neutropenic cancer patients with documented Gram-negative bacteremia was significantly improved with the use of antibacterial combinations with the potential for demonstrating synergy *in vitro* when compared with nonsynergistic combinations.^{133,134} Of 18 patients with profound persistent neutropenia (<100 cells/mm³) whose regimen demonstrated *in vitro* synergism or partial synergism against the infecting pathogen, 8 showed clinical improvement.¹³⁴ In contrast, none of the 13 patients in the same study receiving nonsynergistic antibiotic regimens responded. This difference was statistically significant ($P < 0.005$). Although these results are of interest, this study was performed using older, less potent Gram-negative agents. It is unknown whether synergistic combinations of newer antimicrobials, such as quinolones with carbapenems or piperacillin, would result in similar findings.

Prevention of Resistant Strains

Another argument in favor of antibiotic combination use is that these combinations may prevent or delay the emergence of resistance during therapy. Although resistant bacterial strains have emerged during therapy with monotherapy, it is not clear whether combination therapy will prevent the emergence of resistance during therapy.

AMINOGLYCOSIDE PLUS β -LACTAM COMBINATIONS

Until the 1980s, most febrile neutropenic patients were treated with two-drug combination regimens that contained an aminoglycoside (gentamicin, tobramycin, or amikacin) plus a β -lactam antibiotic, such as antipseudomonal penicillin or a third-generation cephalosporin. This combination is one of the

most established empiric treatment regimens for the management of febrile neutropenia.¹⁰

Numerous studies have been conducted to evaluate the efficacy of combination therapy of an aminoglycoside with an antipseudomonal cephalosporin. Both ceftazidime^{65,79,83,104–106,129,135–146} and cefepime^{138,139,147,148} have been evaluated as part of a combination regimen. Cephalosporins without antipseudomonal activity (e.g., ceftriaxone) have also been investigated in combination with aminoglycosides, although this regimen is not routinely recommended.¹⁴⁹ Antipseudomonal penicillins plus β -lactamase inhibitors (in combination with an aminoglycoside) would also be considered.

The duration of combination therapy consisting of an aminoglycoside plus a cephalosporin has also been evaluated. A study conducted by the EORTC evaluated the effectiveness of full-course versus short-course amikacin plus ceftazidime in neutropenic patients with Gram-negative bacteremia.¹⁴⁹ A better outcome was demonstrated with full-course amikacin plus ceftazidime than with a short course (3 days) of amikacin plus a full course of ceftazidime. These data confirm the superiority of combined therapy of ceftazidime plus a full course of an aminoglycoside in profoundly neutropenic patients with Gram-negative bacteremia.

Carbapenem antibiotics are more frequently evaluated as monotherapy in this patient population. Therefore, relative to the numerous trials examining the role of combination therapy with cephalosporins, there are limited studies examining the combination of an aminoglycoside with either imipenem-cilastatin^{99,142} or meropenem¹⁰⁴ in this patient population. However, in one such evaluation, the combination of imipenem-cilastatin plus amikacin was found to be superior to imipenem-cilastatin monotherapy.¹⁵⁰ Carbapenems (in combination with aminoglycosides and vancomycin) have been recommended as empiric initial therapy for patients who are clinically unstable.³

Aminoglycosides have generally been considered the backbone of combination regimens because of their potential for bactericidal action against various bacteria. However, the addition of an aminoglycoside is associated with increased costs for therapeutic monitoring.^{150,151} The benefit of an aminoglycoside for empiric therapy has not been consistently demonstrated.^{150,151} In addition, there is an increased potential for the development of nephrotoxicity and ototoxicity.¹⁵¹ This concern is especially relevant in patients receiving concomitant nephrotoxins such as cisplatin and cyclosporine. Despite these issues, B.L. may benefit from the empiric institution of an aminoglycoside/ β -lactam combination because he is profoundly neutropenic (ANC <50 cells/mm³). Serum concentrations of the aminoglycosides should be monitored as needed to achieve optimal outcomes while reducing the risks of toxicity.

12. Seven days into therapy, despite rehydration, B.L.'s SrCr and BUN rose to 2.0 g/dL and 45 mg/dL, respectively. Because B.L. has developed nephrotoxicity (believed to be secondary to the aminoglycoside), what other combination regimens (excluding those containing aminoglycosides) could be used? Are these regimens as effective as aminoglycoside-containing regimens?

[SI units: SrCr, 176.8 mmol/L; BUN, 16.07 mmol/L urea]

DOUBLE β -LACTAM COMBINATIONS

Although numerous β -lactam combinations (usually consisting of either moxalactam or a cephalosporin plus an antipseudomonal penicillin) have been studied, overall response rates have not been significantly different from those of patients treated with aminoglycoside/ β -lactam regimens. However, experience is limited with double β -lactam combinations in patients with neutropenia or patients with documented infections caused by *P. aeruginosa*, and the available results are somewhat disturbing. Winston et al. observed a lower response in patients with profound, persistent neutropenia who were treated with moxalactam plus piperacillin (48%) compared with those treated with moxalactam plus amikacin (77%).¹⁵² Because the number of patients studied was small, these differences approached but did not achieve statistical significance ($P < 0.08$). A poorer response in patients with infection caused by *P. aeruginosa* was observed. One of five patients treated with moxalactam plus piperacillin versus seven of nine patients treated with moxalactam plus amikacin responded ($P < 0.06$). Two patients with bacteremia caused by *P. aeruginosa* initially susceptible to the double β -lactam regimen relapsed with isolates resistant to multiple β -lactam antibiotics. These results are compatible with the selection of bacteria producing high amounts of the chromosomally mediated β -lactamase, which is capable of inactivating third-generation cephalosporins and other less stable β -lactams.

OTHER COMBINATIONS

As previously stated, ciprofloxacin has been studied in combination with other antibacterials (either an aminoglycoside or a β -lactam, including an antipseudomonal penicillin) as initial empiric therapy for treatment of suspected infection in febrile neutropenic patients.^{122–125} These studies, however, were associated with increased Gram-positive infections in ciprofloxacin-treated patients. In addition, the in vitro activity of ciprofloxacin against *P. aeruginosa* has declined significantly (to $< 70\%$ in many institutions).^{115,116} Therefore, if used as part of combination therapy, ciprofloxacin should be combined with an antimicrobial with favorable in vitro activity against this pathogen.

Summary

Given the limited experience with these regimens in patients with profound persistent neutropenia or infections caused by *P. aeruginosa*, empiric therapy with double β -lactam regimens should not routinely be used as primary therapy. They can be considered, however, in cases where combination therapy is indicated, but the addition of an aminoglycoside may be contraindicated.

Regardless of the empiric regimen selected, patients must be closely monitored for nonresponse, emergence of secondary infections, adverse effects, and the development of drug-resistant organisms.

Empiric Vancomycin

13. B.L. is begun on a three-drug regimen of ceftazidime, tobramycin, and vancomycin. What is the rationale for adding vancomycin to the regimen?

As previously discussed, the number of infections due to Gram-positive pathogens is increasing. Because cephalosporins lack activity against methicillin-resistant staphylococci, vancomycin is often added to empiric regimens. A growing proportion of *S. aureus* infections are methicillin-resistant (as many as 50% in some institutions).¹² However, excessive use of vancomycin has been associated with the rise in vancomycin resistance among Gram-positive organisms, such as VRE. Finally, emergent resistance in *S. aureus* has been seen in the form of vancomycin intermediately resistant *S. aureus* and rare case reports of *S. aureus* fully resistant to vancomycin.

Clinical studies evaluating the need for vancomycin as initial empiric therapy have reached different conclusions, primarily due to differences in the measured end points.¹⁵³ For example, febrile neutropenic patients with cancer had more rapid resolution of fever, fewer days of bacteremia, and a lower frequency of treatment failure when vancomycin was added to an initial regimen of antipseudomonal penicillin plus an aminoglycoside.^{154,155} Similarly, the addition of vancomycin to ceftazidime showed improved results compared with ceftazidime alone or with a three-drug combination.¹⁵⁶ However, other studies have concluded that mortality was not increased when vancomycin therapy was delayed.^{157–159} The mortality from staphylococcal infections is generally considered to be low ($< 4\%$) during the first 48 hours after the onset of fever.¹⁵³ In contrast, the mortality associated with viridans streptococcal infections may be higher among patients who are not initially treated with vancomycin.¹⁶⁰ Some strains of viridans streptococci are either resistant or tolerant to penicillin, but antibacterials such as piperacillin, cefepime (not ceftazidime), and carbapenems demonstrate excellent activity in vitro against these strains.^{160,161}

There has been considerable debate over whether vancomycin should be included in the initial empiric regimen for febrile neutropenic patients. Many clinicians believe that this decision should be based on both patient and institution factors.¹⁰ In general, empiric vancomycin use should be discouraged.^{3,10,162} At institutions where these fulminant Gram-positive infections are rare, vancomycin should not be routinely used unless culture results indicate the need. However, for institutions frequently isolating invasive Gram-positive bacterial pathogens (e.g., those caused by viridans streptococci), vancomycin should probably be included in the initial empiric regimen. Other patients in whom empiric vancomycin should be considered in the initial regimen include the following:

- Patients with clinically suspected catheter-related infections^{10,163}
- Patients receiving intensive chemotherapy (e.g., high-dose cytarabine) that produces substantial mucosal damage and subsequent increased risk for penicillin-resistant streptococcal infections (i.e., viridans streptococci)^{10,163,164}
- Patients receiving prior fluoroquinolone or TMP/SMX prophylaxis¹⁶⁵
- Patients with a previous history of colonization with β -lactam-resistant pneumococci or MRSA
- Patients with blood cultures positive for Gram-positive bacteria prior to identification and susceptibility testing
- Patients with hypotension or septic shock without an identified pathogen^{10,163,164}

Vancomycin has been studied in combination with various antibiotics, including imipenem-cilastatin, meropenem, ceftazidime, cefepime, and various aminoglycosides. The addition of vancomycin to an aminoglycoside-containing regimen should be done with caution because data support an increased risk of aminoglycoside-induced nephrotoxicity in patients receiving these agents concomitantly with vancomycin.¹⁶⁶ Empiric vancomycin should be discontinued after 3 days if a Gram-positive infection is not identified.^{3,10}

ALTERNATIVES TO VANCOMYCIN

Options exist for the treatment of invasive Gram-positive infections. Linezolid is an oxazolidinone that can be administered IV or orally.¹⁶⁷ A randomized, double-blind trial comparing the use of linezolid to vancomycin for empiric therapy demonstrated comparable safety and efficacy.¹⁶⁸ It is associated with thrombocytopenia and secondary neutropenia, especially when given for prolonged periods. Considering the reduced marrow reserve in cancer chemotherapy patients, these adverse events are of particular concern. Quinupristin-dalfopristin is available for IV administration only, and concerns regarding potential drug interactions and patient tolerability (including musculoskeletal pain) may limit its use.¹⁶⁷ Daptomycin provides potent in vitro activity against many multidrug-resistant Gram-positive pathogens (including VRE and MRSA), but requires IV therapy and should not be used for the treatment of pneumonia. Further studies are needed with both agents before they could be routinely recommended as an alternative to vancomycin in this patient population.

In the case of B.L., empiric use of vancomycin is not warranted based on the previous discussion, and it should be discontinued unless cultures indicate the need for this antibiotic.

ANTIBIOTIC DOSING, ADMINISTRATION, AND MONITORING CONSIDERATIONS

Intermittent Versus Continuous Infusion of Intravenous Antibiotics

14. Should B.L.'s antibiotics be given intermittently (i.e., divided doses) or as a continuous infusion?

β -lactam antibiotics exhibit time-dependent (i.e., concentration-independent) pharmacodynamic activity.¹⁶⁹ Studies with these agents in both animal and in vitro models of infection suggest that prolonged exposure of bacteria to drug concentrations above the minimum inhibitory concentration (MIC) of the organism for a significant period of time may be linked to improved bacterial killing and survival.¹⁶⁹ Based on these observations and the poor prognosis of neutropenic cancer patients with bacteremia, noncomparative, open-label trials were conducted to evaluate the role of continuous infusions of β -lactams (i.e., ceftazidime) in the empiric treatment of suspected infection in cancer patients.^{170–172} These noncomparative trials showed that continuous-infusion ceftazidime was a treatment option and should be evaluated in larger, comparative trials.

In contrast to β -lactam antibiotics, aminoglycosides exhibit concentration-dependent (time-independent) pharmacodynamic activity in both animal and in vitro models of infection.¹⁶⁹ Despite such properties, improved response with

continuous rather than intermittent infusion of the aminoglycoside has been reported.¹⁷³ Such reports are difficult to evaluate because many of the patients were entered into the studies after “failing” to respond to previous antibiotic regimens. Patients often differed significantly in their immune status (e.g., differences in incidence of neutropenia among study groups, uncontrolled use of granulocyte transfusions), and the total daily dose of the aminoglycoside was often greater in the continuous infusion group. In the only randomized, prospective study conducted to date, no significant difference in efficacy was observed between the two modes of administration.¹⁷³ The most convincing argument against the continuous infusion of aminoglycosides relates to the incidence of toxicity. Studies in established animal models of aminoglycoside-induced nephrotoxicity showed that the uptake of aminoglycosides into renal cortical tissue increased, and glomerular function decreased more when the drug was infused continuously rather than given as single or divided doses.¹⁷⁴

In conclusion, the maintenance of β -lactam antibiotic concentrations above the MIC of the suspected pathogen (as might be provided by continuous infusion) appears rational. However, data demonstrating improved effects with newer, more potent agents in cancer patients are unavailable. Considering the potential for toxicity with this route of administration, B.L. should not receive tobramycin by continuous infusion. Although consideration could be given to administering ceftazidime by continuous infusion, this method of administration would require an IV line dedicated for continuous drug administration. This technique may limit B.L.'s ability to receive intermittent tobramycin infusions unless additional IV ports or lines are available for use. Finally, there are no data showing that this method is superior to intermittent administration.

Consolidated (“Once-Daily”) Aminoglycoside Dosing

15. What is the role of consolidated (“once-daily”) aminoglycoside dosing in febrile neutropenic patients such as B.L.?

Because of the concentration-dependent pharmacodynamic properties of aminoglycosides and the convenience of administration, studies have been conducted to describe both the pharmacokinetic properties and efficacy of consolidated dosing of aminoglycosides in animals and in neutropenic patients. Pharmacokinetic studies with amikacin^{175,176} and gentamicin^{177,178} have not revealed pharmacokinetic differences when compared with other populations. Several clinical studies have included consolidated aminoglycoside dosing for amikacin,^{104,135,137,139,148,179,180} gentamicin,^{147,181–183} and tobramycin.¹⁴⁰ However, most of the studies in this population were not designed to evaluate differences between consolidated aminoglycoside dosing compared to similar regimens using intermittent dosing.^{10,184} In general, the various studies suggest that consolidated dosing is as effective and possibly less nephrotoxic than traditional dosing. Therefore, consolidated dosing of aminoglycosides appears reasonable in empiric therapy of neutropenic patients.¹⁸⁴

Outpatient Administration

Continued administration of antimicrobials in the outpatient setting has been suggested in a subset of low-risk

patients.^{61,179,185–187} The criteria used to eligibility for outpatient therapy are generally similar to those established and previously discussed for oral therapy. Therefore, outpatient administration of parenteral antibiotics can be considered in a subset of low-risk patients with close medical follow-up.³

HOST FACTORS INFLUENCING RESPONSE TO THERAPY

16. What factors may have influenced B.L.'s clinical response to antimicrobial therapy?

The most important prognostic determinants of a favorable outcome in patients with neutropenia and infection are the recovery of the granulocyte count and (for the patient with infection) the selection of agents with appropriate antimicrobial activity against the pathogen.¹⁰ Patients with profound, persistent neutropenia (<100 cells/mm³ that does not rise during therapy or an initial ANC of 100–500 cells/mm³ that declines during therapy) tend to respond to antibiotics less favorably than patients whose bone marrow recovers.¹⁰ The initial granulocyte count appears to be less important than the trend toward granulocyte recovery in influencing the patient's overall response to therapy. The site of infection also influences outcome. Septic shock and pneumonia are associated with high mortality in bacteremic neutropenic patients.^{10,53}

MODIFYING INITIAL EMPIRIC ANTIBIOTIC THERAPY

17. M.H., a 24-year-old woman with a recent diagnosis of ovarian cancer, developed neutropenia (ANC <150 cells/mm³) following chemotherapy. Five days after becoming neutropenic, she developed a fever of 101°F and was begun on an empiric antibiotic regimen of ceftazidime 2 g IV Q 8 hr. Although she remained febrile, her initial cultures remained negative at 48 hours. Should M.H. be continued on the same regimen, or should modifications be made? How do the culture results influence this decision? How long should empiric therapy be continued?

Following initiation of empiric antibiotics, a minimum of 3 days (72 hours) of empiric treatment are generally required to determine initial efficacy in the absence of worsening of clinical status. During this time, daily assessments should include history and physical examinations, review of laboratory results, assessment of response, and evaluation of any antibiotic-related toxicities. Modification of the initial empiric treatment is based on whether the fever has resolved or is trending toward normal, whether the patient's condition has improved or deteriorated, ANC, and whether an etiologic pathogen or infection site has been identified.¹⁰ Adjustments to empiric antibiotic therapy should be made prior to 3 days if pneumonia or bacteremia is documented or if the patient's condition deteriorates.

Premature withdrawal of antibiotics may predispose these patients to recrudescence of bacterial infection and increase the risk of infection-related morbidity and mortality. In a clinical study, 142 cancer patients with unexplained fever who became afebrile following empiric antibiotics were randomized to continue or discontinue antibiotic therapy after 7 days.¹⁸⁸ The patients whose neutropenia resolved had no infectious sequelae regardless of whether antibiotics were continued or dis-

continued. For persistently neutropenic patients randomized to continue or discontinue antibiotic therapy until their ANC was >500 cells/mm³, the percentages of patients remaining febrile without infections complications were 94% and 41%, respectively.

Responding to Initial Therapy

No Etiology Identified

In general, if the fever improves, and the patient is stable or improves following initiation of empiric antibacterials but no identifiable etiology is identified, empiric therapy should be continued for a minimum of 7 days.^{3,10} Patients for whom no infection is identified after 3 days of treatment, who are afebrile for 24 hours or more, and who have an ANC of at least 500 cells/mm³ for 2 consecutive days can be considered for treatment discontinuation.³ Although it is most desirable that the patient's ANC be at least 500 cells/mm³ and increasing, discontinuing antibacterials after 7 to 14 days can be considered for stable patients with prolonged neutropenia in the absence of infection, with no disruption in mucous membranes and integument, and in whom no invasive procedures or ablative chemotherapy is planned. Such patients receiving initial parenteral therapy can be considered for switch to oral therapy. Patients at higher risk of infectious complications (ANC <500 cells/mm³ at day 7 with initially severe neutropenia [ANC <100 cells/mm³] or mucositis or who are clinically unstable) should continue antibacterial treatment.^{3,10}

M.H.'s slow response to empiric ceftazidime suggests that this regimen may be suboptimal. However, it is prudent to wait at least 72 hours to make that assessment in the absence of clinical worsening. If at 72 hours M.H. becomes afebrile and remains so for 5 to 7 days, it would be reasonable to discontinue ceftazidime after 7 days as long as she appears clinically well and has no apparent evidence of infection. Although it is desirable for M.H.'s ANC to be >500 cells/mm³ before treatment is stopped, therapy may be discontinued before this time as long as she is closely monitored for recurrent fever and/or evidence of new infection.

Etiology Identified

18. On day 3, M.H.'s temperature is normal (97.6°C). However, two sets of blood cultures drawn 3 days ago have grown *S. aureus* resistant to methicillin and susceptible to vancomycin. Her ANC is 170 cells/mm³. How should therapy be modified in M.H.? For how long should antibiotics be continued?

Pizzo et al. treated 78 neutropenic cancer patients with documented Gram-positive bacteremias with a single drug (e.g., oxacillin, nafcillin) or a broad-spectrum combination regimen that provided Gram-positive coverage (carbenicillin plus cephalothin plus gentamicin).¹⁸⁹ Of the 15 patients treated with pathogen-directed therapy who remained neutropenic for >7 days, 7 developed a secondary infection. In contrast, none of the 24 patients who continued to receive the broad-spectrum combination regimen developed any secondary infections.

In general, the duration of antibiotic therapy for documented infections in the patient responding to therapy should be based on neutrophil recovery, the rapidity of defervescence, site of infection, and pathogen. For patients such as M.H. for whom an infectious cause of fever is identified but who are

afebrile at 3 to 5 days, additional antimicrobials or antibiotic dosage adjustments (based on antimicrobial susceptibility tests and antibiotic serum concentrations) may be required^{3,10} (Table 68-2). Despite such modifications, broad-spectrum antibacterial coverage should be maintained in patients who remain persistently neutropenic.^{3,10} If M.H.'s neutropenia resolves, broad-spectrum antimicrobials may be discontinued, and narrow-spectrum therapy directed against the infecting pathogen should be continued for duration appropriate for that indication. However, because M.H. remains neutropenic, the ceftazidime should be continued for a minimum of 7 days or until her ANC is >500 cells/mm³. Vancomycin should be added to treat the MRSA bacteremia and should be continued for an appropriate treatment course of 10 to 14 days (assuming an uncomplicated infection).

Nonresponder to Initial Therapy

No Etiology Identified

19. S.B. is a 55-year-old woman with chronic myelogenous leukemia (CML). She was admitted to the hospital with a 4-day history of fevers and night sweats. On admission, her temperature was 102.3°F, and her WBC count was 100,000 cells/mm³, with an ANC of 500 cells/mm³. Blood and urine cultures were obtained, and ceftazidime plus tobramycin was empirically started. Over the next 3 days, S.B. remained persistently febrile and neutropenic. All cultures remained negative. How should she be treated?

One of the most challenging and controversial aspects of empiric antibacterial therapy in the neutropenic host is the management of patients without a microbiologically documented infection who remain persistently febrile on broad-spectrum antibacterial therapy. A persistent fever may be due to tumor lysis, an infection caused by resistant bacteria, slow response to appropriate therapy, drug-related fever, superinfection, infections caused by nonbacterial pathogens (e.g., fungi, viruses), inadequate serum or tissue levels of antibiotics, or avascular infection (e.g., abscess). By day 3 following the initiation of empiric antibiotics, S.B. should be reassessed in an attempt to identify any one or more of these causes.¹⁰ A meticulous physical examination and a thorough review of all culture results should be done. If indicated, additional cultures, diagnostic imaging of suspected areas of infection, and serum drug concentrations should be obtained.

Based on the results and reassessment, options for management are to continue the current empiric regimen, change antimicrobials, or add empiric antifungal therapy with or without changes to antibacterial therapy¹⁰ (Table 68-2). Each treatment option is discussed separately.

Guidelines published in 2002 by IDSA suggest that even if fever persists after 5 days, the initial empiric regimen can be continued without modification as long as the patient remains stable and does not clinically deteriorate.¹⁰ This treatment decision arm works best in patients with neutropenia expected to resolve within the subsequent 5 days.¹⁰ Additional consideration should be given to discontinuing vancomycin (if applicable) in the absence of evidence for a Gram-positive infection. Treatments are generally continued for a minimum of 4 to 5 days after the resolution of neutropenia.¹⁰ The need for further antibiotics can then be reassessed. Patients for whom neu-

tropenia does not resolve generally receive at least 2 weeks of therapy, at which time treatment needs can be reassessed.¹⁰

Modify Initial Antibiotics

20. S.B., on day 4, continues to feel “lousy” and has started to complain of abdominal pains. What is the significance of this complaint? Should her antibiotic regimen be modified again?

In persistently neutropenic patients with evidence of disease progression or who are clinically unstable, the initial empiric regimen is generally modified (Table 68-2). Such evidence may include catheter site drainage, abdominal pain, or pulmonary infiltrates. In such cases (or in the event of drug-related toxicities), consideration should be given to adding antibiotics or changing to a different antibiotic regimen to broaden coverage against resistant organisms. Because S.B. has developed new abdominal pains suggestive of enterocolitis, her antibiotic regimen should be modified. Although cefepime provides excellent coverage against the common Gram-negative pathogens, it has limited activity against select Gram-positive pathogens (e.g., MRSA or VRE) and anaerobes. A change from cefepime to imipenem-cilastatin or another broad-spectrum regimen with both aerobic and anaerobic activity should be considered.

Antifungal Therapy

21. S.B.'s antibiotic regimen was changed to imipenem-cilastatin plus tobramycin. Despite the change, she continues to have a low-grade fever and does not feel better. What is S.B.'s risk for developing a systemic fungal infection? What is the significance of fungal infections in neutropenic cancer patients?

The incidence of invasive fungal infections in febrile neutropenic patients varies between studies due to differences in definitions, methods of detection, specific patient populations studied, and prior use of antifungal prophylaxis.¹⁹⁰ In one retrospective review, the incidence of documented invasive fungal infections in patients with leukemia was 27% (32 of 119).¹⁹¹ However, the diagnosis of invasive fungal infection was established before death in only nine of the patients. In general, patients with hematologic malignancies have a higher incidence of fungal infections than those with solid tumors.¹⁹⁰ Early diagnosis and prompt treatment of such systemic fungal diseases are critical to patient survival.¹⁹⁰ However, significant challenges exist in making an accurate and timely diagnosis of invasive fungal infections. Therefore, patients with protracted fever and neutropenia for ≥ 5 days despite the administration of broad-spectrum antibiotics should be considered for empiric antifungal therapy. Recent studies have also indicated the potential to use newer diagnostic tests (e.g., β -D-glucan tests or galactomannan assays), along with additional diagnostic support, to initiate early pre-emptive therapy prior to the development of severe infection.¹⁹²

Most fungal infections in neutropenic cancer patients are caused by *Candida* and *Aspergillus* species.^{193–195} Other less common but important pathogenic fungi are those associated with zygomycosis (e.g., *Mucor* and *Rhizopus* species) and other emerging pathogens (non-albicans *Candida*, *Trichosporon beigelii*, *Malassezia* species, *Cryptococcus neoformans*, and *Fusarium* species).^{193–195}

Table 68-2 Modifications of Initial Empiric Antibacterials in Patients With Neutropenia and Fever

| Clinical Condition | Type of Modification(s) |
|---|---|
| Responding within 3–5 days of treatment No etiology identified | Low risk: change to ciprofloxacin + amoxicillin-clavulanate (adults) [alternate clindamycin if penicillin allergic] or cefixime (children). High risk: continue antibiotic therapy. |
| Etiology identified | Adjust antibiotics to most appropriate therapy based on infection. |
| Unresponsive (3–5 days) without clinical or microbiological evidence of infection | Clinically stable: continue antibiotics. Unstable: broaden antibacterial coverage to include anaerobes, resistant Gram-negative rods, and resistant Gram-positive organisms. Consider empiric antifungal therapy on days 4 and 5, especially if resolution of neutropenia is not imminent and the patient is at high risk of fungal infection. If initial regimen did not include vancomycin: re-evaluate risk factors for Gram-positive infection, consider adding vancomycin. Consider addition of G-CSF or GM-CSF. |
| Positive Gram stain | Gram-positive: add vancomycin, pending further identification (especially in blood culture institutions with high rate of methicillin-resistant <i>S. aureus</i>). Gram-negative: if monotherapy, consider adding aminoglycoside to carbapenem or β -lactam monotherapy. |
| Documented infection | |
| Head, eyes, ears, nose, throat Necrotizing ulceration/gingivitis | If initial regimen did not include anaerobic therapy (carbapenem or β -lactam/ β -lactamase inhibitor; i.e., piperacillin-tazobactam), consider adding clindamycin or metronidazole or switch to carbapenem (imipenem-cilastatin or meropenem). Consider adding antifungal (topical or systemic) and/or antiviral therapy. |
| Oral vesicular lesions | Add antiviral therapy for <i>Herpes simplex</i> virus. |
| Oral thrush | Add topical (e.g., oral clotrimazole, nystatin) or systemic (e.g., fluconazole) antifungal therapy. |
| Sinus tenderness, periorbital cellulitis, nasal ulceration | Suspicion of mould infection: add amphotericin B preparation or voriconazole; consider combination antifungal. Vancomycin for periorbital cellulitis. Reassess antistaphylococcal activity of empiric regimen; consider vancomycin. |
| Gastrointestinal tract | |
| Esophagitis | Add antifungal agent (see text); if no response, add acyclovir. Assess CMV risk and (if high) consider ganciclovir or foscarnet. |
| Acute abdominal pain/perianal | If initial regimen did not include carbapenem or β -lactam/ β -lactamase inhibitor (i.e., piperacillin-tazobactam), consider adding clindamycin or metronidazole, or switch to imipenem-cilastatin or meropenem. Assure pseudomonal coverage for perirectal infection. Consider enterococcal coverage for infection (not colonization). Consider antifungal. |
| Diarrhea | Add metronidazole if <i>C. difficile</i> documented or suspected. Contact isolation of rotavirus documented. |
| Liver abnormalities | Consider anaerobic and enterococcal coverage. Antifungal or antiviral therapy added based on results of diagnostic studies. |
| Respiratory tract | |
| Interstitial infiltrates | PCP: institute trial of TMP-SMX or (for sulfa-allergic patients) pentamidine. Atypical pathogens (<i>Mycoplasma</i> , <i>Legionella</i>). Add fluoroquinolone, macrolide, or doxycycline. CMV: add ganciclovir if high risk. Consider influenza. Oseltamivir (preferred) or other directed therapies when indicated. |
| Focal lesion on chest radiograph | If evidence of mould infection, add voriconazole (preferred) or amphotericin B formulations. Consider growth factors (G-CSF, GM-CSF). Consider antibiotic coverage for pathogen causing atypical pneumonia. |
| Skin and skin structure infection | |
| Vesicular lesions | HSV, VZV treatment: acyclovir, famciclovir, or valacyclovir. |
| Cellulitis, wound infection | Consider adding vancomycin therapy. |
| Vascular access device infection, tunnel tract infection | Remove catheter. Consider adding empiric vancomycin therapy initially. Adjust based on culture and susceptibility results. |
| Central nervous system | β -lactam (cefepime, ceftazidime, meropenem [imipenem if meropenem not available, + vancomycin]). Add ampicillin if concern for <i>Listeria</i> . Consider high-dose acyclovir. |

CMV, cytomegalovirus; G-CSF, granulocyte colony-stimulating factor; GM-CSF, granulocyte-macrophage colony-stimulating factor; HSV, herpes simplex virus; PCP, *Pneumocystis carinii*; TMP-SMX, trimethoprim-sulfamethoxazole; VZV, varicella-zoster virus.

Adapted from references 3 and 10.

It is difficult to compare clinical trials evaluating empiric antibiotic therapy in neutropenic cancer patients due to clinical trial design elements, such as inclusion of low-risk patients, lack of blinding, changes in concomitant antibacterials obscuring antifungal therapy endpoints, prior antifungal prophylaxis, use of composite endpoints of safety and efficacy, and different endpoint criteria.¹⁹⁰ Although select studies have also demonstrated that empiric antifungal therapy can decrease fungal-related deaths, overall mortality has not been affected.^{196,197} This is the case particularly for patients with invasive disease and persistent neutropenia.

Considerations regarding the choice of empiric antifungals should include prior or current antifungal prophylaxis, risks of antifungal-related toxicities, drug interactions, route of administration, and costs. Although prompting evaluation, fever alone does not necessarily indicate the need for intervention with an antifungal in stable patients receiving mould-active prophylaxis.

EMPIRIC AMPHOTERICIN B THERAPY

22. Should amphotericin B therapy be considered in S.B.?

Historically, amphotericin B deoxycholate was most commonly used in this setting because of its reliable activity in vitro against most *Candida* and *Aspergillus* species.^{16,198,199} Pizzo et al. demonstrated the impact of empiric amphotericin B deoxycholate in persistently febrile neutropenic patients.²⁰⁰ After 7 days of empiric broad-spectrum antibiotics, 50 patients with unexplained fever, prolonged granulocytopenia, and evidence of GI colonization with *Candida* species were randomized to one of three groups. Patients in group 1 continued to receive broad-spectrum antibiotics, those in group 2 had their antibiotics discontinued, and those in group 3 had amphotericin B added empirically to their antibiotic regimen. Infectious complications (e.g., bacterial or fungal infection, shock) developed in 9 of 16 patients (56%) in group 2 within 3 days of stopping antibiotics. Of the 16 patients in group 1 who continued to receive antibiotics until neutropenia resolved, an infectious complication developed in 6 (38%), 5 of which were caused by fungal infections. In the 18 patients randomized to receive amphotericin B, only 2 patients developed infectious complications. One of these infections in the latter group was caused by an amphotericin B-resistant organism (*P. boydii*).

Comparative trials have evaluated the role of lipid-based formulations of amphotericin B in the treatment of suspected or documented infections in this population.^{201–209} Liposomal amphotericin B,^{201–203,205} amphotericin B lipid complex,²⁰³ and amphotericin B colloidal dispersion²⁰⁴ have demonstrated reductions in nephrotoxicity compared to amphotericin B deoxycholate. In addition, liposomal amphotericin B offers the potential for reducing infusion-related side effects.²⁰² However, efficacy appears comparable between the preparations, and the lipid formulations are substantially more expensive based on acquisition costs. Therefore, their use is often restricted to patients with underlying renal dysfunction or those with significant risk factors for amphotericin B-induced nephrotoxicity. Although there are limited data to suggest that the continuous infusion of amphotericin B deoxycholate may also reduce nephrotoxicity,²¹⁰ efficacy regarding this method of administration has not been established and cannot be recommended at this time.

Because of the alternate treatments options currently available, empiric use of amphotericin B products is generally reserved for patients at highest risk of mould infections. When initiated as empiric therapy, amphotericin B administration is often preceded by attempts to minimize nephrotoxicity (e.g., saline loading) and premedications to minimize infusion-related reactions. Close monitoring of tolerability, renal function, and electrolytes is required during administration. When initiated, amphotericin B is generally continued (in the absence of a documented fungal infection) in a clinically stable patient until the resolution of neutropenia. Clinically stable patients without evidence of fungal infection but with persistent neutropenia often receive a 2-week course of therapy. Patients with documented (invasive) fungal infections are treated with variable durations of treatment, depending on the fungal diagnosis.

ALTERNATIVES TO AMPHOTERICIN B

In stable patients at low risk of mould infections with *Aspergillus* and drug-resistant *Candida* species (e.g., *C. krusei* and some strains of *C. glabrata*), fluconazole may be an acceptable empiric alternative to amphotericin B.^{211,212} Patients with suspected mould infections (e.g., aspergillosis) or for whom fluconazole was used as prophylaxis should be excluded. Although itraconazole possesses enhanced activity in vitro against *Aspergillus* spp. and has reduced toxicity relative to amphotericin B, issues regarding oral tolerability, potential for cross-resistance with other azoles, and considerations of alternate treatment options limited its usefulness in this situation. Voriconazole (an azole antifungal agent with increased activity against *Aspergillus* and non-albicans *Candida* relative to fluconazole) has also been tested in this population. When compared with liposomal amphotericin B, it failed to meet the pre-established criteria for noninferiority. However, some believe that voriconazole should be considered as an alternative to amphotericin B preparations for empiric therapy in patients requiring initial empiric antifungal therapy and are at increased risk of mould infections (due to receipt of prior azole prophylaxis). Others continue to support the superiority of liposomal amphotericin B for empiric therapy in this population.²¹³ Because of the increased potential (relative to fluconazole) for drug interactions (including immunosuppressives and chemotherapy) and adverse events (e.g., phototoxicity, hepatotoxicity), voriconazole therapy should be monitored closely.

The echinocandins (e.g., caspofungin, micafungin, anidulafungin) are a class of antifungals with in vitro activity against *Candida* species (including non-albicans *Candida*) and *Aspergillus* species. Caspofungin was found to be at least as effective and better tolerated than liposomal amphotericin B as empiric therapy in this patient population.²¹⁴ Because of its safety profile, caspofungin is often considered for patients requiring initial empiric antifungal therapy and who are at increased risk of mould infections (due to receipt of prior azole prophylaxis); it is currently FDA approved for such use. Published experience with other echinocandins (e.g., micafungin, anidulafungin) as empiric therapy in the febrile neutropenic patient is lacking at present.

Antiviral Therapy

Although necrotizing ulceration in the oropharynx, oral vesicular lesions or esophagitis may be symptoms of a viral

infection, empiric use of antiviral agents in the febrile neutropenic patient are not indicated without evidence of such disease.¹⁰ In contrast, clinical evidence of *Herpes simplex* or varicella-zoster virus involving the skin or mucous membranes should be treated with antivirals (e.g., acyclovir, valacyclovir, famciclovir).¹⁰ When oral therapy is used, valacyclovir and famciclovir might be favored due to improved oral bioavailability and need for less frequent dosing. With the exception of patients undergoing bone marrow transplantation,²¹⁵ CMV is an uncommon source of infection in the febrile neutropenic patient. However, ganciclovir, valganciclovir, foscarnet, or, less commonly, cidofovir treatment should be initiated in patients with documented CMV infections. Likewise, if influenza or RSV is identified, appropriate antiviral therapy should be initiated.

ANTIMICROBIAL ADJUVANTS

23. S.B. became afebrile 2 days after amphotericin B was initiated, yet she remained neutropenic with an ANC of 480 cells/mm³. An induction chemotherapy regimen consisting of idarubicin plus cytarabine was initiated for her CML. Because the chemotherapy will further reduce her ANC 7 to 10 days after treatment, is there any way to facilitate marrow recovery and reduce the duration of neutropenia in S.B.?

As previously discussed, the duration of neutropenia is the most important factor affecting outcome in neutropenic cancer patients. Because of this, there has been considerable interest in enhancing the immune system in these patients.

Granulocyte Transfusions

One of the earliest approaches used to boost the patient's defense against infections was the transfusion of WBCs. In the 1970s, granulocyte transfusions were used adjunctively in patients with persistent neutropenia and documented infections who, despite appropriate antibiotics, failed to respond after 24 to 48 hours. This approach had limited value because of the difficulties in obtaining adequate cells for transfusion, as well as the problems with alloimmunization and risk of infection transmission. In addition, the questionable efficacy of WBC transfusions has decreased the use of this strategy.²¹⁶ Therefore, granulocyte transfusions are not routinely indicated in this population. However, patients with progressive bacterial or fungal infections unresponsive to appropriate antimicrobial therapy may be considered as candidates.³

Hematopoietic Growth Factors

The introduction of hematopoietic colony-stimulating factors (CSFs) such as G-CSF (filgrastim), pegylated G-CSF (pegfilgrastim), or GM-CSF (sargramostim) in clinical practice has raised the hopes of improving survival in cancer patients.²¹⁷ CSFs act on various stages of cell proliferation and differentiation in the bone marrow (see Chapter 89). Studies in cancer patients receiving myelosuppressive or myeloablative chemotherapy have demonstrated that concurrent use of the CSFs can reduce the duration of neutropenia.²¹⁷ Rash, bone pain, headache, fever, and myalgias have been reported as side effects with both G-CSF and GM-CSF.²¹⁷ Bone pain is usually mild to moderate and often responds to nonopioid analgesics (acetaminophen or ibuprofen). The pain usually resolves on discontinuation. A flu-like syndrome consisting of fever, chills, rigors, headache, and GI symptoms has been reported in many patients receiving GM-CSF.²¹⁷ The selection of one CSF agent over another is often based on practitioner preference rather than clinical data.

Because these agents have not demonstrated a consistent and significant effect on other infection-related parameters (e.g., duration of fever, use of antibiotics, costs of treatment),²¹⁷ routine use of CSFs as adjunctive therapy to antibiotics for febrile neutropenic patients should be avoided. However, patients with high risks for infection-related complications may be considered.³ Such risks include expected prolonged (>10 days) and profound (<100 cells/mm³) neutropenia, age older than 65 years, uncontrolled malignancy, pneumonia, hypotension and multiorgan dysfunction (characteristic of sepsis syndrome), and invasive fungal infection.

Immunoglobulins

Data regarding the use of immunoglobulins as adjunctive therapy for the treatment of select infections in the neutropenic cancer patient is primarily limited to case reports. Patients with pneumonia secondary to CMV may benefit from adjunctive immunoglobulin therapy. In addition, IV immunoglobulin G should be considered in those patients with hypogammaglobulinemia.³

Summary

G-CSF administration, although likely to reduce the duration of her chemotherapy-induced neutropenia, is not indicated in S.B., who is otherwise stable.

CONCLUSIONS 69-30

INTRODUCTION

Potent combinations of antiretroviral drugs (also called *highly active antiretroviral therapy* [HAART]) have dramatically altered the natural progression of human immunodeficiency virus (HIV) infection, and significantly improved the quality of life for many patients infected with HIV. As a result, a pronounced decline has occurred in the reported number of new acquired immunodeficiency syndrome (AIDS)-related opportunistic infections and deaths.^{1,2} For many, the use of HAART has shifted the outlook of HIV infection from a fatal to a manageable disease. Advances continue to be made for HIV therapy, and most recently include new and more potent antiretroviral agents in existing therapeutic drug classes, new antiretroviral agents in new therapeutic drug classes, and novel, potent combinations of antiretrovirals. Despite these remarkable advances, clinicians working in the area of HIV remain cautious. Although many patients will benefit from these new and more potent regimens, data have shown that up to 25% of patients will fail therapy in the first year,³ and approximately 25% will have to change regimens within the first year owing to drug-related adverse events.⁴ Remaining concerns include the development of resistance and long-term adverse events, suboptimal patient compliance and management of HAART failures, and the rampant spread of HIV throughout developing countries.

This chapter focuses on the antiretroviral treatment of HIV infection. Although many therapeutic options exist, a thorough understanding of viral pathogenesis is essential for clinicians managing patients infected with HIV. By understanding the

principles of therapy as they relate to viral pathogenesis, clinicians will be able to rapidly assimilate new data as they become available. Consensus panel recommendations have been published that can be used as a framework for clinical decision making.⁵⁻⁷ Given the complexity of therapy, this chapter focuses only on treatment of adult HIV infection; the reader is referred to the various Consensus Panel Guidelines on treatment of perinatal transmission, pediatric HIV, and postexposure prophylaxis for both occupational and nonoccupational HIV exposures (located at <http://www.hivatis.org>).

EPIDEMIOLOGY

Despite a dramatic decline in the number of AIDS-related opportunistic infections and deaths in industrialized countries,^{1,2} infection with HIV remains a leading cause of death throughout many regions of the world. Access to newer, more potent antiretroviral regimens and monitoring techniques are often limited, however, by economics and politics. Infected patients residing in countries with a strong economic standing have reasonable access to medications (North America, western Europe, Australia, and New Zealand), whereas patients residing in countries with scarce resources (Africa, south and southeast Asia, the Pacific, Latin America, and the Caribbean) do not. This is extremely alarming given that most infected patients worldwide reside in developing regions of the world.⁸

As of December 2006, the worldwide estimate of persons living with HIV infection is calculated as 39.5 million: 37.2 million adults (17.7 million women) and 2.3 million children

<15 years of age. In 2006, it is estimated that 4.2 million people were newly infected with HIV and 2.9 million people died from AIDS. Two-thirds (63%) of all adults and children infected with HIV live in sub-Saharan Africa, and almost three-quarters (72%) of all adult and child deaths caused by AIDS occurred there in 2006. In the past few years, the number of people living with HIV has increased in every region of the world, but the most striking increases occurred in east Asia, eastern Europe, and central Asia: the number of people living with HIV increased by 21% from 2004 to 2006.⁹ Intervention strategies to educate and protect young people have only been effective and sustained in Zimbabwe, where national adult HIV prevalence is declining. Although treatment strategies are difficult to implement in developing countries because of social, political, financial, and resource limitations, expanded provision of antiretroviral treatment has gained an estimated 2 million life years in low- and middle-income countries since 2002.⁸

In the United States, the availability of antiretroviral therapy has resulted in an 80% decline in AIDS death rates between 1990 and 2003. In the past year, approximately 30,000 people died from AIDS, whereas an estimated 1.2 million people are HIV infected. A significant proportion of people (25%) are unaware that they are HIV-positive, and approximately 65,000 acquired HIV infection in the past year. Racial and ethnic minorities continue to be disproportionately affected by HIV: between 2001 and 2004, 50% of AIDS diagnoses were among blacks (who only constitute 12% of the U.S. population) and 20% of AIDS diagnoses were among Hispanics (who constitute 14% of the U.S. population). Compared with white men and women, the rate of new HIV or AIDS diagnoses is 7 times higher in black men and 21 times higher in black women.⁸

Transmission through sexual intercourse remains a predominant route of infection, with unsafe sex between men accounting for approximately 44% of cases, and heterosexual intercourse accounting for approximately 34% of cases. The proportion of women newly diagnosed has increased dramatically (from 15% in 1995 to 27% in 2004). Additionally, patients >50 years of age represent a rapidly expanding group, both from new infections and as a result of effective antiretroviral therapy extending life expectancy.⁸

PATHOPHYSIOLOGY

Infection with HIV can be acquired through unprotected sexual intercourse (both anal and vaginal), injectable drug use, receipt of tainted blood products, and mother-to-infant transmission (both perinatal infection and postpartum through breast feeding).⁵ Infection can also be acquired from occupational exposures among health care workers after needle sticks from patients infected with HIV. Rarely, HIV infection has been documented after oral sex.^{10,11}

Unprotected sexual intercourse has accounted for approximately 80% of all documented HIV infections to date.⁸ Transmission between sexual partners depends on a number of factors, including the HIV viral subtype, stage of infection in the index partner, genetic susceptibility to infection of the potential host, and the fitness (or pathogenicity) of the infecting viral strain. Infectivity via male-to-male receptive anal intercourse represents the greatest sexual risk factor followed by male-to-female vaginal transmission and then female-to-male vaginal transmission.¹²

The HIV attacks and binds to specific cells of the immune system, including monocytes, macrophages, and T-cell lymphocytes (also known as CD4+ T cells, helper T cells, T cells).^{13–16} These cells display specific receptor proteins known as CD4 receptors to which HIV binds. Once bound to the CD4 receptor, coreceptor proteins are required for fusion (CCR-5, CXCR-4).^{17,18} CCR-5 coreceptors are found on both monocytes and T lymphocytes, and are more abundant in patients newly infected with HIV.^{18,19} CXCR-4 coreceptors are predominantly found on T lymphocytes and are more abundant in patients who have been on long-term antiretroviral therapy. The CD4–coreceptor complex causes conformational changes to key HIV proteins (gp41 and gp120) allowing for a more close association between the virus and host cell.^{20,21} HIV fuses with the cell and releases its contents into the host cell's cytoplasm: this includes the virus' RNA and specific enzymes necessary for replication (Fig. 69-1). The single-stranded viral RNA is transcribed via reverse transcriptase into a double-stranded proviral DNA that is subsequently incorporated into the host cell's genetic material via the integrase enzyme. HIV then uses the infected cell's machinery to translate, transcribe, and produce immature viral particles that bud and break from the infected cell. For these immature virions to become infectious, the HIV protease enzyme must cleave large precursor polypeptides into functional proteins.^{22,23} Once complete, the mature virion is free to infect new host cells and subsequently produce more infectious virus. Over time, HIV-infected host cells can be destroyed by a number of mechanisms: (a) a direct cytolytic effect of the virus (e.g., formation of syncytium induction, cellular dysfunction); (b) the identification and elimination of the infected cell by the host's immune response (e.g., via cytotoxic T-cell lymphocytes); or (c) the cell's natural life cycle coming to completion.¹⁶ In addition, HIV infection can inhibit the production of new CD4 cells.²⁴

Once a patient becomes infected, an initial burst of viremia occurs and causes latent infection in various tissues (e.g., lymph nodes) and cells (CD4, macrophages and monocytes).^{25,26} Most infectious HIV virions (~99%) reside inside lymph nodes and other immune-cell rich tissues found throughout the body.^{15,25,27,28} The immune system reacts by producing antibodies against HIV; however, given the rapid production of new HIV particles and the development of various new viral strains (a result of the error-susceptible HIV reverse transcriptase), the antibody response is inadequate.²⁹ After this burst of viremia, a transient depletion of CD4 cells occurs (Fig. 69-2). Initially, patients may complain of nonspecific symptoms, such as fever, lymphadenopathy, rash, fatigue, and night sweats.^{30,31} This phase of infection is known as the *acute retroviral syndrome*. In most cases, patients are unaware that they are infected. Within 6 months, the host's immune response is able to control the infection to a point where the number of virus particles produced per day equals the number of particles destroyed per day. This steady-state is often referred to as the patient's viral "set point."

The higher a patient's viral set point, the greater the risk for disease progression, because the larger the viral population in a host, the greater the chance for more widespread viral infection and destruction of immune cells and lymphoid tissue. Why some patients establish higher or lower viral set points is currently under investigation, but this may be a consequence of differences in immune responses, cellular receptor populations,

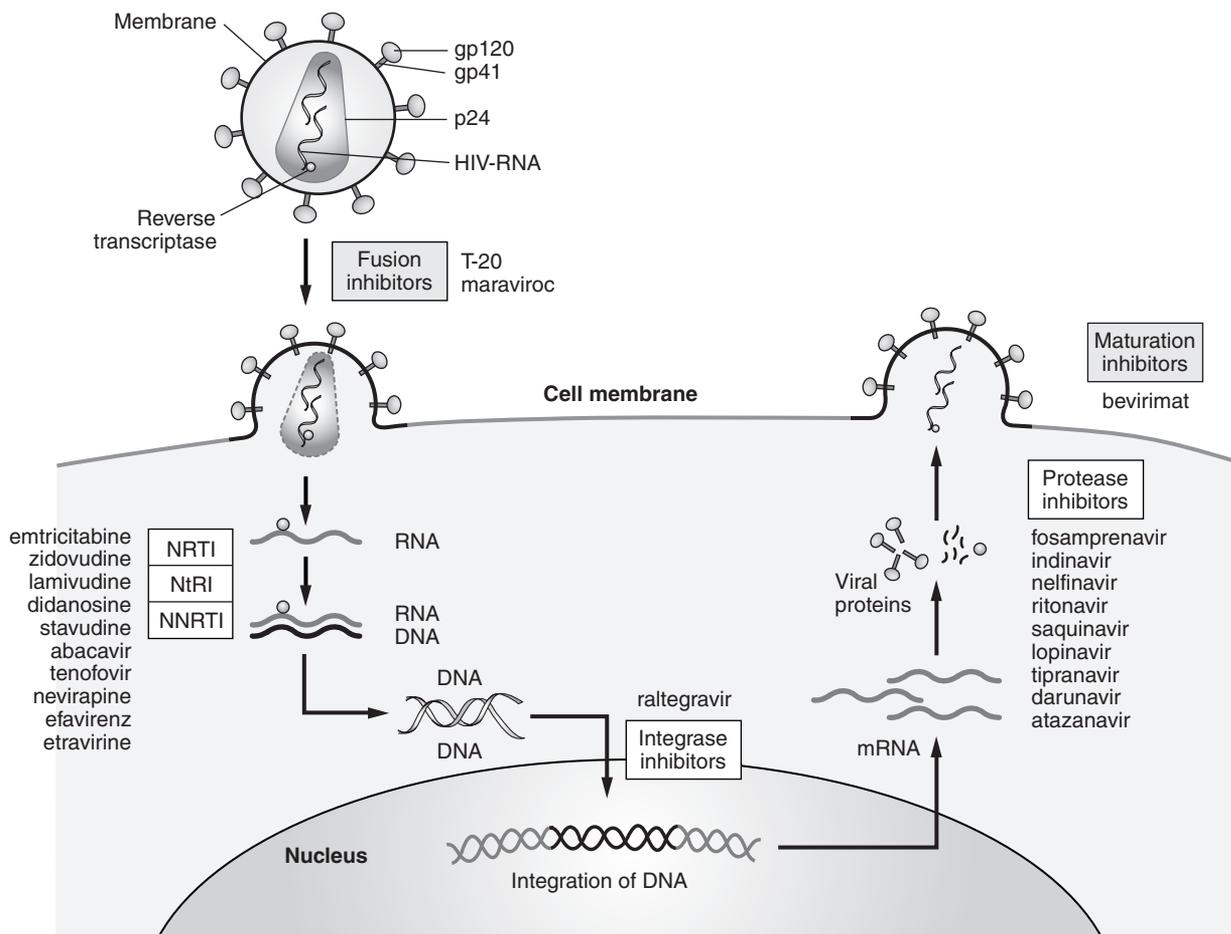

FIGURE 69-1 Schematic Representation of the HIV-1 Life Cycle. Four classes of antiretroviral drugs are available at present. Fusion inhibitors inhibit the entry of virions into a new target cell. The step of reverse transcription can be targeted, using nucleoside/tide analogues or non-nucleoside reverse-transcriptase inhibitors (NRTIs, NtRTI, and NNRTIs, respectively). The class of integrase inhibitors prevent integration of viral DNA into host cell DNA. The class of protease inhibitors interferes with the last state of the life cycle, the proteolytic processing of the viral proteins, which results in the production of non-infectious particles. (Adapted with permission from Simon V, Ho DD. HIV-1 dynamics in vivo: implications for therapy, *Nat Rev Microb* 2003 Dec;1:181.)

viral subtypes, viral fitness, or a combination of these factors. This understanding of viral pathogenesis may lead to a new paradigm of therapy: using antiretrovirals in the acute phase of infection to lower viral set points and potentially reduce the risk of disease progression. A significant challenge, however, remains in identifying patients with acute infection.³²

Once the initial burst of viremia has been controlled and the viral set point established, infection with HIV results in a constant battle between viral replication and suppression of that replication by the immune system. Mathematical models have calculated the production of HIV at 10 billion particles per day.^{15,33–35} To keep the infection controlled, the body must produce an equal immune response. Over time, HIV depletes the body of T cells, which places the host at an increased risk for opportunistic infections (Fig. 69-3). Direct measurements of HIV RNA concentrations in plasma (also called “viral load”) can predict disease progression (see below).^{36–38} Higher viral load measurements represent an inability of the host to control viral replication, and a greater risk for immune cell destruction. Long-term “nonprogressors” (e.g., patients with asymptomatic HIV infection for >10 years; 5% of all HIV-infected patients)

consistently have lower baseline viral loads than patients with rapidly progressive disease (e.g., AIDS within 5 years of infection; 20% of all HIV-infected patients).^{39,40}

Without intervention, the natural progression of HIV infection results in depletion of 50 to 100 T cells/mm³/year.^{25,41} The severity of immune dysfunction, as evidenced by T-cell loss, is highly predictive of the potential for developing specific types of opportunistic infections. For example, *Pneumocystis carinii* pneumonia rarely occurs when T-cell counts are >200 cells/mm³, whereas retinitis from *Cytomegalovirus* (CMV) infection infrequently occurs in patients with CD4 counts >75 cells/mm³ (Figs. 69-2 and 69-3). The diagnosis of AIDS is made when a significant amount of immune deterioration has occurred, either by direct depletion of CD4 cells or because of the development of new opportunistic infection (Table 69-1 and Table 69-2).^{25,42} It is important to recognize that not every patient with HIV has a diagnosis of AIDS. On average, without appropriate drug therapy, death occurs within 10 to 15 years after infection.^{25,42}

The interplay between viral load and CD4 T-cell counts is often compared with that of a train heading toward a particular

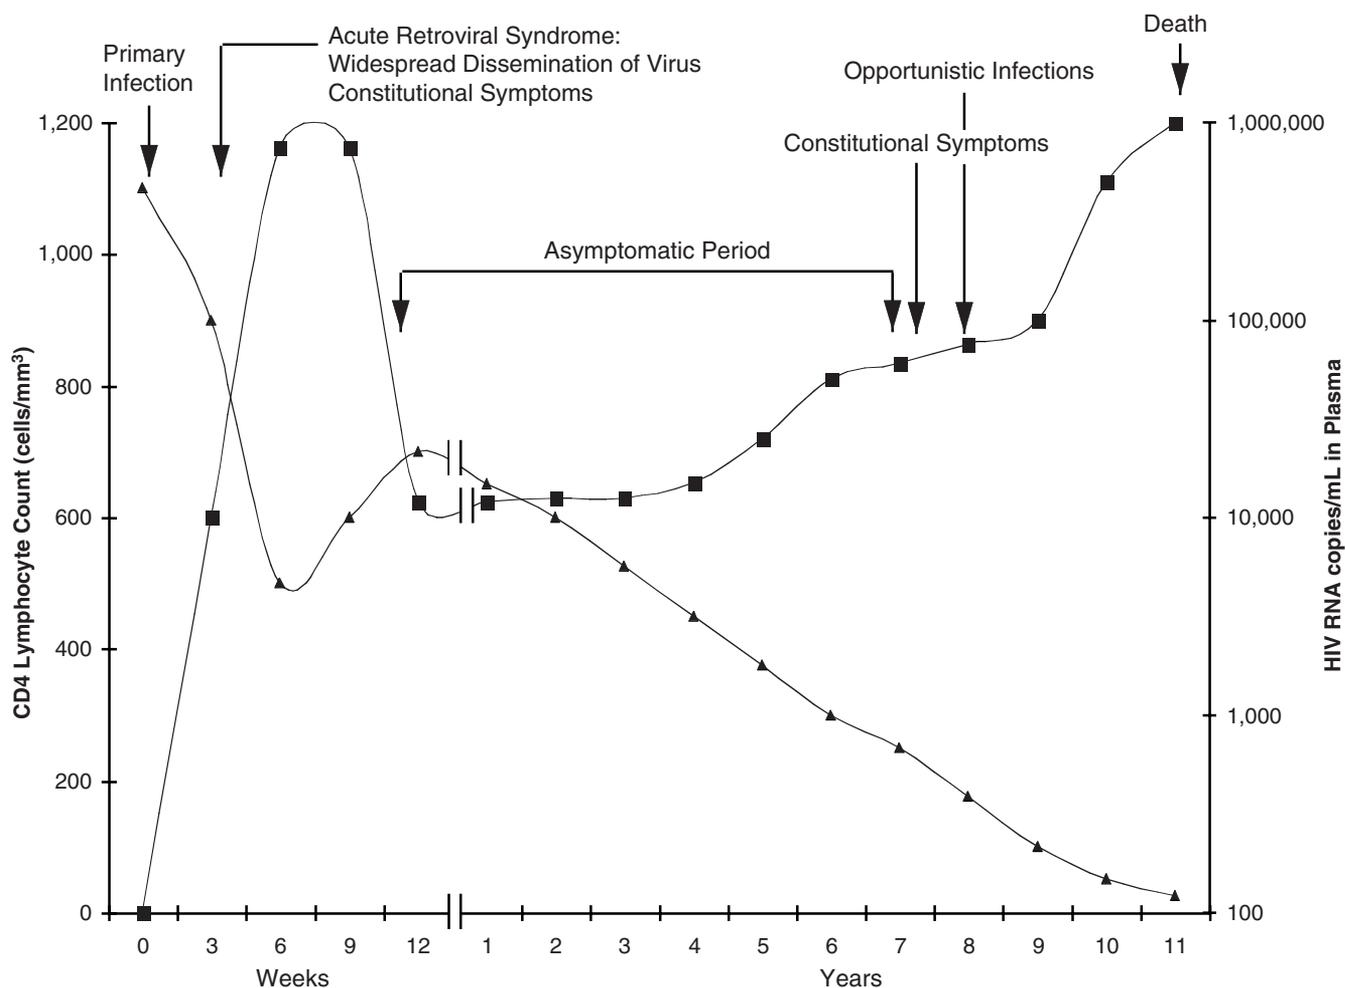

FIGURE 69-2 Sample disease course for an untreated HIV-infected individual showing relationship among immunologic, virologic, and clinical outcomes over time. Constitutional symptoms include fever, night sweats, and weight loss. ■ Viral load values; ▲ CD4 T lymphocytes. (Adapted from References 21 and 25.)

destination. If the destination is immune system destruction (and eventually death), then the T-cell count is the distance of the train from this destination, and the viral load (concentration of HIV RNA in plasma) is the speed of the train. As both higher speeds and shorter distances reach destinations faster, so does a high viral load and low T-cell count result in quicker onset of immune destruction (and death). Potent antiretroviral regimens, by decreasing viral replication, dramatically alter the natural course of infection, and prolong the time to opportunistic infection and death (Fig. 69-4).⁴³

PHARMACOTHERAPY

Pharmacotherapy of HIV has been directed at inhibiting key areas of the HIV life cycle (Fig. 69-1; Table 69-3). Much research has been focused on agents that inhibit the reverse transcriptase enzyme. Nucleoside or nucleotide analogue reverse transcriptase inhibitors (NRTIs: zidovudine, didanosine, lamivudine, abacavir, tenofovir, emtricitabine, and stavudine), inhibit this enzyme by incorporating false nucleic acids into the newly forming proviral DNA.⁴⁴ This results in a DNA strand

that cannot continue elongation. Non-nucleoside reverse transcriptase inhibitors (NNRTIs: nevirapine and efavirenz), inhibit reverse transcriptase by directly binding to the enzyme itself, and prevent DNA transcription from RNA.⁴⁵ Protease inhibitors (PI: saquinavir, amprenavir, nelfinavir, indinavir, lopinavir, atazanavir, ritonavir, tipranavir, and darunavir) directly bind to the catalytic site of HIV protease, inactivating the enzyme and preventing maturation of the HIV virion.^{46,47} Unlike reverse transcription, which occurs relatively early in the course of the HIV life cycle, protease enzyme activity occurs late in virion development. As a result, inactivation of the protease enzyme inhibits viral replication in any infected cell regardless of the current stage of HIV replication within that cell. In contrast, reverse transcriptase inhibitors can protect newly infected cells only before formation and insertion of proviral DNA into the host cell's genetic material. Subsequently, these agents provide no benefit for those infected cells that are actively producing new strains of virus.

Fusion inhibitors, such as T-20, prevent HIV and CD4+ T cells from being pulled closer together after HIV binds to CD4 and CCR5 or CXCR-4 coreceptors. T-20 prevents

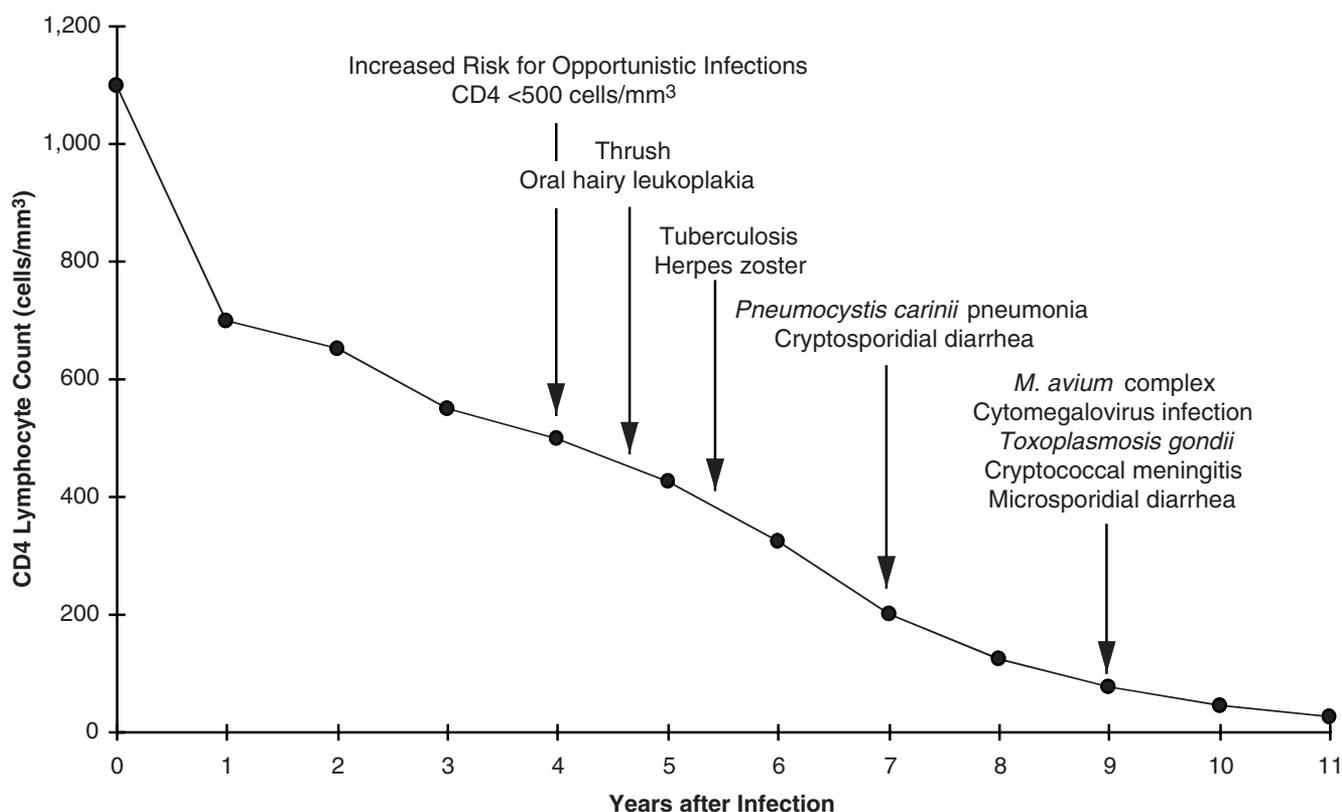

FIGURE 69-3 Relative risk for development of opportunistic infections based on CD4 lymphocyte counts over time.

fusion of the virus with the T-cell by binding to a double coil-coil complex at the gp41–gp120–CD4 receptor area.²¹ Two new classes of antiretroviral agents are coreceptor blockers (e.g., via CCR5 and CXCR-4 blockade) and HIV integrase inhibitors.^{48,49}

With the development of newer, more potent antiretroviral regimens, researchers have speculated about the possibility of eradicating HIV from an infected patient. This may require complete inhibition of viral replication in all cell lines and body stores where HIV resides (Fig. 69-5).¹⁵ One problem that exists is that some cell lines have shorter half-lives than others (e.g., peripheral T cells, 1–2 days versus macrophages 14 days).^{50,51} In addition, long-lived infected T cells with half-lives lasting more than 6 to 44 months have been identified.^{52,53} This may require complete HIV suppression for 60 years or more

to eradicate infection.^{52–54} Another complicating factor is the potential for HIV to reside in sites that achieve low antiretroviral concentrations, thereby serving as sanctuaries for HIV replication (e.g., central nervous system [CNS], testes). Once therapy is discontinued, these sites could theoretically release unaffected virions and repopulate the host. As a result, research has shifted toward immune-based therapies that can identify and destroy HIV-infected cells, in addition to preventing HIV acquisition.

DIAGNOSIS

1. E.J. is a 27-year-old man who presents to your clinic with new complaints of fevers, night sweats, weight loss, and a white

Table 69-1 1993 Revised Classification System for HIV Infection and the Expanded CDC Surveillance Case Definition for AIDS in Adults and Adolescents^a

| CD4 + T-Cell Categories | Clinical Categories | | |
|---|---------------------------------------|--|-------------------------------|
| | (A) Asymptomatic, Acute (Primary) HIV | (B) Symptomatic, Not (A) or (C) Conditions | (C) AIDS-Indicator Conditions |
| 1. >500/mm ³ | A1 | B1 | C1 |
| 1. 200–499/mm ³ | A2 | B2 | C2 |
| 1. <200/mm ³ (AIDS indicator T-cell count) | A3 | B3 | C3 |

^aThe modifications to the prior 1986 Surveillance Case Definition, which have been included in the 1993 revision, include the use of CD4 cell count (<200 cells/mm³) or CD4 cell percent (<14%) and the additional AIDS-indicating conditions of pulmonary tuberculosis, recurrent pneumonia, and invasive cervical cancer (see Table 69-2). AIDS, acquired immunodeficiency syndrome; CDC, Centers for Disease Control and Prevention; HIV, human immunodeficiency virus.

Table 69-2 Conditions Included in the 1993 Surveillance Case Definition**Category A**

Asymptomatic human immunodeficiency virus (HIV) infection
 Persistent generalized lymphadenopathy
 Acute HIV infection with accompanying illness or history of HIV infection

Category B

Bacillary angiomatosis
 Candidiasis, oropharyngeal (thrush)
 Candidiasis, vulvovaginal; persistent, frequent, or poorly responsive to treatment
 Cervical dysplasia or carcinoma *in situ*
 Constitutional symptoms, such as fever >38°C or diarrhea >1 mo
 Hairy leukoplakia
 Herpes zoster (shingles), involving at least two distinct episodes or more than one dermatome
 Idiopathic thrombocytopenic purpura
 Listeriosis
 Pelvic inflammatory disease, particularly if complicated by tubo-ovarian abscess
 Peripheral neuropathy

Category C

Candidiasis of bronchi, trachea, or lungs
 Candidiasis, esophageal
 Cervical cancer, invasive

Coccidioidomycosis, disseminated or extrapulmonary
 Cryptococcosis, extrapulmonary
 Cryptosporidiosis, chronic intestinal (>1 mo)
 Cytomegalovirus disease (other than liver, spleen, or nodes)
 Cytomegalovirus retinitis (with loss of vision)
 Encephalopathy, HIV-related
 Herpes simplex: chronic ulcer(s) (>1 mo); or bronchitis, pneumonitis, or esophagitis
 Histoplasmosis, disseminated or extrapulmonary
 Isosporiasis, chronic intestinal (duration >1 mo)
 Kaposi sarcoma
 Lymphoid interstitial pneumonia, pulmonary lymphoid hyperplasia, or both^a
 Lymphoma, Burkitt's (or equivalent term)
 Lymphoma, immunoblastic (or equivalent term)
 Lymphoma, primary, of brain
Mycobacterium avium-intracellulare complex or *M. kansasii*, disseminated or extrapulmonary
Mycobacterium tuberculosis, any site (pulmonary^b or extrapulmonary)
 Mycobacterium, other species or unidentified species, disseminated or extrapulmonary
Pneumocystis carinii pneumonia
 Pneumonia, recurrent^b
 Progressive multifocal leukoencephalopathy
Salmonella septicemia, recurrent
 Toxoplasmosis of brain
 Wasting syndrome resulting from HIV

^aChildren <13 years of age.

^bAdded in the 1993 expansions of the acquired immunodeficiency syndrome (AIDS) surveillance case definition for adolescents and adults.

exudate in his mouth. He states that these symptoms have been present for the past 4 to 6 weeks. On physical examination, it is concluded that E.J. has thrush caused by *Candida albicans*. E.J. admits to intravenous drug use in the past; however, he states that he has been "clean" for 3 years. HIV infection is suspected and consent for an HIV test is obtained. Why is HIV suspected and how is it confirmed?

In otherwise healthy, immunocompetent individuals, the appearance of opportunistic infections, such as thrush, is rare. This is because an intact cell-mediated immunity protects against infection. In immunosuppressed individuals, such as those infected with HIV or cancer, the immune system is significantly damaged and places patients at risk for opportunistic infections. Infections such as shingles (*Herpes zoster*), active tuberculosis, oral thrush, and recurrent candidal vaginal infections in an otherwise healthy person warrant further evaluation. More advanced diseases, such as *Pneumocystis jirovecii* pneumonia, *Mycobacterium avium* bacteremia, and *Cytomegalovirus* retinitis infections, among others, generally occur in patients with severely depressed immune systems and strongly suggest HIV infection. This is especially true for those patients with risk factors for HIV infection. Despite E.J.'s discontinuation of intravenous drugs, his prior use places him at risk for HIV infection. Given his social history and current clinical presentation, an HIV test is warranted.

Testing for HIV is based on detection of an antibody to the virus. The most commonly used methods include the enzyme-linked immunosorbent assays (ELISA) and confirma-

tory Western blot tests.^{55,56} ELISA is highly sensitive and specific (>99%) and therefore represents a good screening test. Using this method, the patient's serum is placed in wells coated with HIV antigens. After incubation and washing, an enzyme-labeled antihuman antibody is added, followed by a substrate. If HIV antibodies are present, a color change takes place; this is confirmed with a spectrophotometer. Reactive ELISA are subsequently repeated and, if both tests are positive, a Western blot confirmatory test is performed. The Western blot involves the addition of the host's serum to known HIV antigens that have been separated by gel electrophoresis. After washing and incubation, antihuman immune globulins linked to an enzyme or radioactive probe are added. The spectrum of band patterns on the gel is then interpreted and compared with controls for HIV diagnosis.

Although these tests when used together are highly specific and sensitive, there are situations where both false-negative and false-positive findings can occur.⁵⁷ The most troublesome is the situation in which a patient is truly infected but both ELISA and Western blot results are negative, known clinically as *acute HIV infection*. This occurs because, once infected, it takes 1 to 2 months for a person to develop antibodies to HIV.⁵⁸ Because both these tests rely on antibody detection, this "window" period of acute infection could result in a false-negative test finding for HIV. If this is suspected, clinicians may wish to order an HIV polymerase chain reaction (PCR) test (viral load measurement; see below); measurements >10,000 copies/mL are present only among patients who are HIV infected. Acute HIV infection is increasingly implicated in sexual transmission

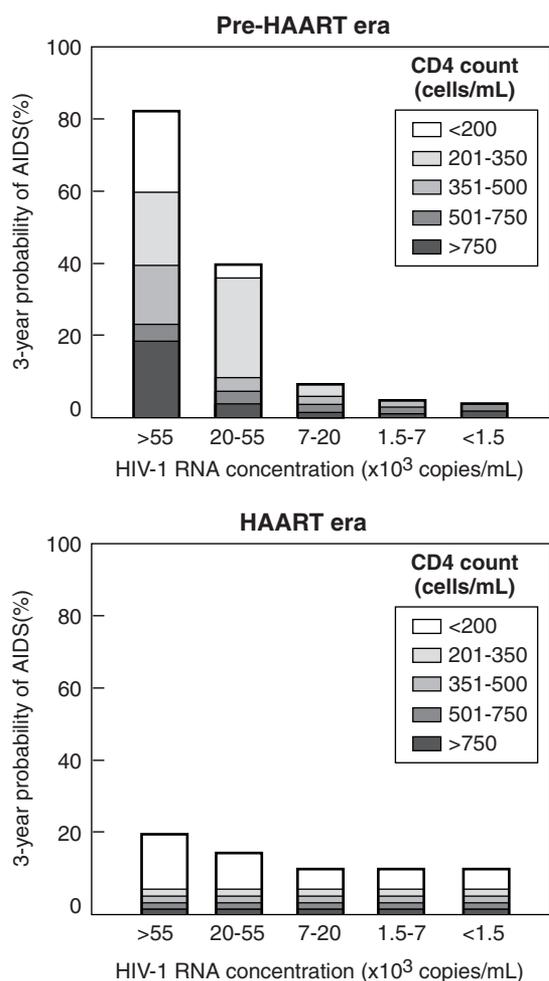

FIGURE 69-4 Prognosis According to CD4 Cell Count and Viral Load in the Pre-HAART and HAART Eras. (Adapted with permission from Elsevier The Lancet, Egger M, et al. ART Cohort Collaboration. Prognosis of HIV-1-infected patients starting highly active antiretroviral therapy: a collaborative analysis of prospective studies, *Lancet* 2002 Jul 13; 360:119.)

of HIV, and cost-efficient methods to detect acute infection using routine viral load measurements have been developed.⁵⁹ In all situations, a confirmatory Western blot test should be performed to rule out false-positive findings and mislabeled samples.

Results of the ELISA test take up to 1 to 2 weeks, and this delay means that patients must contact their providers for test results. According to the Centers for Disease Control and Prevention (CDC), in the year 2000 approximately one-third of individuals who tested positive for HIV did not return to the clinic to learn their results. Newer test methods have been developed that allow clinicians to supply definitive negative and preliminary positive results to patients within 20 minutes or less of screening, using whole blood, serum, plasma, or oral fluid.⁶⁰ The sensitivity and specificity of these new, rapid screening tests are comparable to those of ELISA. Similar to ELISA, a positive rapid test result should be confirmed by a supplemental test. The use of rapid HIV tests should be strongly considered when expected return rates for test results are low. The CDC

has published guidelines on the use and quality assurance of these rapid HIV tests.⁶¹

SURROGATE MARKER DATA

2. E.J.'s ELISA and Western blot tests both return positive, and he is informed of his HIV status the next week at his follow-up examination. Before making any decisions regarding therapeutic options, what additional laboratory tests should be obtained? What cautions should be used when interpreting these values?

To determine whether therapeutic interventions are necessary, the severity of immune damage and potential for disease progression must be assessed. As stated, HIV predominantly infects and destroys T cells. The larger the viral load, the greater the risk for T-cell destruction and opportunistic infections. Therefore, quantitative measurements of E.J.'s HIV viral load and T-cell counts are necessary to "stage" the severity of infection, assess the risk for disease progression, and provide a reference point (e.g., baseline) for future therapeutic decisions.

Identification and measurement of T-lymphocyte subsets (e.g., CD4, CD8) are based on flow cytometry readings of fluorescent-labeled monoclonal antibodies.^{5,42} These values can display wide variability on repeated laboratory evaluations, even in clinically stable patients. Patient samples can display up to 30% intra- and interlaboratory variability.⁵ In at least one study, sufficient interlaboratory variability existed to potentially result in conflicting treatment recommendations in 58% of patients (e.g., initiating therapy when T-cell counts fell <500 cells/mm³).⁶² Consequently, it is important to realize that assessment of T-cell measurements should always be interpreted as trends and not as individual values. Variability can also be minimized by using the same laboratory and by sampling patients at a consistent time of day.

The measurement of HIV viral load can be performed by one of three methods: reverse transcriptase-polymerase chain reaction (RT-PCR), branched-chain DNA (bDNA) assay, or nucleic acid sequence-based amplification (NASBA).⁶³ Measurements using RT-PCR are obtained when viral RNA is amplified and counted. In contrast, bDNA amplifies and enumerates the signal from target probes attached to the viral RNA. NASBA allows real-time, high throughput amplification of viral RNA. All methods report HIV RNA in plasma as the number of copies per milliliter, but have differing lower limits of quantitation.⁵ It should be recognized that plasma viral RNA values measure the amount of free virus in the periphery and not the lymph nodes. Because viral concentrations are substantially greater in the lymph node, plasma measurements of HIV indirectly reflect spill over from replication in that compartment.^{64,65}

Similar to CD4 counts, viral load measurements (copies/milliliter) can vary by as much as threefold (0.5 log) in either direction.⁵ When obtaining a patient's baseline value, a number of issues must be considered. On initial infection with HIV, a burst of viremia occurs until the host's immune responses are able to control the infection. Subsequently, viral load measurements obtained during the first 6 months of infection may not accurately reflect a true baseline value.⁵ In addition, factors that activate the immune system, such as the development of a new opportunistic infection or immunizations,⁶⁶ can result in transient elevations of viral load measurements. In these situations,

^aIn clinical trials, the non-nucleoside reverse transcriptase inhibitor (NNRTIs) was discontinued because of rash in 7% of patients taking nevirapine, 4.3% of patients taking delavirdine, and 1.7% of patients taking efavirenz. Rare cases of Stevens-Johnson syndrome have been reported with all three NNRTIs.

APV, amprenavir; ARV, antiviral; BID, twice daily; CNS, central nervous system; DRV, darunavir; ENF, enfuvirtide; fAPV, fosamprenavir; FDA, U.S. Food and Drug Administration; IDV, indinavir; NRTIs, nucleosides; NVP, nevirapine; PI, protease inhibitor; PO, orally; QD, every day; QHS, four times daily; RTV, ritonavir; SC, subcutaneously; TDF, tenofovir disoproxil fumarate; TID, three times daily; TPV, tipranavir; TPV/r, tipranavir/ritonavir.

concentrations obtained within 4 weeks of the event may not accurately reflect the baseline viral load measurement.⁵ Some clinicians would recommend that at least two separate viral load measurements, which are obtained within 1 to 4 weeks of each other, be performed before making decisions regarding therapeutic options.⁶⁷ As with T-cell values, viral load measurements should be evaluated as trends.

In addition to quantifying the viral load, baseline resistance testing should be considered, using either genotypic or phenotypic testing,⁵ to guide the selection of the initial regimen. Resistance testing is recommended in most clinical situations before beginning treatment, because the rate of transmission of virus resistant to at least one drug is estimated to be between 6% and 16% in European and American cohorts^{68–74} (see Resistance, Viral Genotyping, Phenotyping, and Viral Fitness case for further discussion).

E.J. should have a baseline T-cell count, viral load measurement, and viral genotype obtained. A complete blood count, electrolyte panel, and renal and liver function tests should also be performed. These laboratory values help in selecting therapeutic options (see below) and establish baseline values in the event that problems are encountered in the future.

ANTIRETROVIRAL THERAPY

3. E.J.'s T-cell count and viral load measurement (two separate levels obtained within the past 2 weeks) return at 225 cells/mm³

and 145,000 copies/mL (by RT-PCR assay). Should antiretroviral therapy be initiated?

In deciding to initiate antiretroviral therapy, it is important to consider both the potential benefits of therapy and the potential risk of therapy, including both short-term and long-term side effects and potential for the development of drug resistance (and cross-resistance; see below). Antiretroviral therapy should be offered to any patient who is symptomatic, regardless of T-cell count and viral load measurements. “Symptomatic” refers to any new opportunistic infection or increases in constitutional symptoms (e.g., fevers, night sweats, unexplained weight loss). These events suggest a faltering immune system that necessitates therapy. In patients who are asymptomatic, assessment of the patient’s surrogate marker data (T-cell count, viral load measurements), concurrent medical conditions, medication adherence history (if any), and motivation to initiate therapy are necessary. The results of resistance testing should be considered before initiating therapy.

Knowledge of both the T-cell count and the baseline viral load values is necessary to “stage” the severity of infection. In otherwise healthy, immunocompetent persons, T-cell measurements are >1,200 cells/mm³. In patients who have been chronically infected with HIV, significant T-cell destruction occurs. When T-cell counts fall below 500 cells/mm³, patients are at increased risk for opportunistic infections (Fig. 69-3). The optimal time to initiate antiretroviral therapy among asymptomatic patients with HIV infection is unknown. Data from

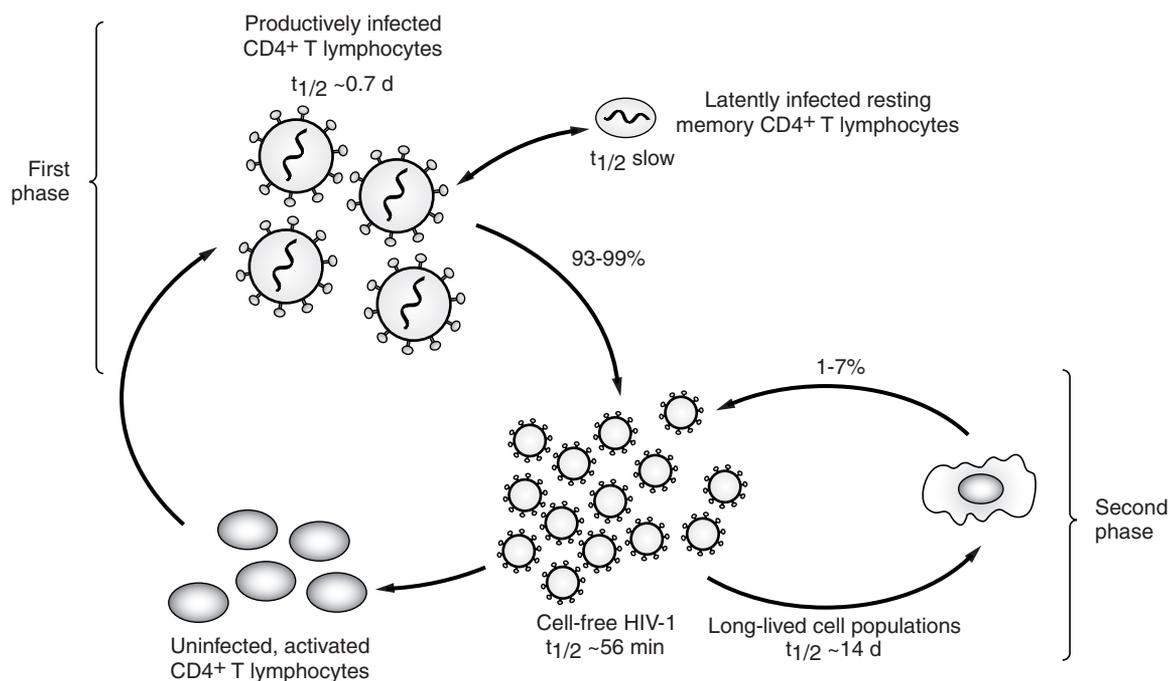

FIGURE 69-5 Schematic summary of the turnover rates of virions and the relative contribution of the different HIV-1-infected cell populations. After initiation of HAART, the viral burden decreases rapidly by several orders of magnitude, which corresponds to the rapid clearance of plasma virions and productively infected T lymphocytes (first phase). Certain cell populations that initially are responsible for only a small proportion of the circulating virions in an untreated HIV-1-infected individual display slower turnovers. Long-lived infected T lymphocytes, latently infected cells that become activated and release of virions from follicular dendritic cells, contribute to the second phase of plasma virus decay. (Adapted with permission from Simon V, Ho DD. HIV-1 dynamics in vivo: implications for therapy, *Nat Rev Microb* 2003 Dec; 1:181.)

both clinical trials and observational cohort studies have shown a clear benefit for antiretroviral therapy when CD4 cell counts are <200 cells/mm³.^{3,5} Currently, the optimal time to initiate antiretroviral therapy in patients with CD4 cell counts between 200 cells/mm³ and 350 cells/mm³ is unknown. Information from randomized, controlled trials to guide treatment initiation is lacking, but observational cohorts provide some information on disease progression and initiation of treatment. The risk of disease progression is closely tied to CD4 cell counts, with low CD4 counts (<200 cells/mm³) predicting both short- and long-term risk of disease progression.^{36–38,75,76} High viral load

($>100,000$ copies/mL), increasing age, acquisition of infection through intravenous drug use, and a previous AIDS diagnosis also increase the risk of disease progression in observational cohorts. Based on these data, the Department of Health and Human Services (DHHS) published guidelines on when to consider antiretroviral therapy in those infected with HIV (Table 69-4). These guidelines provide general principles for when to initiate therapy in an antiretroviral-naïve patient; however, they are not absolute. Most clinicians would prefer to begin therapy before CD4 cell counts become <200 cells/mm³, and many use <350 cells/mm³ as a point to begin discussions with the

Table 69-4 Indications for the Initiation of Antiretroviral Therapy in the Chronically HIV-1-Infected Patient^a

| Clinical Category | CD4+ T-Cell Count | Plasma HIV RNA | Recommendation ^b |
|-------------------------------------|--------------------------------------|----------------------|--|
| Symptomatic (AIDS, severe symptoms) | Any value | Any value | Treat |
| Asymptomatic | CD4+ T cells <200 /mm ³ | Any value | Treat. The 3-year probability of progressing to AIDS or death is 9%–20%. |
| Asymptomatic | CD4+ T cells 200–350/mm ³ | Any value | Treatment should be offered. The 3-year probability of progressing to AIDS or death is 4.7%–6.1%. |
| Asymptomatic | CD4+ T cells >350 /mm ³ | $>100,000$ copies/mL | Most experienced clinicians defer therapy, but some may consider initiating treatment. The 3-year probability of progressing to AIDS or death is 4.4%. |
| Asymptomatic | CD4+ T cells >350 /mm ³ | $<100,000$ copies/mL | Defer therapy. The 3-year probability of progressing to AIDS or death is 3.4%. |

^aThe optimal time to initiate therapy in asymptomatic individuals with >200 CD4+ cells is not known. This table provides general guidance rather than absolute recommendations for an individual patient. All decisions to initiate therapy should be based on prognosis as determined by the CD4+ T-cell count and plasma HIV RNA, the potential benefits and risks of therapy shown in Table 69-4, and the willingness of the patient to accept therapy.

^bProbability of progression to AIDS or death obtained from DHHS Treatment Guidelines, October 2006.

AIDS, acquired immunodeficiency syndrome; HIV, human immunodeficiency virus.

DHHS: Department of Health and Human Services

patient regarding initiating therapy. Increasing data from longitudinal cohort studies suggest that patients who begin HAART therapy at higher CD4 cell counts are more likely to achieve CD4 cell count recovery than patients who begin at counts <200 cells/mm³,⁷⁷⁻⁷⁹ although the potential clinical implications of this remain unknown. This evidence plus the ease of dosing and tolerability of new HAART regimens may tip the balance to early treatment. Thus, treatment is offered to patients with CD4 cell counts between 200 cell/mm³ and 350 cells/mm³. In the case of CD4 cell counts >350 mm³, most clinicians would defer treatment, unless viral load is very high (i.e. $>100,000$ copies/mL), which increases the potential for CD4 cell count decline, and thus the risk of disease progression. In this situation, clinicians may elect to take an approach to early treatment and offer therapy to prevent further immune compromise.

The decision to initiate therapy should not be taken lightly nor should it be based solely on surrogate marker data. Antiretroviral regimens may improve the quality and duration of a patient's life, but they are not without significant risks and adverse effects. Once therapy is initiated, antiretroviral therapy is a lifetime commitment. For some patients, this may be a difficult realization, particularly if the patient is relatively healthy. In addition, the fear of adverse events and toxicities must also be overcome. These guidelines, therefore, should be used as a springboard for discussions with the patient regarding the risks and benefits of therapy. It is critical for practitioners to talk openly with patients about their fears and concerns and make an assessment about their motivation to initiate therapy and ability to take a lifelong regimen. The patient should always make the final decision after careful discussions with the practitioner.

E.J. has a number of significant risk factors for disease progression. He is clinically symptomatic with oral thrush and nonspecific constitutional symptoms (e.g., fevers, night sweats, and weight loss). His surrogate maker data place him at risk for greater disease progression (T-cell count <350 cells/mm³ and viral load $>100,000$ copies/mL). Based on these values, E.J. should be counseled on his risk of disease progression, potential adverse events associated with both starting and deferring treatment, and his willingness to adhere to a regimen.

4. After careful discussions, E.J. agrees to initiate therapy. What should be the goals of therapy? What other factors or information needs to be considered in selecting an appropriate regimen?

Before developing a patient-specific regimen, it is important to recognize the benefits and limitations of therapy and identify obtainable and realistic goals.

Goals of Therapy

Goal 1: Maximally and Durably Suppress Viral Load

The ability to measure viral loads has shown that maximal viral suppression often results in significant increases in T-cell counts and improved clinical outcomes.⁵ Based on our understanding of viral pathogenesis, this is not surprising. Lower amounts of replicating virus result in decreased risk for T-cell infection and destruction and, subsequently, a more intact immune response. Therefore, therapy should suppress viral repli-

cation as much as possible, preferably to nondetectable levels in the plasma, for as long as possible.^{5,6} The development of new antiretroviral agents with improved potency and adverse event profiles, in addition to more convenient dosing regimens, makes viral suppression a reasonable goal in most patients, even those who previously have received multiple suboptimal regimens. In the treatment-experienced patient, however, special care must be given to designing a regimen that will suppress viral load, yet not contribute to the development of drug resistance that limits future treatment options. Consultation with an expert in antiretroviral resistance patterns is critical to designing a salvage regimen in such patients.

The development of drug resistance is a consideration in the selection of regimens for patients who are antiretroviral naïve as well. In any given viral population, the potential exists for a spontaneous mutation to occur, which results in a resistant isolate. The larger the population, the greater the risk. HIV replication is a highly error-susceptible process, especially the reverse transcriptase enzyme. Given the high rate of viral replication, the potential exists for the daily production of thousands of replication-competent viral mutants to each and every site on the HIV genome ($\sim 10,000$ nucleotides in length).^{7,35} Under selective pressures from inadequate antiretroviral therapies, isolates with reduced susceptibility to the given regimen eventually flourish and repopulate the host. This is of particular concern given the potential for cross-resistance between antiretroviral agents (see following discussion of resistance). Therefore, the use of a regimen that fully suppresses viral replication reduces the potential for mutations and the development of cross-resistance.

Although >20 U.S. Food and Drug Administration (FDA)-approved antiretroviral agents are currently available to use in combination therapies, many of these agents display similar resistance profiles. As a result, by developing resistance to one or more agents in a given regimen, the loss of activity to other agents with similar resistance profiles can occur (i.e., cross-resistance).⁷ Whether drug resistance develops is determined by the genetic barrier associated with the individual agents. Some agents have low genetic barriers; that is, only one or two critical changes in the virus are necessary for resistance to occur. An example of a class of agents with a low genetic barrier is the NNRTIs. One critical point mutation in the viral genome is required for loss of activity among this class of agents.⁷ In contrast, the PIs have a wide genetic barrier in that it takes multiple viral changes to incur resistance.⁷ It should be recognized, however, that just because an agent has a low genetic barrier does not mean it is virologically inferior or less potent. Potent regimens containing NNRTIs have been shown to be highly effective and provide durable treatment responses.⁵ It is also important to realize that the potency of the regimen as a whole is critical to determining whether or not drug resistance develops. If viral replication is suppressed, the development of resistance will be minimal. When viral replication does occur, however, the greater the replication, the greater the risk for development of resistance.^{5,6} In situations in which viral replication does occur, having an agent(s) in the antiretroviral regimen with a low genetic barrier may be risky and could result in the loss of activity of the individual agent, the development of cross-resistance to other agents, or both. As a result, it is critical to select an antiretroviral regimen that has a high likelihood of suppressing viral replication and to

which the patient will strictly adhere (either through ease of dosing or minimization of adverse drug events).

Given the increased rate of transmission of resistant viruses to patients newly infected with HIV,^{68–71,80} current guidelines recommend obtaining a resistance test before initiation of therapy to help in the selection of appropriate agents in the antiretroviral regimen.^{5,6} If a regimen is initiated that contains an agent(s) to which the virus has already developed resistance, the potency of the entire regimen may be insufficient for complete viral suppression and further antiretroviral resistance may develop. Because of its more rapid turn-around time, a viral genotype is generally preferred over a viral phenotype.⁵

Goal 2: Preserve and Strengthen the Immune System

Suppression of viral replication usually leads to increased CD4 cell counts and strengthens and preserves the immune system. With increased cell counts, patients are at decreased risk for the development of opportunistic infections and death. With newer and better regimens, strengthening and preserving the immune system may be possible even in treatment-experienced patients, although drug regimens must be designed carefully to prevent development of further resistance. Although full immune reconstitution may not be possible after prolonged time periods with low CD4 cell counts, it is reasonable to attempt to restore immune function as fully as possible. Despite advances in drug therapy, it is important to remember that HIV remains an incurable condition.

Goal 3: Limit Drug Adverse Events, Promote Adherence, and Improve Quality of Life

Treatment with combination therapy has been shown to be highly effective in suppressing HIV replication and improving survival among patients who are HIV infected. Maximal viral suppression, however, should not be obtained at the expense of

a patient's overall health and safety. Lifelong adherence to an antiretroviral regimen can be a complex and difficult task,^{4,5} although advances in coformulation of drug products and the advent of ritonavir-boosted protease inhibitors have simplified treatment considerably. Several once-daily regimens are recommended as first-line therapy (Tables 69-3 and 69-5). The patient's ability to adhere to therapy may, however, still be the difference between a regimen that fails and one that results in a clinical benefit, and the first regimen generally provides the best chance for treatment success. Adverse events make tolerating these regimens difficult, minimizing drug adherence and subsequent response to therapy. Changes in body composition (known as lipodystrophy), increases in lipids and triglycerides, bone and joint fractures, increased risks for cardiac disease, and the development of lactic acidosis are serious concerns.⁸¹ In addition, both acute and long-term adverse events can be fatal if not properly identified and managed.

Data from studies evaluating nonadherence among those HIV infected shows that at least 10% of patients on PIs miss a dose each day and that at least 20% miss a dose every 2 days.⁸² The exact degree of adherence required for clinical success is currently unknown, and patients should be counseled to always take their regimens as prescribed. The four most common reasons for skipping antiretroviral doses among those infected with HIV are simple forgetfulness, a change in daily routine, being too busy with other things, and being away from home.^{83,84} Factors associated with poor adherence include (a) the number of medications (the greater the number, the greater the likelihood of poor adherence); (b) the complexity of the regimen (special meal requirements, escalating or de-escalating doses, dose frequency); (c) special storage requirements; (d) interference of medication with lifestyle and daily activities; and (e) poor communication with primary care providers and other health care professionals.^{83,84}

Table 69-5 Recommended Antiretroviral Agents for Initial Treatment of Established Human Immunodeficiency Virus (HIV) Infection^a

| | <i>Preferred</i> | <i>Alternatives</i> |
|---|---|---|
| Dual NRTIs Options | Tenofovir + emtricitabine (coformulated) Abacavir + lamivudine (coformulated) | Zidovudine + lamivudine (coformulated) Didanosine + (lamivudine or emtricitabine) |
| NNRTIs (one NNRTIs + two NRTIs) | Efavirenz ^b | Nevirapine ^c |
| PIs (one or two PIs + two NRTIs) | Atazanavir + ritonavir Fosamprenavir + ritonavir twice daily Lopinavir/ritonavir (coformulated) twice daily | Atazanavir ^d Fosamprenavir Fosamprenavir + ritonavir once daily Lopinavir/ritonavir (coformulated) once daily Saquinavir + ritonavir |
| Not recommended: Should not be offered | All monotherapies, dual nucleoside regimens, NRTIs-sparing regimens, triple NRTIs regimens | |

^aThis table provides a guide to the use of available treatment regimens for individuals with no prior or limited experience on human immunodeficiency virus (HIV) therapy. In accordance with the established goals of HIV therapy, priority is given to regimens in which clinical trials data suggest the following: sustained suppression of HIV plasma RNA (particularly in patients with high baseline viral load), sustained increase in CD4+ T-cell count (in most cases >48 weeks), and favorable clinical outcome (i.e., delayed progression to acquired immunodeficiency syndrome [AIDS] and death). Additional consideration is given to the regimen's pill burden, dosing frequency, food requirements, convenience, toxicity, and drug interaction profile compared with other regimens. It is important to note that all antiretroviral agents have potentially serious toxic and adverse events associated with their use.

^bExcept during the first trimester of pregnancy or in women with high pregnancy potential (women who are trying to conceive or who are not using effective and consistent contraception).

^cAs an alternative in adult females with CD4+ T-cell counts <250 cells/mm³ and adult males with CD4+ T-cell counts ≤400 cells/mm³.

^dWhen used with tenofovir, atazanavir should be combined with ritonavir 100 mg/day.
NRTIs, nucleotide analogue reverse transcriptase inhibitor; PI, protease inhibitor.

Incorporating these factors into the selection of a patient-specific regimen may improve adherence and, subsequently, the chance for an improved clinical outcome.

Goal 4: Prevent HIV-related Morbidity and Mortality

By successfully treating HIV (i.e., suppressing viral load and restoring immune function), patients are at decreased risk for acquiring HIV-associated opportunistic infections (Fig. 69-3). By achieving goals 1 through 3, goal 4 naturally follows, and truly this is the ultimate goal of the pharmacotherapy of HIV infection. With modern-day HAART therapy, patients infected with HIV are more frequently dying from non-HIV-related conditions that are common in the general population (i.e., cardiovascular disease, hepatic disease, non-HIV-associated malignancies)⁸⁵ than in the past. Although this represents a significant achievement in care, it also provides increased complexity in caring for those infected with HIV who are both at risk for HIV-related illness and also receiving treatment for comorbid conditions. This increases the potential for drug–drug and drug–disease interactions that must be considered to optimize patient care and prevent morbidity and mortality.

5. On questioning, E.J. states that he has had two bouts of alcohol-induced pancreatitis in the past. The last episode was approximately 1 year ago. He admits to occasional binge drinking even though he knows it is not good for him. E.J. has no known drug allergies and is currently taking only temazepam periodically to help him sleep. He is employed as a construction worker and during the day hours is extremely busy. His complete blood count, electrolyte, and liver and renal panel all return within normal limits. E.J. has no particular preference for a specific regimen and appears highly motivated to take control of his disease. What factors should be considered when selecting an appropriate antiretroviral regimen?

The selection of a patient-specific regimen can be a complex decision. Many potential combinations can be used, but a number of general principles should be followed:

General Rules of Therapy^{5,6}

1. Initiate therapy when the potential clinical benefits outweigh the potential risks. Many of the current regimens reduce viral replication to below detectable levels in most patients, and result in durable treatment responses. Reasons for these

improved response rates compared with older regimens include the simplification of the regimens (e.g., less pills per day, less frequent dosing per day, use of fixed-dose combination products), improvement in overall potency of the regimens, and minimization of short-term side effects. Consequently, if the correct patient-specific HAART regimen is selected as initial therapy, the patient should be able to adhere to therapy and gain both a virologic and clinical benefit from the regimen.

2. Select the type of antiretroviral regimen. The use of combination HAART therapy is standard medical care and should be considered in all patients. Monotherapy with any agent should be avoided because clinical trials have shown these regimens to be inferior. In addition, the use of dual nucleoside-only-containing regimens should be avoided because initial viral suppression may not be sustained. In general, two types of initial strategies—NNRTIs- or PI-based—are preferred. (Table 69-6). Both types of regimens are potent and can produce sustained virologic response. Currently, no evidence definitively recommends one type over another, and the selection is dependent on patient-specific factors, such as concomitant disease states (i.e., hepatitis, diabetes, cardiovascular disease), and provider preference. In selected patients with compelling reasons to avoid use of a PIs or NNRTIs, triple nucleoside therapy may be considered with lamivudine (3TC), zidovudine (ZDV), and abacavir (ABC), but this regimen should not be routinely used as first-line treatment, particularly in patients with high viral loads (i.e. > 100,000 copies/mL).
3. Avoid regimens with overlapping toxicities. In general, the concomitant use of the “D” NRTIs (didanosine [ddI] and stavudine [d4T]) should be avoided owing to an increased risk of pancreatitis and neuropathy. Atazanavir and indinavir can both cause severe hyperbilirubinemia, and concomitant use should be avoided.
4. Avoid regimens that are not virologically additive or synergistic. Zidovudine (ZDV) and d4T should not be used together because both in vitro and in vivo studies have shown these agents to be antagonistic. 3TC and emtricitabine (FTC) should not be used together because they have similar resistance profiles, and concomitant use will not confer any additional virologic benefit. Amprenavir oral solution and fosamprenavir should not be used together, because fosamprenavir is simply the prodrug of amprenavir.

Table 69-6 Advantages and Disadvantages of Antiretroviral Components for Initial Antiretroviral Therapy^a

| ARV Class | Possible Advantages | Possible Disadvantages |
|------------|---|---|
| Dual NRTIs | <ul style="list-style-type: none"> • Established backbone of combination antiretroviral therapy | <ul style="list-style-type: none"> • Rare but serious cases of lactic acidosis with hepatic steatosis reported (d4T > ddI=ZDV>TDF=ABC=3TC=FTC) |
| NNRTIs | <ul style="list-style-type: none"> • Less fat maldistribution and dyslipidemia than PI-based regimens | <ul style="list-style-type: none"> • Low genetic barrier to resistance (single mutation confers resistance) • Cross resistance among approved NNRTIs |
| PI | <ul style="list-style-type: none"> • Save PIs options for future use • Higher genetic barrier to resistance • Save NNRTIs for future use | <ul style="list-style-type: none"> • Skin rash • Potential for cytochrome P450 drug interactions • Metabolic complications (fat maldistribution, dyslipidemia, insulin resistance) • Cytochrome P450 substrates, inhibitors, and inducers (potential for drug interactions) |

^a Adapted from DHHS treatment guidelines January 2008.

Department of Health and Human Services.

3TC, lamivudine; ABC, abacavir; d4T, stavudine; ddI, didanosine; FTC, emtricitabine; HAART, highly active antiretroviral therapies; NNRTIs, non-nucleoside reverse transcriptase inhibitors; NRTIs, nucleoside reverse transcriptase inhibitor; PI, protease inhibitor; TDF, tenofovir; ZDV, zidovudine.

The use of tenofovir and didanosine as initial therapy is not recommended owing to the potential for virologic failure, suboptimal immunologic response, and the potential for development of drug resistance.

5. If PI-based HAART is desired, consider using a ritonavir-boosted regimen. Various PIs have been evaluated in combination with ritonavir, including saquinavir, lopinavir, indinavir, fosamprenavir, tipranavir, atazanavir, and darunavir. Ritonavir, a potent inhibitor of cytochrome P450 metabolism and p-glycoprotein activity, interacts significantly with a number of agents, including other PIs.⁴⁷ This inhibition can be exploited to decrease the metabolism or increase the absorption of the other PIs. In some cases, such as lopinavir, tipranavir, and darunavir, the use of coadministered ritonavir is required for virologically relevant concentrations. The result is a regimen with more potent viral suppression than a regimen using either agent alone. In addition, this combination allows for more convenient once- or twice-daily dosing, often lowers the total daily pill burden, and removes the need for drug/food restrictions. Given that ritonavir can cause significant gastrointestinal side effects in some patients at increased doses and that only small amounts of ritonavir are needed to inhibit metabolism, low doses are sufficient (e.g., 100–200 mg). It should also be remembered that ritonavir interacts with a number of medications and, depending on the severity of the interaction, may require dosage adjustments of other agents or the inability to use ritonavir in the given regimen.^{5,6}
6. Avoid regimens shown to be detrimental in specific patient populations. Examples include the use of efavirenz (Pregnancy Class D) in women of child-bearing potential not using reliable methods of birth control or in the first trimester of pregnancy, because this drug has been associated with teratogenic effects; the use of propylene glycol-containing amprenavir solutions in high-risk patients, such as pregnant women, children <4 years of age, patients with renal or liver dysfunction, and those undergoing treatment with metronidazole or disulfiram. Nevirapine has the potential for hepatotoxicity in patients with higher baseline CD4 cell counts (>250 cells/mm³ for women, >400 cell/mm³ for men).

6. What initial antiretroviral regimen should E.J. receive?

When selecting a patient-specific regimen, these steps should be followed:

Step 1: Determine Which HAART-Based Regimen Will Be Used

A careful review of the advantages and disadvantages of each interventional strategy should occur (Table 69-6). For example, efavirenz may be avoided for patients with a psychiatric history. Protease inhibitors may be less favored with a familial history or current medical condition consisting of coronary artery disease, hyperlipidemia, or diabetes mellitus.⁸¹

After discussions with E.J., it appears that he is highly motivated to take control of his disease and is willing to initiate therapy. Subsequently, the use of a combination regimen with either a PI-based or NNRTIs-based regimen is appropriate. Potential treatment options are listed in Table 69-5.

Step 2: Optimize Agents in the Regimen

The next step requires the selection of agents for the regimen. In many situations, absolute contraindications and significant

drug–drug interactions limit the agents available for use in the regimen. In this case, ddI is a relative contraindication given a history of alcohol abuse and pancreatitis. The remaining nucleoside or nucleotide reverse transcriptase inhibitors, including ZDV, 3TC, d4T, tenofovir (TDF), FTC, and ABC, are all potential options. With respect to drug interaction issues, any NNRTIs or PIs class can be administered safely with zidovudine.

Step 3: Quality-of-Life Considerations

When selecting a regimen, assessment of quality-of-life issues, potential adverse drug events, and patient requests should receive as much consideration as drug–drug interactions and absolute contraindications. In some situations, these issues could mean the difference between a regimen that is effective and one that is not. Considering E.J.'s lifestyle and work requirements, it is best to select a regimen that will minimally interfere with his daily activities. The selection of a regimen with once- or twice-daily dosing is appropriate (Table 69-3), although once-daily dosing might be preferred. The combinations of nucleosides recommended as initial therapy can be given once or twice daily, and are available as coformulated products (Table 69-3). Examples of potential regimens include 3TC plus ABC (dosed once daily) or FTC plus TDF (dosed once daily) with efavirenz, which is the preferred first-line NNRTIs. Using the same nucleoside agents, atazanavir–ritonavir administered once daily, fosamprenavir–ritonavir administered twice daily, or lopinavir–ritonavir administered twice daily are the preferred PI-based regimens.

7. E.J. is starting emtricitabine, tenofovir, and efavirenz (coformulated for once-daily dosing as Atripla). How should therapy be monitored? Are any additional laboratory tests necessary?

Short-Term Assessments

Three important criteria determine whether an antiretroviral regimen is effective: clinical assessment, surrogate marker responses, and regimen tolerability.^{5,6} In patients who are clinically symptomatic (e.g., constitutional symptoms such as fatigue, night sweats, and weight loss; new opportunistic infections), the initiation of an appropriate antiretroviral regimen often results in resolution of symptoms, increased strength and energy, and improvement in overall well-being. In some patients, however, the effect may not be as prominent. A careful assessment of clinical symptoms should therefore be regularly performed at all follow-up appointments.

In all patients, repeat viral load and T-cell measurements are necessary. HIV RNA concentrations should be obtained within 2 to 8 weeks of therapy initiation.^{5,6} This early value allows clinicians to assess the magnitude of response and ensures declining viral load measurements. Therapy with an effective regimen will result in at least a threefold (0.5 log) and tenfold decrease (1.0 log) in viral load counts by weeks 4 and 8, respectively.^{5,6} The viral load should continue to decline over the next 12 to 16 weeks and, in most patients, it will become undetectable.^{5,6} Long-term response to therapy correlates with the magnitude of viral suppression on initiation of a regimen. The greater the suppression, the greater the durability of response to that regimen.^{86–88} The speed and magnitude of suppression, however, can be affected by a number of factors, including clinical status of the patient (e.g., more advanced

disease—low T-cell counts, high viral load value), adherence to therapy, and overall potency of the regimen.^{5,6} When the virologic response is less than optimal, evaluation of compliance should be assessed, repeat viral load measurements performed, and drug concentrations of key antiretroviral agents evaluated for subtherapeutic values before considering a change in therapy.

In response to declining viral replication, T-cell destruction decreases and subsequently CD4 counts increase. The magnitude of this rebound can vary significantly, with some patients experiencing large increases and others experiencing little or no change. Given that T-cell changes do not occur rapidly, once therapy is initiated, repeat T-cell counts should be obtained at the 3- to 4-month follow-up visit.^{5,6}

Failure either by surrogate marker data or clinical symptomatology can occur when inadequate serum concentrations of antiretrovirals are achieved. The most common reason for this is failure to adhere to the prescribed regimen. It is important to determine the reason for nonadherence so that it can be quickly and adequately addressed (e.g., by education on the management of adverse events, or by switching to a better-tolerated regimen). Drug exposures can also be affected by the addition of new drugs or herbal products to a patient's regimen. Both garlic and St. John's wort have been shown to lower the exposure to non-ritonavir-boosted protease inhibitors.^{89,90} In addition, certain medications require specific food requirements to ensure optimal exposure (Table 69-3). Therefore, careful evaluation of new drugs, herbs, and dosing habits should be performed at each follow-up visit. If after discussions with the patient, the clinician does not identify adverse events, adherence issues, and new drug–drug, drug–herb, or drug–food interactions as potential causes of failure, then changing to another viable regimen should be considered. In some cases, therapeutic drug monitoring may assist in identifying physiologic factors such as malabsorption or rapid metabolism.

8. After initiation of therapy, E.J.'s viral load values are 7,000 copies/mL at 4 weeks, and <50 copies/mL (undetectable) at 14 weeks. His T-cell counts have increased from 225 to 525 cells/mm³. In addition, E.J. states that his night sweats and fevers have disappeared, he “feels great” and that he has had no drug-related problems. Is the therapy effective? How should therapy be monitored?

E.J.'s response to the emtricitabine, tenofovir, and efavirenz does indicate efficacy. Clinically, his symptoms have subsided and his overall health is much improved. His viral load measurements have responded appropriately and are now below the level of assay detection. T-cell counts have increased by 300 cells/mm³. Finally, E.J. has experienced no drug-related adverse events. Given the response to date, no changes are required and the current regimen should be continued.

Long-Term Assessments

Once the prescribed regimen has been stabilized, the long-term goals of therapy are to maintain maximal viral suppression, sustain clinical and immunologic improvements, and maintain drug tolerability. Periodic assessments should be made of viral load (every 3–4 months) and T-cell counts (every 3–6 months).^{5,6} These surrogate marker data allow clinicians to monitor trends in viral activity and immunologic status and assist them in identifying early regimen failure. Clinical as-

essment of the patient and questioning of tolerability to the prescribed regimen should occur at the 3- to 6-month follow-up visits.

Treatment Failure

9. E.J. has remained on FTC, TDF, and efavirenz for more than a year. To date, his T-cell counts have remained stable at 550 cells/mm³, and his viral load measurements have remained below the limit of assay detection. He presents with new complaints of fevers and malaise. E.J. reports that he has been compliant with therapy and has not started any new medications. Repeat laboratory tests now show E.J.'s viral load is 3,000 copies/mL and his T-cell count is 375 cells/mm³ (both repeated and validated). Should E.J.'s regimen be changed?

Up to 25% of patient on HAART fail therapy within the first year.³ Reasons for failure are not fully known; however, risk factors include a history of low T-cell counts, high viral loads, and extensive use of antiretroviral agents.^{3,4} Assessment of regimen failure should be based on data similar to when therapy is initiated: (a) clinical symptoms, (b) surrogate marker data, and (c) regimen tolerability and adherence.^{5–7}

In many patients, the first sign of failure is a change in clinical signs and symptoms. These changes can be subtle (e.g., increase in constitutional symptoms, new onset of oral thrush) or more severe (e.g., new opportunistic infections). These situations suggest a failing regimen and necessitate a change in therapy.

Assessment of efficacy should also involve evaluation of surrogate marker data (e.g., T cells and viral load). In many situations, changes to these markers occur before any noticeable clinical signs and symptoms. Therefore, careful evaluation of surrogate marker data may allow clinicians an opportunity to intervene before any significant immune destruction occurs. Virologic failure, defined as new or continued viral replication despite appropriate antiretroviral therapy, suggests a failing regimen. For example, patients with repeated detection of virus in plasma after initial suppression to undetectable levels should be evaluated as potential treatment failures. In patients who do not achieve viral suppression to below detectable levels, a significant increase in viral replication (defined as a three-fold increase or greater) should also be viewed as a treatment failure.^{5,6}

When assessing viral load, it is important to recognize that these values can increase from vaccinations or other concurrent infections (see Question 2). Therefore, a thorough medical history should be taken to rule out other causes of increasing viral load. In addition, laboratory values should be interpreted as trends over time and not necessarily as individual measurements. A repeat viral load should be performed and evaluated within 4 weeks of the initial viral load increase. In some cases, transient viral “blips” occur (increases in viral load measurements just above the level of assay detection (e.g., 50–1,000 copies/mL), which become undetectable at the next visit.^{91–93} The clinical significance of viral blips is unknown and, although they may not directly reflect treatment failure, they may represent the potential for near future viral breakthrough, either because of patient nonadherence or insufficient antiretroviral potency. Careful follow-up of these patients is therefore required, as changes to the current HAART regimen may be necessary.

In response to increasing viral replication, T-cell destruction occurs. A significant decrease in CD4 cells is defined as a decrease of >30% in absolute numbers, or a decrease of 3% in percentage.^{5,6} Persistently declining T-cell counts, with or without increasing viral load measurements, represent treatment failure and suggest a change in therapy is warranted.

Other potential causes for failure include nonadherence and drug–drug interactions. When a patient has not taken the prescribed regimen as directed, discussions regarding tolerability, number of doses missed, duration of nonadherence, and lifestyle changes should take place. The decision to reinstate a prescribed regimen should take into account the future likelihood of adherence and the potential development of resistant strains. In those patients with a history of long-standing nonadherence, the success of reinstituting the prescribed regimen may be limited. The precise effect of the duration and extent of nonadherence on the development of resistance, however, has not been fully evaluated. For the virus to mutate, sufficient drug pressure must be placed on the virus. Some estimate this requires moderate patient adherence of 50%.⁹⁴

Significant drug–drug, drug–food, and drug–herb interactions could also contribute to therapeutic failure. Interactions between a new medication and an herbal product could decrease the bioavailability or increase the metabolism of the HIV medications leading to low serum concentrations.^{5,89,90} In addition, many medications require certain food requirements to allow maximal drug absorption. A careful review of all new medications and their potential for clinically significant drug interactions should be evaluated at all visits (Tables 69-7 and 69-8).

Currently, E.J. has a number of signs and symptoms that suggest a failing regimen. E.J. is experiencing new symptoms of fevers and malaise not attributable to any other cause. E.J.'s viral load value has become detectable at 3,000 copies/mL without evidence of concurrent infections or vaccinations in the past 4 weeks. E.J.'s T-cell counts have declined from 550 cells/mm³ to 375 cells/mm³. Finally, it appears that E.J. has been adhering to his therapy and has not started any new medications that could affect the efficacy of his current regimen. Therefore, a change in therapy is necessary.

10. What potential antiretroviral regimen(s) can be considered for E.J.?

In addition to the general rules of therapy described in Question 5, other issues should be considered when selecting an alternative regimen for a patient failing therapy.

General Rules for Changing Therapies^{5,6}

1. If possible, the new regimen should contain all new antiretroviral agents to which the patient has not been exposed. If this is not possible, the new regimen should contain at least two new agents that are not currently contained in the failing regimen. The potential for cross-resistance between antiretroviral drugs should be considered when choosing new regimens, and therefore resistance testing should provide useful information (see Question 12).
2. Given that antiretroviral drug resistance is more likely to occur with increased and prolonged viral replication in the presence of antiretroviral agents, changes to therapy should occur close to the time of treatment failure. Prolonged treatment with a failing regimen is likely to result in the accu-

mulation of resistance mutations (particularly with protease inhibitors), which may limit future treatment options.

3. Resistance testing is recommended to guide the selection of future drug regimens. Optimally, testing via genotype, phenotype, or virtual phenotype should occur while the patient is taking the failing regimen, or within 4 weeks of discontinuation to increase the likelihood of detecting resistant isolates. These tests cannot reliably detect mutations at viral concentrations <1,000 copies/mL, and may have limited usefulness in patients with persistent low-level viremia.
4. To prevent the development of resistance, one new drug should never be added to a failing regimen. An exception to this rule is if the initial response to a first regimen has been inadequate (e.g., nondetectable viral load at 16–20 weeks). In this situation, some clinicians decide to intensify therapy with an additional agent provided that the viral load measurements were trending downward since initiation of therapy.
5. If possible, a regimen that has failed in the past should not be reinstituted; an isolate resistant to the failed regimen could continue to reside within various compartments of the body. If a regimen to which the patient had previously failed were restarted, unimpeded viral replication of the resistant strain would occur, repopulate the host, and eventually result in treatment failure. In some situations (e.g., patients with advanced disease, limited treatment options and prior exposure to most antiretroviral agents), it may be necessary to reinstate agents or regimens in combination with additional new agents with the goal of suppressing viral replication.
6. When treatment failure is a direct result of drug toxicity (rather than poor drug efficacy), the offending agent should be replaced with an alternative drug from a similar class provided that the potential for cross-resistance is minimal.
7. If an agent in a given regimen must be stopped, it is recommended that all agents in the regimen be stopped and restarted simultaneously to prevent the development of resistance. An exception to this rule is when components of a regimen have differing half-lives, such as NNRTIs and NRTIs. In this situation, if all drugs are discontinued simultaneously, effective NNRTIs monotherapy is likely to result, because detectable concentrations of the NNRTIs will persist for days or weeks longer than detectable NRTIs concentrations. In this situation, many experts would recommend continuing the NRTIs agents for 1 to 2 weeks past NNRTIs discontinuation to provide combination therapy during the NNRTIs elimination “tail.”

It should be recognized that many alternative regimens are based on theoretic benefits or limited data. In addition, many potential options could be limited in some patients based on prior antiretroviral use, toxicity, or past intolerances. Therefore, the clinician should carefully discuss these issues with the patient before changing therapy.

Because E.J. is failing to respond to his current regimen, a new antiretroviral regimen must be chosen. In addition to selecting susceptible agents from resistance testing, the new regimen should take into consideration quality-of-life issues. In E.J.'s situation, it is reasonable to switch to a ritonavir-boosted PIs regimen, with two or more nucleoside agents as dictated by the viral resistance profile.

Table 69-7 Drug Effects on Concentration of PI^r

| Drug Affected | Fosamprenavir | Atazanavir | Lopinavir/Ritonavir | Nelfinavir | Ritonavir | Saquinavir* | Tipranavir |
|------------------------------------|---|---|---|---|---|---|--|
| Protease Inhibitors | | | | | | | |
| Darunavir (DRV) | No data. | Levels: ATV concentrations from ATV 300 mg QD when administered with DRV/r were similar to ATV/r 300/100 mg QD. DRV was unchanged. Dose: Administer ATV 300 mg QD with DRV/r for exposure similar to ATV/T 300/100 mg QD | Levels: DRV AUC and C _{min} ↓ 53% and 65%, respectively. LPV AUC and C _{min} ↑ 37% and 72%, respectively. Dose: Should not be co-administered, as doses are not established. | No data. | Levels: 14-fold ↑ in DRV exposure in combination with RTV 100 mg bid. Dose: DRV should only be used in combination with RTV 100 mg bid to achieve sufficient DRV exposure | Levels: DRV AUC and C _{min} ↓ 26% and 42%, respectively. SQV exposure similar to when administered with RTV 1000/100 mg bid. [†] Dose: Should not be co-administered, as doses are not established. | No data. |
| Fosamprenavir* (FAPV) | Levels: With fAPV/ATV 1,400/400 QD, ATV AUC & C _{min} ↓ 33% and 57%, respectively. fAPV AUC and C _{min} ↑ 78% and 283%, respectively. With fAPV/r 700/100 mg BID + ATV 300 mg QD, ATV AUC and C _{max} ↓ 22% and 24%, respectively; fAPV unchanged. Dose: Insufficient data for coadministration of these agents is not recommended because of potential for additive hyperbilirubinemia. | Levels: With fAPV/ATV 1,400/400 QD, ATV AUC & C _{min} ↓ 33% and 57%, respectively. fAPV AUC and C _{min} ↑ 78% and 283%, respectively. With fAPV/r 700/100 mg BID + ATV 300 mg QD, ATV AUC and C _{max} ↓ 22% and 24%, respectively; fAPV unchanged. Dose: Insufficient data for coadministration of these agents is not recommended because of potential for additive hyperbilirubinemia. | Levels: With coadministration of fAPV 700 mg BID and LPV/r capsules 400/100 mg BID, fAPV C _{min} 64% and LPV C _{min} ↓ 53%. An increased rate of adverse events was seen with coadministration. Dose: Should not be coadministered, as doses are not established. | * | Levels: fAPV AUC and C _{min} ↑ 100% and 400% respectively, with 200 mg RTV. Dose: fAPV 1,400 mg + RTV 200 mg QD; or fAPV 700 mg + RTV 100 mg BID. | Levels: APV AUC ↓ 32%. Dose: Insufficient data-for dose recommendation | Levels: APV AUC and C _{min} ↓ 44% and 55%, respectively, when given as APV/r 600/100 BID with TPV/r. No data with fAPV; but a ↓ in AUC is expected. Dose: Should not be coadministered, as doses are not established. |
| Indinavir (IDV) | Levels: APV AUC ↑ 33%. Dose: Not established. | Levels: With ATV 300 QD +LPV/r 400/100 BID, ATV C _{min} ↑ 45%; ATV AUC and C _{max} were unchanged. LPV/PK similar to historic data. | Levels: IDV AUC and C _{min} ↑. Dose: IDV 600 mg BID. | Levels: IDV ↑ 50%; NFV ↑ 80%. Dose: Limited data for IDV 1,200 mg BID + NFV 1,250 mg BID. | Levels: IDV ↑ 2–5 times. Dose: IDV/RTV 400/400 mg, 800/100 mg, or 800/200 mg BID. Caution: Renal events may ↑ with ↑ IDV concentrations. Additional ritonavir is generally not recommended. | Levels: IDV-No effect SQV 14-7 times† Dose: Insufficient data. | No data. Should not be coadministered, as doses are not established. |
| Lopinavir/Ritonavir (LPV/r) | * | Levels: With ATV 300 QD +LPV/r 400/100 BID, ATV C _{min} ↑ 45%; ATV AUC and C _{max} were unchanged. LPV/PK similar to historic data. | * | * | * | * | Levels: LPV AUC and C _{min} ↓ 55% & 70% respectively. Dose: Should not be co-administered, as doses are not established. |

(continued)

Table 69-7 Drug Effects on Concentration of PI^a (Continued)

| Drug Affected | Fosamprenavir | Atazanavir | Lopinavir/Ritonavir | Nelfinavir | Ritonavir | Saquinavir* | Tipranavir |
|-------------------------|---|--|---|---|-----------|--|--|
| Nelfinavir (NFV) | Levels: APV AUC ↑ 1.5-fold. Dose: Insufficient data. | No data | Levels: With LPV capsules, LPV ↓ 27%; NFV ↑ 25%. Dose: No data with LPV/r tablets. No dosing recommendation. | No data | No data | No data | No data. Should not be co-administered, as doses are not established. |
| Ritonavir (RTV) | No data | Levels: ATV AUC ↑ 238%. Dose: ATV 300 mg QD + RTV 100 mg QD. | Lopinavir is co-formulated with ritonavir as Kaletra®. Additional ritonavir is generally not recommended. Levels: SQV [†] AUC and C _{min} ↑ Dose: SQV 1,000 mg BID; LPV/r standard. | Levels: RTV - No effect NFV ↑ 1.5 times. Dose: not established | No data | Levels: RTV no effect SQV ↑ 20 times. ^{†‡} Dose: 1,000/100 mg SQV hgc/RTV BID or 400/400 mg BID. | Levels: TPV AUC ↑ 11-fold. |
| Saquinavir (SQV) | Levels: APV AUC ↓ 32%. Dose: Insufficient data. | Levels: SQV AUC ↑ 60% with SQV/ATV/RTV 1,600/300/100 QD, compared with SQV/RTV 1,600/100 QD. Dose: No dose recommendations can be made. | Levels: SQV [†] AUC and C _{min} ↑ Dose: SQV 1,000 mg BID; LPV/r standard. | Levels: SQV ↑ 3–5 times; NFV ↑ 20%. [†] Dose: NFV standard; Fortovase 800 mg TID or 1,200 mg BID. | No data | No data | Levels: SQV AUC and C _{min} ↓ 76% and 82%, respectively, when given as SQV/r 600/100 BID with TPV/r. Dose: Should not be co-ad ministered, as doses are not established. |

*Several drug interaction studies have been completed with saquinavir given as Invirase or Fortovase. Results from studies conducted with Invirase may not be applicable to Fortovase.

[†]Study conducted with Fortovase.

Table 69-8 Drug Effects on Concentration of NNRTIs

| Drug Affected | Delavirdine | Efavirenz | Nevirapine |
|------------------------------------|---|---|---|
| Fosamprenavir (fAPV) | Levels: Presumably, similar PK effects as APV: APV AUC ↑ 130%, and DLV AUC ↓ 61%. Dose: Co-administration not recommended. | Levels: fAPV C _{min} ↓ 36% (when dosed at 1,400 mg QD with 200 mg RTV). Dose: fAPV 1,400 mg + RTV 300 mg QD; or fAPV 700 mg + RTV 100 mg BID. | No data |
| Atazanavir (ATV) | No data. | Levels: With unboosted ATV, ATV AUC ↓ 74%. EFV no change. Dose: ATV 300 + RTV 100 mg QD with food - ATV concentrations similar to unboosted ATV; if desired ATV concentrations not achieved with ATV/r 300/100 mg, may need to increase the dose of ATV/r - insufficient information for specific recommendation. EFV dose - standard. | No data. A decrease in ATV levels is expected. Co-administration is not recommended. Effect of NVP on ritonavir-boosted ATV combination unknown; if used, consider monitoring ATV level. |
| Darunavir (DRV) | No data | Levels: DRV AUC and C _{min} ↓ 13% and 31%, respectively. EFV AUC and C _{min} ↑ 21% and 17%, respectively. Dose clinical significance unknown. Use standard doses and monitor closely. Consider monitoring levels. | Levels: NVP AUC and C _{min} ↑ 27% and 47%, respectively. DRV unchanged. [†] Dose: Standard. |
| Indinavir (IDV) | Levels: IDV ↑ >40%; DLV-No effect Dose: IDV 600 mg q8h. DLV standard | Levels: IDV ↓ 31%. Dose: IDV 1,000 mg q8h; consider IDV/RTV. EFV standard. | Levels: IDV ↓ 28%; NVP no effect. Dose: IDV 1,000 mg q8h, or consider IDV/RTV. NVP standard. |
| Lopinavir/Ritonavir (LPV/r) | Levels: LPV levels expected to increase. Dose: Insufficient data | Levels: With LPV/r tablets 600/150 mg BID + EFV 600 mg QD, LPV C _{min} and AUC ↑ 35% and 36%, respectively. No formal study of LPV/r tablets 400/100 mg BID + EFV. EFV no change. Dose: LPV/r tablets 600/150 mg BID, when used with EFV in tx-experienced patients. EFV dose - standard. | Levels: With LPV/r capsules, LPV C _{min} dec. 55%. Dose: LPV/r tablets 600/150 mg BID, when used in combination with NVP in tx-experienced patients. NVP standard. |

Considerations in Antiretroviral-Experienced Patients

11. H.G. is a 46-year-old, HIV-positive man with an extensive history of treatment with a variety of antiretroviral agents. He took ZDV monotherapy in the late 1980s and early 1990s. When 3TC became available, he took the combination of ZDV and 3TC until he failed therapy about 8 years ago. At that time, he began experiencing ZDV-induced myopathies. Since that time, H.G. has been “on and off” various regimens without sustained clinical benefit. He is currently taking 3TC, d4T, TDF, ritonavir, and saquinavir with a CD4 count and viral load measurement of 55 cells/mm³ and 48,000 copies/mL, respectively. These laboratory values have been stable for the last 9 months. How do patients with extensive antiretroviral histories differ from antiretroviral-naïve patients? Are there any special considerations when selecting therapeutic regimens for patients such as H.G.?

Patients who have been infected for 10 or more years may have been treated with many different regimens, both experimental and FDA approved. As a result, many potential reg-

imens have already been exhausted and therefore may not represent viable choices. Care of such patients is a clinical challenge. Data from clinical trials and clinical experience suggest that many patients previously treated with multiple antiretroviral regimens will exhibit a decreased response and decreased durability to older protease inhibitors such as indinavir and nelfinavir.^{5,6} Several newer agents, such as tipranavir, darunavir, etravirine and enfuvirtide, have been developed specifically for highly treatment-experienced patients, and they have the ability to achieve viral suppression in these patients. Maraviroc, the first CCR-5 receptor antagonist approved by the FDA, is also an option for treatment-experienced patients infected with HIV-1 utilizing this coreceptor and failing current treatment. Maraviroc is not recommended for use in patients with dual-trophic viral populations (i.e., able to use CXCR-4 or CCR-5 as coreceptors) or CXCR-4-trophic virus and, thus, patients with extensive treatment histories should undergo tropism testing before maraviroc is initiated. Additional agents in clinical development, including both new drug classes and drugs in existing classes with improved

resistance profiles, are expected to further advance the treatment of antiretroviral-experienced patients. Despite these advancements, some highly treatment-experienced individuals will have extensive resistance patterns that limit therapeutic options. In such patients, full suppression of viral load and immune reconstitution may not be possible.

Patients who have experienced several antiretroviral regimens present other unique challenges for clinicians and require consideration of the following factors:

1. *Regimen tolerability*^{95–97}: Patients with advanced HIV disease display decreased tolerability to many medications, including antiretroviral agents. Although this is not fully understood, it is probably a result of HIV-induced immune alterations and cytokine dysregulations. Subsequently, clinicians evaluating patients with advanced disease should be alert for possible drug-induced adverse events.
2. *Drug interactions*: Many patients with advanced disease take numerous medications for primary or secondary prophylaxis of various opportunistic infections, as well as other medications for comorbid disease states. Subsequently, the risk for a drug–drug interaction is increased. The addition of any new medication, either prescription or over-the-counter, should be carefully evaluated for potential interactions with the patient’s current antiretroviral regimen (see Table 69-7). In addition, any change to the current antiretroviral regimen should also be checked against the patient’s current medication list.
3. *Altered bioavailability*: Patients infected with HIV with advanced disease may have unreliable absorption of many medications. Reasons for this finding include episodes of severe diarrhea, anorexia, weight loss, wasting, and gastric achlorhydria. As a result, the bioavailability of some agents, especially certain PIs that require specific dietary requirements, may be affected (Table 69-3). Any changes in dietary habits or bowel function should be carefully assessed as to the potential impact on the patient’s antiretroviral regimen.
4. *Antiretroviral drug histories and resistance testing*: The most useful information to guide the choice of alternative regimens is a detailed drug history, in conjunction with appropriate resistance testing. Among patients with extensive prior antiretroviral use, it is critical to identify previously failed regimens and determine the precise cause of the failures. In an experienced patient who has taken many different regimens over a lifetime, the number of remaining viable agents and regimens may be limited. Therefore, it is important to determine whether prior regimens truly failed for virologic reasons or some other cause (e.g., regimen intolerance or an inadequate trial period). In addition, detailed knowledge of regimen intolerabilities and which agent(s) caused the adverse event will help in the selection of a new appropriate regimen. In some situations, the offending agent may be reinitiated if the adverse event was minimal or can be appropriately managed.

RESISTANCE, VIRAL GENOTYPING, PHENOTYPING, AND VIRAL FITNESS

12. Will viral genotyping and phenotyping assist in selecting an appropriate therapeutic regimen for H.G.? What are these tests?

What are their limitations and when should they be used? What is viral fitness, and does it have a role in clinical decision-making?

Viral genotyping and phenotyping are tests that assess viral resistance patterns to antiretroviral agents. Genotyping evaluates mutations in the virus’ genetic material, whereas phenotyping assesses the ability of the virus to grow in the presence of increasing concentrations of antiretroviral agents. The three potential causes for the development of resistance are

1. Initial infection with a resistant isolate^{68–71}
2. Natural selection of a resistant isolate as a consequence of inefficient, error-susceptible viral replication^{35,98,99}
3. Generation of resistant isolates via selective pressures from antiretroviral therapies that do not fully suppress viral replication^{7,100–109}

Mutations are generated when naturally occurring amino acids in the HIV genome are replaced with alternative amino acids. For example, resistance to 3TC occurs when the amino acid methionine (M) is replaced by valine (V) at the 184th amino acid in the protein chain.^{7,110} This mutation is subsequently referred to as an *M184V mutation*. These amino acid substitutions change the proteins that are produced and may alter the shape, size, or charge of the viral enzyme’s substrate or primer.^{111–113} Subsequently, antiretroviral drug binding to the active site is decreased, affinity for natural substrates is increased, or there is an increased removal of the antiretroviral agent from the enzyme by the virus (known as *pyrophosphorylation*).¹¹⁴ Whether a mutation results in a clinically resistant, less viable, or indifferent isolate depends on which amino acid(s) is replaced. In addition, certain mutations or combination of mutations have been shown to produce viral isolates that display increased sensitivity to various antiretroviral agents (known as *hypersusceptibility*). Alterations to certain key amino acids can also result in cross-resistance between various antiretrovirals.⁷

Two key enzymes have been extensively studied with regard to their potential for development of resistance: reverse transcriptase (RT) and protease. Replication by the RT enzyme is highly error susceptible. Given that the HIV genome is approximately 10,000 nucleotides in length and that mutations via the RT enzyme occur approximately once in every 10,000 nucleotides copied, it has been estimated that a mutation occurs with every viral replication cycle. With up to 10 billion particles of virus being produced per day, the potential exists for 1,000 to 10,000 mutations occurring at each site in the HIV genome every day.³⁵ Key mutations to the antiretroviral agents are identified in Figure 69-6 and are updated periodically by expert panels of clinicians.

Over time, countless viral subpopulations known as “quasi-species” develop. In any given host, at any given time, many different quasi-species can exist. In addition, within any compartment of the body (e.g., CNS, testes, lymph nodes), many different quasi-species can also exist. Because these mutant strains represent only a small number of isolates in the total viral population, they must have some replicative disadvantage when compared with the “wild-type” virus.^{100,101} Under selective pressures from antiretroviral therapies, however, these mutant isolates can replicate. For example, if wild-type viral replication is inhibited by an antiretroviral regimen, and if any one viral strain of the quasi-species is more fit for growth in the presence of that regimen, then the viral mutant will have

MUTATIONS IN THE GP41 ENVELOPE GENE ASSOCIATED WITH RESISTANCE TO ENTRY INHIBITORS

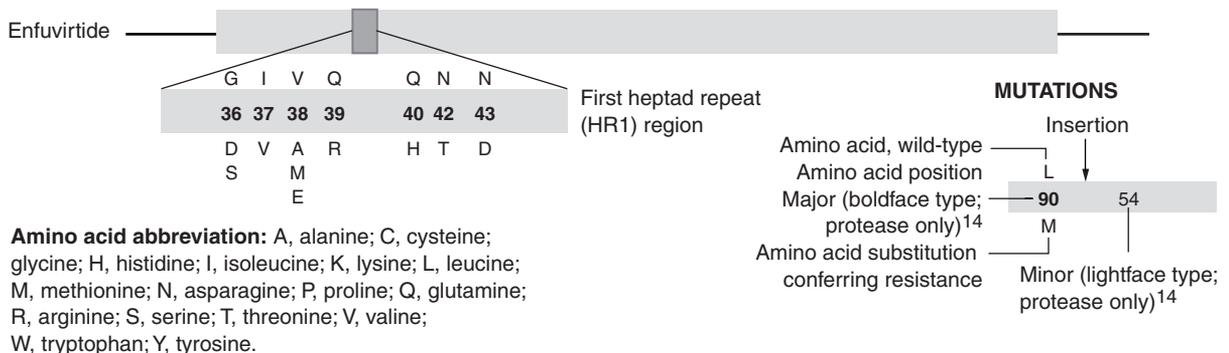

FIGURE 69-6 (Continued)

a competitive advantage.¹¹⁵ It should be recognized that for resistance to develop, viral replication must occur. When viral replication is completely inhibited, the development of resistant isolates is uncommon.

Genotypic analysis involves sequencing the viral genetic material via PCR amplification. Mutations associated with resistance to a given agent are identified by analysis of key sequences of the RT or protease enzymes. These tests can be rapidly processed; however, they detect mutations present only in more than 25% of all HIV isolates in the body, and can only reliably detect resistance patterns in samples with HIV RNA > 1,000 copies/mL. Because pressures from antiretroviral therapies select resistant isolates, these tests may not provide information regarding rare, yet potentially clinically significant, isolates.⁵

Phenotypic analysis involves growing virus in the presence of various concentrations of drug and then determining viral susceptibilities (e.g., inhibitory concentrations [IC₅₀]). Phenotyping is limited because it evaluates only one viral isolate at a time and could fail to identify other clinically relevant isolates. In addition, the amount of drug required to inhibit viral growth within a test tube may not represent concentrations required in a given patient, or within various compartments of the body.⁵

An additional methodology, known as the *virtual phenotype*, is also currently available, and compares the genotype information from a sample of interest to a large database of viral isolates where both genotype and phenotype have been performed.⁵ This method is only as reliable and robust as the databases from which the virtual phenotype is generated, and may be limited for newer agents with less available genotype-phenotype data.

Genotyping and phenotyping have the potential to provide useful information to clinicians who treat patients with HIV infection. Evidence to date suggests that these tests are effective at predicting which agents will not work, but they are less useful in predicting those that will work.^{5,7,116} For example, if testing identifies resistance to an agent, it is highly unlikely this agent will be effective. If testing identifies an agent as susceptible, however, it does not necessarily predict that this agent will be effective. Clinical trials evaluating the use of genotyping and phenotyping for selection of alternative antiretroviral regimens have shown positive treatment responses.^{5,6} As with all clinical decisions made for those who are HIV infected, careful assessment of the results in combination with the treatment history are essential for proper clinical decision-making. Consultation with an expert in antiretroviral drug resistance patterns is highly recommended.

One other measure available to clinicians is “viral fitness” or “replication capacity.” The genetic changes that occur in a virus to become resistant to antiretroviral therapy often impair the virus’ ability to grow.^{40,117–119} This measure of growth ability is called “fitness” and is measured by replication capacity during phenotypic evaluation. During amplification of the virus before measuring phenotype, the replication capacity (RC) of the virus is measured and compared with a reference wild-type, drug-sensitive virus. A virus with normal fitness has a RC between 70% and 120% of the reference viral strain; isolates with values <70% are considered to be less fit than wild-type virus. In general, the more mutations that occur to the virus, the more compromised the virus and the lower the fitness (in some situations the interplay between mutations can

result in a viral isolate that is relatively fit). Recent data have shown that, despite persistent viral replication, unfit viruses may not cause the same degree of immune destruction as fit viruses.¹¹⁹ This is important for patients with limited treatment options because they may be able to stay on a HAART regimen that is not completely suppressive, but that produces an unfit virus, with less T-cell depletion. In these situations, it may be best to keep patients on their current therapy despite measurable viral load measurements (provided their CD4 cell counts are stable) until newer treatment options become available.

Given H.G.’s extensive antiretroviral drug history and his current failure, a genotype, phenotype, or virtual phenotype will likely provide some insights into potential therapeutic options.

SPECIAL CIRCUMSTANCES

Immune System Reconstitution

13. Results from H.G.’s genotype analysis suggest that a regimen containing tenofovir, 3TC, ABC, and darunavir–ritonavir may be useful. After thorough discussions with H.G., and careful evaluation of potential drug–drug interactions, this regimen is initiated. Within 2 weeks, H.G.’s T-cell counts increased from 55 to 127 cells/mm³; however, he now complains of progressive visual loss in his right eye. Physical examination shows macular edema and retinal inflammation consistent with *Cytomegalovirus* infection. Is this a treatment failure? Should H.G.’s antiretroviral regimen be discontinued or changed?

If H.G.’s therapy were evaluated based solely on the rules of therapy (see Questions 7, 8, and 9), this situation would represent a treatment failure. This case, however, is an example of immune reconstitution with disease reactivation after the initiation of potent antiretroviral therapies.^{120–122} In patients with advanced HIV disease (e.g., CD4 < 100 cells/mm³), significant immune dysfunction causes an inability to mount an appropriate response to subclinical infections. As a result, these infections replicate unimpeded and often remain undetected by the host (also known as *quiescent disease*). When potent antiretroviral therapies are initiated, immune function is often restored leading to symptoms that can be used to identify and eliminate smoldering infections. During the first 12 weeks of therapy, this increased immune response primarily results from redistribution of memory cells.^{123–126} Because of this phenomenon, inflammation at the site of infection often occurs.

The immune reconstitution syndrome can present in any organ system where quiescent disease exists (e.g., CNS, eyes, lymph nodes). Most cases occur within 1 to 4 weeks after the initiation of potent antiretroviral therapies. These cases often occur despite significant increases in T-cell counts to levels well above those generally associated with the detected opportunistic infection.

Although most reports of immune system reconstitution and inflammatory responses have involved infections, one report describes the recurrence of hypersensitivity reactions to trimethoprim-sulfamethoxazole (TMP-SMX) in a small group of subjects (N = 4).¹²⁷ All had undergone desensitization protocols or dose reductions and were taking TMP-SMX for *Pneumocystis carinii* pneumonia prophylaxis. On initiation of HAART, patients experienced fever (4/4), maculopapular rash

(2/4), and leukocytosis (4/4). The fever did not resolve until TMP-SMX was discontinued. Clinicians should be aware of the possibility of recurrence of hypersensitivity reactions after the initiation of HAART therapies.

In this case, H.G. presents with signs and symptoms of immune reactivation-associated (CMV retinitis, including new onset of visual complaints and inflammation consistent with CMV retinitis on physical examination, in the face of increased T-cell counts (from 55–127 cells/mm³). Because the new opportunistic infection is a result of immune reconstitution and not clinical failure, the regimen does not need to be discontinued or changed. Appropriate treatment for CMV, however, should be implemented.

Discordant Surrogate Markers

14. H.G. was successfully treated for CMV retinitis and the regimen of tenofovir, 3TC, ABC, and darunavir–ritonavir was continued. Over the following 6 months, H.G.’s T-cell counts increased to 325 cells/mm³ and his viral load value declined to 5,000 copies/mL. At the last two clinic visits H.G.’s viral load (copies/mL) and CD4 counts (cells/mm³) were 2,000/275 and <400/225, respectively. H.G. reports no new clinical complaints or adverse drug events. In addition, H.G. states that he has been compliant with therapy. Are changes to therapy necessary?

In most cases, declines in viral load measurements result in increases in CD4 cell counts and increasing viral load measurements result in declining CD4 cell counts. In approximately 20% of cases, however, T cells decline along with viral load decline or T cells increase along with viral load increases.^{5,127,128} These situations are referred to as *discordant surrogate marker data*.

In this situation, it may be wise to continue current treatment and monitor the patient closely, because changing or adding an additional drug may not increase CD4 cell counts.⁶ When T-cell counts increase despite increasing viral load measurements, decisions regarding therapeutic options are unknown. Although these patients may continue to observe a clinical benefit from the current antiretroviral regimen for a period of time, data suggest that long-term stability of the CD4 count is unlikely.⁶ Because this may be an early warning sign of impending CD4 cell destruction, many clinicians would change antiretroviral therapies. Other clinicians, however, might decide to follow patients carefully and change therapies at the first sign of T-cell declines or new clinical signs and symptoms. In these situations, other potential causes of viral load increases (e.g., recent infection, vaccination) should be carefully evaluated to prevent inappropriately changing a nonfailing regimen.

Therapeutic Drug Monitoring

15. P.P. is a 30-year-old HIV-positive man who has failed prior antiretroviral regimens. Based on phenotypic resistance testing, it appears that a regimen including lopinavir–ritonavir may be able to overcome the viral isolate’s resistance pattern. Will plasma measurements of P.P.’s antiretroviral drug concentrations be useful? What measurement should be used, which agent(s) should be measured, and how should the samples be collected?

Pharmacokinetic evaluations of various antiretrovirals, including the NNRTIs and PI, have shown wide interpatient variability in drug exposures among cohorts of patients taking the same dose of drug under the same conditions.^{46,129,130} Many factors contribute to interpatient variability in drug exposure, such as pharmacogenetics, environment, different physiologic conditions, regimen adherence, and drug–drug, drug–food, and drug–nutraceutical interactions. For most antiretrovirals, a drug exposure–response relationship exists (e.g., the higher the exposure, the faster and more prolonged the viral suppression).¹³¹ In addition, most antiretrovirals also have exposure–toxicity relationships.¹³⁰

Therapeutic drug monitoring (TDM) is currently recommended for selected clinical situations.¹³¹ In patients failing a first regimen, or a regimen that initially was fully suppressive, TDM may identify suboptimal drug concentrations. For patients with uncharacterized drug–drug or drug–food interactions and those with impairments in gastrointestinal, hepatic, or renal function, drug concentrations may help to identify concentrations outside of the recommended range that can be corrected with a dosage adjustment. TDM may also be useful for assuring that a novel antiretroviral combination does not have any unpredictable adverse drug interactions. In treatment-experienced patients, knowledge of drug concentrations and viral susceptibility to the given agent may help to design an optimal dosage regimen in the face of partial viral resistance. Conversely, patients experiencing toxicities thought to be concentration-dependent (e.g., neuropsychiatric effects of efavirenz) may benefit from TDM as well. Monitoring adherence and evaluating pharmacokinetics in special populations, such as pregnant women or pediatric patients, are additional indications for TDM.

Pharmacology experts currently recommend obtaining trough concentrations immediately before the next dose of a PI or an NNRTI. For efavirenz, which is usually taken in the evening, samples may be obtained at the 12-hour time point owing to its long half-life.¹³¹ Many factors can affect the trough values of various antiretroviral agents. For proper interpretation of the concentrations, patients should provide a dosing history from the last several days, a list of concomitantly administered drugs to screen for interactions, and the exact time the last dose was taken. The exact time the TDM sample was collected should also be recorded. Another factor that can affect interpretation of drug concentrations over time is inpatient variability. Although not fully evaluated, it appears that under stringent pharmacokinetic study conditions (e.g., study conditions in which dosing, concomitant food administration, drug–drug interactions, and adherence all are controlled) the day-to-day variability of drug concentrations over time is minimal.^{132–134} Outside of a clinical study, however, where patients take their medications under conditions that vary from day to day, the concentrations could be highly variable at clinic visits over time, and a few samples might be required to determine trends in the drug exposure before making a dose adjustment. Finally, to minimize laboratory variability and error in measuring these concentrations, it is also recommended that a laboratory that routinely measures antiretrovirals and participates in both internal and external quality control programs be used. A list of such laboratories can be obtained from www.hivpharmacology.com.

In general, total drug concentration ranges for defining efficacy and toxicity have been developed for PIs and NNRTIs.¹³¹ A limitation of obtaining total drug concentrations is that unbound, active drug fraction is not quantitated. These agents are generally highly protein-bound, and alterations in the bound or unbound fraction can contribute to both reduced efficacy and increased toxicity within accepted total drug concentration ranges. Despite this, total concentrations are generally used owing to technical challenges inherent in determining unbound drug concentrations, and because a reasonable relationship exists between these concentrations and clinical outcomes. The plasma or serum concentrations of NRTIs, however, may or may not be reflective of the active intracellular triphosphate moiety, but may be useful to measure in certain situations. Researchers are evaluating the intracellular triphosphate concentrations of the NRTIs in various cell types, including peripheral blood mononuclear cells (PBMC). Limitations to determining intracellular concentrations include the sophisticated processing of the cellular components before storage, the technical difficulty of the assay itself (generally only found in pharmaceutical companies and academic centers), and the limited availability of instrumentation to measure the low concentrations of these moieties (e.g. femtomoles/10⁶ cells).

The interpretation of the drug concentration itself will vary according to the clinical situation. Among treatment-naïve patients with wild-type viral isolates, an assessment should be made whether the concentration lies within a range of the population concentrations: how that range is defined tends to be clinician-specific, but can be the interquartile range, the 90% confidence interval, and so on. If the concentration is below the desired cut-off, and the patient is not responding well to the therapy, the clinician should consider giving more drug or using a pharmacokinetic-enhancing technique (e.g. adding ritonavir). If the concentration is above the cut-off, and the patient is experiencing drug toxicity, a dose reduction should be considered. Clinical trials evaluating TDM among antiretroviral-naïve patients initiating PI-based HAART have shown improved clinical responses compared with patients given standard of care without TDM.^{135,136}

Among patients with antiretroviral resistance, the interpretation of the concentration is much more complex and may require the additional assessment of phenotypic resistance data. Higher drug exposure may be needed for patients with drug-resistant viruses to achieve efficacy. Preliminary investigations have evaluated the ratio between drug exposure and viral susceptibility (in a similar fashion to the antimicrobial efficacy ratios of C_{min} : minimal inhibitory concentration [MIC] or area under the curve [AUC]: MIC), also called an inhibitory quotient (IQ).¹¹⁵ Interpretation of the current IQ data is difficult, however, owing to the various methodologies used for its calculation.¹³¹ Ongoing research is focused on standardizing calculation methods to improve the prediction of appropriate antiretroviral concentrations for maximal efficacy.

In the current case, assuring that P.P.'s lopinavir trough concentration is at least above the IC₅₀ value from the phenotype may help improve his chances of optimal antiviral response. If P.P.'s response to treatment is inadequate (e.g., unsatisfactory decline in HIV RNA), then a concentration should be obtained from a trough sample, with a careful concomitant drug and dosing history, and sent to a reliable laboratory for analysis.

Metabolic Complications of Antiretroviral Therapies

16. J.F. is a 37-year-old HIV-positive man who has been taking stavudine, lamivudine, ritonavir, and saquinavir for the past 4 years. Since starting this regimen, J.F.'s T-cell counts have increased from 65 to 475 cells/mm³, and his viral load has declined from 70,000 to <400 copies/mL (using RT-PCR). J.F. is concerned because he has noticed that his arms and legs have gotten quite thin and the veins in his calves are now very pronounced. In addition, his cheeks have “disappeared,” and he cannot seem to get the extra weight off around his belly. Otherwise, he “feels fine.” On physical examination, you notice an abnormal accumulation of fat on his posterior neck and upper back. Laboratory tests reveal increased total cholesterol at 8.2 mmol/L (normal, <5.17 mmol/L), triglycerides at 3.8 mmol/L (normal, <2.82 mmol/L), and a fasting blood glucose of 230 mg/dL (normal, <126 mg/dL) with no evidence of ketones or sugar on urine analysis. Before starting this regimen, all laboratory values were within normal limits. J.F. admits to smoking two packs of cigarettes per day, occasional alcohol consumption, poor dietary habits including eating fast foods, and rarely exercising. Are the changes in laboratory values and body shape a result of his current antiretroviral regimen? Is J.F. at increased risk for cardiovascular disease since starting HAART? What interventions, if any, may help?

The discovery and widespread use of HAART in clinical practice has resulted in significant antiviral, clinical, and survival benefit among individuals infected with HIV. These compounds, however, can cause metabolic complications, such as abnormal distribution of body fat, lipid abnormalities (e.g., hypercholesteremia, hypertriglyceridemia, increases in low-density lipoprotein [LDL] and decreases in high-density lipoprotein [HDL]), and new-onset diabetes.^{81,137–144} Coronary artery disease, myocardial infarctions, and vascular complications among relatively young patients who are HIV infected taking HAART-containing regimens have also been reported.^{145–150} Large observational studies suggest an increased risk for cardiovascular disease among patients taking HAART, particularly among those receiving protease inhibitors. Several theories for the mechanism of these effects have been proposed. One theory is that a sequence of the HIV-1 protease enzyme contains homology to human proteins such as LDL-receptor-related protein, and cytoplasmic retinoic-acid binding protein.¹³⁷ By inhibiting these proteins, PIs may inhibit adipocyte growth or promote adipocyte lysis, leading to alterations in serum lipid concentrations, visceral fat accumulation, and impaired insulin signaling. A second theory is that PIs interfere with retinoid signaling within adipocytes (excessive levels of certain retinoids can resemble the lipodystrophy syndrome).^{151–153} Additionally, nucleoside analogs can inhibit mitochondrial DNA polymerase and, as a result, have been implicated in lipoatrophy.¹⁵⁴ Finally, metabolic abnormalities have also been reported in patients who are HIV infected before receiving HAART, and may also be a consequence of HIV infection or pre-existing metabolic disorders that are exacerbated by HAART.¹⁵⁵

Up to 40% of patients on PI-based HAART are reported to experience impaired glucose intolerance owing to significant insulin resistance.¹⁵⁶ Patients with type 2 diabetes mellitus are at increased risk, and PI-based regimens should be avoided if possible in these patients.⁸¹ Fasting glucose

measures for all patients are recommended before and during therapy (e.g., every 3–6 months) with PI-based HAART.⁸¹ In many cases, the hyperglycemia will respond to diet and exercise modifications; however, if pharmacologic interventions are necessary, insulin “sensitizers” (thiazolidinediones, metformin) may be most effective.^{81,157} For more pronounced hyperglycemia, oral sulfonylureas or insulin may be appropriate, although oral agents may be less efficacious in those who are HIV infected with those who are not HIV infected.⁸¹ Although hyperglycemia is reversible on discontinuation of PIs therapy, the potential benefit of sustained viral suppression with HAART-containing regimens often outweighs the risks for complications in those patients whose hyperglycemia can be controlled.

Elevations in serum levels of triglycerides, total cholesterol, and LDL, with mild decreases in HDL, have also been reported after the initiation of HAART.^{81,157,158} These abnormalities may be seen as early as 2 weeks after the initiation of therapy.⁸¹ Although all PIs have been implicated, these laboratory abnormalities appear to occur more frequently in ritonavir-containing regimens, and less frequently in patients receiving atazanavir.¹⁵⁵ The NNRTIs can also cause lipid alterations, although at a lower incidence than the PI. Both efavirenz and nevirapine have been shown to increase HDL concentrations among patients receiving HAART. Generally, nevirapine may have the least detrimental lipid profile (i.e., greater increases in HDL concentrations and less effect on LDL elevations).¹⁵⁹ Of the NRTIs, stavudine appears to affect lipid profiles to the greatest extent: two prospective clinical trials have shown greater increases in triglycerides and total cholesterol among patients receiving stavudine-based HAART compared with zidovudine- or tenofovir-based regimens.^{81,155}

The management of HAART-associated hyperlipidemias should involve dietary modifications and regular physical exercise with pharmacologic interventions reserved for those patients who meet criteria for treatment as with the general population. The goals of therapy for patient who are HIV infected are the same for those who are not HIV infected and follow the American Heart Association guidelines.^{81,155} When drug therapy is warranted, hydroxymethylglutaryl coacetyl-A reductase inhibitors (HMG-CoA) may be used for hypercholesterolemia and fibric acid derivatives for hypertriglyceridemia.^{81,155} Both HMG-CoA reductase inhibitors and PIs are metabolized by the hepatic cytochrome P450 enzyme system, which may result in significant drug–drug interactions (most importantly, decreased clearance of the HMG-CoA reductase inhibitor from the PI, resulting in an increased risk for rhabdomyolysis, myositis, and transaminase elevations). When concomitantly administered with ritonavir, simvastatin concentrations increase significantly, atorvastatin concentrations increase modestly, and pravastatin concentrations decrease significantly.¹⁶⁰ Consequently, simvastatin should not be used in patients receiving ritonavir-based HAART, whereas atorvastatin can be used with caution. Among patients who experience increases in lipids or triglycerides and who are virologically controlled, it may be possible to substitute the current PIs for a different agent that has a lower propensity for raising these laboratory values.^{161–170} An NNRTIs, an alternative protease inhibitor, or possibly abacavir may be reasonable options to replace the pro-

tease inhibitor. It should be recognized that a detailed history of prior resistance must be known before switching therapies to prevent virologic failure.

Alterations in body composition, both fat loss (arms, legs, face, buttocks) and fat accumulation (dorsocervical fatty deposits or “buffalo humps”, increased abdominal girth) are commonly observed among patients taking HAART. Up to 40% to 50% of patients have been reported to experience these changes, although the exact rate is confounded by differences in definition and assessment.⁸¹ Risk factors for this complication include higher baseline body mass index, increased duration of exposure to antiretroviral agents, lower CD4 nadir at time of initiation of HAART and CD4 response to therapy, increasing age, female sex, and prolonged duration of HIV infection. In general, the nucleoside analogs are believed to be responsible for lipoatrophy, and the PIs are believed to be responsible for lipoaccumulation.⁸¹ Because these agents are given in combination, it is difficult to precisely identify which class of agents is responsible for which adverse event.

The causes of lipodystrophy are unknown. For the nucleoside analogs, the greater the ability to inhibit mitochondrial DNA polymerase *in vitro* (e.g., stavudine), the greater the propensity for lipatrophy. Studies involving the substitution of one NRTIs for another have been done.^{166–171} Although the substitution of stavudine with an alternate agent such as zidovudine, tenofovir, or abacavir has shown statistically significant increases in arm and leg fat, and decreases in trunk fat using objective radiographic tests (e.g., dual-energy x-ray absorptiometry, computed tomography scans), these improvements are so modest that they may not be clinically significant. The use of recombinant human growth hormone, an agent with lipolytic effects, has been shown to decrease the size of buffalo humps and abdominal girth; however, once use of the agent is stopped, the growth often returns.⁸¹ Surgical excision or liposuction may be effective; however, recurrences have been reported. In addition, caution should be exercised when using surgical interventions for abdominal girth because of concerns about intestinal perforation and intraperitoneal bleeding. For facial wasting, injection of fat or synthetic polymers into the recessed areas of the cheeks have shown good results but require frequent costly administration, and lack long-term safety data.

Other important long-term complications include nucleoside-associated lactic acidosis, osteonecrosis, and osteopenia.⁸¹ Lactic acidosis has been predominantly associated with the use of stavudine,⁵ but it can occur among all nucleoside analogs. This can be managed by discontinuing therapy until lactate levels return to normal and then reinitiating therapy with a nonstavudine or non-nucleoside analog-containing HAART regimen, if possible.

Currently, J.F. has elevated serum levels of cholesterol, lipids, and fasting blood sugars. In addition, he has the classic clinical presentation of body habitus changes with thinning of his arms, legs, and face, as well as accumulation of central fat and a modest buffalo hump on his neck. Although the current antiretroviral regimen has been effective in lowering J.F.’s viral load and increasing his T-cell counts, interventions are necessary to prevent long-term complications such as premature heart disease and other vascular complications. Initially, nonpharmacologic interventions such as diet, exercise, and

life-style modifications (e.g., smoking cessation) should be tried. In addition, given the increased reported incidence of these adverse events with ritonavir- and stavudine-containing regimens, modification of J.F.'s current antiretroviral regimen may be reasonable and should be based on treatment history, resistance profiles, and drug intolerances. If these interventions fail, gemfibrozil, atorvastatin, metformin, or a thiazolidinedione (e.g., pioglitazone or rosiglitazone) should be considered.

Limited interventions are currently available for treatment of the buffalo hump. J.F. could consider surgery or recombinant human growth hormone; however, he should be advised that the hump might return. In addition, if the facial lipoatrophy is of significant concern, J.F. should consult a dermatologist who specializes in HIV-associated facial reconstruction.

Structured Treatment Interruptions and Target-Controlled Interventions

17. T.D. is a 32-year-old man infected with HIV whose antiretroviral therapy was initiated with stavudine, lamivudine, and lopinavir–ritonavir 2 years ago when he was first diagnosed with HIV at a routine physical examination. At that time, his CD4 cell count was 125 cells/mm³ and his viral load was 85,000 copies/mL. T.D. has done well with his current regimen; he has been without any adverse drug events, and his CD4 cell counts have been stable at 575 cells/mm³ and his viral load measurements have been undetectable (<50 copies/mL). T.D. is concerned about long-term adverse events from HAART and asks if he can stop therapy or at least minimize his exposure to these agents. Can therapy be discontinued once it is stable? If so, how should it be monitored? Are there any interventions that can be implemented to minimize drug exposures and potentially long-term adverse events?

Although HAART-based therapies have been shown to improve survival and minimize the risk for development of opportunistic infections, these agents do have significant adverse effects associated with their use. In addition, given the improved survival rates from HAART, new and more complex long-term adverse events are now recognized. Previously, the goal of antiretroviral therapy was to prolong survival; now, with the use of HAART, the management of HIV has shifted to chronic health maintenance. Consequently, any intervention that can decrease the risk for long-term adverse events or minimize drug exposures over time may represent a key strategy for managing infection with HIV, provided that the intervention does not cause immunologic harm to the patient. Two strategies have been investigated to minimize antiretroviral exposure: structured treatment interruptions (STI) and CD4/viral load–guided discontinuations of therapy.

Structured treatment interruption interventions involve starting and stopping HAART at controlled time points in hopes of minimizing drug exposure, maintaining immunologic control, and minimizing drug resistance. Various dosing schedules have been used (e.g., 7 days on, 7 days off; 3 months on, 2 months off; 5 days on 2 days off) with mixed, although generally unfavorable, results.^{172–179} Additionally, this strategy is difficult to adhere to, and short-term adverse drug events may occur when therapy is reinitiated, including the acute retroviral syndrome.^{179–181} It appears that antiviral resistance may occur

using STI interventions, and should not be undertaken with regimens that contain agents with low genetic barriers or long half-lives.^{182,183}

Target-controlled therapy involves patients discontinuing and reinitiating therapy only when certain target values are reached (e.g., CD4 cell counts, viral load, or both).^{173,174} This intervention is of particular interest for patients whose therapy was initiated in the past when their CD4 cell counts were >350 cells/mm³ or for patients whose immune systems have improved to values >350 cells/mm³ for extended periods of time. Earlier clinical trial data using target values of CD4 cell counts falling <350 cells/mm³ or a decline of 25% to 30% from baseline demonstrated promising results.^{173,174} More recent, larger studies, however, do not support this approach.^{184,185} In fact, the most recent studies have been discontinued prematurely because of increases in morbidity and mortality in the treatment interruption arms.

Because of the conflicting evidence and uncertainty surrounding treatment interruption, current guidelines do not recommend these interventions outside of a clinical trial setting.^{5,6} As such, if available at the clinical center, T.D. could be referred to a clinical study for close-follow-up and care during treatment interruption. If the patient truly desires cessation of therapy, the clinician should initiate a discussion to explain fully the potential risks, such as disease progression and death, and allow the patient to participate in the decision to stop treatment. The patient should also be counseled that follow-up care and careful monitoring will be required to monitor disease progression and the need to reinstitute antiretrovirals. If treatment is continued, or when it is reinitiated, given the increased risk for side effects with stavudine, it may be reasonable to replace stavudine with ZDV, ABC, or TDF.

KEEPING CURRENT

The management of HIV infection continues to evolve. The overwhelming data presented at scientific meetings and in journals has made staying informed about current issues and new developments a daunting task. As a result, many clinicians, even those actively caring for patient who are HIV infected, remain cautious and often confused as to which therapeutic options to use.

New technologies for the dissemination of medical information are constantly evolving. The internet has allowed clinicians worldwide to exchange ideas, teach new concepts, and obtain access to limited resources. In addition, many research centers, patient advocacy groups, and academic institutions have posted sites on the internet that have resulted in access to large amounts of high-quality medical information. This new technology has also allowed, however, for the dissemination of incomplete, misleading, or inaccurate information. Therefore, clinicians must remain cautious and carefully evaluate the information obtained from various websites.

When evaluating the quality of a website, clinicians should look for a few basic standards:

1. *Author qualifications.* Is the author qualified to write the article or perform the research? Is his or her affiliation or relevant credentials provided?

2. **Attribution.** Are references provided to confirm statements? Are all relevant copyrighted information noted?
3. **Currency.** When was the content posted? Is the website updated regularly?
4. **Disclosure.** Who owns the website? Is there a conflict of interest between what is being posted and any commercial interest?

Any internet site that fails to meet these basic competencies should be viewed with caution. In general, the most accurate and informative websites for HIV-specific information come from academic institutions, government organizations, medical societies, and patient advocacy groups. Table 69-9 lists high-quality websites that provide timely and accurate information. A periodic evaluation of these sites often provides sufficient information to stay up-to-date on current issues and controversies.

CONCLUSIONS

Despite significant advances made in the treatment of patients infected with HIV, a cure continues to be out of reach. Pharmacists are in a unique position to assist both clinicians and patients in the general management of HIV infection. In particular, the number of drug–drug interactions in HIV management is unprecedented compared with other therapeutic areas. A basic understanding of drug–drug interactions, absolute contraindications, and adverse event profiles for antiretroviral agents can substantially improve patient compliance, minimize adverse events, and improve clinical outcomes. Although the pharmacologic management of HIV is rapidly evolving, a basic understanding of viral pathogenesis and drug interactions provides a framework that can be used to evaluate new information as it becomes available.

 - Pharmacologic Intervention 70-42

The acquired immunodeficiency syndrome (AIDS) is characterized by the gradual erosion of immune competence and the development of opportunistic infections (OIs) and malignancies. Since the era of highly active antiretroviral therapy (HAART) began in 1996, AIDS-related mortality has declined in the United States.^{1,2} This decline in mortality more specifically is described by a decline in opportunistic infection associated deaths over the pre-HAART (1992–1995), peri-HAART (1996–1999), and post-HAART (2000–2003) eras with an increase in noninfectious AIDS-related mortality.³ In 1997, the

year after HAART initiation, the U.S. Centers for Disease Control and Prevention (CDC) estimated that approximately 60,000 AIDS-related opportunistic illnesses had occurred in the United States during 1996.¹ This report represents the first calendar year in which the overall incidence of AIDS-associated OIs did not increase in the United States; the 1996 figure represented a decline of 6% compared with 1995. Patients with human immunodeficiency virus (HIV) infection are susceptible to an array of diseases, but most OIs are caused by a few common pathogens, including *Pneumocystis jirovecii*

Table 70-1 Conditions Included in the 1993 Surveillance Case Definition

| Category A | Category C (Continued) |
|---|--|
| Asymptomatic HIV infection | Cryptococcosis, extrapulmonary |
| Persistent generalized lymphadenopathy | Cryptosporidiosis, chronic intestinal (>1 month) |
| Acute HIV infection with accompanying illness or history of HIV infection | CMV disease (other than liver, spleen, or nodes) |
| | CMV retinitis (with loss of vision) |
| | Encephalopathy, HIV related |
| | Herpes simplex: chronic ulcer(s) (>1 month); or bronchitis, pneumonitis, or esophagitis |
| | Histoplasmosis, disseminated or extrapulmonary |
| | Isosporiasis, chronic intestinal (>1 month's duration) |
| | Kaposi sarcoma |
| | Lymphoid interstitial pneumonia and/or pulmonary lymphoid hyperplasia ^a |
| | Lymphoma, Burkitt (or equivalent term) |
| | Lymphoma, immunoblastic (or equivalent term) |
| | Lymphoma, primary, of brain |
| | <i>Mycobacterium avium-intracellulare</i> complex or <i>M. kansasii</i> , disseminated or extrapulmonary |
| | <i>Mycobacterium tuberculosis</i> , any site (pulmonary ^b or extrapulmonary) |
| | <i>Mycobacterium</i> , other species or unidentified species, disseminated or extrapulmonary |
| | <i>Pneumocystis carinii</i> pneumonia |
| | Pneumonia, recurrent ^b |
| | PML |
| | <i>Salmonella</i> septicemia, recurrent |
| | Toxoplasmosis of brain |
| | Wasting syndrome due to HIV |
| Category B | |
| Bacillary angiomatosis | |
| Candidiasis, oropharyngeal (thrush) | |
| Candidiasis, vulvovaginal; persistent, frequent, or poorly responsive to treatment | |
| Cervical dysplasia/carcinoma in situ | |
| Constitutional symptoms, such as fever >38°C or diarrhea >1 month | |
| Hairy leukoplakia | |
| Herpes zoster (shingles), involving at least two distinct episodes or more than one dermatome | |
| Idiopathic thrombocytopenia purpura | |
| Listeriosis | |
| Pelvic inflammatory disease, particularly if complicated by tubo-ovarian abscess | |
| Peripheral neuropathy | |
| Category C | |
| Candidiasis of bronchi, trachea, or lungs | |
| Candidiasis, esophageal | |
| Cervical cancer, invasive | |
| Coccidioidomycosis, disseminated or extrapulmonary | |

^aChildren <13 years old.

^bAdded in the 1993 expansions of the AIDS surveillance case definition for adolescents and adults. HIV, human immunodeficiency virus; PML, progressive multifocal leukoencephalopathy.

(*carinii*), cytomegalovirus (CMV), fungi, and mycobacteria. Persons with AIDS also are susceptible to neoplastic diseases (lymphoma and Kaposi sarcoma [KS]) and other conditions, such as wasting syndrome.^{2,4}

The 1993 revised classification system for HIV infection and expanded surveillance case definition for AIDS included stratification for the CD4⁺ lymphocyte count, as well as subgrouping by clinical categories (Table 70-1). These AIDS-defining OIs or malignancies may also occur in asymptomatic HIV-infected patients (Table 70-1).⁴

The Natural History of Opportunistic Infections

The Decline of the CD4⁺ Lymphocyte

Within the immune system, the CD4⁺ lymphocyte functions as a “helper cell” that modulates the actions of the other key cellular components of the immune system. The eventual loss of CD4⁺ lymphocytes is the underlying pathophysiologic problem that leads to AIDS. (See Chapter 69, Pharmacotherapy of Human Immunodeficiency Virus Infection, and comprehensive immunology texts for a more detailed explanation of immune function and inflammation associated with HIV infection).^{5,6} The infected CD4⁺ lymphocyte can function normally for a period of time, but eventually becomes dysfunctional, as manifested by an abnormal response to soluble mitogens.^{7,8} It is this cellular functional deficit, compounded

by the eventual decline in the absolute number of CD4⁺ lymphocytes, that leads to OIs, malignancies, and neurologic dysfunctions. The CD4⁺ count declines gradually over several years in the untreated HIV-infected person. The average rate of decline of CD4⁺ lymphocyte cells (CD4 slope) is approximately 40 to 80 cells/mm³/year in the absence of antiretroviral therapy. An accelerated decline in the CD4⁺ count occurs at 1.5 to 2 years, just before an AIDS-defining diagnosis.^{9,10} Without therapy, the course of infection averages approximately 10 years from the time of initial infection to an AIDS-defining diagnosis. There is individual variation in the decline of the CD4⁺ count. Some patients have a rapid decline after the acute retroviral presentation, whereas approximately 5% to 15% have a CD4⁺ count of 500 for longer than 8 years; these patients are considered chronic nonprogressors.¹¹

The CD4⁺ count dictates the need for OI prophylaxis, affects the differential diagnosis of the OI, and is an independent indicator of prognosis. For these reasons, the CD4⁺ count has become a primary surrogate marker of immune suppression and antiretroviral activity.¹² HIV-1 RNA is the other clinical surrogate marker most predictive of survival and antiretroviral activity.

OIs range from relatively minor events (e.g., oral candidiasis or oral hairy leukoplakia) to sight-threatening episodes of CMV retinitis, or life-threatening *P. jiroveci* (*carinii*) pneumonia (PCP). The risk for specific OIs varies with the degree of immunosuppression.^{13,14,15} Asymptomatic patients with

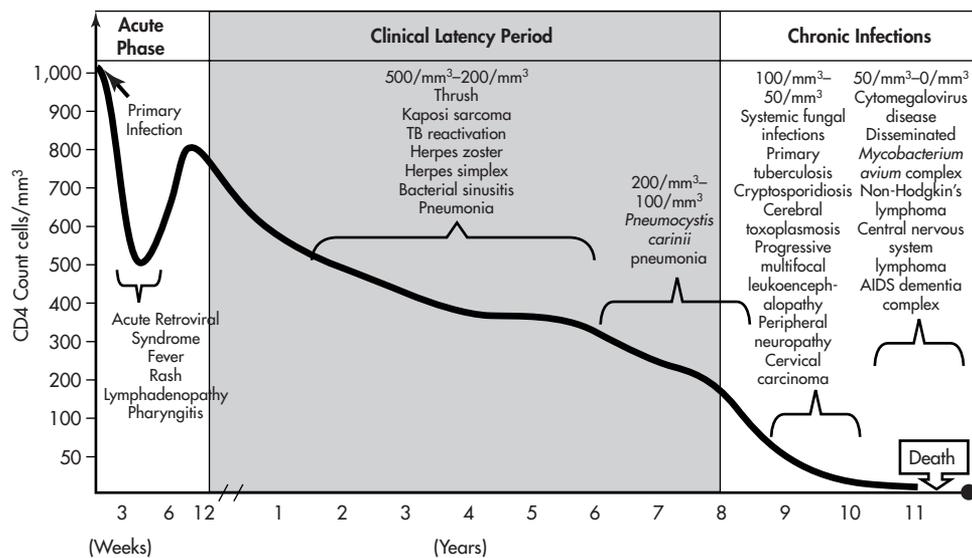

FIGURE 70-1 Natural history of CD4⁺ cell count in the average HIV patient without antiretroviral therapy from the time of HIV transmissions to death. (Illustration by Mary Van, PharmD.)

moderate immunosuppression (CD4⁺ counts 200–500) may become infected with herpes viruses and *Candida* species and/or develop pneumonias, enteric infections, and meningitis with common pathogens. Massive destruction of the immune system occurs when the CD4⁺ count is below 200, which increases the risk for opportunistic pathogens (e.g., PCP), opportunistic tumors, wasting, and neurologic complications. With a CD4⁺ count of 50 to 100, invasive candidiasis, cerebral toxoplasmosis, cryptococcosis, and various protozoal infections are observed. When the CD4⁺ count falls below 50, the patient is in an advanced immunosuppressed state, which is associated with non-Hodgkin lymphoma (NHL), CMV, and disseminated *Mycobacterium avium* complex (MAC; Fig. 70-1). Without treatment, the median survival associated with a CD4⁺ count below 200 is 3.1 years, and the time to an AIDS-defining infection ranges from 18 to 24 months.^{9,12,13,15} With the implementation of HAART, the 3-year probability of AIDS (which includes in many cases OIs) has dramatically declined as compared with before HAART; however, much of this may be attributed to the use of prophylactic regimens for OIs.¹⁶

The Effect of Opportunistic Infections on Viral Load and Survival

Acute OIs upregulate HIV replication, resulting in higher HIV-1 RNA concentrations in the plasma and lymphoid tissues of HIV-infected patients.^{17–20} This enhanced replication is presumably caused by antigen-mediated activation of HIV-1 replication in latently infected cells. To assess the impact of OIs on survival, data from a cohort of 2,081 HIV-infected patients followed (in the preprotease inhibitor era) for a mean of 30 months were analyzed.²¹ CD4⁺ counts and incidence of opportunistic disease were used as independent variables. These investigators found that PCP, CMV, MAC, esophageal candidiasis, KS, NHL, progressive multifocal leukoencephalopathy (PML), dementia, wasting syndrome, toxoplasmosis, and cryptosporidiosis were independently associated with death.²¹ Additionally, data from a prospective longitudinal study of HIV infection in homosexual men initiated in 1984 (Multicenter AIDS Cohort Study) demonstrated that plasma HIV-1 RNA concentrations

strongly predict the rate of decline of the absolute CD4⁺ count as well as clinical progression to AIDS and death.²² More recent investigations in the era of HAART have demonstrated that CD4 count is the strongest prognostic factor in patients starting therapy.¹⁶

Impact of Antiretroviral Agents on the Natural History of Opportunistic Infections

REDUCTION IN THE INCIDENCE OF OPPORTUNISTIC INFECTIONS AND DEATH

The introduction of protease inhibitors, combination therapy, prophylaxis therapy, and improved medical care has reduced the incidence of OIs and death resulting from AIDS in HIV-positive patients. HAART usually consists of two nucleoside reverse transcriptase inhibitors, in addition to one or more protease inhibitors or one non-nucleoside reverse transcriptase inhibitor. HAART generally refers to an antiretroviral regimen that can be expected to reduce the viral load in antiretroviral-naïve patients to fewer than 50 copies/mL. A panel of experts convened by the U.S. Department of Health and Human Services and the Henry J. Kaiser Family Foundation recommended HAART as the standard of care for all HIV-infected patients.²³ These potent antiretroviral agents and effective management of OIs have led to an improved quality of life and prolonged duration of survival among HIV-infected patients in the United States.^{24–26} A significant decrease in the incidence of OIs and death was first reported in February 1996, when preliminary data from a pivotal study became available. The data demonstrated that the addition of ritonavir to an existing reverse transcriptase regimen in severely immunocompromised patients decreased the incidence of OIs and death.²⁷ Several studies^{16,27,28,29–32} since have shown a decrease in the incidence of OIs in AIDS patients receiving HAART therapy. One such study, a retrospective cohort design of patients in an HIV outpatient clinic observed from January 1994, through June 1997, demonstrated a significant decline in OIs in 1996 and 1997. The most common conditions with reported reduced incidence included KS, HIV wasting, and infections such as PCP, MAC, and CMV.²⁹

Since the introduction of the protease inhibitors, the CDC has reported a deceleration in the rate of AIDS diagnosis.³¹ This finding was observed in homosexual men and in intravenous (IV) drug users, but was not observed in heterosexual exposure groups. Notably, a decrease in incidence of OIs was not observed in HIV-positive, non-Hispanic blacks and Hispanics. The decline in AIDS-associated mortality is probably the result of improved medical care, increased use of HAART therapy, and effective prophylaxis. Unfortunately, the number of deaths caused by AIDS has increased among women and heterosexual transmission groups.

Changes in the Natural History of Opportunistic Infections

OIs and cancers result from long-standing immunosuppression from HIV infection.^{13–15} Several studies have reported a change in the natural history of certain OIs after the initiation of antiretroviral agents.^{33,34} Before HAART, approximately 40% of all AIDS patients developed CMV retinitis, with the most cases occurring at CD4⁺ counts below 100. Since the implementation of HAART, a decrease in the incidence of CMV retinitis and a decline in the rate of retinitis progression have been noted.^{33,35}

Ironically, HAART therapy also has been associated with a worsening or an unmasking of occult OIs in patients with advanced AIDS. When antiretroviral therapy strengthens the immune system, inflammatory symptoms in response to infection are more clinically pronounced.^{32,36} This syndrome has been referred to as immune reconstitution inflammatory syndrome or IRIS. A subclinical MAC infection syndrome, characterized by severe fever, leukocytosis, and lymphadenitis, was observed in five patients after initiating HAART.³² CMV retinitis occurred in five patients previously treated with HAART despite a marked improvement in CD4⁺ counts (195 cell/mm³) before diagnosis.³⁵ Elevated liver function tests (LFTs) and hepatitis C viremia have been documented after the initiation of HAART.³⁷

The initiation of HAART typically results in an increase in CD4⁺ lymphocytes and a decrease in HIV-1 RNA to undetectable levels. It is unclear whether the CD4⁺ lymphocytes associated with HAART therapy are as functional as the cells previously lost over the course of the HIV infection. It is also unknown whether this increase in total CD4⁺ lymphocytes reflects an increase in memory subtypes, and whether these subtypes mediate a subclinical inflammatory response.³⁶

Improvement or Resolution of Opportunistic Infections

With the initiation of HAART, reports of improvement or resolution of some OIs were published.^{38–42} These OIs included KS,³⁸ PML,³⁹ CMV,^{33,35} microsporidiosis, cryptosporidiosis,⁴⁰ and molluscum contagiosum,⁴¹ a viral infection caused by a member of the *Poxviridae* family. Furthermore, there are reports of restored immunity and clinical improvement in patients with chronic hepatitis B infection (not classified as a CDC-defined AIDS indicator condition) upon the initiation of HAART.⁴² These infections were not eradicated, and in some cases improvement was only transient. Clinical resolution most likely results from immunologic improvement, and the protective immunity against OI is sustained only as long as HAART remains effective.

Pharmacotherapeutic Management of Opportunistic Infections

Successful pharmacotherapeutic management of OIs requires an understanding of the natural history of HIV-associated OIs, including recognizing that OIs occur with declining CD4⁺ lymphocyte counts, the clinical presentation of each disease, diagnostic techniques, and effective treatment and preventive strategies.^{43,44} Management issues, complicated by multiple-drug therapy for OIs and HIV suppression, include adherence, toxicities, resistance, drug interactions, and cost. HIV-infected patients are usually less tolerant to drugs such as flucytosine, trimethoprim-sulfamethoxazole (TMP-SMX), and pyrimethamine. Therapeutic options are often limited; therefore, more efficacious agents (e.g., for the treatment of cryptosporidia and microsporidia) and less toxic agents (e.g., than pyrimethamine and sulfadiazine) need to be developed.⁴⁵

In 1995, the U.S. Public Health Service (USPHS) and the Infectious Diseases Society of America (IDSA) issued guidelines for the prevention of OIs in HIV-infected patients; these were revised in 1997,⁴⁶ 1999,⁴⁷ and 2002.⁴⁸ Nineteen OIs, or groups of OIs, are addressed, and recommendations are included for preventing exposure to opportunistic pathogens, preventing first episodes of disease by chemoprophylaxis or vaccination (primary prophylaxis), and preventing disease recurrence (secondary prophylaxis). Additionally, in 2004 the CDC published the first edition guidelines for treatment of OIs.⁴⁹

Primary Prophylaxis

Primary prophylaxis is defined as therapy that is initiated before the appearance of an OI in high-risk asymptomatic persons. It is used to prevent the initial occurrence of an infection. Primary prevention of OIs is important, considering the inevitable immune depletion associated with chronic HIV infection.^{44,50,51} PCP and MAC prophylaxis have significantly prolonged survival and delayed the onset of illness (see sections about PCP and MAC prophylaxis).^{50,51}

The guidelines strongly recommend primary prophylaxis against PCP, toxoplasmosis, *Mycobacterium tuberculosis*, MAC, and varicella-zoster virus (VZV). Vaccinations to prevent *Streptococcus pneumoniae*, hepatitis B virus, hepatitis A virus, and influenza virus infection generally are recommended for all HIV-infected patients. Primary prophylaxis for fungal infections (*Cryptococcus neoformans* and *Histoplasma capsulatum*), CMV, and bacterial infections are not routinely recommended for most patients, except in unusual circumstances (Table 70-2).

DISCONTINUATION OF PRIMARY PROPHYLAXIS THERAPY

HAART has diminished the incidence of several OIs.^{33,34,38,40} Therefore, it may be possible to discontinue prophylactic OI therapy when CD4⁺ counts rise above the threshold associated with risk for infection. These data have been particularly encouraging in patients who had PCP prophylaxis discontinued with an increase in CD4⁺ counts.^{48,52–54} In one observational PCP prophylaxis study, no episodes of PCP were observed after discontinuation of primary and secondary PCP prophylaxis.⁵² These studies suggest that patients who respond to HAART therapy with a sustained increase in CD4⁺ count

Table 70-2 Primary Prophylaxis of Opportunistic Infections in HIV-Infected Adults and Adolescents

| Pathogen | Indication | Preventive Regimens | | | D/C Prophylaxis |
|---|---|---|--|--|--|
| | | First Choice | Alternatives | | |
| Strongly Recommended as Standard of Care | | | | | |
| <i>Pneumocystis jiroveci</i> (<i>carinii</i>) | CD4 ⁺ count <200 or oropharyngeal candidiasis | TMP-SMX, 1 DS PO QD or TMP-SMX 1 SS PO QD | Dapsone 50 mg BID or 100 mg/day; dapsone 50 mg QD + pyrimethamine 50 mg QW + leucovorin, 25 mg PO QW; dapsone, 200 mg PO + pyrimethamine 75 mg PO + leucovorin, 25 mg PO QW; aerosolized pentamidine, 300 mg QM via Respigard II nebulizer, atovaquone, 1,500 mg PO QD; TMP-SMX 1 DS 3×/wk | | Patients on HAART with sustained CD4 >200 cells for ≥3 months may discontinue PCP prophylaxis. Reintroduce if CD4 ⁺ <200. |
| <i>M. tuberculosis</i> | | | | | |
| Isoniazid sensitive | TST reaction ≥5 mm or prior positive result without treatment or contact with case of active tuberculosis regardless of TST result | Isoniazid 300 mg PO + pyridoxine 50 mg PO QD ×9 months or isoniazid 900 mg PO + pyridoxine, 100 mg PO BIW ×9 months | Rifampin 600 mg PO QD ×4 months or rifabutin 300 mg PO QD ×4 months: PZA 1,520 mg/kg PO QD ×2 months + rifampin 600 mg PO QD ×2 months or rifabutin 300 mg PO QD ×2 months | | |
| Isoniazid resistant | Same; high probability of exposure to multidrug resistant tuberculosis | Rifampin 600 mg PO QD or rifabutin 300 mg PO QD ×4 months | Pyrazinamide 15–20 mg/kg PO QD ×2 months; + either rifampin 600 mg PO QD ×2 months or rifabutin 300 mg PO QD ×2 months | | |
| Multidrug resistant (INH and RIF) | Same; high probability of exposure to isoniazid-resistant tuberculosis | Choice of drugs requires consultation with public health authorities | None | | |
| <i>T. gondii</i> | IgG antibody to <i>Toxoplasma</i> and CD4 ⁺ count <100 | TMP-SMX, 1 DS PO QD | TMP-SMZ, 1 SS PO QD: dapsone, 50 mg PO QD + pyrimethamine, 50 mg PO QW + leucovorin, 25 mg PO QW; dapsone 200 mg PO QW + pyrimethamine 75 mg PO QW + leucovorin 25 mg PO QW; atovaquone, 1,500 mg PO QD with or without pyrimethamine 25 mg PO QD + leucovorin, 10 mg PO QD | | Patients on HAART with sustained CD4 >200 for ≥3 months may discontinue toxoplasmosis prophylaxis. Restart if CD4 <200. |
| MAC | CD4 ⁺ count <50 | Azithromycin, 1,200 mg PO QW or clarithromycin 500 mg PO BID | Rifabutin, 300 mg PO QD; azithromycin, 1,200 mg PO QW + rifabutin, 300 mg PO QD | | Patient on HAART with sustained CD4 >100 for ≥3 months may discontinue MAC prophylaxis. Restart if CD4 <50,100. |
| VZV | Significant exposure to chicken pox or shingles for patients who have no history of either condition or, if available, negative antibody to VZV | VZIG 5 vials (1.25 mL each) IM administered 96 hr after exposure, ideally within 48 hr | | | |
| Usually Recommended | | | | | |
| <i>S. pneumoniae</i> | CD4 ⁺ >1,200 | 23 valent polysaccharide Pneumococcal vaccine 0.5 mL IM | None | | |

(Continued)

Table 70-2 Primary Prophylaxis of Opportunistic Infections in HIV-Infected Adults and Adolescents (continued)

| Pathogen | Indication | Preventive Regimens | | |
|--|---|--|--|-----------------|
| | | First Choice | Alternatives | D/C Prophylaxis |
| Usually Recommended (continued) | | | | |
| HBV | All susceptible (anti-HBc-negative) patients | Hepatitis B vaccine 3 doses | None | |
| Influenza virus | All patients (annually before influenza season) | Inactivated trivalent influenza virus vaccine 0.5 mL/yr IM | Oseltamivir 75 mg QD (influenza A or B); Rimantadine, 100 mg PO BID, or amantadine, 100 mg PO BID (influenza A only) | |
| HAV | All susceptible (anti-HAV-negative) patient at increased risk for HAV or patients with chronic liver disease (including HBV or HCV) | Hepatitis A vaccine; 2 doses | None | |
| Not Recommended for Most Patients; Indicated for Use Only in Unusual Circumstances | | | | |
| Bacteria | Neutropenia | G-CSF 510 mg/kg SC QD ×24 wk or GM-CSF 250 mg/m ² SC ×24 wk | None | |
| <i>C. neoformans</i> | CD4 ⁺ count <50 | Fluconazole 100–200 mg PO QD | Itraconazole 200 mg PO QD | |
| <i>H. capsulatum</i> | CD4 ⁺ count <100, endemic geographic areas | Itraconazole 200 mg PO QD | None | |
| CMV | CD4 ⁺ count <50 and CMV antibody positive | Oral ganciclovir 1 g PO TID or valganciclovir 900 mg PO QD | None | |
| <small>BID, twice a day; CMV, cytomegalovirus; DS, double strength; G-CSF, granulocyte colony-stimulating factor; GM-CSF, granulocyte-macrophage colony-stimulating factor; HAART, highly active antiretroviral therapy; HAV, hepatitis A virus; HBc, hepatitis B core; IM, intramuscularly; INH, isoniazid; MAC, <i>Mycobacterium avium</i> complex; PO, orally; QD, daily; QW, weekly; RIF, rifampin; SC, subcutaneously; SS, single strength; TMP-SMX, trimethoprim-sulfamethoxazole; TST, tuberculin skin test; VZIG, varicella-zoster immune globulin; VZV, varicella-zoster virus. Adapted from USPHS/IDSA Guidelines. <i>MMWR Morbid Mortal Wkly Rep</i> 2002;51(RR-8):152.</small> | | | | |

can have their primary prophylaxis safely discontinued. The OI prophylaxis guidelines suggest that primary PCP prophylaxis may be discontinued for patients on HAART when the CD4⁺ count is above 200 for at least 3 months. Primary prophylaxis for MAC may also be discontinued when the CD4⁺ count increases to above 100.^{48,55} In addition, the guidelines suggest discontinuing primary prophylaxis for toxoplasmosis when the CD4⁺ count increases to higher than 200 for at least 3 months.

Acute Therapy

Prompt diagnosis and immediate initiation of therapy are essential to the management of acute infections. Most common OIs can be classified into one of two groups. The first group consists of infections that can be treated by conventional or investigational agents. These include PCP, tuberculosis (TB), cryptococcosis, CMV, MAC, and histoplasmosis. Treatment may result in either effective or moderately effective resolution. These infections may recur if chronic suppressive or secondary prophylaxis is discontinued without an accompanying elevation in the CD4⁺ count and viral load suppression. The second group includes pathogens for which no therapeutic regimen is

currently effective (Table 70-3). These include cryptosporidiosis, microsporidiosis, and PML.⁴³

Secondary Prophylaxis or Chronic Suppressive Therapy

Secondary prophylaxis is used to prevent recurrence of an OI once the patient has developed signs and symptoms of active infection. In some cases, secondary prophylaxis regimens can be discontinued after patients achieve a certain CD4⁺ level. The USPHS and IDSA strongly recommend secondary prophylaxis for PCP, toxoplasmosis (reduced dosage), MAC, CMV, *Salmonella* species, and infections caused by endemic fungi and *C. neoformans*.⁴⁸

DISCONTINUATION OF SECONDARY PROPHYLAXIS OR CHRONIC SUPPRESSIVE THERAPY

In 1999, the USPHS/IDSA guidelines first reported that stopping primary or secondary prophylaxis for certain pathogens was safe if HAART led to an increase in the CD4⁺ count to above specified threshold levels. The 2002 USPHS/IDSA guidelines incorporated more data to support these initial recommendations and expanded recommendations to other pathogens. Criteria for discontinuing chemoprophylaxis are

based on specific clinical studies and vary by duration of CD4⁺ count increase and duration of treatment of the initial episode of disease (in the case of secondary prophylaxis).

Multiple case series have reported that maintenance therapy for CMV can be discontinued safely in patients who have maintained a CD4⁺ count of >100 to 150 for >6 months on HAART.^{33,34,56–60} Whereas CMV retinitis typically reactivated <6 to 8 weeks after stopping CMV therapy in the pre-HAART era, these patients have remained disease free for >30 to 95 weeks. Plasma HIV RNA levels varied among these patients, demonstrating that the CD4⁺ count is the primary determinant of immune recovery to CMV. The decision to stop CMV prophylaxis should be made in consultation with an ophthalmologist and is influenced by factors such as the magnitude and duration of CD4⁺ increases and viral load suppression, anatomical location of retinal lesions, and vision in the contralateral eye. Regular ophthalmic examination is critical.^{33,34,48,59–61} Secondary PCP prophylaxis may be discontinued among patients whose CD4⁺ counts have increased to >200 for >3 months while on HAART. Secondary prophylaxis for disseminated MAC may be discontinued among patients who have completed 12 months of MAC therapy, have no signs or symptoms of MAC, and have had a CD4⁺ count of >100 for >6 months in response to HAART. Similarly, secondary prophylaxis for toxoplasmosis may be discontinued in patients who have completed initial therapy, have no signs or symptoms of infection, and have had CD4⁺ counts of >200 for >6 months. Using the same criteria, patients with cryptococcosis can discontinue secondary prophylaxis if they have had CD4⁺ counts of >100 to 200 for >6 months.

Although there are considerable data concerning the discontinuation of primary and secondary prophylaxis, there are no data regarding restarting prophylaxis if the CD4⁺ count decreases again to levels at which the patient is likely to again be at risk for OIs. For primary prophylaxis, it is unknown whether the same threshold at which prophylaxis can be stopped should be used or whether the threshold below which initial prophylaxis is recommended should be used. For prophylaxis against PCP, the 2002 guidelines use a CD4⁺ count of 200 as the threshold for restarting both primary and secondary prophylaxis.

PNEUMOCYSTIS JIROVECI PNEUMONIA

As an indication of the relative obscurity of this organism, no comprehensive text on PCP was available until 1983.⁶² Since

that time, this organism has been reclassified from a protozoan to a fungus on the basis of ribosomal RNA sequence comparisons.⁶³ The morphologic resemblance of *P. carinii* to a protozoan has led to its life cycle being described as a cyst form, with up to eight sporozoites per cyst. The trophozoite or extracystic form has different staining characteristics (i.e., it does not stain with toluidine-blue O or Grocott-Gomori stains) compared with the cyst or sporozoites. In addition, current literature refers to PCP as *Pneumocystis jiroveci* as opposed to the original terminology of *Pneumocystis carinii*. The former species is the one responsible for infectivity in humans.

Clinical Presentation

1. J.R. is a 38-year-old, HIV-seropositive man who was diagnosed 5 years ago when he had an outbreak of herpes zoster. He refused antiretroviral therapy and was determined to treat himself using natural teas and herbs. J.R. developed a mild, nonproductive cough that has persisted for the last 4 weeks. He has also had a low-grade fever but denies any chills or pleuritic chest pain. His chest radiograph demonstrates a diffuse, symmetric, interstitial infiltrate. Arterial PaO₂ is 80 mmHg (normal, 80–105). His last CD4⁺ count approximately 3 months ago was 180 cells/mm³ (normal, approximately 1,000 cells/mm³) and his viral load was 60,000 copies/mL. He refused primary PCP prophylaxis. After hypertonic saline nebulization for sputum induction and subsequent bronchoalveolar lavage, examination of the specimens with the modified Giemsa stain revealed both intracystic bodies and extracystic trophozoites. How is the clinical presentation of J.R. consistent with PCP?

The clinical features of PCP in AIDS patients differ from non-AIDS patients in that a more subtle onset, with mild fever, a cough, tachypnea, and dyspnea, is typically seen in HIV-infected patients.⁶⁴ J.R.'s low-grade fever and mild, nonproductive cough of 4 weeks' duration are consistent with this description of PCP. His history of HIV infection and the finding of trophozoites on Giemsa stain further support a diagnosis of PCP. The characteristic diffuse interstitial pulmonary infiltrates on J.R.'s chest radiograph are consistent with PCP. Limited data exist with regard to the latent state of *P. carinii* after host infection. Some investigators hypothesize that most persons are asymptomatic unless the host immune system becomes impaired. Others believe that the infection is caused by reinfection as opposed to reactivation.⁶⁵

Antimicrobial Selection

2. A diagnosis of PCP is made and J.R. agrees to be treated. What patient factors are important to consider when selecting an antimicrobial? What would be a reasonable drug for J.R., and how might his course of PCP be monitored?

The treatment of acute PCP is determined by the degree of clinical severity on presentation. The arterial oxygen status on presentation is an important indicator of overall outcome. In one study, surviving patients had a mean PO_2 of 70 mmHg, whereas the mean PO_2 of the nonsurvivors was 55 mmHg.⁶⁵ Key factors to consider when initiating therapy for PCP include arterial blood gas findings, whether it is an initial or repeat episode of PCP, the need for parenteral therapy, and a prior history of adverse drug reactions or hypersensitivity. Concomitant therapy must also be considered.

Patients with PCP often can be classified as having mild, moderate, or severe disease, based on their oxygenation. Patients with mild PCP often have a room air alveolar-arterial (A-a) oxygen gradient of <35 or $[PO_2] >70$ mmHg, patients with moderate or severe disease have a gradient >35 mmHg or $[PO_2] >70$ mmHg. With the advent of corticosteroid use for moderate to severe cases of PCP (discussed later), it is useful to calculate the (A-a) gradient and/or $[PO_2]$. The A-a gradient (normal range, 5–15 mmHg) can be calculated as $PiO_2 - (1.25 \times PCO_2) - PO_2$, where PiO_2 is the partial pressure of oxygen (150 mmHg in room air), and PCO_2 and PO_2 are arterial levels of CO_2 and O_2 , respectively, expressed in mmHg.⁶⁶

Several other clinical tests have been used to identify and monitor PCP. The lactate dehydrogenase (LDH) concentration in serum or bronchoalveolar lavage fluid has been used to diagnose and monitor therapy and to predict outcome of PCP. However, many patients have overlapping diseases, preventing LDH from being used alone. Chest radiographs also are variable. The most common picture is one of bilateral diffuse interstitial pneumonitis, but atypical patterns, such as pleural effusion, cavities, pneumatoceles, and nodules, may occur as well. A normal chest radiograph is associated with a better clinical outcome.

The natural course of PCP among untreated HIV-infected patients is progressive dyspnea and hypoxemia. The increased experience with treatment of PCP in AIDS patients (compared with non-HIV-infected patients) indicates that a longer duration of therapy is needed.⁶² Despite the greater appreciation of PCP in AIDS patients, some patients may not respond to therapy; many experience worsening hypoxemia during the first 3 to 5 days after treatment is initiated. This period of clinical worsening is least tolerated by those patients with moderate to severe PCP ($PO_2 <70$ mmHg). In sicker patients, this period may lead to respiratory failure and the need for intubation with continued critical care. Although many would associate the need for intensive care unit admission as a poor prognostic factor, many patients do well despite the need for mechanical ventilation and IV antibiotics. In light of the role of corticosteroids, patients with PCP and respiratory failure may be viewed as manageable if treated aggressively (Table 70-4).

Trimethoprim-Sulfamethoxazole

The decision to hospitalize a patient is based on the severity of his or her illness. Patients who present with mild PCP with

reasonable oxygenation and without evidence of clinical deterioration can be managed as outpatients. Patients with reasonably good gas exchange (i.e., $PO_2 >70$ mmHg), but with signs of clinical deterioration, most often are admitted to the hospital and given oxygen by nasal cannula and are usually started on IV TMP-SMX (15–20 mg/kg/day TMP, 75–100 mg/kg/day SMX) for 21 days. The dosing of IV TMP-SMX must be modified in patients with renal dysfunction. TMP reversibly inhibits dihydrofolate reductase, and sulfamethoxazole competes with para-aminobenzoic acid in the production of dihydrofolate, synergistically blocking thymidine biosynthesis. TMP-SMX is always the first choice for the treatment of PCP unless the patient has a history of life-threatening intolerance. In the treatment of PCP, TMP-SMX is either as effective as, or superior to, all alternative agents. A good response may be expected in $>70\%$ of patients receiving TMP-SMX.

TMP-SMX is often prescribed because of its availability as an oral formulation. Tablets are $>90\%$ bioavailable. The usual dose is 15 mg/kg (dosed by the TMP component) Q 8 hours for 21 days. Because one double-strength tablet of TMP-SMX contains 160 mg TMP plus 800 mg SMX, a standard regimen is two double-strength tablets three times per day (or Q 8 hours). Taking two double-strength tablets Q 6 hours (eight double-strength tablets per day) does not improve efficacy and causes increased toxicity (gastrointestinal [GI] intolerance, nausea, vomiting, anorexia, and abdominal pain).

Although the TMP-SMX regimen is very efficacious, 25% to 50% of patients may be intolerant. Adverse effects include an erythematous, maculopapular, morbilliform rash and, less commonly, severe urticaria, exfoliative dermatitis, and Stevens-Johnson syndrome. GI intolerance (nausea, vomiting, abdominal pain) is common. Hematologic side effects may include leukopenia, anemia, and/or thrombocytopenia. Neurologic toxicities and hepatitis also may occur. The role of excessive doses, plasma concentration monitoring, and metabolic capability (i.e., rapid or slow acetylation of SMX) in the development of hypersensitivity reactions remains unclear and is under investigation.^{67,68} Most patients who develop a mild hypersensitivity (skin rash) reaction can be managed with antipruritics or antihistamines without discontinuation of TMP-SMX. In some patients with mild hypersensitivity reactions, the agent can be restarted after the rash has resolved, using gradual dosage escalation or rapid oral desensitization to reduce adverse effects (Table 70-5).⁶⁹ Patients with severe adverse reactions should be switched to another agent rather than being rechallenged with this drug.

Because J.R. seems to have a mild to moderate case of PCP (PO_2 , 80 mmHg), has not previously experienced an episode of PCP, and has no history of adverse effects to TMP-SMX, an outpatient course of TMP-SMX would be reasonable.

Alternatives to Trimethoprim-Sulfamethoxazole

3. J.R. experienced exfoliative dermatitis on day 7 of TMP-SMX treatment. What other drugs could be prescribed to treat his PCP?

Because J.R. presents with a significant adverse effect to TMP-SMX, it should be discontinued and he should not be rechallenged or desensitized. Instead, he should be treated with an alternative regimen (Table 70-4).⁷⁰

Table 70-4 Treatment of *Pneumocystis jiroveci* Pneumonia

| Regimen | Dose | Route | Adverse Effects/Comments |
|----------------------------|--|-------------|---|
| Approved | | | |
| TMP-SMX | 15–20 mg/kg TMP (75–100 mg/kg SMX) daily administered IV or PO Q 6–8 hr or 2 DS tabs BID | IV, PO | Hypersensitivity, rash, fever, neutropenia ↑LFTs, nephrotoxicity (15 mg/kg/day preferred to 20 mg/kg/day because of reduced toxicity) |
| Pentamidine isethionate | 4 mg/kg IV daily over 60–90 min ×21 days | IV | Pancreatitis, hypotension, hypoglycemia, hyperglycemia, nephrotoxicity |
| Trimetrexate + leucovorin | 45 mg/m ² IV/day ×21 days 20 mg/m ² PO or IV Q 6 hr ×24 days | IV PO/IV | Hematologic, GI, CNS, rash |
| Atovaquone ^a | 750 mg BID with meals ×21 days (suspension) | PO | Headache, nausea, diarrhea, rash, fever, ↑LFTs |
| TMP ^a + dapsone | 15 mg/kg/day | PO | Pruritus, GI intolerance, bone marrow suppression |
| | 100 mg/day ×21 days | PO | Methemoglobinemia, hemolytic anemia (contraindicated in G6PD deficiency) |
| Clindamycin + primaquine | 600 mg IV Q 8 hr or 300–450 mg PO Q 6 hr | PO or IV | Rash, diarrhea |
| | 15–30 mg (base) daily ×21 days | PO | Methemoglobinemia, hemolytic anemia (contraindicated in G6PD deficiency) |
| Prednisone | Within 72 hr of anti- <i>Pneumocystis</i> therapy 40 mg Q 12 hr ×5 days, then 40 mg QD ×5 days then 20 mg/day ×11 days | PO | Initiation in patients with moderately severe or severe disease PO ₂ <70 mmHg or A-a gradient >35 mmHg |

^aUsed only in mild to moderate PCP.

A-a, alveolar-arterial; BID, twice a day; CNS, central nervous system; DS, double strength; GI, gastrointestinal; G6PD, glucose-6 phosphate dehydrogenase; IV, intravenous; PCP, *Pneumocystis jiroveci* pneumonia; PO, oral; QD, daily; LFTs, liver function tests; TMP-SMX, trimethoprim-sulfamethoxazole.

IV pentamidine isethionate can be used to treat acute PCP. The mechanism of action against the organism is unknown, but may be related to interference with oxidative phosphorylation, inhibition of nucleic acid biosynthesis, or interference with dihydrofolate reductase. Pentamidine generally is more toxic than TMP-SMX.^{70,71} In a 5-year review of 106 courses of IV pentamidine, 76 (72%) had adverse reactions (nephrotoxicity, dysglycemia, hepatotoxicity, hyperkalemia, and hyperamylasemia). Drug discontinuation occurred in 31 (18%) of the severe cases. Nephrotoxicity and hypoglycemia were the most common causes of drug discontinuation. Nephrotoxicity occurred in 25% to 50% of the patients and was associated with dehydration and concurrent use of nephrotoxic drugs. Hypoglycemia was noted in 5% to 10% of patients after 5 to 7 days of treatment, or several days after discontinuation of treatment. Hyperglycemia is a consequence of decreased β -cells and results in diabetes mellitus in 2% to 9% of patients. Other less common adverse effects and toxicities include thrombocytopenia, orthostatic hypotension, ventricular tachycardia, leukopenia, nausea, vomiting, abdominal pain, and anorexia.⁷¹

Patients receiving IV pentamidine should be monitored closely, and serum concentrations of glucose, potassium, blood urea nitrogen (BUN), and creatinine should be obtained daily or every other day during treatment. Other tests for periodic monitoring include a complete blood count (CBC), LFTs, amylase,

lipase, and calcium.⁷¹ Renal toxicity often responds to a reduction in the dosage of pentamidine to 3 mg/kg/day or 4 mg/kg Q 48 hours (creatinine clearance <10 mL/min); however, the drug should be discontinued in patients who develop signs and symptoms of pancreatitis. Risk factors for pentamidine-induced pancreatitis include prior episodes of pancreatitis and concurrent therapy with other drugs known to cause pancreatitis. The prior use of didanosine or stavudine may be a risk factor for pancreatitis during pentamidine therapy.⁷²

The daily pentamidine dose of 4 mg/kg is based on clinical tolerance rather than target plasma concentrations. The exact mechanisms for elimination of pentamidine are not well understood. The drug is not excreted by renal mechanisms, and no metabolites have been identified.⁷³ The half-life of pentamidine is prolonged with multiple dosing and may increase up to 12 days after the last dose.⁷³ Nebulized pentamidine should not be considered as an alternative to IV pentamidine.

Trimetrexate (Neutrexin), a lipid-soluble derivative of methotrexate, is a highly potent inhibitor of dihydrofolate reductase. It was first studied as salvage therapy in patients failing to respond to available drugs. The ability of trimetrexate to enhance survival in these often-fatal situations gave hope to the future of this treatment. However, results of subsequent studies have not been as promising. Nonetheless, trimetrexate has been approved for patients with moderately severe and severe cases of PCP who are intolerant or unresponsive to

TMP-SMX.⁷⁴ Most clinicians reserve trimetrexate for hospitalized patients intolerant of both TMP-SMX and IV pentamidine. Recently, however, trimetrexate is no longer readily available for routine use in patients. Serious complications associated with trimetrexate administration include bone marrow suppression, oral or GI ulcerations, renal dysfunction, and hepatotoxicity. Patients receiving trimetrexate should be monitored for myelosuppression with daily CBCs and platelet counts. They should also be given leucovorin (80 mg/m² daily) to counteract trimetrexate-associated leukopenias. Leucovorin should be continued for 3 to 5 days after completion of trimetrexate therapy (45 mg/m² IV once daily over 60–90 minutes for 21 days).⁷⁴ Comparative studies with TMP-SMX demonstrate faster resolution of the A-a oxygen gradient and overall superiority of TMP-SMX.^{74,75}

Atovaquone (Mepron) suspension, 750 mg BID, is available for treatment of mild to moderate PCP.^{75–80} Atovaquone interrupts protozoan pyrimidine synthesis and demonstrates activity against *P. carinii* and *Toxoplasma gondii* in animal models. Thus, this compound may benefit patients with more than one OI. Atovaquone is approved by the U.S. Food and Drug Administration (FDA) for the treatment of mild to moderate PCP in patients intolerant of TMP-SMX. Atovaquone is also an alternative for primary and secondary prophylaxis for both PCP and toxoplasmosis.⁴⁸ Atovaquone is well tolerated compared with other PCP therapies. Adverse effects include rash, fever, elevated LFTs, and emesis. A comparative study with oral TMP-SMX in patients with mild to moderate PCP demonstrated fewer side effects with atovaquone but greater efficacy

with TMP-SMX.⁷⁸ When compared with IV pentamidine in the treatment of mild to moderate PCP, atovaquone and pentamidine were equally efficacious, but significantly more toxicities occurred with pentamidine.⁷⁹ Most atovaquone studies were performed using the moderately absorbed oral tablets; reformulation of this drug as a suspension has improved bioavailability by at least 30%. Concomitant administration of fatty foods with atovaquone doubles the absorption.

An oral regimen of dapsone plus TMP is another alternative to TMP-SMX. Dapsone-TMP can be used to treat mild to moderate PCP in patients intolerant of TMP-SMX. Dapsone is a sulfone antimicrobial that is used for leprosy. Although monotherapy (200 mg/day) with dapsone is ineffective for the treatment (not prophylaxis) of PCP, the addition of TMP (20 mg/kg/day) to dapsone (100 mg/day) is an effective alternative regimen.^{75,81,82} In a small comparative trial of TMP-dapsone versus TMP-SMX, response rates of 93% and 90% were observed, respectively.⁸³ When dapsone is coadministered with TMP, the resulting plasma concentrations for both drugs are higher than when either drug is taken alone. In combination with TMP, a pyrimidine, synergistic inhibition of folic acid synthesis occurs.⁸⁴ Dapsone-TMP should not be used in sulfonamide-allergic patients with a history of type I hypersensitivity reaction, toxic epidermal necrolysis, or Stevens-Johnson syndrome. Dapsone is associated with hematologic toxicities, including hemolytic anemia, methemoglobinemia, neutropenia, and thrombocytopenia. Patients with glucose-6-phosphate dehydrogenase (G6PD) deficiency cannot detoxify hydrogen peroxide⁸⁵ and are at an increased risk for hematologic toxicity from dapsone.

Clindamycin-primaquine has activity in animal models against *P. carinii*. A few trials with small sample sizes have reported success rates of 70% to 100% with clindamycin (600 mg IV Q 6 hours or 600 mg orally TID) given in conjunction with 30 mg/day of primaquine base. Although skin rashes are common with this combination, they often subside with continued therapy. Some patients experience toxicities (fever, rash, granulocytopenia, and methemoglobinemia) requiring discontinuation.^{75,83,85} As with dapsone, before starting primaquine, patients should be screened for G6PD deficiency. Patients who test positive for G6PD deficiency are at risk for developing hemolytic anemia.⁸⁵

A double-blind efficacy and toxicity study of 181 patients with mild to moderate PCP compared three oral drug regimens: TMP-SMX versus dapsone-TMP versus clindamycin-primaquine. The doses of TMP-SMX and dapsone-TMP were weight based, and the dosage of clindamycin-primaquine was 600 mg clindamycin TID and primaquine 30 mg/day. All patients with moderately severe PCP (A-a oxygen gradient >45) were treated with prednisone (40 mg BID for 5 days, then once daily for 3 weeks). The three groups differed in toxicities. Rash was the most frequent dose-limiting toxicity: TMP-SMX, 19%; dapsone-TMP, 10%; clindamycin-primaquine, 21% ($p = 0.2$). Hematologic toxicities were observed more frequently in the clindamycin-primaquine arm. Elevated LFTs (five times above baseline) were more frequent in the TMP-SMX arm ($p = 0.003$). The clindamycin-primaquine group demonstrated better quality of life scores at day 7, but by day 21 these differences became less significant.⁸² TMP-SMX, dapsone-TMP, and clindamycin-primaquine demonstrated equal efficacy in patients with mild to moderate PCP.

J.R. should be hospitalized to better manage his severe adverse reaction and to complete his treatment of PCP. Because of his severe reaction to TMP-SMX, dapsone-TMP will not be administered because dapsone is a sulfone with a high risk of cross-reaction in patients who present with severe sulfa allergies. IV pentamidine is an option for J.R., but is associated with an extensive adverse effect profile and should be reserved for patients with a more severe PCP presentation. Trimetrexate is used as a parenteral alternative to treat severe PCP in patients who are intolerant of or not responsive to TMP-SMX and IV pentamidine. Although it may be better tolerated, it is not as potent as TMP-SMX or IV pentamidine and is not readily available. Atovaquone is a reasonable option for patients with mild PCP who are intolerant to TMP-SMX and have no evidence of GI dysfunction, but it is not as effective as TMP-SMX or IV pentamidine. Clindamycin-primaquine is as efficacious as TMP-SMX for the treatment of mild to moderate PCP and can be administered orally. Consequently, it is the drug of choice in this patient.

The decision was made to start J.R. on oral clindamycin-primaquine for his mild to moderate PCP. J.R. tested negative for G6PD deficiency and was treated with clindamycin-primaquine for 14 days, completing a 21-day course of PCP therapy (Table 70-4).

Initiation of Corticosteroids

4. Should J.R. receive corticosteroid therapy with PCP treatment? When should corticosteroids be initiated, and what would be a reasonable regimen for patients with PCP?

Corticosteroids have an important role in the management of patients with acute PCP who are clinically ill and have a low PO_2 (<70 mmHg) or an A-a oxygen gradient >35 .^{86–89} Many patients who are started on PCP therapy have an acute period of clinical deterioration, which may be associated with an acute inflammatory reaction to the rapid killing of *Pneumocystis* organisms. Particularly among patients with moderate to severe PCP (A-a oxygen gradient >35 mmHg or $PO_2 <70$ mmHg on room air), the use of prednisone during the first 72 hours of treatment may prevent fatal acute deterioration.⁹⁰ Data suggest that corticosteroids may also have some benefit in patients

exhibiting acute respiratory failure after 72 hours of conventional PCP therapy.⁹¹ The recommended dosing of prednisone is 40 mg given orally twice daily for 5 days, then 40 mg/day for 5 days, and then 20 mg/day for 11 days, for a total of 21 days. Patients requiring IV corticosteroids may receive methylprednisolone at 75% of the prednisone dose. The impact of this therapy on further immunosuppression has not been clearly defined. The major concern is activation of latent infections (such as TB) or exacerbation of an active undiagnosed condition (especially fungal infections). However, the beneficial role of corticosteroids as adjunctive therapy outweighs the relative risk of short-term steroid use in this population.⁹² More common side effects of short-term corticosteroids include ulcerative esophagitis, increased appetite, weight gain, sodium and fluid retention, headache, and elevated LFTs. While corticosteroids are being given, it may be prudent for patients with a history of candidiasis to receive suppressive fluconazole therapy; those with a positive TB skin test should receive suppressive TB therapy. Corticosteroids should be used with caution in the presence of uncontrolled diabetes, active GI bleeding, and uncontrolled hypertension.⁹³

Considering his mild hypoxemia ($PO_2 >70$ mmHg), J.R. is not a candidate for corticosteroid therapy.

Prophylaxis

5. J.R. was hospitalized and responded well to treatment. He now is a candidate for secondary prophylaxis. What secondary prophylaxis would be a good choice for J.R. when he is discharged from the hospital?

The early recognized efficacy of TMP-SMX prophylaxis⁵⁰ led to the eventual widespread application of prophylaxis and the development of guidelines for PCP prophylaxis (Tables 70-2 and 70-6).^{48,94,95} A clear relationship between the $CD4^+$ count and the occurrence of PCP led researchers to conclude that most of the initial episodes of PCP could be prevented or delayed by instituting primary prophylaxis. Studies that examined HIV-infected patients who were not receiving antiretroviral agents or antimicrobial prophylaxis observed a PCP prevalence of 8.4%, 18.4%, and 33.3% at 6, 12, and 36 months, respectively, in patients with a $CD4^+$ count of <200 .⁹⁵ These

Table 70-6 Antibiotic Regimens for Prophylaxis of *Pneumocystis jirovecii* Pneumonia

| Regimen | Dose | Route |
|--|---|----------------------------|

BID, twice a day; DS, double strength; IM, intramuscularly; IV, intravenously; PO, orally; QD, daily; SMX, sulfamethazole; SS, single strength; TMP, trimethoprim.

data have formed the basis on which patients receive PCP prophylaxis. In addition to patients with CD4⁺ counts of <200, other patients at risk for PCP include those with a CD4⁺ count of <14%, a history of an AIDS-defining illness, a history of oropharyngeal candidiasis, and possibly those with CD4⁺ counts of 200 to 250.⁴⁸ J.R. refused primary prophylaxis and developed PCP. Because the expected relapse rate without prophylaxis among patients (before the use of protease inhibitors) has been documented to be 66% at 12 months' follow-up, secondary prophylaxis is necessary for J.R. to prevent recurrence.

The same agents and dosing schedules are recommended for primary (before an acute event) and secondary (after an acute event) prophylaxis of PCP.^{48,96,97} TMP-SMX, one double-strength tablet daily, is the most efficacious prophylactic regimen; a single-strength tablet daily is less toxic and nearly as efficacious.⁹⁸ Anti-*Pneumocystis* prophylaxis (TMP-SMX or dapsone) increases survival by 9 to 12 months, improves quality of life, and decreases hospitalization.^{27,31,45,48} Patients with a history of non-life-threatening rash or fever owing to TMP-SMX, such as J.R., may benefit from rechallenge with the original (or half) dose, or a dose-escalation technique (desensitization regimen). Desensitization is preferred over switching to an alternative agent and seems to be more successful than the direct rechallenge method.^{99,100} Desensitization involves initiating very low doses of TMP-SMX and gradually increasing to the maximum dose over days to weeks (Table 70-5). In addition, patients who develop PCP while receiving prophylactic doses of TMP-SMX usually respond to full therapeutic doses for acute therapy.

The alternative agents used for prophylaxis include dapsone alone, dapsone plus pyrimethamine (with leucovorin), atovaquone suspension, and aerosolized pentamidine administered by the Respigard II nebulizer (Tables 70-2 and 70-6). TMP-SMX confers additional protection against toxoplasmosis and certain bacterial infections. Regimens containing dapsone plus pyrimethamine or atovaquone with or without pyrimethamine also protect against toxoplasmosis.^{48,70,86,96,97} Investigational prophylaxis agents with unproven efficacy include oral clindamycin-primaquine, intermittently administered IV pentamidine, oral pyrimethamine-sulfadiazine, IV trimetrexate, and aerosolized pentamidine administered by other nebulizing devices.⁴⁸ TMP-SMX is more efficacious than dapsone or aerosolized pentamidine in the prevention of PCP.¹⁰¹

Extrapulmonary (e.g., lymph nodes, spleen, liver, bone marrow, adrenal gland, GI tract) *P. carinii* has been noted in patients receiving inhaled pentamidine prophylaxis,^{102,103} a finding rarely observed with IV administration. In addition, aerosolized pentamidine alters the usual chest radiograph findings associated with PCP, complicating the diagnosis of this disease. Upper lobe infiltrates, cystic lesions, pneumothoraces, cavitory lesions with nodular infiltrates, and pleural effusions have been associated with aerosolized pentamidine prophylaxis. Pentamidine prophylaxis is more expensive than TMP-SMX or dapsone but less expensive than atovaquone suspension.

The guidelines for primary prophylaxis indicate that it may be possible to discontinue prophylactic antimicrobial therapy when CD4⁺ counts rise above the threshold associated with risk for infection (i.e., <200 for PCP).^{48,49,52,56–58,104} Reports from three observational studies, one randomized trial, and a

combined analysis of eight prospectively followed European cohorts support discontinuing secondary PCP prophylaxis in patients whose CD4⁺ counts have increased to >200 for ≥3 months.^{104–108} The guidelines recommend that prophylaxis be reintroduced if the CD4⁺ count decreases to <200, or if PCP recurs at a CD4⁺ count of >200.⁴⁹

J.R. responded well to his PCP treatment with clindamycin-primaquine in the hospital. However, because this regimen is unproven for secondary prophylaxis, it cannot be recommended. Considering his intolerance to TMP-SMX, the best selections would be dapsone (with or without pyrimethamine) or atovaquone suspension.

Children

The prophylaxis of PCP in children needs further clinical research. The CD4⁺ threshold of 200 is unreliable in infants because they have higher normal values for lymphocyte counts. The current guidelines recommend administering primary PCP prophylaxis to (a) HIV-infected or HIV-indeterminate children born to HIV-infected mothers aged 1 to 12 months (prophylaxis should be discontinued for children subsequently determined not to be infected with HIV); (b) HIV-infected children ages 1 to 5 years with a CD4⁺ count <500 or CD4⁺ percentage <15%; and (c) HIV-infected children ages 6 to 12 years old with a CD4⁺ count <200 or CD4⁺ percentage <15%. One study of HIV-infected children in Zambia demonstrated a beneficial effect of cotrimoxazole on mortality and hospitalizations.^{109,110} The recommended regimen is oral TMP-SMX (150/750 mg/m²/day) twice daily three times a week on consecutive days. Acceptable alternative dosing strategies include a single oral dose given three times a week on consecutive days, or two divided doses daily, or two divided doses three times per week on alternate days. HIV-infected children with a history of PCP should be administered lifelong secondary prophylaxis to prevent recurrence, because the safety of discontinuing secondary prophylaxis among HIV-infected children has not been studied extensively.⁴⁸

Pregnancy

Primary and secondary PCP prophylaxis is recommended for all HIV-infected women who are pregnant. TMP-SMX is the recommended agent, and dapsone is an alternative. Because of the theoretical risk of teratogenicity from drug exposure during the first trimester, withholding prophylaxis until the second trimester may be considered. As an alternative during this time, aerosolized pentamidine is not systemically absorbed and may be administered during the first trimester.⁴⁸

TOXOPLASMA GONDII ENCEPHALITIS

Clinical Presentation

6. W.O. is a 40-year-old man discovered to be HIV positive during admission to a detoxification program for alcohol and heroin dependency. W.O. presented to the AIDS clinic with esophageal candidiasis, a CD4⁺ count of 60 cells/mm³ (normal, approximately 1,000 cells/mm³), a viral load of 150,000 copies/mL, and a *Toxoplasma* immunoglobulin G (IgG) titer of 1:256. W.O. was started on HAART therapy. He remained well until 2 years later, when he presented to the emergency department reporting two seizures in the past 24 hours. His medications at that time included

daily zidovudine (AZT), lamivudine, lopinavir/ritonavir, and inhaled pentamidine 300 mg monthly. His temperature was 100.1°F, and he was observed to have difficulty walking. His CD4⁺ count is 90 cells/mm³ (previously 230 cells/mm³), viral load is 70,000 copies/mL (previously 4,000), and white blood cell (WBC) count is 4,200 cells/L (normal, 3,800–9,800). A magnetic resonance image (MRI) of the head reveals several ring-shaped lesions in the brain stem. *Toxoplasma* encephalitis is presumptively diagnosed. Should W.O. be isolated from other patients and health care workers to prevent the spread of this organism?

T. gondii is a parasitic protozoan that can infect people and is spread by environmental factors, such as the consumption of raw or undercooked meats and contact with cats. Immunocompetent persons infected with *T. gondii* may develop mild symptoms resembling infectious mononucleosis. However, these symptoms are generally transient and associated with minimal problems (except in pregnant women). Recrudescence of disease from *T. gondii* is problematic in patients with a suppressed cellular immune system, including those infected with HIV. Any HIV-positive patient infected with *T. gondii* is at risk for developing clinical disease, particularly at CD4⁺ counts <100, as illustrated by W.O.^{111,112} W.O. presents with encephalitis (an inflammation of the brain or brain stem), the most frequent manifestation of *T. gondii* in HIV-positive patients.

All HIV-infected patients should be tested for IgG antibody to *T. gondii* after HIV diagnosis to detect latent infection. In the United States, as many as 70% of healthy adults are seropositive to *Toxoplasma*. The prevalence of *Toxoplasma* encephalitis among HIV-positive patients varies depending on the geographic region. In the United States, only 3% to 10% of AIDS patients actually develop encephalitis. In countries such as France, El Salvador, and Tahiti, where uncooked meat commonly is ingested, seropositivity is >90% by the fourth decade of life. *Toxoplasma* encephalitis may develop in as many as 25% to 50% of AIDS patients in these countries.¹¹¹

The two major routes of transmission of *Toxoplasma* to humans are oral and congenital. W.O. need not be isolated from other patients and health care workers. HIV-infected patients should be advised not to eat raw and undercooked meat (internal temperature of meat should be at least 165–170°F), especially patients who are IgG negative for *T. gondii*. Patients should wash their hands after touching uncooked meats and soil, and fruits and vegetables must be washed before eating. HIV-infected patients should avoid stray cats, keep their cats inside, and change the litter box daily. If no one else is available to change the litter box, patients should wash their hands thoroughly afterward.⁴⁸

Diagnosis

7. Is there sufficient clinical evidence to establish a presumptive diagnosis of *Toxoplasma* encephalitis in W.O.?

The diagnosis of *Toxoplasma* encephalitis usually is presumptive because demonstration of cysts or trophozoites in brain tissue is required for a definitive diagnosis. The clinical signs and symptoms of *Toxoplasma* encephalitis can be either focal (indicating a specific region of the brain that is infected or inflamed) or generalized (indicating diffuse inflammation of the brain). *Toxoplasma* encephalitis usually occurs in patients with CD4⁺ counts of <100. Serum titers of antibodies

against *T. gondii* typically reflect past infection with the organism and unfortunately do not help delineate whether acute infection is present. In addition, cerebrospinal fluid (CSF) polymerase chain reaction (PCR) for *Toxoplasma* is not always a reliable diagnostic tool. Without prophylaxis, 45% of seropositive HIV-infected patients develop encephalitis as a reactivation of a latent infection. Most patients with encephalitis have single or multiple lesions demonstrated on computed tomography (CT) scan or MRI of the head. Brain biopsy is reserved for patients with symptoms of encephalitis who are seronegative and for those who do not respond to presumptive antitoxoplasmosis therapy.^{111–113} Because of the nonspecific diagnosis of *Toxoplasma* encephalitis, a high index of suspicion for other causes of encephalitis (e.g., central nervous system [CNS] lymphoma or TB) should be maintained throughout the treatment period for presumed *Toxoplasma* encephalitis.¹¹² W.O. has overwhelming clinical evidence suggestive of *Toxoplasma* encephalitis. He is HIV positive, has a CD4⁺ count of <100, a positive *Toxoplasma* titer of 1:256 IgG, and a ring-shaped lesion in the brain stem on MRI. The development of this infection, in addition to the decline in CD4⁺ T cells and the increase in plasma HIV RNA concentrations, may signal antiretroviral failure. W.O.'s current antiretroviral therapy should be reassessed, including his adherence to the regimen.

Prophylaxis

8. Should W.O. have been receiving prophylactic therapy for *T. gondii*?

Similar to many other OIs associated with HIV, therapy for toxoplasmosis can be categorized into primary prophylaxis, treatment of acute disease, and secondary prophylaxis. Primary prophylaxis is currently recommended in HIV-infected patients with CD4⁺ counts of <100 who are also IgG positive for *T. gondii* (Table 70-2). Many of the agents used to prevent PCP have activity against *T. gondii* and afford protection: TMP-SMX, dapsone-pyrimethamine, and atovaquone with or without pyrimethamine are effective as primary prophylaxis for *T. gondii*.^{48,115–118} The increased use of PCP prophylaxis with these agents has significantly decreased the incidence of *Toxoplasma* encephalitis.^{2,31} The double-strength TMP-SMX tablet daily dose is recommended as first-line prophylaxis. Data do not support the use of macrolides or aerosolized pentamidine for *Toxoplasma* prophylaxis. Similarly, data are conflicting regarding the efficacy of pyrimethamine as monotherapy for primary prophylaxis.^{119,120}

Primary prophylaxis may be discontinued in patients who have responded to HAART with an increase in the CD4⁺ counts to >200 for >3 months. Multiple observational studies^{121–123} and two randomized trials^{124,125} have reported minimal risk in discontinuing *Toxoplasma* encephalitis prophylaxis in these patients. In these studies, median follow-up ranged from 7 to 22 months. Primary prophylaxis should be reinstated when CD4⁺ counts drop below 200.

W.O. is currently receiving inhaled pentamidine for PCP prophylaxis. Because of the localized delivery of inhaled pentamidine, this agent has no antitoxoplasmosis activity, so W.O. was at risk for the development of *Toxoplasma* encephalitis. Considering his CD4⁺ count and IgG seropositivity, he should have received primary prophylaxis for *T. gondii*.

Treatment

Acute Therapy

9. How should W.O.'s presumptive *Toxoplasma* encephalitis be treated?

Approximately 80% of patients with acute *Toxoplasma* encephalitis can be treated successfully with a combination of sulfadiazine 4 g/day in three or four daily divided doses and pyrimethamine as a single 200-mg loading dose, followed by 50 to 75 mg/day as a single daily dose plus leucovorin 10 to 25 mg orally every day.^{111,112} Induction therapy should be continued for 6 weeks after resolution of symptoms (a treatment course of approximately 8 weeks) followed by maintenance therapy (secondary prophylaxis). Sulfadiazine toxicity may limit the completion of a full course of therapy in as many as 40% of patients.¹²⁶ However, successful desensitization has been documented.¹²⁷ W.O.'s clinical and radiologic response should be monitored closely and other diagnoses considered if there is no improvement.

Alternative therapy includes pyrimethamine plus leucovorin with clindamycin 600 to 900 mg IV Q 6 to 8 hours or 300 to 450 mg orally Q 6 hours for at least 6 weeks. One controlled trial compared the efficacy and tolerability of pyrimethamine plus sulfadiazine versus pyrimethamine plus clindamycin. Although both regimens were effective, pyrimethamine-sulfadiazine was found to be superior to pyrimethamine-clindamycin. The risk of progression of *Toxoplasma* encephalitis was higher for patients who received pyrimethamine-clindamycin therapy. Furthermore, the rate of relapse was twice as high in the pyrimethamine-clindamycin group. The rate of side effects was similar with both regimens; however, pyrimethamine-clindamycin led to fewer discontinuations than pyrimethamine-sulfadiazine (11% versus 30%, respectively).¹²⁸ Additionally, anticonvulsants should be given to patients with *toxoplasma* encephalitis and a history of seizures and corticosteroids may be warranted for focal lesions and/or edema, but should be used cautiously.

10. W.O. is treated with sulfadiazine-pyrimethamine. What are the limitations to the use of the sulfadiazine component for the treatment of *Toxoplasma* encephalitis?

As with other sulfonamides in HIV patients, rashes commonly occur with sulfadiazine therapy.¹²⁶ Similar to TMP-SMX, various desensitization regimens have been recommended^{69,127}; however, it may be simpler to use alternative regimens.

Renal function should be monitored throughout therapy.^{129–133} Elevated serum creatinine (SrCr) levels, hematuria, or decreased urine output may occur secondary to sulfadiazine-induced crystalluria. The water solubility of sulfadiazine is less than that of other sulfonamides; therefore, hydration (2–3 L/day) is needed to prevent crystalline nephropathy, and aggressive hydration and alkalinization can be used in cases of crystal formation. Although few manufacturers market sulfadiazine, this drug is available from the CDC and from Eon Labs Manufacturing, Inc.^{134,135}

11. What toxicities are associated with the pyrimethamine component?

Pyrimethamine can suppress bone marrow function; thus, concomitant therapy with other medications that suppress mar-

row function (e.g., AZT or ganciclovir) may not be tolerated. Leucovorin (10–25 mg/day) is always given in conjunction with pyrimethamine to maintain bone marrow function, although it may not always be successful. Folic acid (not folinic acid) should be avoided because it can be used for growth by protozoal organisms, potentially antagonizing pyrimethamine-sulfadiazine activity.^{136–138} Vitamin preparations containing large quantities of folic acid should be discontinued during therapy for *T. gondii*.

W.O. is not taking any medications that would make him particularly susceptible to the myelosuppressive effects of pyrimethamine and he is not neutropenic. Consequently, he should be given sulfadiazine and pyrimethamine.

Suppressive Therapy (Secondary Prophylaxis)

12. Once W.O. has completed acute therapy for his *Toxoplasma* encephalitis, should he receive suppressive therapy?

Most antiprotozoal agents do not eradicate the cyst form of *T. gondii*. Therefore, patients should be administered lifelong suppressive therapy unless immune reconstitution occurs as a consequence of HAART. The combination of pyrimethamine plus sulfadiazine plus leucovorin is very effective. Pyrimethamine (25–75 mg/day) plus sulfadiazine (500–1,000 mg PO QID) plus leucovorin is significantly more efficacious than taking this combination twice weekly.¹³⁹ A commonly used regimen for patients who cannot tolerate sulfa drugs is pyrimethamine plus clindamycin.¹⁴⁰ However, only the combination of pyrimethamine plus sulfadiazine provides protection against PCP as well. Additionally, one retrospective chart review of 35 patients receiving maintenance therapy for *Toxoplasma* encephalitis suggested that sulfadiazine-pyrimethamine was more effective than clindamycin-pyrimethamine or pyrimethamine alone.¹⁴¹ Low-dose, intermittent pyrimethamine monotherapy has been associated with an unacceptably high rate of mortality.¹⁴² The use of atovaquone with or without pyrimethamine is also effective as prophylaxis for both *toxoplasma* and PCP.

Patients receiving secondary prophylaxis are at low risk for recurrence of *Toxoplasma* encephalitis when they have completed initial therapy for *Toxoplasma* encephalitis, remain asymptomatic, and have a sustained increase in their CD4⁺ count to >200 after HAART therapy for >6 months. Clinicians may obtain a brain MRI as part of the evaluation to determine whether to discontinue therapy. There are data to support that discontinuation of primary and secondary prophylaxis for toxoplasmosis is safe if patients are receiving effective antiretroviral therapy and their CD4 count has increased to >200 for ≥3 months.¹²⁵ Secondary prophylaxis should be reintroduced if the CD4⁺ count decreases to <200.

Children aged >12 months who qualify for PCP prophylaxis and who are receiving an agent other than TMP-SMX or atovaquone should have serologic testing for *Toxoplasma* antibody. Severely immunosuppressed children who are not receiving TMP-SMX or atovaquone and are found to be seropositive for *Toxoplasma* should receive prophylaxis for both PCP and toxoplasmosis (i.e., dapsone plus pyrimethamine). Children with a history of toxoplasmosis should be given lifelong prophylaxis to prevent recurrence. The safety of discontinuing primary or secondary prophylaxis among HIV-infected children receiving HAART has not been studied extensively.

In pregnancy, TMP-SMX can be administered for prophylaxis against *Toxoplasma* encephalitis as described for PCP. Because of the possible risk associated with pyrimethamine treatment and the low incidence of *Toxoplasma* encephalitis during pregnancy, chemoprophylaxis with pyrimethamine-containing regimens can reasonably be deferred until after pregnancy. In rare cases, HIV-infected pregnant women who have serologic evidence of toxoplasmic infection have transmitted *Toxoplasma* to the fetus in utero. However, there are no specific guidelines for continuing secondary prophylaxis during pregnancy. Pregnant HIV-infected women who have active toxoplasmosis or evidence of a primary toxoplasmic infection should be evaluated and managed in consultation with appropriate specialists. Infants born to women who have serologic evidence of infections with HIV and *Toxoplasma* should be evaluated for congenital toxoplasmosis.

W.O. will be continued on sulfadiazine-pyrimethamine for suppressive therapy for his *Toxoplasma* encephalitis because his CD4⁺ count has decreased to <100. W.O. is currently receiving aerosolized pentamidine for PCP prophylaxis, but because sulfadiazine-pyrimethamine is also protective against PCP, the aerosolized pentamidine can be discontinued. Clindamycin-pyrimethamine is an inferior option because it does not protect against PCP.^{48,140}

Alternative Therapies

13. What treatment options exist for patients who cannot tolerate sulfadiazine and do not wish to undergo desensitization?

Clindamycin can be substituted for sulfadiazine in the acute treatment of toxoplasmosis (900–1,200 mg IV Q 6 hours or 300–450 mg PO Q 6 hours) plus pyrimethamine and leucovorin at standard doses.^{140,143–145,146} Monotherapy with atovaquone,^{147–151} trimetrexate, and the tetracyclines, doxycycline and minocycline, has been successful.⁴⁹

Combination therapy with pyrimethamine and folinic acid plus azithromycin (1.2–1.5 g/day), clarithromycin (1 g BID), or atovaquone (750 mg PO QID) was relatively successful in non-comparative trials with limited numbers of patients.^{111,151,152}

CYTOMEGALOVIRUS DISEASE

Diagnosis

14. P.Z., a 39-year-old man with AIDS, complains of floating spots, light flashes, and difficulty reading road signs when he drives. His most recent BUN was 17 mg/dL (normal, 8–25) and SrCr was 0.8 mg/dL (normal, 0.5–1.7). His CD4⁺ count was 40 cells/mm³ (normal, approximately 1,000), and his viral load was 80,000 copies/mL 3 months ago. His current weight is 63 kg. P.Z.'s medications include tenofovir, emtricitabine, atazanavir, ritonavir, dapsone (PCP prophylaxis), and azithromycin (MAC prophylaxis). He has a history of hematologic intolerance to AZT and TMP-SMX. His WBC count is 1,200 cells/L (normal, 3,800–9,800) with 63% polymorphonuclear neutrophil leukocytes. P.Z. is known to have a positive CMV IgG antibody titer. Funduscopic examination reveals alternating areas of hemorrhage and scar tissue (a “cottage cheese and ketchup” appearance) in the proximity of the retina in his left eye. What is the likely cause of P.Z.'s visual problems?

[SI units: BUN, 6.07 mmol/L (normal, 2.9–8.9); SrCr, 70.72 mol/L (normal, 44–150); WBC count, $1.2 \times 10^{10}/L$ (normal, 3.8–9.8) with 0.63 polymorphonuclear neutrophil leukocytes]

P.Z. seems to have an inflammation of the retina (retinitis), most likely because of CMV. Many HIV patients have been previously infected with CMV, and reactivation typically occurs when CD4⁺ counts are <50. Before HAART, the prevalence of CMV disease in HIV patients with a CD4⁺ count of <50 was 20% to 40%, and the incidence varied between 15 and 20 per 100 patient-years. Since the introduction of HAART, a more than fivefold decrease in the incidence of CMV disease has been reported by several authors.¹⁵⁴ Although CMV can cause colitis, pneumonitis, esophagitis, hepatitis, and neurologic disease, retinitis is the most common manifestation of active infection. CMV retinitis in HIV patients accounts for 75% to 85% of CMV end-organ disease. A recent investigation describing patients with CMV retinitis in the post-HAART era found a diverse demographic group with infection; most of them had received HAART; and as expected they had very low CD4 counts.¹⁵⁵ In addition, characteristics of the disease in this group were similar to those in the pre-HAART era. A panel of physicians with clinical and virologic expertise was convened by the International AIDS Society to review the available data and develop recommendations for treatment and diagnosis of CMV disease.⁴⁴ Diagnosis is usually presumptive because biopsy is difficult given the inaccessibility of the retina. Serology is indicative of previous CMV infection but not active disease. Cultures (serum, urine, and/or saliva) may be useful for monitoring therapy, considering that patients frequently have disseminated CMV disease. Patients with positive cultures for CMV, while receiving therapy, may be at a higher risk for relapse.¹⁵⁶ Typically, the diagnosis of CMV retinitis is based on observations made during a dilated retinal examination and indirect ophthalmoscopy, as was done for P.Z. Lesions appear as fluffy, white retinal patches with retinal hemorrhage.

Once CMV retinitis is diagnosed, the patient should be thoroughly examined for extraocular CMV disease. P.Z. will require regular ophthalmologic examinations, along with retinal photographs, for life. As with HIV therapy, CMV DNA quantification in plasma or blood cells by quantitative branched-chain DNA (b-DNA) or PCR may have a role in evaluating treatment efficacy and predicting symptomatic development of CMV disease.^{157–159}

Drug Therapy

15. What are the treatment options for CMV retinitis, and which one would be preferred for P.Z.?

Several treatment options exist for CMV retinitis: oral valganciclovir, IV ganciclovir, IV ganciclovir followed by oral valganciclovir, IV foscarnet, IV cidofovir, and ganciclovir intraocular implants with valganciclovir for induction and maintenance therapy. Alternatives include combined IV ganciclovir plus foscarnet, intraocular injections of ganciclovir, foscarnet, cidofovir, or fomivirsen sodium (Vitrvane).^{44,160–162} The efficacy of combined parenteral ganciclovir and foscarnet is similar to monotherapy, but it is more toxic. This latter therapy should be reserved for patients with refractory disease (Table 70-7).¹⁶³

Intraocular implants and intraocular injections of ganciclovir have similar efficacy in the treatment of CMV retinitis,

Table 70-7 Treatment of Cytomegalovirus Retinitis^a

| | IV Ganciclovir | Valciclovir | IV Foscarnet | Combination IV Ganciclovir and IV Foscarnet Sodium | IV Then Oral Ganciclovir | Intraocular Ganciclovir Implant | IV Cidofovir |
|--|--|--|---|---|---|--|--|
| Dosing regimens | <i>Induction:</i> 5 mg/kg Q 12 hr for 14–21 days <i>Maintenance:</i> 5 mg/kg QD | <i>Induction:</i> 900 mg Q 12 hr for 14–21 days <i>Maintenance:</i> 900 mg QD | <i>Induction:</i> 90 mg/kg Q 12 hr for 14–21 days <i>Maintenance:</i> 90–120 mg/kg QD; 750–1,000 mL of 0.9% saline or D ₅ W solution with each dose | <i>Prior ganciclovir induction:</i> both IV foscarnet 90 mg/kg Q 12 hr and IV ganciclovir 5 mg/kg QD for 14–21 days <i>Maintenance:</i> both IV foscarnet 90–120 mg/kg and IV ganciclovir 5 mg/kg QD | <i>Induction:</i> same as IV ganciclovir <i>Maintenance:</i> 3,000–6,000 mg/day in 3 divided doses with food | <i>Surgical:</i> intraocular implantation of ganciclovir (4.5 mg) implant releasing 1 mg/hr (duration 68 months; then replacement required every 58 months) <i>Maintenance:</i> 5 mg/kg every 2 wk (<i>Note:</i> dose reduction to 3 mg/kg for SrCr by 0.3–0.4 mg/dL above baseline; all doses given with probenecid and IV fluid) | <i>Induction:</i> 5 mg/kg every wk for 2 wk |
| Refractory disease induction: 7.5 mg/kg Q 12 hr for 14–21 days | <i>Alternative regimen:</i> with ganciclovir intraocular implant 900 mg QD | | | <i>Prior foscarnet sodium induction:</i> both IV ganciclovir 5 mg/kg Q 12 hr and IV foscarnet 90–120 mg/kg QD | | | |
| <i>Maintenance:</i> 10 mg/kg QD (<i>Note:</i> dosage should be adjusted for creatinine clearance <70 mL/min; see Table 70-8.) | | | | <i>Reinduction:</i> IV ganciclovir 5 mg/kg and IV foscarnet 90 mg/kg Q 12 hr for 14–21 days | | | |
| Select adverse effects | Neutropenia, thrombocytopenia, catheter sepsis | Same as ganciclovir | Nephrotoxicity, electrolyte abnormalities, anemia, catheter sepsis, nausea/irritability, genital ulceration | Same as IV ganciclovir and IV foscarnet | Neutropenia, diarrhea/nausea | <i>Surgical complications:</i> transient blurred vision, infection, hemorrhage | Nephrotoxicity, neutropenia, probenecid adverse effects (rash, fever, nausea, fatigue), uveitis, alopecia, hypotonia |

| | | | | | | |
|------------------------------------|---|---|---|--|--|--|
| Important drug interactions | Neutropenia, with AZT, cancer chemotherapy didanosine levels | Same as ganciclovir | Nephrotoxicity with other nephrotoxic drugs (e.g., amphotericin B, aminoglycosides, IV pentamidine) | Same as IV ganciclovir and IV foscarnet | Same as IV ganciclovir | Nephrotoxicity with other nephrotoxic drugs (e.g., amphotericin B, aminoglycosides, IV pentamidine, NSAIDs) Probenecid: Level of most proximal tubular-excreted drugs |
| Adjunctive therapy | G-CSF/GM-CSF effective for neutropenia | Same as ganciclovir | IV or oral hydration essential; potassium, calcium/magnesium supplements, antiemetics may be required | Same as both IV ganciclovir and IV foscarnet | Same as IV ganciclovir | Systemic anti-CMV therapy recommended (oral ganciclovir, 4,500 mg/day) |
| Advantages | Systemic therapy; anti-HSV activity | Increased bioavailability and decreased pill count compared with PO ganciclovir | Systemic therapy; anti-HSV (acyclovir-resistant) activity; anti-HIV activity | Increased efficacy compared with either IV ganciclovir or IV foscarnet alone; improved response for relapsed disease | Systemic therapy; oral administration; fewer catheter/sepsis complications | Systemic therapy; no indwelling catheter required; infrequent dosing |
| Disadvantage | Hematologic toxicity; requires daily infusions; indwelling catheter | Must have adequate GI absorption; less clinical data than with ganciclovir | Nephrotoxicity; requires daily infusions/indwelling catheter; supplemental hydration required; prolonged infusion time; requires infusion pump or controlled rate infusion device | Same as IV ganciclovir and IV foscarnet; prolonged daily infusion time and impact on quality of life | Faster time to reinitiation; high pill count; poor oral bioavailability (6%) | Requires probenecid and IV hydration; probenecid toxicity; nephrotoxicity (may be prolonged) |
| Monitoring requirement | Induction therapy: (a) CBC with WBC differential, platelet count weekly; (b) SrCr weekly | Same as ganciclovir | Induction therapy: (a) SrCr twice weekly; (b) serum Ca ⁺⁺ , albumin Mg ⁺⁺ , phosphates, and K ⁺ twice weekly; (c) Hgb and Hct weekly | Same as both IV ganciclovir and IV foscarnet | Induction therapy: IV ganciclovir | Within 48 hr before each induction and maintenance: (a) SrCr quantitation proteinuria; (b) WBC with differential cell count; monitor intraocular pressure and slit-lamp examination at least monthly |

but their benefit is localized and they may lead to an increased risk of contralateral retinitis and extraocular CMV disease. Concomitant systemic anti-CMV therapy is therefore recommended (e.g., oral valganciclovir or IV ganciclovir). Use of ganciclovir intraocular implants with oral valganciclovir has shown to be more effective at preventing relapse of retinitis than IV ganciclovir and likely oral valganciclovir.^{164,165} Therefore, many providers prefer this as first-line therapy, although others chose oral valganciclovir as first line. The choice of agents typically depends on drug efficacy, toxicity, stage of disease, and quality-of-life issues.

Ganciclovir

Ganciclovir is an acyclic nucleoside with CMV activity superior to acyclovir.^{166,167} Similar to other nucleosides, ganciclovir must be taken into cells and phosphorylated before it can compete with endogenous nucleotides for binding to viral DNA polymerase.¹⁶⁸ Ganciclovir is poorly absorbed orally (bioavailability, approximately 5%–9%) and its disposition is biexponential after IV administration (terminal half-life, approximately 2.5 hours). The total body clearance is highly dependent on glomerular filtration and tubular secretion.¹⁶⁹

The induction dose of ganciclovir is 5 mg/kg per dose Q 12 hours IV for 14 to 21 days. It is approximately 80% effective in delaying the progression of CMV retinitis.^{44,170–172} The dose-limiting toxicity is bone marrow suppression, with neutropenia occurring in approximately 50% of patients. Thrombocytopenia is also observed. Absolute neutrophil counts (ANCs) and platelets should be monitored weekly during ganciclovir therapy. If the ANC falls to $<1,000$ cells/mm³ or the platelet count to $<50,000$ /mm³, the monitoring frequency should be increased to twice weekly.^{44,173} Ganciclovir is available in two other dosage forms, oral capsules and an intraocular implant (Table 70-7).^{44,48} Dosage adjustments must be made in patients with renal dysfunction (Table 70-8).

Patients who develop ganciclovir-induced bone marrow suppression can be given granulocyte colony-stimulating factor (G-CSF). Both G-CSF (filgrastim) and granulocyte-macrophage colony-stimulating factor (GM-CSF [sargramostim])^{174,175} have been used successfully. Although neither of these agents is FDA approved for this indication, use of the colony-stimulating factors may result in sight-saving or life-prolonging therapy. Because GM-CSF may stimulate HIV replication in macrophage cell lines,^{176,177} patients should receive concomitant antiretroviral therapy.

Valganciclovir

Valganciclovir is an oral monoethyl ester prodrug that is rapidly hydrolyzed to ganciclovir. The absolute bioavailability of ganciclovir from valganciclovir is 60%, and a dose of 900 mg results in ganciclovir blood concentrations similar to those obtained with a dose of 5 mg/kg of IV ganciclovir. The effects of oral valganciclovir to those of IV ganciclovir as induction therapy for newly diagnosed CMV retinitis were compared in patients with AIDS.¹⁶⁵ Seventy-seven percent of patients in the IV ganciclovir group and 72% of patients in the valganciclovir group had a satisfactory response to induction therapy. The median times to progression of retinitis were 125 days in the IV ganciclovir group and 160 days in the oral valganciclovir group. The mean values for the area under the curve (AUC) for the ganciclovir dosage interval were similar at both induction

doses and maintenance doses. The frequency and severity of adverse events were similar in the two groups. Based on these data, oral valganciclovir is as effective as IV ganciclovir for induction treatment and is convenient and effective for the long-term management of CMV retinitis in patients with AIDS.

Cidofovir

Cidofovir is a nucleotide analog that is phosphorylated intracellularly to an active diphosphate metabolite. It is the most potent of all the available anti-CMV compounds and is active against herpes simplex virus (HSV) and VZV, including the acyclovir-resistant isolates. Cidofovir does not require viral activation. Because nucleotide analogs do not require virally encoded kinases for their activity, they remain a treatment option for patients who have failed to respond to ganciclovir. Cidofovir is poorly absorbed orally (bioavailability, $<5\%$) and has an intracellular half-life of 17 to 65 hours, resulting in once-weekly induction and every-other-week maintenance therapy. This feature substantially enhances the quality of life relative to foscarnet or ganciclovir, which must be administered much more frequently.

Eighty percent of this poorly soluble agent is excreted unchanged in the urine via filtration and tubular secretion. Cidofovir is nephrotoxic; however, administration of probenecid (2 g administered 3 hours before the start of infusion and two 1-g doses administered at 2 and 8 hours after infusion) blocks tubular secretion and reduces nephrotoxicity. Prehydration with 1 L of normal saline is required 1 hour before each dose and, if tolerated, repeated concomitantly with or after the cidofovir infusion. Because nephrotoxicity is the most significant dose-limiting toxicity, other nephrotoxic agents should be discontinued (e.g., nonsteroidal anti-inflammatory drugs, aminoglycosides), and renal function should be carefully monitored throughout therapy (BUN, SrCr, proteinuria) (Table 70-7). Dosage adjustments must accompany deterioration in renal function (Table 70-8).

The CBC should be checked at baseline because neutropenia has been reported in approximately 20% of patients in clinical trials. Hypotony (reduction in intraocular pressure) and uveitis (inflammation of the uveal tract of the eye) have also been reported. Thus, monthly intraocular pressure checks and slit-lamp examinations of the retina are necessary.^{44,178,179}

The role of cidofovir remains unclear. It offers the advantage of weekly and biweekly dosing, but its toxicity greatly limits its utility. Cidofovir appears to be as efficacious as foscarnet and ganciclovir in the treatment of CMV retinitis, but no comparative studies have been performed. Finally, the efficacy of cidofovir in the treatment of extraocular CMV (e.g., GI disease, pneumonitis, encephalitis) remains to be established.^{44,178,179}

Foscarnet

Foscarnet is a pyrophosphate analog that acts by selectively inhibiting viral DNA polymerases and reverse transcriptase. At doses currently recommended for induction therapy (60 mg/kg Q 8 hours or 90 mg/kg IV Q 12 hours), peak plasma foscarnet concentrations are attained that should inhibit CMV in vitro (Table 70-7).¹⁸⁰ The dose-limiting toxicity of foscarnet is nephrotoxicity, probably because its poor solubility results in crystallization in nephrons.^{173,181}

In one prospective randomized trial, patients receiving foscarnet for CMV retinitis survived approximately 4 months

Table 70-8 Dosage Adjustment for Cytomegalovirus Medications

| Drug | Normal Dosage | CrCl (mL/min/1.73 m ²) | Adjusted Dosage |

BID, twice a day; BIW, twice a week; IV, intravenously; QD, daily; QOW, every other week; QW, weekly; SrCr, serum creatinine; TID, three times a day; TIW, three times a week. Modified from references 46, 48, and product information.

longer than those receiving ganciclovir.¹⁸² However, foscarnet-treated patients with reduced creatinine clearance (<1.2 mL/min/kg) had a poor survival rate. Whether the improvement was because of the anti-HIV activity of foscarnet or the ability of foscarnet-treated patients to continue receiving AZT (which was not the case with ganciclovir) is unknown and remains controversial.^{183,184}

Because P.Z. has a low ANC, the bone marrow suppressive effects of ganciclovir and valganciclovir are of concern. Adjunctive therapy with G-CSF is an option. Because he has good renal function (SrCr of 0.8 mg/dL), foscarnet or cidofovir probably would be preferred.

NEPHROTOXICITY

16. P.Z. will receive foscarnet, 90 mg/kg IV over 2 hours Q 12 hours. How can the risk of nephrotoxicity be minimized?

During foscarnet therapy, adequate hydration is important to prevent nephrotoxicity. To establish diuresis, 750 to 1,000 mL of normal saline or 5% dextrose should be administered before the first infusion of foscarnet. With subsequent infusions, 500 to 1,000 mL should be administered, depending on the foscarnet dose. Careful dosage titration based on P.Z.'s estimated creatinine clearance may also minimize nephrotoxicity (Table 70-8). The SrCr clearance should be measured at least twice weekly and the dosage recalculated if the creatinine clearance changes. CMV infection itself may also cause an acute increase in the SrCr owing to acute interstitial nephritis. Drugs with nephrotoxic potential, such as amphotericin B or aminoglycosides, should be avoided if possible.^{181,182}

ADVERSE EFFECTS

17. What toxicities other than nephrotoxicity have been associated with foscarnet therapy?

Hypocalcemia can occur because foscarnet, a pyrophosphate analog, can bind to unbound calcium. Electrolyte complications can be minimized by avoiding high foscarnet plasma concentrations. Therefore, foscarnet should be infused slowly over 1 to 2 hours.¹⁸⁵ Unbound serum calcium and phosphate levels should be monitored twice weekly during induction therapy and weekly during maintenance therapy, ideally when foscarnet is at its highest concentration. Fatal hypocalcemia occurred in an AIDS patient receiving both foscarnet and parenteral pentamidine; thus, coadministration of these drugs should be avoided.¹⁸⁴

Penile ulceration from foscarnet has been problematic, especially in uncircumcised men. Characterized as a fixed-drug eruption, careful attention to genital hygiene may minimize the potential for penile ulceration. Other adverse events associated with foscarnet include seizures, hypomagnesemia, anemia, nausea, fever, and rash. Twice-weekly albumin, magnesium, and potassium levels are required during induction therapy and then weekly during maintenance therapy. In general, patients tolerate foscarnet more poorly than ganciclovir.¹⁸⁶

DOSAGE ADJUSTMENTS

18. After 12 days of foscarnet therapy, P.Z.'s SrCr has increased from 0.8 mg/dL to 1.2 mg/dL despite the coadministration of 2 L of normal saline daily. What dosage adjustments should be made for the remainder of the foscarnet treatment?

[SI units: SrCr, 70.72 and 106.08 mol/L, respectively]

Valganciclovir, ganciclovir, foscarnet, and cidofovir are highly dependent on renal elimination, and dosages (or dosing intervals) should be adjusted for even a modest reduction in renal function (Table 70-8). For example, the creatinine clearance threshold for dosage reduction of ganciclovir is 70 mL/1.73 m²/min; for dosage reduction of foscarnet, it is 1.6 mL/min/kg. In contrast, the renal threshold for acyclovir and many other drugs is a creatinine clearance of <50 mL/min. Therefore, careful monitoring of renal function is important throughout CMV therapy. P.Z.'s estimated creatinine clearance is 1.2 mL/min/kg; therefore, his foscarnet induction dosage should be adjusted to 70 mg/kg IV Q 12 hours (Table 70-8).^{44,183}

Ganciclovir-Foscarnet Combination

In a prospective, randomized, controlled trial of patients with persistent or relapsed retinitis, ganciclovir and foscarnet monotherapy were compared with combination low-dose therapy.¹⁶³ Mortality and adverse effects were similar in all three groups. However, combination therapy was associated with significantly delayed time to retinitis progression (median 1.3 and 2 months with foscarnet and ganciclovir monotherapy, respectively, versus 4.3 months in the combination arm). However, the overall prolonged daily infusion time (up to 4 hr/day) and adverse effects detracted from quality of life.¹⁶³ Consequently, combination therapy should be reserved for more refractory cases of CMV retinitis^{187,188} (see Relapse or Refractory Retinitis).

Suppression Therapy

19. P.Z. completes 21 days of foscarnet induction therapy. How can his CMV retinitis be suppressed in the future?

The currently available antiviral agents used to treat CMV disease are not curative. After induction therapy, chronic maintenance therapy is indicated for the remainder of P.Z.'s life, unless immune reconstitution occurs as a result of HAART. Regimens that have been shown to be effective in randomized controlled clinical trials include parenteral or oral ganciclovir, parenteral foscarnet, combined parenteral ganciclovir and foscarnet, parenteral cidofovir, and (for retinitis only) ganciclovir administration via intraocular implant or repetitive intravitreal injections of fomivirsen. Oral valganciclovir is approved for both acute induction and maintenance therapy, but the published clinical data are limited. The current guidelines do not include this as a preferred option for maintenance, but this may change in the future. In uncontrolled case series, repeated intravitreal injections of ganciclovir, foscarnet, and cidofovir have been shown to be effective for prophylaxis of CMV retinitis. However, because this therapy is effective only locally and does not protect the contralateral eye or other organ systems, it is usually combined with oral ganciclovir.

Foscarnet 90 mg/kg Q 12 hours as IV induction for 14 to 21 days is usually followed by IV foscarnet 90 to 120 mg/kg/day as a single daily maintenance dose. The maintenance dose of 120 mg/kg/day is more efficacious, but may be more toxic than the lower maintenance dose.^{189,190} Ganciclovir IV induction (5 mg/kg/dose Q 12 hours) may be followed by IV ganciclovir maintenance (5 mg/kg/day 5–7 times per week). Ganciclovir IV induction may also be followed by oral ganciclovir 3,000 to

6,000 mg daily in three divided doses administered with food. Cidofovir, with induction doses of 5 mg/kg IV each week for 2 weeks followed by a maintenance dose of 5 mg/kg IV every 2 weeks, offers a more convenient dosing schedule and negates the need for an indwelling IV catheter (Table 70-7).

Guidelines suggest that discontinuation of prophylaxis may be considered in patients with CMV retinitis who are taking HAART with a sustained (>6 months) increase in the CD4⁺ count to >100 to 150. These patients must have remained disease free for >30 weeks. The decision to discontinue suppression should be based on the magnitude and duration of the CD4⁺ increase and viral load suppression, the anatomical location of the retinal lesions, and the degree of vision loss. An ophthalmology consultation is recommended.⁴⁸ All patients who have had anti-CMV maintenance therapy discontinued should continue to undergo regular ophthalmologic monitoring for early detection of CMV relapse as well as for immune reconstitution uveitis.

Relapse or Refractory Cytomegalovirus Retinitis

20. After 5 months of maintenance therapy with foscarnet, a routine funduscopic examination reveals retinal CMV disease progression. How should P.Z.'s retinitis be managed at this time?

Most patients with CMV disease eventually relapse.^{44,190} For the first relapse, repeat induction therapy followed by maintenance therapy with the same drug is beneficial in most patients. Because P.Z. has tolerated foscarnet therapy thus far, he should receive another course of induction therapy. After reinduction, P.Z. should receive a higher maintenance dosage (120 g/kg/day).⁴⁸

It is important to distinguish between relapse and refractory disease. Relapse, as in the case of P.Z., is defined as recurrence of clinically apparent viral activity and is usually caused by a decline in immune function, insufficient delivery of drug into the eye, or resistant CMV strains. Relapse can be effectively managed by repeat induction therapy of the same drug.⁴⁴ If the relapse is due to a resistant virus, the patient may benefit from a change in therapy. Ganciclovir-resistant CMV strains occur by two mechanisms. DNA polymerase mutation at the UL54 gene is observed in approximately 20% of ganciclovir-resistant strains. This mutation usually confers resistance to cidofovir and, to a lesser extent, foscarnet.^{44,191,192} Most ganciclovir-resistant CMV strains have UL97 mutations. UL97 mutations are incapable of monophosphorylating ganciclovir. Cidofovir and foscarnet are appropriate alternatives to treat strains with UL97 mutations. Patients who receive extensive ganciclovir treatment (>6–9 months) may present with highly ganciclovir-resistant strains containing UL54 and UL97 mutations.¹⁹³ Cidofovir may be considered in most patients who relapse while receiving ganciclovir or foscarnet. Although ganciclovir- and foscarnet-resistant strains of CMV have been reported, their precise role in the clinical failure of these regimens is not known.¹⁹⁴ Because of the different mechanisms of action of ganciclovir and foscarnet, strains resistant to one drug may retain sensitivity to the other.^{191,195} Resistant or relapsing CMV retinitis may be treated by administration of local ocular therapy via intravitreal injection of ganciclovir, foscarnet, or fomivirsen. Fomivirsen is a phosphorothioate oligonucleotide that inhibits the replication of the human CMV through an anti-

sense mechanism. Fomivirsen has potent activity against CMV, including strains resistant to ganciclovir, foscarnet, and cidofovir. Fomivirsen demonstrates a 30-fold greater local activity than ganciclovir.^{194,196,197} Ganciclovir intraocular implants are also a potential option (see Local Treatment).

Refractory CMV retinitis is defined by disease progression because of ineffective therapy. This phenomenon is observed in two clinical situations: when the disease persists with minimal or no response during induction therapy, and when long-term control is inadequate with maintenance therapy. Refractory CMV disease has been defined in clinical trials as two relapses occurring within 10 weeks despite repeat induction and maintenance therapy. Treatment options for refractory CMV retinitis include reinduction with ganciclovir at higher dosages (7.5 mg/kg/dose Q 12 hours, followed by maintenance doses of 10 mg/kg/day) or reinduction using combination therapy (IV ganciclovir plus foscarnet).⁴⁴ Refractory CMV retinitis can be treated with local ocular therapy via intravitreal injection of ganciclovir, foscarnet, or fomivirsen as well as intraocular implants.^{194,196,197}

Local Treatment

Intravitreal Injections

21. What is the role of intravitreal injections in CMV retinitis?

Intravitreal administration of ganciclovir or foscarnet through a small-gauge needle is a method of selectively delivering the drug to the site of infection.^{44,198–200} Ganciclovir and foscarnet doses of 0.2 to 2 mg and 1.2 to 2 mg, respectively, are administered two or three times per week for active disease, followed by weekly maintenance injections. Intravitreal fomivirsen induction 330 g (0.05 mL) once a week for 2 doses (days 1 and 15) followed by maintenance doses once every 4 weeks also has been used.¹⁹⁷ Potential complications of intravitreal injections include bacterial endophthalmitis, vitreous hemorrhage, and retinal detachment. Ocular inflammation, with iritis and vitritis, is the most frequently observed adverse experience with fomivirsen (25%); this complication usually responds to topical corticosteroids.¹⁹⁷ Intravitreal therapy is relatively uncommon because intraocular implants are available. Importantly, in contrast with systemic therapy, local instillation of a drug is associated with a higher risk of CMV disease developing in the contralateral eye as well as extraocular sites (Table 70-7).

Intraocular Ganciclovir Implants

22. Is P.Z. a candidate for ganciclovir intraocular implants?

The intraocular implant is a surgically implantable delivery device (Vitrasert implant) capable of delivering ganciclovir into the vitreous humor at a constant rate of approximately 1 g/hr over a period of 5 to 8 months.^{160,201–203} The implant delivers a much higher concentration into the vitreous cavity than can be achieved with systemic therapy. Implants may be an acceptable initial choice for newly diagnosed patients or patients with imminently sight-threatening disease. Surgical complications, such as retinal detachments, infections, and hemorrhage, can occur during or after the procedure. To reduce the risk of contralateral retinitis or extraocular CMV disease,

patients receiving the intraocular implant should also be given oral ganciclovir (1,000 mg TID) (Table 70-7).²⁰⁴

P.Z. should be reinduced with foscarnet therapy and maintained on a higher foscarnet dose. Neither alternating regimens nor intravitreal administration of antiviral agents is appropriate at present.

Oral Ganciclovir

23. What is the role of oral ganciclovir in the treatment of CMV retinitis? Would P.Z. be a candidate for oral ganciclovir (Cytovene) therapy?

Oral ganciclovir is available in the United States for the suppressive treatment of CMV retinitis in AIDS patients. When taken with food, oral ganciclovir at a dosage of 1,000 mg three times a day provides daily drug exposure (e.g., AUC) that is approximately 75% that of IV doses (5 mg/kg). Peak concentrations associated with oral dosing are substantially lower, but trough levels are higher than with IV dosing. The bioavailability of oral ganciclovir is increased by 22% when administered with food. Therefore, patients should be counseled to take all doses with food to maximize their drug exposure.²⁰⁵ Although oral ganciclovir is a viable alternative to IV ganciclovir as maintenance therapy, the time to relapse may be shorter.²⁰⁵ As with the IV formulations, neutropenia or anemia occurs in 40% to 60% of patients; however, the risk seems to be lower with oral administration.

An esterified ganciclovir, valganciclovir, is available. This agent yields an AUC approximately equivalent to that associated with the IV administration of ganciclovir. The maintenance dosage is two 450-mg tablets of valganciclovir once daily.

The expense of oral versus parenteral ganciclovir is controversial. Cost comparisons must take into consideration catheter-associated costs as well as the additional cost of catheter-associated complications, such as sepsis. Furthermore, quality-of-life issues may weigh in favor of oral ganciclovir. Oral ganciclovir seems to suppress CMV disease effectively and is a maintenance therapy option for patients with stable, non-sight-threatening disease. The limited bioavailability decreases its efficacy; however, larger dosages (e.g., 4,500 or 6,000 mg/day) seem more efficacious.^{44,204–206} However, OI treatment guidelines state that ganciclovir is not recommended for routine use as treatment or maintenance of CMV owing to the superiority of IV ganciclovir and the availability of valganciclovir.⁴⁹ Considering his previous history of neutropenia, P.Z. should not receive oral ganciclovir. Furthermore, oral ganciclovir is less effective as maintenance therapy in sight-threatening cases of retinitis, which exists in P.Z.

24. What is the role of oral ganciclovir or valganciclovir for initial CMV prevention?

The role of oral ganciclovir for primary prophylaxis of CMV retinitis has been evaluated in two studies.^{207,208} Oral ganciclovir decreased the 1-year incidence of disease by approximately 50% in one study,²⁰⁷ but did not demonstrate appreciable efficacy in the second investigation.²⁰⁸ These two studies had important differences in study design that likely explain the disparate results. One cost-effectiveness study estimated that oral ganciclovir prophylaxis would cost >\$1.7 million

per year of anticipated life expectancy.²⁰⁹ Valganciclovir has demonstrated a trend in higher mortality in patients using it for CMV primary prevention.⁴⁸ These issues, in addition to adverse effects such as neutropenia and anemia, the lack of proven survival benefit in HIV-infected patients, and the risk for ganciclovir-resistant CMV, are concerns that should be addressed when deciding whether to institute prophylaxis in individual patients. Prophylaxis with oral ganciclovir or valganciclovir is not “strongly recommended as standard of care” by the guidelines, but rather is “usually recommended” for patients who are seropositive and have a CD4⁺ count of <50 (Table 70-2).^{44,48}

CRYPTOCOCCOSIS

Clinical Presentation and Prognosis

25. A.S., age 28, is infected with HIV. She weighs 48 kg. Her boyfriend was an IV drug user who died of AIDS 2 years ago. She presents with a fever (103°F) and a 2-week history of “splitting headaches.” Laboratory test results include hemoglobin (Hgb), 11.2 g/dL (normal, 12.1–15.3 for females); WBC count, 4,100 cells/mm³ (normal, 3,800–9,800); platelets, 73,000/L (normal, 150,000–450,000); SrCr, 0.9 mg/dL (normal, 0.5–1.7); glucose, 94 mg/dL (normal, 65–115); and CD4⁺ count, 92 cells/mm³. She is highly nonadherent and has not been to the clinic in more than a year, at which time she was prescribed AZT, lamivudine, fosamprenavir, and ritonavir. Physical examination reveals no nuchal rigidity. With the exception of moderate lethargy, her neurologic examination is unremarkable. Her chest radiograph and three sets of blood cultures for bacteria and fungi are negative. A CT scan is nondiagnostic. Lumbar puncture reveals the following CSF findings: glucose, 45 mg/dL (normal, 40–80); protein, 90 mg/dL (normal, 15–45); WBC count, 10 cells/mm³ (normal, <5); and a cryptococcal antigen titer of 1:2,048. Her intracranial pressure (ICP) is 240 mm H₂O (normal, 80–220). How is A.S.’s clinical presentation typical of a patient with AIDS and cryptococcal meningitis? What is her likely prognosis?

[SI units: Hgb, 112 g/L (normal, 121–153); WBC count, $4.1 \times 10^{10}/L$ (normal, 3.8–9.8); platelets, 73 $10^{10}/L$ (normal, 150–450); SrCr, 79.56 mol/L (normal, 44–150); peripheral glucose, 5.2 mmol/L (normal, 3.6–6.3); CSF glucose, 2.5 mmol/L (normal, 60%–70% of peripheral glucose); CSF protein, 0.9 g/L]

In the pre-HAART era, cryptococcosis developed in approximately 6% to 10% of AIDS patients in the United States, with meningitis being the most common clinical presentation.²¹⁰ In the era of HAART and azole prophylaxis, a significant decline in the incidence of cryptococcosis has been observed.^{31,210} After HIV encephalopathy and toxoplasmosis, cryptococcosis is the most common CNS infection associated with AIDS.²¹⁰ The initial portal of entry is the lungs, where the organism is normally contained by an intact immune system. Cryptococcal disease typically develops in patients with profound defects in cell-mediated immunity (i.e., CD4⁺ counts <100). Unlike bacterial meningitis, cryptococcal CNS infection has a much more insidious onset; the most common symptoms are fever and headache. Less frequent signs and symptoms include nausea and vomiting, meningismus, photophobia, and altered mental status. Focal neurologic deficits and seizures are observed in <10% of patients. CSF glucose is decreased, whereas CSF

proteins are usually elevated. CSF cryptococcal antigen titer and CSF culture are frequently positive. These findings, along with the clinical presentation, form the basis for the diagnosis. The overall outcome is poor, with a mean survival of 5 months. Relapse within 6 months occurs in 50% of patients who do not receive suppressive therapy. Altered mental status at baseline, CSF WBC count of <20 cells/mm³, high CSF cryptococcal antigen titer ($>1:1,000$), and an elevated initial CSF opening pressure of >200 mm H₂O have all been associated with a poor prognosis.²¹⁰

A.S.'s CD4⁺ count is 92. She has a temperature of 103°F and has experienced "splitting headaches" for about a week. Her clinical presentation is typical of an AIDS patient with cryptococcal meningitis. The CSF WBC count of 10 cells/mm³, high cryptococcal antigen titer, and ICP >200 mm H₂O, suggest a poor prognosis.²¹¹ If left untreated, cryptococcal meningitis is fatal.

Treatment

Amphotericin B

26. How should A.S.'s acute cryptococcal meningitis be managed?

The current treatment recommended for cryptococcal meningitis is amphotericin B, 0.7 mg/kg/day IV, plus flucytosine (100 mg/kg/day) given orally in four divided doses as induction therapy for 14 days. Once the patient is stable (e.g., afebrile, with resolution of symptoms), then consolidation therapy with oral fluconazole 400 mg/day for 8 weeks or until CSF cultures are sterile can be initiated. After consolidation therapy, daily suppressive therapy with fluconazole 200 mg should be continued indefinitely unless immune reconstitution occurs with HAART.²¹¹ Lipid-based formulations of amphotericin B (specifically the liposomal amphotericin, AmBisome) dosed as 4 mg/kg/day has shown to be effective.²¹⁰

Although the aforementioned regimen is highly effective, the ability to rapidly reduce A.S.'s ICP will also significantly improve her clinical course. Removal of 10 to 20 mL of spinal fluid by repeat lumbar puncture is recommended for patients with an ICP >200 mm H₂O (A.S.'s ICP is 240 mm H₂O). Additional interventions to consider to reduce A.S.'s elevated ICP include administration of acetazolamide (a carbonic anhydrase inhibitor that decreases CSF production) and the insertion of an intraventricular shunt.^{210,211}

27. What is the evidence for adding flucytosine to amphotericin B in the acute treatment of A.S.? What are the disadvantages of this combination?

Amphotericin B binds to sterols in the fungal cell membrane, resulting in leakage of cytoplasmic contents.²¹² Flucytosine is an antimetabolite type of antifungal drug that is activated by deamination within the fungal cells to 5-fluorouracil. It inhibits fungal protein synthesis by replacing uracil with 5-fluorouracil in fungal RNA, and it also inhibits thymidylate synthetase via 5-fluorodeoxy-uridine monophosphate, interfering with fungal DNA synthesis. Although in vitro data have demonstrated synergy between amphotericin B and flucytosine, the addition of the latter agent remains controversial, particularly in AIDS patients, because of the potential for bone marrow toxicity.^{210,213} Flucytosine, a purine analog, is approximately 10% converted to 5-fluorouracil, an antimetabolite.

A classic prospective study conducted in HIV-negative patients favored the use of the combination.²¹⁴ The protocol randomized patients to receive either amphotericin B monotherapy (0.4 mg/kg/day IV for 6 weeks followed by 0.8 mg/kg/day IV every other day for 4 weeks) or amphotericin B plus flucytosine (150 mg/kg/day orally divided Q 6 hours) for 6 weeks. Fewer failures or relapses, more rapid CSF sterilization, and less nephrotoxicity occurred in the combination group, although overall mortality was no different. However, approximately one-fourth of the patients in the combination arm developed leukopenia, thrombocytopenia, or both.

The addition of flucytosine to the therapeutic regimen in HIV-positive patients warrants careful monitoring. In a retrospective review of 89 AIDS patients with cryptococcal meningitis confirmed by CSF culture, no survival difference was noted between those who received amphotericin B monotherapy and those who were treated with the combination.²¹² Flucytosine-induced bone marrow suppression, possibly exacerbated by amphotericin B-induced renal dysfunction, resulted in discontinuation of flucytosine in more than half of the patients. Neutropenia, thrombocytopenia, and diarrhea are more common with sustained blood levels >100 mg/dL. However, not all patients with high blood concentrations experienced adverse effects, suggesting variable patient responses. If flucytosine is chosen as adjunctive therapy, renal function and CBCs should be monitored closely. Whether prospective evaluation of flucytosine blood levels to maintain peak levels <100 mg/dL reduces the incidence of toxicity remains unknown. A.S. is at increased risk of granulocytopenia because of her HIV disease and her concomitant myelotoxic AZT therapy.

The comparative trial forming the basis for the current recommendations for treatment of acute cryptococcal meningitis in HIV-positive patients evaluated a higher dose of IV amphotericin B (0.7 mg/kg/day) with or without flucytosine given at a lower dose (25 mg/kg/dose PO Q 6 hours) for 2 weeks.²¹¹ The study evaluated 381 patients with an acute first episode of cryptococcal meningitis. The second part of this trial re-randomized stable or improved patients to either a fluconazole or itraconazole treatment arm for an additional 8 weeks as consolidation therapy. Sixty percent and 51% of patients receiving amphotericin B plus flucytosine, and amphotericin B alone, respectively, had sterile CSF cultures at 2 weeks of therapy. No significant differences were noted between groups in the percentage of patients who were culture negative at 2 weeks. Importantly, the addition of flucytosine to amphotericin B was not associated with a significant increase in drug toxicities at 2 weeks. Fluconazole and itraconazole were similar in efficacy. However, multivariate analysis revealed two factors that were independently associated with a higher rate of CSF sterilization: the addition of flucytosine and the randomization to fluconazole. Consequently, amphotericin with flucytosine is the preferred initial regimen.

INTRATHECAL OR INTRAVENTRICULAR AMPHOTERICIN B

28. Should A.S. also receive intrathecal or intraventricular amphotericin B?

Although amphotericin B does not penetrate readily into CSF, IV therapy for cryptococcal meningitis is adequate in most patients. One small retrospective review of 13 patients with a first episode of cryptococcal meningitis and underlying malignancy favored insertion of an Ommaya reservoir

(a device inserted into the ventricle of the brain to enable the repeated injection of drugs into the CSF).²¹⁶ However, the number of subjects was small, and complications from using the Ommaya reservoir occurred in 30% of these patients (e.g., chemical ventriculitis, bacterial superinfection, headache, fever, and tinnitus). Considering the lack of clear efficacy and documented complications associated with the direct instillation of amphotericin into CSF, this method of administration should be avoided.

Fluconazole

29. Could A.S. be treated with fluconazole instead of amphotericin B for acute cryptococcal meningitis?

Fluconazole, one of the triazole antifungal agents, inhibits a fungal cytochrome P450 enzyme necessary for the conversion of lanosterol to ergosterol. Without ergosterol, the fungal cell membrane becomes defective and loses its selective permeability properties.²¹⁷ Unlike itraconazole, fluconazole is well absorbed orally even in the presence of an elevated gastric pH. Fluconazole has excellent CNS penetration and a good safety profile,²¹⁷ but is likely a secondary choice in the initial treatment of cryptococcal meningitis. In a prospective, randomized, multicenter trial, the National Institute of Allergy and Infectious Diseases Mycoses Study Group and the AIDS Clinical Trial Group (ACTG) compared amphotericin B with 200 mg/day of oral fluconazole (after a 400-mg loading dose) for 10 weeks in 194 patients.²¹⁸ The dose of amphotericin B (mean dose, 0.4–0.5 mg/kg/day) and the possible addition of flucytosine were left to the discretion of the individual investigators. Although the overall mortality was similar (14% for amphotericin B versus 18% for fluconazole), more fluconazole-treated patients died during the first 2 weeks of treatment (15% versus 8%; $p = 0.25$). Furthermore, the median time to the first negative CSF culture in the successfully treated patients was shorter in the amphotericin B group compared with fluconazole (16 versus 30 days). In a small, prospective, randomized trial of 20 male patients with AIDS, oral fluconazole (400 mg/day) for 10 weeks was compared with IV amphotericin B (0.7 mg/kg/day for 1 week, followed by the same dose thrice weekly for 9 weeks) combined with flucytosine (150 mg/kg/day).²¹⁹ There were four deaths in the fluconazole group and none in the amphotericin B group ($p = 0.27$). Eight of the 14 patients in the fluconazole group failed to respond to treatment, whereas none of the amphotericin B patients failed to respond. The mean duration of positive CSF cultures was 41 days in the fluconazole group and 16 days in the amphotericin B group ($p = 0.02$). These results, taken together, have led most clinicians to choose amphotericin, with or without flucytosine, as initial treatment for severe cryptococcal meningitis. Although increased doses of fluconazole have been proposed, it is unknown whether these will result in improved outcomes. High doses of fluconazole are being investigated further for patients in the developing world where use of IV amphotericin may not always be feasible. Considering the severity of her meningitis, A.S. should be treated acutely with amphotericin and not fluconazole.

Itraconazole

30. What is the role of itraconazole (Sporanox) in the treatment of cryptococcal meningitis?

Although CSF penetration of itraconazole is poor, it has been efficacious in an animal model of cryptococcal meningitis.²²⁰ In a small, uncontrolled trial, all symptoms resolved and cultures were negative in 10 of 14 AIDS patients with cryptococcal meningitis. The median survival of these patients exceeded 10.5 months. In another small, controlled trial, 42% (5 of 12) of itraconazole-treated patients (200 mg orally twice daily) responded completely, compared with 100% (10 of 10) of patients who received amphotericin B (0.3 mg/kg/day IV) plus flucytosine (150 mg/kg/day) for 6 weeks ($p = 0.009$).²²¹ The lack of efficacy may be the result of erratic absorption of itraconazole capsules and poor penetration into the CSF. The suspension and IV formulations of itraconazole offer better bioavailability and thus may result in improved outcomes. In both studies, itraconazole generally was well tolerated, but its role as initial therapy for acute cryptococcal meningitis remains to be clarified.

In a comparative study of amphotericin B plus flucytosine versus amphotericin B alone for 2 weeks, patients were randomized to receive either fluconazole or itraconazole for an additional 8 weeks of consolidation therapy. Itraconazole produced a lower rate of CSF sterilization than fluconazole. The researchers concluded that itraconazole could be used in consolidation therapy of cryptococcal meningitis only for patients who could not tolerate fluconazole.²¹¹ Itraconazole seems to have a limited role in the treatment of cryptococcal meningitis in HIV-positive patients.

Duration of Therapy

31. For how long should treatment continue for A.S.'s cryptococcal meningitis?

Once A.S. completes 2 weeks of acute induction therapy with amphotericin B and flucytosine, she should be switched, if stable, to oral fluconazole 400 mg/day for consolidation therapy. However, itraconazole could be used if A.S. is intolerant to fluconazole. Consolidation should be continued for an additional 8 to 10 weeks, followed by lifelong suppressive therapy with fluconazole 200 mg/day²¹¹ (see Maintenance Therapy).

Maintenance Therapy

32. Should A.S. receive maintenance therapy after successful treatment?

After induction and consolidation treatment of cryptococcal meningitis, A.S. and all AIDS patients should receive maintenance therapy indefinitely, unless immune reconstitution occurs as a result of HAART.^{48,210,211} A higher relapse rate and a shorter life expectancy have been observed in patients who did not receive chronic secondary prophylaxis.²¹⁵ Fluconazole (200 mg once daily) has emerged as the suppressive treatment of choice. In a randomized, placebo-controlled trial of 61 AIDS patients, four recurrent cases of meningitis developed in the placebo group and none in the fluconazole group ($p = 0.03$).²²² One multicenter, comparative trial randomized patients to receive either weekly amphotericin B 1 mg/kg/day IV or 200 mg/day of fluconazole orally.²²³ Of 189 patients enrolled, 18% of the patients in the amphotericin B group relapsed, compared with 2% in the fluconazole group. Serious toxicities were more frequent in the amphotericin B group. Although data are limited, four of five patients maintained on itraconazole (200–400 mg/day) for 3 to 12 months had a

three- to sixfold decline in CSF cryptococcal antigen titers. The fifth patient refused repeat lumbar punctures (see previous section on itraconazole). Thus, itraconazole should be used only as an alternative to fluconazole.^{211,224}

According to the OI guidelines,⁴⁹ adult and adolescent patients are at low risk for recurrence of cryptococcosis when they have completed a course of initial therapy, remain asymptomatic, and have a sustained increase (e.g., >6 months) in their CD4⁺ counts to >100 to 200 after HAART. This has been evaluated in limited numbers of patients. Nonetheless, discontinuing chronic maintenance therapy among such patients is reasonable. Recurrences may happen, and certain specialists may perform a lumbar puncture to determine if the CSF is culture negative before stopping therapy. Maintenance therapy should be reinitiated if the CD4⁺ count decreases to 100 to 200.

Primary Prophylaxis

33. What is the role of primary prophylaxis in cryptococcal meningitis?

Primary prophylaxis against cryptococcal disease in HIV-infected patients has been studied in a few clinical trials.^{225,226} In one open-label study, fluconazole (100 mg/day) was administered to all patients (329 HIV-infected patients) with CD4⁺ counts <68. These results were compared with 337 historical controls from the pre-HAART era.²²⁶ Sixteen cases of cryptococcal meningitis occurred in the historical controls (4.8%) compared with only one case in the fluconazole group (0.3%). In a prospective, randomized ACTG study, fluconazole 200 mg/day was compared with clotrimazole troches (10 mg five times a day) for the prevention of fungal infections in 428 patients with advanced HIV disease. After a median follow-up of 35 months, 32 cases of invasive fungal infection were confirmed. Of these, the majority (17 of 32) were cryptococcosis: 2 cases in the fluconazole group and 15 cases in the clotrimazole group. The greatest benefit derived from fluconazole was observed in patient with CD4⁺ counts of <50.²²⁶ However, no effect on survival was noted.

The risk for fluconazole resistance has been a concern with primary prophylaxis because fluconazole resistance has been reported in HIV-infected patients receiving long-term therapy.²²⁷ In addition to the potential for resistance, other concerns include the lack of survival benefits associated with prophylaxis, the possibility of drug interactions, and cost. In light of these concerns, the CDC currently does not recommend primary prophylaxis for this disease (Table 70-2).⁵⁶ Fluconazole in a daily dose of 100 to 200 mg is reasonable for patients with a CD4⁺ count of <50.

Additional Therapies

34. What other acute therapies have been investigated for cryptococcal meningitis?

The combination of fluconazole plus flucytosine appears to be superior to fluconazole alone. High-dose fluconazole alone (800–1,600 mg/day for up to 6 months) was compared with high-dose fluconazole and flucytosine (150 mg/kg/day for 4 weeks) in 36 AIDS patients.²²⁸ Nine of 12 (75%) patients in the combination group survived and became CSF culture negative, whereas only 7 of 24 (29%) patients on fluconazole

monotherapy had similar outcomes. In a dose-escalation trial of high-dose fluconazole with or without flucytosine, a significant increase in efficacy was observed as fluconazole doses were increased. Potentially, combination fluconazole and flucytosine are useful because of the excellent oral bioavailability of both agents, which is particularly important in developing countries. A randomized trial of 58 AIDS patients with cryptococcal meningitis compared fluconazole and flucytosine with fluconazole monotherapy. Thirty patients received fluconazole 200 mg once daily for 2 months and flucytosine 150 mg/kg/day for the first 2 weeks versus 28 patients who received only fluconazole 200 mg once daily for 2 months. Those who survived for 2 months received fluconazole maintenance therapy at a dose of 200 mg three times a week for 4 months. Combination therapy significantly increased the survival rate compared with monotherapy. No serious adverse effects were observed in either group. Fluconazole and short-term flucytosine may be a cost-effective and safe regimen in developing countries.²²⁹ Additionally, higher doses of fluconazole in these settings (1,800–2,000 mg/day) may be the best option for patients due to the limitations of obtaining and administering flucytosine. These doses are under investigation.

MYCOBACTERIUM TUBERCULOSIS

Clinical Presentation

35. C.J., a 45-year-old male prison inmate with AIDS, presents with fever, cough, and occasional night sweats. A tuberculin purified protein derivative (PPD) skin test is negative, but C.J. is assumed to be anergic based on his response to other skin test antigens. Two acid-fast bacilli (AFB) sputum smears are also negative. Chest radiograph reveals hilar adenopathy with a questionable right middle lobe localized infiltrate. No cavitory lesions are seen. Why is infection with *M. tuberculosis* a strong possibility in C.J.? His antiretroviral medications include abacavir, lamivudine, and efavirenz. Three months ago his CD4⁺ count was 320 cells/mm³ (normal, approximately 1,000 cells/mm³) and his viral load was 5,200 copies/mL.

One-third of the global population is infected with *M. tuberculosis*, with 7 to 8 million new cases every year. Mortality is 2 to 3 million people annually, making TB the most common infectious cause of death worldwide.²³⁰ In 2005, of the 1.6 million deaths due to TB, 195,000 were HIV among infected individuals.²³¹ The incidence of TB in the United States from 1985 to 1992 increased by 20%, approximately 40,000 more cases than expected.^{232–234} Factors associated with this resurgence include the HIV epidemic, urban homelessness, drug abuse, and the dismantling of public health TB control resources. At that time, HIV disease was believed to be a major factor contributing to the emergence of multidrug-resistant *M. tuberculosis* (MDRTB). The recognized link between HIV and TB, along with an increase in clinical and public health resources, has subsequently resulted in a decline in the incidence of TB in the United States.²³⁵ Fortunately in 2006, incidence in the United States was 4.6 per 100,000 persons, the lowest reported rate since TB surveillance began.²³⁵ Nevertheless, TB is the leading cause of death in HIV-infected persons worldwide, and pulmonary TB is an AIDS-defining illness. Furthermore, *M. tuberculosis* strains resistant to isoniazid and rifampin, with or without resistance to other agents,

have become a major public health concern.^{231–237} MDRTB is defined by resistance to both isoniazid and rifampin. More recently the emergence of extensively drug-resistant TB is increasingly becoming a global health concern as identified in South Africa from 2000 to 2004.²³⁵ In 1991 in New York City, 33% of *M. tuberculosis* cases were resistant to at least one drug and 19% were resistant to both isoniazid and rifampin.²³⁸ In 2005, the first year with complete drug-susceptibility data, 124 cases of MDRTB were reported in the United States.²³⁵ These drug-resistant strains have been identified primarily in large urban areas (e.g., New York and Miami), in coastal or border communities, and in institutional settings.^{234,236} Nine outbreaks of MDRTB in hospital and prison settings in New York and Florida in 1990 were investigated by the CDC. A high prevalence of HIV infection (range, 20%–100%), a high mortality rate (72%–89%), and a short median duration of survival (range, 4–16 weeks) were common to these outbreaks. MDRTB strains have been transmitted to health care workers and prison staff.^{234,236}

A Community Programs for Clinical Research on AIDS survey evaluating MDRTB in eight metropolitan regions in the United States observed drug-resistant isolates among 37% of all HIV-positive patients versus 18% of HIV-negative patients in New York City. In areas outside of New York City, resistance rates were approximately 15% in both groups.²³⁹

C.J. presents with fever, cough, night sweats, and a right middle lobe infiltrate with hilar adenopathy, consistent with TB. Furthermore, his HIV status in combination with his incarceration increases the probability of *M. tuberculosis* infection, including multidrug-resistant isolates. C.J. will be started with the standard four-drug regimen: isoniazid, rifampin (or rifabutin), pyrazinamide, and ethambutol.²⁴⁰ (See Chapter 61 for a more comprehensive approach to TB treatment.)

36. Sputum cultures from C.J. document *M. tuberculosis* resistant to both isoniazid and rifampin. Why are the negative tuberculin skin test, negative sputum smears for AFB, and lack of cavitory lesions in C.J. still consistent with *M. tuberculosis* infection?

The clinical presentation of TB is often different in patients with HIV infection. As many as one-half to two-thirds of AIDS patients presenting with TB have evidence of extrapulmonary sites of infection.²⁵⁰ These extrapulmonary sites include lymph nodes, bone marrow, spleen, liver, CSF, and blood. *M. tuberculosis* was rarely cultured from blood before the AIDS era; however, bacteremia is well documented today.²³⁹ HIV-infected patients with TB infection are also at risk for developing tuberculous meningitis.²⁴¹ The chest radiograph in HIV-infected patients may reveal hilar or mediastinal adenopathy or localized infiltrates in the middle or lower lung fields.

In HIV-infected patients, it is unusual to see typical apical infiltrates or cavitations. Furthermore, concomitant PCP may confuse interpretation of chest radiographs. In addition, AFB smears of sputum are negative in approximately 40% of HIV-infected patients despite a positive culture, as in this patient.²⁴² Finally, anergy is extremely common in HIV disease. Only 10% to 40% of HIV-infected patients with TB have a positive tuberculin skin test. Anergy testing is not generally recommended because of lack of standardization of anergy test reagents, poor reproducibility, and a failure to show efficacy of prophylaxis in anergic patients.^{48,243} Thus, definitive diagnosis of TB rests

on positive cultures from sputum or other tissue and body fluid specimens.

Treatment

37. How should C.J. be treated?

C.J.'s organism is resistant to both isoniazid and rifampin (by definition, MDRTB). These two agents should be discontinued, and at least two more drugs should be added to his regimen. The organism must be known to be susceptible to at least three agents in the regimen.^{236,238} Treatment additions for C.J. may include an aminoglycoside (e.g., streptomycin, kanamycin, amikacin), capreomycin, and a fluoroquinolone (e.g., ofloxacin, ciprofloxacin, levofloxacin).^{236,238} C.J.'s physician decided to treat him with pyrazinamide, 20 mg/kg/day orally (maximum dose, 2 g), ethambutol 15 mg/kg/day orally (maximum dose, 2.5 g), amikacin 15 mg/kg/day IV or intramuscularly, and levofloxacin 500 mg orally or IV daily.

The optimal duration of treatment for MDRTB has not been established. The National Jewish Center for Immunology and Respiratory Medicine treats MDRTB for 24 months after sputum cultures become negative. Parenteral medication is continued for 4 to 6 months if toxicity remains manageable (e.g., amikacin ototoxicity, nephrotoxicity).^{234,237,238} Intermittent therapy (administered two or three times per week) is allowable as long as it is directly observed.²⁴⁴ All patients infected with organisms resistant to either isoniazid or rifampin should have their ingestion of antitubercular medications directly observed. Although directly observed drug regimens are labor intensive, overall they are cost effective.²⁴⁴

Whenever isoniazid- or rifampin-resistant organisms are isolated, a medical expert should be consulted. Because many patients suffer from adverse events related to their antituberculosis regimens (particularly GI effects), the National Jewish Center recommends that initial therapy begin in the hospital to monitor toxicity.²⁴⁴ To minimize side effects, this center also initiates therapy with small doses of each agent followed by gradual escalation to the target dose over 3 to 10 days.

In patients with organisms resistant only to isoniazid, suggested regimens include rifampin or rifabutin, pyrazinamide, and ethambutol daily for 14 days then twice weekly for 6 to 9 months, or for 4 months after sputum conversion. If the organism is resistant only to rifampin, suggested regimens include isoniazid, pyrazinamide, and ethambutol plus streptomycin daily for 8 weeks, then isoniazid, pyrazinamide, and streptomycin two or three times per week for 30 weeks. An alternative to this regimen for rifampin resistance includes isoniazid, pyrazinamide, and ethambutol plus streptomycin daily for 2 weeks, then the same regimen two or three times a week for 6 weeks, followed by isoniazid, pyrazinamide, and streptomycin two or three times a week for 30 weeks.

If the organism is sensitive to both isoniazid and rifampin, then the preferred regimen consists of isoniazid, rifampin, pyrazinamide, and ethambutol or streptomycin for 2 months. The third and fourth drugs (pyrazinamide and ethambutol or streptomycin) may be discontinued after 2 months. The dosing regimens for HIV-infected patients and for non-HIV-infected patients are the same. Treatment should continue for 9 months for both non-HIV-infected and HIV-infected patients. If HIV-positive patients demonstrate a slow or suboptimal response, therapy should be prolonged on an individual

Table 70-9 Tuberculosis Treatment Recommendations for Patients Coinfected With HIV and Tuberculosis

| Induction | Maintenance | Comments |
|--|---|---|
| Rifampin-based Therapy (no concurrent use of PIs or NNRTIs) | | |
| INH/RIF/PZA/EMB (or SM) daily ×2 months | INH/RIF daily or 2–3×/wk × 18 wk | RIF-containing regimens used with caution with protease inhibitors and NNRTIs |
| INH/RIF/PZA/EMB (or SM) daily ×2 wk, then 2–3×/wk ×6 wk | INH/RIF 2–3×/wk × 18 wk | HIV status should be assessed at 3-month intervals to determine need for antiretroviral therapy |
| INH/RIF/PZA/EMB (or SM) 3×/wk ×8 wk | INH/RIF/PZA/EMB (or SM) 3×/wk ×4 months | |
| Rifampin-based Therapy (concurrent use of PIs or NNRTIs) | | |
| INH/RFB/PZA/EMB daily ×8 wk | INH/RFB daily or 2×/wk ×18 wk | Monitor for RFB toxicity, arthralgias, uveitis, leukopenia |
| INH/RFB/PZA/EMB daily ×2 wk, then 2×/wk ×6 wk | INH/RFB 2×/wk ×18 wk | Dose modifications of RFB and PIs/NNRTIs when given concurrently (Table 70-10) |
| • Nucleoside analogs and nucleotides: not contraindicated/ no dosage changes recommended | | |
| Streptomycin-based Therapy (concurrent use of PIs or NNRTIs) | | |
| INH/SM/PZA/EMB daily ×8 wk | INH/SM/PZA 2–3×/wk ×30 wk | SM is contraindicated in pregnant women |
| INH/SM/PZA/EMB daily ×2 wk, then 2–3×/wk ×6 wk | INH/SM/PZA 2–3×/wk ×30 wk | If SM cannot be continued for 9 months, add EMB and treatment should be extended to 12 months |
| EMB, ethambutol; INH, isoniazid; NNRTI, non-nucleoside reverse transcriptase inhibitor; PI, protease inhibitor; PZA, pyrazinamide; RFB, rifabutin; RIF, rifampin; SM, streptomycin. Adapted from <i>MMWR</i> 2002;51(RR-8):152, and references 47 and 254. | | |

basis.^{231,236} All HIV-infected patients receiving isoniazid are at risk for peripheral neuropathy and should receive pyridoxine (Table 70-9).^{237,244}

38. How should C.J.'s response to therapy be monitored?

C.J.'s response to therapy should be monitored by drug efficacy and toxicity. Efficacy may be assessed by the resolution of symptoms. Symptoms usually improve within 4 weeks, and sputum cultures become negative within 3 months. C.J. should be monitored for a decrease in the frequency of his fevers and night sweats, as well as improvement in his cough. Sputum smear and culture should be monitored at least monthly until a negative culture is documented. Chest radiography may be the last parameter to improve.^{235,236,240} In some patients, recurrence of symptoms may be caused by nontuberculous complications associated with HIV. This paradoxical reaction is associated with the initiation of antiretroviral therapy²⁴⁵ and is the consequence of immune reconstitution. Recovery of delayed hypersensitivity occurs with increases in CD4⁺ counts, resulting in increased reactions to mycobacterial antigens. Continuation of antimycobacterial and antiviral treatment is recommended, and a short course of prednisone may be considered for severe symptoms.²⁴⁵

The second monitoring parameter is drug toxicity. Recommended baseline tests include LFTs, SrCr, CBC, and platelet count. Baseline uric acid is required for patients receiving pyrazinamide. Patients receiving ethambutol require baseline visual acuity and red–green color perception assessment. Reassessment should be performed at least once monthly. Laboratory monitoring usually is not recommended unless symptoms suggest toxicity. Isoniazid and, secondarily, rifampin and pyrazinamide are the agents most associated with hepatotoxic-

ity (see Chapter 61). C.J. is not receiving isoniazid or rifampin but is receiving pyrazinamide. Therefore, if transaminase levels increase to higher than five times the upper limits of normal, pyrazinamide should be discontinued and an alternative agent given. When his LFTs return to their normal limits, pyrazinamide can be reintroduced.²⁴⁰

Prophylaxis

HIV-Infected Persons: Multidrug-Resistant Tuberculosis

39. An HIV-infected nurse inadvertently entered C.J.'s room without taking adequate precautions and suctioned respiratory secretions. Four weeks later, her tuberculin skin test converted to positive. What prophylactic regimen should be initiated for this nurse?

There is no known prophylactic regimen with proven efficacy against MDRTB,^{48,236} but several regimens have been recommended: pyrazinamide (25–30 mg/kg/day) combined with ethambutol (15–25 mg/kg/day); pyrazinamide with ofloxacin (400 mg BID); and pyrazinamide combined with ciprofloxacin (750 mg BID).^{236,246} Other fluoroquinolones, such as levofloxacin, are associated with good in vitro activity and may prove beneficial. Considering that C.J. is HIV infected, multidrug prophylaxis should continue for 12 months.^{48,246} The choice of drugs must be based on susceptibility tests and consultation with public health authorities (Table 70-2).⁴⁸

HIV-Infected Persons: Drug-Susceptible Tuberculosis

40. K.D., a 26-year-old HIV-infected man, comes in for a routine clinic visit. It is discovered that he is a household contact of a

person known to have active, untreated, drug-susceptible TB. His CD4⁺ count is 350 cells/mm³. A tuberculin skin test (5 tuberculin units of PPD) and two other skin test antigens are administered, and he is instructed to return to the clinic in 48 hours. His PPD has been negative in the past, and he has demonstrated delayed hypersensitivity responsiveness. How should the results of K.D.'s skin tests be interpreted, and should he receive prophylaxis considering his known exposure to TB?

The CDC and the American Thoracic Society currently recommend 9 months of isoniazid prophylaxis (300 mg/day PO) plus pyridoxine (50 mg/day PO) for all HIV-infected persons who have at least a 5-mm induration reaction to PPD and no evidence of active TB (negative chest radiograph and no clinical symptoms), unless otherwise contraindicated and regardless of Bacillus Calmette-Guerin (BCG) vaccination status. The administration of BCG vaccine to HIV-infected persons is contraindicated because of the potential to cause disseminated disease.⁴⁸ A >5-mm reaction in HIV-infected persons contrasts to a >10-mm cutoff for HIV-negative persons.^{48,240} Few isoniazid prophylaxis failures have been reported, although this finding has not been systematically studied. Additional preferred regimens in instances of questionable compliance include isoniazid 900 mg twice weekly plus pyridoxine 50 mg twice weekly for 9 months, both administered under direct observed therapy. A short-course preferred regimen includes rifampin (600 mg/day) plus pyrazinamide (20 mg/kg/day) for 2 months (Table 70-2).^{48,247}

An inverse relationship exists between anergy and a CD4⁺ count of <500.²⁴⁸ If K.D. proves to be anergic, he should still be given isoniazid prophylaxis, considering his exposure history.⁴⁸ All HIV-infected persons, irrespective of age, PPD results, or prior course of chemoprophylaxis, should be given chemoprophylaxis if they are in close contact with persons who have active TB. Prophylaxis also should be considered for anergic, HIV-infected persons who are members of groups known to have a prevalence of TB infection of >10%. In the United States, these groups include IV drug users, prison inmates, residents of homeless shelters, and persons born in Latin American, Asian, or African countries with high rates of TB. The efficacy of primary prophylaxis in this group has been demonstrated.^{48,240,244} Before any prophylactic regimen is begun, active TB needs to be ruled out. K.D. should undergo chest radiography and clinical evaluation to rule out active disease. HIV-infected patients who are anergic or have a negative reaction when tested do not require prophylaxis if they are not close contacts of TB-infected patients.^{48,240,244} The CDC no longer recommends routine anergy testing, because several studies have demonstrated inconsistent results.^{48,249}

HIV-Infected Persons: Protease Inhibitors or Non-Nucleoside Reverse Transcriptase Inhibitors

41. F.C., a 36-year-old HIV-infected woman, diagnosed 6 months ago, was found to have active TB (pulmonary infiltrates on chest radiographs, sputum AFB stain and culture positive, culture pansensitive). She is taking AZT, lamivudine, lopinavir/ritonavir, and fluconazole, and CD4⁺ count is 300 cells/mm³. What factors must be considered when selecting TB therapy for F.C.?

The use of protease inhibitors in the treatment of HIV patients coinfecting with TB increases the potential for drug

interactions with rifamycin derivatives (rifampin, rifabutin). Because the rifamycins are potent inducers of the hepatic cytochrome P450 system (e.g., CYP3A4), they can induce metabolism of the protease inhibitors, resulting in subtherapeutic levels. Conversely, the protease inhibitors elevate rifamycin serum levels by inhibiting their metabolism and increasing toxicities, such as uveitis (inflammation of the uveal tract of the eye; see Chapter 61).

According to recent guidelines, rifampin should not be coadministered with any standard protease inhibitors (boosted or not with ritonavir) and delavirdine.²⁵⁰ Rifampin may be used with efavirenz and nevirapine; however, optimal doses are not known for all populations and additive hepatotoxicity exists when nevirapine and rifampin are coadministered. When using rifampin with maraviroc or raltegravir an increased dose of maraviroc (600 mg BID) may be used and the recommended dose of raltegravir (400 mg BID); however, there is no reported clinic experience for these regimens. Rifabutin may be used in place of rifampin but should not be used with the saquinavir (without ritonavir) or delavirdine. Rifabutin should be given at 50% of the usual dose (i.e., reduce from 300 to 150 mg/day) with indinavir, nelfinavir, amprenavir, and fosamprenavir. Rifabutin should be used at 25% of the usual dose (i.e., 150 mg every other day or three times a week), with atazanavir, lopinavir/ritonavir, or any ritonavir-boosted protease inhibitor. When rifabutin is administered with indinavir as a single protease inhibitor, the dosage of indinavir should be increased from 800 mg Q 8 hours to 1,000 mg Q 8 hr or given as 800 mg twice daily with ritonavir 100 mg twice daily. Rifabutin should be given with efavirenz at dosages of 450 to 600 mg/day. There are no data on using rifabutin in the HAART setting of efavirenz plus a protease inhibitor. In this situation, rifabutin dosing may need to be decreased. Rifabutin can be used in full doses with nevirapine and etravirine.²⁵⁰

The CDC has recommended three treatment options for patients receiving protease inhibitors and non-nucleoside reverse transcriptase inhibitors (NNRTI). If the patient has not yet been started on a protease inhibitor or NNRTI, it may be best to delay therapy and start antituberculosis medication immediately. If the patient is receiving a protease inhibitor or NNRTI, some physicians may decide to discontinue this treatment for the duration of the antituberculosis medication. If the decision is made to continue or initiate protease inhibitor or NNRTI therapy, an antituberculosis regimen must be selected that modifies the doses of rifampin or rifabutin (Table 70-9).^{240,251}

There are currently five options for concomitant TB and antiretroviral therapy; the first three are CDC-recommended options. These are initiating therapy with regimens that do not contain a protease inhibitor or an NNRTI (e.g., abacavir, lamivudine [3TC], AZT), using a concomitant protease inhibitor or NNRTI with streptomycin-based therapy with no use of rifamycins, and initiating rifabutin-based therapy with dose adjustments of the concomitant protease inhibitor or NNRTI (Table 70-9).²⁵² The other two options are not recommended by the CDC. They are using isoniazid, ethambutol, and pyrazinamide for 18 to 24 months²⁵³ with concomitant protease inhibitor or NNRTI therapy, and using efavirenz 800 mg/day (plus two NNRTIs) plus rifampin 600 mg/day or 600 mg twice weekly.²⁵⁴

Discontinuing the protease inhibitor for F.C. is not an option considering the rapid viral replication and the risk of

developing resistant isolates, especially considering that she recently was started on protease inhibitor therapy and is clinically responsive. A reduced dose of rifabutin (150 mg every other day or three times per week) is recommended when coadministered with lopinavir/ritonavir. Considering that F.C. is receiving lopinavir/ritonavir, she will be treated with a rifabutin-based regimen. She will receive isoniazid, rifabutin, pyrazinamide, and ethambutol daily for 8 weeks followed by isoniazid and rifabutin daily or twice weekly for 18 weeks. An alternative regimen could be isoniazid, rifabutin, pyrazinamide, and ethambutol daily for 2 weeks, then two times weekly for 6 weeks, followed by isoniazid and rifabutin, twice weekly for 18 weeks. Considering the lopinavir/ritonavir-associated reduction in metabolism, rifabutin should be administered 150 mg every other day or three times weekly (Table 70-10).

Drug Interactions

42. What additional non-antiretroviral-related drug interactions are of concern to patients like F.C. who are taking antituberculosis medications?

Rifampin induces hepatic microsomal enzymes and therefore increases the metabolism of many drugs frequently prescribed for HIV-positive patients. For example, serum concentrations of fluconazole and ketoconazole are decreased by 25% and 80%, respectively,^{255,256} and dapsone concentrations are lowered by as much as 90% with concomitant administration of rifampin. Rifampin may induce acute withdrawal when given with methadone. The activity of oral contraceptives and warfarin anticoagulants also may be reduced. Rifampin also lowers serum concentrations of theophylline, anticonvulsants, corticosteroids, sulfonyleureas, and digoxin.

F.C. is receiving rifabutin rather than rifampin. Rifabutin also induces hepatic microsomal enzymes, but the effect is less pronounced. Rifabutin reduces the activity of several agents, including warfarin, barbiturates, benzodiazepines, β -adrenergic blockers, chloramphenicol, clofibrate, corticosteroids, cyclosporine, diazepam, digitalis, doxycycline, haloperidol, oral hypoglycemics, ketoconazole, phenytoin, theophylline, quinidine, and verapamil. A significant reduction in activity is observed with oral contraceptives, dapsone, and methadone (Tables 70-10 and 70-11).

Cytochrome P450 system inhibitors, such as certain macrolides, quinolones, and antifungal azoles, prolong the half-life of rifabutin. The macrolides erythromycin and clarithromycin result in a fourfold increase in rifabutin.^{48,234} F.C. is concomitantly taking fluconazole; thus, rifabutin serum levels might increase when given with fluconazole, leading to possible uveitis.²³³ However, F.C. is currently taking half the usual dose of rifabutin, minimizing the risk for rifabutin-induced uveitis.

MYCOBACTERIUM AVIUM COMPLEX DISEASE

Clinical Presentation

43. M.E., an HIV-infected 38-year-old woman with a history of IV drug use, presents with fevers, drenching night sweats, a poor appetite, and a 20-lb weight loss (>15% of baseline) over the past 4 months. M.E. has refused all antiretroviral therapy

for the past year because of drug intolerance. She has a past medical history of recurrent herpes zoster, PCP, and cryptococcal meningitis. Her current medications include one TMP-SMX double-strength tablet once daily and an occasional acyclovir dose when she feels the herpes zoster “is beginning to start”; she refuses MAC prophylaxis therapy. Physical examination reveals a cachectic woman with mild hepatosplenomegaly. Pertinent laboratory test results include hematocrit (Hct), 23% (normal, 36%–44.6%); WBC count, 3,500 cells/L (normal, 3,800–9,800) with 68% neutrophils, 2% bands, 22% lymphocytes, and 8% monocytes; absolute CD4⁺ count, 25 cells/mm³; viral load, 200,000 copies/mL; aspartate transaminase, 135 IU/L (normal, 0–35); alanine aminotransferase, 95 IU/L (normal, 30–120). Skin testing reveals anergy. The chest radiograph is unremarkable. Based on these findings, a presumptive diagnosis of MAC infection is made. Why is M.E.’s clinical presentation consistent with MAC infection?

[SI units: Hct, 0.23; WBC count, $3.5 \times 10^{10}/L$ with 0.68 neutrophils, 0.02 bands, 0.22 lymphocytes, 0.08 monocytes; aspartate aminotransferase, 135 U/L (normal, 0–35); alanine aminotransferase, 95 U/L (normal, 0–35); alkaline phosphatase, 186 U/L (normal, 30–120)]

Disseminated MAC infection is common in end-stage AIDS patients. On autopsy, MAC organisms are observed in the lungs, spleen, colon, adrenals, kidneys, brain, and skin.^{257,258} MAC reduces survival; increased mortality is observed in AIDS patients with disseminated MAC, compared with AIDS patients without disseminated MAC.²⁵⁷ The predominant organism in HIV-positive patients is *M. avium* (97% of typeable isolates) followed by *Mycobacterium intracellulare* (3%).²⁵⁹ The risk of developing disseminated MAC infection is strongly associated with a CD4⁺ count of <100; the highest risk is in patients with a CD4⁺ count <50.¹³ Age, gender, and race do not influence the risk of disseminated MAC infection.^{48,257} The overall prognosis is poor, with a mean survival of 3 to 7 months. Poor prognostic indicators include prior OI, severe anemia, AZT dose interruption, and low total lymphocyte count.²⁶⁰

M. avium is a ubiquitous organism found in food, water, soil, and house dust. The most likely portal of entry is either the GI or respiratory tract. Sputum and stool samples frequently are colonized with MAC, although the significance of this finding remains controversial. Common presenting symptoms associated with MAC infection include fever, night sweats, anorexia, malaise, profound weight loss (>10% body weight), anemia, lymphadenopathy, and diarrhea.²⁶¹ M.E.’s fevers, drenching night sweats, poor appetite, 20-lb weight loss, and mild hepatosplenomegaly are consistent with MAC infection. In particular, her CD4⁺ count of 25 puts her at risk for this OI.

Treatment

Initiation

44. Why is it appropriate to initiate M.E.’s drug therapy before blood culture results have documented the presence of MAC?

Disseminated MAC is best diagnosed by peripheral blood cultures. The finding of AFB on a blood smear is diagnostic, but the results are variable.^{261,262} Conventional culture methods using solid media may have a turnaround time of as long as 8 weeks; however, radiometric broth systems signaling the release of C¹⁵-labeled CO₂ from mycobacteria may detect

Table 70-10 Recommendations for Coadministering Rifampin and Rifabutin With Non-Nucleoside Reverse Transcriptase Inhibitors and Protease Inhibitors

| <i>Antiretroviral</i> | <i>Use in Combination With Rifabutin</i> | <i>Use in Combination With Rifampin</i> | <i>Comments</i> |
|------------------------------|---|---|--|
| Saquinavir HGC | Possibly, ^a if regimen also includes ritonavir | No | Coadministration of saquinavir HGC or tablet with rifabutin 150 mg QOD or 3×/wk is recommended but only if ritonavir is used. Coadministration of saquinavir with rifampin is not recommended because of the demonstration of marked elevations in transaminases when saquinavir/ritonavir and rifampin were combined. |
| Ritonavir | Probably | Possibly | If the combination of ritonavir and rifabutin is used, then a substantially reduced-dose rifabutin regimen (150 mg 2–3×/wk) is recommended. Coadministration of ritonavir with usual-dose rifampin (600 mg QD or 2–3×/wk) is possible; pharmacokinetic data and clinical experience are limited. |
| Indinavir | Yes | No | There is limited, but favorable, clinical experience with coadministration of indinavir ^c with a reduced daily dose of rifabutin (150 mg) or with the usual dose of rifabutin (300 mg 2–3×/wk) Coadministration of indinavir with rifampin is not recommended because rifampin markedly decreases concentrations of indinavir. |
| Nelfinavir | Yes | No | There is limited, but favorable, clinical experience with coadministration of nelfinavir ^d with a reduced daily dose of rifabutin (150 mg) or with the usual dose of rifabutin (300 mg 2–3×/wk). Coadministration of nelfinavir with rifampin is not recommended because rifampin markedly decreases concentrations of nelfinavir. |
| Amprenavir and fosamprenavir | Yes | No | Coadministration of amprenavir or fosamprenavir with a reduced daily dose of rifabutin (150 mg) or with the usual dose of rifabutin (300 mg 2–3/wk) is a possibility, but there is no published clinical experience. Coadministration of amprenavir or fosamprenavir with rifampin is not recommended because rifampin markedly decreases concentrations of amprenavir. |
| Atazanavir | Yes | No | Coadministration of atazanavir with a reduced dose of rifabutin (150 mg every other day or 3×/wk) is a possibility, but there is no published clinical experience. Coadministration of atazanavir with rifampin is not recommended because rifampin markedly decreases concentrations of atazanavir. |
| Lopinavir/ritonavir | Yes | No | Coadministration of lopinavir/ritonavir with a reduced dose of rifabutin (150 mg every other day or 3×/wk) is a possibility, but there is no published clinical experience. Coadministration of lopinavir/ritonavir with rifampin is not recommended because rifampin markedly decreases concentrations of atazanavir. |
| Darunavir/ritonavir | Yes | No | Coadministration of darunavir/ritonavir with a reduced daily dose of rifabutin 150 mg every other day is recommended. Coadministration of darunavir/ritonavir with rifampin is not recommended. |
| Tipranavir/ritonavir | No | Possibly | Coadministration of tipranavir/ritonavir is not recommended. A single dose of rifabutin with tipranavir/ritonavir showed an increase in rifabutin concentrations; however, no multidose data are available. No data are available with the coadministration of rifampin with tipranavir/ritonavir. |
| Nevirapine | Yes | Possibly | Coadministration of nevirapine with usual-dose rifabutin (300 mg QD or 2–3×/wk) is possible based on pharmacokinetic study data. However, there is no published clinical experience for this combination. Data are insufficient to assess whether dose adjustments are necessary when rifampin is coadministered with nevirapine. Therefore, rifampin and nevirapine should be used only in combination if clearly indicated and with careful monitoring. Some studies have demonstrated additive hepatotoxicity. |
| Delavirdine | No | No | Contraindicated because of the marked decrease in concentrations of delavirdine when administered with either rifabutin or rifampin. |
| Efavirenz | Probably | Probably ^e | Coadministration of efavirenz with increased doses of rifabutin 450–600 mg QD or 600 mg 3×/wk is recommended. |

^aDespite limited data and clinical experience, the use of this combination is potentially successful.

^bBased on available data and clinical experience, the successful use of this combination is likely.

^cRecommended to increase the indinavir dose to 1,000 mg Q 8 hr or boost with ritonavir (800/100 mg BID) when used in combination with rifabutin.

^dUsual recommended dose is 750 mg TID or 1,250 mg BID. Some experts recommend increasing the nelfinavir dose to 1,000 mg if used TID and in combination with rifabutin.

^eUsual recommended dose is 600 mg QD. Some experts recommend increasing the efavirenz dose to 800 mg QD if efavirenz is used in combination with rifampin.

QD, daily; QOD; every other day.

Adopted from *MMWR* 2000;49:23 and U.S. Department of Health and Human Services Guidelines for Use of Antiretroviral Agents in Adults and Adolescents, Oct 10, 2007.

Table 70-11 Drug Interactions With Tuberculosis and *Mycobacterium avium* complex Medications

| Affected Drug | Interacting Drug(s) | Mechanism | Recommendation |
|---|---|---|--|
| Atovaquone | Rifampin | Induction of metabolism drug concentrations | Concentrations might not be therapeutic; avoid combination or ↑ atovaquone dose |
| Clarithromycin | Ritonavir, indinavir | Inhibition of metabolism ↑ drug concentrations by 77% (w/ritonavir) and 53% with indinavir | No adjustments needed in normal renal function; adjust if CrCl is <30 mL/min |
| Clarithromycin | Nevirapine | Induction of metabolism ↓ in clarithromycin AUC by 35%, ↑ in AUC of 14-OH clarithromycin by 27% | Effect on <i>M. avium</i> prophylaxis might be decreased; monitor closely |
| Clarithromycin | Rifabutin, rifampin | Induction of hepatic metabolism ↓ clarithromycin concentration 50% (w/rifabutin) to 120% (w/rifampin) | Clinical significance of ↓ clarithromycin levels unknown |
| Ketoconazole, rifampin | Isoniazid | ↓ Serum concentration of ketoconazole ↑ Hepatotoxicity | Possible antifungal treatment resistance May consider discontinuing one or both agents if >5× baseline |
| Quinolones | Didanosine, antacids, iron products, calcium products, sucralfate | Chelation that results in marked ↓ in quinolone drug levels | Administer interacting drug ≥2 hr after quinolone |
| Rifabutin | Fluconazole | Inhibition of metabolism with significant ↑ in rifabutin drug levels | Monitor for rifabutin, toxicity such as uveitis, nausea, neutropenia |
| Antifungals, dapsone, methadone, theophylline, oral contraceptives, phenytoin, digoxin, warfarin (all drugs metabolized via CYP450) | Rifampin | Induction of metabolism—significant decrease in drug levels | Monitor drug levels (theophylline, phenytoin, digoxin) Monitor prothrombin time with warfarin Use alternative birth control method |
| Theophylline, warfarin, digoxin | Ciprofloxacin | Inhibition of metabolism theophylline levels, digoxin levels, anticoagulant effects | Monitor theophylline and digoxin levels and prothrombin time |

AUC, area under the curve; CrCl, creatinine clearance; CYP450, cytochrome P450 enzyme system.
Modified from *MMWR* 1999;48(RR-10).

bacterial growth in 7 to 10 days.^{261,262} Identification of the organism (*M. tuberculosis* versus atypical mycobacteria) by conventional biochemical methods may take weeks to months. Techniques using DNA probes make diagnosis possible within several hours.²⁶² Quantitative blood cultures have been useful to monitor the effects of drug therapy, but may not be practical on a routine clinical basis. Radiometric broth methods also may provide in vitro drug susceptibility in another 7 to 10 days. Even with the availability of all of these laboratory tests, results generally are not available for 2 to 3 weeks. In view of this lag time, it is in the patient's best interest to initiate empiric therapy as quickly as possible. Although MAC is typically isolated from blood, the organism can also be demonstrated via acid-fast smears of lymph node, liver, or bone marrow biopsies. Because these organs are rich in monocytes, the target cells for MAC infection, the organism load may be high (up to 10¹¹ colony-forming units [CFU]/mL). Granuloma formation or inflammation may be absent because of profound suppression of cell-mediated immunity in end-stage AIDS patients.^{262,263}

45. What is the relevance of M.E.'s discontinued antiretroviral therapy to her development of MAC infection?

The incidence of disseminated MAC in AIDS patients residing in the United States before HAART was 30% to 40%. Treatment with protease inhibitors and the widespread use of primary MAC prophylaxis since mid-1996 substantially lowered the incidence of disseminated MAC infection.^{262–265} HIV also is known to infect monocytes and macrophages. In in vitro macrophage culture studies, the intracellular growth rate of *M. avium* was greatly enhanced in HIV-infected cells.²⁶⁶ Conversely, if macrophages taken from HIV-infected patients were infected with *M. avium*, latent HIV virus began to replicate in some of these cultures.²⁶⁶ Consequently, the two organisms may act synergistically, leading to a hastened deterioration of the host.²⁶¹ Because M.E. has discontinued antiretroviral therapy, the resultant increase in viral load has contributed to her development of MAC.

Drug Susceptibility as a Basis for Treatment

46. Should M.E.'s therapy be based on in vitro drug susceptibility results?

Correlation between in vitro drug susceptibility results and clinical efficacy has not been clearly established for MAC.

Numerous reasons may account for this finding. First, results are method dependent; MAC isolates are more sensitive to antibiotics if broth is used rather than agar.^{262,267} Second, current in vitro methods are cell free, which does not take into account the intracellular nature of MAC infection. Thus, drugs that have excellent intracellular penetration may be useful clinically, even if in vitro minimum inhibitory concentration (MIC) data suggest otherwise. Conversely, drugs that have favorable MIC data may be ineffective clinically if they do not reach the intracellular environment.^{266,267} An in vitro drug susceptibility testing system that incorporates murine macrophages is under development^{266,267} and eventually may be a better predictor of clinical outcome. Clinical laboratories in the United States widely use the radiometric broth macrodilution utilizing Bactec Technology.^{267,268}

Drug susceptibility studies also may not correlate with clinical efficacy because in vitro results for individually tested drugs may show resistance, but combination therapy may be additive or synergistic.²⁶⁹ Finally, some antimycobacterial agents exhibit large differences between the MIC and maximum bactericidal concentration. This finding may reflect the difficulty in eradicating this organism, particularly in a severely immunocompromised host. Despite these limitations, many clinicians still use in vitro drug susceptibility data as a guide to therapy. In summary, in vitro tests for susceptibility, although used, may not predict clinical efficacy.

Drug Therapy

47. What drug regimens could be selected to treat M.E.?

The CDC recommends a two- or three-drug MAC regimen, and at least one of these drugs must be a macrolide. Clarithromycin (500 mg PO BID) is the preferred agent; azithromycin is an alternative. Ethambutol (15 to 25 mg/kg/day PO) is recommended as the second agent. Several drugs can be used as the third agent, including rifabutin (300 mg/day), ciprofloxacin (500–750 mg/day), and amikacin (15 mg/kg/day). The choice of the third agent depends on the severity of the illness, drug interactions, hepatic and renal function, patient tolerability, patient compliance, and cost. Amikacin (15 mg/kg/day) has been used in acute MAC therapy, but it is toxic and does not seem to have a role in long-term therapy. Long-term therapy may be discontinued in patients who have completed a course of > 12 months of treatment for MAC, remain asymptomatic, and have a sustained increase (e.g., > 6 months) in their CD4⁺ count to > 100 after HAART.⁴⁸

In the late 1980s, whether patients with disseminated MAC infection should be treated at all was controversial. The results of early, uncontrolled trials were disappointing, with poor microbiologic response rates, little improvement in clinical symptoms, and a high incidence of adverse drug reactions. Additional clinical trials have been associated with improvement or eradication of MAC bacteremia and improvement in clinical symptoms. These improved results probably can be attributed to earlier diagnosis, longer follow-up, more potent antiretroviral therapy, and the use of anti-MAC agents that penetrate intracellular spaces more effectively.²⁶⁹

The macrolides have potent antimycobacterial activity. Several studies have shown clarithromycin to be efficacious against MAC.^{270,271} In a small placebo-controlled trial, seven of eight patients who received 2 g/day of clarithromycin monotherapy

eradicated *M. avium* from their blood cultures after 4 weeks. In contrast, all five placebo patients showed increases in CFU/mL. In an uncontrolled, monotherapy trial of azithromycin (500 mg/day), patients showed a mean decrease from 2,028 to 136 CFU/mL. Fevers and night sweats resolved in most patients.²⁷² However, bacteriologic relapse occurred after treatment was discontinued and in 10 patients who elected to continue azithromycin therapy (250 mg/day), suggesting the emergence of resistance. In another investigation, all isolates initially were susceptible to clarithromycin, but after 12 weeks of monotherapy (1–4 g/day), in vitro resistance developed in 16 of 72 (22%) patients.²⁷³

Because monotherapy can lead to breakthrough bacteremia and resistance, MAC infections should be treated with a combination of at least two agents, including a macrolide plus ethambutol. Although clarithromycin and azithromycin have excellent activity against MAC, clarithromycin is preferred because the emergence of resistance is more likely with azithromycin.^{270–272} Both macrolides demonstrate excellent intracellular penetration and have prolonged half-lives.^{274–276} GI toxicity (nausea, vomiting, diarrhea, abdominal pain, and anorexia) is the most frequent adverse effect with either agent.^{271,272} These effects may be dose related. Data show that patients receiving 4 g/day of clarithromycin are more likely to have their therapy discontinued because of GI upset than patients receiving lower doses.²⁷⁷ The dosage of clarithromycin is 500 mg orally twice daily, and the dosage of azithromycin is 500 mg/day.

Ethambutol (15–25 mg/kg/day orally) is preferred as the second agent.²⁷⁸ In a monotherapy study, 800 mg of ethambutol was more effective than either clofazimine or rifampin.²⁷⁷ One or more of the following drugs can be added to the macrolide/ethambutol combination: rifabutin, rifampin, ciprofloxacin, and clofazimine, with or without amikacin. Isoniazid and pyrazinamide are not effective for the treatment of MAC.^{249,266,268}

Although four-drug regimens have been used, one study observed that a three-drug macrolide regimen (clarithromycin, ethambutol, rifabutin) was more effective than a four-drug regimen (ciprofloxacin, clofazimine, ethambutol, rifampin).²⁷⁹ Benefits of the macrolide regimen included more rapid clearing of MAC bacteremia and a longer duration of survival. Rifabutin, at 600 mg/day, induced uveitis in approximately one-third of patients. Subsequently, the rifabutin dosage was lowered to 300 mg/day, and the incidence of uveitis decreased to 5.6%. Although clearance of bacteremia was superior at the higher rifabutin dose, no differences in survival were observed. Several recent studies have demonstrated no bacteriologic or clinical benefit with the addition of clofazimine. Clarithromycin and ethambutol, with and without clofazimine, were investigated for the treatment of MAC bacteremia. Survival was found to be significantly decreased in the clofazimine arm; 61% of the patients died versus 38% in the two-drug arm. Based on this analysis, the FDA no longer recommends the addition of clofazimine to clarithromycin and ethambutol.²⁸⁰

M.E. is placed on a regimen of clarithromycin 500 mg twice daily and ethambutol 15 mg/kg/day. The choice to use two drugs rather than three is based on M.E.'s poor adherence profile. Other considerations for the addition of a third-line agent include the severity of the illness, potential drug interactions, tolerability, hepatic and renal function, and cost. M.E. must

Table 70-12 Drugs Commonly Used in the Treatment of *Mycobacterium avium* Complex Infection^a

| Agents | Dose | Toxicities |
|-------------------------------|----------------------------|--|
| Initial Therapy Agents | | |
| Clarithromycin | 500 mg PO BID ^b | Nausea, vomiting, diarrhea, abdominal pain, serum transferase elevations, bitter taste |
| Azithromycin | 500 mg/day PO | Nausea, vomiting, diarrhea, abdominal pain, serum transferase elevations |
| Ethambutol | 15–25 mg/kg/day PO | Optic neuritis, ^c nausea and vomiting |
| Rifabutin ^d | 300 mg/day PO | Nausea, vomiting, diarrhea, serum transferase elevations, hepatitis, neutropenia, thrombocytopenia, rash, orange discoloration of body fluids, uveitis Clearance of other drugs owing to hepatic microsomal enzyme induction ^e |
| Secondary Agents | | |
| Ciprofloxacin | 500–750 mg PO BID | Nausea, vomiting, diarrhea, abdominal pain, headache, rare insomnia, hallucinations, seizures |
| Amikacin | 10–15 mg/kg/day IV or IM | Nephrotoxicity, ototoxicity |

^aMacrolide plus ethambutol with or without one or more of the drugs listed above.
^bClarithromycin dose >500 mg BID is associated with increased mortality.
^cVisual testing should be done monthly in patients receiving >15 mg/kg/day.
^dRifabutin dose 300–600 mg/day; but should not exceed 300 mg/day if given with clarithromycin or fluconazole.
^eCommon drug interactions include protease inhibitors (see Table 70-10).
 BID, twice a day; IM, intramuscularly; IV, intravenously; PO, orally.

be counseled regarding the slow response to treatment. If she improves, therapy should be continued and HAART therapy should be reinstated.

MONITORING THERAPY

48. How should M.E. be monitored?

The primary goals of MAC therapy are to eradicate or reduce the number of *M. avium* organisms, decrease symptoms, enhance quality of life, and prolong survival. M.E. should be monitored for symptomatic relief (temperature spikes and frequency of night sweats), as well as a microbiologic response (CFU/mL). Clinical improvement may not be observed for 2 to 4 weeks, whereas eradication of bacteremia frequently takes longer (4–12 weeks). If no improvement in clinical manifestations is observed in 4 to 8 weeks, a mycobacterial blood culture should be repeated along with susceptibility testing. If resistance is observed or suspected, two new drugs should be added based on susceptibility testing with or without the macrolide. If the organism is found to be susceptible to macrolides, therapy should be continued and adherence, absorption, tolerance, and drug interactions should be considered.^{281,282} If the problem is determined to be drug absorption, IV agents can be considered. M.E. also should be followed for development of toxicities related to drug therapy. Furthermore, because many drugs used to treat MAC infections are associated with drug interactions, this issue must be considered each time a new drug is prescribed. In some cases, drug doses need to be modified or alternative drugs selected to prevent adverse events or therapeutic failures (Table 70-11).²⁸³

Prophylaxis

49. What drug(s) should be used to provide primary prophylaxis against MAC infection?

The most recent official guidelines recommend oral therapy with clarithromycin (500 mg BID) or azithromycin 1,200 mg

every week for persons with a CD4⁺ count <50. Although the combination of azithromycin and rifabutin is more effective than azithromycin alone, the increased cost, adverse events, potential for drug interactions, and absence of a survival benefit preclude this regimen from being routinely recommended. If neither clarithromycin nor azithromycin is tolerated, rifabutin 300 mg/day may be used⁴⁸ (Tables 70-2 and 70-12).

Before the use of macrolides, rifabutin was the agent of choice for primary prophylaxis. However, no survival benefit has been demonstrated with the use of this agent, and the drug is associated with high cost, complex drug interactions, and an increased risk for uveitis.^{48,283}

Six hundred eighty-two patients with AIDS, CD4⁺ counts <100, and negative MAC blood cultures were randomized to receive clarithromycin (500 mg PO BID) or placebo.⁵¹ The clarithromycin arm had a 69% reduction in MAC bacteremia and fewer (16% versus 6%) cases of MAC infection. Significantly more patients in the clarithromycin arm survived during the 10-month follow-up (68% versus 59%), with an accompanying longer median duration of survival. This trial was the first prospective MAC prophylaxis study demonstrating a survival benefit and a reduced risk of disseminated MAC infection.⁵¹

In a randomized, double-blind, placebo-controlled trial, 182 MAC-negative patients with AIDS and CD4⁺ counts <100 (median 44) were treated with azithromycin 1,200 mg every week or placebo.²⁸⁴ Azithromycin reduced MAC bacteremia by 57% and infection (23.3% versus 8.2%). Survival benefit was not evaluated. GI disturbance was observed more commonly in the azithromycin arm.²⁸⁴

Azithromycin 1,200 mg every week, rifabutin 300 mg/day, and a combination of both drugs in the same doses were compared in patients with AIDS and CD4⁺ counts <100. The incidence of MAC bacteremia was 13.9% in the azithromycin monotherapy arm, 23.3% in the rifabutin monotherapy arm, and 8.3% in the azithromycin, rifabutin combination arm. Time to death was not significantly different among the treatments; however, the combination arm had an increased incidence of adverse drug effects. Although combination therapy was

superior to azithromycin alone, its use is considered second-line because of the increased cost, toxicity, and lack of survival benefit.²⁸⁵

In a similar trial, patients with AIDS and CD4⁺ counts < 100 were randomized to receive clarithromycin 500 mg twice daily, rifabutin 450 mg/day, or both.²⁸⁶ In the midst of the trial, the rifabutin dosage was reduced to 300 mg/day because of a drug interaction with clarithromycin that resulted in rifabutin-induced uveitis. MAC bacteremia occurred in 9% of patients in the clarithromycin monotherapy arm, 15% of patients in the rifabutin monotherapy arm, and 7% of patients receiving the combination. Time to death was not significantly different among the arms, but the combination was more toxic.

The decision to use clarithromycin or azithromycin (both first-line recommendations for primary prophylaxis) is based on patient compliance and the potential for drug interactions. Azithromycin (1,200 mg once weekly) may be preferable for a patient who has difficulty with compliance. In contrast with clarithromycin, azithromycin does not affect the cytochrome P450 enzyme system and is therefore less likely to interact with other drugs. M.E. would have benefited from MAC prophylaxis when her CD4⁺ count decreased to <50.

Patients whose CD4⁺ count increases from 100 for >3 months may discontinue primary prophylaxis (Table 70-2).⁴⁸ However, prophylaxis should be reintroduced if the CD4⁺ count decreases to <50 to 100.

ENTERIC INFECTIONS

50. A.B. is a 38-year-old woman with a 4-year history of HIV infection and a CD4⁺ count of 160 (normal, approximately 1,000). She reports two or three watery, unformed bowel movements per day for approximately 6 weeks, with accompanying abdominal pain. She has refused antiretroviral therapy and is currently taking only one TMP-SMX double-strength tablet each day. What GI pathogens should be considered in the differential diagnosis in HIV-infected patients who develop diarrhea?

GI complications are common in HIV patients (e.g., enteric infections, gastric achlorhydria, pancreatitis, cholangitis, hepatitis, proctitis, KS, lymphoma, carcinoma, and HIV enteropathy). Enteric infections can be caused by fungal, viral, bacterial, or protozoan pathogens. In general, clinical manifestations caused by GI infections appear with a decline in the CD4⁺ count. Similar to A.B., most patients present with a change in bowel habits, predominantly diarrhea.²⁸⁷ When evaluating infectious diarrhea, several factors should be considered. The diarrhea first must be categorized as acute or chronic. Acute diarrhea is defined as “greater than or equal to three loose or watery stools for >10 days with fever, blood in the stool, and/or weight loss.”²⁵⁴ In acute diarrhea in patients with AIDS, all potential etiologies should be evaluated, including medication, dietary, or psychosomatic causes. Acute diarrhea is usually associated with bacterial causes, such as *Salmonella*, *Shigella*, *Campylobacter jejunii*, or *Clostridium difficile*.

Chronic diarrhea is defined as “greater than two to three loose or watery stools per day for >30 days.”²⁵⁴ Chronic infectious diarrhea also can be caused by protozoans, such as *Microsporidia*, *Isospora*, *Cyclospora*, *Cryptosporidia*, *Entamoeba histolytica*, and *Giardia*. Chronic diarrhea may also

have a viral etiology (e.g., HSV or CMV). Bacteria can also be associated with chronic diarrhea, primarily *Salmonella*, *Shigella*, *C. jejuni*, *C. difficile*, and MAC (Table 70-13).

Fungal Infections

In acute infectious diarrhea, fungal infections are rare; they tend to be isolated to the oropharynx and esophagus and are predominantly caused by *Candida* species, primarily *C. albicans*. Other fungal infections in AIDS patients do not commonly involve the GI tract. However, patients with disseminated histoplasmosis may develop diarrhea (Table 70-12).

Viral Infections

Viruses that infect the GI tract of AIDS patients are unlike those associated with diarrhea in non-HIV-infected patients (e.g., rotaviruses, enteric adenoviruses, Norwalk agent, coronavirus, and coxsackieviruses). More common among HIV patients are CMV and HSV infections. Disseminated CMV infection is common in HIV-infected patients with advanced disease, and although retinitis is the most common CMV infection (see questions 14–25), as many as 2% of patients have GI involvement.²⁸⁸ CMV usually involves the colon, and the common presentation is diarrhea. Tissue biopsy is preferred for a definitive diagnosis. CMV infection of the pancreas, liver, gallbladder, and biliary tree also has been described.²⁸⁹ The IV agents used to treat CMV retinitis may also be used to treat CMV disease in the GI tract. In contrast with the treatment of CMV retinitis, therapy for colitis lasts 3 to 6 weeks. Data support the use of ganciclovir over foscarnet for CMV colitis, whereas the efficacy of cidofovir is unknown. Regular ophthalmologic screening for CMV retinitis is recommended for all patients with CMV GI tract disease.⁴⁴

The other common cause of viral GI disease is herpes simplex. The clinical presentation is similar to that of disseminated CMV, but the site of infection and biopsy findings differentiate the viruses. HSV type 1 primarily is associated with ulcerated esophageal lesions. In contrast, HSV type 2 is often the cause of proctitis. Although not usually associated with diarrhea, proctitis may result in bloody, mucousy stools. HSV also can cause large, painful perianal lesions. Herpes simplex GI lesions usually are treated with acyclovir; if herpes-resistant virus is suspected, foscarnet is used (Table 70-12).²⁵⁴

Bacterial Infections

Bacteria such as *Salmonella*, *Shigella*, and *Campylobacter* cause lower GI disease in HIV patients, but these organisms are generally more virulent in HIV-negative patients. The frequency of acute infectious diarrhea caused by *Salmonella* for patients with AIDS is 5% to 15%. *Salmonella* bacteremia is considered an AIDS-defining diagnosis. The clinical features include fever and watery stools, with variable fecal WBCs. Diagnosis is made based on stool and blood cultures. In contrast with immunocompetent persons, antibiotics are recommended for treatment of *Salmonella* in HIV-infected patients; ciprofloxacin (750 mg BID for 2 weeks) is the preferred regimen. Alternative regimens include ampicillin (8–12 g/day IV for 1–4 weeks), amoxicillin (500 mg PO TID to complete a 2- to 4-week course), TMP-SMX (5–10 mg/kg/day IV or PO for

Table 70-13 Enteric Infections Associated With Infectious Diarrhea

| <i>Enteric Infections</i> | <i>Treatment</i> |
|--------------------------------------|--|
| Fungal | |
| <i>Candida albicans</i> ^a | Fluconazole 100–400 mg PO QD; ketoconazole 200–400 mg PO QD; caspofungin 50 mg IV QD; amphotericin B 0.3–0.5 mg/kg IV; liposomal or lipid amphotericin 3–5 mg/kg IV QD; voriconazole 200 mg BID; itraconazole solution 200 mg QD; efficacy of fluconazole is 85% |
| <i>Histoplasmosis</i> | Itraconazole 200 mg PO TID ×3 days, then 200 mg PO BID ×12 wks (liquid formulation has better absorption, limited data available on IV) <i>Alternative:</i> amphotericin B 0.8–1.5 mg/kg IV or liposomal amphotericin 4 mg/kg QD then itraconazole 200 mg BID ×12 wks |
| Viral | |
| CMV | Ganciclovir 5 mg/kg IV BID ×2–3 wk; foscarnet 40–60 mg/kg Q 8 hr ×3–4 wk (efficacy of antiretroviral treatment is 75%) or oral valganciclovir |
| HSV ^a | Acyclovir 200–800 mg PO 5×/day or 5 mg/kg IV Q 8 hr ×2–3 wk |
| Bacterial | |
| <i>Salmonella</i> spp. | Ciprofloxacin 500–750 mg PO/IV BID ×14 days or TMP-SMX 5–10 mg/kg/day PO/IV BID ×2–4 wk or ampicillin 2 g/day PO or 6 g/day IV ×14 days or third-generation cephalosporin or chloramphenicol; treatment may be extended to 4–6 wk |
| <i>Shigella</i> spp. | Ciprofloxacin 500 mg PO/IV BID ×3–7 days; TMP-SMX 1 DS PO BID ×3–7 days; azithromycin 500 mg ×1, then 250 mg QD ×4 days; antiperistaltic agents (Lomotil or loperamide) are contraindicated |
| <i>C. jejuni</i> | Ciprofloxacin 500 mg PO BID ×7 days or azithromycin 500 mg QD ×7 days |
| <i>C. difficile</i> | Metronidazole 250–500 mg PO QID ×10–14 days or vancomycin 125 mg PO QID 10–14 days; antiperistaltic agents (Lomotil or loperamide) are contraindicated |
| Protozoa | |
| <i>Isospora</i> | TMP-SMX 1 DS QID or 2 DS BID <i>Alternative:</i> pyrimethamine 50–75 mg with folinic acid 5–10 mg or fluroquinolone |
| <i>Cyclospora</i> | TMP-SMX 1 DS BID |
| <i>Microsporidia</i> | Albendazole 400–800 mg PO BID until CD4 >200 <i>Alternative:</i> metronidazole, atovaquone, and thalidomide |
| <i>Cryptosporidia</i> | No effective treatment; paromomycin, nitazoxanide, octreotide, azithromycin (marginal benefits and no cure); best treatment approach is antiretroviral therapy to increase CD4 >100. |

^aPrimarily esophagitis.
 BID, twice a day; DS, double strength; IV, intravenously; PO, orally; QID, four times a day; QD, daily; TID, three times a day; TMP-SMX, trimethoprim-sulfamethoxazole.
 Adapted from references 288 and 295.

2–4 weeks), or a third-generation cephalosporin. Eradication of *Salmonella* has been demonstrated only with ciprofloxacin. Bacteremia may be more frequent compared with non-HIV-infected patients and may recur despite antibiotic therapy. For recurrent therapy, ciprofloxacin (500 mg PO BID) is preferred for several months. TMP-SMX (5–10 mg/kg TMP component daily IV or PO) may be considered as an alternative. Lifelong treatment may be required (Table 70-13).^{290,291}

The frequency of *Shigella* is 1% to 3% in acute infectious diarrhea in AIDS patients; *S. sonnei* accounts for approximately 70% of the reported U.S. cases. *S. flexneri* is also reported in young homosexual men. Person-to-person spread is the main route of transmission. *Shigella* causes dysentery, fever, and abdominal cramps, which precede voluminous, watery stools. Bloody mucoid stools with fecal urgency may also develop. Fecal WBCs are common, and diagnosis is made by stool culture. Mild to severe cases of *Shigella* bacteremia have been reported, lasting an average of 7 days if untreated. Because this is a self-limiting illness and resistance is common, treatment is recommended only for severely ill patients. Antibiotic therapy should be selected based on susceptibility patterns. Ciprofloxacin

(500 mg PO BID) or TMP-SMX (1 double-strength tablet PO BID for 3 days) both are effective regimens. Antiperistaltic agents are contraindicated. As with *Salmonella*, *Shigella* infections are associated with an increased frequency of bacteremia in HIV-infected patients who may require prolonged therapy (Table 70-13).^{291,292}

C. jejuni accounts for 4% to 8% of cases of acute infectious diarrhea in AIDS patients. *Campylobacter* enteritis is associated with a prodrome of fever, headaches, myalgia, and malaise 12 to 24 hours before diarrhea and abdominal pain. Diarrhea varies from loose bowel movements to voluminous, watery, and grossly bloody stools. Fecal leukocytes are variable, and the diagnosis is made by stool culture. *Campylobacter* enteritis is self-limiting, lasting only several days; however, some HIV-infected persons have symptoms lasting >1 week and may relapse if left untreated. Antibiotics are recommended for patients with high fevers, bloody stools, more than eight stools per day, and symptoms for >1 week without improvement. Erythromycin (500 mg PO QID for 5 days) and ciprofloxacin (500 mg PO BID for 3–5 days) are the preferred agents. Quinolone-resistant isolates are well documented. Alternatives

to erythromycin or ciprofloxacin include tetracycline, clindamycin, and ampicillin (Table 70-13).²⁹³

HIV-positive patients should take preventive measures against potential enteric pathogens. Close attention to hand hygiene is recommended, as is not handling or eating raw or uncooked poultry, fruits, vegetables, and nonpasteurized dairy products. Fortunately, the widespread use of TMP-SMX for PCP prophylaxis has reduced the frequency of these bacterial infections. Disseminated MAC disease, *M. tuberculosis*, *Helicobacter pylori*, and *C. difficile* also can cause diarrhea in HIV-infected patients.

Protozoal Infections

As a group, protozoal infections are the most common cause of diarrhea among HIV-infected patients. Opportunistic protozoans such as *Cryptosporidium*, *Isospora belli*, and *Microsporidia* are well-known GI pathogens. Other nonopportunistic protozoans such as *Giardia lamblia*, *E. histolytica*, and *Cyclospora cayetanensis* also cause disease.²⁸⁷

Cryptosporidium, a coccidioidin protozoan with a life cycle that occurs entirely within a single host, can be transmitted from animals to humans by fecal water contamination or person-to-person fecal-oral spread.²⁹⁴ HIV-infected patients should be advised to wash their hands after contact with fecal material (e.g., changing diapers), exposure to pets, gardening, or contact with soil, and they should avoid oral-anal sexual practices. HIV-infected patients also should avoid drinking water from lakes and swallowing water during recreational activities. Outbreaks of cryptosporidiosis have been linked to municipal water supplies.²⁹⁵ HIV-infected patients should avoid eating raw oysters because the oocysts can survive in oysters for >2 months.⁴⁸ In patients with AIDS, the frequency of chronic infectious diarrhea owing to cryptosporidiosis is 10% to 30%.²⁹⁴ In contrast to the explosive onset that occurs in non-HIV patients, acute cryptosporidiosis in AIDS patients is more insidious and progresses in severity as the degree of immunosuppression increases. Intestinal cryptosporidiosis may be complicated by concurrent biliary involvement, leading to jaundice and hepatosplenomegaly. Although the diagnosis of cryptosporidiosis formerly depended on intestinal tissue biopsy, newer techniques such as staining oocysts in stool (modified acid-fast methods) and fluorescent antibody assays have been developed.²⁹⁶ No known prophylaxis exists; however, one MAC prophylaxis study suggested that clarithromycin and rifabutin also may prevent cryptosporidiosis.²⁹⁷ The treatment of cryptosporidiosis remains investigational and studies have progressed slowly. Supportive care that includes fluid and electrolytes, parenteral hyperalimentation, and antidiarrheal agents often is necessary.

The long-acting somatostatin analog octreotide acetate (50–500 µg TID subcutaneously or IV at 1 µg/hr) also has been used with limited benefit in some patients. However, it is expensive and the parenteral administration is inconvenient for many patients.²⁹⁶ Trials of α -difluoromethylornithine and oral spiramycin have yielded inconsistent results. Other drugs, such as IV spiramycin, letrozol, hyperimmune bovine colostrum, transfer factor (a dialyzable leukocyte extract obtained from cow lymph nodes), and IGX-CP (an oral formulation of chicken egg yolks immunized with *Cryptosporidium* antigen), have been investigated, but results are not encouraging.²⁹⁶

Paromomycin (500–750 mg PO QID with food for 21 days, then 500 mg PO BID) is a poorly absorbed aminoglycoside antibiotic commonly used to treat HIV-infected patients with cryptosporidiosis.²⁹⁵ Paromomycin, 1 g BID plus azithromycin 600 mg/day for 4 weeks followed by paromomycin alone, 1 g BID for 8 weeks, was associated with improvement of symptoms and a significant reduction in oocyst excretion. Azithromycin, an azalide antibiotic, when used alone, is ineffective.²⁹⁸

Nitazoxanide is an antimicrobial compound with activity against protozoans, helminths, and bacterial organisms. This drug has been approved for use; the usual dosage is 500 mg orally twice daily for 3 days.^{254,296,299} Data have demonstrated a 30% favorable response rate in HIV-negative but not HIV-positive subjects. Higher doses or longer durations of therapy may be needed in HIV-infected patients.

Several reports suggest that treatment with HAART results in improved immune function and subsequent resolution of cryptosporidiosis.^{40,300}

I. belli, a coccidioidin protozoan, has a life cycle similar to that of *Cryptosporidium*. The frequency of *I. belli* is 1% to 3% in chronic infectious diarrhea in patients with AIDS. *Isospora* is rarely identified as a cause of diarrhea (<1%) in the United States and Europe, in contrast to Africa, Haiti, and Latin America.³⁰¹ Clinically, these patients develop diarrhea, steatorrhea, cramping, and weight loss. In AIDS patients, as well as infants or children without AIDS, this disease may become a protracted illness.^{296,301} Similar to *Cryptosporidium*, the diagnosis of isosporiasis is made with acid-fast stains. *Isospora* oocysts are larger and morphologically distinct. Importantly, and in contrast to cryptosporidiosis, isosporiasis can be treated with TMP-SMX (160 mg/day and 800 mg/day, respectively). Chronic suppressive therapy often is needed and can be accomplished with lower doses of TMP-SMX or pyrimethamine-sulfadoxine (Table 70-13).

Microsporidium (a ubiquitous, obligate intracellular protozoan parasite) characterizes the four genera (out of hundreds) of *Microsporidia* known to cause human disease; it is responsible for 15% to 30% of chronic infectious diarrhea in AIDS patients. Among AIDS patients, the cornea, liver, peritoneum, and small intestine have been reported to be infected with *Microsporidium*.³⁰¹ The primary species associated with AIDS patients are *Enterocytozoon bienersi* or *Septata intestinalis*. These can be identified in intestinal biopsy specimens using electron microscopy and hematoxylin-and-eosin stained paraffin-embedded sections. Albendazole (400–800 mg PO BID for >3 weeks) has been found to be efficacious in the treatment of *S. intestinalis*. Some patients have been successfully treated with metronidazole, atovaquone, and thalidomide (Table 70-13).³⁰² Several reports suggest that infection resolves with HAART therapy.^{40,48}

GI manifestations of HIV infection become increasingly common in the advanced stages of HIV infection. A.B. presents with chronic infectious diarrhea (two or three watery stools for >30 days). Review of her current medications (to rule out a medication source for diarrhea) revealed only low-dose TMP-SMX. CMV, MAC, *Microsporidia*, *Isospora*, and *Cyclospora* are common in patients with a CD4⁺ count <100. Stool analyses, including ova and parasites, AFB smears, bacterial culture, *C. difficile* toxin assay, and *Microsporidia* assay, were ordered. A fecal WBC examination was also ordered. The AFB smear

of stool showed *Cryptosporidia* oocysts. A.B. was empirically treated with paromomycin, 500 mg orally four times a day with food for 21 days, then 500 mg orally twice daily with food for chronic suppressive therapy. Baseline auditory and renal function assessment should be done before initiation of therapy to monitor for ototoxicity and nephrotoxicity. A.B. should be treated symptomatically with nutritional supplements and anti-diarrheal agents (Lomotil or loperamide). HAART therapy with immune recovery may reverse the progression of her enteritis and should be recommended.

ESOPHAGEAL DISEASE

51. P.J. is a 45-year-old, HIV-positive man who was started on AZT, 3TC, and lopinavir/ritonavir when he was diagnosed 1 year ago. P.J. is a heroin user and has not been seen in the clinic since his initial presentation. He appears today complaining of difficult, painful swallowing and diffuse pain. Upon examination, localized white plaques are observed in the oral cavity. His CD4⁺ count is 280 (normal, approximately 1,000). What is the most likely cause of this patient's dysphagia and odynophagia?

Esophagitis in HIV-positive patients generally is caused by *Candida* (50%–75% of cases), CMV (10%–20%), HSV (2%–5%), and aphthous ulcers (10%–20%).²⁵⁴ Symptoms include dysphagia, odynophagia, and thrush (with *Candida* infections). Oral ulcers are common with HSV, rare with *Candida*, and uncommon with CMV or aphthous ulcers. Pain is usually diffuse in *Candida* infections and more focused with HSV, CMV, and aphthous ulcers. Fever is primarily associated with CMV.

Up to 75% of AIDS patients develop oral candidiasis, a consequence of a failing immune system and fungal colonization of the oropharynx. Patients with localized white plaques in the oral cavity likely have oral candidiasis (thrush) and should be started on antifungal therapy. Initially, patients may be treated with local antifungal therapy (e.g., “swish and swallow” nystatin suspension 3 million units four or five times daily or clotrimazole troches four or five times daily). If no response is noted or symptoms of esophageal involvement develop (e.g., dysphagia or odynophagia), these patients should be treated with a systemic agent; the azoles are preferred. Many patients with thrush without esophagitis do not respond to topical treatment and also require systemic azole therapy.

Esophagitis owing to *C. albicans* increases in frequency as HIV progresses. Not all patients with thrush develop esophagitis; however, patients who experience esophageal symptoms generally have esophagitis. Diagnosis is made using endoscopy and microbiology. Multiple white or gray plaques are observed endoscopically; they may be discrete or appear as continuous exudates.³⁰³ Esophageal candidiasis must be treated as a systemic infection; local antifungal agents should never be used. Therapy should be initiated with oral fluconazole (Diflucan) 200 mg orally, then 100 mg orally daily for 2 to 3 weeks (up to 400 mg/day). Fluconazole is the preferred azole because of fewer toxicities, fewer drug–food interactions, and a reduced potential for drug–drug interactions. Alternative oral therapies include itraconazole oral solution or ketoconazole (Nizoral). If azole-resistant candidiasis or severe disease is diagnosed, parenteral amphotericin B (0.3–0.5 mg/kg/day IV with or without flucytosine 100 mg/kg/day) should be used.³⁰⁴

CMV esophagitis should be considered in patients who do not respond to a 1-week course of an antifungal. CMV esophagitis is confirmed via endoscopic biopsy demonstrating erythema and single or multiple discrete erosive lesions, usually located distally.^{44,289} Acute treatment consists of ganciclovir 5 mg/kg IV per dose twice daily or foscarnet 40 to 60 mg/kg IV per dose Q 8 hours for 2 to 3 weeks. Maintenance therapy, if used, is usually half the dose used for induction treatment. Patients with CMV esophagitis have a poor prognosis.

Diagnosis of esophageal disease caused by HSV is by endoscopy, which reveals erythema and erosions. These small, shallow ulcers usually coalesce. HSV can be successfully treated with acyclovir or valacyclovir. Aphthous ulcers are similar in appearance and location to CMV, and negative results for *Candida*, HSV, and CMV are suggestive of aphthous ulcers. Acute treatment involves prednisone 40 mg/day for 7 to 10 days, tapered to 10 mg/wk. Thalidomide, 200 mg/day, is a promising regimen; one trial demonstrated a 53% response compared with 7% in the placebo group.³⁰⁵

A presumptive diagnosis of *Candida* esophagitis can be made for P.J. because he presents with oral pharyngeal candidiasis, dysphagia, and odynophagia. P.J. should be empirically treated with fluconazole, 200 mg/day for 14 to 21 days. If he is unresponsive to fluconazole, endoscopy with biopsy and culture should be performed to confirm the diagnosis. If candidiasis is confirmed, P.J. should be checked for medication adherence and potential drug interactions. If the patient is adherent and does not have malabsorption, parenteral amphotericin B should be considered. Anecdotally, fluconazole doses have been increased in some patients with refractory candidiasis, with successful clinical outcomes. This may be an option before amphotericin therapy.³⁰⁶ Relapse is common in patients who do not receive secondary prophylaxis. Chronic suppressive therapy (fluconazole 100–200 mg/day) should be considered in all patients responsive to fluconazole therapy who have frequent or severe recurrent esophagitis. However, this practice has been documented to increase the probability of azole resistance.^{48,307}

HIV WASTING SYNDROME

52. J.R. is a 38-year-old woman who has been followed in the HIV clinic for 8 years. She has been treated with antiretroviral therapy for 5 years from the time she developed PCP. She has chronic oral candidiasis managed with intermittent fluconazole. Her last CD4⁺ count was 90 (normal, approximately 1,000). Over the last two visits, J.R.'s weight has declined from a baseline weight of 140 to 115 lb. She reports two or three loose stools per day, intermittent fevers, loss of appetite, and a generalized weakness for at least 5 weeks. What is the potential cause of J.R.'s weight loss, and how should it be managed?

Rapid disease progression is associated with significant weight loss in HIV-infected patients. Wasting syndrome can be defined as “the unintentional weight loss of >10% of baseline body weight plus chronic diarrhea (more than two loose stools a day for >30 days) or chronic weakness with unexplainable fever that is intermittent or constant for >30 days.”³⁰⁸

The pathophysiology of HIV wasting syndrome is not clearly understood, but it is characterized by depletion of both adipose and lean body tissue. Because weight loss may also

Table 70-14 HIV Wasting Regimens

| <i>Agent</i> | <i>Dose</i> | <i>Side Effects</i> | <i>Comments</i> |
|-----------------------------------|--------------------------------------|---|---|
| Approved | | | |
| Megestrol acetate ^a | 400–800 mg/day | Impotence, GI disturbances, endocrine effects | Dose must be tapered before discontinuation |
| Dronabinol ^a | 2.5 mg BID (before lunch and dinner) | Euphoria, dizziness, confusion, sedation | Use with caution in patients with a history of drug abuse |
| Somatropin (rhGH) ^b | 0.1 mg/kg/day SC (6 mg/day) | Edema, arthralgias, myalgias, paresthesias, diarrhea | Long-term effect unknown Expensive agent |
| Oxandrolone ^b | 520 mg/day | Elevated LFTs | FDA orphan drug |
| Unlabeled Use | | | |
| Oxymetholone ^b | 25–50 mg/day | Irritability and aggression | Monitor glucose tolerance |
| Testosterone ^b | 200–400 mg IM Q 2 wk | Irritability, aggression, gynecomastia, acne | Endogenous testosterone levels must be <400 ng/dL for all anabolic steroid administration |
| Cypionate or enanthate | 4 or 6 mg/day | | |
| Testoderm scrotal patch | 5 mg/day | | |
| TTS patch | 5 mg/day | | |
| Androderm | | | |
| Nandrolone ^b decanoate | 100–200 mg IM Q 2 wk | Elevated Hgb and Hct, dysmenorrhea | Anabolic steroid |
| Thalidomide | 300–400 mg/day | Teratogenicity, somnolence, rash, peripheral neuropathy | FDA orphan drug Enhanced sedation with other CNS depressants |
| Cyproheptadine ^a | 12–20 mg/day | Sedation | Antihistamine |

^aAppetite stimulants: weight gain predominantly fat, not lean body mass.

^bSignificant increases in lean body mass.

CNS, central nervous system; FDA, U.S. Food and Drug Administration; GI, gastrointestinal; Hct, hematocrit; Hgb, hemoglobin; IM, intramuscularly; LFTs, liver function tests; rhGH, recombinant human growth hormone; SC, subcutaneously.

signal an opportunistic infection (e.g., enteric infection, PCP, or MAC), these etiologies must be ruled out.² Wasting syndrome may be multifactorial, resulting from decreased nutritional intake or absorption, accelerated nutrient metabolism, stress, or a combination of these factors.^{309,310} J.R. meets the criteria for wasting with an unintentional 18% weight loss accompanied by chronic diarrhea and weakness.

Three appetite stimulants are routinely used to treat HIV-related wasting (Table 70-14). Megestrol acetate is an oral synthetic progestin related to progesterone. This drug is widely used for the treatment of hormone-responsive malignancies, but it is also approved for HIV-infected patients who have lost at least 10% of their ideal body weight. Megestrol 400 to 800 mg/day has been associated with weight gains of up to 10 kg.^{309,311} However, a significant portion of the observed weight gain appears to be fat mass rather than lean tissue. Hypogonadism, diabetes, and adrenal insufficiency are the most serious side effects. Other side effects include impotence, diarrhea, reduced testosterone levels, hyperglycemia, and alopecia.

Dronabinol (delta-9-tetrahydrocannabinol), the psychoactive component of marijuana, 2.5 mg twice daily has been approved for treating AIDS-related weight loss. The dronabinol significantly increases appetite,³¹² increases body weight (primarily fat), and improves mood. Besides stimulating appetite, dronabinol also has antiemetic effects, which are useful in patients with nausea and vomiting associated with the wasting syndrome. Euphoria, dizziness, confusion, and somnolence occur in 18% of dronabinol-treated patients. A reduction in the

dose of dronabinol to 2.5 mg 1 hour before supper or bedtime may reduce adverse events. Because of its potential for misuse, dronabinol should be used with caution in patients with a history of substance abuse. Patients should be counseled to avoid driving, operating machinery, or other potentially hazardous activity until it is established that they can safely perform these activities. Alcohol or other CNS depressants may result in additive CNS depression.

Cyproheptadine is an antihistamine reported to stimulate appetite in HIV-infected patients. The use of cyproheptadine 12 mg/day has been associated with minimal weight gain as a result of an increase in daily caloric intake. This drug, although used for the treatment of anorexia, is not approved by the FDA for HIV wasting (Table 70-14).

Anabolic steroids and testosterone have been shown to increase muscle mass and strength in people with HIV wasting syndrome. Products include oxandrolone (Oxandrin), nandrolone (Deca-Durabolin), oxymetholone (Anadrol-50), and testosterone.^{313,314} Oxandrolone at a dosage of 15 mg/day significantly increases body weight but does not improve body strength. The usual dosage for males is 10 to 20 mg twice daily; for females the range is 5 to 20 mg/day. This drug has a low androgenic effect, so it is particularly useful in women. Most weight gain is lean body mass. Minimal hepatotoxicity has been associated with this agent.³¹³ Oxandrolone can be administered orally, which may improve adherence.^{313,315}

Nandrolone increases body weight, muscle mass, and strength. Nandrolone has a high anabolic effect and a low

androgenic effect. The dosage of nandrolone for males is 100 to 200 mg intramuscularly every 1 to 2 weeks and for females 25 mg intramuscularly per week or 50 mg intramuscularly every 2 weeks.^{315,316}

Oxymetholone is not recommended for use in women because of its high androgenic potential. Hepatic toxicity is common, so LFTs must be carefully monitored. Doses of 50 mg twice daily are used in HIV-infected male patients.³¹⁵ In an open-label study, oxymetholone produced a mean weight gain of 5.7 kg with improvement in the Karnofsky score in HIV-infected patients with wasting syndrome.³¹⁷ It has high androgenic and some anabolic effects, so it may be better suited for HIV-infected men.

A decrease in testosterone correlates with a decrease in lean body mass in AIDS patients.³¹⁴ Testosterone administration produces a significant increase in lean body mass (mean 1.2 kg) in HIV-positive patients without wasting syndrome. It is available as long-acting intramuscular injections (enanthate and cypionate), short-acting intramuscular injections (propionate), and a transdermal system (2.5, 4, 5, and 6 mg/24 hr). The transdermal systems differ in release rate, surface area, and total testosterone content. Testosterone should be used in patients with low endogenous testosterone levels (<400 ng/dL in men). Testosterone has been associated with improved mood, libido, and energy in clinical trials. It is also associated with acne, gynecomastia, alopecia, and testicular atrophy. Testosterone has been shown to be less effective than oxandrolone or nandrolone for weight gain.^{318,319} In clinical practice, testosterone is sometimes combined with megestrol acetate or nandrolone, but this combination has not been studied.

Growth hormones (which directly influence nitrogen balance and muscle protein synthesis) have been used in the treatment of HIV wasting syndrome. These include recombinant human insulinlike growth factor-1 and somatropin (Seroestim), a recombinant human growth hormone. Disturbances in growth hormone–insulinlike growth factor-1 axis have been described in HIV-positive subjects. In one placebo-controlled trial, 10 mg/day of recombinant human insulinlike growth factor-1 subcutaneously failed to significantly increase weight or lean body mass.³²⁰ Subcutaneous injections of somatropin (0.1 mg/kg/day) have been associated with increases in lean body mass and functional performance.³²¹ Adverse events include edema, arthralgia, diabetes, acute pancreatitis, and carpal tunnel syndrome. The questionable long-term benefits and the tremendous expense of growth hormone diminish its appeal (Table 70-14).³¹⁶

Several cytokine modulators are used in the treatment of HIV wasting. These include pentoxifylline (Trental), thalidomide, ketotifen, and omega-3 fatty acids (fish oil). Altered metabolism of cytokines, tumor necrosis factor (TNF), interleukin-1, or interferon may play a role in the wasting syndrome. As an example, an elevation in serum TNF- α has been noted in HIV patients with advanced disease. Thalidomide and pentoxifylline, which decrease TNF- α levels, have been used in patients with HIV wasting syndrome. Thalidomide has been associated with significant weight gain.^{315,322} However, thalidomide is associated with numerous adverse effects, including somnolence, rash, teratogenicity, and peripheral neuropathy (additive with other drugs known to cause peripheral neuropathy). It may also be associated with an elevation in HIV-RNA levels; however, more studies are needed for confirmation. Pentoxifylline, a drug used to prevent intermittent

claudication, has also been evaluated as treatment for the HIV wasting syndrome. Unfortunately, because pentoxifylline has failed to stimulate the appetite or increase weight gain, it does not have a role in the treatment of HIV wasting.³¹⁵

Exercise has been considered as a possible intervention for HIV wasting. The preliminary results of one study demonstrated an increase in lean body mass and strength after patients underwent an 8-week course of progressive resistance training.³²³

J.R. must be assessed for possible OIs and treated accordingly. Once the diarrhea has resolved, medications to reverse HIV wasting may be started. The patient's lack of appetite should be addressed first with the use of megestrol acetate (400 mg/day oral suspension). In addition, the patient should be started on oxandrolone (10 mg/day PO). A pregnancy test should be performed because most anabolic agents should not be administered to pregnant women. Because of their high androgenic effects, oxymetholone and testosterone should be avoided in J.R.

HIV-ASSOCIATED MALIGNANCIES

53. Despite an extensive microbiologic workup, no organism was identified, and other causes for J.R.'s change in bowel habits were evaluated. What neoplastic conditions could be contributing to J.R.'s GI status?

In addition to the OIs described under enteric infections, GI malignancy is common in patients with HIV. As the CD4⁺ count declines, patients may develop KS (see Kaposi Sarcoma section), lymphoma, and invasive cervical cancer. The reason for the increased occurrence of malignancy is unknown, but it may be related to impaired immune function. In addition, effective antiretroviral therapy and prophylactic anti-infective therapy have extended the life span of patients with AIDS, increasing the likelihood that malignancies will be detected.^{324,325} J.R. has been on HAART therapy and prophylactic anti-infective therapy for many years; thus, she may be at risk for malignancy.

Kaposi Sarcoma

KS previously was well described in non-HIV-infected patients, and its course was fairly uneventful. Consequently, limited studies of innovative chemotherapy regimens were conducted in the past. In contrast, KS in HIV-infected patients is more invasive and is associated with increased morbidity and mortality.³²⁵ Although KS occurs predominantly in homosexual men, the incidence of KS has increased in IV drug users, recipients of blood products, women, and children. The risk of developing KS is 20,000 times higher for HIV-infected patients than for non-HIV-infected persons. The incidence of KS as a presenting AIDS illness has significantly declined since the early 1990s, and this may be indirectly due to HAART.³²⁶ An infectious etiology has been suggested in recent studies. DNA sequencing in KS tissue has detected a herpes virus. A new human herpes virus 8 (HHV-8) has been observed in biopsies of classic KS, African KS, and HIV-positive KS. This finding suggests that HHV-8 is either a causative agent or a recurrent passenger virus (i.e., an "innocent bystander").^{327,328}

Other studies have suggested that the pathogenesis of KS in HIV patients is related to the existence of cells with the potential to become KS lesions. Cytokines released from activated immune cells potentially stimulate the proliferation of KS

precursor cells at a time when the immune function for such cells is becoming progressively impaired. Furthermore, some cells may produce a growth factor for KS cells (e.g., angiogenic factors), and the expression of the *tat* gene by HIV may produce growth factors that induce vascular KS-like tumors.^{324,329–331}

KS presents with three types of lesions: flat, raised, or nodular. The lesions occur primarily on the skin, oral mucosa, GI tract, and lungs. KS lesions may be asymptomatic or painful; intestinal or pulmonary lesions may be associated with significant clinical symptoms such as dyspnea or diarrhea. Cutaneous disease involves initially small, flat lesions that progress to reddish or purple nodules.³³¹ They are generally asymptomatic and follow a pattern of cutaneous lymphatic drainage. Progression of KS leads to lesions in the oral cavity in approximately one-third of cases.³²⁸ KS has a multifactorial presentation without a primary lesion; therefore, staging according to a standard tumor-node-metastasis classification is not appropriate. A staging system proposed in 1989 by the ACTG Oncology Committee divides patients into good- or poor-risk groups based on tumor characteristics, the patient's immunity (measured by CD4⁺ count), and the severity of systemic HIV-associated illness.^{329,330} Whether staging and the choice or response to therapy are correlated is unclear.

The growth of KS is stimulated by inflammatory cytokines, which are increased in acute OIs and active HIV replication. Successful management of KS includes optimal antiretroviral therapy, prophylactic therapy, and effective treatment of OIs. Mild disease is not treated; therefore, management of KS can be divided into local and systemic therapy.³³⁰ Local therapy involves the use of topical liquid nitrogen cryotherapy, intralesional injections of vinblastine 0.01 to 0.02 mg/lesion every 2 weeks for 3 doses, and low-dose radiation therapy (e.g., 400 rads every week for 6 weeks). Local therapy is used in slowly progressive KS without life-threatening organ involvement. Systemic therapy involves the use of interferon- α , 18 to 36 million IU daily intramuscularly or subcutaneously for 10 to 12 weeks, followed by 18 million units per day with additional chemotherapeutic agents. These include paclitaxel (Taxol) 100 to 135 mg/m² IV every 2 to 3 weeks; doxorubicin (Adriamycin), bleomycin, plus either vincristine or vinblastine or bleomycin plus vincristine; liposomal daunorubicin (DaunoXome) 40 to 60 mg/m² IV every 2 weeks; or liposomal doxorubicin (Doxil) 10 to 20 mg/m².³³⁰

The use of interferon- α for KS in patients with AIDS has been well studied alone and in combination with antiretroviral therapy.^{332,333} Early studies demonstrated that AIDS patients receiving high doses of interferon developed neutropenia and neurologic toxicity, and that nonresponders had high circulating levels of endogenous interferon.^{332–335} Later, *in vitro* data indicated that interferon- α was synergistic with AZT against HIV. As a result, interferon therapy was investigated in combination with AZT.^{333,334} Unfortunately, increasing doses of both interferon- α and AZT caused neutropenia, hepatitis, and neurologic toxicity. However, patients who could tolerate the combination had partial or complete remissions and had increased CD4⁺ counts. The hematologic toxicity caused by this combination has prompted researchers to evaluate the concurrent use of colony-stimulating factors such as G-CSF and GM-CSF. Preliminary results indicate that colony-stimulating factors can attenuate the hematologic toxicity.³³⁵ Although interferon may be helpful for certain patients with KS, many cannot tolerate this agent. For this reason, drugs that inhibit the effects of

angiogenic factors are under study. Patients with progressive disease, widespread skin involvement (>25 lesions), extensive cutaneous KS unresponsive to local treatment, and/or visceral organ involvement (especially lung KS) require chemotherapeutic agents. Newer products such as liposomal anthracyclines demonstrate comparable clinical efficacy with reduced toxicities.³³⁶ Experimental therapies include foscarnet, ganciclovir, and cidofovir because of their *in vitro* activity against HHV-8.³³⁷ Intralesional β -human chorionic gonadotropin injections also have produced favorable responses.³³⁸

Non-Hodgkin Lymphoma

NHL is more common than KS in people infected with HIV, particularly those with low CD4⁺ counts (median, 100 cells/mm³).³³⁹ Unlike KS, NHL occurs in all risk groups of HIV-infected patients and does not predominantly occur in homosexual men.³⁴⁰ High-grade NHLs account for approximately 3% of initial AIDS-defining illnesses in adults and adolescents.³⁴¹ The reason for the increased incidence is unknown; however, similar to KS, cytokine dysregulation may play a role.³²⁴

HIV-positive patients often have disseminated disease at the time of diagnosis. In fact, many patients with systemic NHL have extranodal disease (87%–95%). Patients also may present with GI involvement at sites such as the oral cavity, esophagus, small bowel, large bowel, appendix, and anorectum. Involvement of the subcutaneous and soft tissue, epidural space, myocardium, and pericardium has been reported. Patients with CNS lymphomas often present with altered mental status, which may be mistaken for cerebral toxoplasmosis or HIV dementia. Only brain biopsy definitively diagnoses CNS NHL. Poor prognostic risk factors for patients with NHL include a CD4⁺ count of <100, bone marrow involvement, Karnofsky performance status <70, stage IV disease, and a history of a prior AIDS-defining illness. Patients having none of these prognostic risk factors have a threefold greater survival rate compared with patients with one or more of these risk factors.^{341,342}

The treatment of NHL is determined by organ involvement. Patients with evidence of CNS lymphoma often require local radiation or intrathecal chemotherapy. Several systemic chemotherapy regimens have been evaluated,³⁴³ including cyclophosphamide with doxorubicin, vincristine, and prednisone (CHOP); cyclophosphamide with methyl GAG, bleomycin, prednisone, doxorubicin, and vincristine (NHL-7); cyclophosphamide combined with vincristine, intrathecal methotrexate, doxorubicin, and prednisone (L-17); and methotrexate, bleomycin, doxorubicin, cyclophosphamide, and dexamethasone (m-BACOD). Of these regimens, low-dose m-BACOD and low-dose CHOP are considered to be the standard therapies for NHL.³⁴⁴

Patients with NHL tend to have more advanced HIV disease accompanied by reduced bone marrow reserves. As a result, patients with poor prognostic factors do not tolerate full doses of chemotherapy and often develop leukopenia. These patients benefit from low-dose treatment. Patients with good prognostic risk factors may benefit from full-dose chemotherapy along with a colony-stimulating factor (e.g., G-CSF, GM-CSF) and may still be able to remain on antiretroviral therapy.^{341,342}

Because J.R. presents with pathogen-negative, persistent, large-volume chronic diarrhea, KS and NHL must be ruled out.

J.R. has shown no visible skin or oral KS lesions; endoscopy revealed a small GI tumor. Tissue biopsy ruled out KS and confirmed NHL, which was found to be stage II. The bone marrow aspirate was also positive for NHL. The prognostic risk factors for J.R. include a CD4⁺ count <100 and a past history of an AIDS-defining illness (PCP). Consequently, low-dose m-BACOD was initiated with GM-CSF as needed. J.R. will be monitored for resolution of diarrhea as well as toxicities (e.g., hematologic). Her HAART therapy also should be reevaluated.

Cervical Intraepithelial Neoplasia

54. L.P., a 38-year-old woman, was heterosexually infected with HIV. She also has a history of human papillomavirus (HPV) infection successfully treated with imiquimod cream 5%. During a routine HIV clinic visit, a “cheesy” vaginal discharge is noted. L.P. states that her vagina has been itching. Physical examination is unremarkable with the exception of her vaginal discharge. A potassium hydroxide stain of vaginal secretions is positive for hyphae, indicating a yeast infection. CBC values include Hgb, 13.3 g/dL (normal, 12.1–15.3); WBC count, 5,500 cells/L (normal, 3,800–9,800); and platelets, 95,000/mm³ (normal, 150,000–450,000). Notably, for the first time, L.P.’s CD4⁺ count has declined to 435 cells/mm³ (normal, approximately 1,000). She has received no prior antiretroviral therapy. Is L.P.’s gynecologic presentation typical of a woman with early HIV disease?

[SI units: Hgb, 130 g/L (normal, 121–153); WBC count, $5.5 \times 10^{10}/L$ (normal, 3.8–9.8); platelets, $95 \times 10^{10}/L$ (normal, 150–450)]

Four gynecologic disorders occur more frequently, with greater severity, and with less responsiveness in HIV-infected women^{344–346}: HPV, associated cervical intraepithelial neoplasia, *Candida* vaginitis, and pelvic inflammatory disease. All are considered CDC HIV-associated conditions.^{4,348} Cervical neoplasia is a CDC AIDS-defining illness.⁴ Consequently, L.P.’s presentation with vaginitis is typical. Her vaginal yeast infection should be treated with an antifungal agent such as fluconazole (100 mg/day PO) for ≥ 7 days. She should be followed closely to ensure that her infection resolves, because HIV-positive patients may not respond to the standard duration of therapy.

55. L.P. returns to the clinic in a week and her vaginal infection has cleared. A routine Pap smear is performed on this visit, demonstrating cellular changes consistent with a low-grade squamous intraepithelial lesion. What therapeutic intervention should follow this abnormal Pap smear?

Women at increased risk of precancerous cervical cytology include those with HIV infection or HPV infection and cigarette smokers.^{349–351} HPV infections, types 16, 18, and 33, are more prevalent among HIV-positive women than HIV-negative women and have been causally implicated in the development of preinvasive and invasive cervical neoplasms.³⁵² Furthermore, the greater the degree of immunosuppression (CD4⁺ count <200), the higher the risk for cervical intraepithelial neoplasia.³⁵³ Rapidly progressive cervical malignancy and death have been reported in HIV-infected women.^{349,354,355}

All HIV-infected women should have Pap smears every 6 months in the first year of diagnosis.⁴⁷ Among HIV-infected

women, approximately 15% of low-grade squamous intraepithelial lesions progress to high-grade lesions, including moderate to severe dysplasia or carcinoma in situ.^{355,356} Because the risk of progression may be greater among HIV-infected women, many gynecologists recommend colposcopic examination (microscopic inspection of the entire cervical area) with directed biopsy.

If a biopsy confirms precancerous cellular changes, as in L.P., a surgical procedure is indicated to destroy or remove the dysplastic tissue.³⁵⁷ Options include laser therapy, electrosurgery, and cryotherapy. Postsurgical complications may include prolonged bleeding or infertility because of cervical stenosis.^{358,359} After surgery, L.P. should have follow-up Pap smears every 3 months for at least 1 year.^{357,360} The risk of recurrence is much higher in HIV-infected women.³⁵²

Pharmacologic Intervention

56. What pharmacologic intervention has proven to be successful in the treatment of cervical intraepithelial neoplasia? Is L.P. a candidate for this therapy?

Interferon has been suggested for the treatment of cervical intraepithelial neoplasia.³⁶¹ Many uncontrolled studies have been performed, but the number of women who have been evaluated is insufficient to recommend use of this agent. The best results were observed in one small study with systemic administration, but most patients experienced adverse effects.³⁶¹ In an additional trial, 15 women were treated with interferon- β , 2 million IUs intramuscularly daily for 10 days, and their outcomes were compared with 15 women treated with saline.³⁶² After >6 months, 14 of 15 (93%) of the treated women had a complete response compared with 6 of 15 (40%) of the controls. In a placebo-controlled trial using the same dosage regimen,³⁶³ women with earlier stage cervical intraepithelial neoplasia disease responded, but women with more advanced disease responded poorly. A flulike syndrome characterized by fever, chills, headache, malaise, arthralgia, and myalgia was the most common adverse effect, although these symptoms were better tolerated with continued treatment.³⁶¹

Topical interferon- α is associated with a lower incidence of adverse effects, but this route of administration seems less efficacious.^{364,365} Intralesional interferon injections have been tried, but they are inferior to the systemic route, and expert personnel are required for administration.^{366,367} In one trial, women with grade II cervical intraepithelial neoplasia were randomized to receive intramuscular β -interferon, intralesional α -interferon, a combination of both, or conventional therapy. Combination therapy demonstrated the best response with respect to lesion progression.³⁶² L.P. should not be treated with either local or systemic interferon. Systemic therapy seems somewhat more effective in small-scale trials, but it is not well tolerated. The exact role of interferons in the treatment of cervical intraepithelial neoplasia, particularly in HIV-infected women, remains uncertain.

Mycotic (fungal) infections, once observed only occasionally, are now the fourth most commonly encountered nosocomial infection. This increase can be attributed, in part, to the growing numbers of immunocompromised hosts as a result of organ transplants, cancer chemotherapy, and the acquired immunodeficiency syndrome (AIDS) epidemic. Practitioners must be up to date on current concepts in medical mycology that affect the treatment and monitoring of patients with fungal infections. This chapter reviews the mycology, diagnosis, antimycotics, and therapeutics for common mycotic infections. For a more in-depth presentation of the basic biology of fungi, as well as the epidemiology, pathogenesis, immunology, diagnosis, and monitoring of mycotic infections, see Dismukes' *Clinical Mycology*.¹ In addition, other chapters in this book address specific areas of mycology and antifungal therapy. These topics include the treatment of fungal meningitis; endocarditis; intra-abdominal and hepatosplenic infections; bone and joint infections; and infections in immunocompromised patients with and without human immunodeficiency virus (HIV) infections. Treatment of uncommon fungal infections (e.g., paracoccidioidomycosis, alternariosis or fusariosis, mucormycosis, and pseudallescheriasis) is presented associated with immunocompromised hosts.

MYCOLOGY**Morphology**

The pathogenic fungi that infect humans are nonmotile eucaryotes that reproduce by sporulation and they exist in two forms: filamentous molds and unicellular yeasts. These forms are not mutually exclusive and, depending on the growth conditions, a fungus may exist in one or even both of these forms (Table 71-1). The dimorphic fungi (e.g., *Histoplasma capsulatum* and *Blastomyces dermatitidis*) grow as a mold in nature (27°C), but quickly convert to the parasitic yeast form after infecting the host (37°C). This mycelium-to-yeast conversion is an important factor in the pathogenesis of disease caused by these organisms. Other pathogenic fungi, such as *Aspergillus* species, grow only as a mold form, whereas *Cryptococcus neoformans* usually grows as a yeast form. *Candida* species grow with a modified form of budding whereby newly budded cells remain attached to the parent cells and form pseudohyphae. Fungi are aerobic and are easily grown on routine culture media similar to that used to grow bacteria. Most fungi grow best at 25°C to 35°C. Fungi that cause only cutaneous and subcutaneous disease grow poorly at temperatures >37°C. This temperature-selective growth explains, at least in part, why

Table 71-1 Organism Classification**Hyphae (Moulds)**

Hyalohyphomycoses

Aspergillus spp., *Pseudallescheria boydii*
 Dermatophytes: *Epidermophyton floccosum*, *Trichophyton* spp.,
Microsporum spp.

Phaeohyphomycoses

Alternaria spp., *Anthopsis deltoidea*, *Bipolaris hawaiiensis*,
Cladosporium spp., *Curvularia geniculata*, *Exophiala* spp.,
Fonsecaea pedrosoi, *Phialophora* spp., *Fusarium* spp.

Zygomycetes

Absidia corymbifera, *Mucor indicus*, *Rhizomucor pusillus*

Dimorphic Fungi

Blastomyces spp., *Coccidioides* spp., *Paracoccidioides* spp.,
Histoplasma spp., *Sporothrix* spp.

Yeasts

Candida spp., *Cryptococcus neoformans*

these organisms rarely disseminate from a primary focus in the skin or subcutaneous tissues.

Classification

Fungal infections are best classified by the area of the body infected (Table 71-2). Superficial mycoses involve only the outermost keratinized layers of the skin (stratum corneum) and hair. The cutaneous mycoses extend deeper into the epidermis and may also infect the nails. The subcutaneous mycoses infect the dermis and subcutaneous tissues; entry into these sites is by inoculation or implantation of dirt or vegetative matter. The systemic mycoses cause disease of the internal organs of the body. Standard definitions that are useful in daily patient care for invasive fungal infections have been developed for epidemiologic and clinical trials. The guidelines are referenced under each infection. The respiratory tract is the most common primary portal of entry into the patient, and infection in the lungs may be symptomatic or asymptomatic. Systemic infection with *Candida* usually results from a primary focus in the gastrointestinal (GI) tract or skin. In each case, the organism

Table 71-2 Clinical Classification of Mycoses

| Classification | Site Infected | Example |
|------------------|---|--|
| Superficial | Outermost skin and hair | Malasseziasis (Tinea versicolor) |
| Cutaneous | Deep epidermis and nails | Dermatophytosis |
| Subcutaneous | Dermis and subcutaneous tissue | Sporotrichosis |
| Systemic | Disease of more than one internal organ | |
| Opportunistic | | Candidiasis Cryptococcosis Aspergillosis Mucormycosis |
| Nonopportunistic | | Histoplasmosis Blastomycosis Coccidioidomycosis |

may spread hematogenously from the primary focus throughout the body, resulting in disseminated disease. The opportunistic mycoses occur primarily in the immunocompromised host and require more aggressive treatment. The list of fungi that cause opportunistic infection is rapidly expanding, especially with the AIDS epidemic.² The nonopportunistic fungi (primary pathogens) usually cause disease in the immunologically normal host. Some primary pathogens, however, result in unique clinical syndromes when infection occurs in the immunocompromised host, such as histoplasmosis in AIDS.¹

Pathogenesis of Infection**Endogenous**

Fungal infection can be acquired from both exogenous and endogenous sources. The only fungi known to be normal flora (commensals) in humans are *Pityrosporum obiculare*, which causes the noninflammatory superficial condition of tinea versicolor, and *Candida* species. Infections with these yeast organisms primarily develop from the patient's own normal flora (endogenous infection). These endogenous fungal infections of the skin or mucous membranes occur when host resistance is lowered and the organism proliferates in high numbers. Excess heat and humidity, oral contraceptive use, pregnancy, diabetes, malnutrition, and immunosuppression facilitate endogenous local infection by both *Pityrosporum* and *Candida*. Systemic candidal infections occur in the immunocompromised host when the organism colonizing the patient's skin or GI tract is disseminated hematogenously throughout the body.

Exogenous

Exogenous infections occur when the fungus is acquired from an environmental source. In the case of dermatophytes (ringworm fungi), the organism can be acquired from dirt, animals, or another infected individual. The subcutaneous mycoses result from direct inoculation of infected material, often a thorn or other vegetable matter, through the skin. Infections of the skin and subcutaneous tissues by *Aspergillus* and the agents causing mucormycosis (e.g., *Rhizopus*, *Absidia*, *Mucor*) have resulted from contaminated wound dressings and cast materials.³ Exogenous fungi colonized or carried on the hands of health care workers can infect patients; therefore, these health care workers, especially in intensive care units (ICU), must wash their hands to prevent cross-infection between patients.⁴ Other than candidal infections, the systemic mycoses are primarily the result of inhalation of dust contaminated by the infectious spores, with a primary focus of infection in the lungs. If local or systemic host defenses are unable to control the primary infection, the organism may be spread hematogenously to other organs. Some of the systemic mycoses have defined geographic (endemic) areas in which the fungus is more commonly encountered in the environment. For example, histoplasmosis and blastomycosis occur most often in the regions of the Red, Mississippi and Ohio River valleys, whereas coccidioidomycosis is endemic to the southwestern United States and the Central Valley of California.

Host Defenses

Host defenses against fungal infection involve both nonimmune (also known as nonspecific or natural resistance) and

immune (also known as specific or acquired resistance) mechanisms. Nonimmune resistance plays a primary role in preventing colonization and invasion of a susceptible tissue. The normal bacterial flora of the skin and mucous membranes prevent colonization (colonization resistance) by more pathogenic bacteria and fungi. Patients treated with broad-spectrum antibiotics are at greater risk for colonization and infection by fungi because of the alteration in their bacterial flora. The barrier function of the intact skin and mucous membranes is also an important defense against fungal infection. Skin defects, whether the result of intravenous (IV) catheters, burns, surgery, or trauma, predispose individuals to local invasion and fungemia, especially with *Candida* species. When these physical barriers are breached, the polymorphonuclear leukocyte (neutrophil) and monocytes are the cells involved earliest in host defense against fungi. The antifungal activity of neutrophils involves phagocytosis and intracellular killing, but also can include extracellular killing by secreted lysosomal enzymes. Neutropenia is the most common neutrophil defect predisposing to fungal infection, but functional defects of neutrophils, such as those occurring in patients with chronic granulomatous disease of childhood and myeloperoxidase deficiency, have also been associated with an increased frequency of fungal infections, especially with *Candida* and *Aspergillus*.

Antibody and complement may have some role in resistance to certain fungal infections, but they are not the primary effectors of acquired resistance. Cellular immunity, mediated by antigen-specific T lymphocytes, cytokines, and activated macrophages, is the primary acquired (immune) host defense against fungi. Patients with defective cellular immunity (e.g., immunosuppressed organ transplant recipients, patients with lymphomas and AIDS, and those treated with corticosteroids or cytotoxic agents) are at greatest risk for fungal infection. The immunodeficiency noted in these patients is also the primary reason for the poor therapeutic outcome despite appropriate antifungal therapy. An additional factor associated with an increased risk for fungal infection is the use of total parenteral nutrition (TPN).¹

ANTIMYCOTICS

Mechanisms of Action

Table 71-3 lists the U.S. Food and Drug Administration (FDA)-approved topical and systemic antimycotics for the treatment of fungal infections. Griseofulvin and potassium iodide have limited clinical utility and are not used to treat systemic fungal infections. Griseofulvin inhibits growth by inhibiting fungal cell mitosis caused by polymerization of cell microtubules, thereby disrupting mitotic spindle formation. It has activity only against the dermatophyte fungi. The antifungal mechanism of potassium iodide is unclear. It is effective only in the treatment of lymphocutaneous sporotrichosis.

The eight antifungal drugs used for systemic disease fall into five structural classes that act by four mutually exclusive mechanisms. *Amphotericin B* and *nystatin*, polyene macrolides, act principally by binding to ergosterol in the fungal cell membrane, effectively creating pores in the cell membrane and leading to depolarization of the membrane and cell leakage.⁵ *Amphotericin B* binds with greater affinity to ergosterol than to cholesterol.⁶ This phenomenon is believed to be mediated

Table 71-3 Antifungal Agents Approved for Use

| Agent (Brand Name) | Formulation |
|--|---|
| Systemic Agents | |
| Amphotericin B (Abelcet, AmBisome, Amphotec) | IV |
| Amphotericin B (generic) | IV |
| Caspofungin (Cancidas) | IV |
| Fluconazole (Diflucan) | IV, tablet, oral suspension |
| Fluorocytosine [Flucytosine] (Ancobon) | Capsule |
| Griseofulvin (generic) | Tablet, oral suspension |
| Itraconazole (Sporanox) | IV, capsule, oral solution |
| Ketoconazole (Nizoral) | Tablet |
| Miconazole (Monistat) | IV |
| Potassium iodide | Solution |
| Terbinafine (Lamisil) | Tablet |
| Voriconazole (Vfend) | IV, tablet |
| Topicals, Class I | |
| Amphotericin B | Cream, lotion, ointment, oral suspension ^d |
| Butoconazole (Femstat) | Ointment |
| Ciclopirox (Loprox) | Cream, lotion |
| Clioquinol (Vioform) | Cream, ointment |
| Clotrimazole | Cream, lotion, lozenge, pessary, solution, tablet |
| Econazole (Spectazole) | Cream |
| Ketoconazole (Nizoral) | Cream shampoo |
| Miconazole | Aerosol, cream, lotion, pessary, spray, suppository, vaginal tablet |
| Naftifine (Naftin) | Cream, gel |
| Nystatin | Cream, lozenge, ointment, powder, suspension, tablet |
| Oxiconazole (Oxistat) | Cream, lotion |
| Povidone iodine | Douche, gel, suppository |
| Sodium thiosulfate (Exoderm) | Lotion |
| Sulconazole (Exelderm) | Cream, solution |
| Terbinafine (Lamisil) | Cream |
| Terconazole (Terazol 7) | Cream, suppository |
| Tioconazole (Vagistat) | Ointment |
| Tolnaftate (generic) | Cream, gel, powder, solution, spray |
| Undecylenic acid | Cream, foam, ointment, powder, soap |

Classification identified in reference 182, with permission.

through both hydrophilic hydrogen bonding and hydrophobic, nonspecific van der Waals forces. Investigations using P³² nuclear magnetic resonance spectroscopy to study the interactions of polyene macrolides with sterols documented that the presence of the double bond in the side chain of ergosterol (not present in cholesterol) accounts for the greater affinity of amphotericin B for ergosterol.⁵ Amphotericin B, however, also binds to sterols of mammalian cells (i.e., cholesterol), a fact that is believed to account for most of the toxic effects of amphotericin B. Alteration in the lipid content of the pathogens membrane may play a role in the development of resistance,⁷ although this alone is apparently not sufficient to affect that development.⁸ The lethal antifungal effects of amphotericin B are, however, the result of not only cell leakage resulting from ergosterol binding, but also immune stimulation and oxygen-dependent killing.^{6,9}

5-Flucytosine (5-FC), a fluorinated cytosine analog, is believed to act principally by inhibiting nucleic acid synthesis. It is actively transported into susceptible cells by the enzyme cytosine permease, where it is deaminated to the toxic metabolite 5-fluorouracil. Fluorouracil, when converted to 5-fluorouridine triphosphate, functions as an antimetabolite. It is incorporated into fungal RNA, where it is substituted for uracil and thereby disrupts protein synthesis.¹⁰ 5-Fluorouracil can also be converted to fluorodeoxyuridine monophosphate, which inhibits thymidylate synthase and thus disrupts DNA synthesis.¹⁰

The *azole* antifungals and the *allylamines* (naftifine and terbinafine) appear to act by the same principal mechanism: inhibition of sterol biosynthesis by interference with either cytochrome P450-dependent lanosterol C14-demethylase (azoles) or squalene epoxidase (allylamines), critical enzymes in the biosynthesis of ergosterol.^{11,12} The superior affinity of the triazoles (fluconazole, itraconazole, voriconazole) for fungal versus mammalian enzyme, as compared with the imidazoles (ketoconazole, miconazole), generally is believed to account for their reduced toxicity and improved efficacy.¹¹ The consequence of sterol biosynthesis inhibition is a faulty cell membrane with altered permeability. In general, the allylamines and older azoles are viewed as fungistatic in their action. The newer triazoles (voriconazole, posaconazole, and ravuconazole) demonstrate fungicidal activity against some fungal species.¹³ The clinical relevance of *in vitro* fungicidal versus fungistatic action is the subject of considerable debate. Nevertheless, it seems logical that fungicidal action, if it can also be achieved *in vivo*, might be preferable in immunosuppressed hosts.

Lipopeptides, which are potent antifungal agents, include the structural class of *echinocandins* (anidulafungin, micafungin, and caspofungin). All share a common mechanism: they act by interfering with 1,3- β -D-glucan, preventing synthesis of essential cell wall polysaccharides that protect the cell from osmotic and structural stresses. The result is inhibition of fungal cell wall biosynthesis. Targeting the cell wall (as opposed to the cell membrane, which is the target of polyene, azole, and allylamine) has been an important step in selective inhibition of fungal versus mammalian cells; the fungal cell wall does not share target-associated toxicity with the mammalian cell wall.¹⁴

Antifungal Spectrum and Susceptibility Testing

The Clinical and Laboratory Standards Institute (CLSI) recommends standardized broth dilution (M27-A2) and disk diffusion (M44-A)²² methods for determining *in vitro* antifungal susceptibilities for yeasts.¹⁵ This method stipulates test medium, inoculum size and preparation, incubation time and temperature, end-point reading and quality control limits for amphotericin B, flucytosine, fluconazole, ketoconazole, and itraconazole. Minimum inhibitory concentration (MIC) values for use in clinical interpretation are specified for fluconazole, itraconazole, and flucytosine against *Candida* species after 48 hours of incubation. For fluconazole and itraconazole, a susceptible-dose dependent (S-DD) breakpoint was developed based on data supporting a trend toward better response with higher drug levels for isolates with higher MIC.¹⁶ The S-DD range includes MIC of 16 and 32 mcg/mL along with

>0.125 and <0.5 mcg/mL for fluconazole and itraconazole, respectively. *Candida* isolates with MIC less than these ranges are considered susceptible, and isolates with greater MIC are considered resistant. Owing to rapid development of resistance and limited data on correlation of MIC with outcome for flucytosine monotherapy, proposed interpretive breakpoints for this agent are based on a combination of historical data and results from animal studies. *Candida* isolates with a flucytosine MIC ≤ 4 mcg/mL are considered susceptible, isolates with MIC > 16 mcg/mL are considered resistant. Limitations of the M27-A methodology have precluded development of amphotericin B interpretive breakpoints nor have interpretive criteria been proposed for ketoconazole MIC. An E-Test (AB Biodisk; Piscataway, NJ) is commercially available. Difficulties in end-point determination using this method result from frequent, nonuniform growth of the fungus on the agar medium; yet, when properly performed, correlation between the E-Test and M27-A methods has been satisfactory for the azole antifungal agents against most *Candida*.¹⁷ Other techniques under development for antifungal susceptibility testing for yeasts include flow cytometry and direct measurement of alterations in ergosterol synthesis.¹⁸

Recently, the CLSI also approved a standardized broth dilution (M38A) method for determining *in vitro* antifungal susceptibilities for certain spore-producing moulds, namely *Aspergillus* spp., *Fusarium* spp., *Rhizopus* spp., *Pseudallescheria boydii*, and *Sporothrix schenckii*.¹⁹ An E-Test to evaluate mould susceptibilities to the systemic antimycotics is also being studied. Despite these recent advances, the determination of *in vitro* susceptibilities or resistance in clinical practice is of limited utility and not readily available.

Susceptibility testing for clinical isolates is not routinely recommended; however, published data on the susceptibility of the identified species of yeast or mould should guide the clinician's therapeutic choice. Clinical isolates from patients failing high-dose therapy (i.e., refractory oral pharyngeal candidiasis) or unusual pathogenic yeasts in patients with AIDS can be sent for testing.¹⁸ Testing should be performed in a laboratory where the staff is trained in mycoses. Despite these limitations, certain generalities should be emphasized. First, amphotericin B has broad *in vitro* activity and clinical efficacy against the yeasts and filamentous moulds. The echinocandins have *cidal* activity *in vitro* versus *Candida* spp. and *static* activity for *Aspergillus* spp.; they are not active *in vitro* against *Cryptococcus* spp. and many endemic mycoses.²⁰ The azole antifungals generally have clinically significant activity against only the yeasts and most dimorphic fungi. Additionally, itraconazole, voriconazole and posaconazole have excellent *in vitro* activity against *Aspergillus* spp., with clinical efficacy demonstrated for itraconazole, posaconazole, and voriconazole. Unlike other azoles, posaconazole has good *in vitro* activity and has shown clinical efficacy against zygomycetes, fungal infections for which previously only amphotericin B formulations were therapeutic options.^{21,22}

New Frontiers for Antifungal Therapy

Various investigative efforts have been directed toward both enhancing efficacy and reducing the toxicity of older antifungal drugs, including biochemical modifications of the agent, improved delivery systems, and combination therapy. Inhalation
