of amphotericin B, and in lung transplant recipients, lipid complex amphotericin B, has been investigated in immunocompromised patients as a prophylaxis for invasive aspergillosis. Recently, caspofungin has been studied for suitability for aerosol delivery. Antifungal dose and nebulized system required for effective prophylaxis has yet to be established.^{23–26} Even more challenging are the attempts to discover or design new prototype antifungal compounds. Substantial hurdles exist because both mammalian cells and fungal cells are eukaryotes and share many similar biochemical processes, unlike bacterial cells, which are prokaryotes. Traditionally, the drug discovery process depended on the ability to detect compounds (either natural products or synthetic compounds) that selectively inhibit or destroy fungal cells. This process is accomplished by either or both of two approaches: (a) the evaluation of existing compounds (natural or synthetic) for potentially useful antifungal activity and (b) the design and synthesis of new compounds that selectively block fungal targets. Recent advances in genomic sequencing of *C. albicans*, *C. glabrata*, *A. fumigatus*, and *C. neoformans* have allowed for use of this information within the search for new targets. Other less conventional drug discovery approaches include targeting known traditional virulence factors (e.g., adhesions, secreted enzymes). This approach is based on the principle that killing of the microbe need not occur for an anti-infective agent to be efficacious in reduction of disease.

Lead compounds that appear promising for antimycotic therapy include nikkomycins, sordarins, lytic peptides, hydroxypyridones, and cathelicidins. Nikkomycins inhibit chitin synthase. Chitin synthase catalyzes the polymerization of β -(1,4) linkages of *N*-acetyl glucosamine, which is critical to yeast cell membrane stabilization. Sordarins interfere with elongation factor-2, which is essential for protein synthesis, whereas lytic peptides and cathelicidins bind to cell membrane sterols, thereby reducing cell membrane stability. It appears that inhibition of cellular uptake of essential compounds and loss of other compounds are secondary effects of an unknown primary mode of action for the hydroxypyridone antimycotics.²⁷ Sordarins, lytic peptides, hydroxypyridones, cathelicidins and antibody directed therapies (i.e., mycograb: antiheat shock protein 90), a novel approach usually reserved for extracellular pathogens,²⁸ are still in early development.

SUPERFICIAL AND CUTANEOUS MYCOSES

Tinea Pedis: Treatment

1. C.W., a 28-year-old male construction worker, is evaluated for a chronic case of “athlete’s foot.” He wears boots all day at work and notes intense itching of both feet throughout the day. He has been using tolnaftate powder (Tinactin) for 1 week with no real therapeutic benefit. On examination, the web spaces between all the toes are white, macerated, and cracked. A few vesicles are also present over the dorsum of the foot at the base of the toes. Scrapings of the lesions examined as a potassium hydroxide preparation reveal branching, filamentous hyphae compatible with a dermatophyte infection. The diagnosis of “athlete’s foot” is made. What therapeutic options are available for C.W.?

Selection of antifungal therapy should be based on the extent and type of infection. Superficial or cutaneous infections should initially be approached topically. Any follicular, nail, or widespread (>20% of body surface area [BSA]) infection should be treated systemically under medical supervision owing to poor penetration of topical applications. Topical antifungals have been reviewed as a class by the FDA advisory review panel on over-the-counter (OTC) antimicrobial drug products and on an individual basis as newer products have been released. To receive a class I recommendation, each agent (or combination) must have been tested in well-designed clinical trials that show the drug microbiologically and clinically effective against dermatophytosis or candidiasis with insignificant toxicity (irritation). Class I agents are listed in Table 71-4. Class II agents (camphor, candicidin, coal tar, menthol, phenolates, resorcinol, tannic acid, thymol, tolindate) are considered to have higher risk-to-benefit ratios associated with their pharmacotherapy. Class III agents (benzoic acid, borates, caprylic acid, oxyquinolines, iodines, propionic acid, salicylates, triacetin, gentian violet) lack adequate scientific data to determine efficacy. Topical therapy with any class I agent applied twice daily to the affected area for 2 to 6 weeks should be adequate. Therapy should be titrated to response.

Because C.W. could continue tolnaftate powder for 2 to 6 weeks or switch to an antifungal cream or lotion (e.g., miconazole), these products should be applied to the web spaces between all the affected toes twice daily. C.W. should also be careful to use nonocclusive footwear (e.g., cotton rather

Table 71-4 Antimycotic Prophylaxis Regimens and Costs

| Agent | Dose/Day | Formulation | Recommended Regimen | Cost (\$)/day ^a |
|-------------------------------------|--------------------|------------------------------|-----------------------|----------------------------|
| Selective GI Decontamination | | | | |
| Amphotericin B | 400 mg | Oral suspension ^b | Swish and swallow QID | 4.00 ^b |
| Nystatin | 4–12 million units | Oral suspension | Swish and Swallow QID | 16.60–40.80 |
| Systemic | | | | |
| Clotrimazole | 30–80 mg | Trouche | TID–QID | 11.43–40.64 |
| Ketoconazole | 200–400 mg | Oral | QD | 2.78–5.56 |
| Itraconazole | 200–400 mg | Oral | QD | 15.56–31.11 |
| Fluconazole | 50–400 mg | Oral | QD | 5.15–26.48 |

^bMade from parenteral formulation, no longer commercially available.

GI, gastrointestinal; QD, every day; QID, four times daily; TID, three times daily.

than synthetic fiber socks, and leather rather than vinyl boots). Application of an absorbent or antifungal powder to his footwear would also be helpful (see Chapter 38, Dermatotherapy and Drug Induced Skin Disorders).

Tinea Unguium (Onychomycosis): Treatment

2. If C.W. also suffered from an infection of the toenail (onychomycosis), what additional therapy could be offered to him?

Onychomycosis is typically caused by a dermatophyte, a hyphal fungi, or *Candida*. Nail scrapings and culture should be performed to help plan initial therapy. Once culture results are known, therapy can be initiated with either terbinafine 250 mg/day or itraconazole 200 mg/day for 6 (fingernail) to 12 (toenail) weeks. In some cases, however, successful therapy of tinea unguium can require 3 to 6 months for fingernails and 6 to 12 months for toenails. Therapy should be considered successful when several millimeters of healthy nail have emerged from the nailfold to the margin of infected nail, or when a 25% reduction in size of the infected site has been achieved.

For dermatophyte nail or paronychia infections, griseofulvin therapy could be used if an azole or allylamine is contraindicated. Griseofulvin (microsized or ultramicrosized) administered orally at 10 mg/kg/day and titrated to response should be effective.²² Owing to the large doses given for prolonged periods, C.W. should be monitored closely at each prescription refill for signs and symptoms of adverse reactions. Terbinafine or itraconazole most commonly causes symptoms of headache, rash, and GI distress. Griseofulvin is more toxic, often causing hypersensitivity (urticaria, angioedema, type II hypersensitivity reactions), photosensitivity dermatitis, GI distress, and neurologic complications (headache, paresthesias, altered sensorium).²²

Antimycotic pulse therapy is a novel approach to the treatment of onychomycosis. An FDA-approved alternative to daily therapy can now include a course of itraconazole 200 mg twice daily for 1 week in 2 consecutive months for fingernail infections. Double-blind, placebo-controlled trials revealed that this regimen was associated with a 77% clinical response and 73% mycologic response.²⁹ Overall responses and toxicity to therapy were more desirable with pulse regimens than with traditional regimens. Comparative studies demonstrate promising results for itraconazole pulse therapy for toenail infections³⁰ and fluconazole pulse therapy administered as a 150- to 450-mg dose once weekly for up to 12 months for mild disease.^{31,32} Relapse rates after pulse (intermittent) terbinafine for 4 months have been frequent and longer courses of therapy are under study to enhance long-term efficacy.³³ Longer courses of therapy are being evaluated.

Removal of the nail as the sole therapy is not recommended because of the high relapse rate without concomitant systemic therapy. Likewise, IV antifungals are not indicated.

3. Describe the role of corticosteroids, antibacterials, or other additives to the antimycotic regimen in C.W.

Many patients with superficial, cutaneous, or nail infections will have additional morbidity associated with local inflammation and secondary bacterial infections. Inflammation is caused primarily by a type IV hypersensitivity reaction. Topical corti-

costeroids in conjunction with antifungals will often relieve itching and erythema secondary to inflammation. Bacterial (*Proteus* or *Pseudomonas* spp.) superinfection can also occur in these inflamed or macerated areas and may require concomitant topical antibacterial therapy. Pharmaceutical manufacturers of OTC preparations often combine a drying agent or astringent (e.g., alcohol, starch, talc, camphor) to their preparations to increase desquamation of the stratum corneum. Hyperhidrosis also can be relieved by these pharmaceutical additions. Such combination treatments should not be used routinely, however, because they increase the risk of toxicity and have not been proven to increase efficacy. If required for symptomatic relief, they should be used only for the initial days of treatment.

The affected web spaces between C.W.'s toes are macerated and cracked and vesicles are present at the base of his toes. A topical corticosteroid cream will probably facilitate the healing process and make him more comfortable during the first few days of antifungal therapy. The selection of topical corticosteroid formulations is presented in Chapter 38, Dermatotherapy and Drug Induced Skin Disorders.

SUBCUTANEOUS MYCOSES

Sporotrichosis

Treatment Options

4. O.M., a 62-year-old man, has had a painless, slowly enlarging ulcer on his left hand for the past 4 months. He is an avid gardener, but can identify no antecedent local trauma. The primary lesion began as a red papule that slowly enlarged and then ulcerated. At the same time the ulcer developed, O.M. also noted painless, red nodules that spread proximally up his arm. He denies any chills, fever, weight loss, or cough. The ulcer has slowly enlarged despite daily application of a povidone-iodine ointment and 2 weeks of cephalexin treatment. On physical examination, O.M. is afebrile. A 1.5-cm² ulcer is present on the dorsum of the left hand. Extending proximally from the ulcer is a palpable cord and multiple nontender, erythematous nodules distributed linearly up the forearm, elbow, arm, and axilla. A culture of this ulcer obtained 4 weeks ago is now growing *Sporothrix schenckii*. What is the recommended therapy for O.M.?

Sporothrix schenckii is the dimorphic fungi found in the soil and on many plants. Infection is usually secondary to inoculation into the skin from a thorn or sharp plant matter. *S. schenckii* infection most commonly causes lymphocutaneous disease (Fig. 71-1) as illustrated by this case. Rarely, extracutaneous disease may occur and usually involves the lungs, bones, or joints.

Heat Treatment

In the 1930s and 1940s, local heat was applied to very mild plaque or lymphocutaneous disease. Germination rates of this dimorphic fungus actually can be decreased by increased temperature, and heat therapy 1 hour/day for 3 months is effective in 90% of patients with plaques (very mild disease).³⁴ Heat treatment could be particularly useful in pregnant patients when pharmacotherapy may be contraindicated.

Itraconazole

Itraconazole is more active in vitro against *S. schenckii* than other imidazoles or saturated solution of potassium

FIGURE 71-1 Lymphocutaneous sporotrichosis.

iodide (SSKI) and has dramatically improved the therapy of sporotrichosis. SSKI is seldom used for therapy secondary to treatment-limiting toxicity. Cure rates for sporotrichosis cutaneous and lymphocutaneous disease are >90% with itraconazole 100 to 200 mg/day for 3 to 6 months. For extracutaneous disease, higher dosages of itraconazole (200 mg BID) for 1 to 2 years achieve response rates of 81%, but relapse frequently occurs (27%) after therapy is stopped.^{34,35} The toxicity and safety profile for itraconazole also appears favorable in these patients. Patients with extracutaneous disease who are unable to tolerate the higher itraconazole dosages or whose disease continues to progress should be treated with amphotericin B. An amphotericin A total dose of 2.0 to 2.5 g is most often recommended. Although voriconazole, posaconazole and ravuconazole demonstrate amphotericin B in vitro activity against *S. schenckii* (albeit less than itraconazole), their role in the treatment of sporotrichosis has not been defined.³⁶ Neither ketoconazole or fluconazole is effective in the treatment of sporotrichosis.

Terbinafine

Terbinafine has good in vitro activity against *S. schenckii*. Clinical data, although not abundant, also suggest in vivo efficacy.³⁷ An unpublished clinical trial comparing 250 mg or 500 mg BID for 3 months for lymphocutaneous disease revealed responses equivalent to itraconazole. Adverse reactions common in this population included GI distress (dysgeusia, dyspepsia, diarrhea), skin rash, and weight gain. Greater clinical experience

and peer review of the aforementioned trial will further define the role of terbinafine in the treatment of sporotrichosis.

Therefore, in the case of lymphocutaneous disease; itraconazole 100 mg/day for a minimum of 3 months is the treatment of choice. If significant improvement is not observed in the first 6 weeks, the itraconazole dosage should be increased to 200 mg/day and continued for 6 months or until both the ulcer and lymphangitis have resolved. Most patients will respond to this dosage, but an occasional patient may require dosages of 300 or 400 mg/day.

Itraconazole Dosing

5. What instructions should O.M. receive for taking his itraconazole dose?

The peak serum concentrations of itraconazole capsules are ninefold higher when the drug is taken with food (i.e., 0.18 mcg/mL with food and 0.02 mcg/mL in fasting subjects).³⁸ The influence of food on absorption appears to be somewhat dependent on the nature of the food. High-carbohydrate meals decrease the absorption of itraconazole, and high-lipid content meals appear to increase itraconazole absorption.³⁹ Patients who have difficulty eating (e.g., patients with AIDS, those with cancer receiving antineoplastic therapy) may not absorb a sufficient amount from the capsule to achieve therapeutic plasma concentrations following a typical oral dose.⁴⁰ Although itraconazole manifests nonlinear serum pharmacokinetics (i.e., administering the total dose in two divided doses is associated with higher peak serum concentrations than a

single larger dose), no clinical benefit of splitting the dose has been demonstrated. Therefore, O.M. could be instructed to take his itraconazole capsule with his highest fat content meal of the day or itraconazole solution could be substituted to improve absorption.

Itraconazole oral solution is a cyclodextrin formulation that has 55% bioavailability in a fed patient; this increases in a fasting patient. Furthermore, bioavailability of this formulation is not affected by level of gastric acidity. Average serum concentration in a cohort of patients with advanced HIV infection was 2.7 mcg/mL following a 28-day twice daily dosing regimen.⁴¹ O.M. should take his itraconazole solution on an empty stomach twice a day if this formulation is selected.

6. How would instructions for taking itraconazole capsules be modified if O.M. were achlorhydric as a result of medications or AIDS gastropathy?

Itraconazole capsules, as with ketoconazole, require an acidic environment for dissolution and absorption. Thus, patients who are achlorhydric, either as a result of medications, surgery, or underlying disease (e.g., AIDS gastropathy) may not absorb itraconazole adequately.^{40,42} Use of ketoconazole in achlorhydric patients has historically required concomitant administration of 4 mL, 0.2 N hydrochloric acid aqueous solution.⁴³ Etching of tooth enamel by the acid concerned many clinicians, and other alternatives have been explored. The administration of ketoconazole and itraconazole with a low pH liquid (e.g., 8 to 16 fluid ounces of a cola or orange juice) improves absorption in 65.2% of healthy patients who are achlorhydric or taking H₂-blockers (Table 71-5).^{20,44–59}

Voriconazole does not require an acidic environment for adequate oral absorption, but voriconazole should be administered 1 hour before or after meals as high-fat meals have been shown to reduce voriconazole serum concentrations. Quite the opposite, posaconazole plasma levels are four-fold higher following administration with food or a high fat nutritional supplement.

Because serum ketoconazole or itraconazole concentrations <0.25 mcg/mL have been associated with treatment failures, therapeutic drug monitoring is justified in patients in whom therapy is failing.⁶⁰ Serum antimycotic concentrations may be more easily monitored in the future as assays become available and correlations between concentration and efficacy are more clearly established.

SYSTEMIC MYCOSES

Candida Infection

7. L.K., a 21-year-old, 5-foot 8-inch, 170-lb, otherwise healthy man, was admitted to the hospital 16 days ago following a gunshot wound to the abdomen. He has undergone three exploratory laparotomies with repair and resection of damaged small intestine. He was placed on TPN to allow his bowel to rest and Solu-Medrol for stress on admission day 6. Three days ago, he developed a fever of 39.1°C and chills; his blood pressure (BP) of 100/70 mm Hg had dropped >30 mm Hg (systolic). Vancomycin and meropenem were promptly begun after obtaining cultures. Despite 3 days of antibiotics, he remains febrile. His physical examination reveals a Hickman catheter in the right subclavian vein that is functioning

normally; no inflammatory changes are evident at the exit site. A single erythematous nodule about 0.5 cm wide is noted near the left wrist. The fundoscopic examination of both eyes is normal. A chest radiograph is also normal. The white blood cell (WBC) count is currently 10,950 cells/mm³ and renal function is normal. What subjective and objective data in this case are sufficiently suggestive of a possible *Candida* infection to warrant further diagnostic evaluations in L.K.?

Epidemiology

Although L.K. might be infected with bacterial pathogens that are not susceptible to vancomycin and meropenem, the possibility of a candidal infection should be considered. In epidemiologic studies, *Candida* species are the most common nosocomial fungal pathogens. *Candida* species were responsible for 72.2% of mycoses in hospitalized cases, and *Candida albicans* accounted for 55% of these cases in the Centers for Disease Control, National Nosocomial Infections Surveillance System. Attributable mortality associated with disseminated candidiasis from all species is 38%. These statistics may well be an underestimate of the true occurrence because systemic candidiasis is difficult to diagnose. For example, autopsies in neutropenic patients with hematologic malignancies indicate that diagnosis of systemic candidal infection is made in 30% to 50% of patients at postmortem.⁶¹ Therefore, the morbidity for systemic candidiasis may be even higher because of the limited number of autopsies actually performed and our limited ability to diagnose systemic disease.

Characteristics

The diagnosis and monitoring of therapeutic outcomes for systemic candidal infection are difficult because the characteristics of systemic candidal infection are subtle. Salient clinical features include constitutional symptoms (e.g., fever, chills, hypotension) and evidence of end-organ dissemination, such as nodular skin lesions that are usually erythematous, endophthalmitis, liver abscess, and spleen abscess. In addition, only about 50% of patients or fewer will have a single positive *Candida* blood culture. The Mycoses Study Group has utilized a positive culture from a sterile body site and hypotension (systolic blood pressure [SBP] <100 mm Hg or a SBP decrease >30 mm Hg) or abnormal temperature (<35.5°C or >38.6°C on one occasion or >37.8°C on two separate occasions >4 hours apart), or inflammation at a infected site as diagnostic criteria.

Risk Factors

Risk factors for candidemia include central venous catheters, broad-spectrum antibiotic use, extensive surgical procedures, *Candida* colonization, TPN, neutropenia or neutrophil dysfunction, and immunosuppression (e.g., premature infants, burn patients, mannose-binding lectin deficiency and patients with AIDS).⁶²

L.K. has chills, a temperature of 39.1°C and is hypotensive. He is probably immunosuppressed as a result of multiple surgeries and corticosteroids. His Hickman catheter could serve as a possible portal of entry for an infectious agent, and his broad-spectrum antibiotic therapy with vancomycin and meropenem would be expected to be adequate for most of the likely bacterial pathogens. Because L.K. still has manifestations of an

infection despite 3 days of antibiotics, additional diagnostic studies appear warranted.

Diagnostic Tests

8. What diagnostic tests could be ordered for L.K. to evaluate a possible fungal infection?

The diagnosis of fungal infection may be made with varying levels of certainty. Sometimes, the diagnosis is absolutely certain, such as when a pathogenic fungus from a clinical specimen is isolated and identified. This is referred to as a definitive or microbiologically confirmed diagnosis. At other times, the physician can determine only that a high probability of infection exists. This is designated as a presumptive diagnosis. To illustrate, a patient with a chest radiograph showing nodular lesions and a high complement fixation antibody against *H. capsulatum* would have a presumptive diagnosis of histoplasmosis. This may be as certain a diagnosis as is possible without performing a more invasive procedure to obtain lung tissue. In this event, a trial of drug therapy can be undertaken on the presumptive diagnosis alone. A diverse spectrum of tests is available for clinicians to diagnose and monitor therapeutic responses.

DIRECT EXAMINATION

Direct examination of the specimen is often useful in diagnosing fungal infection. Traditionally, the specimen is treated with 10% potassium hydroxide (KOH) to digest the cells and debris, resulting in clear visualization of the hyphae or yeast. Treatment of cerebrospinal fluid (CSF) specimens with KOH is not necessary because this fluid is naturally clear. India ink can be added to CSF to increase contrast and outline the organisms. Calcofluor white, a fluorescent fabric brightener that binds to fungi and fluoresces brilliantly when viewed under the ultraviolet microscope, also can be used to assist in recognition of fungal elements.

Histologic examination of biopsy specimens is an important tool for diagnosing and monitoring the presence of fungal infection, but identifying the precise species of fungus involved may be difficult. This is because only the tissue phase can be observed, and the fungal organisms in the specimen may be few. Because recognizing a fungus in hematoxylin- or eosin-stained sections may be difficult, a number of special stains have been developed.⁶² Periodic acid–Schiff staining binds linked sugar groups in the fungal cell wall intensely magenta, thus making visualization of the fungal form easier. Likewise, several silver precipitation stains, (Gomori methenamine silver) rely on the presence of a charged fungal surface to reduce oxidized silver to metallic silver. This process coats the fungus with a black layer, again outlining the form.⁶³ The mucicarmine stain imparts a deep red color to complex polysaccharides, such as mucin. It will also stain the thick capsule of *C. neoformans*. Because no other yeast has a positive mucicarmine stain, the definitive diagnosis of cryptococcosis can be made.⁶⁴ The size of the organism, manner of budding, and the presence or absence of septae can all help identify the problem.

Monoclonal antibodies against many fungi are now available. Immunohistochemical procedures using these sera on biopsy specimens will enable the pathologist to detect the presence of a fungus, and determine its identity.⁶⁴ Reagents for

in situ oligonucleotide probe hybridization to detect fungi in tissue are being developed and will also be extremely helpful.⁶⁵

CULTURE

The most definitive method for diagnosing or monitoring a fungal infection is with culture. Specimens should be inoculated onto several different types of fungal media, some of which contain antibiotics to inhibit bacterial overgrowth. Swab specimens have a very low yield, especially for hyphal fungi and should be avoided in follow-up cultures. Yeast may grow rapidly and be isolated within 24 to 48 hours, but many fungi grow slowly and 4 to 6 weeks of incubation may be necessary to isolate and identify the organism. After growth, yeasts are usually recognized by their patterns of metabolic activity on a variety of substrates, whereas mycelial organisms may produce characteristic spores and fruiting bodies that are used for identification. Occasionally, a mycelial organism will be slow in producing recognizable spores, and immunologic testing for a characteristic isoantigen may be used for identification.

ANTIGEN DETECTION

Fungi synthesize polysaccharides that cannot be broken down by human enzymatic systems. These polysaccharides can accumulate within the body and be excreted in the urine. These fungal antigens can be detected by using antibodies that specifically recognize a particular species of fungus, thereby providing a diagnosis. The most commonly used antigen detection test is a latex agglutination test for cryptococcal antigen. This assay can be performed on serum or CSF. Antigenemia is present in 80% to 100% of patients with culture-proved cryptococcal meningitis. This test can also be used to monitor patient response to therapy by determining the end-point dilution for the positive reaction and following this end-point over time as the patient is treated. If treatment is successful, the titer will decline.^{66,67}

Tests (quantitative polymerase chain reaction [PCR], enzyme-linked immunosorbent assay [ELISA], latex agglutination) for other fungal antigens are not as well established. Latex particle agglutination tests to detect candidal antigens are available, but their utility has not been clearly demonstrated. Assays for detecting *H. capsulatum* antigen in serum and urine have been reported.⁶⁸ Antigen can be detected in the blood of 50% and in the urine of 80% to 90% of patients with systemic histoplasmosis. Patients with blastomycosis and paracoccidioidomycosis, however, may also have positive cross-reactions. The ELISA for detection of *Aspergillus* galactomannan (GXM) antigen and *Candida* (1–3)- β -D-glucan has been approved by the FDA. Owing to the reported false-positive and false-negative rates, it is unclear if these assays will improve therapeutic decision-making for patients at risk for this infection.

ANTIBODY DETECTION

Detection of antibody can be useful for some fungal diseases but not for others. Serologic diagnosis of systemic candidiasis is complicated because most people have anti-*Candida* antibodies. A rising titer is not specific for infection and may indicate only colonization. Furthermore, dissemination of *Candida* is most likely in people who are immunocompromised and, therefore, may not respond by producing antibody.⁶⁹ On the other hand, seropositivity can be demonstrated in >90% of

patients with symptomatic histoplasmosis.⁷⁰ The most important serologic tests use the complement fixation, immunodiffusion, and enzyme immunoassay (EIA) techniques. Appropriate evolution of serologic results requires an understanding of the sensitivity, specificity, and predictive value of each methodology. In general, serologic tests allow only a presumptive diagnosis of mycotic infections.

Although any of the aforementioned tests could be ordered for L.K., a direct examination of his blood and urine specimens along with an assessment of signs and symptoms of disseminated candidiasis are reasonable first steps in his evaluation. A blood and urine specimen from L.K. should also be cultured on different fungal media. Because a candidal infection is suspected, the culture could isolate *Candida* within 24 to 48 hours. Cultures and histopathologic examination of a biopsy specimen of skin lesions are often helpful not only in confirming a diagnosis of disseminated candidal infection, but also in monitoring response to therapy. The other fungal tests previously described need not be ordered immediately and should await the results from direct examination and culture.

Necessity of Treatment

9. The clinical laboratory reports that a single blood culture obtained from 2 days ago is growing *Candida* species. In addition, a secondary finding of many budding yeast in the urine was reported on urinalysis (UA). Why is therapy necessary in L.K. with only a single positive blood culture?

Case control studies of candidemia noted an 85.6% mortality rate in the untreated patients compared with a 41.8% mortality rate in patients who were treated early. Isolation of *Candida* from a patient's bloodstream is now viewed seriously, and therapy should be initiated immediately. Delays in therapy of up to 1 week can increase mortality rates by 23%.⁷¹ In fact, delaying therapy 24 hours from the time a blood culture is positive or failure to follow Infectious Disease Society of American (IDSA) treatment guidelines increases mortality nearly 50%.^{72,73} Removal of risk factors may improve the clinical outcome of candidemia, and removal of central venous catheters is believed to improve the morbidity and mortality rates.^{74,75} Removal of centrally inserted catheters may make pharmacotherapy difficult, however, and L.K.'s other risk factors (e.g., broad-spectrum antibiotics) are perhaps of even greater importance.

Treatment Options and Combination Therapy

10. What therapeutic options are available to treat candidemia? Which option would be best for L.K.?

Therapeutic options are individualized and based on the competence of a patient's host defenses. In immunocompetent patients, amphotericin B, an echinocandin or a triazole, decreases morbidity and mortality associated with this disease.^{76–80} Echinocandins have been demonstrated as effective as amphotericin B in neutropenic and non-neutropenic patients; however, amphotericin B clears the bloodstream fastest.^{81,82} In the largest, well-controlled comparative trial, 206 non-neutropenic patients were randomized to amphotericin B 0.5 to 0.6 mg/kg/day or fluconazole 400 mg/day for 14 days. Mortality was <9% in both groups with no significant difference in successful outcomes (amphotericin B, 80%;

fluconazole, 72%). Less toxicity was noted in the fluconazole group, however.⁷⁷ Therefore, fluconazole 400 mg/day is probably equally as effective as amphotericin B for non-neutropenic patients infected with susceptible *Candida*. Candidemic (or other mycotic infections discussed in this chapter) patients who are clinically stable and have no evidence of deep-seated infection should be initiated on a triazole or echinocandin for at least 14 days. Patients who are unstable or have deep-seated (organ involvement) infections should be treated with amphotericin B 0.5 to 0.6 mg/kg/day for at least 14 days; with concomitant septic shock, a minimum daily amphotericin B dose is 1.0 mg/kg. A lipid formulation of amphotericin B should be substituted in intolerant patients or those at high risk of adverse event.

In another trial, higher dosages of fluconazole (12 mg/kg/day) alone or in combination with amphotericin B for a minimum of 3 days, followed by step-down therapy to fluconazole, were given to evaluate the effect of combination therapy on improving clinical efficacy. Outcomes were not different from previously reported success rates. Yet, the fluconazole treatment group experienced higher Acute Physiology and Chronic Health Evaluation (APACHE II) scores, making evaluation of the comparison difficult.⁸¹ In contrast, in another clinical trial the combination of amphotericin B and flucytosine appears more effective than single-agent therapy.^{83,84} An amphotericin B-containing regimen does appear more effective in patients with APACHE scores between 10 and 22.

L.K. could be treated with an amphotericin B formulation owing to hemodynamic instability, with the total dose based on clinical response and resolution of positive cultures (see Question 12). The efficacy of this therapy should be monitored by assessing the previously identified patient-specific signs and symptoms of candidemia. Combination therapy should be tried in patients who are not responding clinically along with a complete examination for focal sites of infection (septic thrombi or intra-abdominal abscess). HSP90 antibody may provide improved outcomes in the future.²⁸

11. This fungal species has now been identified as *C. non-albicans*. How does this affect the therapeutic options for L.K.?

Historically, isolation of a non-albicans *Candida* from any patient's blood has been a matter of concern because of decreasing in vitro susceptibilities, clinical resistance observed in animal models, and uncontrolled case reports. Intrinsic resistance (*C. lusitanae* to amphotericin B, *C. parapsilosis* to echinocandins, and *C. kruseii* to fluconazole) or acquired resistance (*C. tropicalis* or *glabrata* against fluconazole) has been reported.^{78,83,84} Acquired in vitro fluconazole drug resistance is probably associated with altered fungal cell membrane permeability, antifungal efflux pumps, and changes in CYP450 enzymes. In observational studies, fluconazole resistance in vitro is up to 9%.^{78,83,84} A large, multicenter study of 232 non-neutropenic patients was unable, however, to demonstrate a relationship between a yeast's MIC and patient outcome.⁷⁸ An inability to demonstrate a relationship is probably a result of a poor understanding or inadequate management of risk factors for infection. For example, the removal of a colonized IV catheter is probably a more important predictor of outcome than the MIC of the isolated yeast. Also, the therapeutic environment is changing with higher doses, new formulations of older agents, and new agents used in therapeutic regimens.

Therefore, the true rate of acquired clinical resistance to azoles and ultimate failure is unknown. Vigilant monitoring and aggressive therapy of infections caused by *non-albicans Candida* is recommended. In patients in whom susceptibilities are available, fluconazole should be avoided when the MIC are >16 mcg/mL. An antifungal should be avoided if the organism has intrinsic resistance.

Amphotericin DOSING

12. How should amphotericin B formulation be dosed and administered to L.K.?

The amphotericin B dose and duration of therapy should be individualized based on the severity of infection and immunocompetence of the patient. Once the patient is stable, therapy should be changed to one of the applicable regimens discussed previously. The dose of amphotericin B formulations should be based on lean body mass. Owing to the difficulty in measuring, many clinicians, however, use ideal body weight. Tissues that contain large numbers of macrophages sequester significant amounts of amphotericin B (liver, 17.5%–40.3%; spleen, 0.7%–15.6%; kidney, 0.6%–4.1%; lung, 0.4%–13%), but it does not distribute well into adipose tissue (<1.0%).^{79,80} Because L.K. is 5 feet, 8 inches tall and not obese, his ideal body weight should be about 70 kg. Therefore, amphotericin B 35 mg/day (0.5 mg/kg) should be initiated because L.K. is not clinically stable and is likely to need the higher-dose regimen. Half the full dose should be given on the first day of therapy and the full dose given on subsequent days. In more seriously ill patients, the full dose of amphotericin B can be initiated immediately. Although the optimal dosing regimen to initiate amphotericin B is not well established, most clinicians gradually titrate the dose upward to minimize infusion-related reactions. Peak amphotericin B serum concentrations achieved after parenteral administration are a function of dose, frequency of dosing, and rate of infusion. When the amphotericin B total dose is <50 mg, the serum concentration is directly proportional to the dose; doses >50 mg show a plateau in serum concentrations. After administration, amphotericin B undergoes biphasic elimination: peak serum concentrations drop rapidly (initial $t_{1/2}$, 24–48 hours), but low concentrations (0.5–1.0 mcg/mL) are detectable for up to 2 weeks (terminal $t_{1/2}$ 15 days).⁸⁵ The long terminal-elimination half-life has been used as a justification for the common practice of every-other-day amphotericin B dosing, in which twice the daily dose is given every other day. Every-other-day regimens have not been carefully evaluated but are rationalized based on the potential for reduced nephrotoxicity. Administration of 0.5 mg/kg/day or 1.0 mg/kg every other day results in trough amphotericin B concentrations with sufficient postdose antifungal effects that inhibit the common pathogenic fungi.⁸⁶ Once L.K.'s clinical status has improved, the potential for renal toxicity could outweigh the concerns of potential reduced efficacy, and implementation of amphotericin B every-other-day therapy should be considered.

PREMEDICATION

Premedication to prevent amphotericin B infusion-related reactions and a test dose of amphotericin B are not needed for L.K. Most practices of premedicating are performed out of ritual rather than predicated on scientific study.⁸⁷ Test dos-

ing with 1 mg before the first dose is not currently used because of the immeasurably low incidence of anaphylactoid reactions. Until clinical trials clarify the risk-to-benefit ratio of premedications, concomitant therapy should be restricted to acetaminophen for fever or headache and heparin to prevent thrombophlebitis when possible.

INFUSION REACTIONS

13. L.K. has no complaints except for fevers and shaking chills that occur during his 6- to 8-hour amphotericin B infusion for the past 3 days. He has been receiving acetaminophen 650 mg 30 minutes before amphotericin B infusion, but he has refused today's amphotericin B dose. What measures can be taken to minimize these infusion-related reactions?

Adverse reactions, which are common with amphotericin B administration, are best classified as acute infusion-related, dose-related, or idiosyncratic reactions. Infusion-related reactions include an acute symptom complex of fever, chills, nausea, vomiting, headache, hypotension, and thrombophlebitis. Dose-related reactions also can be acute (e.g., cardiac arrhythmias) or chronic (e.g., renal dysfunction with secondary electrolyte imbalances and anemia).

Many infusion-related reactions appear to be mediated by amphotericin B-induced cytokine (interleukin- 1β , tumor necrosis factor, prostaglandin E_2) expression by mononuclear cells.^{88,89} Hydrocortisone is extremely effective in suppressing cytokine expression⁸⁸ and it also blunts the fever and chills associated with amphotericin B administration.⁹⁰ Hydrocortisone, however, does not reduce the frequency of chronic dose-related toxicity such as renal insufficiency, and corticosteroid-induced immunosuppression could decrease amphotericin B fungicidal activity.⁹¹ Nonsteroidal anti-inflammatory drugs (NSAID) also prevent fever, most likely by the suppression of prostaglandin E_2 expression.⁹² NSAID, however, cannot be recommended for routine use because of their potential for additive nephrotoxicity when used with amphotericin B.

The mild to moderate elevations in temperature and the other infusion-related symptoms usually subside when the infusion is completed, and tolerance to these effects develops over 3 to 5 days. L.K. initially should be counseled that these reactions will abate over the next few days without intervention. If assessment of the reactions suggests the need for more aggressive premedication, a short course of hydrocortisone should be initiated as outlined in Table 71-6. A dose of meperidine 25 to 50 mg by rapid IV infusion reduces amphotericin B-induced rigors and can be repeated every 15 minutes as required while monitoring for signs and symptoms of opiate toxicity. Administration of an average meperidine dose of 45 mg has been found to resolve chills three times faster than placebo.⁹³

Faster amphotericin B infusion rates (<4–6 hours) are associated with the earlier onset of infusion-related reactions but not with more severe infusion reactions.^{94,95} Many patients prefer rapid infusions (1–2 hours) because the infusion-related reactions abate quickly on completion of the amphotericin B infusion. Electrocardiographic evaluations of 1-hour infusions indicate that this rate of amphotericin infusion is safe at currently recommended doses in patients without renal or heart disease. Rapid infusions are not safe in all patients, however, because cardiac arrhythmias appear to be dose and infusion rate related. If infused too rapidly, high serum concentrations of

Table 71-6 Amphotericin B Desoxycholate Infusion Protocol

1. Administration

Dilute amphotericin in D₅W; the final concentration should not exceed 0.1 mg/mL. Initial dosing (0.25 mg/kg based on ideal body mass) should not exceed 30 mg. Infuse the dose over 0.75–4 hr immediately after a meal. Record temperature, pulse rate, and blood pressure every 30 min for 4 hours. If patient develops significant chills, fever, respiratory distress, or hypotension, administer adjunctive medication before the next infusion. If initial dose is tolerated, advance to maximal dose by the third to fifth day. Consult an infectious diseases clinician for any questions concerning maximal daily dose, total dose, and duration of therapy.
2. Adjunctive Medications
 1. Heparin 1,000 units may diminish thrombophlebitis for peripheral lines. Observe the contraindications to the use of heparin (e.g., thrombocytopenia, ↑ risk of hemorrhage, concomitant anticoagulation).
 2. Administration of 250 mL of normal saline before amphotericin B may help ↓ renal dysfunction.
 3. Acetaminophen administered 30 min before amphotericin B infusion may ameliorate the fever.
 4. Hydrocortisone 0.7 mg/kg (Solu-Cortef) can be added to the amphotericin infusion. Hydrocortisone is given to ↓ infusion-related reactions. It should be used only for significant fever (>2.0°F elevation from baseline) and chills during infusions and should be discontinued as soon as possible (3–5 days). It is not necessary to add hydrocortisone if the patient is receiving supraphysiologic doses of adrenal corticosteroids.
 5. Meperidine hydrochloride 25–50 mg may be used parenterally in adults to ameliorate chills.
3. Laboratory
 1. At least twice weekly for first 4 wk, then weekly: Hct, reticulocyte count, magnesium, potassium, BUN, creatinine, bicarbonate, and UA. The GFR may fall 40% before stabilizing in these patients. Discontinue for 2–5 days if renal function continues to deteriorate and reinstate after improvement. Hct often falls 22%–35% of the initial level.
 2. Monitor closely for hypokalemia and hypomagnesemia. Supplementation with a nonchloride potassium is preferable for metabolic (renal tubular) acidosis associated with hypokalemia.
4. Caveats
 1. Electrolytes. Addition of an electrolyte to an amphotericin solution causes the colloid to aggregate and probably results in suboptimal therapeutic effect. This includes IV piggyback medications containing electrolytes or preservatives.
 2. Filtering. The colloidal solution is partially retained by 0.22-micron pore membrane filter: do not use filters if possible.
 3. The infusion bottle need not be light-shielded.
5. Patients Needing Closer Monitoring
 1. Addisonian patients tolerate infusion poorly. Treatment with corticosteroids improves patient tolerance.
 2. Patients should receive neither granulocyte transfusion nor indium scanning.
 3. Patients with anuria or previous cardiac history may have an ↑ risk of arrhythmias, and slower infusions are recommended.

BUN, blood urea nitrogen; GFR, glomerular filtration rate; Hct, hematocrit; IV, intravenous; UA, urinalysis. From references 20,21,183,184, with permission.

amphotericin B can precipitate severe cardiac adverse events. Arrhythmias have been reported most often in patients who are anuric or who have previous cardiac disease.⁹⁶ Continuous infusion is not recommended based on the pharmacodynamics of this agents and the concentration dependence of activity.

NEPHROTOXICITY

14. On day 4 of therapy with amphotericin B, L.K.'s serum creatinine (SCr) and blood urea nitrogen (BUN) are 2.3 mg/dL and 42 mg/dL, respectively. How could amphotericin B exacerbate L.K.'s renal dysfunction and how could it be prevented from worsening?

[SI units: SCr, 203.32 μmol/L; BUN, 14.99 mmol/L]

Renal dysfunction is the adverse event that most often limits treatment with amphotericin B. The renal toxicity results from amphotericin B-mediated damage to renal tubules, which results in electrolyte wasting and disrupts the tubuloglomerular feedback mechanism. The clinical manifestations of amphotericin B-induced renal damage include azotemia, renal tubular acidosis, hypokalemia, and hypomagnesemia.⁸⁷ Generally, amphotericin B-related renal toxicity is reversible within 2 weeks after therapy has been discontinued. Administration of normal saline (250 mL) immediately before amphotericin B administration can decrease amphotericin B-induced nephrotoxicity⁹⁷ and should be initiated before L.K.'s next dose. Amphotericin B should not be admixed with

normal saline, however, because sodium causes amphotericin B to precipitate into an inactive particulate in IV admixture formulations.⁹⁸ The cumulative dose of amphotericin deoxycholate should be kept below 3 g; other nephrotoxins should be avoided (especially diuretics) (Table 71-7), and patients with already compromised renal function should be closely monitored.⁹⁸ Hypokalemia and hypomagnesemia also should be monitored closely, and replacement therapy should be initiated as soon as significant declines in potassium or magnesium are detected. These measures to prevent further renal deterioration should be implemented and the amphotericin B therapy continued cautiously in this patient with systemic candidiasis. Anemia, associated with decreased renal production of erythropoietin, should resolve after amphotericin B is discontinued and need not be treated.⁹⁹

15. L.K. has developed significant renal dysfunction resulting from acute tubular necrosis. How should his dose of systemic antifungal drugs be altered?

Renal elimination of the antimycotics varies tremendously. For systemically administered amphotericin B, only 5% to 10% of unchanged drug is eliminated in urine and bile during the first 24 hours,⁸⁷ and no evidence indicates it is metabolized to a significant extent. Therefore, no substantial dosage adjustment is required for patients with chronic renal or hepatic failure. Although many clinicians will withhold amphotericin B doses if acute renal dysfunction develops during therapy, concerns

Table 71-7 Significant Drug Interactions

| <i>Antifungal</i> | <i>Interacting agent(s)</i> | <i>Class^a</i> | <i>Onset</i> | <i>Manifestation</i> |
|--------------------------------------|---|--------------------------|--------------|--|
| AmphoB | Acetazolamide | 2 | R | Severe hyperchloremic acidosis secondary to additive or synergistic renal effects |
| | Chemotherapeutic agents: | | | |
| | Doxorubicin, carmustine, cyclophosphamide, fluorouracil | 2 | D | Enhanced chemotherapeutic effect secondary to ↑ cellular uptake. |
| | Cyclosporine | 2 | D | Enhanced nephrotoxicity |
| | Digoxin | 2 | D | AmphoB-induced hypokalemia leading to ↑ digoxin toxicity |
| | Leukocyte transfusion | 1 | R | Severe pulmonary leukostasis with potential for respiratory failure |
| | NSAID | 2 | R | Additive or synergistic nephrotoxicity |
| | Pentamidine | 2 | D | Additive or synergistic nephrotoxicity |
| | Potassium-sparing diuretics | 2 | D | Spironolactone ↓ potassium requirements preventing hypokalemia in neutropenic patients receiving AmphoB |
| CFG | Anticonvulsants: | | | |
| | Carbamazepine, phenytoin, mephenytoin | 2 | D | Carbamazepine and phenytoin to significantly ↓ CFG concentrations through CYP450 induction |
| | Corticosteroids | 2 | D | Dexamethasone induces metabolism of CFG, thus ↓ serum concentrations of CFG |
| | Cyclosporine | 2 | D | Elevations in transaminases (hepatic toxicity); CFG AUC ↑ by 35% |
| | Rifampin | | | Hepatic uptake transporters of CFG might be induced by rifampin; administer CFG 70 mg/day when coadministered with rifampin |
| Griseofulvin | Sedative/hypnotics: | | | |
| | Benzodiazepines, ethanol, barbiturates | 3 | D | ↑ Griseofulvin clearance with concomitant barbiturate or ethanol consumption |
| | Oral contraceptives | 1 | D | ↓ Oral contraceptive efficacy |
| KI | ACE inhibitors | 2 | D | Hyperkalemia |
| | Lithium | 2 | D | Hypothyroidism |
| | Potassium-sparing diuretics | 2 | D | Hyperkalemia |
| Azole Antifungal Interactions | | | | |
| Effect of other drugs on azole(s) | | | | |
| <i>Azole</i> | <i>Interacting Agent(s)</i> | <i>Class</i> | <i>Onset</i> | <i>Manifestation</i> |
| KCZ | Isoniazid | 2 | D | ↓ Serum antifungal concentration and potential treatment failure |
| KCZ | Anticholinergics | 2 | R | ↓ Antifungal absorption; antifungal should not be administered concomitantly |
| KCZ | Sucralfate | 2 | R | 20% ↓ in KCZ concentration |
| KCZ, ITZ | Didanosine | 2 | R | Acid neutralizing agents in didanosine prevent ITZ absorption. KCZ extrapolated |
| ITZ | Dexamethasone | 2 | D | Dexamethasone hepatically induces metabolism of ITZ |
| ITZ | Fluoxetine | 3 | D | Norfluoxetine inhibits CYP3A4, ↑ ITZ concentrations |
| FCZ | Hydrochlorothiazide | 2 | D | Significant ↑ in FCZ concentrations; changes attributed to ↓ FCZ renal clearance |
| KCZ, ITZ, FCZ | Antacids | 2 | R | Poor dissolution of dosage form, therefore ↓ azole availability Administer KCZ and ITZ 2 hr after antacid dose. Note drug formulations containing antacid buffers. |
| KCZ, ITZ, FCZ | H ₂ -blockers | 2 | R | ↓ Antifungal absorption; antifungal should not be administered with H ₂ -blockers. |
| FCZ, PCZ, VCZ | Cimetidine | 2 | R | Alteration of gastric pH ↓ FCZ, and PCZ absorption; VCZ concentrations noted slightly ↑, possibly through nonspecific CYP450 inhibition by cimetidine. |
| KCZ, ITZ, FCZ, VCZ | Carbamazepine | 2 | D | ↓ ITZ serum concentrations and therapeutic failures have occurred. Carbamazepine likely to significantly ↓ VCZ concentration via potent CYP450 induction; coadministration contraindicated. |
| KCZ, ITZ, FCZ, VCZ | Rifampin | 2 | D | Rifampin-potent CYP450 inducer. Significant ↓ in serum antifungal concentrations, potentially leading to treatment failure. Doubling VCZ dose does not restore adequate antifungal exposure; coadministration contraindicated. |
| VCZ | Ritonavir | 2 | D | Ritonavir-potent CYP450 inducer and both substrate for and inhibitor of CYP3A4. VCZ serum concentrations ↓ by ritonavir in dose-dependent manner; coadministration with low-dose ritonavir should be avoided; high-dose ritonavir contraindicated. |
| VCZ | Barbiturates | 3 | D | Long-acting barbiturates likely to significantly ↓ VCZ concentrations. |
| Azole effects on other drugs | | | | |
| KCZ, ITZ | Corticosteroids | 2 | D | Twofold ↑ in serum methylprednisolone observed with concomitant KCZ. Similar reaction with prednisone has been observed. ↑ Systemic effects of inhaled budesonide after ITZ. |
| ITZ | Fexofenadine | 2 | R | Significant ↑ fexofenadin AUC not related to dose of ITZ suggesting mechanism related to inhibition of gastrointestinal P-glycoprotein |
| KCZ, FCZ | Theobromines | 2 | R | Inhibition of theophylline absorption |
| FCZ | Oral contraceptives | 1 | D | ↓ Oral contraceptive efficacy |

Table 71-7 Significant Drug Interactions (Continued)

| <i>Azole</i> | <i>Interacting Agent(s)</i> | <i>Class</i> | <i>Onset</i> | <i>Manifestation</i> |
|-----------------------------------|--|--------------|--------------|---|
| KCZ, ITZ, FCZ, VCZ | Warfarin | 1 | D | ↓ Warfarin protein binding and hydroxylation by liver (poor documentation) leading to ↑ in prothrombin time response; interaction with VCZ proposed via CYP2C9 inhibition. |
| KTZ, FCZ, VCZ | Terfenadine Cisapride Astemizole Pimozide Quinidine | 1 | D | Azoles result in inhibition of metabolism of these drugs. ↑ Plasma concentrations can lead to QT prolongation and rarely <i>torsade de pointes</i> . Coadministration of FCZ or VCZ and terfenadine contraindicated. |
| KCZ, ITZ, FCZ, PCZ, VCZ | Immunologic agents Cyclosporine, Sirolimus, Tacrolimus | 2 | D | Azole inhibition of CYP3A4 produce significant ↑ in serum immunosuppressant concentration and ↑ toxicity. Monitor cyclosporine and tacrolimus whole blood trough concentrations frequently during and at discontinuation of antifungal therapy. Coadministration of VCZ and sirolimus contraindicated. Data extrapolated for sirolimus and ITZ or PCZ. |
| KCZ, ITZ, FCZ, | Sulfonylureas | 2 | D | Significantly ↑ sulfonylurea concentrations. Data extrapolated for VCZ. |
| PCZ, VCZ, KCZ, ITZ, FCZ, PCZ, VCZ | Benzodiazepines | 3 | D | 20% ↓ in chlordiazepoxide clearance demonstrated with KCZ. Inhibition of CYP3A4 by azole significantly ↑ serum concentrations of benzodiazepines metabolized by this enzyme. Monitor adverse effects frequently and consider dose reduction. |
| VCZ | Calcium channel blockers | 3 | D | ↑ Plasma concentrations of calcium channel blockers metabolized by CYP3A4. |
| VCZ | Ergot alkaloids | 1 | D | Ergotism; coadministration of VCZ with ergot alkaloids contraindicated. |
| VCZ | Methadone | 2 | D | R-methadone and S-methadone serum concentrations ↑ via VCZ inhibition of CYP2C9, CYP2C19, and CYP3A4. Monitor for methadone toxicity (QT prolongation). |
| VCZ | Statins | 2 | D | VCZ inhibits lovastatin metabolism <i>in vitro</i> (CYP3A4 inhibition). Monitor for rhabdomyolysis. |
| VCZ | Vinca alkaloids | 3 | D | ↑ Plasma concentrations of vinca alkaloids (CYP3A4 substrates) leading to neurotoxicity. |
| Two-way interactions | | | | |
| KCZ, ITZ, FCZ, PCZ, VCZ | Phenytoin, mephenytoin | 2 | D | Phenytoin induction of UDP-G metabolism decreases PCZ concentrations. ↓ VCZ concentrations thought due to phenytoin as CYP2C9 substrate and CYP450 inducer. Avoid concomitant phenytoin and PCZ use; ↑ VCZ maintenance dose. Phenytoin serum concentrations ↑ after FCZ, PCZ, or VCZ administration; postulated mechanism via CYP3A4 inhibition. Monitor plasma phenytoin concentrations. |
| PCZ, VCZ | Rifabutin | 2 | D | ↓ PCZ concentrations via UDP-G induction. ↓ VCZ concentrations via potent CYP450 induction. ↑ Rifabutin concentrations due to inhibition of CYP3A4 by PCZ and VCZ may ↑ rifabutin adverse effects. Avoid concomitant PCZ or VCZ and rifabutin. |
| VCZ | Efavirenz | 1 | D | Efavirenz is a CYP450 inducer, CYP3A4 substrate and inhibitor. Concomitant administration results in ↓ VCZ and ↑ efavirenz concentrations. Coadministration contraindicated. Data extrapolated to other non-nucleoside reverse transcriptase inhibitors; monitor for drug toxicity or antifungal failure. |
| VCZ | Omeprazole | 2 | R | ↑ Omeprazole and VCZ concentrations via CYP2C19 inhibition. Reduce omeprazole doses of ≥40 mg by one-half. Metabolism of other proton pump inhibitors CYP2C19 substrates may also be inhibited by VCZ. |
| VCZ | Oral contraceptives | 2 | D | ↑ Oral contraceptive and VCZ concentrations via CYP2C19 inhibition; monitor for oral contraceptive and VCZ adverse events. |
| VCZ | HIV protease inhibitors Saquinavir, amprenavir, nelfinavir | 2 | D | VCZ and protease inhibitors inhibition of CYP3A4 metabolism (in vitro); monitor patients for toxicity. |

^aClassification: 1, major; 2, moderate; 3, minor^bClinically significant interaction that the authors recommend the reader should focus on.

ACE, angiotensin-converting enzyme; AmphoB, amphotericin B; CYP, cytochrome P; D, delayed; FCZ, fluconazole; HIV, human immunodeficiency virus; ICZ, itraconazole; KCZ, ketoconazole; KI, potassium iodide; NSAID, nonsteroidal anti-inflammatory drugs; PCZ, posaconazole; R, rapid, UDP-G; VCZ, voriconazole.

of drug-induced nephrotoxicity in L.K. must be balanced against the high likelihood of mortality in untreated patients with deep-seated infections.^{60,61} Alternative systemic antifungal therapy (i.e., azoles or echinocandins) that is less nephrotoxic should also be considered. Dosing recommendations for echinocandins are unchanged in renal dysfunction or liver dysfunction except for caspofungin. For patients in moderate hepatic insufficiency (Child-Pugh score 7–9), the maintenance caspofungin dose should be decreased to 35 mg/day. No data are available for caspofungin used in severe hepatic impairment and a further dosage reduction should be considered.

Ketoconazole and itraconazole undergo first-pass metabolism and have a biphasic dose-dependent elimination.^{38,39} These agents are extensively metabolized and excreted in the bile; small amounts of unchanged drug are excreted in the urine, therefore, no need exists to adjust dosages in patients with renal dysfunction or in patients undergoing dialysis.¹⁰⁰ Fluconazole and voriconazole, unlike ketoconazole and itraconazole, are not extensively metabolized. More than 90% of a fluconazole dose is excreted in urine, of which about 80% is measured as unchanged drug and about 20% as metabolites.¹⁰¹ Because fluconazole is excreted primarily unchanged in the urine, dosages should be adjusted in patients with renal insufficiency (Table 71-5).^{20,21,38–41,87,100–108} Fluconazole or voriconazole may be reasonable alternatives in L.K., but the dosage must be adjusted for renal function based on published nomograms.¹⁰²

16. What is the role of an amphotericin B formulated with a lipid?

Lipid formulations of amphotericin B have been approved by the FDA for patients who are unable to tolerate generic amphotericin B (Table 71-8). In addition, the admixture of amphotericin B in 10% or 20% lipid emulsion has been used for treating systemic mycotic infections. The lipid carriers differ tremendously for each of the amphotericin formulations. The liposomal formulation is a spherical carrier that contains amphotericin both on the inside and outside of the vesicle. Imagine the lipid complex as a snowflake shape, and the colloidal dispersion shaped like a Frisbee with amphotericin bound to the structure. The differences in structure appear to have no effect on therapeutic outcome but confer different protection against amphotericin adverse effects.¹⁰⁹ Amphotericin B admixture with a lipid emulsion cannot be recommended until a stable formulation can be established.¹¹⁰

Limited data are available to assist in the management of this case. A single large controlled trial has evaluated amphotericin B lipid complex for the treatment of disseminated candidiasis. Amphotericin B 0.6 to 1.0 mg/kg/day for 14 days was slightly, but not significantly, superior to the lipid complex formulation at 5 mg/kg/day for mycologic efficacy (68% vs. 63%) or survival.¹¹¹ Renal dysfunction defined as a doubling in serum creatinine, however, was 47% with amphotericin B and 28% with this lipid formulation. Because of the significant cost, lipid formulations of amphotericin B should be reserved for patients who have pre-existing renal dysfunction, and those who have severe adverse reactions to, or are failing, generic amphotericin B. Indications for the lipid formulations are further reviewed in the discussion of sections on aspergillosis and cryptococcosis.

Antimycotic Prophylaxis

17. What measures could have been undertaken to prevent invasive fungal infections in L.K.?

In 2005, the Mycoses Study Group Trial defined patients at high risk patients who could benefit from prophylaxis. Trials are underway to assess efficacy of differing antifungals in those patients who have at least one of the primary risk factors: systemic antibiotics for previous 4 days or presence of a central venous catheter. In addition, each patient would have at least two secondary risk factors: dialysis or use of TPN during previous 4 days; inpatient surgery, pancreatitis, or more than one dose of systemic steroids or immunosuppressive within 7 days before ICU admission. Minimizing these risk factors is instrumental in preventing fungal infections. When such control is not possible, pharmacotherapy should be considered in high risk populations (>10% candidemia incidence).¹¹²

Selective GI decontamination or systemic antimycotic pharmacotherapy can be used in high-risk, immunocompromised, or surgical patients to prevent the development of fungal infections and could have been used for L.K. In critically ill surgical patients, the risk of invasive infection may be reduced by >50% with systemic fluconazole prophylaxis. No change was seen, however, in patient survival.¹¹³ Alternatively, a nonabsorbable antifungal such as amphotericin B or nystatin could be selected. Oral amphotericin B decreases systemic candidal infections threefold to fivefold in high-risk patients.¹¹⁴ Yet, the problems of questionable antifungal stool concentrations,¹¹⁵ decreasing azole cost, and poor compliance have led to preferential azole use. Azoles are more effective in preventing oral pharyngeal candidiasis (OPC) than placebo.^{116,117} Only small studies with inadequate sample sizes have compared the clinical efficacy of azoles with polyene antifungals (e.g., amphotericin B) for prevention of either oropharyngeal or systemic candidiasis.

Prophylaxis should be initiated in L.K. and therapy continued until L.K. develops a systemic infection or until immunosuppression ends. If L.K. is discharged from the hospital and treated as an outpatient, a systemic azole (imidazole or triazole) administered once daily is preferable to a polyene to improve adherence. To reemphasize, however, systemic therapy increases the risk of resistance, adverse effects, drug interactions (Table 71-7), and sometimes cost (Table 71-4).

Candiduria

Treatment

18. M.Y., a 24-year-old man, has been hospitalized in the surgical ICU with multiple traumatic injuries resulting from a motor vehicle accident. Shortly after admission, he underwent an exploratory laparotomy for a ruptured spleen and lacerated liver. He subsequently suffered respiratory and renal failure. M.Y. is currently intubated and on mechanical ventilation. Since admission, he has been nutritionally supported with central hyperalimentation and has been receiving broad-spectrum antibiotics (gentamicin, ampicillin, and metronidazole). A Foley catheter is in place. Two recent UA show budding yeast and cultures were positive for >100,000 colony-forming units of *C. albicans*. M.Y. is currently afebrile, his funduscopic examination is normal, and no macronodular skin lesions are present. The WBC count is 8,900 cells/mm³, and three sets of blood cultures drawn over

the past 2 days are negative. How should M.Y.'s candiduria be treated?

[SI unit: WBC count, $8.9 \times 10^9/L$]

Caution must be used when selecting pharmacotherapy for M.Y. because it is difficult to differentiate among cystitis, urethritis, or systemic infection in the presence of funguria. Similarly, it is difficult to differentiate colonization from infection because candiduric patients are usually asymptomatic. Funguria cannot be used to determine the location or severity of invasion. Signs and symptoms of systemic disease should be

monitored diligently until a diagnosis of colonization, cystitis, or urethritis is confirmed and the risk of dissemination is excluded.

Eradication of fungi in the urine (specifically *C. albicans*) should begin with removal of the indwelling urinary catheter and alleviation of risk factors for fungal disease. If catheter removal does not clear the urine within 48 hours, pharmacotherapy should be considered. If M.Y. is scheduled for a genitourinary procedure, he should receive systemic therapy because the rate of candidemia after surgery is high (10.8%). In addition, any patient at high risk for dissemination into the blood

should be treated (e.g., patients with diabetes, genitourinary abnormalities, renal insufficiency, or immunosuppression).¹¹⁸

Bladder irrigation with amphotericin B has been commonly used and concentrations of 150 mcg/mL effectively kill 5×10^6 *C. albicans* in the urine within 2 hours.¹¹⁹ Clinical studies evaluating the efficacy of continuous amphotericin B 150 mcg/mL irrigations or intermittent irrigations (15–30 mcg/100 mL) retained for 1 hour \times 3 to 7 days are limited, however, and often have had serious design flaws. In two comparative studies, bladder irrigation for 5 days with amphotericin B 50 mcg/mL appeared to be superior to fluconazole 100 mg/day as measured by microbiologic cure rates. Cure rates 2 to 4 weeks days after infection were equal, however, but mortality rates were higher in the amphotericin B-treated groups. Amphotericin B failures may have been associated with dissemination of yeast from the urinary tract.^{120,121} Systemic antifungal therapy with flucytosine 100 to 150 mg/kg/day for 7 days¹²² and azoles (fluconazole 0.6 to 1.4 mg/kg/day for 7 days)^{123,124} also has been used in noncomparative or nonrandomized studies.

Blastomycosis

Etiology

19. C.P., a 17-year-old girl, is admitted to the hospital with a chronic pneumonia that has not responded to antibiotics. Three months ago, she developed a chronic cough that eventually became productive of purulent sputum, which was occasionally streaked with blood. Two months ago, she developed “boils” on her lower extremities and back, which drained spontaneously. She was hospitalized at another hospital but failed to respond to amoxicillin and erythromycin. C.P. denies fever, chills, or night sweats, but has lost 11 pounds. Her temperature is 38.2°C. A 2-cm² subcutaneous, fluctuant, tender mass is seen over the right mandible and a second fluctuant mass about 4 cm wide on the lower back. Also, several 0.5- to 1-cm² ulcers with heaped-up, hyperkeratotic margins are noted on the lower extremities (Fig. 71-2). Rales are heard at the right lung base. C.P.’s leukocyte count is slightly elevated at 13,500 cells/mm³. A chest radiograph shows a masslike infiltrate in the right mid-lung field (Fig. 71-3). A wet preparation of ulcer scrapings and material aspirated from a subcutaneous abscess reveal numerous broad-based, budding yeast forms with refractile cell walls and multiple nuclei typical of *B. dermatitidis*.

Cultures of sputum, skin scrapings, and abscess material eventually confirmed the diagnosis. What was the likely portal of entry for C.P.’s disseminated blastomycosis? Why should it be treated?

[SI unit: WBC count, $13.5 \times 10^9/L$]

Typical of the other endemic mycoses, the primary portal of entry for *B. dermatitidis* is the lungs. A pulmonary origin for C.P.’s infection is also supported by her history of cough with purulent, blood-streaked sputum, evident about a month before cutaneous lesions appeared on her legs and back. An acute pulmonary infection is most often asymptomatic and, when symptomatic, usually requires only observation. Chronic pulmonary or extrapulmonary blastomycosis will develop in an unknown number of these patients. C.P.’s rales at the base of her right lung and persistent pneumonia that is unresponsive to antibiotics indicate that she has a chronic pulmonary infection and will require therapy. Chronic pulmonary disease often presents with radiographic studies that can be mistaken

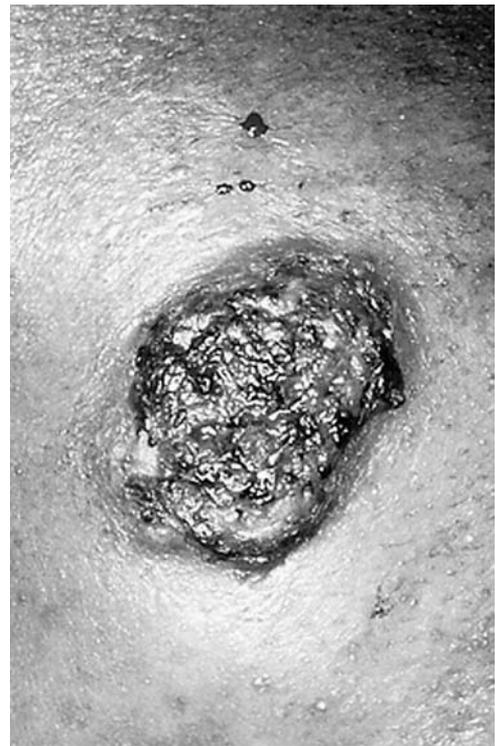

FIGURE 71-2 Disseminated *Blastomyces dermatitidis* skin ulcers.

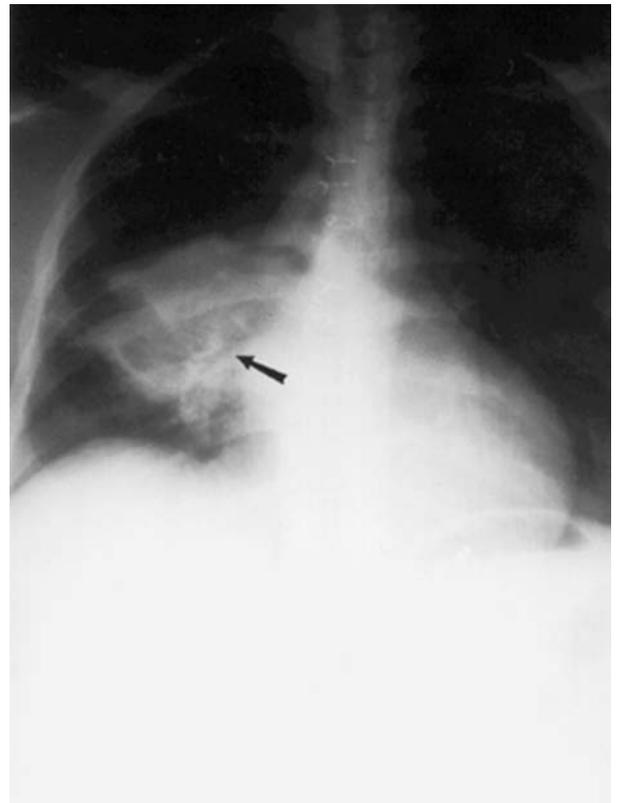

FIGURE 71-3 Chest radiograph of pulmonary *Blastomyces dermatitidis*.

for tuberculosis or lung cancer; the masslike infiltrate in her right lung on chest radiograph also is consistent with chronic pulmonary disease. Extrapulmonary infections can involve the skin (verrucous or ulcerative lesions), bone, genitourinary system (prostatitis, epididymo-orchitis), or central nervous system (CNS) (meningitis or brain abscess). If untreated, these chronic pulmonary or extrapulmonary infections will be fatal in at least 21% of patients.¹²⁵ Because C.P. presents with pulmonary and cutaneous evidence of blastomycosis, she should be treated.

Treatment

20. What specific therapy should be initiated for C.P.?

Historically, amphotericin B was considered the treatment of choice for blastomycosis and total doses of >2 g were associated with 97% cure rates, low relapse rates, yet 70% toxicity.¹²⁵ Ketoconazole and itraconazole currently are advocated as safe and effective alternatives to amphotericin B in patients with non-life-threatening, non-CNS infections. The NIAID-Mycoses Study Group¹²⁶ confirmed the effectiveness of azoles for the treatment of chronic pulmonary and extrapulmonary disease caused by the endemic mycoses, blastomycosis, and histoplasmosis. In uncontrolled evaluations of chronic pulmonary and extrapulmonary infections (excluding life-threatening or CNS), ketoconazole at dosages of 400 to 800 mg/day resulted in cure rates of about 89%, failure rates of about 6%, and relapse rates of about 5%.¹²⁶ In similar studies, itraconazole capsules 200 to 400 mg/day for a median of 6.2 months resulted in cure rates of 88% to 95%.¹²⁷ Fluconazole was ineffective at dosages <400 mg/day. Higher dosages (400–800 mg/day), however, are as effective as ketoconazole in non-life-threatening disease.¹²⁸ Although these trials are neither comparative nor controlled, itraconazole appears to be less toxic than ketoconazole and to have the best benefit (efficacy) to risk (toxicity) ratio.

C.P. has mild to moderate disease and can be treated with an initial itraconazole dosage of 200 mg/day. If no clinical improvement is seen within 2 weeks or if the disease progresses despite therapy, the dosage of itraconazole can be titrated upward in 100-mg increments to a maximal dosage of 400 mg/day. Treatment should continue for at least 6 months. If C.P. develops severe or meningeal disease, itraconazole should be discontinued and amphotericin B 0.3 to 0.5 mg/kg/day should be initiated to provide a total dose of 1.5 g. C.P. should be followed up for 12 months because of the possible risk of relapse. Unlike histoplasmosis, skin and serologic testing are not sufficiently sensitive to diagnose blastomycosis or evaluate the effectiveness of treatment.^{126,129} Rather, patients should be evaluated closely for resolution of symptoms (constitutional, pulmonary), negative microbiologic samples, and improvement in radiographic studies.

Antifungals in Pregnancy

21. C.P. reports she has not menstruated in 3 months, and a urine pregnancy test is positive. How does this information change the therapeutic options for her?

The data on the safety of antimycotics for treating patients who are pregnant or lactating are limited, but comprehensively

reviewed according to FDA categories of the teratogenic risks of drugs (see Chapter 47, Obstetric Drug Therapy).^{130,131} The systemic azoles are categorized risk factor C.¹³² However, we believe they are contraindicated in pregnant or lactating women who are breast-feeding because of their potential teratogenicity and endocrine toxicity in the fetus or newborn. As with the azoles, griseofulvin and flucytosine have been classified as risk factor C. These agents should not be used in C.P. because the risk clearly outweighs the therapeutic benefit. Few or no data exist on the secretion of these agents in breast milk. Therefore, breast-feeding should be discouraged in women receiving these antifungal agents.

Amphotericin B and terbinafine are classified as risk factor B. Therapeutic agents in this category have no fetal risk based on animal studies or, when risk has been found in animals, controlled human studies have not confirmed the results. No reports apparently exist regarding the use of terbinafine in pregnancy. Therefore, this arbitrary designation is of concern and recommendation is to avoid terbinafine use in pregnancy until published data support a B classification. Furthermore, considerable clinical experience with amphotericin B in pregnant women has documented successful treatment of systemic mycoses with no excess toxicity to either the mother or fetus. Thus, amphotericin B formulations have been the mainstay of antifungal therapy in pregnancy.

Histoplasmosis

Treatment

22. J.N., a 47-year-old man with severe rheumatoid arthritis, has been maintained on daily prednisone for the past 6 years; his current dosage is 20 mg/day. For the past 4 weeks, he has experienced daily fevers to 38.4°C, drenching night sweats, anorexia, and an 8.2-kg weight loss. His prednisone dosage was increased to 40 mg/day with little clinical effect. On admission to the hospital, J.N. appears chronically ill and has many of the stigmata of chronic steroid therapy. His temperature is 37.8°C with an associated rapid heart rate of 105 beats/minute. A shallow mouth ulcer is present on the hard palate. The liver is enlarged to a total span of 18 cm, and the spleen is palpable 3 cm below the left costal margin. Stool is positive for occult blood. A chest radiograph shows bilateral interstitial infiltrates (Fig. 71-4A). He is pancytopenic, with a hematocrit (Hct) of 29% (normal, 39%–45%), a WBC count of 3,500 cells/mm³ (normal, 4,000–11,000 cells/mm³), and platelet count of 78,000 cells/mm³ (normal, 130 to 400,000 cells/mm³). The bilirubin is normal but the aminotransferases are elevated to about 1.5 times normal, and serum lactate dehydrogenase is 10 times over normal. A UA reveals 8 to 10 WBC/high-power field. The SrCr is 1.9 mg/dL, and BUN is 42 mg/dL. A bone marrow aspirate and biopsy of the mouth ulcer reveals multiple, small intracellular yeast forms compatible with *H. capsulatum* in macrophages and polymorphonuclear leukocytes (Fig. 71-4B). Cultures of blood and urine, bone marrow aspirate, and mouth ulcer biopsy grew *H. capsulatum*. What should be the primary antifungal therapy in this case of systemic *H. capsulatum*? What clinical parameters should be monitored to assess the efficacy and toxicity of J.N.'s therapy?

[SI units: Hct, 0.29; WBC count, $3.5 \times 10^9/L$; SrCr, 167.96 $\mu\text{mol/L}$; BUN, 14.99 mmol/L urea]

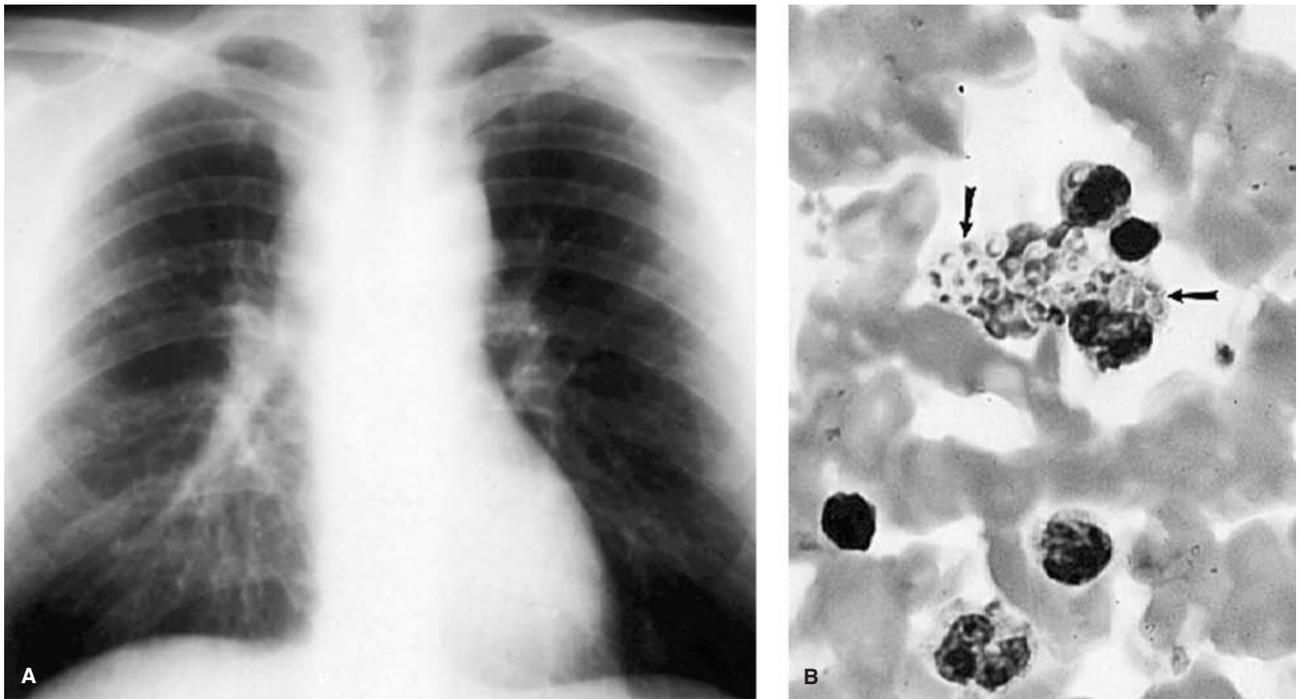

FIGURE 71-4 Histoplasmosis infection. A: Chest radiograph showing bilateral interstitial infiltrate. **B:** Gram's stain of peripheral blood showing leukocytes with intracellular organisms.

The treatment benefits of antifungal therapy in systemic histoplasmosis have not been well investigated. Treatment options for histoplasmosis are outlined in Table 71-9.¹³³ Accordingly, J.N. should be treated with amphotericin B 0.3 to 0.5 mg/kg/day or itraconazole 2.8 mg/kg/day, and his course of therapy should be monitored for both efficacy and toxicity. Amphotericin B was selected for this case.

Blood and urine cultures, pancytopenia (except anemia in amphotericin B-treated patients), constitutional symptoms, serum lactate dehydrogenase (LDH,) and hepatosplenomegaly are excellent measures for evaluating outcome to antifungal therapy of J.N.'s histoplasmosis. Anemia and chest radiographs are poor measures of treatment response. Chest radiographs often reflect calcified granulomas in chronic disease with

Table 71-9 Treatment of Histoplasmosis

| Disease | Primary | Secondary |
|---|---|--|
| Acute Pulmonary | | |
| Prolonged symptomatology (> 2 wks) | Resolves spontaneously | Not applicable |
| Immunocompromised ^c | ITZ 50–100 mg/day (3–6 mos) ^a | AmphoB 0.3–0.5 mg/kg/day ^a |
| Respiratory distress (PaO ₂ <70 mm Hg) | AmphoB lipid formulation ^c | AmphoB 0.3–0.5 mg/kg/day |
| | AmphoB 0.5–1.0 mg/kg/day | ITZ 1.5–2.8 mg/kg/day (≥6 mos) ^a |
| | (TD250–500 mg) ± corticosteroids | ITZ (has not been investigated in life-threatening situations) |
| Chronic Pulmonary | | |
| Active | ITZ 1.5–2.8 mg/kg/day 9 mos) ^{a,b} | AmphoB 0.5 mg/kg/day ^b |
| Inactive | | Or KTZ 400 mg/day (≈6 mos) |
| Histoplasmosis | No treatment | Not applicable |
| Mediastinal fibrosis | Surgery ^d | Not applicable |
| Systemic Disease | AmphoB (total dose recommended: 35 mg/kg) or ITZ 2.8 mg/kg/day ^a | Fluconazole 400–800 mg/day ^e |

^aTreatment should be continued until the patient is symptom free and culture negative for 3 mos. The recommendations for duration of therapy or total doses should be used only as guides for initial therapy.

^bIndicated only for serious symptoms (i.e., hemoptysis).

^cLipid formulations of amphotericin B are preferable to generic amphotericin B in HIV-infected patients.¹³⁵

^dITZ 200 mg QD or BID for 6–18 mos for most patients.

^eFluconazole should only be used in patients who cannot take ITZ.

AmphoB, amphotericin B deoxycholate; ITZ, itraconazole; KTZ, ketoconazole; TD, total dose.

scarring, which rarely resolve even with extensive therapy. Therefore, evaluation of deterioration on radiograph but not of improvement is possible. In addition, amphotericin B-induced renal disease with secondary anemia can confuse evaluation of disease resolution. Anemia must be excluded as a prognostic indicator in patients receiving amphotericin B for durations of 3 weeks regardless of the dose.⁹⁹

Diligent follow-up of patients is required because relapses occur in 5% to 15% of amphotericin B-treated patients within 3 years. Relapses occurred in patients who received <30 mg/kg total dose of amphotericin B, or had concomitant untreated Addison's disease, immunosuppression, vascular infections (endocarditis, grafts, aneurysms), or meningeal infections.^{133,134} More than 90% of HIV-positive patients experience a relapse of histoplasmosis subsequent to adequate amphotericin B therapy. A double blind trial in immunocompromised patients (HIV) revealed that liposomal amphotericin B was superior to amphotericin B deoxycholate. It is not known how itraconazole compares with liposomal amphotericin B in those infected with HIV. If this patient was infected with HIV, a lipid based amphotericin may have been preferred.¹³⁵ Even the initiation of subsequent immunosuppressive therapy is of particular concern because of the potential for reactivation (relapse) and dissemination of histoplasmosis from dormant foci, especially in patients with residual granulomas.

Potential adverse effects to amphotericin B also should be monitored in J.N. (e.g., infusion-related reactions, nephrotoxicity, anemia, hypokalemia, neurotoxicity, thrombophlebitis). In addition, J.N.'s adrenal status should be monitored closely because of his long-term corticosteroid therapy and his histoplasmosis. Patients who are Addisonian secondary to histoplasmosis infections appear to experience more episodes of amphotericin B-induced acute hypotension.

Azole Adverse Effects

23. After treatment with a total amphotericin B dose of 750 mg, clinical improvement of J.N.'s histoplasmosis is subjectively and objectively documented. The clinician selected ketoconazole 400 mg/day as an oral substitute for his amphotericin B regimen because of the patient's economic circumstances. Six weeks later, J.N. complains of impotence and wonders whether this could be caused by his medication. What is the likelihood that ketoconazole is the cause of J.N.'s impotence?

Ketoconazole has been associated with more adverse reactions and greater potential for drug interactions compared with miconazole, itraconazole, and fluconazole. The most common side effects of ketoconazole, however, are nausea and vomiting. GI distress appears to be dose-related because a substantially smaller percentage of patients experience these effects when receiving ketoconazole dosages of 400 mg/day compared with dosages of 800 mg/day.¹³⁴ Endocrine and hepatic toxicities are the most significant adverse effects of ketoconazole requiring monitoring. Dose-splitting from daily to twice daily may decrease the nausea and vomiting. Dose-related endocrinologic toxicities (hypoadrenalism, oligospermia, and diminished libido) have been observed during ketoconazole therapy secondary to inhibition of mammalian sterol synthesis,^{11,136} and usually resolve with drug discontinuation. Therefore, J.N.'s complaints of impotence might well be attributed to his ketoconazole. Liver enzymes should also be monitored because an

approximate 10% risk exists of elevation in transaminases and an occasional case of serious hepatitis and hepatic failure.^{11,136}

The triazoles—itraconazole, fluconazole, and voriconazole—are much better tolerated and require less monitoring than ketoconazole therapy. This has been attributed to the greater affinity of the triazoles for fungal cytochrome enzymes and less interference with mammalian enzymes.¹³⁷ Neither itraconazole nor fluconazole (6 mg/kg/day) exhibit any substantial hepatotoxicity or antiandrogenic effects, and nausea and vomiting occur in substantially fewer patients (<5%) receiving these agents compared with imidazoles. Abnormal elevations in liver function occurred in 2.7% of patients receiving voriconazole during clinical trials. Abnormalities in liver function tests may be associated with higher azole dosages or serum concentrations, but generally resolve either with continued therapy or dosage modification, including drug discontinuance. Liver function should be determined before and periodically throughout azole therapy because cases of serious hepatic reactions have been reported.¹³⁷ A unique adverse event associated with voriconazole is enhanced perception to light, which may be associated with higher plasma concentrations or doses. Generally, drug discontinuance is not required, although monitoring of visual acuity, visual field, and color perception is advised if therapy lasts longer than 28 days. Diarrhea, asthenia, flatulence, and eye pain have been reported with posaconazole therapy.⁵⁴ Based on these data, J.N. should be given a trial of itraconazole.

Azole Drug Interactions

24. J.N. chose to continue his ketoconazole therapy. He now returns with Cushnoid signs and symptoms. What potential drug or disease state interaction could be implicated as a cause of this serious problem in J.N.?

Drug interactions with systemic azoles and polyenes can lead to mild inconveniences or life-threatening events (Table 71-7). The interaction between azoles and glucocorticoids is not as serious as the interaction reporting QT prolongation and ventricular arrhythmias with nonsedating H₁-selective antihistamines.¹³⁸ The interaction with corticosteroids can be multifaceted, however, and is therapeutically challenging. Although it is clinically possible that corticosteroids could affect outcome, no clinical trial has addressed this important question. Drug interaction trials have measured an increase in corticosteroid serum concentrations leading to recommendations to decrease the steroid dose by 50% when ketoconazole is used concomitantly. The interaction has been suggested between glucocorticoids and other azoles.¹³⁹ In addition, dexamethasone has been demonstrated to increase the clearance of caspofungin.

Other significant drug interactions with the azole antifungals revolve around their ability to inhibit the cytochrome (CYP) P450 enzyme system. All five azoles inhibit CYP3A4, but with varying potency: ketoconazole is the most potent inhibitor, followed by itraconazole and voriconazole, then posaconazole and fluconazole. In addition to the interactions documented in Table 71-7, numerous other agents are substrates to cytochrome CYP3A4, but for which no clinical studies have evaluated an interaction. As azole antifungals could increase serum concentrations and therefore increase activity of these substrates, caution should be exercised

during concomitant use. Adding complexity to voriconazole's interactions include its propensity to inhibit CYP2C9 and CYP2C19, two isoenzymes exhibiting polymorphism, thus increasing concentrations of CYP2C9 or CYP2C19 substrates. Conversely, agents that either induce or inhibit the CYP450 system may decrease or increase, respectively, antifungal drug concentrations.

Coccidioidomycosis

Serologic Tests

25. F.W., a 32-year-old Filipino woman and a lifelong resident of the Central Valley in California, is admitted to the hospital with a third recurrence of coccidioid meningitis. Approximately 4 years ago, she was treated with a total amphotericin B dose of 2.2 g, which resulted in a good clinical response. Nine months later, she relapsed and received a second course of amphotericin B to a total of 1.6 g. She did well over the next 18 months and was able to return to work as a secretary. Over the past 4 months, however, F.W. has had chronic headaches, has been unable to concentrate at work, and is reported by family members to have a very labile personality. A computed tomography (CT) scan of the brain reveals mild hydrocephalus. An opening pressure of 19 mm Hg (normal, 10 mm Hg) was documented at lumbar puncture. Analysis of the CSF showed 110 WBC/mm³ (normal, 0 WBC/mm³); glucose, 18 mg/dL (normal, 60% of serum glucose); and protein, 190 mg/dL (normal, <50 mg/dL). Complement fixation antibodies were positive in the CSF at a titer of 1:32. How should serologic tests for coccidioidomycosis be interpreted?

The most important serologic tests for fungal infections use complement fixation (CF), immunodiffusion, and EIA techniques. Tests for complement fixing antibodies (i.e., CF) to the dimorphic fungi (Table 71-1) are well established and various antigens have been used. Coccidioidin is the mycelial phase antigen for *Coccidioides immitis*. Of patients with coccidioidomycosis, 61% will have coccidioidin CF titers of at least 1:32 and 41% will have titers of 1:64. Rising titers are a bad prognostic sign, and falling titers indicate clinical improvement. Therefore, F.W.'s CSF CF titer of 1:32 is consistent with active coccidioidomycosis. Immunodiffusion testing for coccidioidomycosis using coccidioidin reveals that seropositive results appear 1 to 3 weeks after onset of primary infection in 75% of patients and this positivity usually disappears within 4 months if the infection resolves.¹⁴⁰ IgG- and IgM-specific EIA using a combination of antigens for *C. immitis* have been developed. These tests offer sensitivities of >92% and specificities of 98% for serum and CSF. EIA reactivity appears earlier than CF reactivity.^{141,142}

Antifungal Central Nervous System Penetration

26. What is a pharmacokinetic explanation for the treatment failure of F.W.? How might this problem be overcome?

F.W. has received prolonged parenteral amphotericin B administration and the CSF still contains fungal organisms. Treatment failures in this case may partly be owing to the limited penetration of amphotericin B into the CSF.⁸⁷ Because amphotericin B is highly bound to lipid (90%–95%), CSF concentrations achieved are only 2% to 4% of the serum concentration^{87,137}; peritoneal, synovial, and pleural fluid con-

centrations are slightly <50% of the serum concentrations (Table 71-5). Flucytosine is not significantly bound to protein and penetrates the CSF, vitreous, and peritoneal fluids; its volume of distribution approximates that of total body water.¹⁴³ Flucytosine concentration in the CSF is 74% of the serum concentration, resulting in its extensive use in treatment of CNS mycoses. Flucytosine, however, has no activity in coccidioidomycosis and, therefore, cannot be used in F.W.

The volume of distribution of fluconazole approaches that of total body water,¹⁴⁴ and concentrations of fluconazole in CSF are approximately 60% of simultaneous serum concentrations. Ketoconazole has only about 1% of the dose present as free drug because it is highly bound to plasma proteins (>80%) and to erythrocytes (15%). Therefore, ketoconazole penetrates poorly into the CSF except with dosages of 1,200 mg/day. Itraconazole is similar to ketoconazole in that it is >99% protein bound. Itraconazole concentrates intracellularly in host alveolar macrophages, however, and that may account for its efficacy against fungal CNS infection despite its inability to penetrate into the CSF.¹⁴⁵ Echinocandins also poorly (<5%) penetrate into the CSF.¹⁴⁶ Data on terbinafine and posaconazole penetration are currently unavailable. Therefore, fluconazole might be an alternative to CNS instillation of amphotericin B based only on pharmacokinetic considerations.

Preliminary studies with fluconazole, investigated at dosages of 400 mg/day, are promising for control of disease in patients with coccidioidomycosis meningitis. Relapse rates are high once fluconazole therapy is stopped, however.¹⁴⁰ Ketoconazole, which must be given at very high doses and results in significant toxicity, should be used only if other therapies are contraindicated.^{139,147} Oral itraconazole 200 mg twice daily is not superior to fluconazole based on a randomized, double-blind, placebo-controlled trial of nonmeningitis disease; however, it tended toward greater efficiency.¹⁴⁸

Intrathecal Amphotericin

27. What adverse events might be observed with the intrathecal administration of an antifungal in F.W.?

Augmentation of systemic antifungal administration with intraventricular or intrathecal administration may improve the outcome for antifungals with poor penetration into the CSF.^{148–153} Intrathecal amphotericin B doses in adults normally range from 0.25 to 0.5 mg diluted in 5 mL of 5% glucose.^{140,145} A few studies suggest that doses >0.7 mg improve the cure rate and decrease relapse.¹⁴⁷ Cisternal or intraventricular administration is recommended as the routes of choice because of flow characteristics of CSF from the ventricles to the spinal cord.^{148–150} When lumbar administration is necessary, amphotericin B is administered in a hypertonic solution of 10% glucose and the patient is placed in a Trendelenburg position in an attempt to improve distribution of the drug to the basilar meninges and ventricles and reduce local toxicity. Voriconazole, caspofungin, and the lipid amphotericin formulations have not been evaluated.

Cisternal antifungal administration has been associated with headaches, nausea, vomiting, cranial nerve paresis, and cisternal hemorrhage caused by needle trauma.^{149,150–152} An Ommaya reservoir often is used to facilitate intraventricular administration of amphotericin B. Common complications of these devices include shunt occlusion, bacterial colonization

or bacterial meningitis, parkinsonian symptoms, and seizures.^{149–153} Lumbar administration has been used because it is simpler, but it often must be discontinued because of chemical arachnoiditis, headache, transient radiculitis, paresthesia, nerve pulses, difficulty voiding, impaired vision, vertigo, and tinnitus.¹⁵³ Acute toxic delirium, demyelinating peripheral neuropathy, and spinal cord injury have also been reported.^{154–156} Regardless of the substantial and serious adverse effects, intrathecal administration may be effective in treating patients with meningitis who have severe disease or who are pharmacologic nonresponders.

Aspergillosis

Empiric Therapy (Neutropenic Host)

28. M.Z., an otherwise healthy 29-year-old man, presented for allogeneic bone marrow transplantation (BMT) 12 days ago. He has had no serious complications associated with his chloroquine-induced aplastic anemia during his 7-month wait for BMT. On BMT days –5 to –2, induction therapy was initiated with cyclophosphamide (50 mg/kg) and total body irradiation, and then bone marrow from his HLA antigen-compatible brother was infused on day 0. The onset of neutropenia was noted on day 3 and the WBC count was 50 cells/mm³. M.Z. has complained only of stomatitis and diarrhea before day 5. On that morning, he was complaining of fever, chest pain, and headache. On physical examination, his temperature is 37°C. Empiric anti-infectives were added, but by day 8 he was not clinically improving. What therapeutic options should be considered for this patient?

Empiric antifungal therapy in a neutropenic host should be initiated when a patient is febrile for >96 hours on appropriate anti-infectives. Routine empiric therapy for a patient without evidence of deep-seated fungal infection historically has been amphotericin B 0.3 to 0.6 mg/kg/day or fluconazole 200 to 400 mg/day until the absolute neutrophil count is >500 cells/mm³.¹⁵⁷ Therapy results in resolution of signs and symptoms in up to 64% of patients.

Because mould infections are of concern in this neutropenic patient population, drug therapy that is highly active against these organisms should be considered. Assessments of newer antifungals using a composite endpoint for success have failed to show superiority over amphotericin B. A large, well-controlled, double-blind comparison of amphotericin B 0.6 mg/kg/day versus liposomal amphotericin B 3.0 mg/kg/day can be a guide for this case. Patients who were febrile >96 hours and neutropenic (<500 cells/mm³) experienced equal survival and clinical success of approximately 50% for both agents.¹⁵⁸ Success rates studies comparing other agents, liposomal amphotericin B (34%) with caspofungin (34%),¹⁵⁹ voriconazole, or itraconazole^{160,161} have had similar outcomes. It is important to remember that fever is a late and insensitive measure of infection. Prevention of breakthrough invasive fungal infection may be the most important indicator of an agent's efficacy. Using this measure, voriconazole appears superior when comparing trials, voriconazole versus liposomal amphotericin B (1.9% vs. 5%), amphotericin B versus liposomal amphotericin B (3.2% versus 7.8%).^{158,161} Selection of any of these expensive, however less toxic, agents should be weighed against the incidence of invasive fungal disease in institution.

29. What is the role of lipid formulations of amphotericin B in other disease states?

A motivation for developing these formulations was the observation that serum triglycerides and cholesterol decrease adverse drug reactions and may improve efficacy.^{112,162} The advantage of the formulations (Table 71-8) is clear in the treatment of diseases such as aspergillosis, which require long-term therapy that can result in patient intolerance to generic amphotericin B.¹⁰⁹ Multiple uncontrolled or retrospective trials have observed that all four lipid formulations of amphotericin B appear to be less nephrotoxic and may be more effective than amphotericin B deoxycholate. A single large randomized, double-blind trial and a historical controlled trial support these observations.^{147,163}

Few well-controlled prospective comparative trials exist to guide the decision-making process for fungal infections that require a shorter course of therapy. In addition to the data presented for candidemia (Question 16), liposomal and lipid complex amphotericin B have been evaluated for treatment of cryptococcal meningitis and histoplasmosis in patients infected with HIV.^{135,164,165} Each lipid agent appears safer and more effective than amphotericin B deoxycholate. Secondary to the high acquisition cost and relatively low rates of toxicity with short course therapy, generic amphotericin B should be selected over the lipid formulation unless a patient is clearly intolerant, requires extended therapy, or experiences a treatment failure.

Of particular interest are the ongoing studies and case reports in which Intralipid 10% to 20% combined with amphotericin B (1–2 mg/mL) is administered at a dosage of 1 mg/kg/day. This practice cannot be recommended until a prospective, randomized, controlled trial documents efficacy and reduced toxicity of these lipid emulsion–amphotericin B formulations as compared with amphotericin B alone. Current concerns are (a) the inability to formulate a pharmaceutically stable product,¹⁶⁶ (b) difficulty assessing whether inline filtering is required, and (c) the delivery of excessive calories.¹⁶⁷

Treatment of Aspergillosis

30. Chest auscultation on day 8 reveals right-sided rales with a friction rub. Chest radiograph shows a nodular infiltrate in the right middle lobe. Fiberoptic bronchoscopy identified eroded bronchioles with necrotic tissue, and methenamine silver nitrate stain of a biopsy sample revealed fragmented, closely septated hyphal bodies branched at 45 degree angles. The samples were sent to microbiology for cultures. All previous blood and sputum cultures have been negative, except that *Aspergillus niger* growing from sputum before admission was classified as a “contaminant.” The diagnosis at this time is probable aspergillosis. What treatment steps should be taken?

Drug therapy should be approached by first determining whether the infection is likely to be invasive or noninvasive disease (Fig. 71-5). Most patients inhale *Aspergillus* species and never become symptomatic or develop only mild hypersensitivity pneumonitis. Invasive infections are more likely to occur in immunocompromised patients, especially those with prolonged neutropenia associated with bone marrow transplantation. A classic observation reported by radiology is a “halo” sign or a “crescent” sign identified on CT, highly suggestive of this infection. Additionally, an ELISA for a surface protein, galactomannan, has been reported to have high

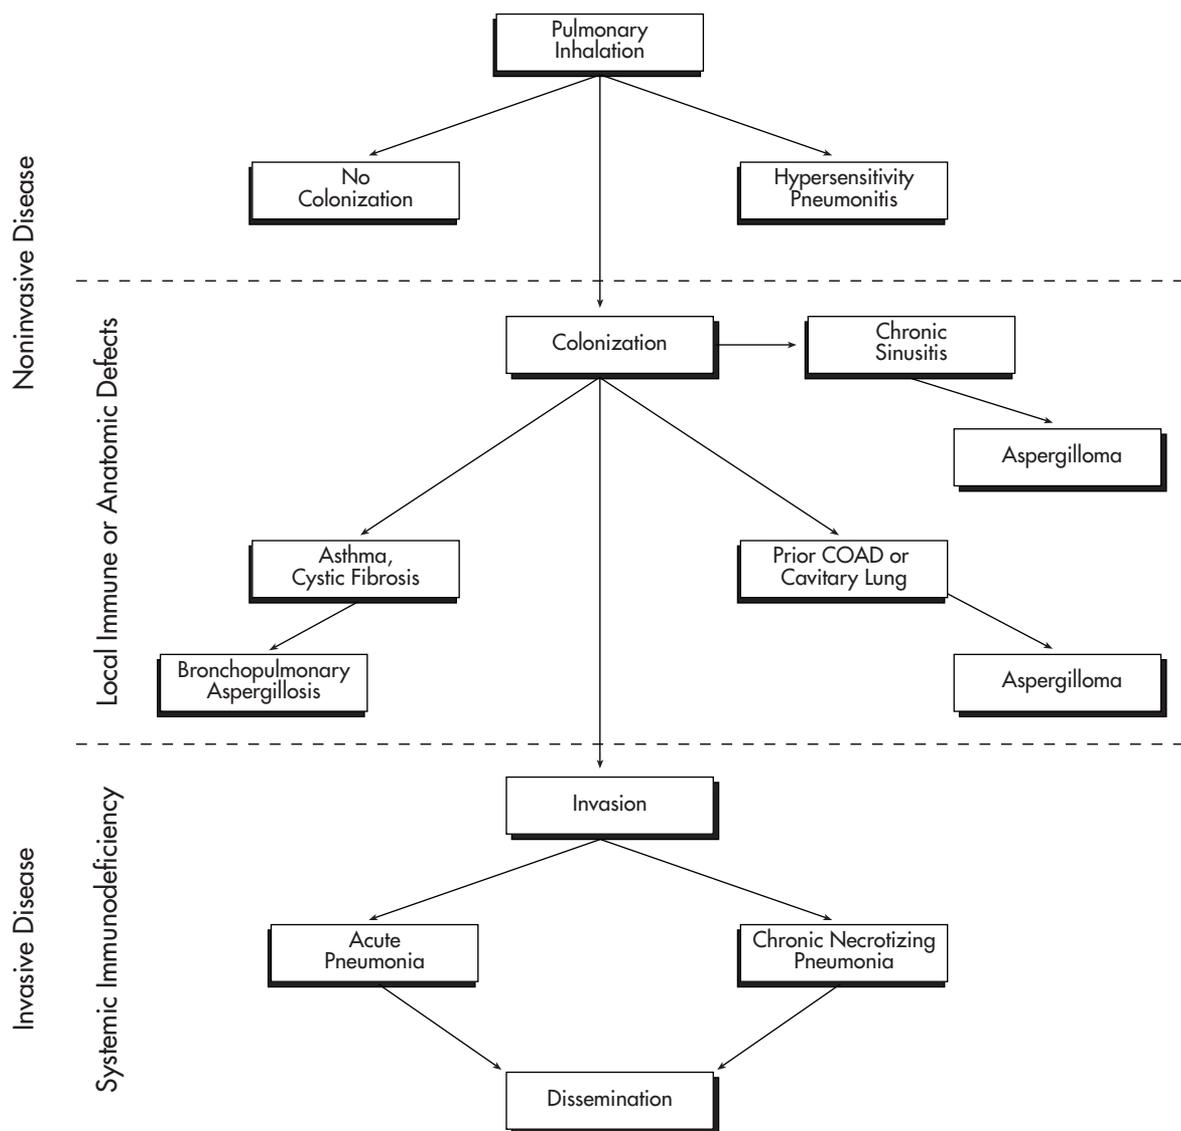

FIGURE 71-5 Classification of Aspergillus infections.

sensitivity in the diagnosis of invasive disease.¹⁶⁸ Positive serum results (optical density index [ODI] >1.5) can be obtained as early as 17 days before clinical symptoms or radiologic signs. Confounding false-positive test findings induced by *Bifidobacterium* sp. colonization in pediatric gastrointestinal tracts, and administration of piperacillin-tazobactam or calcium gluconate, have concerned clinicians using this test for screening in areas with low case rates. This test should be an excellent prognostic indicator for therapeutic outcome in confirmed cases or screening in areas with high case rates. The subjective and objective data in this case clearly represent invasive symptomatic disease and there is a need for aggressive treatment.

Aspergillosis is a model for invasive mould infections that have a propensity to invade blood vessels and tissue. Antimycotic pharmacotherapy should be initiated rapidly and aggressively (Table 71-10) in conjunction with removal or reversal of immunosuppression if possible. Definite or probable invasive aspergillosis should be treated with voriconazole

or high-dose amphotericin B formulation (liposomal amphotericin B 1 mg/kg/day),¹⁶⁹ or combination therapy.¹⁶⁸ Combination of voriconazole and caspofungin for salvage therapy has been associated with reduced mortality when compared with voriconazole alone.¹⁷⁰ Liposomal amphotericin B at doses >1 mg/kg/day have not led to greater responses.¹⁷¹ Despite early and intensive therapy, mortality from invasive aspergillosis can be >50%.¹⁷² In unresponsive patients, an amphotericin B formulation in combination therapy with an echinocandin, flucytosine, rifampin, or itraconazole; or an echinocandin with voriconazole should be considered.^{168,169,173} Flushing, rash, facial swelling, and pruritis can occur with caspofungin administration and is thought to be histamine mediated. Less serious, but more frequent, adverse effects reported in patients receiving caspofungin include fever, elevations in serum transaminases, serum alkaline phosphatase, or both, and headache.¹⁵⁴

Patients with mild to moderate *Aspergillus* should be treated with voriconazole or itraconazole.¹⁷² Clinical and microbiologic cure rates of 50% to 71% have been reported for

Table 71-10 Therapeutic Options for Treatment of Aspergillosis

| Disease | Primary | Secondary |
|---------------------------|--|---|
| Hyalohyphomycetes | | |
| <i>Aspergillus</i> | | |
| Allergic bronchopulmonary | Prednisone 1 mg/kg/day followed by 0.5 mg/kg/day or QOD × 3–6 mos; no antifungal therapy | ITZ 200 mg BID × 4 mos ^a |
| Aspergilloma | Observation | Surgery ^b |
| Systemic (invasive) | Voriconazole 6 mg/kg/day LD, 4 mg/kg/day divided twice daily | Amphotericin B lipid formulation, ^d or AmphoB 1.0–1.5 mg/kg/day ^c |
| Serious | | Amphotericin B lipid formulation, ^d or AmphoB 0.5–0.6 mg/kg/day ^c or ITZ 200 mg TID loading dose × 3 days then 200 mg BID with meals (6-mo minimum) |
| Mild or moderate | Voriconazole 6 mg/kg/day LD, 4 mg/kg/day divided twice daily | |

^aTreatment should be continued until the patient is symptom free and culture negative for 3 months. Noted durations or total doses should be used only as a compass to help guide therapy.

^bIndicated only for serious symptoms (e.g., hemoptysis).

^cLipid formulations of amphotericin B should be utilized preferentially in these patients.

^dLiposomal amphotericin B at doses up to 15 mg/kg/day appears safe in phase I/II trials.¹⁸⁵

AmphoB, amphotericin B; BID, twice daily; ITZ, itraconazole; LD, loading dose; QOD, every other day; TID, three times daily.

voriconazole or itraconazole-treated patients with invasive aspergillosis. Further studies are necessary to define the optimal dose, duration, and route of itraconazole in invasive forms of aspergillosis.

Cryptococcosis

31. D.W., a 48-year-old man, was hospitalized with fever and severe headache. His history was significant for Hodgkin's lymphoma, which is in remission. Lumbar puncture revealed an opening pressure of 280 mm Hg (normal, 10 mm Hg), WBC count of 50 leukocytes/mm³ (normal, 0 leukocytes/mm³), a positive India ink preparation, and a cryptococcal antigen titer of 1:4,096. Serology for HIV infection was negative. Culture of the CSF eventually grew *C. neoformans*. The presumptive diagnosis is cryptococcal meningitis. What are the treatment options for D.W.?

Currently, only two therapeutic options exist for meningeal cryptococcal disease: amphotericin B formulation with or without flucytosine and fluconazole. Flucytosine cannot be used alone for therapy or prophylaxis because of the rapid development of resistance. This yeast is also resistant to echinocandins. Patients, whether infected with HIV or not, have improved treatment outcomes when the combination of amphotericin B and flucytosine is used.^{175,176} Furthermore, when flucytosine (100–150 mg/kg/day divided into four daily doses) is used in combination therapy, the dose of amphotericin B may be reduced to 0.3 to 0.6 mg/kg/day, which decreases the frequency of dose-related amphotericin B toxicity. In patients who cannot be treated with flucytosine, the dosage of amphotericin B must be increased to >0.6 mg/kg/day.

Fluconazole is an alternative to amphotericin B in patients infected with HIV with cryptococcal meningitis. It is important to be mindful of the following caveats, however: sterilization of the CSF occurs more rapidly and mortality is lower during the first 2 weeks of therapy in patients treated with amphotericin B as compared with fluconazole.^{162,177} Early mortality was espe-

cially high in fluconazole-treated patients who presented with altered mental status.^{175,177,178} Thus, initial therapy of cryptococcal meningitis in patients with mental status changes should be initiated with amphotericin B for at least 2 weeks or until the patient has stabilized clinically. At this point, fluconazole may be substituted at an initial dosage of 400 mg/day. The dosage may be titrated upward to a dosage of 800 mg/day depending on clinical response. After a 10-week course of therapy is completed, the dosage of fluconazole is reduced to a maintenance dosage of 200 mg/day for life. Fluconazole 400 mg/day can be used in all other patients. Another alternative may include liposomal amphotericin B 4 mg/kg/day for 21 days.¹⁶⁵ Until larger clinical studies have been completed, however, this regimen cannot be recommended over generic amphotericin B (see Chapter 70, Opportunistic Infections in HIV-Infected Patients).

In D.W., initial treatment should focus on elimination of all factors leading to immunosuppression. Antifungal therapy should then be initiated immediately with amphotericin B 0.3 to 0.6 mg/kg/day plus flucytosine 100 to 150 mg/kg/ for a minimum of 6 weeks to optimize the chance of a cure, especially in transplant recipients.¹⁷⁸ In addition, CSF hypertension, usually presenting as headache, should be resolved through therapeutic spinal tap. Acetazolamide should be avoided in these cases.¹⁷⁹

32. What parameters should be monitored while D.W. is treated with flucytosine?

The most common side effect of flucytosine is GI distress (e.g., nausea, vomiting, diarrhea). Although flucytosine is not metabolized *per se* by mammalian cells, gut flora may be responsible for metabolism of flucytosine to fluorouracil. This toxic metabolite has been speculated to account, in part, for the GI distress and bone marrow toxicity associated with flucytosine therapy.¹⁸⁰ Other flucytosine adverse effects include leukopenia, thrombocytopenia, and hepatotoxicity.

Dose-dependent bone marrow suppression, which can be fatal, generally is seen in patients whose serum concentration of flucytosine is >100 mcg/mL. Thus, it is important to monitor blood concentrations and maintain concentrations below this level.^{176,178} If assays for flucytosine serum concentrations are unavailable, signs and symptoms of bone marrow suppression or worsening renal function should result in a dosage reduction or discontinuation of the drug. Flucytosine is eliminated by glomerular filtration, with 80% to 95% of the dose excreted unchanged in the urine. Renal excretion of flucytosine is directly related to creatinine clearance, and dosages should be adjusted based on creatinine clearance to prevent accumulation to toxic concentrations in patients with renal impairment.¹⁰⁰ Patients with creatinine clearances of 10 to 40 mL/min should have the dosage of flucytosine reduced by 50% (usual dose, 37.5 mg/kg Q 12 hours). For patients with creatinine clearance <10 mL/min, dosing should be initiated at 37.5 mg/kg/day, with frequent monitoring of flucytosine serum concentrations.

Dosage adjustment and close monitoring also are required for patients receiving hemodialysis and it is recommended that the dose be given postdialysis.

33. When is combination antifungal therapy indicated?

In vitro results of antifungal combinations against many common mycotic pathogens have been variable. These incomplete and inconsistent findings have been attributed to variable incubation times, variable concentrations of antifungal agents, and the sequence of antifungal addition.¹⁷⁹ As a result, clinical decisions about combination therapy should be based on patient-specific *in vivo* evaluations. Because of the limited clinical data, combination antifungal therapy should be initiated cautiously. Except for the treatment of cryptococcal meningitis and disseminated aspergillosis, combination therapy should be reserved for cases of treatment failure (disseminated candidiasis) with no other established pharmacologic options for therapy or mould infections with high mortality rates.

- Zinc 72-18
- Echinacea 72-18

Viral infections are common causes of human disease. An estimated 60% of illnesses in developed countries result from viruses, compared with only 15% from bacteria. These may include the common cold, chickenpox, measles, mumps, influenza, bronchitis, gastroenteritis, hepatitis, poliomyelitis, rabies, and numerous diseases caused by the herpesvirus. Upper respiratory tract infections, such as the common cold or influenza, are one of the most common reasons for visits to a health care professional.¹ Although most of these patients have a self-limiting illness, certain viral infections, such as influenza, can cause significant mortality, particularly in the elderly. For example, in the worldwide Spanish influenza epidemic of 1918 to 1920, between 20 million and 100 million people died.² Influenza vaccines can reduce the impact of this illness in susceptible populations, but there are no vaccines against many other potentially severe viral infections, including herpes encephalitis and neonatal herpes. Therefore, the need for safe and effective antiviral agents is obvious.

Substantial progress has been made in antiviral chemotherapy as a result of advances in molecular virology and genetic engineering. Antiviral agents can be designed to inhibit functions specific to viruses; this maximizes their therapeutic benefits while minimizing adverse effects to the host cell.

Current technology also permits rapid diagnosis of viral diseases. It is now possible to make a specific diagnosis of several

viral illnesses within hours to a few days; previously, specific diagnosis took days to months. This has made it possible to select an appropriate antiviral drug early for the treatment of acute viral infection.

This chapter describes the etiology, pathogenesis, and treatment of common viral infections. Specific case presentations illustrate the optimal use of antiviral drugs in patients with viral infections.

HERPES SIMPLEX VIRUS INFECTIONS

Herpesvirus is an extremely important pathogen in humans. It causes many illnesses, including herpes encephalitis and neonatal herpes, which are associated with significant mortality and sequelae, and genital herpes, which causes substantial pain and emotional suffering. Fortunately, antiviral drugs can decrease the morbidity, mortality, and duration of symptoms in most cases.³

Herpes Encephalitis

Herpes simplex virus (HSV) encephalitis is the most common sporadic viral infection of the central nervous system (CNS). The estimated incidence is approximately 2.3 cases per million population per year, although this may be an underestimate

because of the difficulty in diagnosing this disease. It can occur at any age and is characterized by the acute onset of fever, headache, decreased consciousness, and seizures. Any child with fever and altered behavior should be evaluated carefully. This is a devastating infection: without treatment, mortality approaches 70%, and only 2.5% of patients recover enough to lead normal lives.³

Herpes simplex virus type 1 (HSV-1) is the etiologic agent in most patients with herpes encephalitis, but herpes simplex virus type 2 (HSV-2) is more common in newborns. The infection may be localized to the brain or involve cutaneous and mucous membranes. Although any area of the brain can be involved, the orbital region of the frontal lobes and portions of the temporal lobes are most often affected.

Herpes encephalitis is often difficult to diagnose and is always a serious disease. A computed tomography (CT) scan is usually indicated to rule out other conditions, including a brain abscess or other space-occupying lesions that may produce similar symptoms. The CT or radionuclide scans may be unremarkable early in the course of the disease.

Cerebrospinal fluid (CSF) examination usually reveals pleocytosis (predominately lymphocytes) with 50 to 2,000 white blood cells (WBCs)/mm³. Polymorphonuclear leukocytosis and red blood cells (RBCs) may also be seen. Many patients have an elevated protein level in the CSF (median, 80 mg/dL). The presence of antibody to HSV-1 is useful in making the diagnosis.

The electroencephalogram (EEG) is the most sensitive but least specific test. There are usually CT or brain scan abnormalities, but these may take a day or two longer to appear. The EEG, CT, and brain scan findings compatible with HSV encephalitis can be mimicked by other conditions, and a brain biopsy is required to clearly establish the diagnosis. Rapid diagnosis of herpes encephalitis by a polymerase chain reaction (PCR) assay of HSV DNA in the CSF is available at most medical centers. This is a highly sensitive, specific, and rapid method for diagnosing herpes encephalitis.⁴

Clinical Presentation

1. R.F., a 7-year-old boy weighing 20 kg, was seen in the emergency department (ED) after a seizure. Over the previous 3 days, R.F. had decreased appetite, headache, and fever (101°F–102°F), and was lethargic and disoriented. His leukocyte count was 13,000/mm³ with a shift to the left. Ceftriaxone (50 mg/kg given intravenously [IV] Q 12 hr) and dexamethasone (0.15 mg/kg IV Q 6 hr) were initiated for presumed bacterial meningitis. Phenobarbital (5 mg/kg IV Q 24 hr) was given for seizure control. The CSF was normal, and no bacteria could be identified. Over the next 2 days, R.F. became increasingly less responsive and lapsed into a coma. A CT scan of the brain revealed decreased density in a localized area of the left temporal lobe. Because of a high suspicion of herpes encephalitis, a brain biopsy was performed. Acyclovir 20 mg/kg IV Q 8 hr was started immediately after the procedure. HSV-1 was isolated from the biopsy specimen 24 hours later. What findings in R.F. are consistent with the diagnosis of herpes encephalitis? Why was a brain biopsy performed?

[SI unit: leukocytes, 13 × 10⁶/L]

Fever, headache, lethargy, and disorientation are common features of herpes encephalitis. As illustrated by R.F., the CSF examination can be normal in some patients. The CT scan

showing decreased density in the left temporal lobe is suggestive of herpes encephalitis. Finally, a negative CSF culture also suggests the absence of a bacterial infection.⁵ However, these findings cannot establish the diagnosis of herpes encephalitis.

Brain biopsy is the most definitive diagnostic procedure for herpes encephalitis. Biopsy is particularly important because some treatable conditions, such as cryptococcosis and aspergillosis, can be missed by other diagnostic procedures. The morbidity (bleeding) caused by brain biopsy is low (1%) in medical centers with extensive experience.

Treatment: Acyclovir

2. As expected, a specific pathogen (HSV-1) was isolated from the biopsy specimen in R.F. What is the treatment of choice for R.F.'s herpes encephalitis?

Two studies comparing acyclovir and vidarabine have demonstrated that IV acyclovir (10 mg/kg Q 8 hr for 10 days) is the treatment of choice in patients with herpes encephalitis.^{6,7} The 12-month all-cause mortality was 25% in the acyclovir-treated group and 59% in the vidarabine-treated group. Of great importance was the fact that nearly one-third of the acyclovir-treated patients returned to normal life, compared with only 12% of those treated with vidarabine.⁸ In addition, acyclovir is less toxic than vidarabine. Currently, vidarabine is not marketed in the United States.

Acyclovir-resistant herpes is not an important consideration in the management of herpes encephalitis in most patients, but it can be important in AIDS or other immunocompromised patients who receive multiple repeated courses of acyclovir (see Chapter 71). Foscarnet has been successfully used in immunocompromised patients with acyclovir-resistant HSV.^{9,10}

Acyclovir is the treatment of choice for R.F. because it has been shown to decrease morbidity in patients with herpes encephalitis.

The role of corticosteroids in the treatment of herpes encephalitis is not well defined. One small, nonrandomized trial found that corticosteroid therapy, in combination with IV acyclovir, was associated with an improved outcome.¹¹ However, prospective, randomized trials are needed before routine use of corticosteroids can be recommended.¹²

ACYCLOVIR PHARMACOKINETICS

3. Why is the acyclovir dosage regimen appropriate based on the serum concentrations required for the inhibition of viral replication? How should the effect of acyclovir be monitored in R.F.?

In adults receiving single IV doses of acyclovir 2.5 to 5 mg/kg, a peak plasma concentration of 3.4 to 6.8 mcg/mL has been reported.^{13,14} The mean peak and trough plasma concentrations were 9.8 and 0.7 mcg/mL, respectively, after multiple doses of 5 mg/kg every 8 hours.⁸ At larger IV doses of 10 to 15 mg/kg, the peak plasma concentrations of acyclovir have ranged from 10 to 30 mcg/mL¹⁵ (Tables 72-1 and 72-2).

Limited data are available on acyclovir pharmacokinetics in children, particularly premature infants. Acyclovir pharmacokinetics for children older than 1 year of age are similar to those of adults¹⁶ (Table 72-1). In neonates receiving acyclovir 5 to 15 mg/kg IV Q 8 hr, the peak and trough serum concentrations have ranged from 3.1 to 38 mcg/mL and 0.23 to 30 mcg/mL, respectively.^{17,18} Acyclovir distributes into all

Table 72-1 Pharmacokinetic Properties of Antiviral Drugs

| Drug | Dose Used in Study | Peak Serum Concentrations (mcg/mL) | % Recovered Unchanged in Urine | Elimination Half-Life (h) |
|---------------------------------|----------------------------------|------------------------------------|--------------------------------|---------------------------|
| Acyclovir ^{8,13,16,21} | 2.5–10 mg/kg IV 200–800 mg PO | 3.4–22.9 0.83–1.61 | 69–91 NR | 2.5–3.3 2.5–3.3 |
| Amantadine ⁸⁹ | 100–200 mg PO | 0.2–0.5 | 52–88 | 11–15 |
| Famciclovir ^{52,159} | 125–1,000 mg PO | 0.8–6.6 | 73–94 ^a | 2.0–3.0 ^a |
| Oseltamivir ^{87,160} | 75 mg PO | 0.6–3.5 ^b | 99 ^b | 6–10 ^b |
| Ribavirin ¹¹⁷ | 0.82 mg/kg INH × 20 h | 1–3 | NR | 6.5–11 |
| Rimantadine ⁹⁰ | 100–200 mg PO | 0.2–0.7 | 20 | 9–31 |
| Valacyclovir ^{161,162} | 1,000 mg PO | 5.7–6.7 ^c | 46–80 ^c | 2.5–3.3 ^c |
| Zanamivir ^{86,163,164} | 10 mg INH BID | 0.039–0.054 | 7–17 | 2.5–5.1 |

BID, twice a day; INH, inhalation, IV, intravenously; NR, not reported; PO, orally.

tissues, with the highest concentrations occurring in the kidney (10 times the plasma concentration) and the lowest in the CSF (25%–70% of plasma concentration).⁸ For R.F., the regimen is appropriate (Table 72-3). Although the pharmacokinetics in children older than 1 year are similar to those in adults, higher dosages are needed in view of its relatively poor distribution into CSF.

HSV-1 clinical isolates have an ID₅₀ of 0.02 to 13.5 mcg/mL, with a mean of 0.45 to 1.47 mcg/mL.^{8,19} However, antiviral susceptibility testing can be affected by many variables, including the amount of inoculum and the testing method used. The results of antiviral susceptibility tests are usually reported as ID₅₀ (the serum concentration necessary to produce 50% inhibition of the viral cytopathic effect). ID₉₀ may correlate better than ID₅₀ with clinical outcome, but the results are unpredictable.²⁰ Consequently, the clinical status of patients is monitored for efficacy of acyclovir. Most patients begin to improve within 48 hours after starting treatment.

ADVERSE EFFECTS

4. What type of adverse effects can occur as a result of IV acyclovir therapy in R.F.? How should these be monitored, and how can they be minimized?

Acyclovir is a relatively safe drug, but renal toxicity associated with IV acyclovir should be considered (Table 72-4). Blood urea nitrogen (BUN) and serum creatinine (SrCr) levels can increase in approximately 5% to 10% of patients. These changes are generally reversible. Acyclovir is relatively insoluble: maximum urine solubility at 37°C is 1.3 mg/mL. Therefore, a transient crystal nephropathy may occur at high acyclovir concentrations.²¹

Other common adverse effects include gastrointestinal (GI) complaints such as nausea and vomiting and neurologic disturbances, including lethargy, tremors, confusion, hallucinations, and seizures.^{21,22} Neurotoxicity appears to be more common in patients with impaired renal function and tends to be reversible. Transient elevation of liver enzymes may occur. Finally, IV acyclovir can cause phlebitis and pain at the injection site.²¹ This can be minimized by administering acyclovir at a concentration of about 5 mg/mL (maximum, 7 mg/mL).²²

Renal function tests, including BUN, SrCr, and urine output, should be monitored closely. To minimize the risk of acyclovir

nephrotoxicity, R.F. should be well hydrated, and each acyclovir dose should be infused over 1 hour. In addition, the IV infusion site should be inspected for inflammation and pain, and R.F. should be asked about pain at the infusion site.

CONVERSION TO ORAL THERAPY

5. After 7 days of IV acyclovir, R.F. is alert, responsive, actively moving about, and eating a normal diet. The intern suggests switching him to oral acyclovir and discontinuing IV therapy. Why is this not appropriate?

Oral therapy is inappropriate for R.F. Based on studies in adults, the absorption of acyclovir after oral administration is variable, slow, and incomplete. The bioavailability of acyclovir is low ($F = 0.15$ – 0.30) and decreases with increasing doses.²¹ The mean peak plasma concentration has ranged from only 0.83 to 1.61 mcg/mL after multiple acyclovir doses of 200 to 800 mg.^{21,23} Thus, with only approximately 50% of acyclovir penetrating the blood–brain barrier, the concentrations of acyclovir in the CSF may be inadequate for R.F. Therapy with IV acyclovir should be continued to complete a 10-day course (Table 72-3). The role of long-term oral antiviral agents following IV therapy to further reduce morbidity is currently being studied.^{5,24}

Neonatal Herpes

Most neonates acquire herpes from the infected genital secretions of the mother at delivery.²⁵ The incidence ranges from 1 in 3,000 to 5,000 deliveries per year in the United States. The infection can present in one of three forms: localized to the skin, eye, and mouth (45%); encephalitis (30%); or disseminated disease (25%). The effects of neonatal herpes can be devastating, and severe disabilities persist in many afflicted children.²⁵ With currently available antivirals, the mortality has ranged from 4% in those with CNS involvement to 29% in those with disseminated disease.²⁵ Neonatal HSV-1 infections may also be acquired after birth through contact with family members with symptomatic or asymptomatic oral-labial HSV-1 infection or from nosocomial transmission. When the virus is transmitted from the mother, clinical evidence of infection in the neonate usually is present 5 to 17 days after birth. Although skin vesicles are the hallmark of infection, at least one-third

Table 72-2 Clinical Pharmacokinetics of Antiviral Drugs

| Drug | Type of Patient | Total Clearance | Elimination | | Comments |
|------------------------------------|--------------------------------------|-----------------------------------|-----------------------------|----------------|---|
| | | | Volume of Distribution | Half-Life (hr) | |
| Acyclovir ^{8,14,16,18,21} | Adults | 327 mL/min/1.73 m ² | 59 L/1.73 m ² | 2.5–3.3 | Use 100% of recommended dose, but extend dosage interval to 12 and 24 hr if Cl _{Cr} ranges from 25–50 and 10–25 mL/min/1.73 m ² , respectively; use 50% of recommended dose Q 24 hr if Cl _{Cr} ranges from 0–10 mL/min/1.73 m ² . |
| Amantadine ⁸⁹ | Neonates | 98–122 mL/min/1.73 m ² | 24–30 L/1.73 m ² | 3.2–4.1 | Adjust doses in renal failure: 200 mg on day 1, then 100 mg/d if Cl _{Cr} 30–50; 200 mg on day 1, then 100 mg QOD if Cl _{Cr} 15–29; 200 mg Q 7 days if Cl _{Cr} <15 mL/min/1.73 m ² . |
| | Adults | 2.5–10.5 L/hr | 1.5–6.1 L/kg | 11–15 | |
| Famciclovir ^{49,159,165} | Adults | 0.37–0.48 L/hr/kg | 1.1 L/kg | 2.2–3.0 | Use 100% of recommended dose, but extend dosage interval to 12 and 24 hr if Cl _{Cr} ranges from 40–59 and 20–39 mL/min, respectively; use 250 mg Q 24 hr if Cl _{Cr} <20 mL/min. |
| Oseltamivir ^{87,160,166} | Adults | 18.8 L/hr (renal clearance) | NA | 6.0–10 | Use 75 mg/d in patients if Cl _{Cr} 10–30 mL/min. The effect of hepatic impairment has not been determined. |
| | Pediatrics (1–12 y) | 0.63 L/h/kg | NA | 7.8 | Dosage recommendations are based on body weight and age. Use 30 mg BID if patient is 15 kg and 1–3 yr, 45 mg if patient is 15–23 kg and 4–7 yr, 60 mg if patient is 23–40 kg and 8–12 yr and normal adult dose if >40 kg and older than 13 yr. |
| | Adolescents | 0.32 L/h/kg | NA | 8.1 | |
| Rimantadine ⁹⁰ | Adults | 20–48 L/hr | 25 L/kg | 9–31 | Because it undergoes extensive metabolism, dose may have to be adjusted in patients with severe liver disease. Dose adjustments may also be necessary in elderly and in those with severe renal failure (Cl _{Cr} <10 mL/min). Manufacturer recommends 50% reduction in such cases. |
| Valacyclovir ²³ | See acyclovir (prodrug of acyclovir) | | | | Use 100% of recommended dose, but extend dosage interval to 12 and 24 hr if Cl _{Cr} ranges from 30–49 and 10–29 mL/min, respectively; use 500 mg Q 24 hr if Cl _{Cr} <10 mL/min. |
| Zanamivir ⁸⁶ | Adults | 2.5–10.9 L/hr | 15.9 L | 2.5–5.1 | 4%–17% of inhaled dose systemically absorbed. Although only limited studies with renal or hepatic impairment, dosing adjustment likely unnecessary. |
| Valganciclovir | See ganciclovir | | | | Use 50% of recommended dose if Cl _{Cr} ranges from 40–59 mL/min; use 450 mg Q 24 hr if Cl _{Cr} ranges from 25–39 mL/min; use 450 mg QOD if Cl _{Cr} <25 mL/min. |

BID, twice a day; Cl_{Cr}, creatinine clearance; QD, every day; QOD, every other day.

to one-half of neonates never have skin lesions.²⁶ In 70% of patients, the disease may progress from isolated skin lesions to involve other organs, including the lungs, liver, spleen, CNS, and eyes.

Diagnosis of this infection can be made by direct fluorescent antibody examination of epithelial cells from the infant or the mother. Examination of the base of a vesicular lesion may show giant cells and intranuclear inclusions, which are characteristic of HSV infections. Serologic test

results are also helpful in making a diagnosis of neonatal herpes.

Risk Factors

6. S.P., an 18-year-old woman, was admitted to labor and delivery with premature rupture of the membranes. Four hours later, S.P. vaginally delivered a 2.5-kg baby boy, R.P., who had an estimated gestational age of 33 weeks. Twenty-four hours after

| Influenza A | Amantadine ^c (Symmetrel) | >9 yr: 100 mg BID | PO | 10 days (treatment), 14–28 days (protection with vaccine), 90 days (protection without vaccine) |
| | | 1 to 9 yr: 4.4–8.8 mg/kg/days but <150 mg/days | PO | |
| | Rimantadine ^c (Flumadine) | >14 yr: 100 mg BID | PO | 7 days (treatment, not approved for treatment in children) up to 6 wk for prophylaxis |
| Influenza A and B | Oseltamivir (Tamiflu) | >13 yr (or >40 kg): 75 mg BID | PO | 5 days (treatment) |
| | | >13 yr (or >40 kg): 75 mg QD | PO | 10 days (prophylaxis) Up to 6 wk (community outbreaks) |
| | | 23–40 kg: 60 mg BID 15–23 kg: 45 mg BID >1 yr–15 kg: 30 mg BID | PO | 5 days (treatment) |
| | Zanamivir (Relenza) | 23–40 kg: 60 mg QD 15–23 kg: 45 mg QD >1 yr–15 kg: 30 mg QD | PO | 10 days (prophylaxis) |
| | | >7 yr: 10 mg (2 inhalations) BID | Inhalation | 5 days (treatment) |
| | | Adolescent and Adult: 10 mg (2 inhalations) QD | Inhalation | 10 days (prophylaxis) 28 days (community outbreak) |
| Respiratory syncytial virus | Ribavirin (Virazole) | >5 yr: 10 mg (2 inhalations) QD | Inhalation | 10 days (prophylaxis) |
| | | 6 g in 300 mL over 12–18 hr/days | Inhalation | 3–7 days |

^aFDA-approved dose is 10 mg/kg. Although doses of 15–20 mg/kg have been used, safety has not been established at these doses.

^bFoscarnet 40 mg/kg IV Q 8 hr is recommended for acyclovir-resistant herpes simplex virus or varicella-zoster virus.

^cAmantadine and rimantadine are no longer recommended as drugs of choice for either prophylaxis or treatment of influenza A.

BID, twice a day; IV, intravenously; PO, orally; Q, every; QD, every day; QID, four times a day.

Table 72-4 U.S. Food and Drug Administration-Indicated Drugs for Various Viral Infections**Adverse Effects of Approved Antiviral Drugs**

| Drug | Adverse Effects |
|----------------|--|
| Acyclovir | Local irritation, phlebitis (9%); increased SrCr, BUN (5%–10%); nausea, vomiting (7%); itching, rash (2%); increased liver transaminases (1%–2%); CNS toxicity (1%) |
| Amantadine | Nausea, dizziness (lightheadedness), insomnia (5%–10%); depression, anxiety, irritability, hallucination, confusion, dry mouth; constipation, ataxia, headache, peripheral edema, orthostatic hypotension (1%–5%); suicide ideation/attempt (<1%) |
| Cidofovir | Nephrotoxicity (53%); neutropenia (34%); rash (30%); headache (27%); alopecia (25%); anemia (20%); abdominal pain (17%); fever (15%); infection (12%); ocular hypotonia (12%); nausea, vomiting (8%); asthenia (7%); diarrhea (7%) |
| Famciclovir | Headache (6%–9%); nausea (4%–5%); diarrhea (1%–2%) |
| Foscarnet | Fever, nausea, vomiting (47%); renal dysfunction (33%); anemia (9%–33%); diarrhea (30%); headache (26%); electrolyte abnormalities (6%–15%); bone marrow suppression (10%); seizure (10%); anorexia (5%); abdominal pain (5%); mental status changes (5%); paresthesia, peripheral neuropathy (5%); cough, dyspnea (5%); rash (5%); first-degree AV block, ECG changes (1%–5%) |
| Ganciclovir | Increased ScCr (35%–69%); anemia (15%–25%); neutropenia, pancytopenia, thrombocytopenia (5%–8%); abdominal pain, anorexia (15%); diarrhea (44%); nausea, vomiting (13%); retinal detachment, vitreous hemorrhage, cataracts, corneal opacification (6%–15%); neuropathy; rash |
| Oseltamivir | Nausea, vomiting (9%–15%); diarrhea (3%); abdominal pain (2%); dizziness, vertigo, insomnia (1%); self-injury and psychosis |
| Ribavirin | Worsening of respiratory status, bacterial pneumonia, pneumothorax, apnea, ventilator dependence; cardiac arrest, hypotension; rash; conjunctivitis |
| Rimantadine | CNS (insomnia, dizziness, headache, nervousness, fatigue); GI (nausea, vomiting, anorexia, dry mouth, abdominal pain) (1%–3%) |
| Trifluridine | Burning or stinging on instillation (4.6%); palpebral edema (2.8%); keratopathy; hypersensitivity reaction; stromal edema; hyperemia; increased intraocular pressure |
| Valacyclovir | Headache (14%); nausea (15%); vomiting (6%); dizziness (3%); abdominal pain (3%) |
| Valganciclovir | Neutropenia (27%); thrombocytopenia (6%); diarrhea (41%); nausea, vomiting (21%–30%); abdominal pain (15%); increased ScCr (3%); insomnia (16%); peripheral neuropathy (9%); paresthesias (8%); ataxia, dizziness, seizures, psychosis, hallucinations, confusion, drowsiness (<5%); retinal detachment (15% during treatment of CMV retinitis); hypersensitivity |
| Zanamivir | Bronchospasm; decline in respiratory function, especially if underlying respiratory disease; nasal/throat irritation and/or congestion (2%); headache (2%); cough (2%); diarrhea (3%); nausea, vomiting (1%–3%) |

AV, atrioventricular; BUN, blood urea nitrogen; CMV, cytomegalovirus; CNS, central nervous system; ECG, electrocardiogram; GI, gastrointestinal; ScCr, serum creatinine.

delivery, S.P. reported the onset of vesicles in the genital area; she had a history of previous episodes of genital herpes. The last infection was during her first trimester of pregnancy. Is R.P. at risk of developing herpes infection?

R.P. is at risk of acquiring herpes infection because the mother had genital herpes during the first trimester and because he was delivered vaginally rather than by cesarean section.²⁷ The risk of a newborn acquiring the disease from an infected mother with primary disease is about 35%; that from a mother with reactivation is 3%.

Treatment: Acyclovir

7. Ten days after birth, R.P. developed poor feeding patterns, irritability, and respiratory distress. Three days later, skin lesions appeared. How should R.P. be treated?

R.P. is manifesting signs of HSV infection and should be treated with antiviral therapy (Table 72-3). The drug of choice for neonatal herpes simplex virus infections is IV acyclovir.^{25,26} Vidarabine was the first antiviral agent used in the treatment of neonatal HSV. Because of the drastic reduction in morbidity, it became the standard of therapy to which other antiviral agents were compared. In clinical trials comparing vidarabine with acyclovir, acyclovir was shown to be as effective as vidarabine in infants with skin, eye, mouth (SEM) involvement, encephalitis, and disseminated HSV infection.²⁸

Although both agents were equally effective, acyclovir was safer and easier to administer, making it the standard of care for neonatal HSV.

ACYCLOVIR ADMINISTRATION

8. What dosage of acyclovir should R.P. receive?

Although an IV dosage of 30 mg/kg given in three divided doses has been shown to be effective in the treatment of neonatal herpes, the use of 60 mg/kg has been shown to have additional benefits in decreasing morbidity and mortality. The higher dose of acyclovir is associated with a higher frequency of hematologic abnormalities, especially neutropenia.^{29,25,30} The minimum duration of therapy should be 14 days, for neonates with only SEM involvement, whereas longer courses (e.g., 21 days) are indicated in infants with CNS involvement or disseminated disease.²⁵

The role of prolonged oral suppressive therapy in newborns with SEM involvement has been investigated. Acyclovir, given orally (PO) at 300 mg/m² per dose three times a day (TID), resulted in a reduction in the recurrences of lesions. Half of these patients developed neutropenia. One patient had lesions resistant to acyclovir.³¹ Because the long-term benefits cannot be fully attributed to the use of suppressive acyclovir, suppressive therapy for patients with SEM involvement is not recommended.³²

Oral-Facial Herpes

Both primary and recurrent oral-facial HSV-1 infections can be asymptomatic. Gingivostomatitis and pharyngitis are the most common clinical manifestations of a first episode of HSV-1 infection, and recurrent herpes labialis is most commonly caused by reactivated HSV infection. Clinical features include fever, malaise, myalgia, inability to eat, and irritability. Immunocompromised patients with oral-facial herpes have severe pain, extensive lesions, and prolonged viral shedding; thus, they are candidates for antiviral therapy.

Herpes labialis (cold sores) is the most common oral-facial HSV infection. Clinical features include pain or paresthesia and erythematous or papular lesions followed by vesiculation and swelling. These lesions usually crust and heal in the next few days. Viral cultures often are positive within 2 to 3 days. Rapid diagnosis can be made by visualizing viral particles in vesicular fluid with electron microscopy or fluorescent antibody staining of cells from vesicles.

Indications for Antiviral Treatment

9. M.K., a 26-year-old man, developed pain and erythematous skin lesions on his face and around his mouth over a 2-day period after contact with a person with active lesions. Over the next 2 days, significant swelling was noted. M.K. has no previous history of cold sores or any other illnesses. Should he be treated with antiviral drugs?

Most patients with herpes labialis have a self-limiting benign course. Antiviral drugs (e.g., acyclovir, valacyclovir) are indicated only when the patient has a primary infection, an underlying illness, or a compromised immune system that may lead to prolonged illness or dissemination.

Although ice, ether, lysine, silver nitrate, and smallpox vaccine have been used to treat cold sores, no data support their efficacy. Aspirin and acetaminophen are sometimes suggested for symptomatic relief.

10. P.L., a 16-year-old boy diagnosed with acute lymphocytic leukemia 8 months ago, is now admitted for a bone marrow transplant. Admission laboratory tests reveal that he has antibodies against HSV-1 and that 4 months ago, during a course of chemotherapy, he developed an oral-facial herpes infection. What is the significance of these findings for P.L., who is about to undergo a bone marrow transplant?

Immunosuppressed patients have more frequent and severe mucocutaneous HSV infections. Therefore, IV acyclovir should be considered to suppress the reactivation of oral-facial HSV infections.^{33,34} Oral therapy with famciclovir is approved for use in HIV-infected patients,³⁵ but efficacy in other immunocompromised patients is not yet established.

ANTIVIRAL TREATMENT

11. P.L. did not receive antiviral therapy. Two weeks later, he developed oral-mucosal and skin lesions on his face, which were painful and associated with malaise. HSV was identified from the lesion by an immunofluorescence technique. What is the treatment of choice for P.L.?

Acyclovir is administered IV at 5 mg/kg Q 8 hr for 7 days²¹ or until the lesions are healed, followed by oral acyclovir 200 mg TID for about 6 months. In patients with marrow

transplants and culture-proven recurrent mucocutaneous herpes simplex, oral acyclovir (400 mg five times daily for 10 days) is significantly more effective than placebo in reducing pain, virus shedding, new lesion formation, and lesion healing time.³⁶ Studies have shown that oral valacyclovir has similar pharmacokinetic parameters as IV acyclovir and may be used as an alternative to IV therapy.³⁷ However, clinical efficacy of valacyclovir in this population has not been established. The immunocompromised patients in these studies included those receiving corticosteroids, those with leukemia, and recipients of renal allografts.^{36,37}

12. N.B., a 43-year-old woman, experiences eight to ten cold sores a year. These are typically preceded by “colds” or sun exposure. She requests a prescription for acyclovir to “prevent” cold sores when she feels one coming on. What is the role of antiviral medications in the acute treatment and prevention in immunocompetent patients with recurrent herpes labialis?

Topical agents which are approved by the U.S. Food and Drug Administration (FDA) for the treatment of recurrent herpes labialis in immunocompetent patients include acyclovir (Zovirax) 5% cream and ointment, docosanol (Abreva) 10% cream, and penciclovir (Denavir) 1% cream. Clinical trials showed that each agent resulted in decreased healing time and decreased pain associated with herpes lesions, when started at the first sign or symptom of a cold sore.^{38–44} Penciclovir also decreases viral shedding. Some data have indicated that penciclovir cream may be more effective than acyclovir cream and ointment.^{41,42} An advantage of docosanol over the other agents is that it is available without a prescription. The topical agents must be applied within 1 hour of the first sign or symptom of a cold sore and then Q 2 hr for 4 days while awake.

Oral antiviral medications can decrease the duration of pain and healing time in immunocompetent patients. Oral acyclovir 400 mg five times daily for 5 days started within 1 hour of the development of a cold sore was more effective than placebo in reducing mean duration of pain and healing time in immunocompetent patients with a history of one to five episodes of herpes labialis per year.⁴⁵ Valacyclovir, 2 g at the first signs of a cold sore followed by 2 g 12 hours later, and famciclovir 1,500 mg as a single dose showed similar clinical efficacy.^{46,47} No studies have directly compared the efficacy of the different oral antiviral medications.⁴⁸ Frequency of dosing and cost should be considered when choosing a particular agent.^{20,23,49}

Daily suppressive therapy may be recommended in patients with six or more recurrences per year or in patients with severe episodes. In immunocompetent patients with six or more episodes of herpes labialis, oral acyclovir 400 mg twice a day (BID) for 4 months was more effective than placebo in decreasing the number of recurrences in patients with herpes labialis.⁵⁰ Although not approved by the FDA for suppressive therapy, valacyclovir, 500 mg once daily, also appears to be efficacious in decreasing the number of recurrences.⁵¹

N.B. should be treated with either a topical antiviral medication or an oral antiviral for the acute episode of herpes labialis. She should be instructed to start treatment as soon as the first sign or symptom of the cold sore appears. If suppressive therapy is desired, N.B. should be treated with continuous oral acyclovir or valacyclovir.

Resistance

13. How should an acyclovir-resistant HSV infection be treated?

The incidence of acyclovir-resistant herpes is higher in immunocompromised patients compared with immunocompetent patients. Current estimates of HSV resistance in the immunocompromised population are about 5%; some populations, such as bone marrow transplant patients, have a resistance rate approaching 30%.^{52,53} IV foscarnet 40 mg/kg Q 8 hr was found to be more effective and less toxic than IV vidarabine 15 mg/kg/day in patients with AIDS and mucocutaneous herpetic lesions unresponsive to IV acyclovir.⁵⁴ More concerning, however, are the reports of foscarnet-resistant HSV, particularly in the bone marrow transplant population.^{55,56} Cidofovir has been used with moderate success in such cases. In patients with recurrent acyclovir-resistant genital herpes, limited evidence suggests that topical imiquimod 5% cream may be effective.⁵⁷

VARICELLA-ZOSTER INFECTIONS

Chickenpox

Chickenpox used to be a common childhood infection, but the incidence has decreased by up to 84% in states with moderate rates of use of the varicella-zoster virus (VZV) vaccine since 1995.⁵⁸ This vaccine is now considered a routine childhood vaccine by the American Academy of Pediatrics (see Chapter 96). Before the vaccine was available, approximately 3.5 million cases occurred per year in the United States: 60% of cases occurred in children 5 to 9 years of age, and 80% occurred in those younger than 10 years. Although it is a benign disease in most patients, complications and mortality (7/10,000 cases) can occur in patients younger than 5 years and older than 20 years, and in immunocompromised patients.

This is a highly contagious disease. Children are considered infectious from 2 days before the onset of rash until all vesicles have crusted (usually 4–6 days after the onset of rash). After household exposure, more than 90% of susceptible individuals become infected. Thus, the history can assist in making a diagnosis. A smear of cells scraped from the lesions will show multinucleated giant cells. Viruses also can be identified in vesicular lesions by electron microscopy, or antigen can be detected by countercurrent immunoelectrophoresis. Chickenpox is a primary varicella-zoster infection, whereas herpes zoster (shingles) is caused by reactivation of VZV.

Clinical Presentation

14. A.V., a 10-year-old boy, was admitted to the hospital for evaluation and treatment of possible recurrent chickenpox with progressive lesions. According to his mother and his physician, he had a mild case of chickenpox at age 4 years. At admission, A.V. had a 10-day history of progressive vesicular and pustular lesions that began on his neck and spread to his back, trunk, extremities, and face. Although he had been febrile (up to 40.5°C PO) over the past 3 days, his temperature on admission was 37°C. A.V. had episodes of vomiting during the 4 days before admission. On admission, he was alert, cooperative, and well oriented but had overt ataxia with abnormal cerebellar signs. Lesions consistent with VZV infection were extensive and confluent over the face, neck, chest, and back.

Stages of lesions varied from tiny thin-walled vesicles with an erythematous base to umbilicated vesicles. Few crusted lesions were present. Blood analysis revealed a BUN of 9 mg/dL, SrCr of 0.2 mg/dL, and slightly elevated serum transaminase levels (AST 65 IU/L [normal, 0–34] and ALT 122 IU/L [normal, 0–34]). Because of the possibility of cerebellar involvement with VZV infection and possible underlying immunodeficiency, therapy with acyclovir 550 mg IV Q 8 hr (1,500 mg/m²/day) was instituted. Oral diphenhydramine was also prescribed for itching, but A.V. required only two doses on the first hospital day.

New lesions were noted on the second day of acyclovir therapy, but by the third day, no new lesions appeared and previous lesions were healing. The ataxia improved daily. He was discharged on day 7 with no further complaints of nausea and vomiting. Follow-up serologic evaluation demonstrated a fourfold rise in the optical density for the VZV enzyme-linked immunosorbent assay (ELISA) from day 20 to day 60 after the onset of infection. These results suggested primary VZV infection. Why is the use of acyclovir in A.V. appropriate?

[SI units: BUN, 3.213 mmol/L; SrCr, 15.25 μmol/L; AST, 1.084 mkat/L; ALT, 2.034 mkat/L]

Antiviral Treatment

Neonates, adults, immunocompromised hosts, patients with progressive varicella, and those with extracutaneous complications can benefit from acyclovir therapy. In clinical trials, acyclovir has been shown to be effective in preventing dissemination of VZV infection, accelerating cutaneous healing, and decreasing fever and pain.^{59,60} A.V. had a prolonged progressive course of varicella and demonstrated an extracutaneous manifestation of varicella infection (e.g., ataxia with abnormal cerebellar signs). Because of the concern of possible cerebellar involvement, the use of IV acyclovir was appropriate in A.V.

15. C.J., an 8-year-old boy, developed a case of chickenpox and was kept home from school. Four days later, his 15-year-old brother, K.J., began to exhibit similar symptoms. What is the role of acyclovir in immunocompetent patients with chickenpox? Should C.J. or K.J. be treated with acyclovir?

Three studies in children (2–18 years of age) have shown that oral acyclovir 20 mg/kg (when initiated within 24 hours of disease onset) four times a day (QID) for 5 to 10 days was more effective than placebo in accelerating healing and decreasing the formation of new lesions, fever, and itching. However, acyclovir produced only modest benefits (usually healing 1 day sooner than placebo) and was not effective in reducing the complications of varicella.⁶¹ Thus, acyclovir is not indicated for C.J.

Adolescents and adults are more likely to develop complications (e.g., pneumonia, encephalitis) than children. Acyclovir 800 mg PO QID for 5 days in adolescents and 800 mg PO five times daily for 5 days in adults (initiated within 24 hours of disease onset) was more effective than placebo in decreasing the number of lesions, time for healing, fever, and itching. The effect of acyclovir on severe complications could not be assessed.^{62–64} Thus, acyclovir therapy should be considered in those at increased risk of severe chickenpox, for example, those like K.J. who are older than 14 years or those with chronic respiratory or skin disease.⁶⁵ No data are available to show if famciclovir and valacyclovir are as effective as acyclovir.

Supportive Treatment

16. What is the role of supportive treatment in A.V. and C.J.?

Cool baths and application of calamine or other topical antipruritic agents may decrease itching. In severe cases, a systemic antipruritic/antihistamine preparation may be useful because some degree of sedation may be desired. In A.V. and C.J., aspirin should not be used because Reye syndrome has been associated with the use of salicylates in chickenpox or flulike illness (see Chapter 94).

Shingles (Herpes Zoster)

Herpes zoster infections are caused by the reactivation of dormant VZV in the sensory neurons. Reactivation is believed to occur because of waning immunity. The incidence of herpes zoster is higher in immunocompromised patients (e.g., those with HIV or cancer or those receiving immunosuppressive medications), and the incidence of zoster increases with age. It tends to be more severe in the elderly.

Acute herpes zoster infection is characterized by pain, which is described as deep aching or burning. It may be accompanied by excessive sensitivity to touch. Many patients develop a rash that presents initially as erythematous patches and progresses to vesicles that crust in 7 to 10 days. By 1 month, the rash is usually gone, but scarring can occur.

Postherpetic neuralgia (PHN) is pain that continues more than 1 month after the onset of the rash. It is estimated that 10% to 70% of patients experience PHN. PHN is the most common complication of acute herpes zoster, and its prevention is important because PHN pain is difficult to treat.

The goal of pharmacotherapy in acute herpes zoster is to inhibit viral replication to reduce pain and duration of rash. Ultimately, it is hoped that by inhibiting the virus, nerve damage can be prevented, and the incidence and severity of PHN can be decreased. Unfortunately, no therapy can prevent all cases of PHN.

With the approval of the herpes zoster vaccine (Zostavax), it is hoped that the incidence of herpes zoster and the resulting PHN will be reduced (see Chapter 95).

Antiviral Therapy in Immunocompetent Patients

17. E.O. is a 72-year-old, previously healthy man who complains of a burning pain under his left arm for the last 2 days. The pain radiates across his chest. The pain is worse when the area is touched. This morning, he noticed a rash that starts under his arm and continues to his midline. Pertinent laboratory findings include BUN of 15 mg/dL (normal, 8–18) and SrCr of 2.0 mg/dL (normal, 0.6–1.2). He has not received the herpes zoster vaccine. A diagnosis of herpes zoster is made. What therapy should be initiated?

[SI units: BUN, 5.4 mmol/L; SrCr, 177 micromolar/L]

Acyclovir is the standard antiviral agent against which new therapies are compared. In immunocompetent patients, oral acyclovir 800 mg five times daily for 7 to 10 days is moderately beneficial in reducing acute pain during the first 28 days. Acyclovir therapy should be initiated within 72 hours of the onset of the rash. The effects of acyclovir in reducing PHN and chronic pain are unclear. Although a number of trials showed no benefit in reducing PHN, a meta-analysis of five placebo-

controlled trials of acyclovir treatment in herpes zoster found that the number needed to treat was 6.3 to reduce the incidence of PHN at 6 months.⁶⁶

Famciclovir (Famvir) is approved for the treatment of acute herpes zoster infection. Famciclovir is rapidly absorbed and converted to the active drug penciclovir in the intestine. The bioavailability of famciclovir is higher than acyclovir, resulting in higher concentrations of active drug in the infected cells. In addition, the half-life of famciclovir is considerably longer compared with acyclovir, allowing less frequent administration. In a large clinical trial comparing famciclovir with acyclovir, famciclovir 500 mg TID was as effective as acyclovir 800 mg five times a day in reducing the duration of acute pain and healing of the rash.⁶⁷ In another study comparing famciclovir with placebo, famciclovir did not decrease the incidence of PHN but reduced the duration of PHN versus placebo.⁶⁸

A limitation of acyclovir is its poor oral bioavailability (15%–30%). In an attempt to overcome this, valacyclovir (Valtrex), a prodrug of acyclovir, was developed. Valacyclovir is rapidly and extensively absorbed and converted to acyclovir in the body after oral administration. In clinical trials, valacyclovir 1 g TID was equally effective as acyclovir 800 mg five times a day in terms of rash progression and time to rash healing, and valacyclovir was more effective than acyclovir in relieving zoster-associated pain.⁶⁹ In comparison to famciclovir, valacyclovir was comparable in duration of acute zoster-associated pain and PHN.⁷⁰

E.O. should be started on acyclovir, famciclovir, or valacyclovir for the treatment of his herpes zoster. Famciclovir or valacyclovir may be preferred because adherence with a three-times-daily regimen will likely be better than with acyclovir, which must be administered five times a day. Therapy should be initiated as soon as possible because most of the clinical trials began therapy within 72 hours of the rash onset. Although therapy may not prevent PHN, it may have an effect on the duration of pain. Because these agents are renally eliminated, the dosage should be adjusted based on E.O.'s creatinine clearance (Table 72-2).

18. Should E.O. receive a corticosteroid to treat or prevent the pain associated with herpes zoster?

The use of corticosteroids such as prednisone or prednisolone remains controversial.⁷¹ A number of studies have examined the effect of steroids on pain during acute neuralgia and on the development of PHN. Early studies indicated benefit for both acute pain and PHN, but these studies were small and uncontrolled, lacked statistical analysis, and used various corticosteroid regimens. Studies suggest possible relief of the acute pain but no decrease in PHN.^{72–75} Adverse effects of the corticosteroids and the theoretical possibility of dissemination of herpes zoster resulting from their use should be considered when deciding whether to initiate therapy. Based on recent studies demonstrating lack of benefit in preventing PHN, the theoretical concerns of herpes zoster dissemination, and the beneficial effects of antiviral agents such as acyclovir, famciclovir, and valacyclovir for acute pain, corticosteroids should not be used in E.O.

19. Two months after the onset of the rash, E.O. continues to complain of pain. A diagnosis of PHN is made. What FDA-approved treatments for PHN should be prescribed for E.O.?

Although many different agents have been studied, the only FDA-approved treatments for PHN are topical capsaicin, topical lidocaine 5% patches (Lidoderm), and pregabalin (Lyrica). Capsaicin depletes substance P, a mediator that transmits pain from the periphery to the CNS. The largest double-blind, placebo-controlled trial of capsaicin evaluated 143 patients with PHN for at least 6 months. After 6 weeks of treatment with capsaicin 0.075% cream, pain scores were reduced in 21% and 6% of the capsaicin and placebo groups, respectively. Following the double-blind phase of the study, a subset of patients continued to use capsaicin cream for up to 2 years, and most patients experienced prolonged pain relief.⁷⁶ Lidocaine 5% patches have only been compared with placebo and have been shown to relieve pain for 4 to 12 hours following administration. Either capsaicin cream or lidocaine patches can be considered as a first-line options for E.O. Capsaicin should be applied three or four times per day. A common adverse effect is a burning sensation after application, which is intolerable in up to one-third of patients. The burning sensation usually lessens with continued use.

If lidocaine patches are prescribed, E.O. should be instructed to apply up to three patches to the painful area. Patients should be instructed to wear the patches for a maximum of 12 hours a day, and proper disposal of used patches should be emphasized. Because even a used patch contains a large amount of lidocaine, small children or pets could suffer serious consequences from chewing or swallowing a used patch.⁷⁷

Pregabalin, a newer agent approved for the treatment of PHN, appears to be effective but is associated with a greater risk of adverse effects. Pregabalin binds to a subunit of calcium channels, thereby decreasing calcium influx at nerve terminals and reducing the release of several neurotransmitters, including glutamate, norepinephrine, and substance P.⁷⁸ Dizziness and somnolence are common. In clinical trials, dizziness was experienced by 29% of patients treated with pregabalin compared to 9% of placebo-treated patients; somnolence was noted in 22% of patients who received pregabalin compared to 8% of placebo-treated patients. Dizziness and somnolence usually occur soon after the pregabalin is started and appears to be dose dependent.⁷⁸

Other agents that have been used in the treatment of PHN include tricyclic antidepressants (e.g., amitriptyline, desipramine), anticonvulsants (e.g., gabapentin), and opioids.⁷⁹

Antiviral Therapy in Immunocompromised Patients

20. R.F. is a 68-year-old woman seen in the ED with a chief complaint of vesicles on her face associated with severe pain. She has a history of polymyalgia rheumatica and possible temporal arteritis causing headaches that are generally responsive to steroids. She had been having increasing headaches on the right side of her forehead 5 days before admission. Two days before admission, her family physician increased the dosage of prednisone from 30 mg/day to 60 mg/day. Vesicles developed on her face 1 day before admission. She was admitted for pain control and diagnosed with herpes zoster infection. Six hours after admission, R.F. began having visual hallucinations, hearing noises, and talking to herself. A lumbar puncture was performed with the following results: three WBCs (two lymphocytes and one monocyte); three RBCs; protein, 84 mg/dL; and glucose, 86 mg/dL. VZV was isolated from the CSF. IV acyclovir was started at a dosage of

10 mg/kg Q 8 hr. Why is antiviral therapy indicated in R.F.? Should her prednisone be continued or discontinued?

Antiviral therapy is indicated for R.F. Acyclovir may halt the progression of acute herpes zoster infection in immunocompromised hosts such as R.F., who has been taking large doses of corticosteroids.⁸⁰

In clinical trials, IV acyclovir 10 mg/kg Q 8 hr has been shown to be effective in severely immunocompromised patients. Alternatively, in less severely immunocompromised patients, oral therapy with acyclovir 800 mg five times a day, valacyclovir 1,000 mg TID, or famciclovir 500 mg TID, along with close monitoring, can be used.⁸¹ In patients with cutaneous dissemination of disease, there was a more rapid clearance of the herpes zoster virus from vesicles. Pain relief occurred faster in patients who received acyclovir, and fewer acyclovir-treated patients reported PHN, but the differences were not statistically significant.⁸⁰ There are no data available regarding the use of famciclovir or valacyclovir in severe herpes zoster infection in an immunocompromised host.

Systemic corticosteroids are of unproven usefulness and may slow the healing of lesions. Therefore, if possible, R.F.'s prednisone should be slowly tapered.

ACYCLOVIR TOXICITY

21. On the fourth day of acyclovir therapy, R.F. developed severe nausea and vomited three times. The laboratory data showed a BUN of 45 mg/dL and SrCr of 3.2 mg/dL (baseline BUN, 10 mg/dL and SrCr, 1.0 mg/dL). Why must R.F.'s acyclovir dosage be altered?

[SI units: BUN, 16.07 and 3.57 mmol/L, respectively; SrCr, 282.88 and 88.40 micromolar/L, respectively]

Nausea and vomiting have been reported with acyclovir therapy in patients with herpes zoster infections.²¹ Similarly, elevations of SrCr and BUN can occur in association with acyclovir therapy. This may be secondary to acyclovir crystallization in the renal tubules, particularly when fluid intake is inadequate (Table 72-4). Because R.F.'s creatinine clearance is between 10 and 25 mL/minute per 1.73 m², the acyclovir dosage interval should be extended to 24 hours. Every effort should be made to maintain adequate hydration for the duration of acyclovir therapy. (See Table 72-2 and Chapter 2 for creatinine clearance calculation.)

INFLUENZA

Influenza is an acute infection caused by the virus of the *Orthomyxoviridae* family. Epidemics of influenza are usually caused by the type A virus; type B virus is generally associated with sporadic infection. Infection is transmitted by the inhalation of virus-containing droplets ejected from the respiratory tract of a person with influenza. It can be spread by direct contact, large droplets, or articles recently contaminated by nasopharyngeal secretions. The incubation period is typically 2 days (range, 1–4 days).

Influenza A viruses are classified into subtypes of hemagglutinin (H) and neuraminidase (N) surface antigens. Three subtypes of hemagglutinin (H₁, H₂, H₃) and two subtypes of neuraminidase (N₁, N₂) have caused influenza in humans. Infection with a virus of one subtype may confer little or no

Table 72-5 Persons Who Should Receive the Influenza Vaccine⁸²

- All healthy children ages 6–59 mo
- All persons 50 years or older
- Nursing home or chronic care facility residents
- Children and adults with chronic pulmonary or cardiovascular disease
- Children and adults who have required medical follow-up because of chronic metabolic diseases (e.g., diabetes mellitus), renal dysfunction, hemoglobinopathies, or immunosuppression (due to medications or diseases such as HIV)
- Children and adults who are at risk for aspiration (e.g., cognitive dysfunction, spinal cord injuries, seizures)
- Children (6 mo–18 yr) receiving long-term aspirin therapy
- Women who will be pregnant during influenza season
- Health care workers
- Household members of person in high-risk groups (including contacts of infants and children 0–59 mo)

protection against viruses of other subtypes. In addition, significant antigenic variation (antigenic drift) within a subtype may occur over time. Thus, infection or vaccination with one strain may not protect against a distantly related strain of the same subtype. This is why major epidemics of influenza continue to occur and influenza vaccines are reformulated each year with likely viral strains to maximize immunity.

Persons at highest risk for influenza infection (Table 72-5) should receive the influenza vaccine each year. Each year's vaccine contains three virus strains (generally two type A and one type B) that are likely to circulate in the community for the upcoming season. The efficacy depends on the similarity of the components of the vaccine to the circulating viruses that year and the immunocompetence of the host. If there is a good match with the circulating viruses, the vaccine can prevent illness in approximately 70% to 90% of healthy adults and children. It appears to be effective in preventing hospitalization and pneumonia in 70% of elderly persons living in the community and in 50% to 60% of elderly persons residing in nursing homes. However, the efficacy of the vaccine in preventing illness is often only 30% to 40% among the frail elderly. Despite the lower efficacy, the illness is less severe, and the risk of complications is reduced in vaccinated individuals.

Individuals who can transmit influenza to persons at high risk include physicians, nurses, and other personnel in both hospital and ambulatory settings; employees of nursing homes and chronic care facilities; providers of home care services; and household members, including children.

Persons at high risk and those who may transmit the virus to those at high risk should be vaccinated annually. Table 72-6 describes the types of vaccines, dosage, number of doses, and route of administration. The optimal time for vaccine administration is between mid-October and mid-November because influenza activity peaks between late December and early March in the United States. Vaccinating an individual too early in the season could result in waning antibody concentrations before the influenza season is over. However, influenza vaccine should be offered throughout the influenza season, even if outbreaks of influenza have already been documented in the community.⁸²

Table 72-6 Influenza Vaccines⁸²

| Age | Dosage | Number of Doses |
|----------|---|---------------------|
| 6–35 mo | 0.25 mL IM ^a inactivated vaccine | 1 or 2 ^c |
| 36–59 mo | 0.5 mL IM ^a inactivated vaccine | 1 or 2 ^c |
| 5–49 yr | 0.5 mL IM ^a inactivated vaccine or 0.5 mL IN ^b live vaccine | 1 or 2 ^c |
| ≥50 yr | 0.5 mL IM ^a inactivated vaccine | 1 |

^aThe recommended site is the deltoid muscle for adults and older children and the anterolateral aspect of the thigh in infants and young children.

^bThe live vaccine should not be used in patients with chronic pulmonary or cardiovascular disease and in those with underlying immunodeficiencies.

^cTwo doses given at least 1 mo apart for children younger than 9 years who are receiving the vaccine for the first time.

IM, intramuscularly; IN, intranasally.

Because the parenteral influenza vaccine is an inactivated vaccine and contains no infectious viruses, it cannot cause influenza. The most common adverse effect is soreness at the administration site lasting for up to 2 days.⁸³ Fever, malaise, myalgia, and other systemic reactions occur infrequently; these may develop within 6 to 12 hours after the vaccine is given and persist for 1 to 3 days.^{83,84} Immediate hypersensitivity to egg protein (hives, angioedema, allergic asthma, or systemic anaphylaxis) rarely occurs. Persons with anaphylactic hypersensitivity and those with acute febrile illness should not be given the vaccine. However, minor illnesses with or without fever are not contraindications for the influenza vaccine, particularly in children with a mild upper respiratory tract infection or allergic rhinitis. When the vaccine is contraindicated, a neuraminidase inhibitor (oseltamivir or zanamivir) should be used for prophylaxis.⁸² Amantadine and rimantadine are no longer recommended for prophylaxis of influenza because of widespread resistance in the United States.

Clinically, it is impossible to differentiate between influenza A and B. Definitive diagnosis can be made by isolating the virus from throat washings or sputum and by a significant increase in antibody titers during the convalescent period.

Clinical Presentation

22. K.B., a 40-year-old woman, comes into the pharmacy and says she has “the flu.” She recently started a new job and is afraid she will lose her job if she misses too many days from work. What questions would you ask her to differentiate the common cold from an influenza infection?

It can be difficult to differentiate the common cold from an influenza infection. Influenza infections typically occur from December through March in the United States. Patients with influenza generally experience more systemic symptoms, such as fever higher than 102°F, headache, myalgia, and cough. Rhinorrhea, nasal congestion, and sneezing are more pronounced in patients with the common cold. Sore throat can occur with both a cold and the flu. Bacterial sore throat (e.g., strep throat) is differentiated from a viral sore throat in that a viral sore throat usually has a slower onset and the throat pain is less severe. Lymph nodes are only slightly enlarged and not tender in a viral sore throat, whereas with a bacterial sore throat, lymph nodes are large and tender.⁸⁵

K.B. should be questioned about her symptoms and exposure to ill contacts, and investigation into whether influenza has been documented in the community should be performed to help differentiate an influenza infection from the common cold.

Treatment

23. K.B. describes symptoms consistent with an influenza infection for the past 24 hours. What treatment options exist for the treatment of influenza? Why is she a candidate for a neuraminidase inhibitor agent such as zanamivir or oseltamivir?

Two agents known as the neuraminidase inhibitors for the treatment of influenza A and B in adults were approved in 1999. Zanamivir (Relenza) and oseltamivir (Tamiflu) work by selectively inhibiting the enzyme neuraminidase, an enzyme necessary for viral replication and spread. Oseltamivir is currently indicated for the prevention and treatment of influenza in patients 1 year of age and older; zanamivir is indicated for the prevention of influenza in patients 7 years of age and older and for the treatment of influenza in patients 5 years of age and older.^{86,87}

Zanamivir is available as an oral powder for inhalation. For the treatment of influenza infection in adults, 10 mg (two inhalations) BID for 5 days should be used. Patients should inhale two doses separated by at least 2 hours on the first day and then two doses separated by 12 hours on days 2 through 5.⁸⁶ Bronchospasm after use can occur, and if bronchodilators are also prescribed, the bronchodilator should be used before zanamivir.⁸⁶ Proper use of the delivery system (Rotadisk Diskhaler) is important, and thus patients should be instructed on proper use, with a demonstration of delivery technique, by the pharmacist.

Oseltamivir is pharmacologically related to zanamivir but has significantly better oral bioavailability, allowing oral dosing. The dosage of oseltamivir for the treatment of influenza in adults is 75 mg BID for 5 days.⁸⁷ As with zanamivir, treatment with oseltamivir must be started within 2 days of the onset of symptoms. Common side effects include nausea, vomiting, and headache.⁸⁷ In addition, there are reports, predominantly in children, of self-injury and delirium, following the administration of oseltamivir.⁸⁸

Amantadine is approved for patients 1 year of age or older. Rimantadine is only approved for the prevention of influenza A in children.^{89,90} However, the incidence of resistance to amantadine and rimantadine has increased dramatically in recent years. In one study, 92% of strains of influenza A demonstrated resistance to influenza A. Consequently, these agents are no longer recommended for the routine prevention or treatment of influenza infections.⁸²

When administered within 2 days of onset of illness, zanamivir and oseltamivir reduce influenza symptoms by approximately 1 day.^{91–93} Information regarding the effectiveness of the neuraminidase inhibitors in preventing serious complications of influenza, such as pneumonia or worsening of chronic diseases, is limited.⁸² Advantages of the neuraminidase inhibitors over amantadine and rimantadine include the efficacy against influenza B or resistant influenza A. Because the causative agent is unknown and symptoms have been present for more than 2 days, K.B. may benefit from a neuraminidase

inhibitor. Oral oseltamivir is easier to administer than inhaled zanamivir. Although oseltamivir will not cure influenza, it may reduce the severity and duration of symptoms by about 1 day. Because K.B. is concerned about missing too much time from work, she should be treated with a 5-day course of oseltamivir.

24. J.T., a 74-year-old man, is brought to the ED from a nursing home with chief complaints of fever (103°F), shaking chills, cough, headache, malaise, anorexia, and photophobia. He has been ill for the past 48 hours but suddenly became worse this evening. On physical examination, he appeared flushed, his skin was hot and moist, and he was working hard to breathe. Vital signs were blood pressure, 150/90 mmHg; pulse, 108 beats/minute; respiratory rate, 22 breaths/minute; and temperature, 103°F. Rales were audible on auscultation of both lungs. A chest roentgenogram showed bilateral infiltrates but no consolidation. Blood gas studies showed significant hypoxia, with a PaO₂ of 50 mmHg and a PaCO₂ of 50 mmHg. J.T.'s medical history was significant for chronic bronchitis and a stroke 16 months ago. Blood, sputum, and urine cultures were obtained, and J.T. was started on antibiotics (gentamicin 140-mg loading dose, then 90 mg Q 12 hr IV piggyback and clindamycin 900 mg Q 8 hr IV piggyback). Gram stain of the sputum sample showed many WBCs but no bacteria. He was started on oxygen therapy at 4 L/minute via nasal cannula. Twenty-four hours later, his respiratory symptoms worsened, and his arterial blood gases deteriorated slightly (PaO₂, 40 mmHg; PaCO₂, 55 mmHg). J.T. was intubated, and a sputum sample was obtained and sent to the virology lab. Three days later, influenza A virus was isolated from the sputum. Blood, urine, and sputum cultures were all negative for bacterial pathogens. Why is this presentation consistent with influenza infection? Is antiviral treatment indicated in J.T.?

[SI units: PaO₂, 6.665 and 5.332 kPa, respectively; PaCO₂, 6.665 and 7.332 kPa, respectively]

Although symptoms of influenza may vary depending on age, most patients with influenza A have an abrupt onset of fever, chills, cough, and headache. In elderly patients such as J.T. and those with underlying diseases, the course of influenza can worsen quickly, and patients are more likely to require hospitalization.

Antiviral therapy in J.T. is inappropriate. None of the antiviral agents has been studied in patients presenting with symptoms after 48 hours of onset. In addition, the antiviral agents have shown efficacy only in uncomplicated influenza.⁸²

Prevention

25. Over the next 3 weeks, two other nursing home patients develop influenza A infections. What measures should be taken to prevent a further outbreak of influenza among other residents?

Influenza Vaccines

The nursing home residents and staff should receive influenza vaccine plus chemoprophylaxis with oseltamivir, or zanamivir. The Centers for Disease Control and Prevention (CDC) recommends immunization of all high-risk groups⁸² (Table 72-5). The top-priority groups include all individuals who are at high risk for influenza-related complications and their household contacts. Second in priority are otherwise healthy adults 50 years of age or older and children with chronic metabolic

diseases severe enough to warrant regular follow-up during the preceding year. Any child younger than 9 years in which the vaccine is indicated requires two doses of the vaccine for optimal effectiveness. The first dose should be administered in September, and the second dose is given before influenza infection is present in the community. However, the efficacy of influenza vaccine is incomplete (70%).⁹⁴ Therefore, the CDC recommends the use of oseltamivir or zanamivir in high-risk individuals who may not develop an adequate antibody response (e.g., patients with advanced HIV infection) to supplement the protection by vaccine.⁸²

A live, attenuated influenza vaccine (FluMist) is an option for healthy, nonpregnant individuals between the ages of 2 and 49 years. In clinical studies with matched influenza strains, live, attenuated influenza vaccine was approximately 87% effective in preventing influenza in children and provided 85% efficacy in adults.⁹⁵ Advantages of the intranasal route of administration include ease of administration and patient acceptability of an intranasal preparation compared to an intramuscular (IM) injection. However, because the vaccine is live, viral shedding can occur for 2 or more days after vaccination. Consequently, patients who are immunosuppressed and close contacts of patients who are severely immunocompromised (including health care workers who care for them) should not receive the live vaccine. Others who should not receive the live vaccine include patients with asthma or other chronic disorders of the pulmonary or cardiovascular systems, those with chronic metabolic diseases such as diabetes, renal dysfunction, hemoglobinopathies, and children or adolescents who are receiving aspirin or other salicylates.⁸²

Oseltamivir and Zanamivir

Analysis of clinical trials of oseltamivir in the prevention of influenza showed a decreased incidence of laboratory-confirmed influenza: 4.8% in the placebo group and 1.2% in the treatment group.⁹⁶ The incidence of influenza in a skilled nursing facility was 4.4% in the placebo group and 0.4% in the oseltamivir group. In addition, oseltamivir lowered the rate of infection in patients exposed to influenza at home from 12% to 1%. Zanamivir also showed decreases in subsequent cases among individuals exposed to influenza in the home setting, although zanamivir is currently not indicated for prophylaxis of influenza.^{97,98}

Comparative studies between neuraminidase inhibitors have not been published. Because oseltamivir is available in an oral formulation, it may be easier to administer in nursing home patients compared with zanamivir, which requires proper use of the delivery device and a coordinated inspiratory effort.

AVIAN FLU

Avian flu is an illness caused by an influenza virus that is commonly found in wild poultry. Although many wild birds carry the avian influenza viruses in their intestines, this virus does not commonly cause illness in wild birds. However, the virus is quite contagious and can be deadly in domesticated birds, such as chickens, ducks, and turkeys.

There are two types of avian influenza: the North American H5N1 strain and the Asian H5N1 strain. The low pathogenic or North American strain is common in wild birds and rarely causes symptoms of disease. This strain does not cause disease

in humans. Conversely, the high pathogenic or Asian strain spreads rapidly to domesticated poultry and often results in death. This strain is endemic in Asia and has spread to Europe. This strain can infect humans, especially after direct contact with infected birds. There are only rare reports of human-to-human transmission, with none occurring in the United States.

To date, the two H5N1 avian flu strains have not caused widespread disease in humans. For an avian flu pandemic to occur, the virus must be easily spread from human to human. Currently, the transmissibility among humans is poor.

Clinical Presentation

26. D.D. presents to the urgent care complaining of fever, difficulty breathing, cough, and blood in his sputum. Of note, he works for the poultry industry, and recently, a large number of chickens have died. On physical exam, he is febrile (101.5°F), tachypneic (55 breaths/minute), and has crackles on chest exam. He has a slightly elevated WBC with leukocytosis. Blood, sputum, and respiratory secretions were sent for culture. The PCR for influenza A returns as positive. What signs and symptoms in D.D.'s history support a diagnosis of avian flu?

The signs and symptoms of infection with avian flu vary widely. Persons infected with the virus can demonstrate signs and symptoms typically seen with human influenza infections, such as fever, cough, sore throat, and muscle aches. Alternatively, infected individuals may have a more fulminant course with pneumonia, severe respiratory distress, and other life-threatening complications. If an avian flu pandemic occurred, those most likely to be seriously affected would be infants, the elderly, and those with chronic medical conditions.⁹⁹ Specimens from patients should be sent to the CDC for additional testing if the patient has had a history of contact with poultry or domestic birds and tests positive for influenza A by either PCR or antigen detection testing.¹⁰⁰

Treatment

27. How should D.D. be treated?

For cases of human infection with H5N1, the neuraminidase inhibitors oseltamivir and zanamivir may improve clinical outcome if administered early. Oseltamivir has been used more than zanamivir, but clinical studies are limited. It is believed that the H5N1 virus is susceptible to the neuraminidase inhibitors. Although traditional antibacterial agents are not effective for the H5N1 virus, antibiotics may have a role in secondary bacterial infection such as pneumonia, which often occurs following influenza infections.

In April 2007, the FDA approved the first influenza H5N1 virus vaccine or avian influenza vaccine. The inactivated vaccine is indicated for the immunization of individuals between the ages of 18 and 64 years who are at increased risk of exposure to avian influenza. The vaccine is given as a two-dose series, with the doses separated by 21 to 35 days. In clinical trials, the vaccine has been found to reduce the risk of avian influenza in about 45% of the recipients. In the remaining 55% of recipients, although the antibody concentrations were below the protective threshold concentration, the vaccine may potentially

reduce disease severity, influenza-related hospitalizations, and deaths.¹⁰¹

RESPIRATORY SYNCYTIAL VIRUS INFECTIONS

Respiratory syncytial virus (RSV) is an important pathogen causing bronchiolitis and bronchopneumonia. RSV infection commonly affects infants younger than 2 years, with more than one-half of the infants becoming infected in the first 2 years of life. Of these infants, approximately 1% to 2% will require hospitalization.¹⁰² Children with underlying congenital heart disease or lung disease may be at increased risk of mortality due to RSV.¹⁰³ Patients with RSV infection before 3 years of age appear to be at an increased risk of wheezing and asthma during childhood.^{104–106}

RSV infections usually occur in the winter. The chest radiograph and blood gases are often abnormal, and the virus can be isolated in the nasopharyngeal secretions.

Clinical Presentation and Ribavirin Therapy

28. J.R., a 6-month-old infant who is lethargic, tachypneic, and cyanotic, is brought to the ED. J.R.'s medical history is significant for congenital HIV. He has a fever (102°F), his breathing is labored, and wheezing is audible on expiration. The chest roentgenograms show a flattened diaphragm and hyperinflated lung parenchyma. Because of hypoxemia and hypercarbia, J.R. is placed on ambient oxygen to maintain the alveolar oxygen pressure at >60 mmHg. RSV is present in the respiratory secretions. What type of therapy is indicated for J.R., who has an underlying immunodeficiency?

The goal of therapy is to decrease airway resistance in a patient such as like J.R.¹⁰⁷ Treatment of RSV is highly individualized, depending on the presenting signs and symptoms. Oxygen is first-line therapy. Decreases in airway resistance may be achieved with the use of bronchodilators or corticosteroids. However, bronchodilators have led to minimal clinical improvement in only approximately 25% of infants with RSV.¹⁰⁸ The use of corticosteroids in the treatment of RSV is not recommended.¹⁰⁹ Although individual studies differ on the clinical benefits of oral corticosteroids, two meta-analyses found no benefits in decreasing length of stay or disease severity.^{110,111}

The use of ribavirin (Virazole), an antiviral agent that possesses unique inhibitory activity against a large number of both DNA and RNA viruses, for the treatment of RSV remains controversial. Early studies with ribavirin showed significant clinical improvement compared to placebo in both healthy children and those with underlying disease.¹¹² These studies reported clinical recovery and improvement in arterial oxygenation. Subsequent studies found ribavirin to be ineffective in patients with a variety of risk factors.^{113,114} Consequently, the routine use in previously healthy infants and children has not been clearly established. Whether ribavirin decreases the long-term sequelae and severity of illness in high-risk groups (including premature infants, patients with bronchopulmonary dysplasia, congenital heart disease, cystic fibrosis, and immunodeficiency) has not been determined.¹¹⁵ Current recommendations include consideration for use of ribavirin in infants with severe disease or those at risk for severe disease such as infants

who may be immunocompromised and/or have hemodynamically significant cardiopulmonary disease.¹⁰⁹ Because J.R. has an underlying immunodeficiency, ribavirin may be considered if J.R.'s condition worsens.

RSV immune globulin (RSV-IGIV, RespiGam) is an IV product made from the blood of donors with high titers of RSV-neutralizing antibodies. The use of RSV-IGIV has been evaluated in children at high risk for severe infections and in previously healthy children. Although administration of RSV-IGIV was safe, studies have shown no efficacy with the use of immune globulins in the treatment of RSV.¹¹⁶ Thus, this is not recommended for use in the treatment of RSV.

Administration of Ribavirin

29. How is ribavirin administered, and what precautions should be taken during drug administration in J.R.?

Ribavirin is administered as an aerosol through a collision generator that generates particles small enough (1–2 micron wide) to reach the lower respiratory tract. This ensures that high concentrations of ribavirin penetrate the respiratory secretions at the site of viral replication while minimizing systemic absorption. The concentration of the ribavirin solution in the reservoir is 20 mg/mL (6 g in 300 mL of sterile water). The dose is administered over 12 to 18 hours, although in non-ventilated patients, 2 g over 2 hours TID (using a 60-mg/mL solution) has been successfully used.¹¹⁴ Ribavirin therapy is continued for 3 to 7 days.¹¹⁷

Ribavirin is approved for use in patients requiring mechanical ventilation. However, ribavirin is hygroscopic, and aerosol particles can deposit in the tubing and around the expiratory valve of a ventilator. The precipitated drug can obstruct the expiratory valve and alter the peak end-expiratory pressure.¹¹⁷ Ribavirin has been safely used in such patients,^{118,119} but close monitoring of respiratory therapy is advised to prevent this problem. In addition to the inspection of tubing, modifications of standard ventilatory circuits have been suggested.¹¹⁷

Adverse Effects

30. What are the important adverse effects of ribavirin?

The most common adverse effects of ribavirin are rash, initial mild bronchospasm on drug initiation, and reversible skin irritation.¹²⁰ Although long-term follow-up data are limited, a study evaluating the effects of ribavirin in patients 1 year after administration showed a reduction in the incidence and severity of reactive airway disease, as well as in hospitalizations related to respiratory illness. Further long-term evaluation is still necessary.¹²¹

Ribavirin is contraindicated in women who are or may become pregnant during exposure to the drug. Although there are no human data, ribavirin has been found to be teratogenic and/or embryolethal in nearly all animal species in which it has been tested. Teratogenesis was evident after a single oral dose of 2.5 mg/kg in hamsters and after daily oral doses of 10 mg/kg in rats. Malformation of the skull, palate, eye, jaw, skeleton, and GI tract were noted in animals. Ribavirin has reduced the survival of fetuses and offspring of animals tested. It is lethal to rabbit embryo in daily oral doses as small as 1 mg/kg. There are no studies that address teratogenicity in humans, but hospital

personnel who are pregnant or may become pregnant should avoid exposure to this drug.¹¹⁷

It is important to consider the environmental effects of ribavirin on the personnel involved with its administration. One study found no detectable plasma or urine concentrations of ribavirin in 19 nurses, whereas another reported its presence in the RBCs of a nurse caring for a patient who received ribavirin via oxygen tent.¹²² The ribavirin concentration in the air was highest when it was administered via oxygen tent, followed by mist mask, and was lowest after administration via endotracheal tubes of mechanically ventilated patients. This has led to several recommendations: (a) ribavirin aerosol should be administered solely via endotracheal tube of mechanically ventilated patients in a closed filtered system¹⁰²; (b) children receiving ribavirin should be placed in a containment chamber equipped with a high-efficiency particulate air filter exhaust in an isolation room with negative air pressure¹¹⁷; (c) disposable full-body coverings and either a powered air-purifying respirator or disposable particulate respirator should be made available to all health care personnel¹¹⁷; and (d) men and women planning to have children should not care for patients receiving ribavirin via oxygen tents.¹²² ICN Pharmaceuticals markets an aerosol delivery system for oxygen and ribavirin that decreases the liberation of ribavirin into the environment.¹¹⁷

Prevention

31. S.N. is a 7-month-old boy born prematurely at 31 weeks' gestation. He has bronchopulmonary dysplasia (BPD) and uses oxygen at home. RSV season will begin next month. What treatments to prevent RSV infection are available? Why is S.N. a candidate for such treatment?

Two products are available for the prevention of RSV infections. RSV-IGIV may be used to prevent or decrease the severity of lower respiratory tract infections caused by RSV in children younger than 24 months with BPD or a history of premature birth before 35 weeks' gestation. Infants who were born prematurely and who have underlying pulmonary disease (e.g., BPD), cardiovascular disease, or immunodeficiency states are at higher risk for death because of RSV than other infants.

In a large study of infants with BPD and/or prematurity, monthly infusions of RSV-IGIV during RSV season (starting in mid-November and continuing for three to five monthly doses) decreased the number of RSV lower respiratory tract infections, hospital admissions, duration of hospitalizations, and days in the intensive care unit.¹²³ Other studies have demonstrated similar results.¹²⁴

Palivizumab (Synagis), a humanized monoclonal antibody made from recombinant DNA, is active against RSV and is indicated for children at high risk of RSV respiratory tract infections (e.g., infants with BPD or a history of premature birth prior to 35 weeks' gestation). The efficacy of palivizumab was demonstrated in a randomized, double-blind, placebo-controlled trial involving 1,502 children who had a history of prematurity or BPD.¹²⁵ Children received monthly IM injections of placebo or palivizumab for 5 months during RSV season. Palivizumab-treated children had a reduction in RSV hospitalizations and intensive care admissions, and had shorter hospitalizations for RSV disease. Palivizumab is preferred over

RSV-IGIV for most high-risk infants because it is easier to administer (IM vs. IV), does not interfere with the response of live vaccines such as measles-mumps-rubella or varicella vaccine, and is not likely to transmit blood-borne diseases because it is a synthetic product rather than one derived from human blood.¹²⁶

Based on S.N.'s age and his underlying immunodeficiency, he is a candidate for palivizumab therapy.¹⁰⁹

Palivizumab Dosage and Administration

32. How are the doses of RSV-IGIV and palivizumab calculated, and how should they be given?

RSV-IGIV 750 mg/kg is given as an IV infusion. The dose of palivizumab is 15 mg/kg given IM. For both products, the first dose is given before the start of the RSV season, and then monthly doses are given throughout the RSV season. In the Northern Hemisphere, the RSV season is typically November through April.

Because adverse reactions to RSV-IGIV may be related to the infusion rate, infusion titration is important. During the initial 15 minutes, RSV-IGIV should be infused at 1.5 mL/kg/hour (using a 50-mg/mL solution). The infusion rate can then be increased to 3 mL/kg/hour for the next 15 minutes, and, if tolerated, the rate can be increased to a maximum of 6 mL/kg/hours.

HANTAVIRUS INFECTIONS

Rodents are the primary reservoir hosts of Hantavirus, and in the United States, the deer mouse (*Peromyscus maniculatus*) is the main reservoir. These viruses apparently do not cause illness in the reservoir hosts, but infection in humans occurs when infected saliva, urine, and feces are inhaled as aerosols produced by the rodent. Most patients recall exposure to rodents or rodent feces within 6 weeks of the onset of illness.¹²⁷ Person-to-person transmission has not been documented.

Four serotypes of Hantavirus have been identified. The case definition used by the CDC includes clinical evidence of (a) febrile illness characterized by unexplained adult respiratory distress syndrome (ARDS) or acute bilateral pulmonary interstitial infiltrates; or (b) an autopsy finding of noncardiogenic pulmonary edema resulting from an unexplained respiratory illness. In addition, laboratory evidence consists of (a) a positive serology (i.e., presence of Hantavirus-specific immunoglobulin M or rising titers of immunoglobulin G), or (b) positive immunohistochemistry for Hantavirus antigen in a tissue specimen, or (c) positive PCR for Hantavirus RNA in a tissue specimen.¹²⁸

Hantavirus infection can cause three different clinical diseases: hemorrhagic fever with renal syndrome, nephropathia epidemica, and Hantavirus pulmonary syndrome (HPS). Hemorrhagic fever with renal syndrome and nephropathia epidemica occur in Asian and European continents. HPS occurs only in the Western Hemisphere, including North America.¹²⁹ As of March 2007, there have been 465 cases of HPS in the United States, with 35% of the cases resulting in death.¹³⁰ Most have occurred in the southwestern United States during spring and summer.

Clinical Presentation

33. K.C., a previously healthy 55-year-old woman, presented with an abrupt onset of fever, cough, myalgia, and shortness of breath. K.C. lives in western Texas and has not traveled out of state during the past 6 months. Diagnostic evaluation, including a complete blood count with differential and blood and sputum cultures, was negative. On day 3, K.C. remained febrile and had vomiting, hypotension, hypoxemia, and bilateral diffuse infiltrates on the chest radiograph.

Abnormal laboratory findings included a leukocyte count of $22,000/\text{mm}^3$ with a shift to the left, platelets $70,000/\text{mm}^3$, and albumin concentration of 2 g/dL. K.C. suddenly developed ARDS. The Hantavirus immunoglobulin M ELISA titer performed from K.C.'s serum specimen at the CDC was elevated. What signs and symptoms are consistent with Hantavirus infection?

The clinical features of patients with HPS include fever, myalgia, headache, and cough. Abdominal pain, nausea, and/or vomiting may also be present. The physical examination has been unreliable. Laboratory abnormalities may include leukocytosis, thrombocytopenia, and hypoalbuminemia. The chest radiograph may initially be normal but can progress rapidly to bilateral infiltrates and ARDS. Other viral pneumonias do not typically progress to ARDS as rapidly as Hantavirus infections. Because of the nonspecific signs and symptoms, some patients may be misdiagnosed as having influenza.

Treatment

34. How should K.C. be treated?

Supportive treatment is important. Oxygen therapy and mechanical ventilation may be necessary. Hypotension can be treated with vasopressor agents and judicious use of IV crystalloids to prevent worsening of pulmonary edema. Universal precautions and respiratory isolation should be instituted.¹²⁹

There is no FDA-approved drug to treat Hantavirus infections. Based on one study in 242 patients, IV ribavirin was more effective than placebo in reducing the mortality and the morbidity (oliguria and hemorrhage) in patients in China. IV ribavirin was given as a loading dose of 33 mg/kg, followed by 16 mg/kg Q 6 hr for 4 days and 8 mg/kg Q 8 hr for the next 3 days. Each dose was infused over 30 minutes. Reversible anemia was the main adverse effect of ribavirin.¹³¹

Two other clinical trials, however, did not show similar clinical efficacy in the treatment of HPS. One open-label trial conducted by the CDC showed a mortality rate of 47% in patients who received ribavirin compared with 50% to those who did not. Therefore, the trial was inconclusive.¹³² In addition, a double-blind, placebo-controlled trial conducted at the National Institutes of Health enrolled 36 patients randomized to either IV ribavirin or placebo.¹³³ Although the trial was discontinued early and lacked the power to detect statistical differences, ribavirin did not demonstrate trends toward improved clinical outcomes. At this time, the use of ribavirin is controversial and is not recommended.

K.C. should receive supportive treatment, including vasopressors, fluids, oxygen, and mechanical ventilation, if necessary.

WEST NILE VIRUS

West Nile virus (WNV) was first identified in the United States in 1999 in New York City. Since then, the virus has had rapid geographic expansion and has infected individuals in most states in the continental United States.¹³⁴ Although WNV normally occurs in tropical climates, the increase in international travel and changes in weather patterns have led to its spread.

WNV is a member of the Flaviviridae family. Culicine mosquitoes (including *Culex pipiens*, *Culex restuans*, and *Culex quinquefasciatus*) are the vectors, and they infect both birds and humans. Infection with the virus involves direct inoculation by the infecting mosquito. WNV can infect a number of vertebrates, including horses. Transmission requires a mosquito bite, and transmission from person to person or bird to bird is not known to occur. Birds are reservoir hosts. Because of the seasonal variations in the life cycle of the mosquito, cases are most commonly seen during the summer and early fall.

Diagnosis is usually made by high clinical suspicion and laboratory tests. WNV can cause a wide range of illness, from an asymptomatic disease to West Nile fever to encephalitis. Mortality is low except in those with encephalitis. Mortality rates in the elderly, particularly those older than 70 years, can be nine times higher than in the general population.¹³⁵ The CDC classification of WNV encephalitis consists of (a) febrile illness with neurologic symptoms plus isolation of the WNV antigen or genomic sequence from a tissue, blood, CSF, or other body fluids; (b) WNV IgM antibody in a CSF sample; (c) a fourfold rise in the antibody titer to WNV; and (d) demonstration of an IgM or rising titers of IgG to WNV in a single serum sample.¹³⁶

Clinical Presentation

35. A.G. is an 84-year-old woman. She is very active and runs the yearly flower festival in the community. She was brought to the ED by her granddaughter, who found her at home, confused and complaining of a headache, fatigue, and increasing muscle weakness. She is found to have a temperature of 103°F. Her Mini-Mental Status Exam score was 21 of 30. She has decreasing muscle strength and an erythematous, macular, papular rash on her arms and legs. The complete blood count and electrolytes were normal, with the exception of slightly decreased sodium. The CSF had increased WBCs, increased protein and normal glucose, and positive IgM antibody to WNV. A CT scan showed no abnormalities. What signs and symptoms are indicative of WNV encephalitis?

Acute signs and symptoms of WNV include sudden onset of fever, anorexia, weakness, nausea, vomiting, eye pain, headache, altered mental status, and stiff neck. A rash may be present on the arms, legs, neck, and trunk. The rash is typically erythematous, macular, and papular with or without morbilliform eruption. Laboratory parameters may show normal or elevated WBC counts. Low serum sodium concentrations may be seen in patients with encephalitis. CSF usually shows pleocytosis, mostly with an elevation of lymphocytes, elevated protein levels, and normal glucose levels. Magnetic resonance imaging (MRI) shows some enhancement of the leptomeninges or the periventricular areas in approximately one-third of

patients, but no other abnormalities or evidence of acute disease are present on either CT or MRI examination.

With disease progression, further muscle weakness and hyporeflexia may be seen. Patients may progress to a diffuse, flaccid paralysis similar to Guillain-Barré syndrome. Ataxia, extrapyramidal symptoms, cranial nerve abnormalities, myelitis, optic neuritis, and seizures may be seen.

Treatment

36. What treatment options are available to A.G.?

Currently, treatment of WNV infection is supportive. Patients with febrile infection usually have a self-limiting course. In severe cases, patients with muscle weakness and signs of encephalitis will require admission to an intensive care unit, and many will need mechanical ventilation. The available antiviral medications do not have any activity against WNV in vivo, although ribavirin inhibits replication in vitro.¹³⁷ Combination therapy of high-dose ribavirin and interferon- α -2b has been used in patients with severe disease with limited success. Although optimal doses have not been established, the doses needed to inhibit the virus were 2 million units of interferon and 2,400 mg of ribavirin daily.¹³⁸ Clinical trials are ongoing to establish the safety and efficacy of intravenous immune globulin, and α -interferon. In addition, a new agent, AVI-4020, is undergoing preclinical trials to determine the pharmacokinetic and safety profile.

SEVERE ACUTE RESPIRATORY DISTRESS SYNDROME

Severe acute respiratory distress syndrome (SARS), a highly infectious disease, was first identified in China in early 2003. Since then, the viral syndrome has been reported in several countries in East Asia, North America (particularly Canada), South America, and Europe. As of April 2004, approximately 8,000 cases have been reported, with a case fatality rate of about 10%.^{139,140} Many of the cases reported in Asia and Canada have been traced to a single index case, with outbreaks clustered in apartments, hotels, health care facilities, or biomedical facilities. There is some evidence to suggest that increased age (older than 60 years) may be associated with an increased mortality risk.¹⁴¹

The disease is easily spread by airborne microdroplets. Geography and a history of recent travel to affected areas are believed to be important to an individual's likelihood of contracting the disease. In a sample of 100 suspected patients in the United States, 94% traveled within the 10 days before illness onset to an area listed in SARS case definitions.¹⁴² SARS is believed to be transmitted mostly by close contact with an infected person (e.g., sharing eating utensils, <3-foot conversations).

A novel coronavirus, SARS coronavirus (SARS-CoV), was isolated from patients and identified as the causative agent of SARS. Inoculations of a Vero E6 cell line with throat swab specimens from patients with the diagnosis of SARS showed cytopathologic features.¹⁴³ Although the natural reservoir of SARS-CoV has not been identified, the virus has been detected in the Himalayan masked palm civet, the Chinese ferret badger, and the raccoon dog.

Clinical Presentation

37. N.Z. is a 48-year-old Asian female who returned 3 days ago from a business trip to Taiwan. Two days after her return, she complained of fatigue, myalgia, chills, and headache. On the third day, she awoke feeling feverish and diaphoretic. Her temperature was 101°F. She complained of a sore throat with cough and shortness of breath when she climbed stairs. She visited her local physician, who noted rales during chest auscultation. As there was concern for SARS, the patient was admitted and placed under quarantine in a local hospital. A chest radiograph revealed bilateral interstitial infiltrates. A routine pneumonia workup was performed with pulse oximetry, blood cultures, and sputum Gram stain and culture. Blood was also collected for antibody analysis. Complete blood count and clinical chemistries were obtained, and the tests were remarkable only for lymphopenia. What signs and symptoms in N.Z. suggest that this is a case of SARS?

The case definition established by the CDC includes clinical, epidemiologic, laboratory, and exclusion criteria.¹⁴⁴ Symptoms of early disease include fever, chills, rigor, myalgia, headache, diarrhea, sore throat, or rhinorrhea. Mild-to-moderate illness includes temperature higher than 100.4°F and clinical findings of lower respiratory illness such as cough or shortness of breath. Severe illness includes the previous criteria plus radiographic evidence of pneumonia or acute respiratory distress syndrome. N.Z. presents to her physician with severe respiratory illness.

Probable or likely exposure to SARS-CoV is a critical component of the SARS case definition. Travel to a location with documented or suspected recent transmission of SARS-CoV or close contact with a person with mild-to-moderate or severe respiratory illness in the 10 days prior to the onset of symptoms are defined as possible exposures to SARS-CoV. Likely exposure is defined as close contact with a person with confirmed disease or symptoms of disease. In N.Z.'s case, travel to Taiwan classifies her as having possible exposure.

For patients suspected of having SARS in the United States, laboratory diagnosis can be confirmed by an enzyme immunoassay detecting serum antibody to SARS-CoV, isolation of SARS-CoV from a clinical specimen, or detection of SARS-CoV RNA by a reverse transcriptase PCR. Both the enzyme immunoassay and the PCR are validated by the CDC. Information regarding the most recent criteria for laboratory diagnosis can be found at the CDC website.

Although the majority of cases of infection are self-limited, initial symptoms may be followed by hypoxemia, which may progress to the need for intubation and mechanical ventilation. Typically, patients do not manifest neurologic or GI symptoms.

Treatment

38. What treatment options are available to N.Z.?

Treatment for SARS during the 2002–2003 outbreak included broad spectrum antibiotics, ribavirin, lopinavir/ritonavir, corticosteroids, interferon, and immunoglobulin.¹⁴⁵ Broad spectrum antibiotics are recommended to cover other potential pathogens until SARS-CoV is isolated. Ribavirin has been used in doses ranging from 400 mg IV every day to 2 g IV followed by 1 g IV Q 6 hr.¹⁴⁶ Treatment ranged from 4 to

14 days. Efficacy of ribavirin in the treatment of SARS is unknown due to the self-limiting nature of the disease and the coadministration of other agents. Studies have determined, however, that ribavirin does not inhibit SARS-CoV in vitro, and viral loads remained elevated postmortem despite therapy with ribavirin.^{147,148} A high percentage of persons developed adverse drug reactions, including hemolytic anemia (61%), hypocalcemia (58%), and hypomagnesemia (46%). Two of three in vitro studies of lopinavir and ritonavir showed activity against SARS-CoV. Lopinavir 400 mg PO BID with ritonavir 100 mg BID may be effective in reducing mortality in patients with SARS, but data are limited.¹⁴⁵ Treatments with various corticosteroids, interferon, and immunoglobulin remain controversial. No treatment guidelines are available due to the lack of prospective randomized controlled trials.

THE COMMON COLD

The most prevalent viral infection is the common cold. In the United States, approximately 62 million cases of the common cold occur annually.¹⁴⁹ An estimated 20 million and 22 million days of absence from work and school, respectively, occur. The frequency of the occurrence of a cold is greater in younger children and decreases with increasing age. Although the common cold is self-limiting, otitis media occurs in approximately 20% of children following infection.¹⁵⁰

Many viruses have been isolated from patients with respiratory infections, but rhinovirus is the most common viral pathogen.¹⁵¹ Rhinovirus accounts for approximately 34% of all respiratory illnesses. More than 100 different serotypes of rhinovirus exist, and the prevalence of each varies with time and geography. Other pathogens include coronavirus, parainfluenza, RSV, adenovirus, and enterovirus. Because of the number of pathogens known to cause the common cold, development of an effective vaccine remains difficult.

Treatment for the common cold is directed at pharmacologic treatment of symptoms. Nonsteroidal anti-inflammatory drugs, oral or intranasal decongestants, antihistamines, and antitussives may be used. However, these products provide minimal relief of symptoms¹⁵² and do not shorten the natural course of infection.¹⁵³ In pediatric patients younger than 2 years, the use of cough and cold medications is not recommended by the FDA due to the deaths associated with their use.^{154,155} Currently, there are no specific antiviral treatments for the common cold.

Prevention

39. J.C. comes into the pharmacy asking for an herbal product that will help him prevent colds this upcoming cold season. He states that last year he had three colds and his neighbor had none. His neighbor had mentioned an herbal product he had been taking. J.C. cannot remember the name of the product but wonders if there are any products that may be helpful.

Zinc

Zinc, a dietary supplement, has been studied in both the prevention and treatment of the common cold. The proposed mechanism of action is that the rhinovirus 3C protease is inhibited by zinc, and the inhibition of this enzyme prevents viral replication. In vitro, zinc has been shown to have antiviral activity. Several trials conducted in the past several decades have produced conflicting results on the benefits of zinc in decreasing symptom severity or duration. A meta-analysis found no clear evidence to support the use of zinc lozenges in the treatment or prevention of the common cold.¹⁵⁶ Patients who took zinc lozenges for the common cold complained of mouth irritation, unpleasant taste, feeling sick, and diarrhea. Zinc is not currently recommended for treatment or prophylaxis of the common cold.

Echinacea

Echinacea is an herbal product extracted from the *Echinacea* plant, which belongs to the *Compositae* family. Echinacea is believed to stimulate the immune system, specifically phagocytosis. Some clinical trials using echinacea have shown positive results in decreasing the incidence of infection when compared to placebo, but the results remain inconclusive. No benefits were shown in decreasing the severity and duration of the common cold when compared to placebo. In trials evaluating the effectiveness of echinacea in the treatment of the common cold, 9 of 16 trials found a decrease in the severity and duration of symptoms.¹⁵⁷ A recent study showed no benefit of echinacea over placebo but did show an increased incidence of rash in the treatment group.¹⁵⁸ Because the current data are inconclusive and due to the variability of echinacea concentrations in the available products, use of echinacea in the prevention and treatment of the common cold is not recommended.

SUMMARY 73-47

One of the first references to epidemic jaundice was ascribed to the philosopher Hippocrates. Over the centuries, several epidemics, usually associated with poor hygiene, were observed, especially during wartime. The possibility of a viral etiology was considered as recently as the turn of the 20th century.

Since the 1970s, five distinctly separate hepatitis viruses have been identified with liver disease as their major clinical manifestation, all of which have been characterized and cloned. A sixth virus also has been identified, but has yet to be implicated in liver disease. Five of these viruses are RNA viruses; and one is a DNA virus. The mode of transmission differs, as do the natural history and outcomes. The individual viral types can be distinguished by serologic assays and, in some instances, by genotyping. Although significant progress in the area of disease prevention has occurred, advances in treatment have been limited because of the large amount of virus produced and its rapid mutation. People with chronic hepatitis C produce approximately 1 trillion virus particles daily, compared with 100 billion particles daily for those infected with chronic hepatitis B and 10 billion particles daily for those with HIV infection. This chapter reviews the virology, epidemiology, pathogenesis, clinical manifestations, diagnosis, natural history, prevention, and treatment strategies for viral hepatitis.

CAUSATIVE AGENTS AND CHARACTERISTICS

Viral hepatitis is a major cause of morbidity and mortality in the United States.^{1,2} At least six distinct agents are responsible for viral hepatitis. These hepatotropic viruses are identified by the letters A through G as follows: (a) type A hepatitis caused by hepatitis A virus (HAV), (b) type B hepatitis caused by hepatitis B virus (HBV), (c) type C hepatitis caused by hepatitis C virus (HCV), (d) delta hepatitis caused by the HBV-associated hepatitis D virus (HDV), (e) type E hepatitis caused by the hepatitis E virus (HEV), and (f) type G hepatitis, caused by the hepatitis G virus (HGV) and the GB agents (Table 73-1). Hepatitis A through E viruses primarily affect the liver and have the potential to cause inflammation and hepatocellular necrosis, whereas the clinical manifestations of HGV are unknown.³ These viruses differ in their immunologic characteristics and epidemiologic patterns (Table 73-2). Fecal-oral transmission is the primary mode of infec-

tion for HAV and HEV, whereas percutaneous transmission is characteristic of HBV, HCV, and HDV.⁴⁻⁷ HGV also appears to be transmitted percutaneously, primarily through volunteer blood donors.^{8,9} Several other viruses primarily affect nonhepatic organ systems and may secondarily induce a hepatitis-like syndrome. These include the Epstein-Barr virus (infectious mononucleosis); cytomegalovirus (CMV); herpes simplex viruses; varicella-zoster virus; and rubella, rubeola, and mumps viruses (Table 73-3).

Definitions of Acute and Chronic Hepatitis

Viral hepatitis can present as either an acute or chronic illness. Acute hepatitis is defined as an illness with a discrete date of onset with jaundice or increased serum aminotransferase concentrations >2.5 times the upper limit of normal.¹⁰ Acute viral hepatitis infection is a systemic process and lasts as long as, but not exceeding, 6 months.

Chronic hepatitis is an inflammatory condition of the liver that involves ongoing hepatocellular necrosis for 6 months or more beyond the onset of acute illness.¹¹ The causes of chronic hepatitis are shown in Table 73-3. The most common cause of chronic hepatitis is chronic viral hepatitis, caused by HBV or HCV.^{12,13} Drug-induced and autoimmune chronic hepatitis occur less frequently, whereas metabolic disorders and HDV chronic hepatitis are relatively rare.¹⁴⁻¹⁶ Neither HAV nor HEV infections cause chronic hepatitis. The long-term effects of HGV continue to be investigated, but the virus does not appear to cause liver (or any other) disease, even in immunocompromised patients.¹⁷

Serologic Evaluation in Presumed Chronic Hepatitis

Because the clinical manifestations and incubation periods are similar among patients with hepatitis, serologies are useful in diagnosing the type of viral infection that is occurring. Appropriate tests include detecting specific antibodies against hepatitis A virus (anti-HAV), hepatitis B surface antigen (HBsAg) and hepatitis C antibody (anti-HCV). A diagnosis of acute hepatitis A virus infection includes the presence of IgM anti-HAV. If HBsAg is present, further testing for hepatitis B envelope antigen (HBeAg) and HBV-DNA is

Table 73-1 Hepatitis Nomenclature

| Hepatitis Type | Antigen | Corresponding Antibody | Comments |
|----------------|--------------------------------------|---|---|
| A | Hepatitis A virus (HAV) | Hepatitis A antibody (anti-HAV) | RNA virus; present in stool and serum early in course of hepatitis A |
| B | Hepatitis B surface antigen (HBsAg) | Hepatitis B surface antibody (anti-HBs) | DNA virus; found in serum in >90% of patients with acute hepatitis B, anti-HBs appears following infection and confers immunity |
| | Hepatitis B core antigen (HBcAg) | Hepatitis B core antibody (anti-HBc) | Anti-HBc detected in serum during and after acute infection |
| | Hepatitis B envelope antigen (HBeAg) | HB envelope antibody (anti-HBe) | HBeAg correlates with infectivity; suggestive of active viral replication |
| C | Hepatitis C antigen (HcAg) | Hepatitis C antibody (anti-HCV) | RNA virus; previously known as posttransfusion NANB hepatitis |
| D | Hepatitis D antigen (HDAg) | Hepatitis D antibody (anti-HDV) | Defective RNA virus; requires presence of HBsAg |
| E | Hepatitis E antigen (HEAg) | Hepatitis E antibody (anti-HEV) | RNA virus present in stool; cause of enteric NANB hepatitis |
| G | Hepatitis G antigen (HGAg) | Not available | RNA-like virus; named GBV-A, GBV-B, and GBV-C; thought to be of tamarin origin |

NANB, non-A, non-B hepatitis.

indicated to document the presence of active viral replication and assess the viral load. Testing for hepatitis D antibody (anti-HDV) also should be performed in patients with hepatitis B to evaluate the possibility of coexisting delta hepatitis. If the hepatitis serology is negative, rare but treatable causes of chronic active hepatitis should be excluded. These include alcoholic liver disease, Wilson disease, α_1 -antitrypsin deficiency, and drug-induced chronic active hepatitis. Drugs associated with reversible chronic active hepatitis syndrome include methyl dopa,¹⁸ nitrofurantoin,¹⁹ isoniazid,²⁰ and rarely, sulfonamides²¹ and propylthiouracil.²²

Following exclusion of these conditions, the patient should be evaluated for the presence of circulating immunologic markers associated with the autoimmune (idiopathic) form of

chronic hepatitis. These tests include antismooth-muscle antibody, antimitochondrial antibody, antinuclear antibody titers, and increased serum immunoglobulins.

HEPATITIS A VIRUS

Virology and Epidemiology

Hepatitis A virus is a 27-nm diameter, single-stranded RNA virus that is classified as a picornavirus (Table 73-2).²³ Following attachment to a cell surface receptor, the viral RNA is uncoated. The cell host ribosomes then bind to the viral RNA, and form polysomes. Subsequently, HAV is translated into a polyprotein with three distinct regions: P1, P2, and P3 with the

P2 and P3 regions encoding for nonstructural proteins associated with viral replication. HAV appears to replicate within the liver; however, enterocytes may also support viral replication.²³ HAV has a single serotype that remains detectable in intact virions and has four different genotypes (I-IV).²³

Hepatitis A virus has a worldwide distribution.^{4,24-26} The prevalence of infection is related to the quality of the water supply, level of sanitation, and age.^{26,27} Incidence data are unreliable, however, because the disease is frequently mild and often unrecognized, resulting in underreporting.²⁴⁻²⁷ The primary mode of transmission is person-to-person via the fecal-oral route.²⁴⁻²⁷ HAV is passed into the stool in high titer. Considering that the virus resists degradation by environmental conditions, gastric acid, and digestive enzymes in the upper gastrointestinal (GI) tract, it is readily spread within a population.²⁸ Fecally contaminated water or also food is a significant mode of transmission.^{24,25,28} Children are considered an important reservoir of infection for others.^{29,30}

In the United States, the reported incidence of HAV is 10.8 cases per 100,000, and it is usually associated with outbreaks in lower socioeconomic groups or common-source outbreaks (e.g., day-care centers).^{25,27,28,30} Rates in males are greater than those in females by about 20%.^{25,28} Children aged 5 to 14 years and Native Americans have the highest incidence of HAV.²⁵⁻²⁷ Recent data suggest, however, that with vaccination in children, the incidence of HAV infection is approximately 1.9 cases per 100,000 population, the lowest rate ever recorded.²⁹ Similar rates of decline have been demonstrated in Native Americans and Hispanics. Additionally, cyclic outbreaks of HAV have been reported among users of injecting and noninjecting drugs and in men who have sex with men.²⁹ Considering the widespread presence of hepatitis A antibody (anti-HAV), the virus has a high attack rate, with 70% to 90% of those exposed ultimately becoming infected.^{24,25}

The most common risk factors for acquiring HAV include close contact with a person positive for HAV (26%), employment or attendance at a day-care center (14%), injection drug use (11%), recent travel (4%), and association with a suspected

food- or water-borne outbreak (3%).^{4,24,25,27,29} Up to 42% of reported HAV infections have no known source for infection.²⁶ Exceedingly rare causes of HAV include transfusion of blood or blood products collected from donors during the viremic phase of their infection and from contact with experimentally infected nonhuman primates.^{7,25,27,31} Percutaneous transmission is rare because no asymptomatic carrier state for HAV exists, and the incubation period is brief.^{1,26,30,32} Occupations at risk for HAV include sewage workers, hospital cleaning personnel, day-care staff, and pediatric nurses.^{27,30,31} Furthermore, HAV is the most common preventable (e.g., vaccination) infection in travelers visiting locations with poor hygienic conditions.^{30,33} Up to 22% of patients with acute HAV may need to be hospitalized with an associated cost of managing HAV and workdays lost accounting for >\$400 million annually.²⁹

Pathogenesis

Theoretically, HAV infection results in both a cytopathic and immunologic hepatocyte injury; however, the exact mechanism of injury is unknown.^{28,33,34} Viral replication occurs within the liver, based on immunohistochemical analysis in primates. The presence of IgM in sinusoidal cells and hepatitis A viral antigen (HAVAg) in Kupffer cells likely result in the histologic manifestations and functional impairment observed in HAV disease.³⁰ In addition, circulating T lymphocytes have been isolated from the liver of patients with acute HAV infection.³⁰

Nonspecific mechanisms of hepatocyte injury may involve natural killer (NK) cells and lymphokine-activated killer (LAK) cells, which are believed to precede the initiation of damage caused by cytotoxic T lymphocytes (CTL).^{30,35} Subsequent hepatocyte death results in viral elimination and eventual resolution of the clinical illness.

Natural History

Hepatitis A virus is typically a benign, self-limited infection, with recovery within 2 months of disease onset. Two atypical courses of acute HAV infection have also been described: prolonged cholestasis and relapsing hepatitis.³⁰ In patients with prolonged cholestasis, the duration of jaundice exceeds 12 weeks and is associated with pruritus, fatigue, loose stools, and weight loss. Aminotransferase concentrations during this period are <500 U/L. Spontaneous recovery often occurs, yet corticosteroids have been administered to facilitate resolution of the cholestatic phase. Relapsing or polyphasic HAV occurs in 6% to 12% of both adult and pediatric patients and can be characterized by an initial phase of acute infection followed by remission (duration of 4–15 weeks), with subsequent relapse. Aminotransferase concentrations often normalize during the time of remission but increase to >1,000 U/L with relapse. Also, HAV RNA is detectable in the serum, and HAV is usually recovered from the stool during relapse. The pathogenesis of relapsing hepatitis has not been elucidated. Fulminant hepatitis A is rare, occurring in 0.014% to 3.0% of the population infected with HAV, but often fatal.^{30,36} Patients >40 years of age or <11 are more susceptible to HAV-induced fulminant hepatic failure (FHF). Chronic HAV does not exist. Typically, the course of HAV includes an incubation phase, an acute hepatitis phase, and a convalescent phase. Complete clinical recovery is

usually seen within 2 months in 60% of patients and virtually all patients within 6 months following HAV infection.

Clinical Manifestations

1. E.T., a 34-year-old medical sales representative, presents to the emergency department (ED) with acute onset of jaundice and “dark urine.” He was in good health until 2 weeks ago, when he noted feeling fatigued and weak, which he attributed to his demanding work schedule. He also recalled having a mild headache, loss of appetite, muscle pain, diarrhea, and low-grade fevers from 99°F to 101°F. He attributed these symptoms to the flu and took acetaminophen with plenty of fluids. His symptoms persisted until yesterday, when they seemed to resolve unexplainably. He then noted his urine was cola-colored. This morning, he noted jaundice of his eyes and skin and sought medical attention.

E.T.’s medical history includes a recent respiratory tract infection, treated successfully with levofloxacin. His social history is significant for frequenting the local oyster bar, where he regularly ingests raw oysters. He denies smoking and recent travel outside the United States, but admits to occasional alcohol consumption. E.T. has no history of sexual exposure, needle use, or transfusions. His current medications include oral (PO) diazepam 5 mg at bedtime (HS) as needed (PRN) for “muscle spasms,” but he has not taken diazepam for “several months.” He also has a seizure disorder sustained after a motorcycle accident 2 years before admission, for which he takes phenytoin 400 mg PO HS.

Physical examination is significant for a well-developed, well-nourished man in no acute distress. He is alert and oriented, with a temperature of 99°F. His sclerae and skin are icteric, and his abdomen is positive for a tender, enlarged liver, and right upper quadrant (RUQ) pain. Laboratory tests reveal the following values: hemoglobin (Hgb), 16 g/dL (normal, 12.3–16.3 g/dL); hematocrit (Hct), 44% (normal, 37.4%–47.0%); white blood cell (WBC) count, 5,500 cells/mm³ (normal, 3.28–9.29 × 10³); aspartate transaminase (AST), 120 U/L (normal, 5–40 U/L); alanine aminotransferase (ALT), 240 U/L (normal, 5–40 U/L); alkaline phosphatase, 86 U/L (normal, 21–91 U/L); total bilirubin, 3.2 mg/dL (normal, 0.2–1.0 mg/dL); direct bilirubin, 1.5 mg/dL (normal, 0–0.2 mg/dL); and phenytoin concentration, 12 mg/L (normal, 10–20 mg/L). The albumin, prothrombin time (PT), blood glucose, and electrolytes all are within normal limits. E.T. is negative for anti-HCV, HBeAg, HBsAg, and hepatitis B core antibody (anti-HBc), but is positive for IgM anti-HAV. What clinical features and serologic markers are consistent with viral hepatitis in E.T.?

[SI units: Hgb, 160 g/L (normal, 123–63); Hct, 0.44% (normal, 0.374–0.47%); WBC count, 5,500 × 10⁹ cells/L (normal, 3,280–9,290 × 10⁹); AST, 120 U/L (normal, 5–40); ALT, 240 U/L (normal, 5–40); alkaline phosphatase, 86 U/L (normal, 21–91); total bilirubin, 54.72 μmol/L (normal, 3.42–17.1); direct bilirubin, 25.65 μmol/L (normal, 0–4)]

The incubation period for HAV is 15 to 50 days (average, 30) following inoculation (Table 73-2). The host is usually asymptomatic during this stage of the infection; thus, E.T. is beyond the inoculation phase of the disease. Because HAV titers are highest in the acute-phase fecal samples, and the period of infectivity is between 14 and 21 days before the onset of jaundice to 7 or 8 days following jaundice, he should be considered in-

fectious at this time. In HAV infections, acute-phase serum and saliva are less infectious than fecal samples, whereas urine and semen samples are not infectious. Family members and persons recently in immediate contact with E.T. should be notified to limit the possibility of disease transmission.

The symptoms of acute viral hepatitis caused by HAV, HBV, HCV, HDV, and HEV are similar. The onset of symptoms in HAV infection, however is less insidious than those seen with HBV and HCV infection.^{28–30} Generally, symptoms of HAV present a week or more before the onset of jaundice. The likelihood of having symptoms is related to age. In children age <6 years, 70% of infections are asymptomatic, whereas older children and adults have symptomatic disease with jaundice occurring in >70% of cases. E.T. has signs and symptoms of acute HAV infection, including the nonspecific prodromal symptoms of fatigue, weakness, anorexia, nausea, and vomiting. Abdominal pain and hepatomegaly are common. Less common symptoms include fever, headache, arthralgias, myalgias, and diarrhea. Within 1 to 2 weeks of the onset of prodromal symptoms, patients may enter an icteric phase with symptoms, including clay-colored stools, dark urine, scleral icterus, and frank jaundice. The dark urine is caused by bilirubin, generally occurring shortly before the onset of jaundice. E.T. should be questioned about the presence of pale stools (light gray or yellow), which usually is observed during the icteric phase. His scleral icterus is strongly suggestive of viral hepatitis. Icteric infections usually occur in adults, and are 3.5 times more common than the nonicteric presentation that is seen in children.³⁷

The results of E.T.’s liver function tests (LFT) (e.g., elevations in AST, ALT, and bilirubin) also are consistent with viral hepatitis. Serum transaminase concentrations increase during the prodromal phase (usually ALT >AST) of HAV infection, peaking before the onset of jaundice. These concentrations are often >500 U/L, and decline at an initial rate of 75% per week, followed by a slower rate of decline thereafter. Serum bilirubin peaks following aminotransferase activity and rarely exceeds 10 mg/dL. Bilirubin levels decline more slowly than aminotransferases and generally normalize within 3 months. Right upper quadrant tenderness, mild liver enlargement and splenomegaly may also be present in patients with acute HAV infection.

Extrahepatic Manifestations

2. Are there any additional complications that E.T. could develop from his acute HAV infection?

With the appearance of jaundice, prodromal pruritus and extrahepatic manifestations can occur, usually in patients with a more protracted illness. Thus, E.T. should be monitored for additional manifestations of HAV infection, including immune complex-associated rash, leukocytoclastic vasculitis, glomerulonephritis, cryoglobulinemia (less likely than with HCV), and arthritis. Rare extrahepatic manifestations include epidermal necrolysis, fatal myocarditis, renal failure in the presence of hepatic failure (hepatorenal syndrome), optic neuritis, and polyneuritis.^{30,38,39} Hematologic abnormalities, although infrequently reported, include autoimmune hemolysis and thrombocytopenic purpura, aplastic anemia, and red cell aplasia.^{30,38}

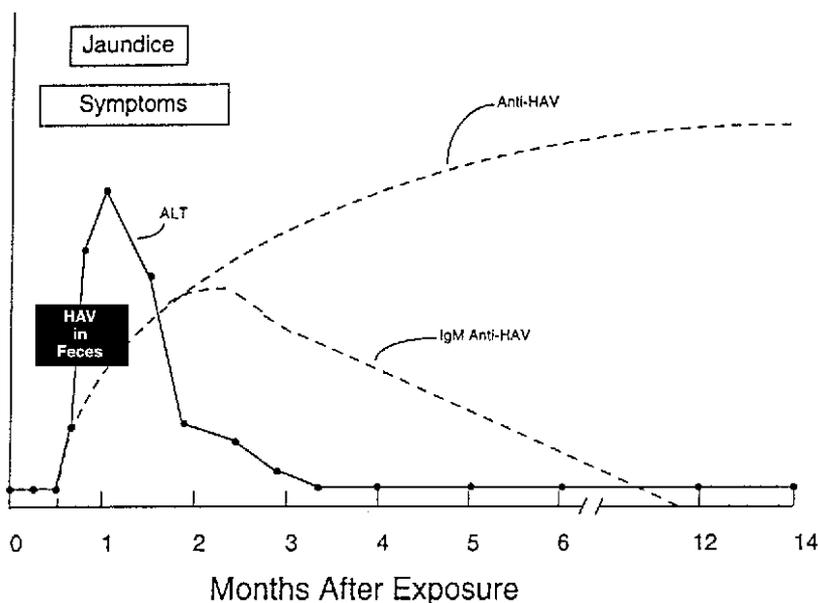

FIGURE 73-1 Typical course of hepatitis A. ALT, alanine aminotransferase; anti-HAV, antibody to HAV; HAV, hepatitis A virus. From reference 40, with permission.

Diagnosis and Serology

Several diagnostic methods are available for detecting HAVAg (antigen) and anti-HAV (antibody). HAV can be detected in stool specimens 1 to 2 weeks preceding clinical illness. Viral RNA can be detected in body fluids and serum using the polymerase chain reaction (PCR), an expensive method usually reserved for research purposes. Because most patients present when the virus is no longer in stool, serum antibody can be detected by radioimmunoassay (RIA) or enzyme-linked immunosorbent assay (ELISA). Two classes of HAV antibodies are detectable: IgM and IgG (Fig. 73-1). Detection of IgM to HAV in a patient who presents with clinical characteristics of hepatitis or in an asymptomatic patient with elevated transaminases is consistent with acute HAV infection. HAV IgG appears following IgM and is indicative of previous exposure and immunity to HAV, whereas a rising IgG is consistent with recent exposure.^{28,30,40} Anti-HAV IgM is commonly present throughout the disease course (16–40 weeks), usually peaking early and declining to undetectable levels 3 to 4 months after the initial infection.^{30,41} One-quarter of patients infected with HAV have IgM present for up to 6 months, and occasionally longer. HAV IgG appears early in the convalescent phase and is detectable for decades after the acute infection resolves, with a slowly declining titer.³⁰ Both ELISA and RIA methods of antibody detection are sensitive, specific, and reliable to diagnose acute HAV infection. E.T. has a positive IgM anti-HAV, consistent with acute HAV infection. E.T. has a negative IgM anti-HBc test, ruling out acute HBV infection.³⁰

Treatment

General Measures

Hepatitis A virus infection is usually a self-limited disease that does not require a specific therapy. Many treatments have been recommended for acute viral hepatitis, but none signif-

icantly alter the course of the disease. The patient with acute viral hepatitis may be treated as an outpatient if symptoms are mild to moderate and regular medical evaluation occurs. Patients infected with hepatitis A usually do not require hospitalization, unless they develop complications of hepatic insufficiency, such as encephalopathy or hemorrhage secondary to hypoprothrombinemia. Patients should continue their normal activities as much as possible while avoiding physical exhaustion. Intravenous (IV) fluid and electrolyte replacement is necessary in some patients with severe nausea and vomiting. Patients should abstain from alcohol during the acute phase of the disease. Following resolution of symptoms and serum biochemical abnormalities, moderate alcohol intake is no longer contraindicated. Ultimately, any patient with fulminant hepatic failure caused by HAV infection should be evaluated for liver transplantation.

Adjustment of Medication Doses

3. Should E.T.'s medications be adjusted during the acute phase of hepatitis A infection?

Dosage adjustments for hepatically eliminated drugs in the setting of liver disease are difficult to predict. This is because hepatic metabolism is complex, involving numerous oxidative and conjugative pathways that are variably affected in hepatic disease. In renal disease, creatinine serves as an endogenous marker to predict the clearance of renally eliminated drugs. In hepatic disease, however, no reliable endogenous markers exist to predict drug hepatic clearance. Laboratory tests that approximate the synthetic function of the liver (albumin, PT) and biliary clearance (bilirubin) are used to estimate the degree of hepatic impairment, but these tests are not dependable in predicting alterations in pharmacokinetic parameters for hepatically metabolized drugs.

Table 73-4 Half-Life Data for Various Agents in Acute Viral Hepatitis Compared With Reference Normal Controls

^aNo change indicates that the difference between patients with acute viral hepatitis and normal controls is not statistically significant.

Because of the difficulty in predicting hepatic drug clearance, unnecessary and potentially hepatotoxic medications are best if avoided during the acute phase of the illness. When drug therapy is indicated with agents that undergo hepatic elimination, it is prudent to use the lowest doses possible to achieve the desired therapeutic effect. Data from small pharmacokinetic studies in patients with acute viral hepatitis are shown in Table 73-4.⁴²⁻⁶⁰

E.T. should be advised to discontinue diazepam (Valium) because this medication undergoes extensive hepatic biotransformation and limited data suggest this agent accumulates in the setting of acute viral hepatitis.⁴⁷ If E.T. should require drug therapy for muscle spasms, he should either decrease the diazepam dose or consider using an alternative agent (e.g., lorazepam) that does not accumulate in acute viral hepatitis.⁴⁹ Patients with acute viral hepatitis do not require phenytoin dosage adjustments.⁵⁵ Because E.T.'s plasma phenytoin concentration is within the desired therapeutic range, no dosage adjustment is needed at this time.

Prevention of Hepatitis A

Prevention of hepatitis A infection can be achieved through immunoprophylactic measures. Immunoprophylaxis may be passive, active, or a combination of both. In passive immunization, temporary protective antibody in the form of immunoglobulin is administered. In active immunization, a vaccine is administered to induce the formation of protective antibody. Prophylaxis can be administered before (pre-exposure prophylaxis) or after exposure (postexposure prophylaxis).

Pre-exposure Prophylaxis

4. M.D., a 22-year-old student, is preparing for a 2-week vacation to Thailand. He plans to travel 3 months from now and wonders if he should receive prophylaxis for HAV.

IMMUNOGLOBULIN

Before hepatitis A vaccine was available, the sole therapy for pre-exposure prophylaxis of hepatitis A infection was immunoglobulin. Immunoglobulin is an injectable solution containing a full complement of antibodies normally present in human serum. Current preparations are manufactured by cold ethanol fractionation of pooled plasma collected from at least 1,000 human donors, providing protective levels of anti-HAV. Although passive immunization with immunoglobulin alone is highly effective in preventing hepatitis A virus infection,⁶¹ the duration of protection is short. When used for pre-exposure prophylaxis (e.g., in travelers who are allergic to a vaccine component or decide against vaccination), a dose of 0.02 mL/kg of immunoglobulin administered intramuscularly (IM) confers protection for <3 months, and an IM dose of 0.06 mL/kg confers protection for ≥ 5 months.^{29,30,61} Patients with continued exposure to hepatitis A require IM administration of immunoglobulin 0.06 mL/kg every 5 months for adequate protection.^{29,62}

VACCINE

Active immunization with hepatitis A vaccine has largely supplanted the use of immunoglobulin for pre-exposure prophylaxis of infection caused by HAV. Formulations of inactivated hepatitis A vaccine available in the United States include Havrix and Vaqta. Both vaccines are formalin-inactivated preparations of attenuated HAV strains. The manufacturers use differing units to express antigen content of their respective vaccines. Havrix dosages are expressed in ELISA units (EL.U.), and Vaqta dosages are expressed as units (U) of hepatitis A antigen.

Dosing Regimen

Havrix is available in two formulations that differ according to age: for persons 12 months to 18 years of age, 720 EL.U. (0.5 mL) per dose in a two-dose schedule; and for persons >19 years of age, 1,440 EL.U. (1.0 mL) per dose in a two-dose schedule (Table 73-5).^{29,30} This vaccine is usually injected IM into the deltoid muscle using a needle length appropriate for

Table 73-5 Recommended Doses of Hepatitis A Vaccines

| Age at Vaccination | Dose (Volume) ^a | Schedule (Months) ^b |
|------------------------|----------------------------|--------------------------------|
| Havrix | | |
| Children 12 mos–18 yrs | 720 EL.U. (0.5 mL) | 0, 6–12 |
| Adults >19 yrs | 1,440 EL.U. (1.0 mL) | 0, 6–12 |
| Vaqta | | |
| Children 12 mos–18 yrs | 25 U (0.5 mL) | 0, 6–18 |
| Adults >19 yrs | 50 U (1.0 mL) | 0, 6 |

^aEnzyme-linked immunosorbent assay (ELISA) units.

^bZero months represents timing of the initial dose; subsequent numbers represent months after the initial dose.

From references 29,62, with permission.

the person's age and size, with a booster dose administered 6 to 12 months later. Of note, the pediatric Havrix formulation (three-dose schedule) is no longer available. In comparison, Vaqta is available in two formulations, and the formulations differ according to the person's age: for persons 12 months to 18 years of age, 25 U (0.5 mL) in a two-dose schedule; for persons >19 years of age, 50 U (1.0 mL) per dose in a two-dose schedule (Table 73-5).^{29,30} Likewise, this vaccine is usually injected IM into the deltoid muscle with a booster dose administered 6 to 18 months later.²⁹

The levels of anti-HAV necessary to prevent infection have not been definitively established. The manufacturer-specified protective levels for Havrix and Vaqta are >20 mIU/mL (or >33 mIU/mL in recent studies) and >10 mIU/mL, respectively. The immune response to each preparation has been rapid and complete, with >94% of patients achieving protective antibody levels 1 month after vaccination.^{29,62} Following administration of a second dose, 100% of vaccine recipients achieve protective antibody titers.^{29,63} Additionally, both vaccines are extensively immunogenic in children (including those with Down syndrome) and adolescents, with 97% to 100% of persons between the age of 2 to 18 years achieving protective antibody levels 1 month after receiving the first dose; 100% achieve protective levels 1 month following the second dose.²⁹ Additionally, data indicate that inactivated hepatitis A vaccines are immunogenic in children aged <2 years who do not have passively acquired maternal antibody. Vaccination among this group achieves a protective antibody level.²⁹

COMBINATION VACCINE

The US Food and Drug Administration (FDA) has also licensed a combined HAV and HBV vaccine (Twinrix, GlaxoSmithKline Biologicals, Rixensart, Belgium) for use in persons aged ≥8 years.^{29,64} Twinrix is composed of the same antigenic components used in Havrix and Engerix-B. Each dose of Twinrix contains at least 720 EL.U. of inactivated HAV and 20 mcg of recombinant hepatitis B surface antigen (HBsAg). Trace amounts of thimerosal (<1 mcg) is also present from the manufacturing process.

Primary immunization consists of three doses, given on a 0-, 1-, and 6- month schedule, the same that is used for single antigen hepatitis B vaccine.^{29,64} Any person 18 years of age or older having an indication for both hepatitis A and hepatitis B vaccine can be given Twinrix, including patients with chronic liver disease, users of illicit injectable drugs, men who have sex with men, and persons with clotting factor disorders who receive therapeutic blood products.^{29,64} For international travel, hepatitis A vaccine is recommended; hepatitis B vaccine is recommended for travelers to areas of high or intermediate hepatitis B endemicity who plan to stay for longer than 6 months and have frequent close contact with the local population.^{29,64}

Data from 11 clinical trials in adult patients ages 17 to 70 years indicated, at 1 month after completion of the three-dose series, that seroconversion for anti-HAV (titer >20 mIU/mL) was elicited in 99.9% of vaccines, and protective antibodies against HBsAg (anti-HBs >10 mIU/mL) were elicited in 98.5% of vaccinees.^{29,64} Thus, the efficacy of Twinrix likely is comparable with existing single antigen hepatitis vaccines. The persistence of anti-HAV and antibody to hepatitis B surface antigen (anti-HBs) following administration is similar to that following single antigen hepatitis A and B vaccine admin-

istration at 4-year follow-up. Observed adverse effects were generally similar in type and frequency to those reported following vaccination with monovalent hepatitis A and B vaccines and no serious vaccine-related adverse events were observed in clinical trials.^{29,64}

Efficacy, Safety, and Duration of Response

The efficacy of the hepatitis A vaccine is well established with protective efficacy of 94% to 100%.⁶⁴⁻⁶⁶ The vaccine is well tolerated with soreness at the injection site, headache, myalgia, and malaise as the most commonly reported adverse effects. A recent postmarketing surveillance study of >6 million doses of vaccine revealed <0.01% of patients reporting adverse events.⁶⁷

The duration of protection has not been studied extensively; however, the little data that exist suggest persistence of protective antibody titers for periods of 6 years with Havrix and 5 to 6 years with Vaqta.²⁹ Estimates of antibody persistence derived from pharmacokinetic models of antibody decline indicate that protective concentrations of antibody could be present for >20 years.^{29,68,69} The US Advisory Committee on Immunization Practices (ACIP) does not have a recommendation regarding the need for booster doses at this time.

Indications

The ACIP continues to recommend administering hepatitis A vaccination for several high-risk groups, including travelers to countries with high endemicity of infection (South and Central America, Africa, South and Southeast Asia, Caribbean, and the Middle East), travelers to countries with intermediate endemicity of infection (Eastern and Southern Europe and the former Soviet Union), children living in communities with high rates of hepatitis A infection and periodic hepatitis A outbreaks (Alaskan Native villages, American Indian reservations), men who have sex with men, IV drug users, researchers or persons who have occupational risk for hepatitis A (health care workers), persons with clotting factor disorders, and persons with chronic liver disease who are at increased risk for fulminant hepatitis A.²⁹ Because M.D. will not travel for another 3 months, he should receive either Havrix 1,440 EL.U. or Vaqta 50 U as soon as possible and no later than 1 month before travel. This initial injection will provide adequate protection from HAV infection during his travel, and he can receive the booster injection on his return, at least 6 months after the first injection.

Postexposure Prophylaxis

5. L.W., a 26-year-old man, recently was diagnosed with HAV infection. He attends college and works part-time as a retail clerk. He lives with his wife and infant daughter. Which of L.W.'s contacts require postexposure prophylaxis for HAV?

The ACIP recommends using immunoglobulin for people who have been recently exposed to HAV and who have not been previously vaccinated. The recommended dose is 0.02 mL/kg, administered IM as soon as possible but no later than 2 weeks after exposure. Contacts who have received a dose of hepatitis A vaccine at least 1 month before exposure do not need immunoglobulin, because protective antibody titers are achieved in >95% of patients 1 month after vaccination.^{29,62}

Administration of immunoglobulin within 2 weeks of exposure to HAV is 80% to 90% effective in preventing acute HAV

infection.^{29,70} In most cases, when given early, immunoglobulin prevents both clinical and subclinical HAV illness. Protection following immunoglobulin administration is immediate and complete; however, long-lasting immunity to HAV does not develop.

Immunoglobulin is recommended for close personal contacts (household and sexual) of persons with acute hepatitis A infection. L.W.'s wife and infant daughter should receive prophylactic administration of immunoglobulin. Vaccination is not required at this time. Prophylaxis is not recommended for casual contacts at work or school.

Other situations in which immunoglobulin administration may be indicated include hepatitis A infection in day-care centers and in settings with infected persons who prepare and serve food. Immunoglobulin is recommended for all staff and children in day-care settings when a case of hepatitis A virus infection is diagnosed among employees or attendees.^{29,62} When a food handler is diagnosed with hepatitis A, immunoglobulin is recommended for other food handlers at the same location. Given the improbability of disease transmission to persons consuming food prepared or served by workers infected with hepatitis A, the routine administration of immunoglobulin in this setting is not recommended.^{29,62}

Unvaccinated patients with continued exposure to hepatitis A require IM administration of immunoglobulin 0.06 mL/kg every 5 months for adequate protection.²⁹ When immunoglobulin is required for infants or pregnant women, preparations that do not contain thimerosal should be used.²⁹ Additionally, immune globulin does not appear to impede the immune response to inactivated vaccines or to oral poliovirus vaccine or yellow fever vaccine. Immune globulin may, however, interfere with the response to live attenuated vaccines such as measles, mumps, rubella (MMR) vaccine and varicella vaccine when administered as either individual or combination vaccines. Therefore, MMR and varicella vaccine should be delayed for at least 3 months following administration of immune globulin for HAV prophylaxis. Immune globulin should not be given within 2 weeks after the administration of MMR or varicella vaccine. Finally, if immune globulin is administered within 2 weeks of MMR, the person requires revaccination, but not sooner than 3 months after the immune globulin administration for MMR. Serologic tests for varicella vaccination should be performed 3 months after immune globulin administration to determine if revaccination is required.

HEPATITIS B VIRUS

Virology

Hepatitis B virus is a partially double-stranded DNA virus that is a member of the *Hepadnaviridae* family of viruses (Table 73-2).^{13,71-74} Unlike HAV, HBV is antigenically complex, and results in an acute illness with or without a chronic disease state. Intact HBV virions are 42 nm wide and contain four major genes (core, X protein, surface X, and polymerase) associated with viral replication.^{13,71-76} The core gene encodes the core nucleocapsid protein which aids in viral packaging and production of HBeAg. The surface gene encodes for several proteins (pre-S1, pre-S2, and S). The X gene encodes an X protein that is considered to be associated with hepatic carcinogenesis. Lastly, the polymerase gene encodes a large

protein that is responsible for viral packaging and DNA replication. On the surface, coating HBV, is the HBsAg, which is the virus's major envelope protein. This antigen is found in patients with acute or chronic HBV infection and chronic carriers. Two additional proteins, L and M, are also present in the viral envelope. The function of the L protein appears to be viral binding to the hepatocyte surface, whereas the function of the M protein is unknown. Inside the surface envelope of the intact hepatitis B virion is a 27-nm structure called the internal nucleocapsid core, which consists of several copies of the viral core protein or HBcAg surrounding the viral DNA and the virally encoded polymerase. The HBeAg is a secreted product of the nucleocapsid core of HBV, and its presence is also indicative of viral replication.⁷¹⁻⁷⁶ In addition to intact virions, several subviral particles (S proteins) are produced that are non-infectious; however, they are severely immunogenic and promote the formation of neutralizing antibodies.⁷¹⁻⁷⁶ These particles were used to develop the first HBV vaccines.

Our understanding of HBV replication is based on experiments performed in animals; thus, extrapolation of these results to human disease must be made with caution.^{74,76,77} The life cycle of HBV can be summarized as follows: (a) viral attachment and entry; (b) viral uncoating in the cytoplasm through direct membrane fusion; (c) synthesis of complete double-stranded DNA in the nucleus: conversion of relaxed circular HBV-DNA into double-stranded covalently closed circular DNA (ccc-DNA), catalyzed by HBV viral DNA polymerase; (d) synthesis of RNA that forms the template for DNA synthesis by host RNA polymerase; (e) translation of viral transcripts in the cytoplasm, which yields the viral envelop, core, pre-core, and X proteins, as well as the viral DNA polymerase; (f) encapsidation or packaging of RNA in the cytoplasm with production of viral cores; (g) RNA synthesis of minus strand DNA by reverse transcriptase (RT); and (h) envelopment of viral cores with excretion of infective virions, or transport of viral core back into the nucleus (Fig. 73-2). The final step of replication facilitates horizontal spread of infection throughout the liver.

A basic understanding of the HBV life cycle has provided unique opportunities for drug development. Of special importance, the HBV polymerase functions as both an RT for synthesis of the negative DNA strand from genomic RNA and as an endogenous DNA polymerase. Because the HBV polymerase is remotely related to the RT enzymes of retroviruses (e.g., human immunodeficiency virus [HIV]), it is apparent that some inhibitors of HIV polymerase or RT might have activity against the HBV polymerase. Thus, several RT inhibitors have been evaluated for treating and preventing HBV. Because the proof-reading function of the RT is nonexistent, an extremely high mutation rate for HBV occurs resulting in viral resistance to many of these agents.

Epidemiology

Approximately 5% of the world's population is infected with HBV.^{1,6,12,73,78} It is estimated that >1.25 million carriers (defined as persons positive for hepatitis B surface antigen for >6 months) occur in the United States, many of whom are immigrants from endemic areas and Alaskan natives (6.4%).^{1,6,71,73,78} The incidence of acute HBV has been on the decline in the United States.^{1,6,71,73,78} Over the past

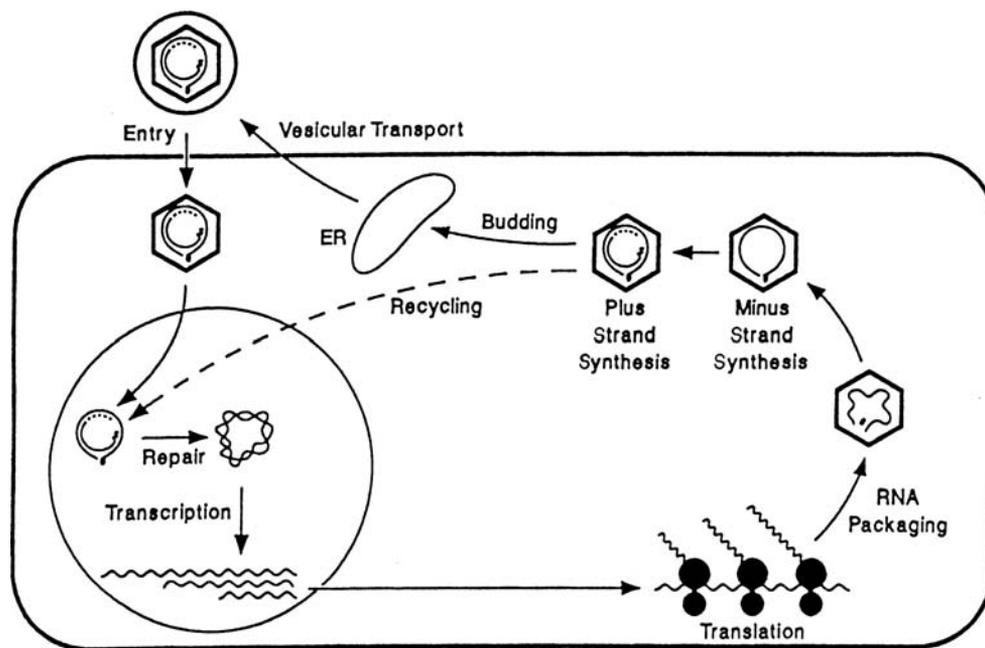

FIGURE 73-2 Life cycle of hepatitis B virus. From Ganem D. Hepadnaviridae: the viruses and their replication. In: Fields BN, Ed. *Fundamental Virology*. 3rd ed. Philadelphia: Lippincott-Raven; 1996:1199, with permission.

decade, HBV has been reduced from a rate of 438,000 infections per year in the late 1980s to an estimated 185,000 cases in 1997. This reduction has occurred in all age, racial, ethnic, and high-risk groups. The most significant reduction is in children and health care workers, groups with the highest rate of vaccination. The reduced incidence of HBV infection may be attributed to changes in behavior, which has led to decreased transmission of infection. High-risk groups in the United States for acquiring HBV infection include certain ethnic groups (Alaskan natives, Pacific Islanders), first-generation immigrants from regions of high endemicity (Southeast Asia), injection drug users, gay men, black Americans (compared with white Americans), and males (more than females).^{1,73,78-80} The most prominent risk factors associated with acute HBV include heterosexual contact (42%), men having sex with men (15%), and injection drug use (21%).^{73,78-80} HBV vaccination opportunities include clinics for sexually transmitted disease (and contacts) and in prisons and holding centers for incarceration.

The epidemiology of chronic HBV infection is less well known than that of acute disease. Within the United States, it is estimated that 0.2% of the population is HBsAg positive.^{73,78-80} Blacks are more likely to be HBsAg positive than whites, but the highest reported rates of HBsAg symptoms are among Asian Americans, especially those from China and Southeast Asia. In population-based surveys, HBV is responsible for 1% to 14% of chronic liver disease with chronic infection more likely to develop in infants compared with adults.⁶

Transmission

Hepatitis B virus is transmitted by sexual contact, percutaneous or perinatal exposure, and by close person-to-person contact allegedly through open cuts and sores, especially among children in hyperendemic areas. These modes of transmission of HBV are summarized in the following sections.

Sexual Transmission

Sexual activity is the most significant mode of HBV transmission worldwide, including North America, where the prevalence of infection is low.^{73,78-81} Heterosexual intercourse accounts for the majority of United States infections (26%). In heterosexuals, factors associated with an enhanced risk of HBV infection include duration of sexual activity, number of sexual partners, and history of sexually transmitted diseases (STD). Sexual partners of injection drug users, prostitutes, and clients of prostitutes are at a very high risk for infection. Sexual partners of infected individuals are at high risk for infection, even in the absence of high-risk behavior. Studies of household of the infected and sexual contacts have reported that 0% to 3% of the spouses or sexual partners and 4% to 9% of the children are HBsAg positive. Because most patients with chronic HBV infection are unaware of their infection and are "silent carriers," sexual transmission is likely to be a significant mode of worldwide transmission. The use of condoms appears to reduce the risk of sexual transmission.^{73,78-80}

From 1980 to 1985, a very high rate of HBV infection was observed in homosexual men, accounting for 20% of all reported cases of infection.^{73,78-80} Multiple sexual partners, anal-receptive intercourse, and duration of sexual activity were the most common factors associated with HBV acquisition in this population. Current rates of HBV infection in this population have fallen and are estimated to be about 8%, possibly as a result of modifications of sexual behavior in response to HIV. Similar to heterosexuals, the use of condoms in this population may also reduce the risk of sexual transmission.

Blood and Blood Products

Previously, blood was not screened for HBV; by the early 1970s, however, this risk of transmission was significantly reduced through screening of blood (used for transfusions) and blood products before their administration.^{73,78-80} Although

the risk of transfusion-associated HBV infection has been greatly reduced with the screening of blood (tests for HBsAg and anti-HB core) and the exclusion of donors who engage in high-risk activities, it is estimated that 1 out of 50,000 transfused units transmit HBV infection.^{73,78–80}

Perinatal Transmission

Early childhood exposure and perinatal exposure are additional modes of transmission of HBV infection.^{73,78–80} High serum concentrations of virus have been linked with increased risk of transmission by vertical routes (and needlestick exposure). Infants born to HBeAg-positive mothers with high viral replication (>80 pg/mL) have a 70% to 90% risk of perinatal HBV acquisition compared with a 10% to 40% risk in infants born to mothers infected with HBV who are HBeAg-negative. Infection generally occurs via inoculation of the infant at the time of birth or soon thereafter and, even with active and passive immunization, 10% to 15% of babies may acquire HBV infection at birth.

In developing countries with high prevalence rates and in regions of the United States with high endemicity, children born to HBsAg-positive mothers with HBV are at risk for acquiring HBV infection in the perinatal period, with infection rates reported to be between 7% and 13%.^{73,78–80} In addition, children of HBsAg-positive mothers who are not infected at birth remain at very high risk of early childhood infection, with 60% of those born to HBsAg-positive mothers becoming infected by the age of 5 years. The mechanism of the later infection, which is neither perinatal nor sexual, is not known, however. Furthermore, although HBsAg is detectable in breast milk, breast-feeding is not believed to be a primary mode of HBV transmission.

Injection Drug Use

Recreational drug use in the United States and Europe is an important mode of HBV transmission, accounting for approximately 23% of all patients.^{73,78–80} The risk of HBV infection increases with duration of recreational drug use; thus, serologic markers of ongoing or prior HBV infection are usually present after 5 years of drug use.

Other Modes of Transmission

Other risk factors for transmission of HBV include working in a health care setting, transfusion and dialysis, acupuncture, tattooing, traveling abroad, and living in institutions.^{73,78–80} Sporadic cases of HBV transmission have been attributed to nonpercutaneous transmission by way of small breaks in the skin, biting, or mucous membranes. Although HBsAg is found in saliva, tears, sweat, semen, vaginal secretions, breast milk, cerebrospinal fluid, ascites, pleural fluid, synovial fluid, gastric juice, urine, and, rarely, feces of HBsAg-positive persons, only

semen, saliva, and serum actually contain infectious HBV in experimental transmission studies. Thus, kissing is not considered to be a significant means of HBV transmission, but biting could be.

Pathogenesis

Similar to HAV infection, clinical observations suggest that host immune responses are more important than virologic factors in the pathogenesis of liver injury.^{71,73,78,82,83} Host cellular and humoral immune responses are linked to T lymphocytes, which enhance viral clearance from hepatocytes and cause liver injury.^{71,73,78,82,83}

Diagnosis

The presence of HBsAg in serum is diagnostic for HBV infection. In 5% to 10% of acute cases in which the HBsAg levels fall below sensitivity thresholds of current assays, the presence of IgM anti-HBc in serum confirms a recent acute hepatitis B infection. Another highly reliable marker of active HBV replication and diagnosis is the presence of HBV DNA in serum through qualitative or quantitative assays, detectable early during the course of acute HBV infection.^{71,73,78,84,85} Persisting levels of HBV DNA indicate ongoing infection and a high degree of active viral replication and infectivity.

Diagnostic methods for HBV DNA have expanded in recent years.^{71,73,78,86,87} Tests detecting HBV DNA can be classified as (a) dependent on hybridization of labeled probe to the DNA with quantification (Genostics assay; branched-DNA [bDNA]) and (b) PCR-based assays in which viral DNA is amplified with detection through gel electrophoresis. Genostics and bDNA are moderately sensitive in detecting DNA in HBsAg-negative and HBeAg-positive patients and they have high specificity. Values obtained by these assays are not interchangeable and are used primarily as research tools. In general the non-PCR-based assays are available with levels of sensitivity from 10^3 to 10^5 genomic copies/mL of serum. Their results usually correlate with clinical response to antiviral therapy. Because of their many limitations, most clinical laboratories use one of many commercially available PCR assays with enhanced sensitivity (10^2 genomic copies/mL or less).

Serology

Serologic patterns, general definitions, and diagnostic criteria of HBV infection are depicted in Table 73-6. Within the first several weeks after exposure (range, 2–10 weeks), HBsAg appears in the blood and is present for several weeks before serum concentrations of aminotransferases increase and symptoms become apparent (Fig. 73-3A).^{41,71,73,78,88,89} Clinical illness usually follows HBV exposure by 1 to 3 months. HBsAg can

Table 73-6 Common Serologic Patterns of Hepatitis B Virus Infection

(From reference 40, with permission.)

be detected in serum until the clinical illness resolves and usually becomes undetectable after 4 to 6 months. Persistence of HBsAg beyond 6 months implies progression to chronic HBV infection. The antibody to HBsAg (anti-HBs) often appears after a short “window” period during which neither HBsAg nor anti-HBs are detectable. In most patients, anti-HBs persists for years after HBV infection, conferring immunity to reinfection (Fig. 73-3A).

A soluble viral protein, HBeAg is detectable early during the acute phase of the disease and persists in chronic hepatitis B infection. HBeAg is a marker of active HBV replication, and its presence correlates with circulating HBV particles. The presence of both HBeAg and HBsAg indicates a high level of viral replication and infectivity and a need for antiviral therapy. Generally, seroconversion from HBeAg to hepatitis B envelope antibody (anti-HBe) results in a reduction in HBV DNA and

suggests resolution of HBV infection. Some patients may, however, continue to have active liver disease and detectable serum HBV DNA levels as a result of the presence of wild-type virus or the presence of precore or promoter mutations that impair HBeAg secretion (HBeAg-negative patients).

Hepatitis B core antigen does not circulate freely in the bloodstream and is not measured. Anti-HBc, the antibody directed against HBcAg, is usually detected 1 to 2 weeks after the appearance of HBsAg and just before the onset of clinical symptoms, and it persists for life. The detection of IgM anti-HBc is the most sensitive diagnostic test for acute HBV infection. During the recovery phase of infection, the predominant form of anti-HBc is in the IgG class. The presence of this antibody suggests prior or ongoing infection with HBV. Furthermore, in areas where HBV is not endemic, isolated detection of anti-HBc in a patient's serum may correlate with low levels of HBV DNA. The presence of HBV DNA may enhance the risk of transmission of HBV and progression to cirrhosis and hepatocellular carcinoma. Patients immunized against HBV do not develop anti-HBc; therefore, the presence of this antibody differentiates successful vaccination from actual HBV infection.

Natural History

Of those patients with acute HBV infection, only 1% develops fulminant hepatic failure (FHF).^{35,71,73,90} These patients generally have coagulopathy, encephalopathy, and cerebral edema.^{35,90} The cause of fulminant infection is a heightened immune response to the virus, provided that HDV or HCV coinfections are ruled out. Patients with acute liver failure often have early clearance of HBsAg, which may complicate the diagnosis, but a positive IgM antibody to HBcAg generally confirms the diagnosis.

Generally, four phases of HBV infection can be determined: immune tolerance, immune clearance, low level replication or nonreplication phase (inactive carrier), and reactivation phase. Up to 12% (average 5%) of immunocompetent patients acutely infected with HBV remain chronically infected (historically defined as detectable HBsAg in serum for 6 months or longer) (Fig. 73-3B).^{71,78,90,91} In these patients, HBsAg generally remains detectable indefinitely and anti-HBs fails to appear. The risk of chronicity following neonatally acquired infection is high (>90%), possibly because neonates have immature immune systems. Of infected neonates, 50% have evidence of active viral replication. Furthermore, patients who have a reduced ability to clear viral infections—including those receiving chronic hemodialysis, immunosuppression following transplantation, chemotherapy, or patients with HIV infection—may have a greater risk for developing chronic HBV infection.^{71,92} The outcomes of these patients are mainly determined by the presence or absence of viral replication and by the severity of liver damage.^{92,93} Approximately 50% of all chronic carriers have ongoing viral replication, especially with elevated aminotransferases, and 15% to 20% of these develop cirrhosis within 5 years.^{71,78,92,93} Spontaneous loss of HBeAg (7%–20%/year) has been reported, possibly as a result of the use of antiviral therapy, whereas loss of HBsAg occurs less frequently (1%–2%/year). In general, chronic carriers remain infected throughout their entire life.^{41,88,89} In one study, the 5-year survival rate was 97% in patients with early histologic changes, including chronic persistent hepatitis (in

which inflammation is limited to the portal areas), compared with 86% in patients with chronic active hepatitis (in which liver cell necrosis and inflammation are present in the hepatic parenchyma) and 55% in patients with documented cirrhosis.⁹⁴ Asymptomatic HBV carriers tend to have mild disease manifestations with few complications, even with a long period of follow-up. Finally, the risk of hepatocellular carcinoma (HCC) is increased up to 300 times in chronic carriers with active viral replication (HBeAg-positive).^{95,96}

Clinical Manifestations

6. W.H. is a 35-year-old man who developed nausea, vomiting, anorexia, scleral icterus, and jaundice within the past month. Within the past week he became increasingly lethargic, confused, disoriented, and lapsed into a coma. He is admitted to the ED, intubated, and transferred to the intensive care unit (ICU).

W.H.'s social history is significant for IV drug use for the past 10 years and alcohol abuse (none for the previous 5 years). Physical findings include an older-than-age-appearing, hypertensive (blood pressure [BP], 158/99 mmHg), bradycardic (heart rate [HR], 58 beats/minute) man in respiratory distress (respiratory rate [RR], 26 breaths/minute) with severe jaundice, scleral icterus, and decreased hepatic dullness to percussion (reduced hepatic mass). He shows sluggish pupillary response and increasing muscle tone; neurologic examination reveals him to be stuporous and nonarousable.

The laboratory evaluation shows the following results: Hct, 42%; Hgb, 14 g/dL; platelets, 85,000/mm³ (normal, 150,000–300,000/mm³); PT, 25.8 sec (control, 12 sec), international normalized ratio (INR), 3.8; AST, 555 U/L (normal, 5–40 U/L); ALT, 495 U/L (normal, 5–40 U/L); alkaline phosphatase, 101 U/mL (normal, 21–91 U/mL); and total bilirubin, 8.4 mg/dL (normal, 0.1–1.2 mg/dL). Hepatitis serologic tests are positive for HBsAg, HBeAg, IgM anti-HBc, and HBV DNA. IgM anti-HAV, IgM anti-HDV, and anti-HCV are negative. STAT blood gases reveal a metabolic acidosis with a compensatory respiratory alkalosis. W.H.'s serum creatinine is 1.8 mg/dL (normal, 0.5–1.2 mg/dL) with a recent reduction in urine output.

What clinical findings does W.H. have that support the diagnosis of acute hepatitis and acute liver failure?

[SI units: Hct, 0.42; Hgb, 140 g/L; AST, 555 U/L (normal, 5–40); ALT, 495 U/L (normal, 5–40); alkaline phosphatase, 101 U/L (normal, 21–91); total bilirubin, 143.6 μmol/L (normal, 1.7–20.5)]

The clinical features of acute HBV infection are similar to those described for HAV infection. W.H.'s initial symptoms included a recent history of nausea, vomiting, anorexia, scleral icterus, and jaundice. These are consistent with diagnosis of acute hepatitis B. His serologies, notably a positive IgM anti-HBc and HBV DNA, also support this diagnosis.

Acute Liver Failure

The most significant complication of acute HBV infection is acute liver failure (ALF), defined as the onset of hepatic encephalopathy within 8 weeks of the onset of symptoms (Table 73-7).^{36,73,78,90} W.H. has several symptoms consistent with ALF. These include recent onset of hepatic encephalopathy, lethargy, confusion, coma, coagulopathy, hemodynamic instability, declining liver function, and acidosis. Patients with ALF often have cerebral edema

Table 73-7 Principal Causes of Acute Liver Failure

| Cause | Agents Responsible |
|---------------------|--|
| Viral hepatitis | Hepatitis A, B, C, D, E virus |
| Toxins | Carbon tetrachloride Amanita phalloides Phosphorus |
| Vascular events | Ischemia Veno-occlusive disease Heatstroke |
| Miscellaneous | Malignant infiltration Wilson disease Acute fatty-liver of pregnancy |
| Drug-related injury | Reyes syndrome Acetaminophen Idiosyncratic |

(80% mortality rate), a complication of a disrupted blood–brain barrier that allows protein-rich fluid to cross into the extracellular spaces of the brain tissue leading to edema and increased intracranial pressure (ICP) (vasogenic model). Toxins also can induce cerebral damage, edema, and subsequent increases in ICP in patients with an intact blood–brain barrier (cytotoxic model) (Table 73-7). Clinical symptoms (sluggish pupillary response and increasing muscle tone) develop when the ICP >30 mmHg.^{36,73,78,90,97–99} Cerebral edema in the confinement of the cranial vault raises the ICP, which may reduce intracerebral perfusion. The edema can result in cerebral ischemia if the cerebral-perfusion pressure (CPP) (systemic blood pressure minus ICP) is not maintained >40 mmHg.

W.H. has symptoms of cerebral edema and may benefit from 100 to 200 mL of a 20% solution of mannitol (0.3–0.4 g/kg) administered by rapid IV infusion to induce an osmotic diuresis with a subsequent decrease in ICP. The dose may be repeated at least once after several hours.^{36,73,78,98,99} Because W.H. also has a BP of 158/99 mmHg, a HR of 58 beats/minute, and is at risk for intracranial hemorrhage, an ICP monitoring device should be placed.^{36,90,100,101} Although placement of this device is invasive, and bleeding is a potential complication, ICP monitoring devices provide important prognostic information. Patients with a CPP >40 mmHg that is refractory to mannitol therapy are not candidates for liver transplantation.

W.H. also has a coagulopathy typical of ALF. Decreased levels of clotting factors II, V, VII, IX, and X normally synthesized by the liver account for his prolonged PT and elevated INR.^{36,90,102} In addition, consumption of clotting factors by low-grade disseminated intravascular coagulation (DIC) is common in ALF. W.H. is also thrombocytopenic and at risk for GI ulceration.^{36,90,98} A platelet transfusion should be considered if his counts drop to <50,000/mm³. Since he is not actively bleeding, fresh frozen plasma is not indicated at this time.^{36,90,103}

W.H. also should be monitored for cardiovascular and renal abnormalities as a result of his ALF.^{36,90,98} These resemble those associated with cirrhosis and septic shock in certain respects, but differ in others. Although W.H. is hypertensive, most patients with ALF are hypotensive and hypovolemic and present with interstitial edema owing to low levels of oncotic proteins. Functional renal failure, also known as hepatorenal syndrome (HRS) or acute tubular necrosis (ATN), occurs in

43% to 55% of patients with ALF.^{36,90} In HRS, renal blood flow is reduced, renin and aldosterone levels are increased, and levels of atrial natriuretic factor are unchanged.¹⁰⁴

As seen in W.H., patients may develop acid-base disturbances, including respiratory alkalosis as a result of central nervous system (CNS)-mediated hyperventilation or a lactic acid-induced metabolic acidosis.^{36,90} Hyponatremia, hypokalemia, hypocalcemia, hypomagnesemia, hypoglycemia, and pancreatitis are additional findings associated with ALF. Thus, sodium, potassium, calcium, magnesium, blood glucose, and amylase should be monitored closely in W.H.^{36,90} Finally, pulmonary complications (hypoxemia, aspiration, adult respiratory distress syndrome [ARDS], and pulmonary edema) or sepsis (bacterial, fungal) occur in patients with ALF.^{36,90,98}

Prognosis

7. What is W.H.'s prognosis?

Although the incidence of ALF is <1%, the prognosis for these patients is poor once encephalopathy has developed.^{36,90,98,105} Survival depends on the etiology and degree of hepatic destruction, the ability of the remaining liver cells to regenerate, and the management of complications that may develop during the course of illness. Survival rates often depend on the etiology of ALF. In one series, patients with non-A, non-B hepatitis and halothane or drug hepatotoxicity had worse survival rates (20% and 12.5%, respectively) compared with those with hepatitis A, hepatitis B, or acetaminophen overdose (66.7%, 38.9%, and 52.9% survival, respectively).¹⁰⁵ Age <14 years, worsening grade of encephalopathy, reduced liver size, and significantly abnormal LFT values (e.g., serum bilirubin, aminotransferases, alkaline phosphatase, PT, and serum albumin) also are poor prognostic indicators in patients with ALF (Table 73-8).^{36,105} Because W.H. has evidence of encephalopathy, cerebral edema, and abnormal LFT values, he has a poor prognosis (Table 73-8).

Table 73-8 Criteria for Predicting Death and the Need for Liver Transplantation in Patients With Acute Liver Failure

| Cause of Acute Liver Failure | Criteria |
|------------------------------|---|
| Acetaminophen poisoning | pH <7.3 (irrespective of grade of encephalopathy) OR PT >100 sec AND Serum creatinine >3.4 mg/dL (300 μmol/L) in patients with grade III or grade IV encephalopathy |
| All other causes | PT >100 secs OR Any three of the following variables (irrespective of grade of encephalopathy): Age <10 yrs or >40 yrs; liver failure caused by non-A, non-B hepatitis, halothane-induced hepatitis, or idiosyncratic drug reactions; duration of jaundice before encephalopathy >7 days; PT >50 secs; serum bilirubin >17.5 mg/dL (300 μmol/L) |

PT, prothrombin time.
From reference 105, with permission.

Treatment

8. Outline an appropriate treatment plan for W.H.'s ALF.

The primary therapy for ALF is supportive care for the comatose patient. Systemic therapies with heparin, prostaglandin, or insulin and glucagon have shown limited efficacy.^{36,90} Blood or plasma exchange, hemodialysis, or other methods implemented to detoxify the blood or improve the coma grade do not result in long-term benefits if liver mass is not reconstituted as well. Thiopental may be useful in lowering ICP, but corticosteroids and prolonged hyperventilation are of no value.^{36,90} W.H. could benefit from prophylactic H₂-blockers because they have been shown to reduce the incidence of upper GI hemorrhage.^{36,90} Blood products (packed red blood cells, fresh frozen plasma, or platelets) should be given as needed if W.H. develops active bleeding, and pulmonary artery monitoring should be implemented to guide management of intravascular volume and gas exchange. W.H. should be closely monitored for additional complications, especially cardiac abnormalities (arrhythmias), hemodynamic changes, renal failure, acidosis, pulmonary complications, and sepsis.

In cases in which prognostic information indicates <20% chance of survival without transplantation, liver transplantation is indicated (Table 73-8). In patients with acetaminophen poisoning resulting in ALF, a pH <7.3, a PT >100 seconds and a serum creatinine >3.4 mg/dL, with grade III or IV encephalopathy usually require transplantation.^{105,106} Other causes of ALF, a PT >50 seconds, or any three of the following variables (irrespective of grade of encephalopathy): age <10 years or >40 years; liver failure caused by non-A, non-B hepatitis, halothane-induced hepatitis, or idiosyncratic drug reactions; duration of jaundice before encephalopathy >7 days or serum bilirubin >17.5 mg/dL indicate a need for transplantation.^{105,106} Several strategies to prevent death have been used before liver transplantation with some success. These include hepatic assist devices (e.g., bioartificial liver), auxiliary partial heterotopic transplants, and partial liver graft from living related donors.^{36,90}

Extrahepatic Manifestations

9. What are the extrahepatic manifestations of acute or chronic HBV infection?

Extrahepatic manifestations, such as arthralgias, rash, angioneurotic edema, and polyarteritis nodosa, have been reported in patients with acute or chronic HBV infection.^{71,78} Chronic and, to a lesser extent, acute HBV infection have been associated with immune complex-associated membranoproliferative glomerulonephritis. Neurologic complications of HBV infection include Guillain-Barré syndrome and polyneuropathy. Pericarditis and pancreatitis are infrequent complications of HBV infection. Additional complications of chronic HBV infection include portal hypertension with variceal and esophageal bleeding, encephalopathy, ascites, spontaneous bacterial peritonitis, and hepatorenal syndrome. Although HCC is not considered extrahepatic, many patients with HBV may develop HCC.^{71,78,96}

Coinfection with other viruses has been reported in patients with HBV infection. For example, markers of prior or active HBV infection are present in >80% of patients with

acquired immunodeficiency syndrome (AIDS), with approximately 10% of these cases seropositive for HBsAg.¹⁰⁷ HIV has also been reported to coexist in up to 13% of patients with chronic HBV infection.¹⁰⁸ Compared with patients with HBV infection alone, patients coinfecting with HBV and HIV have significantly higher levels of viral replication, lower ALT levels, and less severe histologic disease. HBV infection does not reduce survival in HIV-positive patients; however, because these patients live longer, hepatic decompensation and manifestations of HBV may occur.

Prevention of Hepatitis B

Comprehensive strategies should be implemented to prevent and maintain protection against HBV infection and should be widely available to eliminate transmission that occurs during infancy and childhood as well as during adolescence and adulthood. Thus, alterations in sexual behavior, screening of high-risk patients or settings (e.g., STD and HIV testing and treatment facilities, drug abuse treatment and prevention settings, health care settings targeting services to intravenous drug users, health care settings targeting services to men having sex with men, and correctional facilities) and blood products, developing needle exchange programs, and cultural outreach and education may have an impact on HBV transmission. The goals of preventive therapy should be to identify all persons who require immunoprophylaxis for the prevention of infection and provide long-term protection through vaccination to decrease the risk of chronic HBV infection and its subsequent complications, as well as minimizing adverse effects and cost of therapy.

Pre-exposure Prophylaxis

10. P.G., a 55-year-old nursing student, is going to start her clinical rotations. She has no history of hepatitis and has not yet been immunized. She is 5 feet 2 inches and weighs 80 kg. What prophylactic regimen should P.G. receive to prevent hepatitis secondary to HBV?

The available vaccines are manufactured using recombinant DNA technology. Both Recombivax HB (10 mg HBsAg/mL) and Engerix-B (20 mg HBsAg/mL) are yeast-derived HBV vaccines that induce an immunologic response similar to the plasma-derived vaccine (no longer used). Because P.G. will come in contact with potentially infectious bodily secretions during her rotations, she should be immunized against hepatitis B with either Recombivax HB or Engerix-B.

DOSING REGIMEN

The recommended doses of available hepatitis B vaccines are shown in Table 73-9.¹⁰⁹⁻¹¹¹ The preferred vaccination schedule uses a three-dose regimen. The first dose is followed 1 month later by a second dose, and the third dose is administered 6 months after the initial dose. The first two doses function as priming doses, inducing antibody to HB surface antigen (anti-HBs) in >85% of healthy persons. The third dose serves as a booster dose, significantly increasing the anti-HBs titer and conferring optimal protection (>90%). The third dose can be administered up to 12 months after the initial dose with comparable efficacy. A four-dose series has been approved for high-risk patients in whom rapid protection is desired. If this schedule is followed, the fourth dose at 12 months is necessary to ensure protective antibody titers.

Table 73-9 Recommended Doses of Currently Licensed Hepatitis B Vaccines^a

| Group | Recombivax HB | | Engerix-B | |
|--|-----------------|-------|-----------------|-------|
| | Dose (μ g) | (mL) | Dose (μ g) | (mL) |
| Birth to 10 yrs | — | — | 10 | (0.5) |
| Birth to 19 yrs | 5 | (0.5) | — | — |
| Children and adolescents 11–19 yrs | — | — | 10 | (0.5) |
| Adolescents 11–15 yrs ^b | 10 | (1.0) | — | — |
| Adults >20 yrs | 10 | (1.0) | 20 | (1.0) |
| Dialysis patients and other immunocompromised hosts | 40 | (1.0) | 40 ^c | (2.0) |

^aOne dose administered three times: at time 0, 1 month, and 6 months.

^bOne dose administered: two times 0 and 4–6 months.

^cTwo 1.0-mL doses administered at one site, in a four-dose schedule at 0, 1, 2, and 6 months.

From references 109–111, with permission.

The recommended doses for the yeast-derived recombinant hepatitis B vaccines were based on dose-response studies that determined the optimal dose necessary to achieve protective antibody titers. Dose-response studies with Recombivax HB in healthy adults using 1.25, 2.5, 5, 10, and 20 mcg of HBsAg all elicited an immune response. Those patients receiving the 10- or 20-mcg dose developed substantially higher antibody titers than those receiving lower doses. No significant difference was observed between the 10- and 20-mcg dose; thus, the 10-mcg dose was selected as the standard adult dose of Recombivax HB. Similar analyses were performed to determine the 5-mcg adolescent and pediatric dosage. Dose-response trials with Engerix-B demonstrated an optimal immune response at higher dosages. The reason for the differing doses necessary to elicit an adequate immune response is unknown. Some have speculated that differences in the manufacturing process (yeast culture, purification methods) may influence the immunogenicity of the final product. For this reason, hepatitis B vaccines produced by different manufacturers may not be equally immunogenic on a microgram-for-microgram basis.¹¹² Relative potency comparisons are not clinically important because comparative trials using Recombivax HB and Engerix-B in the recommended dosages have demonstrated equivalent immunogenicity and tolerability. P.G. can be immunized with either product, provided she receives the manufacturer's recommended dosage with each injection.

Hepatitis B vaccine should be administered as an IM injection in the deltoid muscle of adults and children or in the anterolateral thigh muscle of neonates and infants. The immunogenicity of hepatitis B vaccine is significantly lower when injections are given in the buttocks, probably because the greater amount of fat tissue in the buttocks inhibits interfacing of vaccine and antigen-recognition leukocytes. The results of a small vaccination series suggest that healthy adults who do not respond to HBV injection to the buttocks have a significantly higher response when vaccinated in the arm. P.G. should be immunized with either Recombivax HB (10 mcg) or Engerix-B (20 mcg) administered as a 1-mL IM injection in the deltoid muscle.

EFFICACY

Recombinant yeast-derived vaccines (e.g., Recombivax HB, Engerix-B) produce similar results.¹¹³ Although a measurable immune response is readily achieved with the current HBV vaccine, a quantitative titer of circulating anti-HBs necessary to prevent infection has not been clearly substantiated. A protective antibody response has been defined as anti-HBs levels ≥ 10 mIU/mL.¹¹¹ This threshold was derived from early HBV vaccine trials in homosexual men, where vaccine recipients with serum antibody levels ≥ 10 sample ratio units (SRU) were protected from HBV infection.^{114–117} A serum antibody level of 10 SRU is roughly equivalent to 10 mIU/mL when the international standard is used. For this reason, an anti-HBs level of ≥ 10 mIU/mL is considered a protective antibody titer and is the standard used by the US ACIP. Although HBV infections have occurred in vaccine recipients with a detectable immune response, almost all infections have been asymptomatic, identified only through the presence of anti-HBc. These infections have been limited largely to patients with no response or a poor response to vaccination.¹¹⁶

NONRESPONDERS

11. P.G. has completed her three-dose vaccination series with Engerix-B. Routine hepatitis serology testing, performed before volunteering for a drug study, reveals that P.G. is anti-HBs negative. Why did P.G. not respond to the hepatitis B vaccine, and how should she be managed?

Two important determinants of vaccine efficacy appear to be the age at vaccination and underlying immune function. In healthy recipients, the immune response to vaccination decreases with advancing age. In one study, 99% of patients age 0 to 19 years, 93% of those age 20 to 49 years, and 73% of those >50 years of age achieved protective anti-HBs levels (>10 SRU) after three doses of the hepatitis B vaccine.¹¹⁸ Immunocompromised patients, including those receiving hemodialysis,¹¹⁹ those infected with HIV,¹²⁰ or children receiving cytotoxic chemotherapy,¹²¹ respond poorly to the HBV vaccine. Patients who smoke^{122–124} or are obese^{122,123} also have a reduced response. P.G. has two risk factors for a poor response to the hepatitis B vaccine: she is >50 years of age and she is moderately obese (ideal body weight for her height is 50 kg).

Vaccine recipients who respond poorly to hepatitis B vaccine have been classified either as hyporesponders who can probably be protected by additional doses of vaccine or as true nonresponders. Patients with inadequate initial response to the HBV vaccine series should be revaccinated. Of hyporesponders (anti-HBs levels <10 mIU/mL), 50% to 90% develop a protective level following a single booster injection^{125,126} or after repeating the entire three-dose series.^{121,129} Of patients not responding to a primary vaccination series with Engerix B, 60% produced an immune response after a three-dose series with HBVax II (Recombivax), suggesting a repeat course with the alternative HBV vaccine may be a reasonable approach in some patients.¹²⁷ Revaccination of nonresponders (no detectable anti-HBs) is less successful, and protective levels, if achieved, are not sustained.¹²⁸ True nonresponders to HBV vaccination are rare in the immunocompetent population, and these persons may have a genetic predisposition

toward nonresponsiveness.¹²⁹ P.G. should be revaccinated with a booster dose of hepatitis B vaccine. Her anti-HBs levels can be rechecked 1 month after the injection. If she still has not responded, it is reasonable to administer an additional two injections to complete a second vaccination series.

INTERCHANGEABILITY OF HBV VACCINES

12. T.M., a 32-year-old hospital laboratory technician, received the first two doses of hepatitis B vaccine with Recombivax HB. He has relocated recently and is due for the third injection. The employee health service at his new job uses only Engerix-B for hepatitis B vaccination. Can hepatitis B vaccines produced by different manufacturers be used interchangeably?

Although it is recommended that patients receive the complete vaccination series with the same product, data suggest this is not absolutely necessary to induce a protective antibody titer. In a study to determine whether a hepatitis B vaccination series initiated with Recombivax HB could be completed with Engerix-B, healthy adults received 10 mcg of Recombivax HB at baseline and 1 month. At 6 months, the subjects were randomized to receive either Engerix-B 20 mcg or Recombivax HB 10 mcg. One month after the third dose, 100% of those who had received Engerix-B and 92% of those who had received Recombivax HB had protective anti-HBs levels.¹³⁰

Chan et al.¹³¹ studied the booster response to either recombinant hepatitis B vaccine or plasma-derived vaccine in children who had been vaccinated originally with the plasma-derived product (Heptavax-B). Children were randomized to either 5 mcg of the plasma-derived vaccine or 20 mcg of Engerix-B. One month after the booster injection, all vaccine recipients had significant elevations in their anti-HBs titers, suggesting recombinant hepatitis B vaccines elicit an adequate booster response in persons who originally received the plasma-derived vaccine.¹³¹ According to the ACIP, the immune response from one or two doses of a vaccine produced by one manufacturer, when followed by subsequent doses from a different manufacturer, is comparable with that resulting from a full course of vaccination with a single vaccine.¹¹¹

T.M. may complete the hepatitis B vaccine series with Engerix-B provided he receives the recommended dosage of 20 mcg administered as a 1-mL IM injection to the deltoid region. This dose will significantly increase his circulating anti-HBs titer, thus conferring optimal protection from HBV infection.

DURATION OF RESPONSE

13. Does T.M. require a booster injection for sustained protection from HBV infection?

The duration of vaccine-induced immunity has been evaluated in many long-term studies.^{117,132-139} The duration of detectable anti-HBs appears proportional to the peak antibody response achieved after vaccination, and protective anti-HBs levels were sustained in 68% to 85% of patients receiving the plasma-derived HBV vaccine in studies with follow-up ranging from 6 to 12 years.¹³²⁻¹³⁶ Importantly, the protective efficacy of the HBV vaccine in these trials was high, even in patients with anti-HBs levels <10 mIU/mL. HBsAg was only rarely detected and most HBV events consisted of asymptomatic seroconver-

sion to anti-HBc. These studies suggest that successful HBV vaccination is associated with long-lasting protection without the need for additional booster doses for up to 12 years.

The mechanism of sustained protection from HBV, despite low or nondetectable anti-HBs levels, is thought to be related to the phenomenon of immunologic memory in previously sensitized B lymphocytes. This amnestic response, in combination with the long incubation period of HBV, may allow the synthesis of protective antibodies sufficiently quickly to block infection in patients rechallenged with HBV.¹⁴⁰

In summary, no need exists for routine administration of HBV vaccine booster doses to immunocompetent persons following successful vaccination. Immunocompromised patients may require a persistent minimal level of protective antibody, and the ACIP does recommend annual antibody testing for patients receiving chronic hemodialysis with administration of a booster dose when antibody levels are <10 mIU/mL.¹¹¹ Based on available evidence, T.M. does not require a scheduled booster dose of hepatitis B vaccine.

INDICATIONS

14. Why is it appropriate for T.M. to be vaccinated with hepatitis B vaccine, and who else should be vaccinated with this vaccine?

The ACIP has recommended pre-exposure hepatitis B vaccination for the following high-risk groups: health care workers with exposure to blood, staff of institutions for the developmentally disabled, hemodialysis patients, recipients of blood products, household and sexual contacts of HBV carriers, international travelers to HBV-endemic areas, injecting drug users, sexually active homosexual men, bisexual men, and inmates of long-term correctional facilities.¹¹¹ Because T.M. is a hospital laboratory technician, he is at high risk for exposure to hepatitis B and should be vaccinated.

UNIVERSAL HEPATITIS B VACCINATION

In addition to the previously listed high-risk groups, all infants should receive hepatitis B vaccination. This recommendation is based on data suggesting the practice of vaccinating only high-risk persons had little impact on decreasing the incidence of HBV disease. Populations at risk for HBV disease (injecting drug users, persons with multiple sexual partners) generally are not vaccinated before they begin engaging in high-risk behaviors. In addition, many persons who become infected have no identifiable risk factors for infection and thus would not be recognized as candidates for vaccination. A program designed to immunize children before they initiate high-risk behaviors is likely to have a greater impact in reducing the incidence of HBV infection. As a means to achieve this goal, the hepatitis B vaccine now is incorporated into the existing pediatric vaccination schedule. The first dose is administered during the newborn period (preferably before the infant is discharged from the hospital) but no later than 2 months of age.¹¹¹ The recommended vaccination schedule is shown in Table 73-10.

15. R.M. is a mother of two children aged 11 years and 2 months. Her infant daughter just received a second dose of hepatitis B vaccine as part of her routine well-baby care. R.M. wonders if her son, who did not receive the hepatitis B vaccine during his normal childhood immunizations, should receive the vaccine now.

Table 73-10 Recommended Schedules of Hepatitis B Vaccination for Infants Born to HBsAg (–) Mothers

| Hepatitis B Vaccine | Age of Infant |
|---------------------|-----------------------------------|
| Option 1 | |
| Dose 1 | Birth (before hospital discharge) |
| Dose 2 | 1–2 mos ^a |
| Dose 3 | 6–18 mos ^a |
| Option 2 | |
| Dose 1 | 1–2 mos ^a |
| Dose 2 | 4 mos ^a |
| Dose 3 | 6–18 mos ^a |

^aHepatitis B vaccine can be administered simultaneously with diphtheria-tetanus-pertussis, *Haemophilus influenzae* type b conjugate, measles-mumps-rubella, and oral polio vaccines.
From reference 111, with permission.

The Centers for Disease Control and Prevention (CDC) has addressed the issue of immunizing children and adolescents born before 1991 who are potentially at risk for hepatitis B infection. The current recommendations suggest that adolescents who have not received three doses of hepatitis B vaccine should initiate or complete the series at ages 11 to 15 years. A schedule of 0, 1 to 2, and 4 to 6 months is recommended.¹⁴¹ It is anticipated that universal vaccination of all infants and previously unvaccinated adolescents aged 11 to 12 years, in addition to ongoing immunization of high-risk persons, will reduce the incidence of acute hepatitis B infection, hepatitis B-associated chronic liver disease, and HCC. R.M.'s son should receive either Recombivax HB 5 mcg or Engerix-B 10 mcg as an IM in the deltoid with repeat doses 1 to 2 months and 4 to 6 months from the initial injection.

ADVERSE EFFECTS

Hepatitis B virus vaccination generally has been well-tolerated. The most common side effect is pain at the injection site, observed in 3% to 29% of patients. Transient febrile reactions (defined as temperature >99.9°F) occur in <6% of recipients, and other reactions, including nausea, rash, headache, myalgias, and arthralgias, are observed in <1% of recipients. Ongoing monitoring of vaccine safety by the FDA and CDC is assessed through the Vaccine Safety Datalink (VSD) project and Vaccine Adverse Events Reporting System (VAERS). On the basis of these reporting systems, additional "causal" adverse effects associated with vaccination include anaphylaxis (1 case per 1.1 million vaccine doses), Guillain-Barré syndrome, and multiple sclerosis. Additional rare adverse events that have been reported but remain to be validated are chronic fatigue syndrome, neurologic disorders (leukoencephalitis, optic neuritis, and transverse myelitis), rheumatoid arthritis, type 1 diabetes, and autoimmune disease.

Postexposure Prophylaxis PERCUTANEOUS EXPOSURE

16. K.N., a 26-year-old medical student, presents to the ED after accidentally sticking herself with a contaminated needle while drawing blood from an HBsAg-positive patient. K.N. was

Table 73-11 Guide to Postexposure Immunoprophylaxis for Exposure to Hepatitis B Virus

| Type of Exposure | Immunoprophylaxis |
|---|---------------------------------|
| Perinatal | Vaccination + HBIG ^a |
| Sexual | Vaccination + HBIG |
| Household contact | |
| Chronic carrier | Vaccination |
| Acute case | None unless known exposure |
| Acute case, known exposure | HBIG – vaccination |
| Infant (<12 months) acute case in primary caregiver | HBIG + vaccination |
| Inadvertent (percutaneous or permucosal) | Vaccination – HBIG |

^aHBIG, hepatitis B immunoglobulin.
From references 111 and 143, with permission.

not vaccinated previously and had no known prior episodes of hepatitis or liver disease. Her tetanus status is current. She weighs 56 kg. How should K.N. be treated for percutaneous exposure to hepatitis B?

Following exposure to HBV, prophylactic treatment with hepatitis B vaccination and possibly passive immunization with hepatitis B immunoglobulin (HBIG) should be considered. The ACIP recommendations for postexposure immunoprophylaxis following hepatitis B exposure are shown in Table 73-11.

K.N.'s percutaneous exposure warrants active immunization with HBV and passive immunization with HBIG. The source of K.N.'s exposure is HBsAg-positive, and K.N. had not been vaccinated previously with the hepatitis B vaccine. She should receive a single dose of HBIG 0.06 mL/kg (3.4 mL) as an IM injection in either the gluteal or deltoid region as soon as possible after exposure, preferably within 24 hours. HBIG is prepared from plasma of persons preselected for high titer anti-HBs. The anti-HBs of HBIG in the United States is 1:100,000 as determined by radioimmunoassay. HBIG is superior to immunoglobulin in the prevention of hepatitis B infection following percutaneous exposure. K.N. also should receive active immunization with IM hepatitis B vaccine (at a separate site) simultaneously with HBIG. The second and third doses should be given 1 month and 6 months later. Passively acquired antibodies against hepatitis B virus from HBIG or immunoglobulin will not interfere with active immunization via hepatitis B vaccine.¹⁴²

If the HBsAg status of the donor source of a percutaneous exposure is unknown, recommendations for prophylaxis of HBV infection depend on whether the donor source is at high risk or at low risk for being HBsAg-positive. High-risk donor sources include homosexual men, IV drug abusers, patients undergoing hemodialysis, residents of mental institutions, immigrants from endemic areas, and household contacts of HBV carriers. Additional ACIP recommendations for hepatitis B prophylaxis following percutaneous exposure are shown in Table 73-12.

SEXUAL EXPOSURE

17. What are the current recommendations for a person who has had sexual contact with an HBsAg-positive person?

Table 73-12 Recommendations for Hepatitis B Prophylaxis Following Percutaneous Exposure¹¹¹

| Exposed Person | Treatment When Source Is Found to Be | | |
|-----------------------|--|---|---|
| | HBsAg-Positive | HBsAg-Negative | Unknown or Not Tested |
| Unvaccinated | Administer HBIG × 1 ^a and initiate hepatitis vaccine | Initiate hepatitis B vaccine ^b | Initiate hepatitis B vaccine ^b |
| Previously vaccinated | | | |
| Known responder | Test exposed person for anti-HBs ^c 1. If inadequate, hepatitis B vaccine booster dose 2. If adequate, no treatment | No treatment | No treatment |
| Known responder | HBIG × 1 ^a as soon as possible, repeat in 1 month OR HBIG × 1 ^a plus one dose of hepatitis B vaccine | No treatment | If known high-risk source, may treat as if source were HBsAg positive |
| Response unknown | Test exposed person for anti-HBs ^c 1. If inadequate, HBIG × 1 ^a plus hepatitis B vaccine booster dose 2. If adequate, no treatment | No treatment | Test exposed person for anti-HBs ^c 1. If inadequate, hepatitis B vaccine booster dose 2. If adequate, no treatment |

^aHBIG dose 0.06 mL/kg given intramuscular (IM).

^bFor dosing information, see Table 73-9.

^cAdequate anti-HBs is ≥10 mIU.

HBIG, hepatitis B immunoglobulin.

Sexual transmission of hepatitis B is an important cause of HBV infection, accounting for approximately 30% to 60% of all new cases annually.¹⁴³ Passive immunization with a single 5-mL dose of HBIG was found highly effective in preventing hepatitis B infection following sexual exposure when compared with a control globulin (with no anti-HBs activity).¹⁴⁴ The CDC recommends that susceptible persons exposed to HBV through sexual contact with a person who has acute or chronic HBV infection should receive postexposure prophylaxis with 0.06 mL/kg of HBIG as a single IM dose within 14 days of the last exposure. Patients also should receive the standard three-dose immunization series with hepatitis B vaccine beginning at the time of HBIG administration.¹⁴³

PERINATAL EXPOSURE

18. S.L., a 3.2-kg boy, was just born to an HBsAg-positive mother. Is S.L. at risk for acquiring HBV infection, and how should he be treated?

In many Asian and developing countries, perinatal (vertical) transmission accounts for most hepatitis B infections. Infants born to HBV-infected mothers have a >85% risk of acquiring HBV during the perinatal period. Of those who become infected, 80% to 90% become chronic HBsAg carriers.¹⁴⁵⁻¹⁴⁷ Although fulminant cases have been reported, most hepatitis infections in neonates are asymptomatic. Despite the usually innocuous initial disease, significant adverse consequences are associated with chronic HBsAg carriage in neonates. Chronic hepatitis B infection is associated with chronic liver disease and has been clearly implicated as a major risk factor in the development of primary HCC.^{148,149}

Mothers who are chronic carriers of hepatitis B, although not acutely infected, pose the risk of transmitting the hepatitis B virus to their infants. The risk is related to the presence of HBsAg and HBeAg (suggesting a high degree of viral replication and infectivity). The likelihood that S.L. will develop HBV infection is high. S.L. requires immediate therapy with HBIG (to provide immediate high titers of circulating anti-

HBs) and simultaneous vaccination with hepatitis B vaccine (to induce long-lasting protective immunity). Screening pregnant women for the presence of HBeAg and administration of HBIG and hepatitis B vaccine is 85% to 98% effective in preventing HBV infection and the chronic carrier state.^{145,147,150} This compares with a 71% efficacy rate for administration of HBIG alone. Simultaneous administration of HBIG and hepatitis B vaccine does not adversely affect the production of anti-HBs in neonates.^{145,147}

Infants born to mothers who are HBsAg positive should receive simultaneous IM injections of the appropriate doses of hepatitis B vaccine (Table 73-9) and HBIG (0.5 mL) within 12 hours of birth. The injections should be administered at separate sites. S.L. should receive HBIG (0.5 mL) as soon as possible after birth, administered as an IM injection. He also should receive 0.5 mL of either Recombivax HB (5 mcg) or Engerix-B (10 mcg) as an IM injection at a separate site.

19. What would the management plan be if the HBsAg status of S.L.'s mother was unknown?

The ACIP has developed recommendations for the prevention of perinatal HBV infection. This includes the routine testing of all pregnant women for HBsAg during an early prenatal visit. HBsAg testing should be repeated late in the pregnancy for women who are HBsAg-negative but who are at high risk of HBV infection or who have had clinically apparent hepatitis. Women admitted for delivery who have not had prenatal HBsAg testing should have blood drawn for testing. While test results are pending, the infant should receive hepatitis B vaccine within 12 hours of birth (Table 73-9). If the mother is found later to be HBsAg-positive, her infant should receive HBIG as soon as possible within 7 days of birth. The second and third doses of vaccine should be administered at 1 and 6 months, respectively. If the mother is found to be HBsAg-negative, her infant should continue to receive hepatitis B vaccine as part of the routine vaccination series.¹¹¹

Evaluation and Management of Patients with Chronic HBV Infection

20. E.A. is a 55-year-old woman who presents to the hepatology clinic with a recent history of mild jaundice. Her previous medical history is unremarkable except for a blood transfusion she received during child birth in 1988. What initial and follow-up tests should be performed to assess the extent of HBV infection in E.A.?

The evaluation of patients infected with chronic HBV is described in Table 73-13. Initially, a thorough history and physical examination should be performed with greater emphasis placed on risk factors for coinfection, alcohol use, and family history of HBV and liver cancer. Laboratory tests should include assessment of liver disease, markers of HBV replication, and screening tests for HCV, HDV, or HIV. Vaccinations for hepatitis A should also be administered as described above. The decision to perform a liver biopsy should be made based on knowledge of a patient's age, the ALT level, HBeAg status, HBV DNA levels, and additional clinical features suggestive of chronic liver disease or portal hypertension. In patients who are not initially considered for treatment (inactive HBV carriers), an algorithm for follow-up based on HBeAg status is

Table 73-13 Evaluation of Patients With Chronic Hepatitis B

Initial evaluation

History and physical examination

Family history of liver disease, hepatocellular carcinoma
Laboratory tests to assess liver disease (CBC, platelets, ALT, AST, bilirubin, prothrombin time/INR) and biopsy
Tests for HBV replication (HBeAg/anti-HBe, HBV DNA)
Tests to rule out coinfection (anti-HCV, anti-HDV, anti-HIV)
Tests to screen for HCC (AFP, and ultrasound for high-risk patients)

Suggested followup for patients not considered for treatment (HBeAg +, HBV DNA >20,000 IU/mL and normal ALT)

ALT every 3–6 months, increasing frequency if ALT becomes elevated.
If ALT > 2 × ULN, recheck ALT every 1 to 3 months; consider liver biopsy if age >40, ALT borderline or mildly elevated on serial tests.
Consider treatment if biopsy shows moderate or severe inflammation or significant fibrosis.
If ALT >2 × ULN for 3–6 months and HBeAg+, HBV DNA >20,000 IU/mL, consider liver biopsy and treatment.
Consider screening for HCC in relevant population.

Inactive HBsAg carrier

ALT every 3 months for 1 year, if persistently normal, ALT every 6–12 months
If ALT >1 to 2 × ULN, check serum HBV DNA level and exclude other causes of liver disease. Consider liver biopsy if ALT borderline or mildly elevated in serial tests or if HBV DNA persistently >20,000 IU/mL. Consider treatment if biopsy shows moderate or severe inflammation or significant fibrosis.
Consider screening for HCC in relevant population.

ALT, alanine aminotransferase; AFP, α -fetoprotein; AST, aspartate aminotransferase; CBC, complete blood count; HCC, hepatocellular carcinoma; INR, international normalized ratio; ULN, upper limit of normal
From references 72, 73, with permission.

described in Table 73-13. Periodic screening for HCC should also be performed in high-risk populations such as Asian men >40 and Asian women >50 years of age, persons with cirrhosis, persons with a family history of HCC, blacks >20 years of age, and any carrier >40 years of age with persistent or intermittent ALT or HBV DNA elevations.

21. C.R., a 28-year-old man, presents to the ED with jaundice, complaints of incapacitating fatigue, and vague intermittent abdominal pain for the past month. C.R. was diagnosed with hepatitis B 2 years before admission. His social history includes IV drug abuse (none for 2 years) and alcohol abuse (none for 2 years). Several weeks ago, C.R. noted darkening of his urine and yellowing of his eyes.

Physical examination reveals a thin man in no apparent distress. He is afebrile, and his BP, HR, and RR are within normal limits. Moderate scleral icterus is noted. The abdomen is soft and nondistended. The liver is enlarged, nontender, and smooth with an edge palpable 5 cm below the costal margin and a span of 15 cm. The spleen is palpable. The cardiac, pulmonary, neurologic, and extremity examinations all are within normal limits.

C.R.'s laboratory evaluation is significant for Hct, 44%; Hgb, 15 g/dL; WBC count, 8.8 cells/mm³; platelets, 225,000/mm³ (normal, 150,000–300,000/mm³); PT, 15.4 sec (control, 12 sec), INR, 1.8; AST, 326 U/L (normal, 5–40 U/L); ALT, 382 U/L (normal, 5–U/L); alkaline phosphatase, 142 U/mL (normal, 21–91 U/L); total bilirubin, 4.2 mg/dL (normal, 0.1–1.2 mg/dL); and albumin, 2.8 g/dL (normal, 3.5–4.5 g/dL). Hepatitis serologic tests are positive for HBsAg, HBeAg, and anti-HBc and negative for IgM anti-HBc, IgM anti-HAV, and anti-HCV. HBV DNA is reported as <200 pg/mL. A liver biopsy reveals periportal inflammation as well as piecemeal and bridging necrosis. What clinical findings does C.R. have that support the diagnosis of chronic hepatitis B infection?

[SI units: Hct, 0.44; Hgb, 150 g/L; WBC count, 8.8 × 10³ cells/L; AST, 326 U/L (normal, 5–40); ALT, 382 U/L (normal, 5–40); alkaline phosphatase, 142 U/L (normal, 21–91); total bilirubin, 71.8 μ mol/L (normal, 1.7–20.5); albumin, 28 g/L (normal, 35–45)]

The chronic occurrence of jaundice and hepatosplenomegaly with significantly elevated AST and ALT in a young patient such as C.R. is suggestive of chronic hepatitis. Although alcoholic hepatitis secondary to long-term alcohol abuse is consistent with these clinical features, his serologic tests are positive for HBV. Hepatitis serology with positive HBsAg and HBeAg suggest ongoing viral replication and a high degree of infectivity.

Serum concentrations of aminotransferases can range from slightly abnormal to greatly elevated, with ALT concentrations generally greater than AST. Serum bilirubin concentrations >3.0 mg/dL are common, serum concentration of alkaline phosphatase usually is increased, and the PT may be prolonged. Patients such as C.R. with a prolonged PT and low serum albumin concentration generally have a more severe form of chronic hepatitis.

Liver biopsy is important for the diagnosis, treatment, and prognosis of patients with chronic hepatitis. C.R.'s liver biopsy reveals the classic triad of periportal inflammation as well as piecemeal and bridging necrosis. The liver biopsy and hepatitis serologic test results are consistent with a diagnosis of chronic hepatitis B infection.

Treatment of chronic HBV infection requires knowledge of the natural history of the untreated disease and the potential benefits of intervention. Currently six agents are approved by the US Food and Drug Administration (FDA) for treating chronic HBV infection.

22. Does C.R. require treatment for chronic hepatitis secondary to hepatitis B?

The decision to treat C.R. depends on the severity of symptoms, the serum biochemistries, and the liver biopsy results. C.R. has evidence of severe chronic HBV infection. He is symptomatic with jaundice, severe fatigue, and abdominal pain, and the results of his LFT and HBV DNA levels suggest his disease is advanced (decreased albumin, elevated PT). Therefore, he should be treated to reduce the replication of HBV, resolve the hepatocellular damage, and prevent long-term adverse hepatic sequelae.

Goals of Therapy

23. What are the goals of therapy for chronic hepatitis secondary to HBV?

Progression of chronic hepatitis to cirrhosis is thought to be related to continued replication of the hepatitis B virus. Loss of active viral replication usually is associated with a decrease in infectivity, a reduction in inflammatory cells within the liver, and a fall of serum aminotransferase activities into the normal range. The disappearance of detectable HBeAg and HBV DNA is considered an indicator of loss of active viral replication.

The goals of therapy in chronic HBV infection are to achieve sustained suppression of HBV replication and remission of liver disease.^{72,73} Ultimately, achieving these goals should lead to resolving ongoing hepatocellular damage and reducing the development of cirrhosis and HCC.^{72,73} Clinical trials for chronic HBV infection have used the following markers as endpoints for successful therapy: seroconversion from HBeAg-positive to HBeAg-negative (with appearance of anti-HBe), reductions in serum aminotransferase activity, elimination of circulating HBV DNA, and improvement in liver histology. The elimination of HBsAg (termination of HBV carrier state) has been difficult to achieve in clinical trials. Additionally, the responses to antiviral therapy of chronic HBV can be categorized as biochemical (BR), virologic (VR), or histologic (HR), and as on therapy or sustained off therapy (Table 73-14).

Drug Therapy

24. Would initiating therapy during the acute phase of the HBV infection have benefited C.R.?

Pharmacologic interventions in the management of acute hepatitis B have been disappointing. Early studies demonstrated a transient decrease in serum aminotransferase activity and bilirubin concentration associated with corticosteroids. More recent studies, however, have resulted in a higher incidence of relapse, and mortality^{152,153} in patients receiving corticosteroids. Other therapies, including Hepatitis B immunoglobulin (HBIG)¹⁵⁴ and α -interferon,¹⁵⁵ have been ineffective in managing acute viral hepatitis secondary to HBV. Nucleoside and nucleotide reverse transcriptase inhibitors reduce HBV DNA levels in patients with chronic

Table 73-14 Definition of Response to Antiviral Therapy

| Category of Response | Characteristics |
|---|--|
| Biochemical Response (BR) | Decrease in serum ALT to within the normal range |
| Virologic Relapse (VR) | Decrease in serum HBV DNA to undetectable levels by PCR assays, and loss of HBeAg in HBeAg-positive patients |
| Primary nonresponse (not applicable to IFN therapy) | Decrease in serum HBV DNA by $<2 \log_{10}$ IU/mL after at least 24 weeks of therapy |
| Virologic Relapse (VR) | Increase in serum HBV DNA of 1 \log_{10} IU/mL after discontinuation of treatment in at least two determinations more than 4 weeks apart |
| Histologic response (HR) | Decrease in histology activity index by at least 2 points and no worsening of fibrosis score compared with pretreatment liver biopsy |
| Complete response (CR) | Fulfill criteria of biochemical and virological response and loss of HBsAg |
| Time of Assessment | |
| On therapy | During therapy |
| Maintained | Persist throughout the course of treatment |
| End of treatment | At the end of a defined course of therapy |
| Off therapy | After the discontinuation of therapy |
| Sustained (SR-6) | 6 months after discontinuation of therapy |
| Sustained (SR-12) | 12 months after discontinuation of therapy |

ALT, alanine aminotransferase; IFN, interferon; PCR, polymerase chain reaction.
From references 72, 73, with permission.

disease^{71,72,74,156–165}; however, their use in acute HBV infection requires further investigation.^{156–158} Thus, administration of antivirals during the acute phase of HBV infection is not recommended in C.R.

INTERFERONS

25. What drug therapy should C.R. receive to treat chronic HBV-associated infection?

Previously, the most effective agents for treating chronic hepatitis B have been interferons,^{166,167} which appear to activate their target cells by binding to specific cell surface receptors to induce synthesis of effector proteins.^{168,169} These intracellular proteins induce the antiviral, antiproliferative, and immunomodulatory actions of the interferons. Gene expression, upregulation of NK cells, cytotoxic T cells, and macrophages are induced by interferons.^{168,169} Their antiviral activity possibly arises from their ability to abate viral entry into the host cells and modulate several steps of the viral replication cycle (e.g., viral uncoating, inhibition of messenger RNA [mRNA], and protein synthesis). Several varieties of interferons are commercially available (Table 73-15). Interferon- α 2b (Intron-A) and pegylated interferon (PegIFN- α 2a), remain the only FDA-approved interferons for the treatment of chronic HBV infection. Pegylated interferons are also used for treatment of HCV infection (see section on Hepatitis C). These agents are known to have increased serum half-life resulting in a prolonged antiviral effect, as well as less immunogenicity.

Table 73-15 Comparison of Interferons Used to Treat Viral Hepatitis

| Agent ^a | Trade | Source | Indication | Dose/Route | Comments |
|---------------------------------------|-----------|----------------|-----------------------------|-------------------------------|--|
| Interferon-α | | | | | |
| Interferon- α 2a | Roferon-A | Recombinant | HCV | 3 MU TIW IM/SC × 12 months | Most commonly used interferon for HCV |
| Interferon- α 2b | Intron-A | Recombinant | NANB/HCV | 3 MU TIW IM/SC × 6 months | Previous standard of care for HCV |
| Interferon- α n1 | NA | Lymphoblastoid | Not FDA approved for HCV | 3 MU TIW IM/SC × 12 months | Originally thought to have higher relapse rate versus recombinant interferon- α (6 months); response rate with 12 months of therapy |
| Interferon- α -con-1 | Infergen | Recombinant | HCV | 9 mcg TIW SC × 6 months | Has greater <i>in vitro</i> effects versus other interferons; proposed enhanced efficacy against HCV type 1 genotype |

^aInterferons may decrease hepatic cytochrome P450 metabolism of drugs.

NA, not applicable; NANB, non-A, non-B hepatitis; IM, intramuscular; SC, subcutaneously; TIW, three times weekly.

Efficacy

Conventional Interferon

Interferon- α is moderately effective in treating chronic hepatitis B in a small percentage of highly selected patients.^{170–174} (Table 73-16 and Table 73-17) HBeAg-positive patients with chronic HBV receiving IFN- α may experience a virologic response based on clearance of HBeAg (27%; range, 15%–41%) or HBV DNA (47%; range, 32%–79%) compared with 9% of untreated controls. Normalization of ALT values is observed in 47% of IFN- α -treated patients versus 13% in untreated controls. Clearance of HBsAg occurs in only 10% to 15% of patients after completion of therapy.^{170–174} In one long-term follow-up study of patients responding to IFN- α , delayed clearance of HBsAg was observed in 65% of patients 3 years after completion of therapy.¹⁷⁵ Relapse after successful therapy is rare. In another prospective study, 103 patients with chronic hepatitis B treated with 2 to 5 million units (MU) of IFN- α for 4 to 6 months compared with untreated patients demonstrated greater HBeAg and HBsAg clearance rates (56% versus 28% and 11.6% versus 0%, respectively; $P < 0.001$) at 5 years.¹⁷⁶ All patients with loss of HBeAg also lost HBV DNA and had newly detectable anti-HBeAg antibodies. A trend toward greater survival and fewer clinical complications was also seen in the treatment group.

Pegylated Interferon

In a recent phase III trial, results using PegIFN- α 2a 180 mcg weekly plus placebo ($n = 271$), PegIFN- α 2a 180 mcg weekly plus lamivudine 100 mg daily ($n = 271$), or lamivudine 100 mg daily ($n = 272$) for 48 weeks were compared. Patients were also followed for an additional 24 weeks after the end of therapy.¹⁷⁷ At the end of the 24-week follow-up, significantly more patients who received PegIFN monotherapy or combination therapy than those who received lamivudine monotherapy had HBeAg conversion (32% versus 19%; $P < 0.001$, and 27% versus 19%; $P = 0.02$, respectively). The use of PegIFN- α 2a (alone or in combination) also resulted in HBsAg conversion in 16 patients compared to none in the lamivudine monotherapy group ($P = 0.001$). Additionally, at the end of treatment, viral suppression was most evident in the group that received combination therapy. This trial suggests that use of PegIFN- α 2a is superior to lamivudine on the basis of HBeAg conversion, HBV DNA suppression, and HBsAg conversion. Similar results were

reported in HBeAg-positive patients receiving PegIFN- α 2b.¹⁷⁸ In the only published trial performed in 552 HBeAg-negative patients, PegIFN- α 2a 180 mcg weekly ($n = 177$) was compared with either PegIFN- α 2a 180 mcg weekly plus 100 mg lamivudine ($n = 179$) or 100 mg lamivudine alone ($n = 181$). Viral suppression was greater in the combination group, but sustained response (HBV DNA and ALT levels at week 72) was comparable in the group that received PegIFN- α 2a alone (or in combination), and superior to the lamivudine monotherapy group (15%, 16%, and 6%, respectively). Loss of HBsAg occurred in 12 patients in the pegylated interferon groups as compared with none in the lamivudine group. Ultimately, the addition of lamivudine to PegIFN did not affect post therapy response rates in this patient population.¹⁷⁹

For these reasons, a trial with IFN (including pegylated IFN) is reasonable for C.R. Long-term follow-up data are sparse in their ability to demonstrate reductions in cirrhosis or hepatocellular cancer in patients receiving IFN- α therapy. Studies comparing the outcome of responders versus nonresponders found that patients who cleared HBeAg had better overall survival and survival free of hepatic decompensation; the benefit was most pronounced in patients with cirrhosis.^{72,73}

Predictors of Response

26. Is C.R. likely to respond to IFN- α therapy?

Certain patient variables can predict the response to therapy with standard and pegylated IFN- α (Table 73-18). The most reliable predictor of a positive response to IFN- α in HBeAg-positive patients appears to be pretreatment ALT and HBV DNA levels.^{71,73,74} Patients with high pretreatment ALT levels (greater than twice the upper limit of normal) and HBV DNA levels < 200 pg/mL (roughly equivalent to 56 million copies/mL on a PCR assay) are more likely to respond to therapy than those with higher levels.^{71,73,171} In addition, data suggest that HBeAg seroconversion with IFN treatment is associated with improved survival and reduced complications. Other predictors of a positive response include a short duration of disease, negative HIV status, and a high histologic activity index (HAI) as demonstrated by liver biopsy.^{71,73,74,175} Currently, some studies also suggest that persons infected with HBV genotypes A and B respond better than those with genotypes C and D.^{72,73,178} No consistent predictor of sustained response

Table 73-16 Responses to Approved Antiviral Therapies Among Treatment-Naïve Patients with HBeAg Positive Chronic Hepatitis B

| | Standard IFN- α | Control | Lamivudine | Placebo | Adefovir | Placebo | Entecavir | Telbivudine | PegIFN- α | PegIFN- α + Lamivudine |

Table 73-18 Factors Predictive of a Sustained Response to Interferon-Alpha in Patients With Chronic Hepatitis

| |
|--|
| Chronic hepatitis B |
| Short duration of disease |
| High serum, aminotransferase concentrations ^a |
| Active liver disease with fibrosis ^a |
| Low HBV DNA concentrations |
| Wild-type (HBcAg positive) virus |
| Absence of immunosuppression |

^aOne of the most commonly associated factors with a high degree of response to therapy

in patients who are HBeAg negative exist. C.R. is a reasonable candidate for IFN- α therapy. His liver biopsy is consistent with chronic disease, he has high pretreatment aminotransferase levels, his HBV DNA is <200 pg/mL, and his duration of chronic hepatitis is short. Before initiating IFN- α , serologic testing for HIV and genotyping should be performed to assist in the evaluation of C.R.'s response to therapy (Table 73-13).

Adverse Effects

27. What adverse effects to IFN- α should be monitored in C.R.?

Adverse effects associated with standard and PegIFN- α therapy are similar and quite common (Table 73-19). These have been categorized as early side effects that rarely limit the use of IFN, and late side effects that may necessitate dose reduction or discontinuation of therapy altogether.^{72,73,167,180} The early side effects of IFN- α therapy generally appear hours after administration and resemble an influenza-like syndrome with fever, chills, anorexia, nausea, myalgias, fatigue, and headache. Virtually all patients receiving IFN- α experience these toxicities, and they tend to resolve after repeated exposure to the

drug. Administration of IFN- α at bedtime may decrease the severity of early side effects. Acetaminophen can be used to treat early side effects of IFN- α therapy, but should be limited to 2 g/day to minimize the risk of hepatotoxicity. The late side effects usually are observed after 2 weeks of therapy and are more serious. These toxicities, which limit the use of IFN- α , include worsening of the influenza-like syndrome, alopecia, bone marrow suppression, bacterial infections, thyroid dysfunction (both hypothyroidism and hyperthyroidism), and psychiatric disturbances (emotional lability: irritability, depression, anxiety, delirium, and suicidal ideation). The use of IFN- α can also cause a flare (increase) in ALT levels in 30% to 40% of patients. These flares are considered to be a favorable prognostic indicator, but they have been reported to cause hepatic decompensation, especially in cirrhotic patients. Finally, rare adverse effects, such as development of autoantibodies, retinal changes, and impaired vision, have been reported. C.R. should be questioned at each clinic visit about new or worsening symptoms as well as any changes in mood or the ability to perform daily tasks of living. Additional monitoring parameters should include a complete blood count (CBC) with differential and platelet count after weeks 1 and 2 of therapy and monthly thereafter during treatment. Thyroid function tests and screening tests for autoantibodies should also be performed following initiation of therapy.

Dosing

28. What dose of IFN- α should C.R. receive?

Standard interferon doses of 2.5 to 10 MU can be administered subcutaneously (SC) daily or three times weekly for 1 to 12 months. The manufacturer of IFN- α 2b recommends 30 to 35 MU/week, administered SC or IM as 5 MU/day or 10 MU three times weekly. For children, the dose should be 6 MU/m² SC three times a week with a maximum of 10 MU. The recommended duration of therapy for patients who are HBeAg positive is for 16 to 24 weeks. Current data suggest that patients with HBeAg-negative HBV infection should be treated for at least 12 months and possibly for 24 months to enhance the rate of sustained response.^{72,73} The recommended dose of PegIFN- α 2a, the only pegylated IFN approved for the treatment of HBV infection in the United States, is 180 mcg SC weekly for 48 weeks. It may be possible, however, to use lower dosages or shorter duration of therapy to achieve a sustained response in HBeAg-positive patients. More trials are needed to support this altered dosing regimen. Whether longer duration of treatment (> 48 weeks) is beneficial in HBeAg-negative patients remains to be determined.

Some authorities believe thrice-weekly administration of IFN- α is associated with more severe flu-like symptoms and headache when compared with daily administration. In contrast, severe bone marrow suppression tends to occur less often with thrice-weekly administration.^{180,181} Treatment questions that still need to be adequately assessed are the optimal schedule of IFN administration (daily versus every other day versus three times weekly) and the benefit of combining IFN with other antiviral agents (see below) for the treatment of HBV infection. Because C.R. is HBeAg positive, has normal WBC and platelet counts, he should initially receive either IFN- α 2b as a 5-MU SC injection daily for 16 weeks or PegIFN- α 2a 180 mcg SC weekly for 48 weeks. The SC route of administration is preferred in C.R. to decrease the possibility of hematoma

Table 73-19 Serious Adverse Events Reported With Interferon- α Therapy

| Central Nervous System | Cardiovascular |
|----------------------------|---------------------------------|
| Psychosis | Cardiac arrhythmias |
| Depression/suicide | Sudden death |
| Delirium/confusion | Dilated cardiomyopathy |
| Extrapyramidal ataxia | Hypotension |
| Paresthesia | Other |
| Seizures | Retinopathy |
| Relapse in substance abuse | Hearing loss |
| Hematologic | Pulmonary interstitial fibrosis |
| Granulocytopenia | Acute renal failure |
| Thrombocytopenia | Hyperthyroidism |

formation because his PT is prolonged. If conventional doses of IFN lead to liver failure, development of sepsis, or bleeding, low-dose therapy may be of benefit based on results from a trial in patients with decompensated cirrhosis.

The dose should be decreased by 50% if granulocyte or platelet counts decline to $<750/\text{mm}^3$ and $50,000/\text{mm}^3$, respectively.¹⁸² Profound thrombocytopenia ($<30,000/\text{mm}^3$) or neutropenia ($<500/\text{mm}^3$); serious changes in mood or behavior; and intractable nausea, vomiting, or fatigue warrant the immediate discontinuation of IFN- α .

NUCLEOSIDE ANALOGS

29. If C.R. does not respond to IFN- α , what additional antiviral therapies are available?

Although IFN has been important in the treatment of chronic HBV infection, patients included in most clinical trials represented a highly select group of chronic HBV carriers. Specifically, patients with decompensated liver disease were excluded because they often have leukopenia and thrombocytopenia as a result of hypersplenism, which limits the dose of IFN that can be administered. In addition to IFN- α , the FDA has approved several antiviral agents for treatment of chronic hepatitis B infection (lamivudine, adefovir dipivoxil, entecavir, and telbivudine) with at least three more (emtricitabine, clevudine, and tenofovir disoproxil) that may be approved in the near future.

Lamivudine (Epivir-HBV) was the first nucleoside analog approved by the FDA for use in patients with compensated liver disease who had evidence of active viral replication and liver inflammation caused by chronic hepatitis B infection. Nucleoside analogs represent an alternative approach to treatment.^{71,73,74,156–165} Lamivudine, the(-) enantiomer of 3'-thiacytidine is an oral 2'-, 3'-dideoxynucleoside that inhibits DNA synthesis by terminating the nascent proviral DNA chain and interferes with the RT activity of HBV.^{183,184} In clinical trials, lamivudine was well tolerated and reduced serum levels of HBV DNA.^{71,73,74,162,163,184,185} In a pivotal randomized, placebo-controlled trial patients received 100 mg lamivudine or placebo as initial therapy for chronic hepatitis B for 52 weeks.¹⁸⁶ Patients receiving lamivudine were more likely to have a histologic response, loss of HBeAg in serum, sustained suppression of HBV DNA to undetectable levels, and reduced incidence of hepatic fibrosis. Additional findings were that lamivudine recipients were more likely to experience HBeAg seroconversion (loss of HBeAg), undetectable levels of serum HBV DNA, and the appearance of antibodies against HBeAg. HBeAg responses were maintained in most patients for 16 weeks following discontinuation of therapy. The most commonly reported adverse effects have been headache, fatigue, nausea, and abdominal discomfort. Less common adverse effects include laboratory abnormalities, such as transient asymptomatic elevation in amylase, lipase, and creatinine kinase levels.^{71,73,74,78,161–163,184} Although this trial led to widespread use of lamivudine, its major use has been as a continuous long-term therapy in HBV-infected individuals, which can result in resolution of disease and loss of HBsAg.

30. What is the risk of development of resistance in C.R.?

Lamivudine Resistance

Lamivudine, however, has a high rate of antiviral resistance. Considering the high rate of viral turnover and the error suscep-

tible nature of the polymerase (particularly the RT), acquisition of resistance mutations would be predicted. The most common mutation leading to lamivudine resistance is a specific point mutation in the highly conserved methionine motif of the HBV polymerase.^{71,73,74,78,96,189} In this mutation, the methionine residue is changed to a valine or isoleucine. These genotypic mutations in the YMDD locus associated with a reduced sensitivity to lamivudine occur following long-term therapy (e.g., 52 weeks). This motif is thought to be representative of the active site of the enzyme, similar to that associated with HIV RT, leading to lamivudine resistance.^{71,73,74,78,161–163,184,187,188} Lamivudine-resistant HBV mutants generally are detectable after 6 months or more of continuous therapy. Integrated data from four studies show a 24% (range, 16%–32%) incidence at 1 year, increasing to 47% to 56% at 2 years of therapy and 69% to 75% at 3 years of therapy.^{71,73,74,78,96,189} The presence of YMDD mutants results in a loss of the clinical response, a rise in ALT levels, and worsening of hepatic histology.^{72,73} Reports of continued improvement despite lamivudine resistance exist, but the long-term consequences of viral resistance (including hepatic decompensation and exacerbation of liver disease) are poor. Thus, lamivudine may have limited benefit in patients similar to C.R. A greater therapeutic benefit in chronic HBV infection would be anticipated with equally or more potent nucleoside analogs with lower rates of resistance.

31. What other drug therapies are available for managing C.R.'s chronic HBV infection?

Adefovir

Adefovir dipivoxil (Hepsera, Gilead) was the second nucleoside analog approved by the FDA for the treatment of chronic hepatitis B in adults with evidence either of active viral replication or of persistent elevations in serum aminotransferases (ALT or AST) or histologically active disease.¹⁹⁰ Adefovir dipivoxil is the oral prodrug of an acyclic nucleotide monophosphate analogue, 9-(2-phosphonylmethoxyethyl)-adenine (PMEA). The active drug is a selective inhibitor of numerous species of viral nucleic acid polymerases and reverse transcriptases. It has broad-spectrum antiviral activity against retroviruses, hepadnaviruses, and herpesviruses. Orally administered adefovir dipivoxil exhibits an inhibitory effect on both the HIV and HBV reverse transcriptases.

Previously, two trials reported the results of adefovir for the treatment of patients who were HBeAg-negative¹⁹¹ and HBeAg-positive.¹⁹² (Table 73-16 and Table 73-17) The first of these trials, patients with chronic hepatitis B who were negative for hepatitis HBeAg were randomly assigned to receive either 10 mg of adefovir dipivoxil (n = 123) or placebo (n = 61) once daily for 48 weeks.¹⁹¹ The primary endpoint in this trial was histologic improvement. At week 48, 64% of patients who had baseline liver biopsy specimens available in the adefovir dipivoxil group had improvement in histologic liver abnormalities (77 of 121), as compared with 33% of patients in the placebo group (19 of 57). Additionally, serum HBV DNA levels were reduced to <400 copies/mL in 61 of 123 patients (51%) receiving adefovir and in 0 of 61 patients (0%) receiving placebo. The median decrease in log-transformed HBV DNA levels was also greater with adefovir-treated patients compared with patients taking placebo (3.91 versus 1.35 log copies/mL; $P < 0.001$).

Biochemical markers (alanine aminotransferase levels) had normalized at week 48 in 84 of 116 (72%) of patients receiving adefovir compared with 17 of 59 (29%) of those receiving placebo. No HBV polymerase mutations associated with resistance to adefovir were identified within the study period. Adefovir resulted in significant histologic, virologic, and biochemical improvement, with an adverse event profile similar to that of placebo. Emergence of adefovir-resistant HBV polymerase mutations was not observed; however, data suggest rates of resistance to be <1% at 1 year and up to 29% after 5 year.^{72,73}

Importantly, it appears that adefovir is capable of inhibiting the enzymatic activity of both wild-type and YMDD mutant variants of both of these viruses. Adefovir resistance may be more common in patients with pre-existing lamivudine resistance, however, and instances of combined resistance have been reported.¹⁸⁹

In the second clinical trial, adefovir was given to HBeAg-positive patients with chronic hepatitis B.¹⁹² Patients were randomly assigned to receive 10 mg or 30 mg of adefovir dipivoxil or placebo daily for 48 weeks. The primary endpoint was histologic improvement in the 10-mg group as compared with the placebo group. After 48 weeks of treatment, significantly more patients who received 10 mg or 30 mg of daily adefovir had histologic improvement (53% and 59%, respectively) versus 25% in placebo patients. In addition, a significant reduction in serum HBV DNA levels, undetectable levels (<400 copies/mL) of serum HBV DNA, normalization of alanine aminotransferase levels, and HBeAg seroconversion were associated with adefovir. Adefovir-associated resistance mutations were identified in the HBV DNA polymerase gene within the study period. The safety profile of the 10-mg dose of adefovir dipivoxil was similar to that of placebo. More adverse events and renal laboratory abnormalities were observed in the group receiving 30 mg/day of adefovir. In summary, adefovir dipivoxil led to histologic liver improvement, reduced serum HBV DNA and alanine aminotransferase levels, and increased rates of HBeAg seroconversion without adefovir-associated resistance. Again, long-term follow-up is required to validate these findings.

Additional data show that adefovir has been associated with primary nonresponse as shown by only a modest reduction in HBV DNA levels and minimal improvement in ALT in up to one-third of patients with HBeAg-positive HBV infection. Primary nonresponse is associated with high pretreatment HBV DNA levels and may occur owing to the moderate potency of adefovir against HBV. Higher doses could be used; however, they are correlated with renal toxicity. Long-term trials with the drug are ongoing and have shown that high rates of response are possible in patients with HBeAg-negative hepatitis B infection.

Entecavir

Entecavir (Baraclude, Bristol-Myers Squibb) is an acyclic guanosine derivative with potent activity against HBV.^{73,74} The drug inhibits HBV replication at three different steps: (a) the priming of HBV DNA polymerase; (b) the RT of the negative strand HBV DNA from the pregenomic RNA; and (c) the synthesis of positive strand HBV DNA. *In vitro* studies have shown that the drug is more potent than lamivudine and adefovir and is highly effective against lamivudine-resistant HBV mutants.

In two published phase III clinical trials, the efficacy of entecavir was reported in patients with HBeAg-positive and HBeAg-negative hepatitis B infection (Table 73-16 and Table 73-17). In the first randomized double-blind trial, 715 patients with compensated liver disease who had not previously received a nucleoside analog were assigned to receive entecavir 0.5 mg (n = 357) or lamivudine 100 mg once daily (n = 358) for a minimum of 52 weeks. By week 48, HBeAg-positive patients receiving entecavir had higher rates of histologic (72% versus 62%; $P = 0.009$), virologic [HBV DNA undetectable by PCR] (67% versus 36%; $P < 0.001$), and biochemical [ALT normalization] (68% versus 60%; $P = 0.02$) responses when compared with lamivudine.¹⁹³ Of note, the seroconversion rates were similar among the two treatment groups (21% versus 18%; entecavir versus lamivudine, respectively). No viral resistance to entecavir was detected during the study period, but follow-up data suggest a low rate of resistance (3% by week 96 of therapy).¹⁹⁴ The authors concluded that entecavir was as safe and had significantly higher histologic, virologic, and biochemical response rates than HBeAg-positive patients treated with lamivudine. In patients who remained HBeAg positive with low levels of HBV DNA replication, a second year of entecavir and lamivudine therapy resulted in seroconversion in 11% and 13% of patients, respectively.¹⁹⁵

In another randomized double-blind phase III trial, results were reported in patients with HBeAg-negative hepatitis B infection receiving either entecavir 0.5 mg (n = 331) or 100 mg lamivudine daily (n = 317) for a minimum of 52 weeks. At week 48, patients receiving entecavir had significantly higher rates of histologic (70% versus 61%; $P = 0.01$), virologic (90% versus 72%; $P < 0.001$) and biochemical (78% versus 71%; $P = 0.045$) response rates.¹⁹⁶ Again, no evidence of resistance was seen among patients receiving entecavir. Safety and adverse events were similar in the two groups. The authors concluded that entecavir was as safe and had significantly higher histologic, virologic, and biochemical response rates than HBeAg-negative patients treated with lamivudine. Thus C.R. could receive entecavir 0.5 mg daily. As with all of the nucleoside agents, renal function should be monitored closely and appropriate dosage adjustments should be implemented when renal function changes (Table 73-20). Furthermore, entecavir may be used for lamivudine-refractory or resistant patients. In these patients, lamivudine should be discontinued to reduce the risk of entecavir resistance. *In vitro* studies showed that entecavir resistant mutations are susceptible to adefovir, but sparse clinical data are available to validate this finding. The dose of entecavir used for lamivudine-resistant patients is 1.0 mg daily.

Telbivudine

Telbivudine (Tyzela, Idenix) is an orally available L-nucleoside analog with potent antiviral activity against HBV.¹⁹⁷⁻¹⁹⁹ In a randomized double-blind phase III trial 1,370 patients with HBeAg-positive (n = 921) or HBeAg-negative (n = 446) chronic hepatitis B infection were randomized to receive 600 mg of telbivudine or 100 mg of lamivudine once daily.¹⁹⁷ (Table 73-16 and Table 73-17). The primary efficacy endpoint was noninferiority of telbivudine to lamivudine for therapeutic response (i.e., a reduction in serum HBV DNA levels to <5 log₁₀ copies/mL, along with a loss of HBeAg, or normalization of aminotransferase levels). Secondary endpoints included

Table 73-20 Adjustment of Adult Dosage of Nucleoside and Nucleotide Analogs in Accordance with Creatinine Clearance

| <i>Creatinine Clearance (mL/min)</i> | <i>Recommended Dose</i> | |
|---|---|-------------------------------------|
| Lamivudine | | |
| ≥50 | 100 mg QD | |
| 30–49 | 100 mg first dose then 50 mg QD | |
| 15–29 | 35 mg first dose, then 25 mg QD | |

| ≥50 | 600 mg daily | |
| 30–49 | 400 mg daily | |
| <30 | 200 mg daily | |
| Hemodialysis patients | 200 mg daily following dialysis | |
| QD, every day | | |
| From references 72, 73, with permission. | | |

histologic response, change in HBV DNA, and HBeAg responses. At week 52, a higher proportion of HBeAg-positive patients receiving telbivudine than lamivudine had a therapeutic response (75.3% versus 67.0%; $P = 0.005$) or a histologic response (64.7% versus 56.3%; $P = 0.01$); telbivudine was also not inferior to lamivudine for these endpoints in HBeAg-negative patients. Elevated creatinine kinase levels were more commonly seen in the patients treated with telbivudine, whereas elevated ALT and AST levels were more common in those treated with lamivudine. Resistance rates were lower among the telbivudine group compared with the lamivudine group during the first year of therapy. The rates of HBeAg loss were similar between the telbivudine and lamivudine treatment groups (26% versus 23%, respectively). With respect to resistance, telbivudine selects for mutations in the YMDD motif. Although resistance rates are lower than those reported with lamivudine, the resistance rate is substantial and increases at a high rate following the first year of therapy.¹⁸⁸ In the phase III trial genotypic resistance after 1 and 2 years of therapy was observed in 4.4% and 21.6% of HBeAg-positive and 2.7% and 8.6% of HBeAg-negative patients who received telbivudine compared with 9.1% and 33% of HBeAg-positive

and 9.8% and 21.9% of HBeAg-negative patients who received lamivudine.^{74,75} Although telbivudine is more potent with lower rates of resistance than lamivudine, the rates of resistance appear to be higher than for other approved therapies. Thus, telbivudine may not be an optimal choice of nucleoside agent for C.R.

Additional Agents

The safety and efficacy of other antiviral agents for the treatment of chronic HBV infection, including tenofovir (PMPA),^{73,74} emtricitabine [Emtriva, FTC (2R,5S)-5-fluoro-1-[2-(hydroxymethyl)-1,3-oxathiolan-5-yl]cytosine],^{73,198} and clevudine [L-FMAU (1-(2-fluoro-5-methyl-L-arabinofuranosyl-uracil)]^{73,74,199} are under investigation. In one study of 248 patients receiving 200 mg daily of emtricitabine (FTC), there were significantly higher rates of histologic (62% versus 25%), virologic (54% versus 2%) and biochemical (65% versus 25%) responses at week 48 compared with placebo. The rates of HBeAg seroconversion were the same in both groups (12%) with FTC resistance rates occurring in 13% of treated patients.¹⁹⁸ Clinical trials with daily clevudine 30 mg for up to 24 weeks demonstrated that the drug is well tolerated and that serum HBV DNA levels were undetectable by PCR assay at the end of treatment in 59% of HBeAg-positive and in 92% of HBeAg-negative patients. A unique characteristic of clevudine is the durability of viral suppression, which persists up to 24 weeks after therapy is discontinued in some patients.¹⁹⁹ Ultimately, this agent has not been shown to increase the rate of HBeAg seroconversion compared with placebo controls and it also may select for mutations in the YMDD motif.

Although several drugs have failed to treat HBV effectively,^{200–203} agents such as tenofovir may prove effective against HBV isolates that are resistant to lamivudine.^{204–206} Novel agents, such as glycosidase inhibitors, hammerhead ribozymes (short RNA molecules that possess endoribonuclease activity capable of degrading target RNA), and antisense phosphodiester oligodeoxynucleotides (short fragments of DNA that are complementary to HBV-RNA, which result in inhibition of RNA translation) are also under investigation.²⁰⁷ Pending the results of these trials and the arrival of HBV protease inhibitors and cytokine therapies, combination antiviral therapy as demonstrated in patients with HIV, may enhance response rates, reduce the progression of liver disease, and ultimately enhance survival in patients with chronic HBV infection.^{208,209} Because of the relatively high resistance rates for lamivudine and telbivudine, and dosing limitations for adefovir, entecavir 0.5 mg daily should be initiated in C.R. if he fails to respond to IFN or PegIFN. Recommendations for treatment of chronic hepatitis B virus can be found in Table 73-21.

Therapeutic Vaccines

Theradigm-HBV (Cytel, San Diego, CA) is a therapeutic vaccine consisting of the viral protein HBcAg peptide, a T-helper peptide (tetanus toxoid peptide) that enhances immunogenicity, and two palmitic acid molecules. The vaccine appears to be well tolerated, has dose-dependent response rates, and appears to work by inducing HBV-specific major histocompatibility complex (MHC) class I-restricted CTL. Phase I and II studies in patients with chronic HBV are in progress.²¹⁰ Another therapeutic vaccine undergoing clinical investigation for chronic HBV is HBV/MF59.²¹¹ This vaccine combines the HBV “Pre

Table 73-21 Recommendations for Treatment of Chronic Hepatitis B

| HBeAg | HBV DNA (PCR) | ALT | Treatment Strategy |
|-------------------|---------------|---------------------|--|
| + | >20,000 IU/mL | $\leq 2 \times$ ULN | Low efficacy with current treatment. Observe, consider treatment when ALT becomes elevated. Consider biopsy in persons >40 years, ALT persistently high normal to $2 \times$ ULN, or family history of HCC Consider treatment if HBV DNA >20,000 IU/mL and biopsy shows moderate to severe inflammation or significant fibrosis |
| + | >20,000 IU/mL | $\geq 2 \times$ ULN | Observe for 3–6 months and treat if no spontaneous HBeAg loss Consider liver biopsy prior to treatment if compensated Immediate treatment if icteric or clinical decompensation (IFN- α /PegIFN- α , LAM, ADV, ETV, LdT may be used as initial therapy) LAM LdT not preferred due to high rate of resistance |
| HBeAg to anti-HBe | | | Endpoint of treatment: seroconversion from Duration of therapy: IFN- α : 16 weeks PegIFN- α : 48 weeks LAM, ADV, ETV, LdT: minimum 1 year, continue for at least 6 months After HBeAg seroconversion IFN- α nonresponders/contraindications to IFN- α \rightarrow ADV/EDV IFN- α /PegIFN- α , LAM, ADV, ETV, or LdT may be used as initial therapy, LAM and LdT not preferred due to high rate of resistance |
| | >20,000 IU/mL | $\geq 2 \times$ ULN | High rate of drug resistance; endpoint of therapy not defined Duration of therapy: IFN- α /PegIFN- α : 1 year LAM, ADV, ETV, LdT: >1 year IFN- α nonresponders/contraindications to IFN- α \rightarrow ADV/EDV |
| | > 2,000 IU/mL | $1-2 \times$ ULN | Consider liver biopsy and treat if liver biopsy shows moderate/severe necroinflammation or significant fibrosis |
| | <2,000 IU/mL | \leq ULN | Observe, treat if HBV DNA or ALT becomes higher |
| \pm | Detectable | Cirrhosis | Compensated: HBV DNA >2,000 IU/mL-treat: LAM/ADV/ETV/ LdT may be used as initial therapy; LAM and LdT not preferred due to high rate of resistance HBV DNA <2,000 IU/mL: consider treatment if ALT is elevated Decompensated: Coordinate treatment with transplant center, LAM (or LdT) + ADV or ETV preferred Refer for liver transplant |
| \pm | Undetectable | Cirrhosis | Compensated: observe Decompensated: refer for liver transplant |

ADV, adefovir; ALT, alanine aminotransferase; ETV, entecavir; IFN- α , interferon alpha; LAM, lamivudine; LdT, telbivudine; PegIFN- α , pegylated interferon alpha; ULN, upper limit of normal.

S2 and S” antigens with an MF59 adjuvant (enhances immune responses).

32. If C.R. fails therapy with entecavir, is combination therapy appropriate?

Combination Therapies

Combination therapy for HIV and HCV have been proved to be more effective than monotherapy. The potential for additive or synergistic antiviral effects and reduced or delayed rates of viral resistance may also be possible in patients with hepatitis B infection. Several combination therapies have been evaluated in patients infected with hepatitis B (PegIFN and lamivudine, lamivudine and adefovir, lamivudine and telbivudine) but none have been proved to be superior to monotherapy in producing a higher rate of sustained response. Furthermore, combination therapies have shown a reduced rate of resistance in patients treated with lamivudine compared with monotherapy, but no data support the use of combination therapy to reduce mutation rates in agents that have a low risk of drug resistance when used alone.

Liver Transplantation

33. If C.R. fails therapy and continued to decompensate from his chronic HBV infection, what nonpharmacologic interventions are available?

One-year survival rates for patients with cholestatic or alcoholic liver disease are >90% in most transplant centers.⁹² Historical data for liver transplants in patients with chronic HBV infection are associated with 1-year survival of 50% compared with non-HBV-infected recipients. In one report, 51 HBsAg-positive patients who received a liver transplant for postnecrotic cirrhosis were compared with 38 transplant recipients with evidence of HBV immunity (HBsAg-negative and anti-HBs-positive).⁹⁵ Early post-transplant mortality was similar between the groups but delayed mortality was greater in the HBsAg-positive arm (63% versus 80%, respectively, in patients who survived at least 60 days, or 45.1% and 63.2%, respectively, overall). Recurrent HBV infection was the primary cause of death in HBsAg-positive patients.⁹² Patients with active viral replication preceding transplantation as indicated by HBeAg or HBV DNA positivity are less likely to have graft

or overall survival compared with those without active viral replication.²¹² Reinfection of the allograft takes place in up to 100% of liver transplant recipients, but morbidity is higher in HBeAg-positive patients. HBV DNA levels may be a better predictor of outcome than HBeAg positivity.²¹² For this reason, pretransplant HBV DNA status has become the preferred predictor of outcome following transplantation. Because of poor outcomes, several centers have excluded HBsAg-positive patients (in the presence of viral replication) from having liver transplantation. This policy is not universally accepted, however, and with appropriate posttransplant prophylactic strategies, patients who are nonresponders to drug therapy can undergo successful liver transplantation.

34. What are the current recommendations for prevention of recurrent hepatitis B infection following liver transplantation?

The most efficacious approach to preventing HBV recurrence following transplantation has been with high-dose IV hepatitis B immunoglobulin in the anhepatic and postoperative periods.^{211,212} Samuel et al. reported that 110 HBsAg-positive patients treated with daily IV HBIG in the early postoperative period to maintain their serum anti-HBs levels ≥ 100 IU/L had an overall survival (84%) that approached that observed in other transplant recipients without HBV infection.²¹¹ These data have been confirmed in a large retrospective analysis of patients (N = 334) undergoing transplantation for HBV infection in Europe. Furthermore, the European trial demonstrated that patients receiving long-term HBIG administration (>6 months) compared with patients receiving short-term HBIG (<6 months) had a lower risk for recurrent HBV infection (35% versus 75%) and longer 3-year actuarial survival (78% versus 48%).²¹¹

HBIG DOSAGE, ADMINISTRATION, AND ADVERSE EFFECTS

Historically, liver transplant centers routinely administer immunoprophylaxis with IV HBIG 10,000 IU (10 vials, 50 mL in 250 mL of saline) in the anhepatic (recipient liver excised) phase, then 10,000 IU (50 mL infused over 4–6 hours) for the next 6 days postoperatively. HBIG (10,000 IU) is administered on a monthly basis for life, or is discontinued if HBsAg becomes positive, indicating treatment failure. This regimen achieves trough anti-HBs titers of approximately 500 IU/L and up to 2,000 IU/L; however, the link of specific titers and protection from recurrence is controversial at this time. Patients may also experience a serum sickness-like syndrome (fever, myalgias) that is reversible after discontinuation of HBIG therapy. An IV preparation of HBIG is now available for patients undergoing liver transplantation for chronic HBV infection.

Long-term concerns associated with HBIG administration include the potential for HBV reinfection from extrahepatic sites despite adequate anti-HBs titers, emerging mutant viruses that no longer bind to the immunoglobulin, and the prohibitive high cost of therapy (>\$60,000/year).^{213,214} Current data suggest that pharmacokinetic modeling and use of maintenance therapy with IM administration of HBIG (e.g., 2.5–10 mL every 2–3 weeks) following a reduced induction dose (e.g., 10,000 IU anhepatically, then 2,000 IU IV \times 6 doses) may achieve similar outcomes and reduce the cost associated with IV administration of the drug.^{215–217}

35. What is the role of oral antiviral agents in liver transplant recipients with HBV?

As previously described, the availability of nucleoside analogs, such as lamivudine, adefovir, and entecavir, are having an impact on the treatment of patients with HBV infection, and they also have a role in patients who undergo transplants for chronic HBV infection.^{71,73,184,218–221} Lamivudine monotherapy is effective in converting HBV DNA-positive patients to negative status before and after liver transplantation. Emerging mutations at the YMDD locus in transplant and nontransplant recipients also have been observed, however, rendering lamivudine ineffective.^{71,73,184,222,223} Nucleoside analogs are still considered investigational at this time for HBV prophylaxis following transplantation because they have not been FDA approved for this indication in the United States. Several transplant centers, however, have implemented clinical protocols that combine lamivudine with HBIG; ultimately, this combination regimen has emerged as a clinical standard because it has been effective, with low rates of resistance. When lamivudine resistance has occurred following transplant and leads to recurrent hepatitis B, the use of adefovir, entecavir, or tenofovir has been successful in the post-transplant setting. Future considerations for preventing recurrent HBV infection following transplantation include combining nucleoside analogs (lamivudine, adefovir, entecavir), HBIG, or various combinations; however, optimal management strategies continue to be determined. In some patients with low HBV DNA before transplant, the use of RT inhibitors may eliminate the administration of HBIG in the early postoperative course or may allow a “switch” to long-term oral nucleoside- or nucleotide-based therapy. More long-term data are required, however, to validate this approach. Thus, patients who are transplant recipients for chronic HBV infection who fail treatment with HBIG and lamivudine should be treated as part of an investigational protocol.

HEPATITIS D VIRUS

Virology and Epidemiology

Hepatitis D virus is a small, single-stranded RNA animal virus (36 nm) that is similar to defective RNA plant viruses (Table 73-2).^{224–226} Discovered in the late 1970s, HDV was found in the nuclei of infected hepatocytes, and it presents in some, but not all, HBV-infected patients. HDV appears to replicate exclusively in the liver via extensive base-pairing that results in the formation of an unbranched rodlike genome. Although replication of the virus can occur within hepatocytes in the absence of HBV, the latter is required for coating the HDV virions and allowing for their cellular spread. The HDV genome is replicated by an RNA intermediate (antigenome) that depends on the host's RNA-dependent RNA polymerase. During replication, the genomic (positive strand) HDV RNA becomes the template for successive rounds of minus-strand synthesis. The multimeric minus strand then serves as a template for positive strand synthesis. Subsequently, autocleavage and ligation form circular genomes that are produced from this multimeric precursor.

Fifteen million persons are infected with HDV, with the highest incidence reported in Italy, Eastern Europe, the Amazon Basin, Colombia, Venezuela, Western Asia, and the South Pacific.^{1,225,226} In the United States, an estimated 7,500 HDV cases occur annually.^{1,226} The prevalence of HDV is greatest among persons with percutaneous exposure (e.g., injection drug users) and hemophiliacs (20%–53% and 48%–80%,

respectively) and may be affected by additional factors such as age of infection.^{1,226} The modes of transmission of HDV are similar to those reported for HBV infection. Thus, HDV clearly represents a potential infectious hazard to patients susceptible to HBV and those who are chronic HBV carriers.^{226,227} Because infection by HDV requires the presence of active HBV, preventing HBV infection will prevent HDV infection in a susceptible patient.^{1,225,226}

Pathogenesis

Limited data suggest that HDVAg (antigen) and HDV RNA may possess direct cytotoxic effects on hepatocytes, whereas other findings implicate the immune response in pathogenesis.^{225,226,228} Furthermore, several autoantibodies associated with chronic HDV infection may play a role in propagating liver

disease and could partially explain the differences in disease severity observed in patients with HDV plus HBV compared with those with HBV alone.

Diagnosis and Serology

The ELISA and RIA tests for IgM anti-HDV are available commercially, whereas detection methods for HDV RNA are available only on a research basis to distinguish ongoing from previous HDV infection.^{226,229} Measurement of anti-HDV is generally not useful for early diagnosis because detectable antibody levels are usually achieved late in the clinical course of the infection (Fig. 73-4A). Anti-HDV IgM is detectable before anti-HDV IgG in acute HDV coinfection and is diagnostic for acute HDV infection. Anti-HDV IgM levels are not sustained in self-limiting HDV infection but may persist in patients with

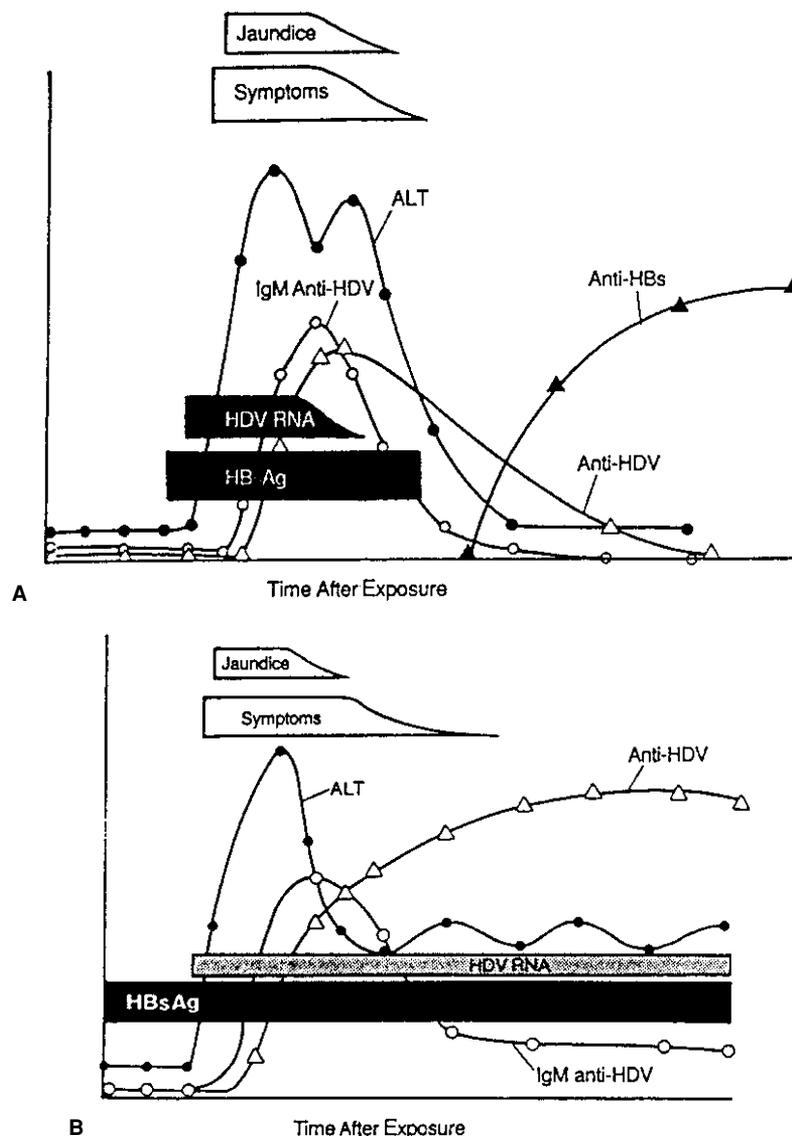

FIGURE 73-4 A: Typical course of acute icteric HBV with HDV coinfection. ALT, alanine aminotransferase; anti-HBs, hepatitis B surface antibody; anti-HDV, antibody to delta hepatitis virus; HBsAg, hepatitis B surface antigen; HDV RNA, delta hepatitis RNA; IgM anti-HDV, IgM antibody to delta hepatitis virus. **B: Typical course of acute icteric HBV with HDV superinfection.** ALT, alanine aminotransferase; anti-HBs, hepatitis B surface antibody; anti-HDV, antibody to delta hepatitis virus; HBsAg, hepatitis B surface antigen; HDV RNA, delta hepatitis RNA; IgM anti-HDV, IgM antibody to delta hepatitis virus.

chronic HDV infection. Also, anti-HDV IgM does not distinguish coinfection (HBV and HDV acquired simultaneously) from superinfection (HDV acquired in chronic HBV carrier) (Fig. 73-4B).

Differentiation between coinfection and superinfection is made by the presence or absence of anti-HBc IgM. In acute coinfection, serum anti-HDV IgM and HDV RNA appear together with anti-HBc IgM, whereas in patients with superinfection, HDV markers are present in the absence of anti-HBc IgM. The presence and titer level of anti-HDV, in the case of persistent infection, also correlate with the severity of disease. Titers of anti-HDV IgG > 1:1,000 indicate ongoing viral replication.

Hepatitis D virus antigen is present in the serum in the late incubation period of acute infection and lasts into the symptomatic phase in up to 20% of patients. Because this antigen is transient, repeat testing may be required to detect its presence. The clinical utility of HDVAg detection by ELISA and RIA is limited by the necessity of precise timing of a sample and by its availability only as a research test. In addition, during persistent infection, HDVAg may not be detectable because it is complexed with anti-HDV.

Hepatitis D virus RNA is an early marker of infection in patients with both acute and chronic HDV infection.^{226,229,230} HDV RNA is detectable in 90% of patients during the symptomatic phase of HDV infection. HDV RNA levels are nondetectable following symptomatic resolution but remain elevated in chronic infection. A significant correlation exists among HDV RNA detection by hybridization assay, positive results for IgM anti-HDV in serum, and positive immunohistochemistry for HDVAg in liver biopsies. Detection of HDVAg by immunohistochemical analysis of liver tissue is the best diagnostic method for persistent HDV infection; however, antigen staining is only available in research laboratories.²²⁹

Natural History

Coinfection with HDV and HBV resulting in acute hepatitis is correlated with a higher risk of severe or fulminant liver disease.²²⁶ The rate of chronic disease following coinfection with HDV is similar to that of HBV infection alone, whereas superinfection with HDV is linked to a high rate of chronicity; however, the clinical course may be variable.^{226,231} Approximately 15% of patients superinfected with HDV develop rapidly progressive disease with hepatic decompensation (e.g., cirrhosis) within 12 months of the infection. Another 15% of patients have a benign course of illness. Most patients (70%) have a slow progression to cirrhosis, depending on age, IV drug use, and level of viral replication.²²⁵⁻²²⁷ Finally, HBsAg-positive, HBeAg-positive patients who are superinfected with HDV are more likely to develop fulminant disease compared with those who are HBsAg-positive with anti-HBe and who are superinfected and develop chronic disease.²²⁵⁻²²⁷

Clinical and Extrahepatic Manifestations

Delta infection may be acquired simultaneously in a patient with acute HBV infection (coinfection), or it may occur in a patient with chronic HBV who is a carrier of HBsAg (superinfection). Infection with HDV can lead to both acute and chronic forms of hepatitis. Another pattern of infection, known

as latent HDV infection, is documented in liver transplant recipients and is characterized by HDV infection being identified in the liver graft before reinfection of the graft with HBV.^{226,232} Acute HDV coinfection is marked by symptoms seen in other acute hepatotropic viral infections. HDV infection also has a unique biphasic increase in aminotransferase activity, which is rarely observed in HBV infection alone. The clinical features of chronic HDV infection are not specific and are similar to those seen in chronic hepatitis from other causes.

Patients who develop chronic infection are at risk for developing cirrhosis and hepatic decompensation. In contrast to patients with chronic HBV infection, a negative association exists between HDV and HCC.^{226,227} Potential reasons for this could be that the delta agent has direct tumor protective effects; delta markers in patients with HCC disappear because the time between infection and cancer detection is longer than in patients with HCC from other causes, or HDV predisposes to early mortality before HCC can develop.²²⁶

Prevention

Hepatitis D virus replication is dependent on HBV replication; therefore, successful immunization with HBV vaccine also prevents HDV infection.²²⁵⁻²²⁷ No immunoprophylactic therapies are available for patients with chronic HBV infection who are also at risk for superinfection with HDV. Prevention of HDV superinfection is based on behavioral modification, such as the use of condoms to prevent sexual transmission and needle exchange programs to minimize transmission by IV drug use.

Treatment

Supportive care is the general strategy used to treat HDV infection. Because the development of fulminant hepatic failure is more frequent with HDV infection, close monitoring for evidence of encephalopathy, coagulopathy, and other signs of liver failure (e.g., acidosis) is warranted. Liver transplantation is the treatment of choice for patients with fulminant or end-stage liver disease following HDV infection. In patients with chronic HDV infection, antiviral therapy has been attempted; however, therapeutic trials in managing chronic HDV infection have been disappointing (Table 73-22).^{226,231} Treatment with either prednisone or azathioprine is ineffective.²³³ The use of IFN- α to treat chronic delta hepatitis has been reviewed using meta-analysis of five small, randomized, controlled trials. Patients treated with IFN- α (5 MU/day or 9 MU three times weekly) for 12 months experienced a 30% rate of complete disease remission (normalization of ALT values) compared with 1% observed in untreated controls.²³⁴ In the largest trial published to date, patients with chronic hepatitis D were randomized to either IFN- α 2b, 5 MU three times weekly for 4 months then 3 MU three times weekly for an additional 8 months, or placebo. Serum ALT reductions of >50% from baseline were observed in 42% of IFN- α -treated patients at 4 months compared with 7% of untreated controls. The treatment effect was not sustained, however, because only 26% of treated patients maintained reductions in ALT levels at 12 months. Relapses after discontinuation of therapy were common, and histologic improvement was not statistically different from controls.²³⁵ A trial using IFN- α (9 MU three times weekly) demonstrated both

Table 73-22 Efficacy of Interferon in Chronic HDV

| Author | N | Interferon | Dosage | Duration (Months) | Response (%) | |

virologic and histologic improvement after 48 weeks of therapy. As in the previous trials, the treatment effect was not sustained, and relapse was common after drug discontinuation.²³⁶ No clinical, serologic, or virologic factors consistently predict response or lack of response to IFN. In uncontrolled trials involving a small number of patients, the duration of the HDV infection may be significant based on the improved response rates in patients who have had their disease for a relatively short period (i.e., IV drug users) compared with response rates in patients from endemic areas whose infections are acquired early in life. Because of the nature of these reports, verification of this association is needed.

Two small open-label trials evaluated the use of PegIFN- α alone²³⁷ or in combination with ribavirin²³⁸ for the treatment of chronic HDV infection. Castelnua et al.²³⁷ evaluated the efficacy of PegIFN- α 2b monotherapy, 1.5 mcg/kg weekly for 12 months in 14 patients with chronic HDV infection. A virologic response, defined as undetectable HDV RNA by PCR, was seen in 57% of patients at the end of therapy and persisted in 43% of patients during the follow-up period. The rate of ALT normalization was higher at the end of follow-up (57%) than at the end of therapy (36%), suggesting that the reduction occurred during the posttreatment phase. A second randomized, controlled trial was performed comparing the efficacy and safety of PegIFN- α alone (1.5 mcg/kg/week) for 72 weeks ($n = 16$) or in combination with ribavirin (800 mg/day) for 48 weeks followed by PegIFN- α monotherapy for 24 additional weeks ($n = 22$).²³⁸ Clearance of HDV RNA at the end of therapy occurred in 19% of patients receiving monotherapy and just 9% of those patients receiving combination therapy. Similarly, the rate of virologic clearance increased to 25% and 19%, respectively, during posttreatment follow-up period. The rates of biochemical response were similar in both groups (25% versus 27% at the end of follow-up) with relapse rates approaching 60%. Although these trials show promise, larger trials with longer follow-up periods are required to confirm the role of PegIFN in HDV infection.

Results from a pilot trial that evaluated the efficacy of 100 mg of oral lamivudine in five patients with HDV (all were positive for HBsAg, antibody to HDV, and HDV RNA) for 12 months demonstrated that serum levels of HBV DNA were

reduced in all five patients. All patients remained HBsAg and HDV-RNA positive, however, and serum ALT and liver histology did not improve.²³⁹ Additionally, in patients with chronic HDV infection who received 100 mg of oral lamivudine for 24 weeks followed by a combination of high-dose interferon (9 MU TIW) and 100 mg of oral lamivudine for 16 weeks, biochemical and histologic test findings were not significantly improved compared with baseline characteristics.²⁴⁰ Nucleoside analogs, such as lamivudine, have not proved to be effective for treating HDV infection because of their inability to cause HBsAg, the only protein required by HDV, to disappear.

In patients with decompensated cirrhosis caused by HDV, liver transplantation is the most appropriate intervention because IFN may precipitate hepatic decompensation.^{212,214,236} The presence and amount of HBV DNA before transplantation is the most significant outcome marker, often predicting the posttransplant reinfection rate. Patients who receive a liver transplant for chronic HDV infection have a lower incidence of posttransplant HBV infection than do those with HBV infection alone (67% versus 32%, respectively).²¹² This is thought to be related to an inhibitory effect of HDV on HBV replication. Furthermore, 3-year survival is higher for patients with HDV cirrhosis than for patients undergoing transplantation for HBV cirrhosis alone (88% versus 44%, respectively) and is similar to patients having liver transplantation for other indications.²¹²

HEPATITIS C VIRUS

Virology

Before the development of methods to identify hepatitis C virus, most post-transfusion hepatitis cases were designated as non-A, non-B (NANB) hepatitis. HCV is recognized now as the most common cause of chronic NANB transfusion-associated hepatitis.^{235–238} HCV is a single-stranded, 50-nm RNA virus related to the flaviviruses, a family that includes the yellow fever virus and two animal viruses, bovine viral diarrhea virus, and classic swine fever virus (Table 73-2).^{241,245,246}

The genome of HCV contains a single outer reading frame (ORF) capable of encoding a large viral protein precursor that,

when cleaved, results in a series of structural (nucleocapsid core and envelopes 1 and 2) and nonstructural (NS2, NS3, NS4a, NS4b, NS5a, and NS5b) proteins.^{245,247,248} The amino terminal region of NS3 encodes a viral serine protease that cleaves viral peptides, whereas the carboxyl end functions as a helicase, which is essential in unwinding of viral RNA during replication. The NS5b protein functions as an RNA-dependent RNA polymerase; the function of the NS5a protein is unknown, but it may play a role in regulating replication. Furthermore, the positive strand RNA of HCV functions as a template for synthesis of negative strand RNA, as a template for translation of viral proteins, and as genomic RNA to be packaged into new virions. Unlike HBV, HCV has no DNA intermediate and therefore cannot integrate into the host genome.^{245,247,248}

The replication process of HCV is poorly understood because there is no *in vitro* or *in vivo* study model system. Available data suggest that viral binding and uptake into the hepatocytes occur through membrane fusion and receptor-mediated endocytosis.^{245,247,248} (Table 73-2). Following incorporation into the cytoplasm of hepatocytes, the nucleocapsid is uncoated to release RNA. Subsequently, the HCV RNA is translated to several polyproteins that undergo co- and post-translational processing. Subsequently, a complex structure (positive strand RNA) is used as a template for synthesis of negative strand RNA. In primates, HCV RNA is detectable within 3 days of infection, persisting in serum during peak ALT elevation. Detection appears to be associated with the appearance of viral antigens in hepatocytes, the major site of HCV replication. The importance of extrahepatic sites for replication (e.g., mononuclear cells) has not been determined. Kinetic studies in HCV-infected patients have depicted a high viral turnover that may partially explain the rapid emergence of viral diversity in patients with chronic HCV infection and the persistence of the infection, through immune escape, following acute exposure. Mechanisms pertaining to viral packaging and release from the hepatocytes are poorly understood.

Epidemiology

The worldwide seroprevalence based on antibody to HCV (anti-HCV) is approximately 3%, with >170 million people infected chronically. Geographic variations exist, from 0.4% to 1.1% in North America to 9.6% to 13.6% in North Africa.^{241,246,249} The prevalence of anti-HCV in the United States has been estimated to be 1.8%, corresponding to an estimated 3.9 million persons infected nationwide. Of these, 2.7 million persons are chronically infected (based on positive HCV RNA), with approximately 230,000 new infections per year.^{241,246,249} HCV is the etiologic agent in more than 85% of cases associated with post-transfusional NANB hepatitis.^{241,243,244} Following HCV antibody screening of blood donors in the early 1990s, transfusion-related reports of HCV have been dramatically reduced, and non-transfusion-related cases have emerged (e.g., injection drug users).^{241,246,250} Sporadic infection with HCV (infection without an identifiable risk factor) accounts for up to 40% of reported HCV infections.^{241,243,246} HCV is transmitted through percutaneous (e.g., blood transfusion, needlestick inoculation, high-risk behavior)^{241,243,246} and nonpercutaneous (e.g., sexual contact, perinatal exposure) routes.^{241,243,246,251,252} The latter appears to occur to a lesser extent than with HBV.

Hepatitis C virus infection occurs among persons of all ages, but the highest incidence is among persons aged 20 to 39 years with a male predominance. Blacks and whites have similar incidence rates of acute disease, whereas persons of Hispanic ethnicity have higher rates. In the general population, the highest prevalence rates of chronic HCV infection are found among persons aged 30 to 49 years and among males.^{241,243,246} Unlike the racial or ethnic pattern of acute disease, blacks have a substantially higher prevalence of chronic HCV infection than do whites.

In the United States, the predominant HCV genotype is type 1, with subtypes 1a and 1b accounting for 70% of cases.^{241,243,246} Knowledge of the genotype or serotype (genotype-specific antibodies) of HCV is helpful in making recommendations and counseling regarding therapy. Patients with genotypes 2 and 3 are almost three times more likely to respond to therapy with IFN- α or the combination of IFN- α and ribavirin. Furthermore, when using combination therapy, the recommended duration of treatment depends on the genotype. For these reasons, testing for HCV genotype is often clinically helpful. Once the genotype is identified, it need not be tested again; genotypes do not change during the course of infection. Because HCV has a high mutation rate during replication, several so-called quasispecies, a heterogeneous population of HCV isolates that are closely related, may, however, exist in an infected individual.^{241,247,248} The number of quasispecies increases over the course of infection, which allows HCV to escape the host's immune system, leading to persistent infection.

Percutaneous Transmission

Before the routine use of blood screening, the incidence of acute HCV infection among transfusion recipients in the 1970s was approximately 5% to 10%. Subsequently, blood donor screening using a first-generation anti-HCV test reduced the risk of transfusion-related hepatitis to 0.6% per patient and 0.03% per unit transfused.^{241,250} Following the use of more sensitive second- and third-generation assays for anti-HCV, the risk and incidence of transfusion-related hepatitis approaches that reported in hospitalized patients who have not received a transfusion.

The incidence of HCV infection is 48% to 90% among injection drug users, and the risk of acquiring the infection in these persons is as high as 90%.^{241,244,253} Of injection drug users with acute NANB hepatitis, 75% are anti-HCV positive and, unlike transfusion-related hepatitis, the incidence of HCV infection associated with injection drug use has not declined.^{241,244,253} Additional risk factors for HCV infection include the presence of HBV or HIV infections.^{241,244,253} Other populations at risk for acquiring HCV include patients receiving chronic hemodialysis (up to 45%)^{241,244,253} and health care workers (0% to 4% seroconversion following needlestick).^{241,244,253,254}

Nonpercutaneous and Sporadic Transmission

Nonpercutaneous transmission includes transmission between sexual partners and from mother to child. This route of transmission is less efficient compared with the percutaneous route, and is supported by data assessing sexual transmission of HCV. Sexual partners of index patients with anti-HCV have an incidence of HCV infection ranging from 0% to 27%, whereas low-risk (anti-HCV negative) index subjects without liver

disease or high-risk behavior (injection drug use or promiscuity) have an incidence of anti-HCV of 0% to 7%.^{241,244} In contrast, sexual partners of subjects with liver disease or high-risk behavior have an incidence of anti-HCV ranging between 11% and 27%.^{241,251} Also, the sexual partners of homosexual men and promiscuous heterosexuals with HCV have shown an increase in anti-HCV positivity.

Compared with the high incidence of perinatal transmission of HBV from mothers to infants, perinatal transmission of HCV infection is relatively low; however, high titers of circulating HCV in the mother may enhance the risk of infection in the infant.²⁴¹ Additional concerns and areas for investigation related to mother-to-infant transmission of HCV include the timing of transmission (*in utero*, time of birth), the relative risk associated with breast-feeding, and the natural history of perinatally acquired infection.

In sporadic HCV infection, up to 40% of patients acquire HCV infection without a known or identifiable risk factor.²⁴¹ This type of HCV infection may be related to a prevalent non-percutaneous or percutaneous route that has yet to be identified.

Pathogenesis

The pathogenesis of liver damage as a result of HCV infection most likely results from both direct and indirect, immune-mediated responses instigated by the virus. Direct cellular injury may be caused by the accumulation of intact virus or viral proteins.^{248,255} The direct mechanism of injury is supported by the observation that patients with high concentrations of HCV RNA (quantified through branched chain DNA assay) have greater lobular inflammatory activity compared with those with minimal inflammation. Whether specific genotypes (i.e., 1, 1b, 2) are correlated with severe disease continues to be assessed. European data suggest that type 1 genotype is associated with higher viral replication, and infection with the type 1b genotype is associated with more progressive liver disease.^{248,256} One reason why HCV genotype 1 may be more difficult to treat than genotypes 2 or 3 is that genotype 1 has a longer half-life (2.9 hours) than that of genotypes 2 or 3 (2.0 hours).^{241,257} Viral half-life can be defined as the time for the original amount of virus to be decreased by half, or in this case, die. Other data do not support these findings and have shown that patients with type 2 genotypes have more severe liver disease.²⁵⁸ Duration of infection is another factor that may be related to disease severity because the expression of genotypes may change over time making the correlation between genotype and severity of disease problematic.

Immune-mediated mechanisms for hepatic injury have been based on the presence of CD8⁺ and CD4⁺ lymphocytes in portal, periportal, and lobular areas in patients with HCV infection.^{248,255} Hepatic CD8⁺ lymphocytes are activated through an alternative antigen-independent pathway that stimulates CTL, which initiate hepatocellular injury. Helper or inducer T cells (CD4⁺) have also been implicated in the pathogenesis of chronic HCV infection; however, other data suggest that CD4⁺ cells may play a protective role against hepatocellular injury. Autoimmune mechanisms of hepatocellular injury (e.g., anti-liver-kidney microsomal antibodies) may play a minor role in the pathogenesis of liver injury.^{248,255}

Diagnosis

Serologic Tests

A test for antibodies to HCV is the initial screening test for suspected HCV infection.^{241,246,259–261} The two types of antibody tests are (a) the enzyme immunoassay (EIA) and the (b) recombinant immunoblot assay (RIBA). These serologic assays were developed using recombinant antigens derived from cloned HCV transcripts to substantiate a diagnosis of HCV. Predictive values of a positive third-generation EIA test are about 99% (in immunocompetent patients), which obviates the need for a confirmatory RIBA test in the diagnosis of patients with clinical liver disease.^{241,246,259–261} A negative EIA test is adequate to exclude a diagnosis of chronic HCV infection in non-immunocompromised individuals.^{241,246,260,261} Occasionally, patients undergoing hemodialysis and those with immune deficiencies may have false-negative findings on EIA. On the other hand, false-positive results can occur in healthy persons without any identifiable risk factors and normal aminotransferases, and in patients with autoimmune disorders.^{241,246,259,260,262} In these groups, the results should be confirmed using an assay for HCV RNA to diagnose chronic HCV infection. Anti-HCV antibodies usually are detected in serum late during the course of acute hepatitis C. In many cases, however, seroconversion may take up to a year or longer following exposure to HCV. Anti-HCV is detectable in serum for a variable length of time after acute infection, but it is not protective and its presence does not differentiate between acute, chronic, or resolved infection. The clinical symptoms, changes in HCV RNA, and serologic changes in acute and chronic HCV infection are shown in Figure 73-5A and B. Because of the enhanced specificity and sensitivity rates of the newer EIA tests, RIBA for antibodies to HCV proteins are infrequently used.

Qualitative HCV RNA Assays

Acute or chronic HCV infection in a patients with EIA positivity should be confirmed by a qualitative HCV RNA (PCR) assay with a lower limit of detection of 50 IU/mL or less (~100 viral gene/mL) or with transcription-mediated amplification (TMA), which has a detection limit of 10 IU/mL.^{241,246,260,262} Both of these test are highly specific (99%). Qualitative tests detect HCV as early as 1 to 2 weeks after exposure and detect the presence of circulating HCV RNA (viral copies/mL). Results are reported as either “positive” or “negative” and are used to monitor patients receiving antiviral therapy. A single positive qualitative assay for HCV RNA confirms active replication but does not exclude viremia and may only detect a transient decline in viral load below the level of detection of the assay.^{241,246,260–262} A follow-up qualitative HCV RNA needs to be obtained to confirm the lack of active HCV replication.^{241,246,260–262}

Quantitative HCV RNA Assays

In comparison, quantitative tests are less sensitive than qualitative tests and they are used to determine the concentration of HCV RNA with assays such as semiquantitative PCR-based Amplicor assay (qPCR) or bDNA signal amplification.^{241,246,260–262} The lower limit of detection with the second-generation bDNA and Amplicor assays are 250,000 viral equivalents/mL and 200 viral copies/mL, respectively. The qualitative HCV viral load test and third-generation bDNA

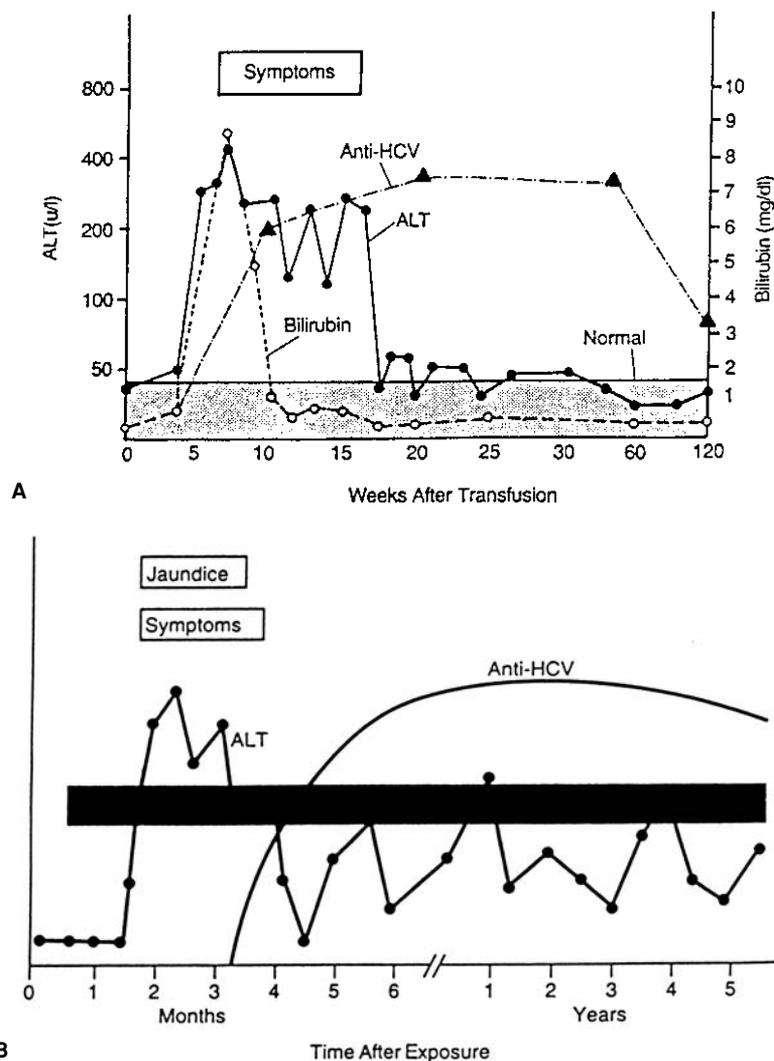

FIGURE 73-5 A: Typical course of acute hepatitis C virus. ALT, alanine aminotransferase; anti-HCV, hepatitis C antibody. **B: Typical course of chronic hepatitis C virus.** ALT, alanine aminotransferase; anti-HCV, hepatitis C antibody.

test have a lower limit of detection (sensitivity) of 50 copies/mL and 2,000 to 3,500 copies/mL, respectively. These tests should not be used to exclude the diagnosis of HCV infection or to determine treatment endpoint. An HCV RNA standard has been attempted to allow normalization of reported viral titers in international units. The reported international unit does not correlate with the actual number of viral particles in a preparation and variability does exist. The clinical utility of serial HCV viral concentrations in a patient is based on continued use of the same specific quantitative assay that was used initially.^{241,246,260-262} These tests provide significant information with respect to response to treatment in patients receiving antiviral therapy.

Biochemical Markers

Testing for serum ALT concentrations is not a sensitive marker for assessing disease activity and at best has a weak correlation with the histopathologic findings on a liver biopsy.^{241,246,260-262} Nevertheless, serial determination of ALT over time appears to be a better indicator of liver injury than is a single ALT test.

Biopsy

Liver biopsy can determine the extent of liver injury caused by HCV.^{241,246,260-262} Although some histologic findings are characteristic of HCV infection, such as portal lymphoid aggregates, steatosis, and bile duct injury, these alone are not sufficiently specific to establish a diagnosis of hepatitis C. Currently, no reliable, readily available tests exist to detect HCV antigens in the liver. With respect to liver biopsy in the management of HCV, a baseline biopsy (regardless of the extent of aminotransferase elevation) is recommended for the initial assessment of disease. Patients age >40 years or those who wish to defer therapy may benefit most from a liver biopsy.

Selection of Tests

All patients with elevated liver aminotransferases without an obvious source, especially those with known risk factors, should be tested for HCV. A diagnosis of acute hepatitis C can be initiated in a patient with symptoms of acute hepatitis and a positive anti-HCV titer. Confirmation is established by using ELISA tests. If patients are anti-HCV positive by ELISA with an increase in ALT concentration and have a known risk

Table 73-23 Diagnostic Tests for HCV Infection

| Test/Type | Application | Comments |
|---|---|---|
| Hepatitis C Virus Antibody (Anti-HCV) | | |
| EIA (enzyme immunoassay) Supplemental assay (i.e., recombinant immunoblot strip assay [RIBA]) | Indicates past or present infection, but does not differentiate between acute, chronic, or resolved infection. All positive enzyme immunoassay (EIA) results should be verified with a supplemental assay | Sensitivity >97% EIA alone has low positive predictive value in low prevalence populations |
| Hepatitis C Virus Ribonucleic Acid (HCV RNA) | | |
| Qualitative tests ^a Reverse transcriptase polymerase chain reaction (RT-PCR) amplification of HCV RNA by in-house or commercial assays (e.g., Amplicor HCV) | Detects presence of circulating HCV RNA Monitor patients on antiviral therapy | Detects virus as early as 1–2 weeks after exposure Detection of HCV RNA during course of infection might be intermittent False-positive or false-negative results might occur |
| Hepatitis C Virus Ribonucleic Acid (HCV RNA) | | |
| Quantitative tests ^a RT-PCR amplification of HCV RNA by in-house or commercial assays (e.g., Amplicor HCV Monitor) Branched chain DNA (bDNA) assays (e.g., Quantiplex HCV RNA Assay) | Determine concentration of HCV RNA Might be useful for assessing the likelihood of response to antiviral therapy | A single negative RT-PCR is not conclusive Should not be used to exclude the diagnosis of HCV infection or to determine treatment endpoint Less sensitive than qualitative RT-PCR |

^aCurrently not US Food and Drug Administration approved; lack standardization.

factor for infection exposure (IV drug abuse, blood transfusions, needle stick), confirmatory assays may not be required (Table 73-23).

Tests for HCV RNA may be indicated for diagnosing HCV when HCV antibody tests are unreliable and when indeterminate results are obtained. Thus, direct testing of HCV RNA is preferred to anti-HCV in the early stages of acute HCV infection before HCV antibodies have been produced, when antibody tests are unreliable (e.g., immunocompromised patients), when intermediate results are reported (e.g., RIBA-2 in blood donors), in differentiation between active and past infection, and in the evaluation of patients with chronic liver disease in whom antibody tests are intermediate.

Natural History

Nonimmunocompromised Patients

Once established, infection with HCV persists in most patients.^{241,245,246,263} Because disease progression is often asymptomatic, patients are typically diagnosed when they receive routine biochemical testing during a physical examination or before blood donation, for example. Because NANB hepatitis (e.g., hepatitis C) was established in 1974, comprehensive data pertaining to the natural history of the disease are limited. It is known, however, that HCV infection leads to progressive liver disease. Following an asymptomatic period, histologic or clinical cirrhosis can be identified in 8% to 42% of patients as early as 15 months following the infection.^{241,245,246,263} Of patients, 10% may also have decompensated liver disease as evidenced by splenomegaly, ascites, coagulopathy, and esophageal varices. In nonimmunocompromised patients, the time between acute infection and manifestations of chronic liver disease is usually 20 to 30 years with rare instances of terminal disease occurring within 3 to 5 years

following acute infection. Patients with chronic HCV infection are also at increased risk for HCC.^{241,245,246,263}

Patients receiving dialysis have a greater incidence of HCV infection compared with the general population (6% to 22%) because they receive multiple blood transfusions.²⁶⁴ Kidney transplant recipients also have a high incidence of HCV infection (6%–28%), which may be acquired through dialysis before transplant or from the allograft or blood products following transplantation.²⁶⁵ Following kidney transplantation, elevation in aminotransferases is more common in anti-HCV-positive compared with anti-HCV-negative patients (48% and 14%, respectively) and cirrhosis has been reported with the former.^{266,267} While HCV infection is associated with liver failure, differences in overall patient and graft survival between HCV-positive and HCV-negative patients do not appear to be significant. Long-term studies are needed to confirm these findings.

Immunocompromised Patients

Chronic HCV infection is the most common indication for orthotopic liver transplantation (OLT) in the United States with up to 40% of patients receiving a transplant for the disease.^{268–271} Recurrence rates of HCV following transplantation are 100%, possibly because of viremia at the time of transplant.^{268–271} In addition, *de novo* acquisition of HCV from the donor liver or from blood products may occur. One-year follow-up studies indicate that 50% of patients with viremia following transplant (HCV RNA) have normal biopsies with no histologic evidence of HCV infection, 40% have mild chronic hepatitis, and 10% have progressive liver damage with chronic active hepatitis and bridging fibrosis or cirrhosis.^{268,269} Histologic evidence of disease may also be present even when aminotransferase levels are normal. Reports suggest that high viral loads, as measured by quantitative HCV RNA, have been correlated with early acute hepatitis in the allograft and that

genotype 1b may predispose OLT recipients to more severe histologic disease compared with recipients of transplants with other genotypes.^{268–270} Controlled trials are needed to further evaluate the relationship between genotype, viral load, amount of immunosuppression, and immunomodulating coinfections (e.g., CMV) and the course of posttransplant HCV infection.

HIV Coinfection

The incidence of HCV infection in HIV-infected patients is variable with up to 100% infection reported in HIV-positive injection drug users.²⁶⁸ In other populations, such as homosexual men, the incidence is marginally greater than that reported in the general population. Some studies suggest that patients with HCV who are coinfecting with HIV may also have more severe hepatic injury and a worse outcome than those infected with HCV alone, whereas other reports contradict these findings.^{268,272–274} These conflicting reports may be affected by several factors, including the duration of HCV infection before HIV infection, the route of HCV infection, the genotype associated with infection, and patient selection.

HBV Coinfection

As mentioned above, both HBV and HCV are transmitted parenterally and coinfection is not uncommon, particularly in IV drug users and in countries with a high prevalence of HBV infection.^{73,241} Coinfection with chronic HBV and HCV results in more severe liver disease than infection with either virus alone, including increased risk of liver cancer and fulminant hepatitis.^{72,241,275,276}

Clinical and Extrahepatic Manifestations

Most patients with acute HCV infection are asymptomatic.^{241,246,263,277} In contrast, patients with chronic HCV infection generally complain of fatigue. Nonspecific symptoms are similar to those seen with HBV infection, including nausea, anorexia, abdominal discomfort, and depression. Once patients develop cirrhosis and portal hypertension, they may experience intractable ascites, spontaneous bacterial peritonitis, GI or esophageal bleeding, poor synthetic function (hypoalbuminemia or prolonged PT), or encephalopathy.^{241,246,263,277} Jaundice occasionally occurs in acute HCV infection, but it is usually present in chronic infection as a result of decompensated liver disease.

Significant extrahepatic manifestations may also develop as a result of HCV infection.^{241,246,263,277} They include membranoproliferative glomerulonephritis, mixed cryoglobulinemia, porphyria cutanea tarda, leukocytoclastic vasculitis, focal lymphocytic sialadenitis, corneal ulcers, idiopathic pulmonary fibrosis, and rheumatoid arthritis.

Prevention of Hepatitis C

Pre-exposure Prophylaxis

No vaccines are effective against HCV, and current measures to prevent hepatitis C infection have largely focused on identifying high-risk uninfected persons and counseling them on risk-reducing strategies to prevent infection.

The CDC and NIH have published recommendations that address these issues.^{241,244} Suggested primary preventative measures are that in health care settings, adherence to universal (standard) precautions for the protection of medical personnel

and patients be implemented and that HCV-positive individuals should refrain from donating blood, organs, tissues, or semen. In some situations, the use of organs and tissues from HCV-positive individuals may be considered. For example, in emergency situations the use of a donor organ in which the HCV status is either positive or unknown may be considered in an HCV-negative recipient after full disclosure and informed consent. Strategies should be developed to identify prospective blood donors with any history of injection drug use. Such individuals must be deferred from donating blood.

Furthermore, safer sexual practices, including the use of latex condoms, should be strongly encouraged in persons with multiple sexual partners. In monogamous long-term relationships, transmission is rare.^{241,244} Although HCV-positive individuals and their partners should be informed of the potential for transmission, insufficient data exist to recommend changes in current sexual practice in persons with a steady partner. It is recommended that sexual partners of infected patients should be tested for antibody to HCV.

In households with an HCV-positive member, sharing razors and toothbrushes should be avoided.^{241,243} Covering open wounds is recommended. Injection needles should be carefully disposed of using universal precaution techniques. It is not necessary to avoid close contact with family members or to avoid sharing meals or utensils. No evidence justifies exclusion of HCV-positive children or adults from participation in social, educational, and employment activities.

Additionally, pregnancy is not contraindicated in HCV-infected individuals. Perinatal transmission from mother to baby occurs in <6% of instances.^{241,244} No evidence indicates that breast-feeding transmits HCV from mother to baby; therefore, it is considered safe. Babies born to HCV-positive mothers should be tested for anti-HCV at 1 year.

Finally, needle exchange and other safer injection drug use programs may be beneficial in reducing parenterally transmitted diseases.^{241,244} Expansion of such programs should be considered in an effort to reduce the rate of transmission of hepatitis C. It is important that clear and evidenced-based information be provided to both patients and physicians regarding the natural history, means of prevention, management, and therapy of hepatitis C.

Postexposure Prophylaxis

Immunoglobulin is no longer recommended for postexposure prophylaxis of hepatitis C infection because it is not effective.^{241,244,279}

Treatment of Acute Hepatitis C

36. R.D. is a 37-year-old, 95-kg professional athlete with multiple arm tattoos and a remote history of IV drug use. In 1993, an unscheduled physical examination was performed on R.D. because of the severe fatigue he experienced following inscription of a tattoo. Laboratory tests at that time revealed the following results: ALT, 350 U/L (normal, 5–40 U/L); serum anti-HCV positive (RIBA-2); and an HCV RNA level of 800,000 viral equivalents/mL (bDNA). What were the clinical and serologic features of HCV in R.D. (at that time), and what drug therapy could have been used to treat his acute hepatitis C?

R.D. clearly had a clinical picture consistent with acute HCV infection, including symptoms of fatigue, elevated ALT,

Table 73-24 Comparative Pharmacokinetics of Pegylated Interferons

| Parameter | Interferon- α | Peginterferon- α 2b (12 kDa) | Peginterferon- α 2a (40 kDa) |
|--|----------------------|-------------------------------------|-------------------------------------|
| Absorption | Rapid | Rapid | Sustained |
| Distribution | Wide | Wide | Blood, organs |
| Clearance | — | 10-fold reduction (hepatic/renal) | 100-fold reduction (hepatic) |
| Elimination half-life (hr) | 3–5 | 30–50 | 50–80 |
| Weight-based dosing | No | Yes | No |
| Increased concentration with multiple dosing | No | Yes | Yes |
| Protected from degradation | No | Probable | Yes |

and positive anti-HCV RIBA-2 assay and HCV RNA levels. Interferon- α has been studied in patients with acute HCV in an effort to reduce the severity and rate of progression of chronic infection. Limited data suggest that patients with acute HCV infection receiving IFN- α had a lower rate of chronic infection (36%–61%) compared with patients who did not receive therapy (80%–100%).^{280,281} These studies, however, have included relatively few patients and used varying dosages and durations (6 months to 1 year). One recent report in Germany evaluated 44 patients with acute hepatitis C.²⁸² Patients received 5 MU of IFN- α 2b SC daily for 4 weeks and then three times per week for another 20 weeks. Serum HCV RNA concentrations were measured before and during therapy and 20 weeks after the end of therapy. At the end of therapy, 43 of 44 patients had undetectable concentrations of HCV RNA in serum and normal serum alanine aminotransferase concentrations. Therapy was well tolerated in all but one patient, who stopped therapy after 12 weeks because of side effects. Thus, if early identification is possible, interferon therapy in the acute phase of the disease appears to be rational. Thus, R.D. could have been started on IFN- α to minimize his risk for developing chronic HCV infection.

Treatment of Chronic Hepatitis C

37. Initially, R.D.'s hepatologist did not initiate IFN therapy. R.D. now presents to the clinic confused (encephalopathic), with mild ascites and scleral icterus. Significant laboratory findings are as follows: total bilirubin, 4.2 ng/mL (normal, 0.2–1.0 ng/mL); direct bilirubin, 2.2 ng/mL (normal, 0–0.2 ng/mL); ALT, 350 U/L (normal, 5–40 U/L); and AST, 330 U/L (normal, 5–40 U/L). Additionally, genotyping of R.D.'s HCV infection shows that he is genotype 2. What pharmacologic agents are effective in the treatment of patients with chronic hepatitis C?

R.D. appears to have an atypical accelerated progression of hepatitis C infection based on the current status of his disease. Chronic hepatitis develops in approximately 80% of patients with acute hepatitis C infection. Of patients chronically infected with HCV, approximately 8% to 42% develop histologic or clinical cirrhosis and disability from end-stage liver disease.^{241,243,246,263} Up to 10% of cases are associated with decompensated disease with splenomegaly, ascites, coagulopathy, and esophageal varices as early as 15 months after the episode of acute HCV infection. The lack of specific immunoprophylaxis and significant morbidity and mortality associated with chronic HCV infection highlight the need for effective antiviral therapy. Previously, symptomatic patients with chronic hepatitis C infection without decompensated liver dis-

ease could be treated with IFN- α ^{283–298} (Table 73-24) or IFN plus ribavirin^{299–301} (Table 73-25) based on controlled studies confirming effectiveness. Furthermore, patients without evidence of fibrosis or significant inflammatory activity are at extremely low risk for the development of cirrhosis or serious hepatic complications; therefore, they can usually defer therapy. Conversely, patients with advanced cirrhosis are poor candidates for current IFN-based treatment regimens because of the increased treatment-associated morbidity seen in these patients and the possible precipitation of decompensation or frank hepatic failure.

GOALS OF THERAPY

The goals of therapy for treating HCV infection are (a) eradicate the virus; (b) decrease morbidity and mortality; (c) normalize biochemical markers; (d) improve clinical symptoms; (e) prevent spread of the disease; (f) prevent progression to cirrhosis and hepatocellular carcinoma; and (g) prevent the development of end-stage liver disease and its manifestations. These goals may be partly achieved through pharmacologic therapy.

Table 73-25 Contraindications to Interferon- α Plus Ribavirin

| Interferon | Ribavirin |
|-----------------------------------|---|
| Absolute neutrophil <1.5 | Unstable cardiac disease |
| Platelets <75,000/mm ³ | Severe chronic obstructive pulmonary disease (COPD), asthma |
| Severe depression | Renal dysfunction |
| Psychiatric instability | Serum creatinine >1.5 mg/dL |
| Active substance abuse | Creatinine clearance <50 mL/min |
| Uncontrolled autoimmune disorders | Anemia |
| Thyroid | Hemoglobin <13 g/dL in males |
| Diabetes | Hemoglobin <12 g/dL in females |
| Rheumatoid arthritis | Hemoglobinopathies |
| Elevated antinuclear antibodies | Thalassemias, sickle cell anemia |

Note: Pregnancy risk:

1. Contraindicated in women who are pregnant or by men whose female partners are pregnant.
2. Negative pregnancy test should be obtained before therapy.
3. Women of childbearing potential and men capable of inducing pregnancy must use two reliable forms of birth control during treatment; contraception should be continued for 6 months following discontinuation of treatment.

Interferon

ASSESSMENT OF INTERFERON RESPONSE AND EFFICACY

Several tests are used to assess therapy in HCV infection. These include biochemical markers such as ALT (less reliable), histologic markers (improvement in HAI), clinical progression and mortality, and viral load (HCV RNA). Patterns of response with respect to viral load can be summarized as follows: (a) nonresponder: no reduction in HCV RNA during treatment; (b) partial responder: reduced HCV RNA during treatment, increased HCV RNA following treatment period; (c) relapser: HCV RNA undetectable during treatment followed by high HCV RNA at the end of therapy; and (d) sustained responder: nondetectable HCV RNA throughout the treatment period and beyond the end (usually 6 months) of therapy (Fig 73-6).

In one of the largest trials published to date, patients with chronic hepatitis C were randomly assigned to 3 MU or 1 MU of IFN- α 2b three times weekly for 24 weeks or placebo.²⁸³ Response to therapy was assessed by serial measurements of ALT values and liver biopsy results before and after treatment. Of 58 patients treated with 3 MU of IFN- α , approximately one-third had normalized ALT values compared with 16% of patients treated with 1 MU of IFN- α and <5% of untreated controls. Improvement in liver histology was noted in patients receiving IFN- α . The responses to IFN- α were rapid (in general, within 12 weeks). End of treatment response, however, was poor following discontinuation of IFN- α .

Because of the suboptimal response of interferon in early clinical trials, several strategies were attempted to enhance efficacy.²⁸³⁻²⁹⁸ Explored strategies included longer courses of therapy, higher doses of interferon, and utilization of different formulations of interferon.³⁰²⁻³¹¹ Also, patients developed anemia, thrombocytopenia, neutropenia, and neurologic adverse effects with the prolonged regimens or higher dosing schedules. Ultimately, there did not appear to be a significant difference in efficacy or tolerability between different forms of interferon (e.g., IFN- γ , consensus interferon).³⁰²⁻³¹⁰

38. Are there additional IFN formulations that R.D. could receive that may be more efficacious than IFN- α monotherapy for treating chronic HCV infection?

Additional Treatment Strategies

RIBAVIRIN PLUS INTERFERON

In 1998, reports were published on the results of blinded, placebo-controlled trials of patients infected with hepatitis C with combination therapy utilizing interferon and ribavirin for treatment naïve patients²⁹⁹⁻³⁰¹ (Table 73-25) and in patients with relapsing HCV.³⁰² In a double-blind, US multicenter trial, patients with chronic HCV infection were randomly assigned to receive recombinant IFN- α 2b plus placebo for 24 weeks or 48 weeks, or the combination of IFN- α 2b and ribavirin for 24 weeks or 48 weeks.²⁹⁷ IFN- α 2b was administered SC at a dosage of 3 MU three times per week, and oral ribavirin (or matched placebo) was given in daily divided doses of 400 mg (AM) and 600 mg (PM) in patients <75 kg or 600 mg twice daily in patients >75 kg. Efficacy was determined based on sustained virologic response (absence of HCV RNA 24 weeks after treatment was discontinued), biochemical response (reduction in serum aminotransferases), and histologic response (hepatic inflammation and fibrosis based on biopsy).

Greater sustained virologic response took place in patients receiving combination therapy with ribavirin for either 24 weeks (70 of 228 patients; 31%) or 48 weeks (87 of 228 patients; 38%) than in patients who received IFN alone for 24 weeks (13 of 231 patients; 6%) or 48 weeks (29 of 255 patients; 13%). The rate of sustained biochemical response similarly was greater among patients who received IFN and ribavirin for 24 or 48 weeks than among those who received IFN alone. Histologic improvement was observed most often in patients receiving the combination regimen for either 24 weeks (57%) or 48 weeks (61%) compared with IFN alone for either 24 weeks (44%) or 48 weeks (41%). Dose-limiting adverse effects were most commonly associated with combination therapy. Of patients on ribavirin, 8% required dosage reduction for hemoglobin concentrations <10 g/dL. Hemoglobin concentrations remained depressed, yet stable, with the dosage reduction throughout the rest of the trial period and returned to baseline within 4 to 8 weeks after treatment was stopped at 24 or 48 weeks. Dyspnea, pharyngitis, pruritus, rash, nausea, insomnia, and anorexia were also more common with combination therapy than with IFN alone. The most common reason for discontinuation of therapy was depression, which ranged from 2% to 9% in all groups. Despite the favorable outcomes with combination therapy, no difference in overall survival was described between the treatment groups.

Similarly, another placebo-controlled, multicenter, randomized trial was performed in 832 patients with compensated chronic HCV infection.³⁰⁰ Patients were assigned to one of three regimens: 3 MU IFN- α 2b three times per week plus oral ribavirin (400 mg followed by 600 mg daily if <75 kg or 600 mg twice daily if >75 kg) for 48 weeks; 3 MU IFN- α 2b three times per week plus oral ribavirin (400 mg followed by 600 mg daily if <75 kg or 600 mg twice daily if >75 kg) for 24 weeks; or 3 MU IFN- α 2b three times per week plus placebo for 48 weeks. The primary study endpoint was loss of detectable HCV RNA (serum HCV RNA <100 copies/mL) at week 24 after treatment. A sustained virologic response was observed in 119 (43%) of the 277 patients treated for 48 weeks with the combination regimen, 97 (35%) of the 277 patients treated for 24 weeks with the combination regimen, and 53 (19%) of the 278 patients treated for 48 weeks with IFN alone.

Discontinuation of therapy for adverse events was more frequent with combination therapy (19%) and monotherapy (13%) given for 48 weeks than combination therapy given for 24 weeks (8%).

PREDICTORS OF TREATMENT OUTCOME

These studies have resulted in the identification of several independent factors predicting sustained virologic response to combination therapy.^{241,311,312} The most significant of which is HCV genotype. Generally, genotype 1-infected patients have poor response to interferon and ribavirin, irrespective of viral load, and require 48 weeks of therapy. Patients with HCV other than genotype 1 with a viral load <2 million copies/mL, however, have higher response rates and require only 24 weeks of therapy. Additional host factors have been identified and may help predict response to, and duration of, therapy, allowing combination therapy to be tailored more effectively.^{241,311,312} In addition to HCV genotype non-1, other factors that predict a good response to interferon and ribavirin include age <40 years, female gender, and little to no portal fibrosis

on biopsy.^{241,311,312} In addition, black patients with chronic HCV infection have lower response rates than whites to IFN monotherapy and are predominantly infected with genotype 1.^{241,311,312}

Based on previous studies, R.D. could have benefited from the combination of ribavirin plus IFN. Other interferon-based therapies exist that are considered to be the standard of care for patients with chronic HCV infection.

Current Treatment Strategies

39. What other IFN-based drug therapy could provide R.D. with therapeutic advantages over IFN alone or IFN plus ribavirin?

Although the advent of combination interferon and ribavirin therapy has led to significant improved clearance of serum HCV RNA and improved both biochemical and histologic evidence of chronic hepatitis, numerous patients with chronic infection are not adequately treated.^{241,299–301,311,312} Thus, research in the last few years has examined methodologies for enhancing the effectiveness of interferon-based treatments. The most promising of these explorations has been the development of pegylated interferons.^{241,313–316} These compounds are formed through the attachment of polyethylene glycol (PEG) to an interferon molecule, thus changing the pharmacokinetic and pharmacodynamic properties of the drug (Table 73-24).^{241,313–316} Of importance, the PEG moiety significantly increases the half-life of IFN, resulting in sustained serum concentrations and permitting once weekly dosing.^{241,313–316} The current “standard of care” is PegIFN plus ribavirin for most patients with chronic hepatitis C infection. Subgroups of patients remain in whom standard IFN plus ribavirin combination or pegylated monotherapy may be preferable. Treatment groups are discussed below.

PEGYLATED INTERFERONS

Currently, two forms of PegIFN are FDA approved for treatment of HCV infection. The linear 12 kDa PegIFN, peginterferon α 2b (Pegintron; Schering-Plough Corporation), was the first to be FDA approved.^{241,313,317,318} The 40-kDa pegylated interferon, peginterferon α 2a (Pegsys; Hoffman La Roche), has also received FDA approval (Table 73-24).^{241,313,319–321}

Efficacy

In a dose-finding study, PegIFN- α 2b (12 kDa) was compared with IFN- α 2b for the initial treatment of compensated chronic hepatitis C.³¹⁷ Patients received either IFN- α 2b 3 MU three-times-weekly or PegIFN- α 2b 0.5 mcg/kg, 1.0 mcg/kg, or 1.5 mcg/kg once weekly. Subjects were treated for 48 weeks and then followed for an additional 24 weeks. All three PegIFN- α 2b doses significantly improved virologic response rates (loss of detectable serum HCV RNA) compared with IFN- α 2b. Unlike the end-of-treatment virologic response, the sustained virologic response rate was not dose related above 1.0 mcg/kg PegIFN- α 2b because of a higher relapse rate among patients treated with 1.5 mcg/kg PegIFN- α 2b, particularly among patients infected with genotype 1. All three PegIFN- α 2b doses decreased liver inflammation to a greater extent than did IFN- α 2b, particularly in subjects with sustained responses. Adverse events and changes in laboratory values were mild or moderate.

In another trial using the 40 kDa PegIFN dosage form, PegIFN- α 2a was compared with IFN- α 2a in the initial treat-

ment of patients with chronic hepatitis C.³¹⁹ A total of 531 patients with chronic hepatitis C were randomized to receive either 180 mcg of PegIFN- α 2a SC once per week for 48 weeks or 6 MU of IFN- α 2a SC three times per week for 12 weeks, followed by 3 MU three times per week for 36 weeks. Patients were assessed at week 72 for a sustained virologic response that was defined as an undetectable level of hepatitis C virus RNA (<100 copies/mL). PegIFN- α 2a was associated with a higher rate of virologic response than was IFN- α 2a at week 48 (69% versus 28%) and at week 72 (39% versus 19%). Sustained normalization of serum alanine aminotransferase concentrations at week 72 was also more common in the PegIFN group than in the IFN group (45% versus 25%). The two groups were similar with respect to the reported adverse events. Authors concluded that in these patients, a regimen of PegIFN- α 2a given once weekly is more effective than a regimen of IFN- α 2a given three times per week.

These trials demonstrate that monotherapy with pegylated interferons is superior to conventional interferon alone. Several trials have evaluated the role of combination pegylated interferon plus ribavirin for the treatment of chronic hepatitis C infection.^{318,321,322}

Manns et al.³¹⁸ compared the combination of PegIFN- α 2b (1.5 mcg/kg/week) plus ribavirin 800 mg/day with PegIFN- α 2b (1.5 mcg/kg/week with a reduction to 0.5 mcg/kg/week after 4 weeks) plus ribavirin 1,000 to 1,200 mg/day and with IFN- α 2b plus ribavirin.³¹² No difference in the sustained response was observed between the lower dose of PegIFN- α 2b (12 kDa) plus ribavirin and standard IFN- α 2b plus ribavirin. The difference in the overall treatment response between PegIFN- α 2b (12 kDa) (1.5 mcg/kg) plus ribavirin and IFN- α 2b plus ribavirin was 6% adjusted for viral genotype and presence of cirrhosis at baseline. As with other IFN-based therapies, patients with genotype 1 infection, regardless of their pretreatment viral load, had a lower response to PegIFN- α 2b (12 kDa) plus ribavirin compared with patients infected with other viral genotypes. The superior efficacy of PegIFN plus ribavirin over standard IFN plus ribavirin was only seen in patients with genotype 1 infection. One-third of patients with both genotype 1 infection and a high viral load (>2,000,000 copies/mL, >800,000 IU/mL) responded to therapy in both groups. Similarly, the efficacy of PegIFN plus ribavirin was the same as that observed with standard IFN plus ribavirin in patients with bridging fibrosis or cirrhosis.

Other researchers have compared the efficacy and safety of PegIFN- α 2a plus ribavirin, IFN- α 2b plus ribavirin, and PegIFN- α 2a alone in the initial treatment of chronic hepatitis C.³²¹ In this trial, patients were randomly assigned to three treatment groups who received at least one dose of study medication consisting of 180 mcg of PegIFN- α 2a once weekly plus ribavirin 1,000 or 1,200 mg/day (depending on body weight), weekly PegIFN- α 2a plus daily placebo or 3 MU of IFN- α 2b three times weekly plus daily ribavirin for 48 weeks. A significantly greater proportion of patients receiving PegIFN- α 2a plus ribavirin had a sustained virologic response (defined as the absence of detectable HCV RNA 24 weeks after cessation of therapy) compared with patients who received IFN- α 2b plus ribavirin (56% versus 44%; $P < 0.001$) or PegIFN- α 2a alone (56% versus 29%; $P < 0.001$). The proportions of patients with HCV genotype 1 who had sustained virologic responses were 46%, 36%, and 21%, respectively, for the three regimens.

Among patients with HCV genotype 1 and high baseline levels of HCV RNA, the proportions of those with sustained virologic responses were 41%, 33%, and 13%, respectively. The overall safety profiles of the three treatment regimens were similar. Based on these results, it appears that PegIFN- α 2a plus ribavirin is superior to IFN- α 2b plus ribavirin or PegIFN- α 2a alone in the treatment of chronic hepatitis C. Pooled data from these trials suggest that the sustained virologic response (SVR) rates were higher among patients with HCV RNA genotype 2 or 3 (76%–84%) and lower among those patients with genotype 1 (42%–52%).

Predictors of Treatment Outcome for Pegylated Interferons

Independent variables associated with a favorable response to pegylated interferon plus ribavirin include genotype non-1, low pretreatment HCV RNA level, light body weight, young age (40 years), and the absence of bridging fibrosis or cirrhosis.^{241,318,321} Ethnicity is also a strong predictor of response to therapy with PegIFN. Based on data from clinical trials, blacks have lower response rates than do whites.³²³ Another predictor of SVR has been established by monitoring the rate of HCV RNA reduction following initiation of therapy.^{325,326} Assessment of antiviral effects through viral kinetics have been shown to help in predicting the likelihood of a SVR. Because the decline in HCV RNA follows a pattern of biphasic reduction, it enables clinicians to determine whether a rapid virologic response (RVR), defined as undetectable HCV RNA, occurs. If this response is observed, it is a strong predictor of obtaining an SVR. Additionally, if patients with genotype 1 do not have an early virologic response (EVR), defined as ≥ 2 log₁₀ decrease in HCV RNA from baseline or undetectable HCV RNA at 12 weeks, they are unlike to achieve an SVR and therapy may be discontinued.

40. Should weight-based ribavirin dosing be recommended in R. D.?

The most appropriate dose of ribavirin administered in combination with PegIFN- α 2b is controversial.^{241,246} The FDA-approved ribavirin dose of 800 mg is lower than that approved for standard IFN- α 2b. The FDA-approved dose was selected because of concerns regarding additive toxicities associated with peginterferon and ribavirin. Additional data from trials of PegIFN- α 2a have suggested that the 800-mg dose is sufficient for treatment of nongenotype 1 infection, but that higher doses (1,000 mg/1,200 mg based on a 75 kg weight) are necessary for effective treatment of genotype 1. Additional data analysis from the pivotal trials has led to patient-specific recommendations for duration and dosing of therapy based on HCV genotype (Fig. 73-6). Patients with genotypes 2 and 3 require only 24 weeks of therapy with 800 mg daily of ribavirin, whereas patients with genotype 1 (and potentially genotype 4), require 48 weeks of therapy and full doses of ribavirin (1,000–1,200 mg daily).

A distinct relationship occurs between successful outcomes (SVR) and exposure to ribavirin. In patients who received <60% of the total ribavirin dose, early virologic response rates and SVR were lower than in patients who had reduced ribavirin exposure (73% versus 79%–84% and 33% versus 57%–67%, respectively).³²⁷ Furthermore subanalysis of the Manns et al.³¹² data established that the dose of ribavirin is predictive of achieving SVR. Recent data from an open label,

multicenter trial suggest that patients with HCV genotype 1 had improved SVR rates in patients receiving PegIFN- α 2b 1.5 mcg/kg/week plus weight-based ribavirin dosing (800–1,400 mg/day) for 48 weeks compared with those receiving PegIFN- α 2b 1.5 mcg/kg/week plus 800 mg of ribavirin daily (34% versus 28.9%; $P = 0.005$) for 24 or 48 weeks.³²⁸ In patients with HCV genotype 2 or 3, rates were not significantly different (61.8% versus 59.5%, respectively) regardless of treatment duration. These findings suggest that PegIFN- α 2b plus weight-based dosing of ribavirin for 48 weeks may be appropriate for patients with genotype 1, whereas same-dose (800 mg ribavirin) for 24 weeks may be adequate for patients with genotype 2 or 3. Additional data are needed to establish individual dosing recommendation for ribavirin based on HCV genotype. Because R.D. has genotype 2, he should be initiated on PegIFN- α 2a in a dose of 180 mcg weekly and oral ribavirin 800 mg daily in two divided doses. At 24 weeks, his aminotransferase and HCV RNA levels should be assessed, and therapy stopped.³²⁹ (Fig. 73-6).

Adverse Effects and Monitoring

41. What adverse effects might be expected if pegylated interferon plus ribavirin are used in R. D., and what are appropriate monitoring parameters?

In the clinical trials with PegIFN and ribavirin, adverse effects resulted in discontinuation of treatment in approximately 10% to 14% of patients.^{317–323} Adverse events were similar between those patients receiving PegIFN plus ribavirin and those receiving IFN plus ribavirin, except for a higher frequency of injection site reactions and a higher frequency of neutropenia in the PegIFN plus ribavirin group. Side effects in both groups included influenza-like symptoms, hematologic abnormalities, thyroid dysfunction, and neuropsychiatric symptoms.^{317–323} The education of patients, their family members, and caregivers about side effects and their prospective management is an integral aspect of treatment.

Regular monitoring of neuropsychiatric side effects, cytopenias, and adherence to HCV therapy is mandatory (Table 73-25). Psychological conditions, particularly depression, are common among persons with hepatitis C and are frequent side effects of interferon.^{314–323} Patients' mental health should be assessed before initiation of antiviral therapy and monitored regularly during therapy, because the ability to comply with the treatment regimen may become compromised. Antidepressants, such as selective serotonin reuptake inhibitors, may be useful in the management of depression associated with antiviral therapy.^{314–323}

In certain patients with persistent cytopenias despite dose reductions, treatment with hematopoietic growth factors (i.e., erythropoietin, granulocyte colony-stimulating factor) may be useful to reduce symptoms and maintain adherence to antiviral therapy.^{314–323} This therapy is costly, however, and the optimal dosage is not yet clear. Additionally, it is not known if the use of hematopoietic growth factors will enhance the likelihood of an SVR. Thus, the potential benefits of these agents need confirmation in prospectively designed trials before they can be recommended.

Of special importance, severe hemolysis from ribavirin can occur in patients with renal insufficiency.^{314–323} In these patients, the ribavirin dose should either be reduced or

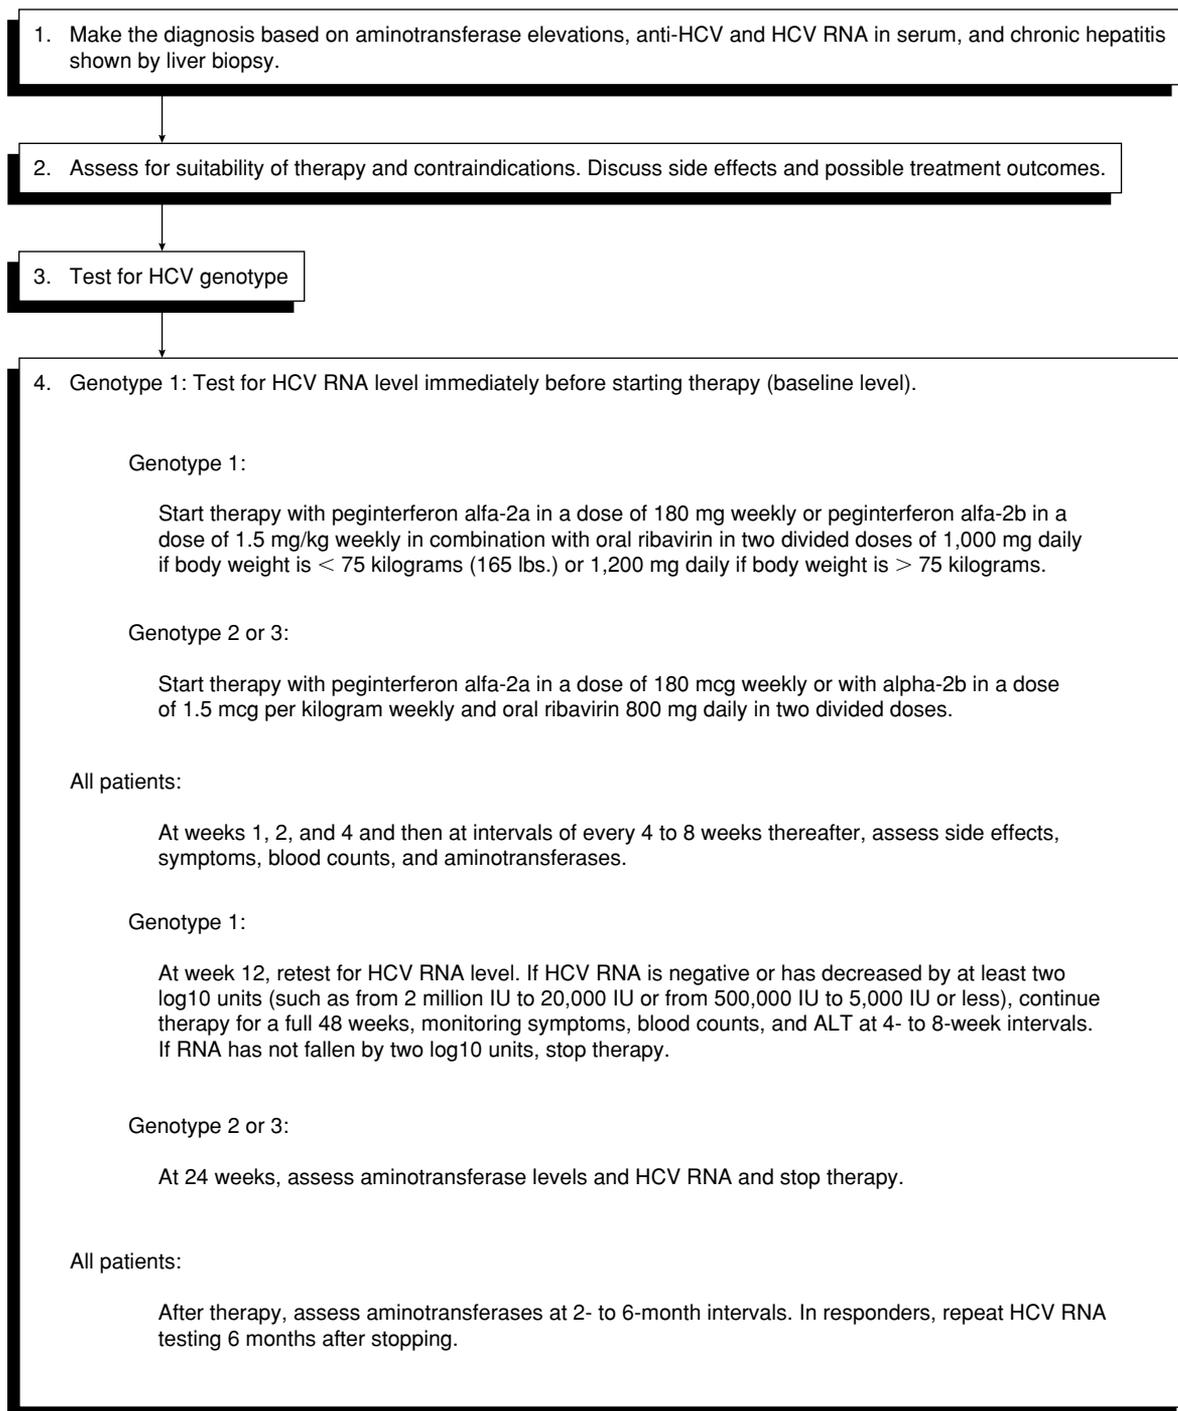

FIGURE 73-6 Algorithm for treatment of hepatitis C. Based on reference 241, with permission.

discontinued. Of note, ribavirin is not removed by hemodialysis. Finally, lactic acidosis may be a rare complication of combination therapy in patients undergoing therapy for HIV and HCV. Thus R.D. should be monitored closely to minimize the risk of severe adverse effects in initiated PegIFN plus ribavirin therapy.

Choosing Interferon Formulations

Pegylated interferons offer the convenience of once weekly versus three times weekly dosing, but PegIFN are associated with

a greater incidence of cytopenias and injection site reactions compared with standard IFN. Moreover, there are subsets of patients in which treatment response with standard IFN- α 2b plus ribavirin is the same with as PegIFN plus ribavirin. These include patients with nongenotype-1 infection and patients with compensated cirrhosis.^{241,246} When deciding whether to treat a patient with PegIFN or standard IFN in combination with ribavirin, the patient and provider should weigh the risks and benefits of the two treatment regimens (Fig. 73-6). For example, in the patient with compensated cirrhosis, particularly if

he or she has leukopenia before therapy, standard IFN might be the preferred treatment because of a short half-life and reduced likelihood of dose reductions for cytopenias.

Interferon or Pegylated Interferon Monotherapy

For patients with contraindications to the use of ribavirin, such as those with unstable cardiac disease, anemia, renal insufficiency, or those who might conceive while receiving treatment or within 6 months of completing therapy, IFN monotherapy or PegIFN should be considered.^{241,246} Pegylated interferons have been shown to be superior to standard IFN α in the treatment of hepatitis C, and PegIFN are the treatment of choice in select patients.^{241,246}

As a result of recent trials, combination therapy is the treatment of choice for naïve patients, that is those who have received neither interferon nor ribavirin therapy and who are able to tolerate ribavirin. Pegylated interferons plus ribavirin offer the convenience of once-weekly dosing, but with only a slight increase in efficacy and an increase in adverse events compared with standard IFN α plus ribavirin.^{241,246} The FDA-approved dose of ribavirin is 800 mg, but higher doses (1,000/1,200 mg based on a 75 kg weight) may be improve efficacy in patients with genotype 1 infection. A ribavirin dose of 800 mg appears adequate for treatment of genotype non-1 infection. Although the results using PegIFN plus ribavirin are encouraging, the benefits of treatment on important clinical outcomes such as prevention of complications of advanced liver disease and the prevention of hepatocellular carcinoma remain to be demonstrated. Finally, no clinical trials have demonstrated the superiority of one type of PegIFN compared with the other (e.g., PegIFN- α 2a versus PegIFN- α 2b).

Treatment Options for Relapse of Chronic Hepatitis C

42. What is the role for combination therapy in patients who have relapse of chronic HCV infection?

As noted, HCV relapse rates (based on HCV RNA reappearance) often occur following discontinuation of IFN therapy despite longer courses of treatment. Based on previous trials, the combination of ribavirin plus IFN may reduce HCV relapse. Results from these trials were confirmed in 345 patients with chronic active HCV who relapsed following IFN.^{302,323} A total of 173 patients were randomly assigned to receive either standard dose IFN- α 2b with ribavirin (400 mg [AM] and 600 mg [PM] in patients <75 kg or 600 mg twice daily in patients >75 kg) for 6 months or IFN and placebo.³⁰² The primary endpoints of the study were the disappearance of HCV RNA from the serum and histologic improvement at the end of the 24-week follow-up period. On completion of treatment, serum levels of HCV RNA were undetectable in 141 of 173 patients who received combination therapy compared with IFN alone (82% versus 47%; $P < 0.001$). Serum HCV RNA continued to be undetectable in 84 patients (49%) in the combination group and in only 8 patients (5%) in the IFN alone group ($P < 0.001$) at 6 months. Patients who achieved a virologic response also had sustained normalization of serum ALT concentrations and histologic improvement. Of note, patients with the greatest response were those with low viral load and genotypes 2 or 3. As in previous trials, patients receiving combined therapy had a significant reduction in their hemoglobin concentrations, but otherwise had a safety profile similar to that of IFN alone.

These results appear to be as good or better than those in patients receiving higher doses and longer courses of IFN. Thus, patients with chronic HCV infection without decompensated liver disease who relapse, may benefit from combination therapy.

Adjunctive Therapies

43. In addition to IFN alone, or the combination of IFN plus ribavirin, or PegIFN, are there any other therapeutic options available for R.D.?

Interferon responders have lower serum iron, iron saturation, and hepatic iron levels (which is believed to upregulate cellular immune responses) than do nonresponders to IFN.³²⁴ In pilot trials, iron reduction by phlebotomy has been correlated with an improvement in aminotransferase levels in patients with chronic HCV infection and iron overload. These limited data suggest an enhanced response to IFN may be achieved through iron reduction by phlebotomy.

Other approaches to treating chronic HCV infection include nonsteroidal anti-inflammatory drugs,³³⁰ pentoxifylline,³³¹ vitamin E,³³² omega-3 fatty acid supplements³³³; herbal remedies, such as glycyrrhizin (licorice root),³³⁴ silymarin (milk thistle),³³⁵ and sho-saiko-to (TJ-9),³³⁶ are unproved for the routine treatment of HCV. These agents are thought to have anti-inflammatory or antifibrotic effects on the liver, which may lead to normalization of biochemical markers (i.e., ALT). Data from patients receiving IL-10 (Tenovil), which inhibits the Th1 T-cell subset, suggest that formation of liver scar tissue may be reduced.³³⁷

Future therapies for treatment of HCV infection are promising and numerous are in development. Recent studies using hydroxymethylglutaryl-coenzyme A (HMG-CoA) reductase inhibitors (e.g., statins) confirm that cholesterol biosynthesis has an impact on HCV replication and that statins may be useful in interrupting this pathway.³³⁸ In addition to conventional and PegIFN, recombinant human albumin or IFN- α fusion protein (Albuferon), which has a prolonged half-life and excellent antiviral activity, has entered phase II trials.³³⁸⁻³⁴⁰ Alternatives to ribavirin have also been developed. Viramidine, a ribavirin prodrug, has limited exposure to red blood cells (RBC) and demonstrated significant antiviral activity and erythrocyte-sparing properties.³³⁸⁻³⁴⁰ In the last few years, the development of *in vitro* replication systems for HCV has led to significant advances in the HCV replication cycle. Specifically targeted antiviral therapy (STAT-C) include those agents that specifically target the viral replication cycle: internal ribosome entry site (IRES) inhibitors, translation (protease, helicase) inhibitors, translation (polymerase) inhibitors, and virus assembly (glycoside) inhibitors.³³⁸⁻³⁴⁰ Cyclophilin inhibitors and immune mediators (IFN- γ - and IFN- β , thymosin, and levovirin) may also prove useful for treating HCV infection.³³⁸⁻³⁴⁰ Finally, an experimental vaccine has also been studied in chimpanzees; however, no efficacy or safety data are available with this agent in humans.³⁴¹ R.D. should not be initiated on these agents at this time as further investigation is needed.

Summary of HCV in Nonimmunocompromised Patients

Overall, many factors have been identified that are associated with an increased or decreased likelihood of response to IFN therapy in patients infected with HCV. Analyses have

generally shown that a decreased pretreatment HCV RNA titer is associated with more favorable response, that genotypes other than type 1b exhibit higher sustained response rates compared with genotype 1b, and that responders have less fibrosis and less inflammatory changes than nonresponders. Furthermore, most trials conducted using IFN or combinations thereof exclude patients with decompensated liver disease (cirrhosis), patients with HCC, patients with cryoglobulinemia or associated membranoproliferative glomerulonephritis, and children infected with HCV. Additional experience is needed in these areas to definitively assess therapy for HCV infection.

Treating Hepatitis C Following Liver Transplantation

44. While discussing treatment options for HCV infection, R.D. experiences a sudden loss of consciousness. He is admitted to the intensive care unit where he will be emergently evaluated for a liver transplant. What are the therapeutic options for preventing or treating HCV-infected patients following liver transplantation?

Uncontrolled trials have reported the efficacy of IFN- α in treating hepatitis C following transplantation.³⁴²⁻³⁴⁴ In one report, 11 patients were treated with IFN- α (3 MU three times weekly for 6 months).³⁴² After therapy was stopped, only one patient had normal liver enzyme levels and IFN was not correlated with precipitating allograft rejection. In a similar trial, 4 of 18 patients (22%) had a sustained biochemical response (normal aminotransferase levels) at the end of treatment and in 6-month follow-up.³⁴⁴ HCV RNA levels were reduced in both responders and nonresponders, but returned to pretreatment levels after discontinuation of IFN. Sustained effects were not observed, nor were improvements in histology. Only one patient had an IFN-associated, biopsy-proved delayed rejection episode. In contrast to these reports, others have identified IFN therapy with precipitating rejection, possibly because of its ability to upregulate the expression of human leukocyte antigen (HLA) class I and II antigens.³⁴⁵

Similar to the nontransplant population, the combination of IFN and ribavirin or ribavirin alone has also been assessed in liver transplant recipients for treating recurrent HCV infection following transplantation.³⁴⁶⁻³⁴⁸ Data from pilot and randomized, noncomparative trials suggest that combination therapy is effective but poorly tolerated.³⁴⁶ Furthermore, transplant recipients appear to have a high incidence of hemolysis, thrombocytopenia, and mental status changes with combination therapy. Transplant recipients should also be closely monitored for rejection during and following cessation of IFN plus ribavirin therapy. Finally, the use of PegIFN alone or in combination with ribavirin has also been considered following liver transplantation.³⁴⁶ Any combination therapy could be considered (based on response criteria for interferon as listed above) in the following areas in liver transplant recipients having transplant because of HCV: (a) as prophylaxis for HCV immediately following liver transplantation (first transplant); (b) as prophylaxis for HCV immediately following liver transplantation (second transplant for recurrent HCV); (c) in patients with HCV recurrence without decompensation with worsening symptoms; and (d) in patients with recurrent HCV with decompensation. These areas are clearly controversial and continue to warrant clinical investigation.

HEPATITIS E VIRUS

Virology, Epidemiology, Transmission, and Pathogenesis

Hepatitis E virus is an icosahedral, nonenveloped virus of the *Caliciviridae* family between 32 and 34 nm wide that was initially identified by immune electromicroscopy in the stool samples of infected persons (Table 73-2).^{349,350} The HEV genome is a single-stranded polyadenylated RNA and, unlike HAV, has an RNA genome that encodes for nonstructural proteins through overlapping open reading frames (ORF). Several ORF encode for nonstructural proteins, structural proteins, or proteins of undetermined function. The HEV polyprotein has several sequences, including an RNA-dependent RNA-polymerase, and RNA helicase, and a virally encoded cysteine protease.

Hepatitis E virus occurs in endemic areas such as Africa, Southeast and Central Asia, Mexico, and Central and South America as both epidemic and sporadic infections.^{349,351} Sporadic infections also occur in nonendemic areas and are usually associated with travel into areas of endemicity. The attack rate (the percentage of exposed patients who become infected) of HEV is low compared with HAV (1% versus 10%, respectively). In endemic areas, outbreaks usually occur between 5 and 10 years apart and are often associated with times of heavy rainfall, after floods or monsoons, or following the recession of flood waters.^{349,351,352} The overall case fatality rate for the general endemic population is 0.5% to 4%, whereas for reasons unknown, pregnant women have a much greater case fatality rate of 20%.^{349,353} In particular, the fetal complication rate is increased, especially if the infection occurs in the third trimester of pregnancy.^{349,354} The frequency of death *in utero* and immediately following birth is also greater than seen with acute hepatitis of other causes.^{349,354}

Transmission of HEV is via the fecal-oral route, and the most common source of transmission is ingestion of fecally contaminated water.^{349,351,353} Poor climactic conditions in conjunction with inadequate personal hygiene and sanitation have led to epidemics of HEV infection. Secondary attacks usually are much lower than that observed with HAV, ranging from 0.7% to 2.2% versus 50% to 75%, respectively.^{349,351,353} The mechanism for this difference could be related to the instability of HEV to its environment, differences in the quantity of virus needed to propagate infection, or a greater frequency of subclinical disease.

Interference with the production of cellular macromolecules, alteration of cellular membranes, and alteration of lysosomal permeability are some of the proposed mechanisms of hepatic injury.^{355,356} In addition, immune-mediated mechanisms are believed to be responsible for lysis of virally infected hepatocytes by direct lymphocyte cytotoxicity or antibody-mediated cytotoxicity.

Diagnosis

Initial assays for detection of anti-HEV used electromicroscopy to detect HEVAg on the surface of HEV particles in stool and serum and immunohistochemistry to detect the antigen in liver tissue.^{349,351,353} Fluorescent antibody-blocking assay is currently used to detect anti-HEV reacting to HEVAg in serum and, although highly specific, this assay lacks sensitivity (50%) in acute HEV infection.^{349,351} Additional cloning

and sequencing of HEV has led to the development of Western blot assays and ELISA that detect anti-HEV by using recombinant expressed proteins from the structural region of the virus. Reverse transcriptase polymerase chain reaction (RT-PCR) has also been used to confirm the diagnosis of HEV by detecting HEV RNA from serum, liver, or stool.^{349,351,353} Clinically, HEV is a diagnosis of exclusion.

Clinical Manifestations, Serology, and Natural History

The incubation period following exposure is listed in Table 73-1. Two phases of illness have been described, including a prodromal and preicteric phase as described for HAV infection. Peak serum aminotransferase levels reflect the onset of the icteric phase and generally return to baseline by 6 weeks.^{349,354} Stool is often positive for HEV RNA at the onset of the icteric phase and persists for an additional 10 days beyond this period. Viral shedding may also occur for up to 52 days after the onset of icterus. Detection in the serum occurs during the preicteric phase, before detection of virus in the stool, and becomes undetectable following the peak in aminotransferase activity. Because HEV RNA is not detectable in the serum during symptoms, diagnostic tests using HEV RNA have limited utility and a correlation between PCR detection and infectivity has not been observed. Serologically, HEV IgM becomes detectable before the peak rise in ALT, whereas antibody titers peak with peak ALT levels and subsequently decline. In most patients, HEV IgM is present for 5 to 6 months following the onset of illness. HEV IgG appears after HEV IgM and remains detectable for up to 14 years after acute infection; however, the duration of protective immunity has not been fully elucidated.^{349,357}

In nonfatal cases, acute HEV hepatitis is followed by complete recovery without any chronic complications. There appears to be protection from reinfection; however, the duration of protection is variable. Fulminant hepatitis has also been associated with HEV infection and has a high association with pregnancy.^{349,351,352,354} Maternal mortality was reported to be 1.5% for HEV infection occurring in the first trimester of pregnancy, 8.5% for those in the second trimester, and 21% for those infected in the third trimester.

Prevention and Treatment

No immunoprophylactic measures exist for HEV disease, and effective prevention strategies are dependent on improved sanitation in endemic areas. Travelers going to endemic areas should be educated regarding the risks of drinking water, eating ice, or eating uncooked shellfish or uncooked and peeled fruits and vegetables. Drinking water should be boiled to inactivate HEV. No vaccines or postexposure prophylaxis are available to prevent HEV infection. Results from a phase II randomized trial suggest, however, that in a high-risk population, a recombinant hepatitis E vaccine can be effective in the prevention of HEV infection.³⁵¹

HEPATITIS G VIRUS

Virology

In 1995, the genomes of two previously unidentified RNA viruses were cloned from experimentally inoculated tamar-

rins.³⁵⁸⁻³⁶⁰ The original inoculate was obtained from a surgeon (initials G.B.) with NANB hepatitis who was thought to have HCV. The viruses were subsequently named GB virus A (GBV-A) and GB virus B (GBV-B).³⁵⁸⁻³⁶⁰ Another unknown RNA virus related to GBV-A and GBV-B was discovered (using representational difference analysis) and was designated GB virus C (GBV-C).³⁵⁸⁻³⁶⁰ Similar methods were also implemented in the discovery of one more previously unknown virus, designated TT virus (TTV), obtained from a patient (initials T.T.). In 1996, another independent research group isolated a novel RNA virus (designated HGV) that was associated with hepatitis.³⁵⁸⁻³⁶⁰ Sequencing studies comparing GBV-C and HGV have shown these isolates to be two genotypes of the same virus. Apparently, only humans and higher primates can be infected by human GBV-C/HGV.³⁵⁸⁻³⁶⁰

The GBV-C/HGV is a single-stranded enveloped RNA virus that consists of 9,100 to 9,400 nucleotides (Table 73-2).³⁵⁸⁻³⁶⁰ GBV-C/HGV belongs to the *Flaviviridae* viruses, and temporarily to the hepacivirus genus together with HCV because the genomic organization of this virus resembles HCV. The biological functions of many GBV-C/HGV proteins have not been entirely defined, although the capsid region of this virus is defective and core proteins are not encoded, unlike with HCV. An envelope region that encodes a surface glycoprotein as well as protease, helicase regions has been identified.³⁵⁸⁻³⁶⁰ Additional phylogenetic analysis has depicted four genotypes: genotype 1 (GBV-C; originated from West Africa), genotype 2 (TTV; originated from the United States), and genotype 3 and 4 (originated from Asia).

Epidemiology

Spread worldwide, GBV-C/HGV infection has been observed in healthy persons and in IV drug users, men who have sex with men, patients receiving multiple transfusions, and patients with fulminant hepatic failure.^{358,359,361} Viremia has been reported to be between 1% and 4% among healthy populations in Europe and North America and even higher rates (10%–33%) have been documented in residents of South America and Africa.³⁵⁸⁻³⁶⁰ The prevalence of resolved GBV-C/HGV infections (using envelope antibodies) appears to be more common than the occurrence of viremic infections. Rates of resolved infections described in blood donors are 3% to 15% in Europe, 3% to 8% in North America, 20% in Africa and South America, and 3% to 6% in Asia.³⁵⁸⁻³⁶⁰

Transmission

Transmission of GBV-C/HGV has been primarily associated with blood transfusions and infections have been observed in the presence of other hepatitis viruses (e.g., HBV, HCV).³⁵⁸⁻³⁶⁰ Additional modes of transmission include injection drug use, hemodialysis, sexual contact, and vertical or perinatal transmission.³⁵⁸ Also, GBV-C/HGV RNA has been isolated in saliva, suggesting that close social contact may be a possible mode of transmission.³⁵⁸⁻³⁶⁰

Pathogenesis and Diagnosis

The pathogenesis and serologic presentation of GBV-C/HGV are poorly described. The natural course of GBV-C/HGV

infection appears to vary from an acute self-limited episode to a chronic infection that may persist from years to decades.^{358-360,362} GBV-C/HGV can cause mild acute hepatitis, but despite persistent infection, it does not appear to cause clinically significant chronic hepatitis.³⁵⁸ Diagnosis is usually established through detection of the virus by RT-PCR methodology (HGV RNA).^{358,363} Additionally, first generation EIA tests have been utilized to detect specific antibodies to the envelope glycoprotein to diagnose previous infection; however, the specificity and sensitivity of these tests have not been fully elucidated. Reliable serologic assays are needed.

Clinical Manifestations and Treatment

Clinical and extrahepatic manifestations of GBV-C/HGV are unknown, but the virus has been found to be in serum for many years in patients with several types of liver diseases.^{358-364,365} No causal relationship has been established between GBV-C/HGV and acute, fulminant, and chronic non B-C-D hepatitis.^{358-360,364,365} The role of the GBV-C/HGV in human hepatitis remains unclear. Published studies provide further evidence that GBV-C/HGV may not be a significant cause of acute or chronic liver disease.³⁵⁸ One report demonstrated that 15% of children with chronic hepatitis C or hepatitis B are infected with GBV-C/HGV; however, GBV-C/HGV coinfection does not appear to cause more severe liver disease. In another report, serum HCV RNA concentrations, liver histology, and response to treatment with IFN- α did not differ between patients with and without GBV-C/HGV coinfection. Loss of serum HGV RNA did not correlate with a biochemical response, whereas loss of serum HCV RNA did. These results show that GBV-C/HGV coinfection frequently occurs in individuals infected with HCV and that GBV-C/HGV does

not influence the severity of liver disease or response to treatment with—IFN- α in patients with chronic hepatitis C. Because the significance of GBV-C/HGV is unclear, screening of blood donors for this virus is not presently justified. Currently, no agents are used to treat or prevent GBV-C/HGV infection.³⁵⁸

SUMMARY

Viral hepatitis continues to be a significant worldwide infectious disease. To date, prevention strategies through universal vaccination are the most efficient methods for minimizing the incidence of HAV, HBV, and HDV. Patient education with respect to the common ways of spreading these infections may also result in behavioral modifications that reduce the overall incidence of infection. Once HBV and HCV progress to chronic infection, more efficacious and better tolerated antiviral therapies are needed to treat these infections. Similarly, therapeutic modalities that reduce the progression of these diseases are necessary to prevent end-stage liver disease and the development of additional complications (encephalopathy, intractable ascites, coagulation disorders, and HCC). As a better understanding of viral replication is established, as well as appropriate models for study, new agents may become available. Furthermore, more diagnostic tools are needed to better identify new hepatitis viruses and monitor response to drug therapies. The economic impact and quality of life of these patients remains to be fully elucidated.

MALARIA**Distribution and Mortality**

Malaria is considered the world's most important parasitic disease, responsible for an estimated 300 to 500 million cases and annual deaths in excess of 1 million.¹⁻⁴ Approximately 27 million U.S. travelers visit malaria-endemic areas each year.⁵ The distribution of the four *Plasmodium* species of malaria varies worldwide, with *Plasmodium falciparum*, which has the highest mortality, primarily acquired in sub-Saharan Africa, Haiti, the Dominican Republic, the Amazon region in South America, and parts of Asia and Oceania.

Life Cycle

Malarial infection is transmitted by the female mosquito of the genus *Anopheles*, which injects the asexual forms or sporozoites into the human host during a blood meal. After a lapse of about 9 to 16 days and an asexual multiplication stage in the liver called *exoerythrocytic schizogony*, daughter cells, or merozoites, are released into the blood to infect red blood cells (RBC). The merozoites develop into the characteristic ring or

trophozoite forms in RBC and then go through another asexual reproductive stage called *erythrocytic schizogony* to produce more merozoites. When the infected RBC ruptures, the merozoites invade new blood cells and repeat the erythrocyte cycle. In 1 or 2 weeks, a subpopulation of merozoites differentiates into the sexual forms, resulting in male and female gametocytes. If the gametocytes in the host blood are ingested by a female *Anopheles* mosquito during a blood meal, fertilization and an asexual division in the mosquito midgut will propagate the infective sporozoites to complete the cycle.

The characteristic malarial paroxysms of chills and fever in patients usually coincide with the periodic release of merozoites and other pyrogens in the blood. In *P. falciparum* infections, this periodicity may not always be apparent. However, intervals of 48 hours between paroxysms are reported for *Plasmodium vivax*, *Plasmodium ovale*, and *P. falciparum* (tertian periodicity), and 72 hours for *Plasmodium malariae* (quartan periodicity). Unlike infections caused by *P. falciparum* and *P. malariae*, infections with *P. vivax* and *P. ovale* have a latent form of the exoerythrocytic phase that can persist in the host liver for months to years. This latent form can produce relapses of the erythrocytic infection (Fig. 74-1).

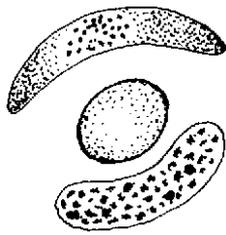

FIGURE 74-1 *P. falciparum* gametocytes.

Epidemiology

Although malaria is endemic to the tropics, approximately 1,324 cases were diagnosed in the United States in 2004.^{3,5} Of the 775 U.S. civilians who acquired malaria while abroad, 160 (20.6%) reported that they had been on a chemoprophylaxis regimen recommended by the Centers for Disease Control and Prevention (CDC).³ Malaria transmission in the United States has occurred from the blood of immigrants and travelers, local transmission, military personnel, and rarely through blood transfusions.^{2,3,5,6} In terms of the species of *Plasmodium* identified in the United States, 49% represented *P. falciparum*, and 81% of these infections were acquired in Africa.³ Transfusion malaria often is the result of *P. malariae*, which can persist in the blood without symptoms for extended periods and has also been reported to cause nephrotic syndrome.^{7,8} Malaria can also be transmitted congenitally and through contaminated needles.^{3,8,9}

Drug Resistance

Chloroquine-resistant *P. falciparum* (CRPF) is widespread and present in all malaria-endemic areas of the world except Mexico, the Caribbean, Central America (north of the Panama Canal), and parts of the Middle East (except Iran, Yemen, Oman, and Saudi Arabia).^{10–14} However, *P. falciparum* malaria, resistant to chloroquine and mefloquine, has been isolated in Thailand, Cambodia, and Myanmar (Burma). Chloroquine-resistant *P. vivax* is an emerging problem in Papua, New Guinea, Irian, Jaya (Indonesia), Myanmar, and Columbia.^{10,12,14,15} Most fatal cases of imported malaria in the United States are the result of travelers' failure to comply with appropriate chemosuppressive regimens, delays in seeking treatment, misdiagnosis by physicians or laboratories, and inappropriate antimalarial regimens.^{2,13} Prophylactic drug regimens for individuals traveling to endemic areas are problematic (see Question 5).^{10,11,15}

Acute Malaria

Signs and Symptoms

1. M.L., a 29-year-old male student, presents to the emergency department (ED) with complaints of malaise, myalgia, headache, and fever of 4 days' duration. A native of Ghana, West Africa, he recently visited his parents and returned to the United States 3 weeks ago. Two days before admission, he had an abrupt onset of coldness and chills, followed 1 hour later by a high fever, headache, nausea, and vomiting. The episode of chills and fever lasted about 24 hours, after which he became asymptomatic. On the afternoon

of admission, he again had a bout of chills that preceded a fever of 40°C.

Physical examination reveals a slender black man who is acutely ill and complaining of severe abdominal pain. Abdominal examination reveals a soft, tender spleen that is slightly enlarged. Blood pressure (BP) is 110/70 mmHg; pulse 120 beats/minute, respiration rate 32 breaths/minute, and temperature 40°C. Laboratory findings include hemoglobin (Hgb) 11 g/dL (normal, 12–16); hematocrit (Hct) 34% (normal, 36%–47%); white blood cell (WBC) count 3,300 cells/mm³ (normal, 4,000–11,000) with 76% neutrophils (normal, 45%–65%), 23% lymphocytes (normal, 15%–35%), and 1% monocytes (normal, 1%–6%); platelets 83 × 10³/mm³ (normal, 150–450); and bilirubin 1.0 mg/dL (normal, 0.1–1). Urinalysis reveals trace amounts of albumin and the presence of urobilinogen. Thick and thin films of M.L.'s blood are prepared. A Giemsa stain of the thin film demonstrates *P. falciparum* gametocytes. Why is the presentation of M.L. consistent with *P. falciparum* malaria?

[SI units: Hgb, 110 g/L (normal, 120–160); Hct, 0.34 (0.36–0.47); WBC count, 3.3 × 10⁹/L (normal, 4–11) with 0.76 neutrophils (normal, 0.45–0.65), 0.23 lymphocytes (normal, 0.15–0.35), 0.01 monocytes (normal, 0.01–0.06); platelets, 3.3 × 10⁹/L (normal, 150–450); bilirubin, 18 mmol/L (normal, 2–18)]

M.L. recently visited Ghana, West Africa, where *P. falciparum* is endemic.^{4,9,11} *P. vivax* malaria accounts for about 50% of all cases of malaria reported in the United States. The prevalence of *P. falciparum* malaria has been increasing, however, and it accounts for about 49% of all malarial cases.³ Infected persons usually experience prodromal symptoms (primarily headache, muscle aches and pains, malaise, nausea, and vomiting) around the second week after exposure.^{4,13} This time frame is consistent with M.L.'s onset of symptoms. The incubation period and the onset of primary symptoms for *P. falciparum* malaria can be delayed for months, however.^{4,11,16} History of travel to an endemic area, the cyclical paroxysmal episodes of chills and fever, the presence of thrombocytopenia and jaundice, and the identification of *P. falciparum* gametocytes in M.L.'s blood confirm the diagnosis of malaria.

Treatment

2. How should the *P. falciparum* malaria in M.L. be treated? How would M.L.'s treatment differ from that used for other *Plasmodium* species?

P. falciparum malaria, the most severe form of malaria, has the highest mortality rate.^{4,5,11,16–25} The fever spikes, unlike those associated with *P. vivax* and *P. ovale* malaria, normally are very high (40°C–41°C), and complications (including confusion, vomiting, diarrhea, severe abdominal pain, hypoglycemia, renal failure, and encephalopathy) are common.^{4,13,18–26}

QUINIDINE AND QUININE

M.L. is very ill and may be unable to tolerate oral medications because of nausea and vomiting. He should be admitted to an acute care unit and started on intravenous (IV) quinidine gluconate.^{4,9,11,18,27} For doses of IV quinidine, see Table 74-1. If >48 hours of parenteral therapy is required, the dosage of quinidine should be reduced by one-third to one-half.^{11,27}

| Doxycycline | <i>Adult:</i> 100 mg daily beginning 1–2 days before departure continuing during stay and 1 wk after return | Nausea, diarrhea and monilial rash |
| Quinine sulfate plus | <i>Adults:</i> 650 PO TID × 3 days <i>Children:</i> 25 mg/kg/day PO TID × 3 days | Cinchonism |
| Pyrimethamine-sulfadoxine (Fansidar) or | <i>Adults:</i> 3 tablets at once (withhold until febrile episode) <i>Children:</i> 1/2–2 tablets (depends on age) ^f | Gastrointestinal, erythema multiforme, Stevens-Johnson syndrome, toxic epidermal necrolysis |
| Mefloquine | <i>Adults:</i> 1,250 mg once <i>Children:</i> 25 mg/kg once (>45 kg) | Dose-related: vertigo, nausea, dizziness, light-headedness, headache, visual disturbances, toxic psychosis seizures |
| Prevention of Relapses (<i>P. vivax</i> and <i>P. ovale</i>) | | |
| Primaquine phosphate | <i>Adults:</i> 52.6 mg/day (30 mg base) × 14 days; this follows chloroquine or mefloquine regimen | Abdominal cramps, nausea, hemolytic anemia in G6PD |
| Scabies | | |
| 5% Permethrin (Elimite cream) | Topical administration | Rash, edema, erythema |
| Alternatives | | |
| Ivermectin | <i>Adults:</i> 200 mcg/kg PO; repeat in 2 wk | Nausea, diarrhea, dizziness vertigo and pruritus |
| Lindane (Kwell) | Apply topically once | Not recommended in pregnant women, infants, and patients with massively excoriated skin |
| Crotamiton 10% (Eurax) | Topically | Local skin irritation |
| Tapeworm^d | | |
| Praziquantel | <i>Adults and children:</i> 5–10 mg/kg PO × 1 dose | Malaise, headache, dizziness, sedation, eosinophilia, fever |
| Hydatid Cysts^e | | |
| Albendazole | <i>Adults:</i> 400 mg BID × 8–30 days, repeat if necessary <i>Children:</i> 15 mg/kg/day × 28 days, repeat if necessary (surgical resection may precede drug therapy) | Diarrhea, abdominal pain, rarely hepatotoxicity, leukopenia |
| Trichomoniasis | | |
| Metronidazole | <i>Adults:</i> 2 g PO × 1 day or 250 mg PO TID × 7 days <i>Children:</i> 15 mg/kg/day PO TID × 7 days | Nausea, headache, metallic taste, disulfiram reaction with alcohol, paresthesia |

^a*Schistosoma haematobium*, *S. mansoni*, *S. japonicum*, *Clonorchis sinensis*, *Paragonimus westermani*.^bQuinacrine is available in the United States: Panorama Compounding Pharmacy, Van Nuys, CA 91406.^cSame dose is recommended in children with *Cryptosporidium parvum*.^d*Diphyllobothrium latum* (fish), *Taenia solium* (pork), and *Dipylidium caninum* (dog), except for *Hymenolepis nana* where the dose is 25 mg/kg × 1 dose.^e*Echinococcus granulosus*, *E. multilocularis*. For neurocysticercosis: 400 mg BID 8–30 days.

BID, twice daily; ECG, electrocardiograph; G6PD, glucose-6-phosphate dehydrogenase; IM, intramuscularly; PO, orally; TID, three times daily.

Because IV quinidine is not routinely used in cardiology care, it may not be available in all hospitals. Because of the serious nature of *P. falciparum* malaria, small stocks of the drug should be kept on hand, or a procedure needs to be established in the hospital to acquire IV quinidine on short notice from an alternative source (Contact Eli Lilly: 800-545-5979).²⁷ Oral quinine and clindamycin or the combination of atovaquone and proguanil (Malarone) can be used until IV quinidine is available.^{4,7,27}

While receiving the IV quinidine, M.L.'s electrocardiogram, BP, and serum glucose should be monitored closely.^{4,7,9} Sup-

portive care, including fluid, IV dextrose 5% to 10% and electrolyte management, dialysis, blood transfusion, and mechanically assisted ventilation, are important adjunctive therapies in seriously ill patients. The serum concentration of quinidine should be determined once daily during the continuous infusion. Quinidine levels should remain between 6.1 and 16.5 mcml/dL. The quinidine infusion should be slowed or stopped if the QRS complex exceeds 25% of baseline, if hypotension is unresponsive to fluid challenge, or if the quinidine serum concentration is >16.5 mcml/dL.^{9,11} When M.L. can be switched to oral therapy, he should receive oral quinine

sulfate 650 mg Q 8 hr to complete 3 to 7 days of total therapy.^{9,11,18} The quinine is administered for 7 days if *P. falciparum* is acquired in Thailand.²⁷

MANAGING CHLOROQUINE-RESISTANT *PLASMODIUM FALCIPARUM*

If M.L. does not respond to the quinidine or quinine regimen within 48 to 72 hours (i.e., failure to reduce parasitemia by 25% of baseline and continued fever over this period), other adjunctive therapies must be considered.^{9,27} One of the recommended drug treatments for CRPF infection, which is added to quinine therapy, is doxycycline 100 mg twice daily for 7 days (doxycycline should overlap the quinine for 2 to 3 days before the latter is discontinued) or clindamycin 900 mg three times a day for 5 days.²⁷ If the patient cannot tolerate oral doxycycline, IV doxycycline 100 mg Q 12 hr can be substituted. An alternative in a patient who can tolerate oral therapy and in whom it is not contraindicated (i.e., history of seizures, or endemic area where *P. falciparum* is not resistant to the agent) mefloquine 750 mg can be initiated, followed by 500 mg 12 hours later.²⁷ M.L. may also be treated with the combination of atovaquone 250 mg and proguanil 100 mg (Malarone). The dose of Malarone is two tablets twice daily for 3 days.^{11,27} Although exchange transfusion has been suggested as an adjunct therapy for serious *P. falciparum* malaria, the role of this intervention remains questionable.¹¹ The CDC suggests that if patients have parasitemia >10%, or if the patient has altered mental status, nonvolume pulmonary edema, or renal complications, exchange transfusion be considered (www.cdc.gov/malaria/pdf/treatmenttable.pdf accessed on 02/26/07).

MANAGING OTHER *PLASMODIA* SPECIES

A patient infected with one of the other species of *Plasmodia* (*P. vivax*, *P. ovale*, or *P. malariae*) should receive oral chloroquine phosphate (Aralen). The initial dose is 1 g (600 mg base) followed by 500 mg (300 mg base) 6 hours later; subsequently, 500 mg (300 mg base) is administered daily for 2 days.²⁷ For patients who cannot tolerate the oral doses of chloroquine, parenteral doses of quinidine can be administered (Question 2 lists doses).²⁷ Patients with *P. ovale* and *P. vivax* also should be given primaquine to prevent relapses from the latent exoerythrocytic stages in the liver. The adult dosage of primaquine is 52.6 mg/day (30 mg base) for 14 days; this should follow the chloroquine regimen.^{7,27}

Chemoprophylaxis and Pregnancy

3. T.P., a male medical resident from Indonesia, is planning to visit his seriously ill mother. His wife, T.R., who is 16 weeks pregnant, and their 4-year-old daughter will accompany him. What prophylactic medications for malaria should be administered to each member of the family?

All travelers to endemic areas should receive chemoprophylaxis for malaria. In Indonesia, including Papua, New Guinea, all four types of malaria are present.^{7,9,11} T.P. and his family may have to take prophylactic therapy for all malarial species, including a regimen that will protect them against CRPF infections. To verify whether a country is included in the CRPF list or to obtain other relevant information on malaria prophylaxis, T.P. should call the CDC Malaria Hotline, which provides a touch tone-activated, computer-assisted service (770–

488-7788).^{2,27} Pregnant women are at greater risk for malaria infection and its complications (especially severe hemolytic anemia and splenomegaly) and should be advised not to travel to areas endemic for malaria, if possible.^{11,13,28–34} Current publications that provide updated information on parasitic diseases and immunization requirements include *Medical Letter, Morbidity and Mortality Weekly Reports, Health Information for International Travel*, and various Internet sites.^{11,13,18}

CHLOROQUINE AND PRIMAQUINE PHOSPHATE

Chloroquine phosphate is an effective chemoprophylactic agent against all species of *Plasmodia* except drug-resistant *P. falciparum*. The adult dosage of chloroquine phosphate is 500 mg (300 mg base) once weekly beginning 1 week before departure and continuing for 4 weeks after last exposure. The pediatric dosage of chloroquine is 5 mg/kg base (8.3 mg chloroquine phosphate) once weekly beginning 1 week before departure and continuing for 4 weeks after exposure. A suspension of chloroquine in chocolate syrup can be prepared for children (5 mg/mL). Chloroquine prophylaxis is safe during pregnancy, and the benefits outweigh the risk of malaria and the drug's possible side effects.^{9,11,13,27,29,31} Mefloquine and Malarone may be options for prophylaxis and treatment in pregnancy^{29–34}; however, these are not recommended for this particular indication in the United States.²⁷

By taking the chloroquine 1 week before travel, the patient can achieve adequate antimalarial chloroquine levels in the blood by the second week. Potential side effects also can be detected early. A weekly dose of 0.5 g of chloroquine phosphate produces average plasma concentrations of chloroquine between 0.47 and 0.78 μmol/L. Most strains of *P. vivax* and *P. falciparum* are susceptible to plasma levels between 0.046 and 0.093 μmol/L, respectively.^{7,18,35} Mefloquine (Lariam) 250 mg (salt) once weekly beginning 1 week before departure and continuing for 4 weeks after leaving a malarious area is an alternative regimen to chloroquine.^{7,18,27,36} Mefloquine is not recommended during pregnancy or in children weighing ≤5 kg, however, because the safety of this agent has not been fully established in these populations.²⁷ Recently, *P. vivax* was reported to be resistant to chloroquine in Indonesia and New Guinea, and despite the lack of data on mefloquine in pregnancy (T.R. is in the second trimester), T.R. may have to be given this agent.^{15,18,32,33,37,38} Chloroquine suppresses the asexual erythrocytic forms of the malaria parasite and has no action against the exoerythrocytic phase of *P. vivax* and *P. ovale*.^{7,18} However, primaquine phosphate prevents relapses of *P. vivax* and *P. ovale* by inhibiting the exoerythrocytic stage; it also has a significant gametocidal effect against all species.^{11,15,18} To prevent an attack after departure from an area where *P. vivax* and *P. ovale* are present, the clinician should also prescribe primaquine phosphate 52.6 mg/day (30 mg base) for 14 days to coincide with the last 2 weeks of the chloroquine regimen. Primaquine should not be administered to pregnant patients.²⁷ The major toxicity of concern, aside from the teratogenic risk, is hemolytic anemia in patients with RBC glucose-6-phosphate dehydrogenase (G6PD) deficiency.^{7,18,28,36,39}

PROPHYLAXIS FOR CHLOROQUINE-RESISTANT *PLASMODIUM FALCIPARUM*

Prophylaxis for CRPF also can be achieved by taking mefloquine in the doses indicated above instead of using the

chloroquine regimen.²⁷ An alternative to mefloquine is doxycycline 100 mg/day beginning 1 day before travel and continuing for the duration of the stay and for 4 weeks after leaving the malarial area. Travelers such as T.P. should be advised to take measures to reduce contact with infected mosquitoes by wearing long-sleeved blouses/shirts and pants/trousers, applying insect repellent containing 31% to 35% meta-N, N-diethyl-metoluamide (DEET) (e.g., HourGuard-12, Amway Corp.; DEET Plus, Sawyer Products), sleeping in a screened room, or using netting impregnated with permethrin.^{30,32,34,37,40} An alternative to the mefloquine chemoprophylaxis regimen in CRPF areas is the combination of atovaquone 250 mg and proguanil 100 mg (Malarone) administered once daily taken 1 to 2 days before departure and continued for 1 week after return.^{1,2,27} The pediatric dosage (Malarone Pediatric) contains 62.5 mg of atovaquone and 25 mg of proguanil.^{1,27} Instead of doxycycline, T.R. could take Malarone as chemoprophylaxis. The advantage of Malarone is that it can also be used as treatment. The recommended therapeutic dose of Malarone for CRPF is two tablets twice daily for 3 days.²⁷ Both prophylaxis and treatment of CRPF in nonimmune subjects and pregnant patients continue to pose special problems.⁴¹⁻⁴⁷ Pyrimethamine has teratogenic effects and sulfonamides are contraindicated in early pregnancy; however, chloroquine, quinine, and quinidine have been suggested as safe treatments during pregnancy.^{2,4,27,29,32,33,39,43} Although not associated with abortions, low birthweight, neurologic retardation, or congenital malformations, mefloquine is associated with an increased risk of stillbirth.^{27,34,35,39}

T.P. and T.R. should reconsider their decision to travel together because of the risks of malarial infection during pregnancy. In view of the recent report of *P. vivax* resistance to chloroquine in Indonesia, the family members should consider using mefloquine.²⁷ The risks and benefits of mefloquine in pregnancy (T.R. is in her second trimester) should be communicated to the family.^{15,39} Physical barriers (e.g., clothes, mosquito nets), insect repellent, and a short stay in the endemic area also should be helpful.^{29,34,48}

Malaria Vaccine

4. Why could T.R. not be vaccinated as an alternative to prophylaxis with 8-aminoquinolines such as chloroquine?

Currently, no vaccination is available. As a result of successful *in vitro* *P. falciparum* cultivation and advances in genetic engineering and monoclonal antibody research, some progress has been made, but this vaccine is probably a few years away.⁴⁹⁻⁵⁴ The malaria plasmodium undergoes many transformations during its development, and each stage expresses a different plasmodial genome that generates a large number of antigens. The development of a malaria vaccine relies on the identification and characterization of these antigens and the subsequent production of monoclonal antibodies.^{49,51}

At present, three types of vaccines against *P. falciparum* are under study: a merozoite vaccine that would induce immunity against the erythrocytic forms of plasmodia in the blood, a sporozoite vaccine that would protect against the exoerythrocytic or liver phase, and a gamete vaccine ("transmission blocking") that would prevent transmission of malaria in endemic areas.⁴⁹ When a vaccine for malaria is available, it is expected to provide an immune response for at least 1 year.

The safety of these vaccines to the fetus and mother during pregnancy will require evaluation.

Multidrug-Resistant *Plasmodium Falciparum* Malaria

5. F.S., a permanent U.S. resident of Cambodian origin, is planning to travel to the Thai-Kampuchean refugee camp. What antimalarial agents should he use for chemoprophylaxis?

F.S. is traveling to the Thai-Burma border, where *P. falciparum* malaria is epidemic. Chemoprophylaxis against malaria in this region of southeast Asia has become progressively difficult because of the appearance of *P. falciparum* strains resistant to chloroquine, pyrimethamine-sulfadoxine, quinine, and even mefloquine.^{7,13,38,41,43,46,47}

F.S. will have to take chemoprophylaxis against both *P. vivax* and multidrug-resistant *P. falciparum*. Mefloquine (Lariam) 250 mg once weekly starting 1 week before travel and continuing weekly for the duration of the stay and for 4 weeks after leaving Thailand is recommended.²⁷ On return from his visit, primaquine phosphate should be added to F.S.'s regimen to prevent an attack of *P. vivax*, because mefloquine has no effect on the exoerythrocytic phase of *P. vivax* (see Question 3 for doses of primaquine).²⁷ Another alternative drug for prophylaxis against *P. falciparum* malaria for F.S. would be doxycycline 100 mg taken once daily beginning 1 to 2 days before departure and continuing for 4 weeks after he returns from Thailand.^{2,27}

A new chemical entity, ginghamosu, has been undergoing field trials and may prove to be useful for resistant *P. falciparum*. Ginghamosu, a plant extract (artemisinin compounds), has been used for many centuries in China for fever and malaria.^{4,7,10,41-45,55-58} Artemisinin and its derivatives (artemether and artesunate) are considered rapidly effective even against CRPF strains and have undergone numerous trials.^{7,18,55-58} The antimalarial agent halofantrine (Halfan) may be another alternative to mefloquine, but this agent has been associated with fatal arrhythmias.²⁷ Clinical trials of fosmidomycin, tefenoquine, lumefantrine, and other new antimalarial agents are ongoing.^{1,14,15,47,55-60}

Side Effects of Antimalarials

6. A.K., a 36-year-old Malaysian man, is seen in the ED with a 2-day history of fever, chills, and bouts of diarrhea following his return from west Malaysia, where he was visiting his parents for 3 weeks. A.K. had not taken any prophylaxis for malaria. A blood smear stained with Giemsa solution demonstrated *P. vivax*, and A.K. was given chloroquine 1 g (600 mg base) initially, to be followed by 500 mg (300 mg base) 6 hours later and 500 mg at 24 and 48 hours. On completion of the chloroquine regimen, A.K. was instructed to take primaquine 52.6 mg/day (30 mg base) for 14 days. However, A.K. was seen again in the ED a day later with complaints of abdominal pain, severe headache, vomiting, and a "bitter taste" in the mouth. What subjective evidence does A.K. exhibit that is compatible with the toxicity of antimalarials?

The major side effects of chloroquine (e.g., nausea, abdominal pain, pruritus, vertigo, headache, and visual disturbances)^{7,18,39} usually are associated with large doses such as those needed for A.K.'s therapy. The gastrointestinal (GI) complaints and severe headache experienced by A.K. are consistent with chloroquine therapy, and the bitter taste he

described is experienced by all patients who are given chloroquine or other 8-aminoquinoline preparations. Because A.K. also will be taking primaquine after the course of chloroquine, he should be told that he probably will experience some GI upset with this drug as well. Abdominal cramps associated with primaquine may be relieved by antacids or by taking the drug after meals. The severe nausea and vomiting may have dehydrated A.K., and he should be encouraged to replenish his fluids. Table 74-1 lists the adverse effects of antimalarials.

Glucose-6-Phosphate Dehydrogenase Deficiency

7. Why is A.K. at risk for primaquine sensitivity?

Primaquine sensitivity, or G6PD deficiency, is an inherited error of metabolism transmitted by a gene of partial dominance located on the X chromosome. Patients with this enzyme deficiency are sensitive to the 8-aminoquinolines, sulfonamides, para-aminosalicylates, nitrofurantoin, sulfone, aspirin, quinine, quinidine, nalidixic acid, and methylene blue.^{27,36,39} G6PD in RBC preserves glutathione in the reduced form (Fig. 88-2, Chapter 88, Drug-Induced Blood Disorders) by regenerating nicotinamide adenine dinucleotide phosphate (NADPH). Reduced glutathione protects RBC membranes from increased oxidant stress. Patients with low levels of glutathione and impaired regeneration of NADPH, as seen with G6PD deficiency, are susceptible to the oxidizing effect of drugs.^{18,30,61–63} Hemolysis reportedly occurs on the third day of drug ingestion and usually is manifested as abdominal discomfort, anemia, and hemoglobinuria.⁶¹

The incidence of G6PD deficiency in the southeast Asian refugee population is approximately 5.2%.⁶³ Because A.K. is a native of Malaysia and may have G6PD deficiency, he may be at risk of hemolysis if primaquine is ingested. Therefore, he should be screened for G6PD deficiency before being treated with this drug.

Although a number of simple and satisfactory screening tests for G6PD deficiency are available, the fluorescent spot test is the simplest, most reliable, and most sensitive. The spot test is based on the addition of a reagent containing NADPH to a hemolysate of the patient's RBC. After an incubation period, the mixture is spotted on filter paper and examined under long-wave ultraviolet light. Fluorescence of the mixture on the filter paper will indicate the presence of NADPH generated by G6PD. In patients who have G6PD deficiency, it will fluoresce only weakly, or no fluorescence will be detected. Large variants exist among those with the mutant gene, and if A.K. has a variant with relatively mild episodic clinical manifestations (variant A, with 10%–60% residual enzyme activity), he may be treated with primaquine at 45 mg/week for 8 weeks.⁶⁴

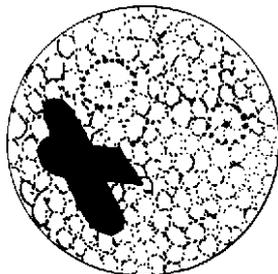

FIGURE 74-2 *E. histolytica*.

AMEBIASIS

Prevalence and Mortality

Amebiasis, caused by the small protozoan parasite *Entamoeba histolytica* (Fig. 74-2), results in amebic dysentery and hepatic abscess.^{65–69} Approximately 10% of the world's population (predominately in Latin America, Africa, and Asia) is infected, and about 100,000 die annually from this infection.^{64,65} In the United States, amebiasis is considered endemic in 33% of immigrants from Mexico and Central and South America and in 17% from those from Asia and Pacific Islands.^{64,66} Most of these individuals are infected with *E. dispar* (80%), an antigenically different strain from the pathogenic *E. histolytica* (10%) that does not seem to cause symptomatic invasive disease.^{66,68} Amebiasis can be asymptomatic, or it can present as colitis or dysentery. Extraintestinal lesions, primarily abscesses in the liver, also can be characteristic.^{65–68}

Life Cycle

The amebic parasite or trophozoite lives in the lumen of the colon and the colonic mucosa (Fig. 74-3). Trophozoites do not survive outside the host body and, if ingested, will be destroyed by gastric juice. In contrast, the encysted trophozoites can survive drying and freezing: they are killed only by temperatures in excess of 55°C or by hyperchlorination of water.^{66,68} Infection occurs by ingestion of cysts present in contaminated water or food. Once ingested by the host, each cyst dissolves in the alkaline media of the small intestine and undergoes asexual division to produce eight trophozoites.^{65–68} The trophozoites, which represent the invasive form of *E. histolytica*, then move to the large bowel, invade the mucosal crypts, and produce ulcerations.^{65–68} Ulcerations of the bowel wall can result in amebic dysentery, inflammatory lesions in the bowel (amebomas), amebic appendicitis, and perforation of the colon or intestine.^{66,68,70–75} The amebae also can enter into the portal vein, which transports them to the liver, where they can initiate multiple abscesses.^{66,68,75–78} Cases of genital and cutaneous amebiasis are rare but have been reported.^{66,68}

Amebic Dysentery

Diagnosis

8. M.B., a 41-year-old Egyptian immigrant, presented to the ED with a 10-day history of abdominal pain and multiple, loose

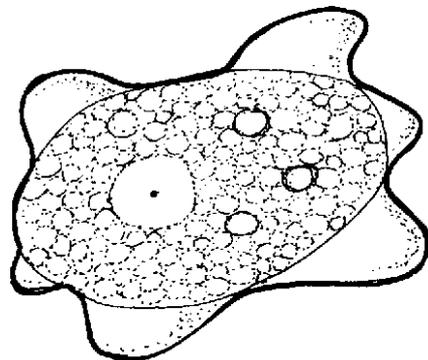

FIGURE 74-3 *E. histolytica* trophozoite.

watery stools with occasional streaks of blood. On physical examination, he is a thin man with abdominal distress. His vital signs are temperature 38°C; pulse 88 beats/minute; and BP 120/80 mmHg. He has no skin lesions, jaundice, or lymphadenopathy. The examination is remarkable for slight abdominal distention with some right lower quadrant tenderness. Rectal examination reveals some tenderness and brown liquid stool positive for occult blood. Proctosigmoidoscopy demonstrates colonic mucosa that is diffusely edematous and friable. A biopsy specimen could not be obtained because M.B. was uncooperative and combative. Initial laboratory findings are Hgb 13.4 g/dL; Hct 40%; leukocyte count, 13,800 cells/mm³ with 68% neutrophils, 14% bands, 5% lymphocytes, and 13% monocytes; albumin 3.1 g/dL (normal, 3.5–5). A liver scan and liver function tests are normal.

On ultrasound examination, a tender mass palpable in the lower right quadrant proves to be a 3-cm collection of fluid consistent with an abdominal abscess. During an exploratory operation, the clinician drains 100 mL of a brownish-yellow material. Smears of the drained material are positive for *E. histolytica* trophozoites, and culture of the material is negative for bacteria. Fresh stool tested for *E. histolytica* by TechLab's *E. histolytica* II antigen detection test (Blacksburg, VA) is positive.

How was amebic colitis differentiated from ulcerative colitis in M.B.? What is the significance of obtaining serology in M.B.?

[SI units: Hgb, 130.4 g/L; Hct, 0.40; leukocyte count, $13.8 \times 10^9/L$ with 0.68 neutrophils, 0.14 bands, 0.05 lymphocytes, and 0.13 monocytes; albumin, 31 g/L (normal, 35–50)]

M.B.'s abdominal symptoms, elevated temperature, right lower quadrant tenderness, and occult blood in the stool examination, together with the proctosigmoidoscopic findings, strongly suggest either a bacterial or a protozoan infection.^{65–69} Stool examination confirms that M.B. has amebiasis; the presence of *E. histolytica* in the abdominal abscess and bloody stools confirm the diagnosis of amebic colitis. Serum antibody tests are useful, especially when the parasite is absent from the stool or abscess material and are considered highly sensitive (>90%).^{66,69} The TechLab *E. histolytica* II antigen detection test, which detects specific antibody to the amebae in stool, is helpful in nonendemic areas for the differential diagnosis between ulcerative colitis and amebic colitis.^{68,79} Although in M.B. a positive finding of *E. histolytica* in the smear from the abdominal abscess is diagnostic, TechLab's *E. histolytica* II test will document the presence of *E. histolytica*.⁶⁹ The test may not differentiate between acute and chronic disease in an area of high endemicity.^{69,79} The TechLab test is specific for *E. histolytica* and does not cross-react with the nonpathogenic *E. dispar*.⁶⁸ When appropriate stool samples are not available in these cases, endoscopic or colonoscopic specimens may be critical for diagnosis, and positive serology will confirm the diagnosis of acute amebiasis.^{65–69} In invasive amebiasis, serum antibodies are found in 90% of individuals by day 7 of illness.^{65,68} A positive antibody test of the stool with the TechLab antigen detection test identifies most patients with invasive amebic colitis; the absence of serum antibodies to *E. histolytica* after 7 days of symptoms is evidence against a diagnosis of invasive amebiasis.^{68,79} M.B.'s positive antibody test for *E. histolytica* in the stool and identification of *E. histolytica* in the abdominal abscess confirm the diagnosis of amebiasis.⁶⁹

Drugs

9. What are the major drugs that can be used to treat M.B.? What regimen might be preferred?

The two classes of drugs that can be used to treat M.B.'s amebiasis are the luminal-acting drugs, which act only in the bowel lumen, and the tissue amebicides, which have activity in the bowel wall, liver, and other extraintestinal tissues.^{27,65–68} Luminal-acting drugs achieve high concentrations in the bowel, but only minimal systemic absorption takes place. These drugs include diiodohydroxyquin or iodoquinol (Yodoxin), diloxanide furoate (Furamide), and paromomycin (Humatin).

M.B. needs to be treated with a tissue amebicide in combination with a luminal agent because he has positive serology, which indicates tissue invasion by *E. histolytica*. Tissue amebicides are well absorbed and attain adequate systemic levels to treat extraintestinal amebiasis.^{27,65–68} Because the concentrations of the tissue drugs in the bowel may be insufficient to eradicate *E. histolytica*, they must be combined with a luminal-acting agent to treat both serious intestinal amebiasis and extraintestinal amebic lesions.^{27,65–68} The tissue amebicides include metronidazole (Flagyl), tinidazole (Tindamax), chloroquine phosphate (Aralen), emetine, and dehydroemetine. Chloroquine is effective only as a liver amebicide.²⁷ Dehydroemetine is very seldom used but if it is needed, it can be obtained from the CDC.⁶⁶ Diloxanide can be obtained from Panorama Compounding Pharmacy, Van Nuys, California (800-247-9767).²⁷

M.B.'s acute amebic dysentery should be treated with a combination of metronidazole and a luminal agent, such as iodoquinol or diloxanide furoate. Either tinidazole or nitazoxanide (Alinia) is an alternative to metronidazole.²⁷ If M.B. is too ill to tolerate the oral tablets, a loading dose of 15 mg/kg of metronidazole can be administered IV over 1 hour, followed by a maintenance dose of 500 mg Q 6 hr.⁷⁹ A single oral dose of 2.4 g of metronidazole for 2 to 3 days or tinidazole 2 g once daily for 3 to 5 days is equally effective^{27,65,66} (for doses of other agents, see Table 74-1).

M.B. needs to be monitored and his stool should be examined over the ensuing 3 months.

Amebic Cyst Passer

10. P.C., a 47-year-old man whose stool was found to be positive for *E. histolytica* cysts on routine examination, was completely asymptomatic. Would you treat P.C.? What are other drug regimens for amebiasis?

P.C. is an asymptomatic cyst passer and the infection may be chronic. Invasive amebiasis and extraintestinal disease are potential threats to P.C., and he is a source of infection to others.^{66,68} For these reasons, he should be treated with a full course of a luminal amebicide (diloxanide or iodoquinol).^{65–67} To verify the eradication of the infection, P.C.'s stool should be examined monthly for 3 months. (For other treatment regimens for amebiasis, see Table 74-1 or reference 66.)

11. If P.C. is not treated, what complications might be encountered?

Failure to treat P.C. might lead to significant medical problems. Amebic liver abscess is one of the most

common complications of amebiasis, with the right lobe of the liver being involved in 90% of all cases.^{65–68,75–78} Patients usually present with fever, tenderness over an enlarged liver, leukocytosis, an elevated sedimentation rate, and anemia.^{65–68} Liver scans (using radioactive isotopes with either technetium-99 or gallium), magnetic resonance imaging (MRI), ultrasonography, and serology (enzyme immunoassay or TechLab) usually confirm the presence of an abscess.^{65,75–78} Liver abscesses can extend to the lungs through fistulas and can cause empyemas and lung abscesses.^{75–79} Amebic peritonitis also can result from liver abscesses.^{65–68} Other complications include amebic pericarditis, brain abscess, amebic strictures secondary to dysentery, and cutaneous amebiasis.^{65–68} Management of these complications includes exploratory surgery to drain the abscesses, needle aspiration directed by radiologic monitoring, appropriate cultures of aspirate fluid, and drug therapy with metronidazole or tinidazole combined with a luminal agent such as iodoquinol.^{27,65–68,79} Most patients respond within 3 days with decreased pain, anorexia, and fever.⁶⁶ Lesions may take 4 to 10 months to resolve; healing can be monitored through periodic radiologic studies.^{66,75}

TREATMENT DURING PREGNANCY

12. C.R., a 24-year-old woman, presented with a 5-day history of watery stools, bloody mucus, and fever after returning from Thailand. She initially was treated with ampicillin, to which she did not respond. She is 22 weeks pregnant, and her medical history includes rheumatic fever at age 5 and heart murmurs. Her temperature is 38.2°C and her abdomen is soft but nontender; she complains of severe cramps. Fresh stool is positive for occult blood, and the wet mount demonstrates trophozoites with ingested RBC. A trichrome stain shows *E. histolytica* trophozoites. Bacterial culture is negative for pathogenic bacteria. An abdominal computed tomography (CT) scan is negative for abdominal or liver amebiasis, and an antiamebic antibody test is negative. A diagnosis of intestinal amebiasis is made. How would you treat C.R.? If C.R. subsequently develops amebic colitis, how would you treat her, and what are some toxicities of concern with the selected regimens?

C.R. needs to receive a luminal amebicide to treat her intestinal amebiasis. Because she is 22 weeks pregnant and has an underlying cardiovascular problem, the therapeutic options are limited. Metronidazole, iodoquinol, and emetine are not preferred regimens for C.R. because of their potential adverse effects to mother or fetus. A drug with minimal systemic effects would be optimal so as not to jeopardize her fetus. Paromomycin, a nonabsorbable aminoglycoside, is effective and has been used in pregnant patients.^{27,66} C.R. should receive paromomycin 25 to 35 mg/kg/day in three divided doses for 7 days.^{27,66} The most common side effect of paromomycin is GI upset, manifested as increased frequency of stools.^{27,67} At the end of the course of therapy, C.R.'s stools should be tested to verify a cure. A serology for serum amebic antibodies also should be evaluated. If her serology is positive, a full course of metronidazole followed by a luminal agent, either iodoquinol or diloxanide furoate, must be considered.^{27,66} Because C.R. would be in the third trimester of pregnancy during this period, her fetus would be less susceptible to the teratogenic effects of the drugs if she develops amebic colitis or hepatic amebiasis.

Used concomitantly with a luminal amebicide, metronidazole or tinidazole remain the drugs of choice for all patients with severe amebic colitis, hepatic abscess, and extraintestinal amebiasis.^{27,66,68,79} The most common side effects include metallic taste, nausea, diarrhea, furry tongue, and glossitis.^{27,36,66} Metronidazole causes disulfiramlike effects if alcohol is consumed concomitantly.^{27,66} Of major concern are the reports of carcinogenicity in rodents and mutagenic activity of metronidazole in bacteria.⁶⁶ The clinical significance of carcinogenicity in the human population has not been fully assessed because a cause-and-effect relationship between use of the drug and malignancy has not been documented adequately.^{27,66} Although metronidazole is considered safe in C.R., who now is in her third trimester, it should be avoided if possible during the first trimester of pregnancy.^{27,66}

If amebic colitis or hepatic amebiasis develops, C.R. needs to receive either iodoquinol or diloxanide furoate to follow her metronidazole or tinidazole regimen. If iodoquinol is selected, the side effects associated with usual dosages include nausea and vomiting, abdominal discomfort, diarrhea, headache, and occasionally enlargement of the thyroid gland.^{36,66,67}

If diloxanide furoate is selected instead of iodoquinol, this agent is essentially free of side effects with the exception of some minor GI symptoms such as flatulence (belching and abdominal distention) and stomach cramps.^{27,66} This may be preferable to iodoquinol for C.R.

GIARDIASIS

Prevalence and Transmission

Giardiasis, manifested as nausea, abdominal cramping, and diarrhea, is caused by the protozoan *Giardia lamblia*.^{80–83} The disease is endemic in many areas of the world, especially where sanitation and sanitary habits are poor.^{80,81} Although the prevalence is low in most developed countries, a number of outbreaks of giardiasis have been reported in Sweden, Canada, and the United States.^{84–86} *G. lamblia* is the most commonly reported pathogen in infectious diarrhea among Americans.⁸¹ Water-borne outbreaks of giardiasis occur more often than food-borne outbreaks.^{80,81,83} Giardiasis seems more prevalent in children, older debilitated individuals, and in those with dysgammaglobulinemias (specifically those with a deficiency of IgA).^{80,81,83,87}

Life Cycle

Giardia lamblia exists in two forms: the trophozoite and the cyst (Fig. 74-4). The cyst is excreted in the stool and, if it is ingested in contaminated water or food, it will excyst in the stomach to produce trophozoites.^{80,81,83} The trophozoites migrate to the small intestine and produce the GI symptoms characteristic of giardiasis. Symptoms appear 5 to 15 days after ingestion of the cyst.⁸⁰

Diagnosis

Signs and Symptoms

13. J.T., a 23-year-old female student, has just returned from Mexico after spending a month there with a local church group. Two days before returning to the United States, J.T. had a bout

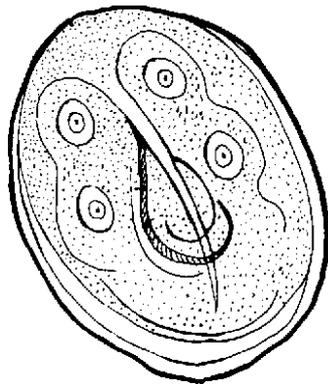

FIGURE 74-4 *G. lamblia* cyst.

of diarrhea with “offensive yellow stools.” She now complains of nausea, abdominal discomfort, and occasional foul-smelling diarrhea alternating with constipation. J.T. indicates that she has lost about 10 pounds over the previous 2 weeks. Three stool samples are examined for ova and parasites, and a stool culture is ordered. Two of the three stool samples are positive for *G. lamblia* cysts, and the culture is negative for bacterial pathogens. Why is this a typical presentation of giardiasis?

The symptoms of giardiasis are variable. Some patients present with profuse watery stools, abdominal distention, and cramping for several weeks; others complain only of mild abdominal discomfort, flatulence, and occasional loose stools.^{80,81,83} J.T.’s symptoms are typical and consistent with the description of giardiasis. Symptoms usually begin about 2 weeks after transmission of the infection and include anorexia, nausea, and diarrhea with bulky, foul-smelling stools.^{80,81,83} The acute phase of giardiasis can be followed by a period of chronic intermittent diarrhea alternating with constipation.^{80,81,83} During this period, anorexia and malabsorption will cause weight loss. Malabsorption from severe or chronic giardiasis can result in steatorrhea and deficiencies in vitamins A and B₁₂.^{80,81,83,88,89} *G. lamblia* cysts usually are found in the stool, although there may be periods when cysts are difficult to detect because of a low count.^{80,81,83} The onset of symptoms, foul-smelling stools, and weight loss are consistent with symptomatic giardiasis in J.T.

14. If the stool examination had been negative for *G. lamblia*, what alternative steps would have been necessary to make a diagnosis in J.T.?

Bacterial infection caused by *Salmonella*, *Shigella*, or *Campylobacter* was ruled out by a negative stool culture in J.T.^{80,83} The next step would be to use the Entero-Test in an attempt to obtain a diagnosis of giardiasis.⁸¹ The Entero-Test consists of a gelatinous capsule attached to a string. The patient swallows the capsule and the other end of the string is secured to the face with tape. After 4 to 6 hours, the string is pulled up and the bile-stained end is examined under a microscope. The Entero-Test sample obtained from the duodenum will demonstrate the trophozoite rather than the cyst and reportedly has a better yield than a stool examination.⁸⁰

Several other tests to detect *Giardia* antigen in the stool have become commercially available.^{80,81,83} These tests have a sen-

sitivity of 85% to 98% and a specificity of 90% to 100%.^{80,81} However, stool samples are still important to document *G. lamblia*.⁸² An immunofluorescence assay using monoclonal antibody against *Giardia* cysts is available (Meridian Diagnostics, Cincinnati, Ohio). Some clinicians may prefer to use these newer tests rather than the Entero-Test. If the Entero-Test finding is negative, however, most clinicians would initiate a therapeutic trial rather than subject a patient to other invasive diagnostic procedures.^{80–83} As a last resort, endoscopy with duodenal fluid sampling and biopsy may be performed.^{80,81,83}

TREATMENT

15. How should J.T. be treated?

Metronidazole is the drug of choice for giardiasis in J.T.²⁷ Metronidazole 250 mg three times daily for 7 days is as effective as quinacrine in the treatment of giardiasis.^{27,36,80–83} Although metronidazole was reported to be mutagenic in bacteria and carcinogenic at high dosages in animals, no evidence suggests that it currently represents a risk in humans.^{80,81,83}

Quinacrine (Atabrine) administered 100 mg three times daily for 5 days, with cure rates of 90% to 95%, was once considered the drug of choice for giardiasis, but is no longer commercially available; it can be obtained from Panorama Compounding Pharmacy (see Question 9).^{27,80,81}

Furazolidone (Furoxone), an alternative to metronidazole, is available as a tablet and suspension for the treatment of giardiasis.^{27,80–83} Furazolidone has cure rates of 80% to 90%, and the adult dosage is 100 mg four times daily for 7 days.⁸¹

Furazolidone, which is available as a suspension, is preferred by some clinicians for children. However, metronidazole should be considered the drug of choice for giardiasis in both adults and children.

Tinidazole (Tindamax), an analog of metronidazole, is now available in the United States and is highly effective for giardiasis.^{27,90} Other alternatives are paromomycin (25–35 mg/kg/day in three divided doses for 7 days), albendazole (400 mg daily for 5 days), and nitazoxanide (100–500 mg twice daily for 3–7 days).^{80,82,91–93}

Following therapy, diarrhea usually subsides within 1 to 2 days and completely resolves in about 10 days.^{80–83} Cyst excretion is disrupted 2 days after initiation of therapy. Complete normalization of intestinal functions, especially recovery from malabsorption, may require 4 to 8 weeks.⁸¹ If J.T. does not respond to one course of therapy, she may need a second course of metronidazole.^{80–83}

ENTEROBIASIS

Prevalence

Enterobiasis is an intestinal infection caused by the pinworm *Enterobius vermicularis* (Fig. 74-5). Pinworm, the most common helminthic infection in the United States, has an estimated annual incidence of 42 million.^{94–98} Enterobiasis is a cosmopolitan disease that usually affects all members of a family when one member is infected. Therefore, all household residents must be treated simultaneously. Institutionalized patients and preschool children in daycare centers may be at greater risk for acquiring enterobiasis.^{94,99}

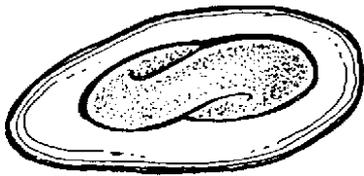

FIGURE 74-5 *E. vermicularis* ovum.

Life Cycle

Infection is initiated with the ingestion of pinworm eggs, which reach the mouth on soiled hands or contaminated food and drink. After ingestion, the eggs hatch in the intestine, releasing the larvae, which attach to the jejunum or upper ileum.⁹⁴ After copulation, the female worm migrates to the lower bowel and produces eggs. Under the stimulus of air or change in temperature, the female releases eggs in the perianal skin.⁹⁴ Cutaneous irritation in the perianal region produced by migrating females and the presence of eggs can cause severe pruritus.^{94,99}

Signs and Symptoms

16. L.C., a 6-year-old boy, is brought in by his mother, K.C., to see the family physician. K.C. states that L.C. was sent home from school because of inattention and disruptive behavior. L.C. has been very irritable and complained of abdominal discomfort and perianal pain on two occasions the previous week. A cellophane tape swab placed over the perianal skin demonstrates the translucent eggs of *E. vermicularis*. Explain the symptoms observed in L.C. What pathologic changes are associated with enterobiasis?

Pinworm infection can be asymptomatic, but the most common symptom is intense pruritus and caused by the presence of the sticky pinworm eggs in the perianal skin. Pruritus can cause constant scratching and can result in dermatitis and secondary bacterial infections.^{94,98,99} A heavy load of worms can cause anorexia, restlessness, and insomnia, resulting in behavioral changes, as illustrated in L.C.^{94,99}

Generally, pinworms do not cause any serious intestinal pathology.^{94,99} Rarely, *E. vermicularis* ectopic lesions can be caused by a gravid worm that has migrated from the perianal region into the vagina, uterus, or fallopian tubes. The adult worm may travel through the fallopian tubes to the peritoneal cavity.⁹⁴⁻⁹⁸ The association between cystitis in young females and enterobiasis presumably results when the female worm enters the urethra and makes its way into the bladder carrying enteric bacteria.^{96,97}

Treatment

Pyrantel Pamoate, Mebendazole, and Albendazole

17. How should L.C. be treated?

Three different preparations are available to treat pinworm infection in L.C.: pyrantel pamoate (Antiminth), mebendazole (Vermox), and albendazole (Albenza).^{27,94,96,99} Either pyrantel pamoate or mebendazole can be considered for this patient. L.C. should receive a single dose of 11 mg/kg (maximum, 1 g) of pyrantel pamoate followed by a second dose in 2 weeks.^{27,94,96,99} Some patients experience mild GI upset, headache, and fever from this therapy.^{27,97} Pyrantel pamoate

acts as a depolarizing neuromuscular blocking agent releasing acetylcholine, which inhibits cholinesterase, thereby leading to paralysis of the worm and expulsion from the host's intestinal tract.^{94,100}

Mebendazole is as effective as pyrantel for enterobiasis, with a cure rate above 90%.^{97,99} Mebendazole, a broad-spectrum antihelmintic agent that also is given as a single dose (100 mg), is repeated in 2 weeks.²⁷ Because mebendazole is poorly absorbed, few systemic side effects are associated with its use, except abdominal pain or diarrhea.^{94,96} Albendazole, another broad-spectrum antihelmintic, is administered as 400 mg once and repeated in 2 weeks.²⁷ Both albendazole and mebendazole inhibit microtubule function and deplete glycogen stores in worms, leading to their death.^{94,99,100}

Household Contacts

18. What advice should be given to L.C.'s mother?

Pinworm infection can recur as a result of reinfection within families.⁹⁹ Therefore, all members of L.C.'s family need to be treated simultaneously. The pinworm's cycle of transmission can be interrupted by encouraging careful handwashing and fingernail scrubbing after using the toilet and before meals.^{94,99} Despite meticulous precautions, it still may be difficult to eradicate the infection because of contact with persons outside the home. It may be necessary to repeat treatment for some members of the family at a later date.^{94,99} K.C. needs to be reassured that pinworm infection in the home does not represent substandard hygiene.⁹⁹

CESTODIASIS

Description

Cestodiasis (tapeworm infection) is caused by members of the phylum Platyhelminths (flat worms), which include, among others, *Taenia solium* (pork tapeworm), *Taenia saginata* (beef tapeworm), *Diphyllobothrium latum* (broad fish tapeworm), and *Hymenolepis nana* (dwarf tapeworm).¹⁰¹⁻¹⁰⁴

The tapeworm's body is made up of an anterior attachment organ called a scolex, accompanied by a chain of segments or proglottids called a strobila. The strobila grows throughout the life of the tapeworm, with the extension taking place just posterior to the scolex.^{101,102} At the end of the strobila, mature or gravid segments contain eggs enclosed in the uterus, which, because of its characteristic shape and size, may be used for identifying tapeworm species.^{101,102}

Tapeworms remain attached to the mucosal wall of the upper jejunum by the scolex, which contains two to four muscular cup-shaped suckers. The parasite lacks an alimentary canal and obtains nutrients directly from the host's intestine. A protrusible structure called a rostellum is located in the center of the scolex and may contain hooks in some species.^{101,102} The scolex, proglottids, and eggs, which are specific for each species, are used for definitive diagnosis.¹⁰¹

Tapeworms cause disease in humans in either the adult or larval stage.^{101,102} The symptoms in the host primarily are GI when the adult form is present. Larvae or cysticerci become encysted in various visceral organs, causing a disease called cysticercosis.^{103,105-107}

Life Cycle

Pork tapeworm (*T. solium*) and beef tapeworm (*T. saginata*) infections are caused by ingestion of poorly cooked meat. The larva or cysticercus is released from the contaminated meat by bile salts and matures in the host jejunum in about 2 months.^{101,102} The pork tapeworm has been reported to reach a length of 10 to 20 feet, and adult beef tapeworms can measure up to 30 feet. Gravid proglottids, which contain the eggs, are passed in the host's feces and are the source of infection in animals. When ingested by animals, the embryos are released from the eggs; these migrate through the lymphatics and blood, developing into cysticerci (encysted larvae) in various muscles.^{101–103}

Cysticercosis, the systemic infection caused by the larval stage of *T. solium*, is usually acquired by ingestion of the eggs in contaminated food or by autoinfection.¹⁰¹ The eggs of *T. solium*, when ingested by the host, are digested by gastric juices and develop into the larvae (oncospheres), which penetrate the small bowel and migrate through the bloodstream throughout the body to produce human cysticercosis. Clinical manifestations range over a broad spectrum of symptoms and include both neurogenic and psychiatric: increased intracranial pressure, chronic severe headache, intellectual deterioration, decreased visual acuity, and focal and generalized seizures.^{103,105–107}

Epidemiology

The pork tapeworm occurs worldwide and is prevalent in Mexico, Latin America, Slavic countries, Africa, southeast Asia, India, and China.^{101,102} The beef tapeworm is cosmopolitan, but is found predominantly in Ethiopia, Europe, Japan, the Philippines, Latin America, and the Middle East.^{101,102} Both occur in the United States, although the prevalence is low.^{101,102}

Diphyllobothrium latum (broad fish tapeworm) inhabits the ileum in the human host, and infection is acquired by ingesting raw or inadequately cooked freshwater fish.^{101,102} *D. latum* also infects other fish-eating animals, including the fox, mink, bear, walrus, and seal. These animals can serve as reservoirs.¹⁰¹

Broad tapeworm disease, or diphyllobothriasis, is common in Finland, Scandinavia, Russia, and the lake regions of North Italy, Switzerland, and France.¹⁰¹ In North America, the highest incidence of infection has been reported in Alaska and Canada.¹⁰¹

Hymenolepis nana (dwarf tapeworm) is cosmopolitan in distribution, with a high incidence in children in the tropics and subtropics.^{101,102} It is the most common human tapeworm in the United States, particularly in the southeastern section. The infection is passed primarily from person to person by contaminated hands or fomites.

Taenia Saginata and Taenia Solium

Signs and Symptoms

19. B.R., a 10-year-old boy from Mexico, has moved to the United States with his parents. The school nurse saw him on several occasions when he complained of vague abdominal discomfort and pain. On questioning, B.R. reports seeing “white noodlelike” objects in his stools. B.R. is seen in the clinic. A cellophane

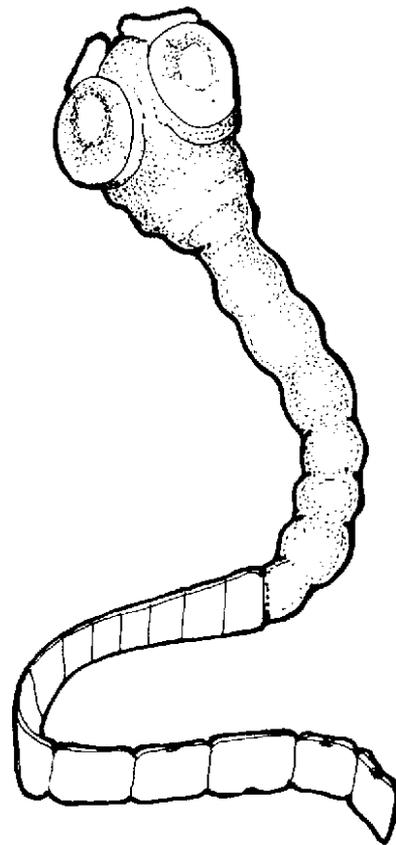

FIGURE 74-6 *T. saginata*.

impression of the perianal region and three stool samples over several days demonstrate infection with *T. saginata* (Fig. 74-6). IgE level and eosinophil count are within normal limits. Explain the presenting symptoms in B.R.

Patients with tapeworm infections (either *T. saginata*, as in B.R., or *T. solium*) present with symptoms ranging from mild epigastric or abdominal pain to a burning sensation, general weakness, weight loss, headache, constipation, and diarrhea.^{101,103} Complications from *T. saginata* include appendicitis, obstruction of pancreatic ducts, and intestinal obstruction.^{101,102} Because the adult worm is weakly immunogenic, some patients present with moderate eosinophilia and elevated IgE levels,¹⁰¹ although B.R. did not. He reported worm segments (“white noodlelike” objects) in the stool. This is commonly how diagnosis is made. Segments are sometimes found in underclothing. An alternative diagnostic method is to use anal swabs (the “Scotch tape” method) as used for pinworm ova.¹⁰¹

Diagnosis

20. How can *T. saginata* infection be differentiated from *T. solium* in B.R.?

The eggs of *T. saginata* and *T. solium* are identical and, when found in the stool, will not aid in diagnosis. The presence of gravid proglottids (Fig. 74-7) or a scolex in the stool is necessary to determine the species.^{101,102}

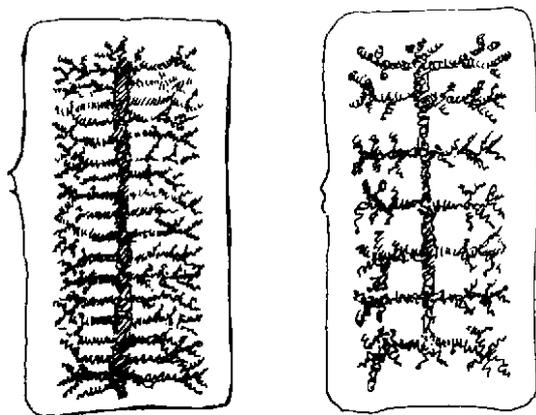

FIGURE 74-7 *T. solium* and *T. saginata* gravid segments.

Placing gravid proglottids from B.R.'s stool between two slides and injecting India ink into the central uterine system will demonstrate the characteristic anatomic differences.^{101,103}

An intact scolex recovered from B.R.'s stool after treatment also will confirm the species. The scolex of *T. saginata* has no hooklets ("unarmed"), whereas that of *T. solium* contains a double row of hooklets ("armed").¹⁰² With *T. solium*, the diagnosis of neurocysticercosis is made based on history, symptoms, and identification of neurologic lesions by CT scanning and MRI.^{103,105–107}

The enzyme-linked immunotransfer blot (CDC-ETIB) assay of cerebrospinal fluid is considered highly sensitive and specific for neurocysticercosis.^{106,107}

Treatment

21. How should B.R. be treated, and how should therapy be evaluated?

The drug of choice for both *T. saginata* and *T. solium* intestinal tapeworm infections is praziquantel (Biltricide) 5 to 10 mg/kg as a single dose.^{27,101,102} Cure rates for both *T. saginata* and *T. solium* have been reported to be high.¹⁰¹ The tablets of praziquantel should be swallowed whole with a liquid during meals. In patients who cannot tolerate the single dose because of severe nausea and vomiting, praziquantel can be administered in divided doses; the interval between doses should be 4 to 6 hours.^{27,100} Praziquantel kills the adult worm but does not destroy the eggs. The intact or disintegrating segments appear in the stool over a week.¹⁰¹ Stool specimens should be re-examined to confirm that no regrowth of *T. solium* (5 weeks after treatment) and *T. saginata* (3 months after treatment).¹⁰¹

Eggs can be released when gravid segments of *T. solium* disintegrate after treatment, and the release of embryos from the eggs can cause cysticercosis. To minimize this possibility, the clinician should give a purgative (magnesium sulfate 15–30 g) 2 hours after administration of praziquantel when *T. solium* infection is suspected.¹⁰² B.R. should be told that segments of the tapeworm will be passed for several days after treatment.

Diphyllobothrium Latum and *Hymenolepis Nana*

22. Could B.R. have *D. latum* or *H. nana* infection? How are these treated?

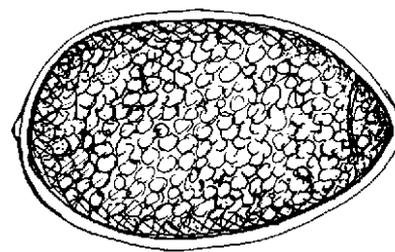

FIGURE 74-8 *D. latum* ovum.

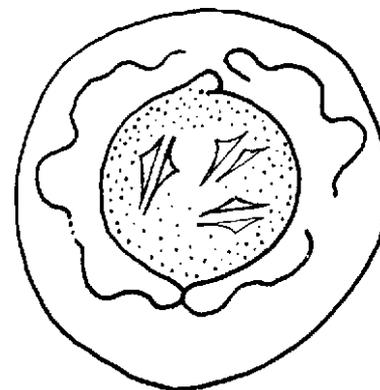

FIGURE 74-9 *H. nana* ovum.

Infection with *D. latum* is highly unlikely in B.R. because diphyllorhosis is almost exclusively found among raw fish-eating populations of the Baltic countries, Alaska, and Canada,^{101,102} and B.R. is from Mexico. In addition, neither the characteristic operculate eggs (Fig. 74-8) nor the distinctive almond-shaped scolex of *D. latum* was found during stool examination.

Hymenolepis nana (dwarf tapeworm) infection is worldwide and is a possibility in B.R. It is unusual to find proglottids of *H. nana* because they usually disintegrate before passage.¹⁰¹ Instead, identification is made by the presence of the characteristic eggs (Fig. 74-9).

Treatment of *D. latum* is identical to that of *T. saginata*, except that a purgative is not necessary after therapy. *H. nana* infections are treated with praziquantel 25 mg/kg as a single dose.²⁷

Cysticercosis and Other Complications

23. V.N. is a 59-year-old native of Guanajuato, Mexico who presented in the E.R at a local hospital with a 3-month history of lethargy, intermittent headaches, and episodes of ataxia. V.N.'s daughter reports that her father had an episode of seizure the previous evening and he fell off the couch while watching TV. V.N. has been in the United States for about 10 years but has made numerous trips to rural Mexico to see relatives. A lumbar puncture ordered on V.N. showed the following: CSF: WBC 4 cells/mm³ (93% lymphocytes and 6% polymorphonuclear cells) (normal <5 cells), protein 94 mg/dL (normal <50 mg/dL), glucose 45 mg/dL (normal <60%–70% of serum). India ink capsule stain was negative with no organisms detected. MRI showed multiple intraparenchymal-enhancing lesions with perilesional edema

and some calcified lesions. Enzyme-linked immunoelectrotransfer blot (ETIB) assay was positive for neurocysticercosis.

[S.I Units: CSF glucose: 2.5 mmol/L (normal 60%–70% of serum glucose); protein: 0.92 g/L]

Neurocysticercosis, the deposition of the larval cysts (fluid-filled bladder containing the invaginated scolex) of *T. solium* in the cerebral parenchyma, meninges, spinal cord, and the ventricular system, is considered the most common parasitic disease of the central nervous system.^{101,103,105–107} However, debate continues regarding the efficacy of anthelmintic therapy and the optimal dosages of these agents for neurocysticercosis.^{103,107,108} If V.N. had subarachnoid or intraventricular cysticercosis, these would normally be treated with surgery. Because of the risk of neurosurgical procedures, others have suggested anthelmintic therapy.¹⁰³ Because V.N. has parenchymal disease (cerebral cysticercosis) and multiple cysts, he will receive medical treatment.^{27,103,107} Hydrocephalus (blockage of the foramen of Monroe or aqueduct of Sylvius), if present, and elevated intracranial pressure are relieved by a ventriculoperitoneal shunt or temporary ventriculostomy.^{101,107} V.N. will need symptomatic therapy (e.g., anticonvulsants) because he presented with seizures and the CT scan and ETIB assay confirmed neurocysticercosis.^{105–107} ETIB assay, which uses purified extract of *T. solium* antigen and which detects the specific antibodies, has a sensitivity of 98% and specificity of 100%.¹⁰⁵ Seizures, which occur in 70% to 90% of these cases, are the most common manifestation of neurocysticercosis. For seizures, V.N. will be started on an anticonvulsant with either phenytoin (doses to attain serum levels of 10–20 mcg/mL) or carbamazepine (doses to attain serum levels of 5–12 mcg/mL) before any surgical or medical therapy. Phenobarbital is the preferred anticonvulsant in children.¹⁰¹ With parenchymal neurocysticercosis, V.N. will receive corticosteroids, which will be used to ameliorate inflammatory reaction from dying parasites. He will be started on this 1 to 2 days before anthelmintic therapy and continued for 4 to 7 days after completion of therapy. However, administration of corticosteroids may not prevent adverse effects in V.N.¹⁰⁵ Dexamethasone 4 to 16 mg/day (or an equivalent dose of prednisone) is the suggested dose for corticosteroid.^{101,105,107} Albendazole 400 mg for 8 to 30 days is the preferred agent and may be more cost effective than praziquantel. However, praziquantel 50 to 100 mg/kg/day in three divided doses for 30 days has also been recommended for parenchymal neurocysticercosis.^{27,105,107–109} It has been suggested that a better understanding of the pathophysiologic mechanisms, primarily the character of inflammatory response of the host, survival and growth of the organism, and mechanism of anthelmintic activity, may help to identify more definitive therapy for neurocysticercosis in the future.^{107,110} On completion of therapy with albendazole (1–3 months), a brain CT scan or MRI and an electroencephalogram should be obtained to monitor the resolution or volume reduction of cysts and seizure activity in V.N.^{105,108–110} Some patients may need two or more courses of antiparasitic therapy.^{107–110}

24. If V.N. had *D. latum* instead of *T. saginata*, what would be some subjective and objective findings?

If V.N. had been infected with *D. latum* instead of *T. saginata*, he may complain of being tired and possibly sleepy,

which may be manifestations of anemia. *D. latum* can cause a megaloblastic anemia because the tapeworm competes with the host for dietary vitamin B₁₂.¹⁰¹ Although 40% of patients with *D. latum* infection have reduced levels of vitamin B₁₂, less than 2% actually develop anemia from this deficiency.¹⁰¹ Decreased levels of other nutritional elements have included ascorbic acid, folic acid, and riboflavin.¹⁰¹ In those who do develop deficiency in vitamin B₁₂ from *D. latum* infection, manifestations may include glossitis, tachycardia, and neurologic symptoms such as weakness, paresthesia, and motor coordination disturbances.^{101,102}

Praziquantel: Side Effects

25. What are the common side effects of praziquantel?

Praziquantel, which is used for *T. saginata* infections, is associated with headache, dizziness, drowsiness, nausea, abdominal pain, myalgia, and urticaria.^{27,102,111} The side effects usually appear about 2 hours after administration and dissipate within 48 hours. The tablets of praziquantel should never be chewed, but should be swallowed whole with fluids, preferably during meals. Chewing the tablets can induce retching and vomiting because of the bitter taste.^{27,100}

PEDICULOSIS

Prevalence

Pediculosis (lice infections) can be caused by head lice (*Pediculus humanus capitis*) (Fig. 74-10), body lice (*P. humanus*), or crab lice (*Phthirus pubis*). Lice infections can be present in all socioeconomic groups, but are seen more often among the poor because of crowded living conditions and infrequent washing.^{112–116}

Life Cycle

Head and body lice have similar life cycles, but their habitat preferences distinguish the two varieties.¹¹³ The adult fertilized female lays eggs, which remain glued to hair or seams of clothing (Fig. 74-11). The oval-shaped eggs (nits) hatch in 7 to 10 days and produce nymphs, which go through a number of molts to evolve into mature adults.^{112,113} Both larvae and adults feed on the host's blood. The lice penetrate the host skin via stylets within their head and attach themselves by a circlet

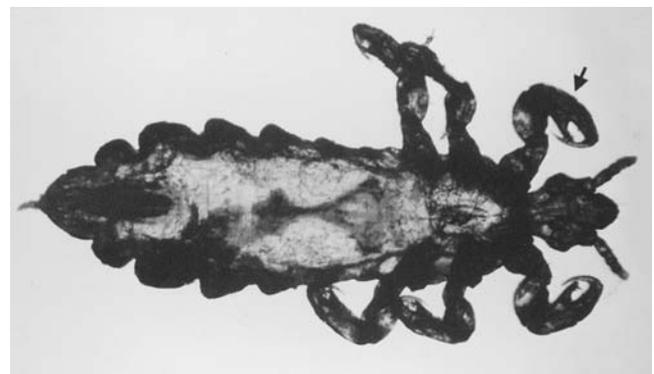

FIGURE 74-10 *Pediculus humanus capitis* (head lice).

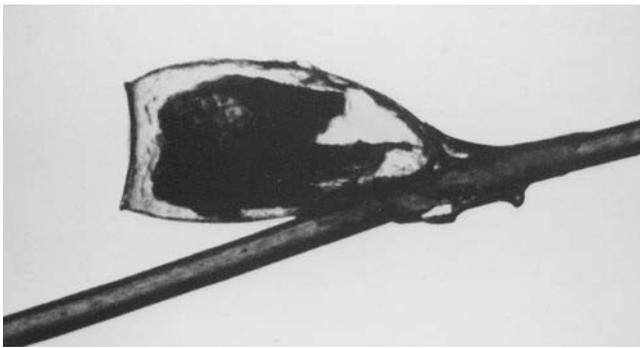

FIGURE 74-11 Nit or egg of lice on hair shaft.

of teeth on their proboscis. Crab lice usually are found in pubic hair, although these organisms can also be found on eyebrows, eyelashes, and axillary hairs.^{112,113}

Epidemiology

The highest incidence of head lice is seen among schoolchildren.^{113,115,116} The incidence of all types of lice infestation in the United States has been estimated to be 6 to 12 million cases.¹¹⁶ Head and body lice are transferred between hosts by personal and clothing contact, whereas crab lice are transmitted by sexual contact.^{112,113}

Signs and Symptoms

26. D.J., a 54-year-old homeless man who lives in a city shelter, is brought to the clinic by his welfare worker. D.J. has excoriations and numerous pustular lesions all over his body. The welfare worker states that D.J. has “lice all over his body.” Why are the symptoms in D.J. consistent with lice infection?

The most common complaint of patients with head and body lice is pruritus of the scalp, ears, neck, and other body parts. With severe infestations, as seen in D.J., intractable itching and scratching can result in folliculitis, hemorrhagic macules or papules, postinflammatory skin thickening, and pigmentation.^{112–116} In contrast, schoolchildren who are exposed frequently to head lice may have only minor pruritus affecting the scalp, ears, and neck.^{112,116}

Treatment

27. How should D.J. be treated for lice infection of the head, body, and genital areas?

Concurrent treatment for the pustular bacterial lesions and lice infestation should be initiated in D.J. Head lice in both adults and children can be treated with 1% permethrin (NIX) liquid rinse. Alternatives are 0.5% malathion (Ovide) lotion and pyrethrin 0.33% plus 4% piperonyl butoxide (RID). Both pyrethrin preparations and malathion 0.5% are as effective as γ -benzene hexachloride or lindane 1% (Kwell).^{27,112,113,116} The eradication rate for lindane is 17% to 61%, compared with 74% to 100% with the new synthetic derivative of pyrethrin, permethrin (NIX).¹¹⁷ Recent studies indicate that there may be differences in efficacy among the topical agents. Ovide lotion (0.5% malathion) was the fastest-killing pediculicide and the most effective; lindane was considered the least effective.¹¹⁷ Growing concern is that lice are becoming resistant to the pyrethrin products in the United States.^{112,113,116,117}

PYRETHRIN, LINDANE, MALATHION, AND IVERMECTIN

Pyrethrin, which contains extracts of chrysanthemum flowers, acts by blocking the transmission of nerve impulses in lice and kills them in a few minutes.^{112,118} Approximately 30 to 50 mL of the pyrethrin lotion should be massaged into D.J.’s scalp, left for about 10 minutes, then rinsed out. The treatment should be followed by a plain shampoo. Nits can be removed from the hair by applying a solution containing equal parts of water and vinegar and using a sturdy fine-tooth comb to remove the nits.^{112,113} The whole course of treatment should be repeated within 7 to 10 days to eradicate the organisms hatched after initial therapy.^{112,113} Patients who have a history of ragweed allergy occasionally react to pyrethrin preparations.¹¹² If D.J. has an allergy to pyrethrin, malathion lotion 0.5% may be an alternative. Malathion should be left on for 12 to 24 hours.

For the body and pubic lice in D.J., a pyrethrin combination lotion should be applied. It may be necessary to leave the lotion on for 4 to 6 hours to eradicate crab lice.¹¹³ The applications should be followed by a warm bath. The treatment should be repeated in 7 to 10 days. The pruritus in D.J. can be symptomatically treated with an antihistamine and a low-potency topical steroid.¹¹²

Alternative treatment for head lice for patients in whom the infestations are not eradicated with either permethrin 1% or lindane are 5% permethrin cream (Elimite) applied to the scalp overnight, or petrolatum (approximately 40 g) applied to the scalp and left overnight while wearing a shower cap.¹¹² After the application of the petrolatum, a shampoo should be used for 7 to 10 days to remove the residue. Children 2 years or younger should not be treated for lice, and only manual removal should be attempted.¹¹³ Other alternative therapies include two doses of ivermectin 200 mcg/kg administered a week apart or albendazole 400 mg once or for 3 days.^{119–121} A recent report advocates use of hot air as a nonpharmacologic treatment for pediculosis.¹²²

PETROLATUM

To remove pubic lice from D.J.’s eyelids or eyelashes, plain petrolatum ointment can be used. Petrolatum is applied to the eyelashes and lid margins with cotton swabs three or four times daily. This regimen will either suffocate the lice or physically remove them.

DECONTAMINATION MEASURES

Treatment for pediculosis should include thorough decontamination to avoid reinfection. All personal articles of clothing, including bedding, should be washed (preferably in the hot cycle of the washer at temperature $>50^{\circ}\text{C}$).¹²³ Hairbrushes, combs, and other plastic articles can be decontaminated by soaking in rubbing alcohol or pediculicide.^{112,113} In institutions and schools where lice infestations are a problem, outer clothing (coats, hats, scarves) of individuals should be isolated in separate plastic bags at the beginning of the day. This measure will reduce reinfection significantly.

Toxicity

28. What are the toxicities of the common pediculicides?

Lindane can cause neurologic symptoms, including tremors, ataxia, insomnia, and seizures in patients who are exposed to it over extended periods.^{124,125} It also is reported to

cause aplastic anemia.¹²⁵ However, when it is applied for 10 minutes to treat head or body lice, it is considered safe and effective in both adults and children. Adverse effects reported with permethrin were local irritative symptoms. Malathion, an organophosphate cholinesterase inhibitor, is degraded rapidly by hepatic enzymes in humans and occasionally can cause some local irritation.¹²⁵ These agents are not contraindicated during pregnancy and can be used for treatment.^{27,125}

SCABIES

Prevalence

Scabies is caused by *Sarcoptes scabiei var. hominis*.^{126–130} The female mite burrows into the skin of the host and lays eggs, which hatch into larvae after 72 to 84 hours. After a number of molts, the adult mites mate and the male dies. The female gravid mite continues to burrow into new areas of skin, primarily in web spaces between the fingers, wrists, elbows, periumbilical skin, and buttocks.^{126,127} The hallmark of scabies is intense itching with erythematous papules and excoriations. In infants, scabies may be vesicular or bullous; secondary pyoderma is not uncommon. Transmission is by intimate contact, and institutional epidemics have been reported.^{126–128,130}

Treatment

29. A.R., a 4-year-old girl, has a pruritic rash with excoriations in the interdigital areas of both hands. Her mother states that A.R.'s 7-year-old brother, G.R., has a similar rash affecting his hands, groin, and feet. The lesions are scraped and microscopic examination reveals mites and ova of *S. scabiei*. How should A.R. and G.R. be treated? What special instructions and precautions should accompany therapy?

LINDANE, PERMETHRIN, AND CROTAMITON

The agents available for treatment of scabies include lindane 1% (Kwell), crotamiton 10% (Eurax), and permethrin 5% cream (Elimite).^{27,125–128,130} The agent that has been used most extensively is lindane, but its safety remains a point of contention.^{124,125} When lindane is left on the skin too long (es-

pecially excoriated skin), percutaneous absorption can cause neurotoxicity.¹²⁴ Crotamiton 10% is presumably safe for infants and pregnant women, but definitive data do not exist. A single application of permethrin 5% cream is more effective than crotamiton or lindane.^{121,126,127} Suggestion is that two doses of ivermectin (Stromectol) (200 mcg/kg separated by 1–2 weeks) can be added to the topical therapy if there is no response to permethrin alone. Although ivermectin is not FDA-label approved for scabies, a significant number of studies have used this agent both topically and systemically for scabies.^{119,121,126,127} Studies indicate that two doses of ivermectin (200 mcg/kg) separated by a week can be used for scabies epidemics, and the cure rate has been around 100% with this regimen.^{119,126}

A.R. and G.R. should have their nails trimmed to minimize further excoriation. They then should be bathed using a soft washcloth to remove loose crusts. Thereafter, permethrin cream should be massaged into the skin from the head (including the scalp) to the soles of the feet.^{125–127} The cream should be left on for 8 to 14 hours before they shower again. Permethrin application should be repeated a week later. If crotamiton is selected, it should be applied to the entire body (including the scalp) and left on for 24 hours after the initial bath. A second 24-hour application is recommended before the children are bathed again. When lindane is used, it is applied to the entire body (avoiding the eyes and mucous membranes) and left on the body for approximately 8 hours.¹²⁷ After 6 to 8 hours, a cool bath should be taken. Pruritus from scabies can be treated symptomatically with an oral antihistamine such as hydroxyzine (Vistaril) or diphenhydramine (Benadryl), or with a low-potency topical steroid.

Clothes and linens belonging to A.R. and G.R. should be freshly laundered (hot cycle at temperatures >50°C), and they should be re-examined after a week. If evidence remains of active infestation (positive microscopic findings), a second treatment course can be initiated in these patients.¹²⁹ They should be informed that pruritus can persist for more than 10 days. Pruritus usually results from retained parts of the mites.

THE TOXINS: TICK PARALYSIS 75-17

Tick Paralysis 75-17

MIXED INFECTIONS 75-17**SUMMARY 75-17****OVERVIEW**

Ticks belong to the class Arachnida, which includes scorpions, spiders, and mites. As a vector of human illness worldwide, ticks are second in importance only to mosquitoes. Ticks transmit more infectious agents than any other arthropod. Disease can be spread by ticks, either by transmission of microorganisms or by injection of tick toxin into a host. Bacterial, rickettsial, protozoal, and viral disease pathogens can be transmitted from ticks to humans¹ (Table 75-1).

Tick Genus

Only two of the three families of ticks are of medical significance to humans: the soft-bodied ticks, *Argasidae*, and the hard-bodied ticks, *Ixodidae*.¹ Four of the 13 genera of *Ixodidae* transmit disease in the United States: *Dermacentor*, *Ixodes*, *Amblyomma*, and *Rhipicephalus*. Among the five genera of *Argasidae*, only *Ornithodoros* are known to transmit pathogens to

humans in the United States. Most hard ticks have a 2-year life cycle, comprising the larval, nymphal, and adult stages. They require one blood meal during each stage before they can mature into the next stage and they usually remain attached to a host for hours or days. In contrast, soft ticks may have multiple nymphal stages, and both nymphal and adult forms can feast on blood multiple times, usually for only 30 minutes. However, *Argasidae* can survive many years without blood sustenance and are long-lived.¹ Humans are the inadvertent hosts for the life cycle of almost all ticks and tick-borne diseases.

LYME DISEASE

Lyme disease, or more accurately Lyme borreliosis, is a multisystem spirochetal disease transmitted by a tick bite.¹⁻⁸ Although the responsible spirochete, *Borrelia burgdorferi*, was not identified until 1982,¹ late manifestations of a dermatitis produced by a *Borrelia* species were described in Europe more than a century ago.

Table 75-1 Tick-Borne Diseases

| Disease | Causative Agent | Tick Vector | Host | Region |
|---------------------------------------|---|--|--------------------------------------|---|
| Lyme | <i>Borrelia burgdorferi</i> | <i>Ixodes</i> | Wild rodents | Worldwide |
| Relapsing fever (endemic) | <i>Borrelia</i> species | <i>Ornithodoros</i> | Wild rodents | Worldwide |
| Southern tick-associated rash illness | <i>Borrelia lonestari</i> ? | <i>Amblyomma</i> | ? | South-central United States |
| Tularemia | <i>Francisella tularensis</i> | <i>Dermacentor</i> <i>Amblyomma</i> | Rabbits, ticks | North America |
| Rocky Mountain spotted fever | <i>Rickettsia rickettsii</i> | <i>Dermacentor</i> <i>Rhipicephalus</i> | Wild rodents, ticks | Western Hemisphere Arizona |
| Spotted fever group | <i>Rickettsia parkeri</i> various rickettsia | <i>Amblyomma</i> various species | Horses? ? | United States Worldwide |
| Boutonneuse fever | <i>Rickettsia conorii</i> | <i>Ixodes</i> | Wild rodents, dogs | Africa, India, Mediterranean |
| North Asian tick typhus | <i>Rickettsia sibirica</i> | <i>Ixodes</i> | Wild rodents | Mongolia, Siberia |
| Queensland tick typhus | <i>Rickettsia australis</i> | <i>Ixodes</i> | Wild rodents, marsupials | Australia |
| Q fever | <i>Coxiella burnetii</i> | <i>Dermacentor</i> <i>Amblyomma</i> | Sheep, goats, cattle, ticks, cats | Worldwide |
| Babesiosis | <i>Babesia</i> species | <i>Ixodes</i> | Mice, voles | Europe, North America |
| Human monocytotropic ehrlichiosis | <i>Ehrlichia chaffeensis</i> | <i>Amblyomma</i> <i>Dermacentor</i> | Deer, dogs Deer | United States, Mexico, Europe, Africa, Middle East |
| Human granulocytic anaplasmosis | <i>Anaplasma phagocytophilia</i> | <i>Ixodes pacificus</i> <i>Ixodes</i> | Deer, elk, wild rodents | United States, Europe |
| Human ehrlichial ewingii | <i>Ehrlichia ewingii</i> | <i>Amblyomma</i> | Dogs? | United States |
| Colorado tick fever | <i>Coltivirus</i> species | <i>Dermacentor</i> | Wild rodents, mammals | North America |
| Tick-borne encephalitis | <i>Flavivirus</i> | <i>Ixodes</i> | Rodents | Eurasia |
| Tick paralysis | Neurotoxin | <i>Dermacentor</i> | N/A | North America, Europe, Australia, South Africa |

Spirochete Identification and Pathology

Three genomic subgroups of *B. burgdorferi* worldwide probably account for the clinical variations observed in the disease. The North American strains identified to date belong to the *B. burgdorferi sensu stricto* group. Although all three groups have been found in Europe, most isolates are *Borrelia garinii* or *Borrelia afzelii*. An example of a disease variation is the condition of acrodermatitis chronica atrophicans (Table 75-2), a skin lesion associated predominantly with *B. afzelii* infection.⁹

Lyme disease is a multisystem condition, affecting the skin, joints, and cardiovascular, central, and peripheral nervous systems. The ailment is named for the villages of Lyme and Old Lyme, Connecticut, where arthritic complications of this disease were first recognized. Lyme disease accounts for 96% of cases of vector-borne illness in the United States, with >15,000 cases reported annually.^{3,5} Worldwide, it is probably the most commonly reported tick-borne disease.¹⁰

Tick Vector

Spirochetal Behavior

The tick acquires the *B. burgdorferi* spirochete from feeding on an infected host. The spirochete remains dormant in the tick's

midgut until the tick feeds again, at which time the spirochete acquires a mammalian plasminogen, allowing it to penetrate the midgut wall and invade the salivary glands of the tick. In the interim, *B. burgdorferi* activates a tick gene, boosting production of a tick salivary protein, Salp-15, to which it binds. This coating helps camouflage the bacterium from mammalian immune cell detection and destruction.¹¹ The spirochete then passes through the salivary ducts of the tick and is injected through the skin of the new host with the tick bite. Few spirochetes are transmitted from the tick to its host during the first 24 to 36 hours of attachment. An infected nymphal tick, however, invariably transfers spirochetes when attached to its host for >72 hours.

Tick Identification

Larval and nymphal ticks are small, <3 mm, the size of a freckle or poppy seed. Therefore, the tick often goes unnoticed, and fewer than half of patients with Lyme disease recall having been bitten by a tick. The tick feeds on small, medium, or large mammals; lizards; or birds during its larval and nymphal (immature) stages. Larval ticks are not relevant vectors for Lyme disease, however, because they are rarely infected and become so only after feeding on an infected host.⁹ Adult ticks parasitize only medium or large mammals.¹ Humans are inadvertent hosts of any stage of the tick.¹ Although the tick can

Table 75-2 Lyme Disease Clinical Manifestations**Early Localized Infection:**

Erythema migrans skin rash

Early Disseminated Disease:*Heart (<4% of untreated patients in United States)*

Myocarditis or pericarditis

Conduction defects, varying degrees of atrioventricular or bundle branch block, but permanent pacing not indicated

Nervous System (Neuroborreliosis)

Cranial nerve (Bell's) palsy

Meningitis, lymphocytic

Radiculoneuritis, myelitis

Sensory or motor peripheral neuropathy

Skin

Multiple secondary erythema migrans lesions; lymphocytoma (lymphadenosis benigna cutis) rare in the United States, but 1% in Europe

Late Disease:*Musculoskeletal (less common in Europe)*

Persistent (<10% of untreated in United States) or intermittent arthritis of >1 large joint, especially the knee

Skin (10% in Europe; rare in the United States)

Acrodermatitis chronica atrophicans (unique to Lyme disease)

Late Neurologic

Peripheral neuropathy, subacute encephalopathy (memory impairment, sleep disturbance, dementia) and in Europe, progressive encephalomyelitis

feed on many different animals, each tick species has preferred hosts. For example, the immature *Ixodes scapularis* prefers to be hosted by the white-footed mouse, whereas the mature tick prefers white-tailed deer. In the northeastern and mid-western United States, *I. scapularis* (formerly *dammini*) is the primary vector, whereas *I. pacificus* is the primary vector in the western United States. In Europe, *I. ricinus* is the vector, and *I. persulcatus* is the primary vector in Asia. The discovery of organisms such as *B. burgdorferi* from *I. ovatus* in Japan and *Haemaphysalis longicornis* in China, both of which parasitize domestic animals and humans, demonstrates a greater diversity of endemic vectors and cycles in Asia. Therefore, the geographic distribution of Lyme disease matches the geographic range of the specific *Ixodes* species that harbor Lyme *Borrelia*.

Host Identification

The host's ability to harbor and transmit the spirochete to the tick (i.e., reservoir competency) is an important consideration in understanding the epidemiology and prevalence of Lyme disease. The reservoir-competent white-footed mouse and the reservoir-incompetent (i.e., incapable of harboring and transmitting the spirochete) white-tailed deer are the preferred hosts for the immature and adult forms of *I. scapularis* in the northeastern United States, respectively.¹ Subadult *I. pacificus* organisms preferentially feed on the western fence lizard, which

is reservoir incompetent. In fact its blood is borreliacidal.^{9,12,13} Deer are not important hosts for mature *I. pacificus* organisms. Similarly, in the southern United States, immature *I. scapularis* ticks feed primarily on lizards. The cotton mouse and cotton rat, however, appear to be the predominant reservoir hosts for the spirochete in the southern United States, which the tick may feed upon. In Europe, various reservoir-competent mice and vole species are reported hosts for *I. ricinus*.¹

How is Lyme borreliosis transmitted to humans in the western United States if the preferred hosts are not reservoir competent? It is suggested that the dusky-footed wood rat and kangaroo rat, which can support *B. burgdorferi*, are the hosts of the spirochete for the few immature *I. pacificus* which incidentally feed on the rats. Thus, an estimated 0% to 14% of *I. pacificus* organisms are infected with spirochetes, contrasting with infection rates for *I. scapularis* in the northeastern United States of 20% to 40%.⁹ In Europe, *I. ricinus* infection rates vary from 4% to 40%. In addition, bird parasitism by ticks enables the ticks to be carried long distances, even intercontinentally, during spring and fall migrations. Birds can bring ticks into new areas and also serve as maintenance hosts.¹

Thus, the complex interplay of spirochete, host, and vector in a particular area influences the risk of Lyme disease after a tick bite. Lyme disease is not transmitted directly between people.⁶

Classification and Laboratory Testing of Lyme Disease

The clinical features of Lyme disease were historically divided into three stages: early localized (stage 1), early disseminated (stage 2), and chronic, persistent, or late disease (stage 3). Many believe that "chronic" Lyme disease is an unproved entity,^{9,14} although some disagree.^{15,16} Currently, Lyme disease is classified as either "early" or "late" disease with the possible existence of post-Lyme disease syndromes.⁹ Although Lyme disease may be debilitating, it is not life threatening.

The most specific marker of Lyme disease is a characteristic skin rash termed *erythema migrans*. This solitary skin lesion occurs in 80% to 90% of patients with the disease.^{4,5} No other physical finding of Lyme disease is diagnostic. No laboratory gold standard for diagnosis currently exists. Laboratory diagnosis of Lyme disease is problematic because sufficiently sensitive and specific tests are lacking; deficiencies in laboratory standardization confound the issue. Positive results of blood tests for an antibody response to the spirochete only support a diagnosis of Lyme disease as seropositivity alone does not prove that a given medical condition is caused by Lyme disease.⁹ The IgM antibody response develops 4 weeks after infection, peaks at 6 to 8 weeks, and declines to the normal range after 4 to 6 months. In some patients, IgM levels may remain high or reappear. The IgG antibody response begins 6 to 8 weeks after disease onset, peaks at 4 to 6 months, and may remain elevated indefinitely.¹⁷ Overuse of serologic testing and over reliance on the results have resulted in excessive and inaccurate diagnoses of Lyme disease.

Treatment

The clinical manifestations of Lyme disease should govern the treatment strategy used (Table 75-3).⁹ To effect a cure, it is not

Table 75-3 Treatment Recommendations for Lyme Disease**Erythema Migrans**

Adults: Doxycycline (Vibramycin) 100 mg PO BID × 10 days

Or

Amoxicillin (Polymox) 500 mg PO TID × 14–21 days

Or

Cefuroxime axetil (Ceftin) 500 mg PO BID × 14–21 days

Children (<8 yrs): Amoxicillin 50 mg/kg/day PO in 3 divided doses (maximum, 500 mg/dose) × 14–21 days or cefuroxime 30 mg/kg/day PO in 2 divided doses (maximum, 500 mg/dose) × 14–21 days

Children (>8 yrs): May use doxycycline 1–2 mg/kg PO in 2 divided doses (maximum, 100 mg/dose) × 14–21 days

Cardiac Disease: third-degree heart block

Adults: Ceftriaxone (Rocephin) 2 g IV Daily × 14–21 days

Or

Cefotaxime (Claforan) 2 g IV Q 8 hr × 14–21 days

Or

Penicillin G (Pfizerpen) 3–4 MU IV Q 4 hr × 14–21 days

Or

For first- or second-degree heart block: doxycycline or amoxicillin in doses as noted above × 14–21 days

BID, twice daily; IV, intravenous; MU, million units; PO, by mouth; TID, three times daily.

necessary to continue antibiotic treatment until all symptoms have resolved.^{5,9}

1. J.S., age 38 years, visits his local physician with symptoms of low-grade fever and muscle aches 3 days after deer hunting in the state of Washington. After hunting for approximately 6 hours, he noticed a small tick on his thigh and immediately destroyed it. A small, itchy spot that he felt at the site of the tick bite is no longer symptomatic. The temporal relationship of the tick bite with his symptoms of fever and myalgias prompts his physician to collect blood samples for Lyme disease antibody testing. Antibiotic therapy also is initiated. Why is the blood test not likely to be of value? Why is empiric antibiotic therapy not appropriate for J.S.?

In general, the use of serologic testing or antimicrobial prophylaxis after a recognized tick bite is not recommended.⁹ The antibody response to *B. burgdorferi* is not detectable for the first 4 weeks after a tick bite.⁵ Therefore, the blood tests for antibodies to *B. burgdorferi* are unlikely to be positive, as J.S.'s tick bite occurred only 3 days ago.

The risk of developing Lyme disease can be affected by the rate of transmission of the spirochete from infected ticks to humans; the length of time before the tick is removed during its bite; the degree of blood engorgement of the tick (“scutal index”); the prevalence of spirochete infestation of ticks in an area, which varies with the tick species; and the reservoir competency of host animals in the region.⁹

Although transmission rates of Lyme disease from an infected tick bite are estimated at approximately 10%, the risk is reduced dramatically if the tick is removed within 24 hours of attachment, as in J.S.'s case. The small, itchy spot experienced by J.S. probably represented a hypersensitivity reaction to the bite. These erythematous, noninfectious skin lesions develop within 48 hours of tick detachment or may occur while the tick is still attached. They are usually <5 cm in diameter; they

may have an urticarial appearance and usually disappear in 1 or 2 days.⁹

Prophylactic antibiotic preventative therapy with a single dose of 200 mg oral doxycycline, or for children 8 years or older at 4 mg/kg to a maximum 200-mg dose, can be offered if the following criteria are met: (a) there are no contraindications to doxycycline use; (b) administration can start within 72 hours of tick removal; (c) the tick can be reliably identified as a nymphal or adult *I. scapularis* tick with certainty of the duration of attachment of 36 hours or more based on the degree of engorgement or time of exposure; and (d) the local rate of infection of ticks by *B. burgdorferi* in the area of exposure is 20% or greater based on current ecological evidence.⁹ Routine testing of ticks themselves for tick-borne infections is not recommended.⁹

Antibiotic prophylaxis after *I. pacificus* tick bites is generally not necessary.⁹ The low infection rate of *B. burgdorferi* in *I. pacificus* ticks may be owing to the observation that the western fence lizard's blood can destroy spirochetes in the tick's tissues during feeding.¹² In summary, J.S. would not require prophylactic doxycycline treatment or serologic testing for his tick bite because of the short duration of tick attachment and low prevalence of *B. burgdorferi* infestation of *I. pacificus* ticks.

ERYTHEMA MIGRANS**Signs, Symptoms, and Disease Course**

2. K.T., a 34-year-old woman, presents with right knee pain and multiple, large, discrete skin rashes that she has had for the past 10 days. Three months ago, in July, she visited friends in Massachusetts and spent much of her time engaged in outdoor activities (e.g., hiking, biking, swimming). Two months ago, her husband noticed a circular area of intense redness, approximately 9 cm wide, in her left armpit. The rash grew considerably larger over the next 2 weeks and had a red outer border. K.T. attributed the expansion of the rash to having scratched the mildly itchy area. The rash gradually disappeared. In late August, K.T. experienced fatigue, nausea, and headache for a week and thought it was “summer flu.” In early September, she experienced right knee pain; ibuprofen produced some relief. On examination, she was afebrile and had mild soft tissue swelling of the right knee. Her white blood cell (WBC) count was normal. Serum samples contained antibody titers to *B. burgdorferi* of 1:60 and 1:400 for IgM and IgG, respectively. A Venereal Disease Research Laboratory (VDRL) test for syphilis and a pregnancy test were negative.

K.T. is started on a 4-week course of oral doxycycline 100 mg twice daily. What characteristics of K.T.'s skin rash are consistent with the erythema migrans of Lyme disease?

The erythema migrans of Lyme disease usually develops within 30 days (median, 7 days) of a usually asymptomatic tick bite at the site of inoculation of the spirochete.^{4,10} The rash begins as an erythematous (red) macule or papule typically in the groin, gluteal fold, axilla, torso, popliteal fossa, or thigh.¹⁸ In children, erythema migrans is often found on the head at the hairline, neck, arms, or legs.¹⁸ It expands outwardly at 2 to 3 cm/day to a diameter of 5 to 70 cm (mean, 16 cm), occasionally with some central clearing.¹⁸ The classic annular or ringlike patch may have complex concentric inner erythematous circles, resembling a bull's eye or target, especially in European

cases.¹⁸ Some cases of erythema migrans in the United States lack central clearing.⁹ The rash may be warm to the touch and is usually painless, but some patients have mild burning or itching.⁴ Up to 50% of patients with erythema migrans have multiple secondary lesions that most likely represent blood-borne spread of the spirochete to other skin sites rather than multiple tick bites.¹⁰ If untreated, erythema migrans generally fades within several weeks; if treated, it usually resolves in several days.

Low-grade fever and other nonspecific symptoms, such as fatigue, malaise, lethargy, headache, stiff neck, myalgia, arthralgia, and regional or generalized lymphadenopathy, may accompany erythema migrans. In the United States, 70% to 80% of patients with Lyme disease display erythema migrans.^{4,5,19} Some may not have the other early symptoms of the disease. Some clinicians prefer abandoning the term “flu-like illness” in favor of “viral-like syndrome” to describe the nonspecific symptoms of early Lyme disease because cough, rhinitis, sinusitis, and gastrointestinal (GI) symptoms do not usually occur.¹⁶

Pitfalls in the diagnosis of erythema migrans exist. Lesions commonly misdiagnosed as erythema migrans include streptococcal cellulitis, urticaria, dermal hypersensitivity reaction, *Rhus* contact dermatitis, granuloma annulare, arthropod hypersensitivity reactions, tinea corporis, and serum sickness rashes.¹⁸ K.T.’s skin rash was large (>9 cm), red, and had a red outer border. It gradually faded over a few weeks. These characteristics are consistent with a diagnosis of erythema migrans.

Serologic Testing

3. What might have been the rationale for the laboratory tests that were undertaken in K.T., and what would be reasonable interpretations of laboratory tests in patients with Lyme disease?

An antibody titer measured by enzyme-linked immunosorbent assay (ELISA) is considered positive for IgM when it is >1:100 and positive for IgG when it is >1:130. K.T.’s results (IgM of 1:60 and IgG of 1:400) support a diagnosis of Lyme disease because the IgM can naturally fall by this time, yet IgG levels may remain elevated indefinitely. Syphilis and other known biologic causes (periodontal spirochetes) of false-positive serologic testing should be excluded. Rheumatoid factor or antinuclear antibody tests usually are negative in Lyme disease. These tests help differentiate rheumatoid arthritis or systemic lupus erythematosus from Lyme disease. The WBC count is normal or mildly elevated in Lyme disease. K.T. had a normal WBC. Pregnancy was ruled out before initiating a tetracycline. Most interesting in K.T. is the presence of secondary erythema migrans lesions, which develop in up to 50% of untreated patients in the United States and represent disseminated infection.

The presence of erythema migrans as an early indicator of Lyme disease gives physicians the best opportunity for early diagnosis and treatment. In the United States, the expression of erythema migrans is the *only* manifestation of Lyme disease that is sufficiently distinctive to allow clinical diagnosis in the absence of confirmatory laboratory information.⁹ Early treatment can prevent the sequelae of disseminated disease.

LYME DISEASE TREATMENT

Antibiotics

4. Why was doxycycline (Vibramycin) chosen to treat K.T.?

Borrelia burgdorferi is susceptible to amoxicillin, tetracyclines, and some second- and third-generation cephalosporins, based on *in vitro* data. It is only moderately sensitive to penicillin G (Pfizerpen) and is resistant to first-generation cephalosporins, rifampin (Rimactane), cotrimoxazole (Bactrim), aminoglycosides, chloramphenicol (Chloromycetin), and the fluoroquinolones.^{9,19}

Penicillin, tetracycline, and erythromycin historically were the drugs of choice for the treatment of Lyme disease because they are given orally; they are relatively inexpensive and appeared to have good *in vitro* activity. Disappointing *in vivo* results, however, were found with all these agents except penicillin. Perhaps tetracycline and erythromycin were under dosed, given in too short a duration, or intrinsically have larger time-to-kill ratios than penicillin. In Europe, in particular, penicillin still is used with continued success. Amoxicillin (Polymox) has better absorption and a longer serum half-life than penicillin V (Veetids) and continues to be effective in treating Lyme disease. Amoxicillin is preferred for Lyme disease treatment in pregnant or breastfeeding women and in children <8 years of age.¹⁹

Compared with the third-generation cephalosporins, the second-generation drug cefuroxime axetil (Ceftin) is available in an oral dosage form and has good *in vitro* activity as well as *in vivo* performance. It is more expensive than oral amoxicillin or tetracyclines. Of the third-generation cephalosporins, ceftriaxone (Rocephin) has the strongest *in vitro* activity. The long half-life of ceftriaxone allows the convenience of once-daily dosing in an outpatient program. Ceftriaxone is expensive, however, and has a higher incidence of diarrhea than other β -lactams, probably because of partial biliary excretion. Risk factors for the development of ceftriaxone-induced biliary disease include age <18 years, daily ceftriaxone dose >40 mg/kg, female gender, and administration of prior courses of the drug. Cefotaxime (Claforan) is an alternative to ceftriaxone that is not associated with biliary complications and comparable in cost, but it must be dosed more frequently.

The macrolides clarithromycin (Biaxin) and azithromycin (Zithromax) may or may not have activity against Lyme spirochetes.⁹ As with erythromycin, they have been less effective for the treatment of Lyme disease in controlled clinical trials.¹⁹ The combination of a macrolide with lysosomotropic agents, especially hydroxychloroquine, anecdotally has been suggested to be associated with increased symptom relief probably because of the combined anti-inflammatory activity rather than direct antimicrobial activity.⁹ Azithromycin is not considered to be a first-line agent in the treatment of Lyme disease.⁹

Doxycycline is well absorbed orally and is less expensive than third-generation cephalosporins that must be administered parenterally. Doxycycline has a long serum half-life of 18 to 22 hours. In addition, doxycycline penetrates into the cerebrospinal fluid (CSF) at concentrations of at least 10% of serum levels even in the absence of meningeal inflammation. Doxycycline can complex with divalent or trivalent cations in the gut, and absorption may be decreased as a result. On the

other hand, administering doxycycline with food, to minimize nausea, is recommended.⁹ Compared with other tetracyclines, doxycycline has the least affinity for divalent calcium cations, and oral absorption is reduced by only 20% if given with milk. The major side effect of doxycycline is phototoxicity, which is of concern because Lyme disease usually occurs during sunny times of the year. A less recognized side effect is the risk of doxycycline-induced esophageal ulceration. Patients should be instructed not to take doxycycline or other tetracyclines for 1 to 2 hours before going to bed or lying down and to take the medication while standing up with at least 240 mL of clear fluid, especially with the capsule formulation. Despite less *in vitro* activity compared with some β -lactam antibiotics, *B. burgdorferi* is sufficiently susceptible to doxycycline, and clinical experience with doxycycline has been very favorable.²⁰

In conclusion, doxycycline was a suitable choice for K.T., and the 4-week duration of therapy matches the recommendation for adult arthritis treatment outlined in Table 75-3.

Antibiotic-Refractory Lyme Arthritis

5. K.T. continues to have knee inflammation for 4 months after receiving a second course of antibiotic treatment (ceftriaxone 2 gm daily for 2 weeks) and is now considered to have antibiotic-refractory Lyme arthritis. Why should antibiotic therapy be repeated (or not repeated) for K.T.'s arthritis?

Antibiotic-refractory Lyme arthritis, which in the United States develops in approximately 10% of patients with Lyme arthritis, has been associated with an increased frequency of the class II major histocompatibility complex allele, HLA-DRB1*0401 human leukocyte antigen, and an immune response to outer surface protein A (OspA).^{21,22} Patients with these markers may be predestined for the development of chronic arthritis despite antibiotic therapy.^{21,22} The HLA-DRB1*0401 allele is associated with lack of response to antibiotic therapy and autoimmunity.^{21,22} Destructive changes in the involved joint may occur, with the synovium showing vascular proliferation, villous hypertrophy, and a lymphoplasmic cellular infiltrate similar to other inflammatory arthritides. In these patients, persistent arthritis is not the result of the persistence of active infection by the spirochete in a protected site. Such patients often respond well to synovectomy, again suggesting that the presence of synovitis may not be the result of persistence of the infection.

If K.T. is HLA-DRB1*0401 positive and has antibody reactivity to the outer surface protein OspA of *B. burgdorferi*, and a negative polymerase chain reaction (PCR) of synovial fluid for *B. burgdorferi* nucleic acids, she will likely be resistant to further antibiotic treatment. Repeat antibiotics are ineffective in this case. Remittive agents, such as hydroxychloroquine or intra-articular corticosteroid injections, may be helpful. Synovectomy may be offered.⁹

Neuroborreliosis

6. E.C., a 54-year-old man, presents with symptoms of late Lyme encephalopathy, including memory deficits, somnolence, and irritability. CSF analyses confirm the diagnosis. Should E.C. be treated with antibiotics? If so, for how long?

Although very rare, neurologic complications of Lyme disease are the major morbidity of the disease.¹⁰ Lyme encephalopathy is more common in Europe than in the United States.⁹ Although the acute neurologic manifestations of Lyme disease can remit spontaneously, IV antibiotic therapy hastens the resolution of symptoms and prevents more chronic sequelae (e.g., mild cognitive dysfunction or low-grade peripheral neuropathies). The development of these other syndromes in E.C. may be evidence of irreversible neurologic damage. Therefore, the approach to diagnosis and treatment should be aggressive. IV antibiotic therapy is indicated according to most clinicians (Table 75-3).²⁰ Most authorities recommend a minimum of 2 to 4 weeks.^{9,19,20} Other candidates for intensive IV regimens of antibiotic therapy include patients with third-degree AV block or acute Lyme meningitis or radiculopathy.²⁰

All patients with Lyme disease should be treated with antibiotics because most cases can be managed effectively with appropriately chosen antibiotics. In conclusion, E.C. should be treated aggressively with a parenteral third-generation cephalosporin such as ceftriaxone 2 g IV daily for 2 to 4 weeks.⁹ Treatment response, however, is usually slow and possibly incomplete. Unless reliable objective measures indicate relapse, retreatment is not recommended.^{9,23}

Laboratory Testing of Lyme Disease

7. P.S., a 35-year-old asymptomatic man with a history of a tick bite from a nonendemic Lyme disease area, just tested positive on ELISA. He was tested because he expressed a fear of Lyme disease. Why is this positive result alone sufficient (or insufficient) to begin treatment for Lyme disease? What other tests could be considered to help confirm the diagnosis?

The *B. burgdorferi* spirochete is long and narrow, with flagella. A flagellar 41-kDa protein is similar to flagellar proteins on other spirochetes, and cross-reactivity can occur. The Osp include two of the major elicitors of antibody response in late Lyme disease, termed OspA and OspB. The OspA antigen was used for vaccine development.

Problems of standardization, sensitivity, and specificity have caused significant interlaboratory and intralaboratory variations in test results in the serodiagnosis of Lyme disease.²⁴ Serologic testing for an antibody response to the spirochete is incapable of distinguishing between active infection and prior exposure. Demonstration of local CSF antibody production and comparison with serum concentrations, however, are highly useful in the diagnosis of neuro-disease, especially in European cases. Despite these problems, detection of the antibody response to *B. burgdorferi* is the most commonly used laboratory procedure for the diagnosis of Lyme disease.

Immunofluorescent assay (IFA) detection of antibody response was the first tool used in the diagnosis of Lyme disease. This test, however, is labor intensive and interpretation of the results is subjective; it has been replaced by ELISA analysis. Even with ELISA, however, 5% to 7% of test results may be false-positives. The Western blot (immunoblotting) test has been shown to increase the specificity of ELISA results, but it is also insensitive in early Lyme disease.⁴ Western blotting supplements ELISA testing but does not confirm it, because they are not independent tests.²⁵

Except for research studies, attempting to culture blood or skin for *B. burgdorferi* or PCR testing is not recommended in routine clinical practice in the differential diagnosis of erythema migrans owing to the expense and cumbersome nature of these tests.⁹

In summary, P.S. should not be treated for active Lyme disease based solely on one positive ELISA test. Seropositivity alone does not prove infection by *B. burgdorferi*.⁹ Although the Western blot might help to establish a diagnosis, only a careful history and physical examination in combination with the serologic testing will accurately diagnose Lyme disease. The erythema migrans rash is key to early diagnosis.

8. A friend from an area not endemic for Lyme disease calls you to say that she has been recently diagnosed with “chronic Lyme disease.” She was never found to have early or late Lyme disease. She’d like more information about it. How should you respond?

Chronic Lyme disease is a confusing term. Most authorities agree that there may be “post-Lyme disease syndromes,” but its definition is evolving and not yet well accepted.⁹ They agree, however, that objective evidence of a prior *B. burgdorferi* infection must be established before using this terminology. Criteria for diagnosing a post-Lyme disease syndrome include fatigue, widespread musculoskeletal pain, cognitive difficulties, or subjective symptoms of such severity that a substantial reduction in previous levels of activities is encountered. Any of these subjective symptoms must have had onset within 6 months of the initial Lyme disease diagnosis and persisted for at least 6 months after completion of antimicrobial therapy. It is considered clear that if someone has adhered to a recommended treatment regimen for Lyme disease, no convincing biologic evidence establishes the existence of symptomatic, chronic infection by *B. burgdorferi*. The organism has not been shown to develop antibiotic resistance.⁹ For these patients with chronic subjective symptoms for >6 months, repeated antibiotic therapy is not useful or recommended.^{9,26}

Is post-Lyme disease an autoimmune disease? The usual markers of autoimmune disease, such as increased erythrocyte sedimentation rates (ESR) or C-reactive protein levels, have not been seen. The usual “clustering” of HLA antigen genotypes seen in autoimmune disease has not been shown in case versus control studies in documented Lyme disease in patients. Is it different than fibromyalgia? One can objectively differentiate post-Lyme disease from fibromyalgia because the usual fibromyalgia trigger or pressure points are negative in patients with post-Lyme disease.

Many have attempted to identify useful tools to track Lyme disease response to therapy or supposed disease progression with markers, such as CD57 lymphocyte tests, soluble cd14 levels, anti-C6 antibodies, C6 peptides by ELISA, urinary antigen testing, following Western blot band changes.^{27–30} None of these tests have proved to be useful.

What is apparent is that the term “chronic Lyme disease” has been used for patients with vague, undiagnosed complaints who have never had the disease. In fact, most patients regarded as having chronic Lyme disease, when rigorously evaluated at university-based medical centers, have had no evidence of current or prior *B. burgdorferi* infection.⁹

Because of a lack of efficacy, supportive data, or potential harm to the patient, the following are *not* recommended for treatment of any manifestation of Lyme disease: excessive dosing, long-term dosing, pulsed-dosed, or combination antibiotics; IV hydrogen peroxide or immunoglobulins; anti-*Bartonella* treatment with macrolides or other antibiotics (although the DNA of *Bartonella* has been found in some *Ixodes* ticks, no convincing evidence indicates that it can be transmitted to humans by tick bite); hyperbaric oxygen; fever therapy; specific nutritional supplements; ozone; cholestyramine; or magnesium or bismuth (bismacine or chromacine) injections.⁹

Your friend should be encouraged to seek an alternate diagnosis. Even in many patients who have had verified Lyme disease, the aches and pains of daily living they experience appear to be more related to their posttreatment symptoms than Lyme disease itself.⁹

Lyme Disease Prevention

9. P.S. is alarmed that his family members may contract Lyme disease. How do you advise him?

Most vector-borne diseases are prevented through vector control. This has proved difficult for tick-borne diseases because of a lack of efficacy or environmental concerns. Methods tried include habitat destruction by fire, chemical spraying, eradication of host deer, or protection of mice from tick infestation.

The prevention of Lyme disease has been limited thus far to personal protection efforts. Tick repellents may be applied to the skin or clothing. N,N-diethyl-m-toluamide (DEET) skin repellents (Repel Sportsmen) combined with a permethrin (Permanone) clothing repellent offer the best overall protection.^{9,19}

DEET has been tested against *Ixodid* ticks for repellence and found to be more effective than dibutylphthalate, dimethylphthalate, pyrethrum, and two combination products. Although DEET was considered safe historically, studies suggest that up to 50% of an applied dose may be absorbed through the skin and distributed to fat, liver, and muscle tissue. Half of it is excreted as metabolites in the urine over 5 days. Because DEET is lipid soluble, it can accumulate in fatty tissue and the brain.

Adverse DEET effects reported in adults include tingling, dryness, and some desquamation around the nasal area after repeated application of a 50% DEET solution to the face and arms. Two days after discontinuation of the solution, these side effects usually resolve.

In children, on the other hand, serious reactions after excessive DEET application have been reported.⁹ These are rare events, however, and if the products are used according to their labeling, the adverse reaction risk is low, even for children >2 months of age.^{4,9} Prolonged or excessive application is not recommended. It may be prudent to use the lowest effective concentration of DEET-containing repellents, such as those containing 20% to 30%. To minimize DEET toxicity apply sparingly, avoid inhalation or introduction into the eyes, wash repellent-treated skin when coming inside, avoid use on children’s hands (that are likely to have contact with the eyes or mouth), and apply it only to intact skin or clothing.

A Centers for Disease Control and Prevention (CDC) recommended insect repellent alternative to DEET is picardin

(Cutter Advanced).³¹ The effectiveness of picardin against *Ixodes* ticks has not been established, however.⁹

Physical barriers to ticks, such as wearing protective garments, long pants, and long-sleeved shirts, tucking shirts into pants and pants into boots, and wearing closed-toed shoes, should help to prevent infection. Ticks can be easier to spot on light-colored clothing. Checking the body for ticks regularly is recommended; any that are found should be promptly removed. Avoiding tick habitats is the best protection against tick-borne diseases. Human vaccine for Lyme disease has been withdrawn from the market. It may have caused autoimmune arthritis in HLA-DR4 positive patients.³² Citing low demand, the U.S. manufacturer discontinued production in 2002.

ENDEMIC RELAPSING FEVER

Relapsing fever exists in two forms: epidemic and endemic. The bacterial spirochete *Borrelia recurrentis*, the agent responsible for epidemic relapsing fever, is transmitted between humans by the human body louse. Epidemic relapsing fever prevails in crowded conditions and occurs in the Middle East, Africa, and Asia; it has not been reported in the United States in recent years.^{33–35} Mortality rates of up to 40% have been reported in some epidemics. Endemic relapsing fever, which is caused by a variety of *Borrelia* species, occurs worldwide, and is spread by ticks.

Spirochete Identification

In Europe, the identified responsible spirochete is *Borrelia hispanica*. In Africa, they are *Borrelia duttoni*, and *Borrelia crocidurae*; in North America, the species are *Borrelia hermsii*, *Borrelia turicatae*, and *Borrelia parkeri*.^{33,34,36} Other *Borrelia* species may produce Lyme-like diseases or relapsing fevers worldwide. The terms “tick-borne” relapsing fever and “endemic” or “sporadic” relapsing fever are considered interchangeable. In contrast to epidemic relapsing fever, death from tick-borne relapsing fever is rare, and most patients recover.³³

As the name implies, this disease is characterized by intermittent bouts of fever of variable duration. The *Borrelia* have the genetic ability to alter their outer surface proteins extensively. This capacity of the spirochetes to vary their surface antigens, thus eluding host defenses, is the presumed explanation for the recurrent nature of relapsing fever.^{33,34,36}

Tick Vector

Tick Identification

The predominant tick vector for relapsing fever is of the genus *Ornithodoros*, a soft-bodied tick. These ticks feed on wild rodents or domestic animals and, incidentally, on humans. In North America, three tick species carry the agents of endemic relapsing fever with apparent strict specificity. In fact, the names of the responsible *Borrelia* species have been adopted from the three tick species that transmit them: *O. hermsii*, *O. parkeri*, and *O. turicata*. Although the ticks themselves may serve as reservoir hosts, the *Borrelia* usually circulate between wild rodents and ticks. The assumption that relapsing fever-causing *Borrelia* species are associated only with soft-shelled ticks is challenged by the isolation of *B. miyamotoi* from *I. persulcatus*, the hard-bodied vector tick for Lyme disease in

Japan.³⁷ Similar to Lyme disease, greater worldwide variations of endemic cycles and vectors for tick-borne relapsing fever may exist than in North America.³⁸

Tick Geography

In North America, relapsing fever is an uncommon disease largely confined to the geographic distribution of the tick species that harbor the *Borrelia*. These ticks are usually found in the remote natural settings of the mountains and semiarid plains of the far west and Mexico. In the United States, most cases of relapsing fever are caused by *B. hermsii*. It can develop when people visit tick- or rodent-infested cabins or summer homes. *O. hermsii* and *O. parkeri* inhabit forested mountain areas, usually at high altitudes, and have been pinpointed as the common source of relapsing fever outbreaks from human exposure in mountain cabins.³⁶ *O. turicata* transmits its *Borrelia* in the semiarid plains, from Kansas to central Mexico, creating outbreaks in people visiting caves, especially limestone ones in central Texas.^{34,36}

Spirochetal Behavior

Ticks acquire spirochetes from blood feeding on small wild rodents. If high levels of *Borrelia* are present in the animal's blood, large numbers of spirochetes will be ingested by the tick and reside in the tick's midgut. During the next few days, the spirochetes invade the midgut wall, traverse the hemolymph system, and within a few weeks infect the salivary glands as well as other tick tissues and organs. They endure through tick molting and by now are practically absent in the midgut. Females may develop infected ovaries and transmit *Borrelia* to offspring in some *Ornithodoros* species, but this is rare in *O. hermsii*.³⁴ Having reached the tick's salivary glands, the spirochetes are poised to invade the next host that the tick feeds upon.

Tick Behavior

In contrast to the hard-bodied ticks, these ticks feed rapidly, often detaching after 30 to 90 minutes.³⁴ They feed at night while people are sleeping, and their bite is usually painless. Therefore, most people are unaware that they have been bitten.³⁶

Disease Characterization

The hallmark of endemic relapsing fever is an abrupt onset of high fever (often >39°C) after an incubation period of 4 to 18 days.^{34,35} The patient may develop shaking chills, severe headache, tachycardia, abdominal pain, myalgias, arthralgias, nausea, vomiting, and malaise. The fever usually breaks in 3 to 6 days in untreated patients. After a variable afebrile period of 3 to 36 days, (usually 7 days), cyclical periods of fever and constitutional symptoms reappear. Each febrile attack progressively diminishes in severity. Three to five relapses typically occur in untreated patients. A transient skin rash lasting 1 to 2 days appears in 6% to 28% of patients, typically when the primary fever has broken. The rash may be localized or generalized and consist of petechiae, macules, or papules. Neurologic involvement, more common with *B. turicata* infection, may be evident.^{33,36}

Routine laboratory testing is of little value. Moderate anemia is common, however, as well as an increased ESR.

Leukocyte counts may be normal, yet thrombocytopenia is regularly encountered but is considered nonspecific.^{34,35,36}

The diagnosis of relapsing fever is made by direct observation of the spirochete on a peripheral blood smear while the patient is febrile.³⁶ The observation of the smear is enhanced with Wright's or Giemsa staining. Further enhancement may be obtained by staining fixed smears with acridine orange. Antibody serology tests, although available, are of little value. Skin biopsy of the rash demonstrating the spirochete is unreliable. Direct culture of the spirochete from the blood into a special culture medium is the most specific diagnostic tool, but this is a slow technique confined to research laboratories.

Treatment

Doxycycline postexposure prophylaxis against a specific species, *B. persica*, of tick-borne relapsing fever has been shown to be successful in an Israeli study.³⁹ Whether this approach can be translated to other settings for other *Borrelia* species is unknown.

Successful treatment regimens usually include a 7 to 10 day course of antibiotics. Tetracyclines are preferred and doxycycline, 100 mg orally two times a day, is usually used.³⁶ Tetracycline or erythromycin is also effective at dosages of 500 mg orally four times a day. Hospitalization and administration of IV antibiotics may be required in severely ill patients.

10. O.T. is a 52-year-old man who visits his family practitioner with a sudden onset of high fever, severe headache, malaise, nausea, vomiting, and myalgias. He returned a week ago, at the end of July, from a stay in a rustic cabin on the north rim of the Grand Canyon. The clinician orders a manual complete blood count (CBC) and chemistry panel and asks the laboratory to observe a blood smear with Giemsa stain. What clues does the physician have to suspect endemic relapsing fever as the diagnosis?

The disease occurs more often in males, and the nonspecific constitutional symptoms exhibited by O.T. match the customary features of the ailment. The history is more revealing. The patient visited a location and setting where prior outbreaks of relapsing fever have been documented. In addition, cases of endemic relapsing fever peak in the summer months when ticks are warmer and more active.

11. After confirming the presence of *Borrelia* in the blood smear, the physician prescribes a 10-day course of tetracycline. Two hours after the first dose, O.T.'s wife calls the physician's office with concerns that the disease is worsening. O.T. is experiencing an increased temperature, is feeling faint and chilled, and has a rapid pulse and respiration rate. A skin lesion appears. What is most likely happening? Is this a drug reaction?

Up to 54% of patients with relapsing fever experience a reaction to the first dose of antibiotic, called a *Jarisch-Herxheimer reaction* (see Chapter 65, Sexually Transmitted Diseases).³⁴⁻³⁶ It may occur in louse-borne relapsing fever, tick-borne relapsing fever, and in other spirochetal diseases, such as syphilis or Lyme.⁹ The dramatic reaction consists of a rise in temperature, chills, myalgias, tachycardia, hypotension, increased respiratory rate, vasodilation, and occasionally exacerbation of skin lesions. Treatment of the reaction consists of supportive care. Severe reactions may require hospitalization for monitoring of vital signs and management of hypovolemia. Although this is

a reaction to the administration of an antibiotic drug, it is not an allergic response, and the antibiotic should be continued.

Southern Tick-Associated Rash Illness (STARI)

12. M.G., a 46-year-old man living in southern Missouri, recently developed a rash resembling erythema migrans after a Lone Star tick bite. Because this tick is not known as a vector for Lyme disease, what could be the cause?

Amblyomma americanum (the Lone Star tick) is found through the southeast and south-central United States and along the Atlantic coast as far north as Maine. This tick aggressively bites humans in the southern states, as opposed to *I. scapularis* ticks. Spirochetes detected by microscopy and culture have been found in 1% to 3% of Lone Star ticks and are named *Borrelia lonestari*.^{40,41} It is more closely related to the relapsing fever group of *Borrelia* than to Lyme *Borrelia* based on DNA sequencing. *B. lonestari* and *B. burgdorferi*, however, were ruled out as the cause of erythema migranslike skin lesions known as STARI in one investigation in Missouri.⁴² Whether antibiotic treatment is even needed for STARI is being investigated.

OTHER BACTERIAL DISEASES: TULAREMIA

Tularemia

Etiology and Epidemiology

In 1911, George W. McCoy and Charles W. Chapin from the U.S. Public Health Service investigated a plaguelike disease in wild ground squirrels harvested in Tulare County, California, and discovered tularemia's cause.⁴³ The bacterium is a small, nonmotile, aerobic, nonencapsulated, gram-negative coccobacillus now named *Francisella tularensis* in honor of Edward Francis for his fieldwork and contributions to tularemia research.⁴³ Three tularemia strains, the more virulent biovar A and the less virulent biovars B and C, are recognized.³⁶ Type A tularemia, formerly thought to exist only in North America was identified as well in Slovakia in 1998.⁴⁴ It is fatal in up to 5% of cases.^{43,45} The important reservoir hosts for the bacteria are hares, rabbits, and ticks. Before 1950, most human cases of the disease developed from direct contact with infected animals, usually hares or rabbits, and tularemia cases that occur in the fall or winter are usually associated with hunting season exposure. The prime source of serious human infections is the domestic rabbit.⁴⁴ Tick bite transmission, however, now accounts for more than half of tularemia cases west of the Mississippi River in the United States. In summer months, tick bites appear to be the main mode of transmission of tularemia to humans.⁴⁴ Other modes of transmission include ingestion of, or contact with, infected meat, water, or soil; inhalation of aerosolized bacteria; or bites from infected animals, mosquitoes, or deerflies.^{43,46} Direct person-to-person spread of the disease is rare.

Tularemia is found in North America, Europe, Russia, Japan, and the Middle East. Most U.S. cases occur in the south and midwest, primarily in Arkansas, Missouri, Oklahoma, Kansas, and South Dakota.^{36,44,47} The North American tick vectors are *Dermacentor variabilis* (dog tick), *Amblyomma americanum* (Lone Star tick), and *Dermacentor andersoni*

(wood tick). Tick-borne tularemia occurs most often in the spring and summer, matching the likelihood of exposure. Reported cases of tularemia in the United States have steadily declined since 1950 from a case report high of 2,291 in 1939 to current levels of <200 per year since 1967.

Clinical Presentation

The clinical manifestations of tularemia are related to the mode of transmission. Classically, six types of tularemia presentation are identified: ulceroglandular, glandular, typhoidal, oculoglandular, oropharyngeal, and pneumonic.⁴³ The last three forms are presumably not tick-borne, reflecting the potential avenues of transmission of the microorganism.

Ulceroglandular is the most common form of tularemia, accounting for 75% to 80% of cases.^{36,43} It is characterized by an ulcer that forms at the site of the tick bite, usually on the lower extremities, perineum, buttocks, or trunk. The lesion starts as a firm, erythematous papule that ulcerates and heals over several weeks. It is accompanied by regional, painful lymphadenopathy, usually inguinal or femoral. Glandular tularemia is defined by painful, swollen lymph nodes without an accompanying skin lesion. Typhoidal tularemia is characterized by fever, chills, headache, debilitation, abdominal pain, and prostration. Fever and chills are common with all forms of tularemia.

After exposure to the bacteria and an incubation period of 4 to 5 days, patients become ill with a sudden onset of fever, chills, headache, cough, arthralgias, myalgias, fatigue, and malaise. The severity of symptoms is quite variable, ranging from a mild, limited disease (probably type B tularemia) to rare cases of septic shock (probably type A tularemia). A hallmark manifestation is a high fever without an accompanying increase in pulse, or pulse-temperature disparity.³⁶ Common complications are mild hepatitis, secondary pneumonia, and pharyngitis. With antibiotic treatment of uncomplicated tularemia, mortality rates are only 1% to 3%. Increased morbidity and mortality are seen in the rare typhoidal forms.

Diagnosis

Laboratory diagnosis of tularemia is limited to the demonstration of an antibody response to the bacteria. Routine laboratory testing is of little help in establishing the diagnosis. Because an antibody response to the illness requires 10 to 14 days for detection, treatment is usually empiric. The diagnosis is based on clinical suspicion from the epidemiologic history and the presence of compatible findings. The customary serologic test demonstrates *F. tularensis* antibody agglutination. Although a single agglutination test with a titer of 1:160 or more in a suspected case is highly suggestive of a tularemia diagnosis, a fourfold or greater rise in titers between the acute and convalescent stages is diagnostic.⁴³

Treatment

In adults, streptomycin 7.5 to 10 mg/kg intramuscularly (IM) or IV Q 12 h for 7 to 14 days is the treatment of choice.⁴³ Pediatric dosing is 20 to 40 mg/kg IM divided twice daily for 7 to 14 days.

13. Streptomycin was historically the drug of choice for tularemia but it is often unavailable commercially. What other antibiotics are alternatives? What are their drawbacks?

Some clinicians believe that gentamicin is the best alternative aminoglycoside for the treatment of nonmeningitic tularemia.⁴³ Its advantages compared with streptomycin include lower minimal inhibitory concentrations (MIC), less vestibular toxicity, and wider commercial availability. Considered fairly comparable in efficacy to streptomycin treatment, gentamicin therapy has been associated with increased treatment failure and relapse, however.³⁶ Some of the case reports and studies of gentamicin may have involved inadequate durations of therapy, treatment delays, or sicker patients. Tobramycin (Nebcin) has been associated with lower cure rates and higher failure rates than gentamicin or streptomycin.³⁶

Initial cure rates and response to tetracycline are equivalent to those for gentamicin, but therapy with tetracycline has resulted in twice as many relapses. Perhaps bactericidal agents are required for successful tularemia treatment.

Reported cure rates for chloramphenicol therapy of tularemia are significantly lower than those for streptomycin. Chloramphenicol is considered bacteriostaticlike tetracycline. Chloramphenicol does not penetrate into the CSF, with or without inflamed meninges, better than aminoglycosides or tetracyclines. Therefore, when tularemic meningitis is suspected, chloramphenicol plus streptomycin should be considered.^{36,43}

Cephalosporins, such as ceftriaxone (Rocephin) and ceftazidime (Fortaz), possess favorable MIC data for *F. tularensis*; but inadequate clinical responses and treatment failures were encountered with ceftriaxone. In general, β -lactams and macrolides cannot be recommended for tularemia treatment.³⁶ Of the fluoroquinolones studied, ciprofloxacin (Cipro) has the optimal minimal bactericidal concentration (MBC) in vitro data. Promising results with ciprofloxacin treatment have been documented.^{36,43,48} Because pneumonia is a common complication of tularemia, concern exists about the potential for overwhelming streptococcal meningitis or sepsis during ciprofloxacin therapy. Fluoroquinolones are relatively contraindicated in children.

It is not entirely clear why the in vitro susceptibility of *F. tularensis* to some antibiotics does not correlate with clinical success in treatment of tularemia. It has been suggested that testing pure cell cultures of the organism ("axenic" media) with antibiotics does not correlate well with clinical response. This may be because *F. tularensis* is predominantly an intracellular organism. One study using an in vitro cell system of tularemia antibiotic sensitivity testing found the highest activity with aminoglycosides, tetracyclines, rifampin, and fluoroquinolones, the drugs found to have the most favorable outcomes in treating tularemia today.⁴⁹

In many of the reported studies of antimicrobial therapy for tularemia, short courses of treatment (~7 days) were used. To prevent tularemia from worsening or relapsing, longer regimens (14 days) should be used. Jarisch-Herxheimer reactions can occur with antibiotic treatment of tularemia. Antibiotic prophylaxis for people exposed to those with tularemia is not recommended, but prophylactic antibiotics might be used for suspected bioterrorism attacks of tularemia. Concern for the use of biological warfare agents, such as anthrax, botulinum toxin, plague, or hemorrhagic fever exists as well for Tularemia. Acute febrile illness with pneumonia and other signs of infection would result 3 to 5 days after exposure to aerosolized or airborne Tularemia organisms from an

intentionally set weapon.⁵⁰ No tularemia vaccines are available in the United States.⁴³

THE RICKETTSIA: ROCKY MOUNTAIN SPOTTED FEVER, RICKETTSIA PARKERI INFECTION, EHRLICHIOSIS, AND ANAPLASMOSIS

Rocky Mountain Spotted Fever (RMSF)

Rocky Mountain spotted fever is the most prevalent and virulent rickettsial disease in the United States. As early as 1872, RMSF infected white settlers of the Northwest and it may have been prevalent in Native Americans of the region before that time. It was first described in residents of the Bitterroot, Snake, and Boise River valleys of Montana and Idaho in the late 1800s. Howard Ricketts discovered the causative agent, *Rickettsia rickettsii*, in 1906. The rickettsiae is a small (0.3 by 1.5 μm), pleomorphic, gram negative, obligate intracellular coccobacillus that can survive only briefly outside of a host.³⁶

Epidemiology

Today, RMSF is reported in every U.S. state except Vermont, Maine, and Hawaii; and in Canada, Mexico, and Central and South America.⁵¹ It has not been documented outside of the Western Hemisphere. The term “Rocky Mountain spotted fever” is actually a misnomer today because the disease has shifted eastward from the Rocky Mountain states, and the greatest incidence of RMSF now occurs in North Carolina, Oklahoma, Arkansas, South Carolina, and Tennessee.⁵² Most RMSF infections arise from tick exposure in rural or suburban locations, yet rare outbreaks in urban environments have occurred.

The prevalence of RMSF is highest in children 5 to 9 years of age.^{36,53} Another peak prevalence is seen in men >60 years of age. Risk factors are male gender, residence in wooded areas, and exposure to dogs that may bring ticks into households and yards.

Tick Vectors and Hosts

In the east, south, and west coasts of the United States, tick vectors for RMSF have been identified as the dog tick, *Dermacentor variabilis*. In the Rocky Mountains states, the wood tick, *Dermacentor andersoni*, is the vector. In Mexico, they are *Rhipicephalus sanguineus* and *Amblyomma cajennense*, with the latter also being responsible in Central and South America. The brown dog tick, *Rhipicephalus sanguineus*, has been identified as a new tick vector for RMSF in a defined area of Arizona.^{36,52,54}

The *Dermacentor* tick feeds on humans only during its adult stage. Larval *Dermacentor* ticks may be infected while feeding on small mammals that develop sufficient rickettsemia for transmission, such as chipmunks, ground squirrels, cotton rats, snowshoe hares, and meadow voles. Dogs are not considered reservoirs for *R. rickettsia* but are susceptible to RMSF and may introduce infected ticks into households.⁵² Adult ticks transmit the rickettsia transovarially to their progeny with high efficiency and establish newly infected tick lines. If the rickettsia burden is large in the adult tick, however, it may cause tick death, thereby reducing infected tick lines. Therefore, there must be nontick reservoirs, as mentioned previously, to develop newly infected tick generational lines; otherwise, RMSF would

slowly disappear. In summary, ticks are both vectors and hosts for *R. rickettsia*.

Disease Course, Symptoms, and Fatalities

Rickettsia rickettsia is usually transmitted to humans from an infected tick bite.⁵¹ The organism can also gain access to humans through broken skin if an infected tick is being crushed with bare fingers, and such crushing may generate infectious aerosols that might be inhaled. Conjunctival contact with infected tick tissues or feces provides another route for rickettsial entry.

After introduction of the organisms into the body, the rickettsia spread hematogenously with a predilection for the vascular endothelium, especially in capillaries. During an incubation period of 2 to 14 days, induced phagocytosis allows rickettsial entry into endothelial cells, where they replicate by binary fission in the cytoplasm and nuclei of infected cells. This induces a generalized vasculitis leading to activation of clotting factors, capillary leakage, and microinfarctions in various organs.⁵¹ In severe infections, hypotension and intravascular coagulation may coexist and culminate in cell, tissue, or organ destruction.

Dehydration is an early sign of RMSF, followed by increased vascular permeability, edema, decreased plasma volume, hypoproteinemia, reduced serum oncotic pressure, and prerenal azotemia. RMSF is a multisystem disease, but a particular organ may be the major focus of the disease. If the brain or lungs are severely infected, death can ensue. An increased severity of illness is associated with edema, particularly in children, and hypoalbuminemia. Hypotension is present in 17% of patients and hyponatremia in 56%. Extensive infection of the pulmonary microvascular endothelium can cause noncardiogenic pulmonary edema.

A common finding in RMSF is myalgia (72%–83%) or muscular tenderness, which are manifestations of skeletal muscle necrosis. Striking creatinine kinase elevations have been described. Thrombocytopenia resulting from consumption of platelets during intravascular coagulation processes occurs in 35% to 52% of patients. True disseminated intravascular coagulation with attendant hypofibrinogenemia is exceptional, however, even in severe or fatal cases. Blood loss or hemolysis in some may cause anemia, which is seen in 30% of patients and reflects blood vessel damage. Fatalities usually occur 8 to 15 days after illness onset if no treatment is given or if treatment is delayed. Long-term sequelae from severe forms of RMSF can include partial paralysis of the lower extremities, gangrene of extremities requiring amputation, deafness or hearing loss, incontinence, and movement or speech disorders.^{52,55}

“Fulminant” RMSF is best defined as a disease with a rapidly fatal course with death occurring in ~5 days. This form of disease is characterized by an early onset of neurologic signs and late or absent skin rash; it is highly associated with glucose-6-phosphate dehydrogenase deficiency, chronic alcohol abuse, advanced age, black race, and male gender.⁵² In the preantibiotic era, RMSF mortality rates were as high as 30%, but they have fallen to 5% in antibiotic-treated cases today.⁵²

The classically defined triad of RMSF symptoms at initial presentation is fever, rash, and headache, but this is found in only 40% of cases.³⁶ The RMSF skin rash typically begins, 2 to 4 days after fever onset, as pink, 1- to 5-mm blanchable macules that later become papules.⁵² It begins on the ankles,

wrists, and forearms and soon thereafter involves the palms or soles. It then spreads to the arms, thighs, and trunk and typically evolves into a petechial exanthem. The utility of these findings in the differential diagnosis is limited because rash may be absent, transient, or late; it may never become petechial or it may have an unusual distribution.

Diagnosis

As for most tick-borne diseases, confirmatory serologic analysis is only retrospective in nature, and antirickettsial treatment should begin immediately to prevent morbidity and mortality.⁵² *R. rickettsia* is hard to culture.³⁶ Immunohistologic demonstration of *R. rickettsii* in biopsy specimens of rash lesions is the only approach that can yield diagnostic results in a timely manner, but this approach is applicable only to those presenting with a skin rash.

The best serologic test for RMSF is the IFA test, but antibodies typically appear only after 10 to 14 days.⁵¹ More striking laboratory abnormalities of RMSF disease include a normal leukocyte count with a shift to the left, hyponatremia, thrombocytopenia, elevated serum transaminases or creatinine kinase, and CSF pleocytosis. These findings are observed late in the disease course, however, and are not helpful in early disease recognition.

Clinical findings and history are key to early diagnosis and successful treatment. In a febrile, tick-exposed person with a rash, RMSF should be considered. RMSF should be strongly considered in febrile children, adolescents, or men >60 years of age, especially if they reside in or have traveled to the southern Atlantic or south-central United States from May through September. A delay in treatment for RMSF beyond 5 days of symptom onset increases the mortality rates from 6% to 22%.⁵⁶

Treatment

In vitro, the MIC for *R. rickettsia* is 0.5 mcg/mL for chloramphenicol, 0.25 mc/mL for tetracycline, and 0.06 mcg/mL for doxycycline. The recommended treatment is doxycycline 100 mg orally or IV two times a day for at least 7 days and for 2 days after the temperature is normal.⁵⁷ Chloramphenicol is reserved for use in pregnancy.⁵¹ The erythromycins, penicillins, sulfonamides, aminoglycosides, and cephalosporins are not effective. Although fluoroquinolones have shown activity in other spotted fever rickettsial diseases, no reports are found of their use in human RMSF disease and they cannot be recommended at this time.^{36,57}

14. Can tetracyclines be given safely to young children with RMSF?

In 1994, the American Academy of Pediatrics (AAP) Committee on Infectious Diseases revised the RMSF treatment options for young children after considering chloramphenicol's potential toxicity and the dental staining concerns for tetracyclines. The AAP now acknowledges tetracyclines as acceptable treatment in children of any age with RMSF. Doxycycline should be the tetracycline agent of choice in pediatric RMSF because it is dosed less frequently than other tetracyclines, which may improve compliance, and does not bind calcium as strongly as other tetracyclines. The dosage is 4.4 mg/kg orally divided into two doses on day 1 followed by 2.2 mg/kg/day orally each day for 7 to 10 days or 2 to 3 days after the fever abates and clinical improvement occurs.⁵⁷

Prevention

In addition to the same guidelines for prevention of Lyme disease, keeping pets free of ticks should reduce exposure. Ticks must not be crushed in a way that might introduce rickettsia into cutaneous lesions, mucous membranes, or the conjunctiva. No RMSF vaccine is available. Antirickettsial antibiotic prophylaxis after a tick bite is not warranted.

Rickettsia Parkeri and other Spotted Fever Group (SFG) Rickettsia

In the last quarter of the 20th century, a distinct spotted fever group (SFG) rickettsia has been discovered worldwide causing novel rickettsioses.⁵⁸ In the United States, SFG rickettsial pathogens other than *R. rickettsia* have recently been recognized, including *R. felis*, *R. akari*, and *R. parkeri*.^{59,60} Three cases of *R. parkeri* human infection transmitted by tick bite have been reported.^{58,60,61} *R. parkeri* infection is associated with fever, malaise, and eschar formation (rarely seen in RMSF), especially at the site of the Gulf Coast tick, *Amblyomma maculatum*, bite.³⁶ *R. parkeri* infection is milder than RMSF and can be diagnosed by PCR testing of an eschar or papule lesion.⁶⁰ Doxycycline treatment has resulted in prompt (<1 or 2 days) resolution of symptoms.^{58,60}

Ehrlichiosis and Anaplasmosis

Species Identification

Three tick-borne rickettsial human diseases have emerged in recent years: human monocytotropic ehrlichiosis (HME), caused almost exclusively by *Ehrlichia chaffeensis*, human granulocytic anaplasmosis (HGA), caused by *Anaplasma phagocytophilum*, and human *Ehrlichia ewingii* infection (HEE).^{9,36,52,62–64} A human mononucleosislike disease first described in Japan in 1954 is caused by *Ehrlichia sennetsu*, a rickettsiallike organism having a fish fluke vector. The disease is termed *Sennetsu fever* and is now indigenous to Japan and Southeast Asia.⁶⁴ The agents of HME, HGA, and HEE parasitize white blood cells.

In 1987, the first reported case of human ehrlichial infection in the United States was found in a soldier at Fort Chaffee, Arkansas. It was initially misinterpreted as being the same agent that infects dogs, *Ehrlichia canis*. Subsequent studies revealed that it was a unique species, *E. chaffeensis*. Cases of HME have now been reported in many states, Europe, and Africa.⁶³ Retrospective analysis revealed that 10% to 20% of unconfirmed, presumptive diagnoses of RMSF were actually HME. The number of HME cases is greater than RMSF in several states today.

Anaplasmosis was first described in 1994. Since HGA's discovery, more cases have been reported than for HME.⁵² During 2001–2002, HGA rates were especially high in Rhode Island, Wisconsin, Minnesota, Connecticut, New York, and Maryland.⁵²

Tick Vectors and Disease Hosts

The primary tick vector of HME is *A. americanum*, the Lone Star tick, and its geographic distribution matches that of most cases of HME, occurring in the south central and southeastern United States.⁶³ *E. chaffeensis* also has been recovered in *Dermacentor variabilis*, *Ixodes pacificus*, and *Amblyomma*

cajennense.⁶³ Cases of HME that have been diagnosed in the northeastern United States are probably caused by *A. americanum*. HME cases in Europe, Africa, and some U.S. states suggest other vectors. An important reservoir for *E. chaffeensis* is white-tailed deer.⁵² Dogs, coyotes, and goats have shown natural infection with *E. chaffeensis*.⁵² HME begins with the introduction of *E. chaffeensis* into the skin of a host from the bite of an infected tick. The bacteria spread throughout the body hematogenously. They become established within the cells of monocytic macrophages in the spleen, lymph nodes, liver, bone marrow, lung, and kidney. Characteristic, microscopically visible intracellular inclusion bodies called *morulae* (for their mulberrylike appearance) develop. Each morula is actually a membrane-bound rickettsial colony that grows and divides within the monocyte's cytoplasm. Necrosis in heavily infected cells occurs, and it is believed that cell rupture and the subsequent release of rickettsia allows infection of more monocytes, repeating the cycle.

Tick vectors that harbor the HGA agent include *I. scapularis* and *I. pacificus*, which are also Lyme disease transmitters. In Europe, *Ixodes ricinus* is the vector. The main reservoir for *A. phagocytophilum* is the white-footed mouse. Other hosts include white-tailed deer, elk, and other wild rodents.⁵² The events after introduction into a patient's skin of the HGA agent by tick bite are unknown. Rather than directly attacking mature granulocytes, it is suspected that the rickettsia infects a myeloid precursor in the bone marrow and survives or multiplies throughout granulocytic cellular maturation.

Tick removal from the body is less likely to be effective for disease prevention than it is in Lyme disease because of the rapid transmission of *A. phagocytophilum* during the nymphal tick bite.⁶⁵ Tick exposure is defined by geography and season. Simply being in an area where ticks can be found, particularly during spring and summer, constitutes exposure.

Clinical and Laboratory Findings

Human ehrlichiosis and anaplasmosis usually present as a non-specific, febrile, flulike illness resembling RMSF. They begin 5 to 21 days after tick exposure.^{9,63,66} Patients may be entirely asymptomatic, but there have been occasional fatalities from the complications of renal failure, respiratory failure, shock, or encephalopathy. HME and HGA share similar clinical features. Both display fever as the major symptom in nearly 100% of cases.⁶⁶ The other common symptoms of malaise, myalgia, headaches, and rigors are found in virtually all cases of HGA but somewhat less in HME. Other less common symptoms for both diseases include diaphoresis, nausea, vomiting, cough, diarrhea, abdominal pain, arthralgia, pharyngitis, rash, and confusion. HEE infection has been seen almost exclusively in immunocompromised patients, yet no fatalities have been documented.^{52,67}

As with many other tick-borne diseases, serologic findings of antibody response to ehrlichiosis assist only by retrospectively confirming the diagnosis. Currently, indirect IFA serology is the gold standard for both HGA and HME.⁶³ Blood detection by PCR or culture has been used for HGA. The following signs often are noted, however: hypertransaminemia, leukopenia (often with a shift to the left), thrombocytopenia, and anemia. These findings may increase the suspicion for HME or HGA infection. A peripheral blood smear showing neutrophilic morulae is diagnostic for HGA, but negative results do not rule out the diagnosis.⁶⁶ In HME, peripheral blood

smears are rarely diagnostic. HME morulae are more likely to be identified in macrophages with biopsy or postmortem specimens of the liver, spleen, or bone marrow anecdotally. A peripheral blood smear examination for morulae should probably be undertaken because this method is the quickest and easiest for making a provisional diagnosis. Confirmatory testing by serology or PCR is still required to establish the diagnosis.^{9,52}

15. Because the clinical findings of HME and HGA are similar, how can they be differentiated?

The nonspecific manifestations of HME and HGA are considered indistinguishable. Although considered an uncommon finding, skin rash is consistent with either disease. In HME, skin rashes are seen in almost 60% of children but in <30% of adults.⁵² In HGA, skin rashes occur in 10% or less of patients and may actually reflect coinfection with Lyme disease.³⁶ Therefore, if a skin rash is present, HME is much more likely than HGA (Table 75-4).

Human monocytotropic ehrlichiosis and HGA can be differentiated by serologic evaluation or PCR. Treatment should never be delayed pending the results of testing because the mortality rate is 2% to 3% for HME and 0.5% to 1% for HGA.^{52,63} Delays in diagnosis and treatment are related to a substantial proportion of death from the diseases.

HME and HGA as Opportunist/Immunosuppressor

Opportunistic cases of HME have appeared in patients with acquired immunodeficiency syndrome (AIDS), and death from overwhelming HME infection has occurred in other immunocompromised patients. Animal models of *A. phagocytophilum* infection have shown impaired defense responses, such as defects in granulocyte emigration and phagocytosis, suppressed CD4 and CD8 counts, and impaired lymphoproliferation of isolated lymphocytes. HGA fatalities have been associated with concomitant candidiasis, cryptococcal pneumonia, severe herpesvirus infection, and invasive pulmonary aspergillosis. Theoretically, opportunistic infections may be secondary to rickettsial-mediated impairment of the immune response.

Treatment and Prevention

Doxycycline (Vibramycin) 100 mg orally twice daily for 10 to 14 days is the drug of choice for both HME and HGA.⁶³ For HGA, doxycycline for only 10 days is sufficient.⁹ In children <8 years of age, doxycycline is given at a dosage of 4 mg/kg/day PO or IV divided into two daily doses. For those >8 years of age but weighing <45 kg, 4 mg/kg of doxycycline Q 12 h is used; adult doses are used for children weighing >45 kg.⁹ (See RMSF for a discussion of the pediatric use of doxycycline.) If tetracyclines are absolutely contraindicated, rifampin 300 mg orally twice daily for 7 to 10 days is an alternative in mild HGA disease.⁹ Pediatric rifampin dosing for HGA is 10 mg/kg (to a maximum 300-mg dose) twice daily for 5 to 7 days.⁶⁸ Chloramphenicol (Chloromycetin) is ineffective in vitro and should not be used.⁶³ Although early in vitro data suggested benefit with fluoroquinolones, this finding has not resulted in a clear role for these agents as this time. Ineffective antibiotics for ehrlichiosis or anaplasmosis include gentamicin (Garamycin), ceftriaxone (Rocephin), cotrimoxazole (Bactrim), erythromycin (E-Mycin), metronidazole (Flagyl), clindamycin (Cleocin), sulfonamides, and penicillin.³⁶ Asymptomatic, seropositive patients with antibodies to *A. phagocytophilum* should not be treated.⁹

Table 75-4 Tick-Borne Disease Findings

Caution: Routine laboratory testing is of little value in diagnosing or differentiating tick-borne diseases.

+, $\leq 25\%$ association; —, not usually associated; CTF, Colorado tick fever; ESR, erythrocyte sedimentation rate; HGA, human granulocytic anaplasmosis; HME, human monocytic ehrlichiosis; LD, Lyme disease; LFTs, liver function tests; RF, relapsing fever; RMSF, Rocky Mountain spotted fever; WBCs, white blood cell counts.

Prevention of ehrlichial disease is preferable to treatment. Tick avoidance and detection strategies, as outlined for Lyme disease, are recommended. No evidence supports the routine administration of prophylactic antibiotics for HME or HGA prevention in patients with known tick bites. Vaccines may be developed.⁶³

16. G.K., a 78-year-old man living outside Duluth, Minnesota, presents with an influenzalike illness in late May. He has a 2-day history of fever, shaking chills, headache, myalgias, nausea, and anorexia. On examination, his temperature is 39.4°C, but other physical findings are unremarkable. No skin rashes are found. During questioning, he stated he had multiple tick bites about 2 weeks ago while he was fur trapping. The physician suspects anaplasmosis and prescribes doxycycline 100 mg PO twice daily for 10 days. Blood is drawn for serology, CBC with differential, chemistry profile, C-reactive protein, and a Wright's stain microscopic examination. Immediately available abnormal results include neutrophilic morulae on microscopy, a WBC count of $2.5 \times 10^9/L$ (normal, 4.0–10.7), a platelet count of $80 \times 10^9/L$ (normal, 150–450), C-reactive protein of 136 mg/L (normal, 4–8), aspartate aminotransferase (AST) of 150 U/L (normal, 16–40), and lactate dehydrogenase of 700 U/L (normal, 80–175). Serology is still pending. Two days later, G.K. defervesced and was feeling better. How does this case fulfill a diagnosis of HGA?

G.K.'s history is significant for HGA. He was in the right place, the upper midwestern United States, and was outdoors during the right season; most patients are diagnosed with HGA in May through August.⁶⁶ The usual incubation period from tick bite to illness onset ranges from 5 to 21 days.⁹

His symptoms are also important. Nearly 100% of patients with HGA have a fever of $>37.6^\circ\text{C}$. Other symptoms in G.K. consistent with HGA are rigors (shaking chills), headache, myalgias, nausea, and anorexia.⁶⁶ Matching laboratory findings include neutrophilic morulae. The observed leukopenia and thrombocytopenia strongly support the diagnosis. Evidence of mild to moderate hepatic injury, as seen by the ele-

vated liver enzyme results, and the elevated C-reactive protein also are helpful in HGA diagnosis.⁶⁶ Finally, the good response to doxycycline, with fever resolution in 2 days, is customary. Fever persisting for more than 2 days after doxycycline treatment suggests that the diagnosis of HGA is incorrect.⁹

THE PROTOZOA: BABESIOSIS

Babesiosis

History

Investigating the deaths of 30,000 to 50,000 head of Romanian cattle with febrile hemoglobinuria in 1888, Victor Babes described an intraerythrocytic organism that was thought to be bacterial, and it was named *Haematococcus bovis*.^{36,69,70} While investigating a hemolytic cattle fever in Texas in 1893, Smith and Kilborne established that the causative organism was a protozoan, *Babesia bigemina*, and introduced the concept of arthropod-borne transmission of the disease.^{36,69,70} The first human case of babesiosis was definitively identified in a 33-year-old Yugoslavian cattle farmer in 1957. His febrile hemoglobinuria and intraerythrocytic organisms were attributed to the bovine pathogen *Babesia divergens*.^{69,70} He had undergone a previous splenectomy and died of the disease. Postmortem inquiry revealed that his cattle were infected with a bovine babesial species. Possible tick vectors identified were *Ixodes ricinus* and *Dermacentor sylvarum*. To date, rare, often fatal, human cases of babesiosis in Europe have been caused by *B. divergens* and *B. microti*.⁹ Sporadic cases of babesiosis have been reported in Asia, South America, and Africa.⁹ European cases present with a fulminant, febrile illness 1 to 3 weeks after a tick bite. In 84% of these cases, the patients have been asplenic. Coma and death has occurred in $>50\%$ of cases. Customary findings are hemoglobinuria, hemolysis, jaundice, chills, sweats, myalgia, pulmonary edema, and renal insufficiency.

The first human babesiosis case in a person with an intact spleen was reported in 1969 in a patient from Nantucket

Island, Massachusetts. Since then, “Nantucket fever” has been found to be caused by the babesial rodent agent *B. microti*. In contrast to most European cases and those reported in California, human babesiosis in endemic areas of the Great Lakes regions and the northeastern United States commonly occurs in normosplenic patients.^{69,70,71} The presenting complaints are usually nonspecific and consist of malaise, fatigue, low-grade fever or shaking chills, headache, generalized musculoskeletal complaints, emotional lability, nausea, emesis, and weight loss. Fatal cases have been found in distinct areas of Wisconsin, Missouri, Rhode Island, and California. Severe, nonfatal cases have occurred in Minnesota, the state of Washington, and California. Additional cases have been reported in New York, Connecticut, Maryland, Virginia, Georgia, as well as in Mexico. Members of *Babesia* and *Theileria* genera are called piroplasms because of their pear-shaped appearance of dividing parasites within erythrocytes. A different type of *Babesia*-like piroplasm has emerged in the western United States: designated WA-1, it was originally isolated in a resident in the state of Washington.⁶⁹ In Missouri, a pathogen called MO-1 has caused babesiosis.^{69,70}

Babesia, Ticks, and Hosts

There are >100 species of *Babesia* having a wide geographic range.^{36,69} To date, only four species are known human pathogens: *B. divergens*, *B. microti*, WA-1, and MO-1.³⁶ They are transmitted by *Ixodes*, *Boophilus*, *Dermacentor*, *Haemaphysalis*, and *Rhipicephalus* ticks. *B. microti* is transmitted in the northeastern United States by *I. scapularis*, the deer tick of Lyme disease and HGA, and in the United Kingdom by *I. trianguliceps*. In Europe, bovine babesiosis is transmitted by *I. ricinus*. In the western United States, *I. pacificus* is the probable vector. High infection rates of *B. microti* in field mice (*Microtus pennsylvanicus*) and white-footed mice (*Peromyscus leucopus*) have been found on Nantucket Island in Massachusetts during investigations of transmission cycles. Other reservoirs for *B. microti* are chipmunks, meadow voles, shrews, and rats.⁶⁹ In the southeastern United States, nymphal stage *I. scapularis* ticks feed on lizards, which are poor reservoirs for *B. microti*, possibly explaining why babesiosis is rarely reported there. *Babesia* species also are transmitted from the larval to nymphal stage of the tick (that is, transstadial transmission occurs).⁶⁹

Symptoms and Diagnosis

17. H.W., age 64 years, spent July on Martha’s Vineyard. A week later, he felt fatigued and lost his appetite. He presents to his local physician in the middle of August with complaints of fever, headache, drenching sweats, aches and pains, and occasional dark-colored urine. He does not recall a tick bite. On physical examination, he has splenomegaly and hepatomegaly. Laboratory tests show a severe normochromic, normocytic anemia, decreased hemoglobin, hemoglobinuria, thrombocytopenia, and increased liver enzymes. His temperature is 40°C. Examination of a Giemsa-stained thin blood smear reveals the presence of un-pigmented ring-shaped intraerythrocytic parasites, some forming tetrads that resemble a Maltese cross, in >10% of his erythrocytes. The physician institutes a clindamycin and quinine regimen. What was the clue to the diagnosis of babesiosis?

The babesiosis diagnosis was confirmed by the direct observation of the protozoan inside the red blood cells. Although

the Giemsa-stained test is a commonly used tool, it is subject to false-negative results because the rate of parasitemia is typically low. Usually, multiple blood smears need to be examined because few erythrocytes may be infected early in the course of the disease when most people seek medical help.⁹ Because blood smear inspection is often not successful in diagnosing babesiosis or may only detect a few parasites, additional supportive laboratory results are advocated, such as serology using IFA for IgM and IgG antibabesial antibodies or PCR detection of babesial DNA in the blood.⁹

Most patients with *B. microti* babesiosis are asymptomatic. This form of babesiosis can be viewed as a distinct occult, asymptomatic disease with few known sequelae. A number of transfusion-acquired infections have been documented, reflecting the existence of the asymptomatic form of babesiosis in blood donors.

A second form of babesiosis is a potentially life-threatening hemolytic one that occurs in people predisposed to severe infection because of advanced age, immune suppression because of human immunodeficiency virus (HIV) disease or malignancy, or prior splenectomy.⁷³ Although babesial infection is as prevalent in children as in adults, it is more severe in adults >50 years of age. Complications seen in severe babesiosis include acute respiratory failure, disseminated intravascular coagulation, congestive heart failure, coma, and renal failure, with a 5% to 9% mortality rate.^{9,36}

In the northeastern United States, infections commonly occur in patients with spleens, as in H.W. Clinically apparent cases are most common in 50- to 60-year-old patients, many of whom do not recall a tick bite. Most symptoms of babesiosis are caused by hemolysis or the systemic inflammatory responses to parasitemia.⁷⁰ The usual incubation period is 1 to 6 weeks after the tick bite.³⁶ Nonspecific, viral-like symptoms that are gradual in onset appear first, as in H.W.’s case, followed several days later by the other symptoms H.W. displayed. A hallmark of the disease is hemolytic anemia of varying severity. A high index of suspicion for babesiosis should be maintained in any patient with an unexplained febrile illness who lives in or has traveled to a region where the infection is endemic during June through August, as in H.W.’s case, particularly if there is a history of tick bite.³⁶

Treatment

18. Why were clindamycin and quinine chosen to treat H.W.? What other drugs have been used?

The discovery of a human babesiosis treatment regimen combining clindamycin (Cleocin) and quinine was a fortuitous one. An 8-week-old infant with presumed transfusion-acquired malaria was initially treated with chloroquine. Because of a lack of response, treatment was switched to quinine plus clindamycin, and the patient defervesced.⁷⁰ A correct diagnosis of babesiosis was subsequently confirmed. Although this treatment combination is still used, frequent side effects (e.g., tinnitus, vertigo and diarrhea) occur, often resulting in dose reduction or discontinuation.^{9,36} Treatment failures with this regimen have occurred in splenectomized patients, patients with HIV infection, or those receiving concurrent corticosteroids.⁹ Dosing recommendations for adults are clindamycin 600 mg orally Q 8 h or 300 to 600 mg IV Q 6 h plus quinine 650 mg orally Q 6 to 8 h for 7 to 10 days; children should receive clindamycin 7 to 10 mg/kg (maximum, 600-mg dose)

orally or IV Q 6 to 8 hours *plus* quinine 8 mg/kg (maximum, 650 mg dose) orally Q 8 hours for 7 to 10 days.^{9,69,70}

Atovaquone (Mepron), the hydroxynaphthoquinone derivative used for opportunistic infections in patients with HIV, has been used with substantial success in patients with *B. microti* infection refractory to conventional therapy. Combination therapy of azithromycin with atovaquone is better tolerated than clindamycin–quinine combinations. This newer regimen is as effective as the clindamycin with quinine combination. The dosing is atovaquone 750 mg orally Q 12 hr *plus* azithromycin 500 mg to 1,000 mg orally on day 1 and 250 mg on subsequent days for 7 to 10 days.⁹ Higher azithromycin doses of 600 mg to 1,000 mg/day may be used in immunocompromised patients.⁹ Children should receive atovaquone 20 mg/kg (maximum, 750 mg dose) Q 12 hr *plus* azithromycin 10 mg/kg (maximum, 500-mg dose) on day 1 and 5 mg/kg (maximum, 250-mg dose) orally thereafter for 7 to 10 days.⁹

Antimicrobials should be used in all patients with active babesiosis owing to the risk of complications. Antibody seropositive, symptomatic patients without identifiable parasites on blood smear or PCR positivity should not be treated. Similarly, asymptomatic patients should not be treated regardless of serologic results, blood smear examinations, or PCR findings. A course of treatment should be considered in asymptomatic patients, however, if these tests are positive and repeat testing demonstrates persistent parasitemia for >3 months.⁹

Partial or complete red blood cell (RBC) transfusions may be life-saving in severe babesiosis for patients having high-grade parasitemia (10% or more infected erythrocytes), significant hemolysis, or pulmonary, renal, or hepatic compromise.⁹ Rapidly increasing parasitemia leading to massive intravascular hemolysis and renal failure mandates immediate treatment for this form of the disease.

Babesiosis prevention is the same as for other tick-borne diseases. Splenectomized patients should avoid areas where babesiosis is endemic. Although developed for use in cattle, babesial vaccines are not available for humans.⁶⁹

THE VIRUSES: COLORADO TICK FEVER AND TICK-BORNE ENCEPHALITIS

Colorado Tick Fever

Disease History

“Mountain fever” has been described since the first immigrants arrived in the Rocky Mountains. It was later renamed Colorado tick fever (CTF) and the Colorado tick fever virus (CTFV) was identified as the cause.

Virus Identification

Colorado tick fever is caused by a double-stranded RNA *Coltivirus*. It is an intraerythrocytic virus. At least 22 strains of CTF virus are known, but the antigenic variation between human strains is low.⁷² The virus is an arbovirus because it replicates inside ticks. The primary nidus of infection is thought to be CTFV invasion of hematopoietic progenitor cell lines and it remains sheltered in mature erythrocytes.⁷²

Ticks and Host Reservoirs

Colorado tick fever is a viral illness transmitted by the bite of an infected tick.^{73,74} Although at least eight tick species have been

found to be infected with the virus, *Dermacentor andersoni* is the primary tick vector that transmits the illness to humans.^{73,72} *D. andersoni* feeds on numerous mammals, but ground squirrels, porcupines, and chipmunks are primary reservoirs for CTFV.^{72–74} Transstadial but not transovarial transmission of CTF virus in the tick has been documented.⁷²

Prevalence

The CTF is contracted in forested mountain areas at higher elevations of the Rocky Mountain regions in the United States and Canada, especially on the south-facing brush slopes and dry rocky surfaces of mountains east of the Continental Divide.^{73,72} Neutralizing CTFV antibodies are found in up to 15% of perennial campers.⁷⁵ Although CTF can develop from March to September, May and June are the peak months for its development.⁷⁵

Symptoms

19. T.M., a previously healthy 28-year-old native of Atlanta, Georgia, returns from a 1-week late spring camping trip in the eastern Colorado Rocky Mountains. Four days later, he experiences fever, chilliness, aching back and leg muscles, photophobia, retro-orbital and abdominal pain, and headache. He recalls no tick bites and has no skin rashes. Suspecting RMSF, his physician prescribes doxycycline. T.M.’s symptoms and fever initially resolve, but 2 days later his symptoms return. Physical examination at this time reveals a temperature of 39°C. Routine laboratory tests are normal, although leukopenia is observed with a WBC count of $2.4 \times 10^9/L$. Why do T.M.’s symptoms suggest a diagnosis of CTF?

Symptoms of CTF usually start 3 to 6 days after a tick bite, although roughly half of patients do not remember being bitten.^{72,74} The most common initial symptoms are fever of rapid onset, headache, and chills without true rigors, and myalgias.⁷⁴ A rash, which may be light colored, is occasionally seen.^{74,75} A biphasic (“saddle-back”) or triphasic pattern of fever and other symptoms lasting 5 to 10 days has been observed.^{72,73,74} CTF infection is usually self-limiting and sequelae are rare, although fatigue and malaise may last for months.⁷⁴ One- to 3-week periods of convalescence are usual. Children, however, experience complications more frequently than adults.⁷³ Severe forms of CTF may involve central nervous system (CNS) infection (aseptic meningitis or encephalitis), hemorrhagic fever, myo- or pericarditis.^{72,75} A prolonged convalescence does not imply persistent viremia, although viremia can last for 3 to 4 months because of the intraerythrocytic location of the virus avoiding immune clearance.^{72,73}

Laboratory Findings

Moderate to significant leukopenia is the most important finding in CTF. Leukocyte counts are usually normal on the first day, but decrease to 2 to $3 \times 10^9/L$ by the fifth or sixth day of illness. In one third of confirmed CTF cases, however, the leukocyte counts remained around $4.5 \times 10^9/L$. Counts return to normal within a week of fever abatement in most cases. Thrombocytopenia may occur.⁷² Occasionally, mildly elevated levels of creatinine phosphokinase and aspartate aminotransferase are reported.

Diagnosis and Treatment

The CTF diagnosis is made serologically, either with IFA staining of erythrocytes, complement fixation, or ELISA.⁷² The most sensitive isolation system is intracerebral injection of infected blood into suckling mice.⁷² Reverse transcriptase PCR was developed for CTF diagnosis.⁷² Treatment is limited to supportive care.^{72,73,75} A few deaths have been reported, all with hemorrhagic signs. Long-term immunity is generally conferred by CTFV infection.⁷² Experimental CTF vaccines are no longer made.⁷²

Tick-Borne Encephalitis (TBE)

Tick-borne encephalitis is divided into three subtypes, European, Siberian, and Far Eastern, and is endemic to central and eastern Europe, Russia, and the Far East, with some overlap in geography.^{76,77} The highest incidence of TBE is in Latvia, the Urals, and western Siberia.

The etiologic agent is an RNA virus in the genus *Flavivirus*. The European subtype is transmitted to humans by *I. ricinus* and the Siberian and Far Eastern subtypes by *I. persulcatus*, although the latter tick and subtype were implicated in a Finnish outbreak.⁷⁷ Occasional TBE cases have followed the consumption of infected unpasteurized milk or cheese directly without a tick vector.⁷⁶ The virus reservoirs are small rodents. Ticks are vectors, and humans are accidental hosts of the virus.⁷⁶ Ticks can become infected for life by the virus at larval, nymphal, or adult stages and can transmit it transovarially and transstadially.⁷⁶

As the disease name implies, the ultimate outcome of the infectious process is manifested as CNS involvement, with symptoms of aseptic meningitis, meningoencephalitis, and meningoencephalomyelitis. TBE begins as a febrile headache with progression to CNS manifestations. Treatment is supportive. Human TBE vaccines are available in some countries.^{76,78}

THE TOXINS: TICK PARALYSIS

Tick Paralysis

20. A.M., a 3-year-old girl residing in Spokane, Washington, complains of weakness in both legs. The next day, she begins experiencing flaccid paralysis in both legs and the lower trunk, although she is alert and oriented. Her mother discovers a tick attached to A.M.'s scalp under her hair and removes it. A.M. is back to full health in 2 days. What happened?

Tick paralysis (tick toxicosis) occurs worldwide in humans and many animals and was first described by the explorer Hovell in Australia in 1824.^{79,80} Although 43 tick species worldwide can produce tick paralysis in animals and humans, it is predominantly caused in humans by *Dermacentor andersoni* and *D. variabilis* in North America.⁸¹ The other ticks implicated here are *A. americanum*, *A. maculatum*, *I. scapularis*, and *I. pacificus*.⁸⁰ In Australia, *I. holocyclus* is the culprit.

Most human cases occur during the spring and summer in Australia and the United States. In the United States, it is most common in the Pacific Northwest and Rocky Mountain states.^{79,80} Female ticks are predominantly responsible.⁷⁹ In children, girls are more commonly affected, but in adults, more males are affected.⁷⁹

The presumed cause of the disease is the secretion of a neurotoxin present in the saliva of a tick, which must usually be attached for 4 to 7 days before symptoms develop.^{79,81} The toxin affects motor neurons and decreases acetylcholine release.⁷⁹ Paresthesias and symmetric weakness in the lower extremities with motor difficulties progress to an ascending flaccid paralysis in several hours or days.⁸² Cerebral sensorium is usually spared, pain is absent, and the blood and CSF are normal.⁸⁰ If the tick is not removed, the toxicosis can progress to respiratory paralysis with death in 10% of cases.^{79–81}

In North America, tick removal commonly results in complete recovery within hours to days. In Australia, the disease is more acute and paralysis may continue to progress for 2 days after tick removal. Recovery from the disease in Australia may take several weeks. Treatment is supportive. Antitoxin derived from dogs is the treatment of choice for animals, but not for humans because of the risk of serum sickness or acute reactions.⁷⁹

MIXED INFECTIONS

21. Because the tick vectors and mammalian hosts are the same for babesiosis, anaplasmosis, and Lyme disease in the northeastern United States, all three diseases, theoretically, could be transmitted to a human from one tick bite. Is there evidence of human coinfection with more than one tick-borne disease?

Human coinfection by the agents of Lyme disease, babesiosis, or anaplasmosis can occur, especially in endemic areas.^{83–85} Some believe that coinfection may alter the natural course for each disease, whereas others have found only an increase in clinical manifestations, especially flulike symptoms, in concurrent Lyme disease with babesiosis or HGA.^{83,84}

Dual infection may affect the choice of initial antibiotic therapy. For example, although amoxicillin is sometimes used to treat early Lyme disease, it is not effective for HGA. Doxycycline, however, is useful in both of these diseases. Thus, some cases of Lyme disease that were believed to be treatment failures may actually have been confounded by coinfection. Patients with concurrent Lyme disease and babesiosis have more symptoms and a longer duration of illness compared with patients with single infections.^{83,84} When moderate to severe Lyme disease is diagnosed, the possibility of concomitant babesial or anaplasma infection should be considered in regions where both diseases are endemic. Neutropenia and thrombocytopenia are associated with anaplasmosis; anemia and thrombocytopenia are associated with babesiosis and neither is routinely found in Lyme disease. For patients with Lyme disease who experience a prolonged flulike illness that fails to respond to appropriate antiborrelial therapy, clinicians should consider testing for babesiosis and anaplasmosis.⁸⁴

SUMMARY

Most of the research into tick-borne human disease demonstrates a close historical relationship of endemic tick-deer-rodent cycles for various microorganisms. These cycles are almost exclusively identified as having occurred at the geologic sites of the terminal moraines of Ice Age glaciers. Given the recent explosion of deer populations in the United States

and Europe, the increase in tick-borne human diseases may reflect the reduction of natural deer predators, the continued expansion of human populations from urban to rural environ-

ments, or both. Therefore, it is likely that we will continue to encounter increasing cases of tick-borne human disease of known or unknown origin.

OVERVIEW

Anxiety can be described as an uncomfortable feeling of vague fear or apprehension accompanied by characteristic physical sensations. It is a normal reaction to a perceived threat to one's physical or psychological well-being. The anxiety reaction is normally provoked by stress of some sort and involves activation of neurobiological systems that, when activated, contribute to self-preservation. Anxiety serves the purpose of alerting us to take appropriate measures for dealing with stressful circumstances. Anxiety involves the perturbation of several different neural systems causing two basic components: mental features (e.g., worry, fear, difficulty concentrating) and physical symptoms (e.g., racing heart, shortness of breath, trembling, pacing). An activation of these same systems can also be caused by certain medical illnesses such as pheochromocytoma or hyperthyroidism or medications such as sympathomimetics, resulting in both the physical and psychological manifestations of anxiety. However, when the anxiety is due to an external cause such as a medical illness or a medication, the anxiety abates when the physiological cause is removed.¹

If the anxiety is not due to an external cause such as a medical illness or a medication, and it is out of proportion to the actual threat or when the anxiety lasts far beyond the presence of the threat, anxiety may impair normal functioning and become an anxiety disorder. The anxiety experienced by a person is excessive for the situation (in intensity or duration) or very distressing, to the point that it interferes with daily functioning. Pathological anxiety can be differentiated according to whether it occurs (a) as a primary anxiety disorder, (b) as a secondary anxiety disorder due to medical causes or substances, (c) in response to acute stress (e.g., loss of a loved one, marital or family problems), or (d) as a symptom associated with other psychiatric disorders. This differentiation can be difficult, but is important in guiding optimal treatment.

Classification and Diagnosis of Anxiety Disorders

The *Diagnostic and Statistical Manual of Mental Disorders, Fourth Edition, Text Revision* (DSM-IV-TR) classifies primary anxiety disorders into six types: generalized anxiety disorder (GAD), panic disorder, phobic disorders (including social anxiety disorder), obsessive-compulsive disorder (OCD), post-traumatic stress disorder (PTSD), and acute stress disorder.¹ The additional category of "Anxiety Disorder Not Otherwise Specified" is used for cases not meeting the diagnostic criteria for any of these six types or for cases in which it cannot be determined whether the anxiety disorder is primary or secondary. Each disorder involves an unhealthy level of anxiety, but the characteristic type and severity of symptoms, as well as course of illness, vary from one disorder to another. Efficacy of drug and nondrug treatments also varies between disorders, indicating underlying biological differences. The DSM-IV-TR secondary anxiety disorders include "anxiety disorder due to a general medical condition" and "substance-induced anxiety disorder."¹ An anxiety disorder may occur in the absence of other psychiatric disorders, but it is often present in addition to other psychiatric disorders, such as mood disorders. Although anxiety disorders and mood disorders are classified separately in the DSM-IV-TR, a perusal of the criteria for both diagnostic categories reveals they have much in common, includ-

ing fatigue, impaired concentration, restlessness, difficulties with sleep, and somatic symptoms. The main difference is that mood disorders have a prominent mood factor. Both anxiety and mood disorders appear to be associated with dysregulations in the limbic system of the brain, which is involved in emotion, learning, and memory.²

Neurobiology of Anxiety

The limbic system is composed of a set of structures that are integral to behavior, including the two key structures, the hippocampus and the amygdala. Hippocampal brain circuits are essential for conversion of short-term to long-term memory and for spatial memory, whereas the amygdala circuits are involved with emotion and its expression. A neurocircuit arising from the output pathways of the central nucleus of the amygdala is believed to mediate fear and anxiety responses in humans.³ Dysregulated or exaggerated output through various amygdala-related circuits may be a common element underlying the different anxiety disorders, but the specific type of dysfunction probably differs among the various disorders. If it is assumed that a dysregulation of the stress response is the basis of anxiety disorders, then the genesis of anxiety is probably related primarily to interactions between neural pathways in and between the limbic system, the sympathetic nervous system, and the hypothalamic-pituitary-adrenocortical (HPA) axis.^{2,4} It is becoming clear that neither anxiety nor depression is solely due to abnormalities of neurotransmitter systems because these systems regulate and are regulated by other neurocircuits. Many neurotransmitter systems interact to modulate the actions of the limbic pathways, including the monoamine neurotransmitters, epinephrine and norepinephrine (NE); corticotrophin-releasing hormone (CRH); the indoleamine, serotonin (5-HT); the inhibitory amino acid, γ -aminobutyric acid (GABA); the excitatory amino acid, glutamate; and the neuropeptides, cholecystokinin (CCK), neuropeptide Y (NPY), and substance P.^{3,5}

Interaction of the Hypothalamic-Pituitary-Adrenocortical, Noradrenergic, and Serotonergic Systems

In the event of an acute threat, the fight-or-flight response stimulates both the peripheral and central sympathetic systems. This results in the peripheral reactions such as increased heart rate, heart stroke volume, and vasodilation of blood vessels carrying blood to the muscles. This is accompanied by a release of NE by the locus ceruleus (LC), the main nidus of NE cell bodies in the brain. Central release of NE results in vigilance and arousal, and the ability to focus attention on the threat and its stimulation in response to stress or fear produces arousal and symptoms of anxiety (tachycardia, tremor, sweating). NE innervation of the hippocampus results in an increased state of memory formation, whereas innervation of the amygdala potentiates the formation of aversive memories.⁴ Normally, this is important in allowing us to encode emotionally laden memories, but when overactive, it may result in a constant state of arousal and hypervigilance.

During a perceived threat, concomitant with activation of the sympathetic nervous system, the HPA axis is also activated. Initially, both CRH and arginine vasopressin (AVP) are released in the hypothalamus. CRH and AVP activate the anterior pituitary to release adrenocorticotrophic hormone (ACTH),

which stimulates the release of glucocorticoid steroids from the adrenal cortex. The glucocorticoids act on cells by increasing gene transcription, which can take up to several hours. This explains why the sympathetic response occurs more rapidly than the glucocorticoid response. The glucocorticoids bind to receptors both peripherally and in the brain. Although short-term elevation of glucocorticoids allows the body to adapt to a stressful situation by supporting HPA activation and mobilizing energy stores, prolonged elevation of the same glucocorticoids impairs neural plasticity and may even result in neuronal death. Both the sympathetic system and the HPA axis responses are modulated by limbic brain circuits innervating the amygdala, hippocampus, and orbital/medial prefrontal cortex. CRH is released not only in the hypothalamus, but also in the amygdala as well as in the LC. Its actions involve more than just activation of the HPA axis. CRH binds to at least two specific receptors in the brain, CR₁ and CR₂ receptors. These receptors modulate the actions of a variety of neurotransmitters, including NE, 5-HT, glutamate, and dopamine. When CRH is infused into the LC in rodents, it causes anxiety-like behaviors.^{2,4}

Although the inhibitory neurotransmitter, 5-HT, is involved in stress reactions, its role is not entirely clear. 5-HT has roles in sleep, appetite, memory, impulsivity, sexual behavior, and motor function, and seems to decrease aggressive behavior. The site of most 5-HT cell bodies in the brain is the raphe nuclei. There is considerable interconnectivity between the raphe nuclei and the LC, and they tend to mutually inhibit one another. Under normal circumstances, 5-HT connections from the hippocampus decrease activity in the amygdala, which would dampen fear and anxiety responses. However, under conditions of stress, the LC accelerates firing, inhibits the raphe nuclei firing, and increases CRH release—all of which sensitize the limbic system and cause arousal and sensitivity to memory of any stressful or aversive stimuli. This primes the system to a state of arousal to deal with the threat.²

One hypothesis is that anxiety states are associated with chronic NE overactivity combined with decreased activity in the 5-HT system.² This would maintain the amygdala and hippocampal and cortical pathways associated with the stress reaction in a stable state of hyperarousal. In this state, a minor fear response might be associated with a disproportionately large fear/aversion response. This would result in a chronic activation of the HPA axis. Chronically elevated corticosteroid levels have been shown to contribute to hippocampal and cerebral atrophy. A loss of inhibitory pathways that contribute to a halting of the stress response could lead to a chronic state of arousal and anxiety in the absence of any specific external stimulation of the stress pathways.

Although the specific etiology of anxiety is only hypothesized, the current use of treatments that activate the 5-HT system, or other inhibitory systems such as the GABA system, support the hypothesis.

Epidemiology and Clinical Significance of Anxiety Disorders

As a group, the anxiety disorders are the most common of psychiatric illnesses. Epidemiologic surveys indicate that one in four Americans suffer from an anxiety disorder at some time in their lives and that 18% are affected in any given year.^{6,7}

Most anxiety disorders are more common in women than in men.⁷

Anxiety disorders are associated with a decrease in quality of life and psychosocial functioning. These factors impact marital, educational, and employment status. Although most anxiety disorders do not require inpatient hospitalization for treatment, their presence is associated with significant impairment in major areas of life functioning.⁸

Today, most anxiety disorders are highly treatable with medications, cognitive or behavioral therapies, or combinations thereof. However, less than one-third of those affected seek help, and many who do are not properly diagnosed.⁷ Most medical care for anxiety disorders is rendered in nonpsychiatric settings. Patients commonly present to primary care providers complaining of physical symptoms that cannot be medically explained, while the anxiety continues unrecognized. A large portion of primary care patients with anxiety do not believe in taking medication for emotional problems or are not taking medication to treat their anxiety because their primary care provider did not recommend it.⁹

Because anxiety is a feeling with which everyone is familiar, there is a tendency to trivialize the impact it can have on a sufferer's functioning and quality of life. An increased understanding about pathological anxiety is needed in society in general and health care professionals in particular so that people seek and receive the treatment they need. Widespread public educational campaigns have been initiated to help increase awareness about anxiety disorders and their potential treatments. Practitioners must be knowledgeable about the clinical characteristics and treatment options for various disorders, and must be able to share this information with patients and other health care professionals. A list of consumer and professional resources for information about anxiety disorders and treatment can be found in Table 76-1.

Clinical Assessment and Differential Diagnosis of Anxiety

1. J.K., a 66-year-old man, complains to his physician of having trouble sleeping, feeling nervous, and worrying constantly. J.K.'s wife passed away 1 year ago, and he recently retired from his job as an accountant. Since then, he has become very involved in his hobbies of gardening and writing short stories but claims that he often cannot concentrate well enough to write. J.K. has mild chronic obstructive pulmonary disease (COPD) and suffered a myocardial infarction (MI) 2 years ago. His currently prescribed medications include lisinopril (Zestril), furosemide (Lasix), atorvastatin (Lipitor), niacin, and sucralfate. He also takes over-the-counter (OTC) loratadine and pseudoephedrine for allergies, naproxen for back pain, and docusate sodium as needed (PRN) for constipation. J.K. states that he drinks several cups of coffee each morning and one or two glasses of beer several nights a week to help him calm down when he has had a stressful day. He denies any history of psychiatric illness but states that he has always been a "high-strung" individual. What factors should be considered in the clinical assessment and differential diagnosis of J.K.'s symptoms of anxiety?

A diagnostic decision tree such as that in Figure 76-1 can be used to assist the clinician in differentiating among various causes of anxiety and the different anxiety disorders. According to DSM-IV-TR criteria for primary anxiety disorders, the symptoms should not be secondary to any medical (drug or

disease) causes. As illustrated in Table 76-2, the potential “organic” or secondary sources for anxiety symptoms are numerous.

Secondary Causes of Anxiety

A diagnosis of *anxiety disorder due to a general medical condition* is warranted when symptoms are believed to be the direct physiological consequence of a medical condition.¹ In patients such as J.K. who have a number of medical conditions, these illnesses must be considered as possible underlying precipitants of anxiety. A complete physical and laboratory workup, with a thorough medical and psychiatric history, are also needed to exclude other, possibly reversible causes before a primary anxiety disorder diagnosis is considered. In most cases of new-onset anxiety in elderly persons, symptoms can be attributed to some medical or substance-related cause.

Hypoglycemia, hyperthyroidism, electrolyte abnormalities, and angina pectoris are notably associated with anxiety symptoms.¹⁰ Persons with chronic medical conditions such as COPD, Parkinson disease, cardiomyopathy, post-MI, Graves disease, and primary biliary cirrhosis have prevalences of anxiety that are markedly increased compared with healthy controls.¹⁰ Medical illness in general, especially in older patients such as J.K., is associated with higher rates of both anxiety and depression compared with the general population.¹⁰ In some cases, the anxiety is physically induced by the medical condition, but reactional anxiety may also occur in response to being faced with a medical illness, especially a serious illness. In either case, the presence of anxiety may complicate the medical picture and have a negative impact on the course of illness. Successful management of the medical condition often relieves anxiety in such cases, but short-term use of anxiolytic medications or nondrug therapies (biofeedback, psychotherapy) can also be very helpful.

When evaluating for possible causes of anxiety, it is also important to consider all medications a person is taking, including OTC drugs such as cough and cold preparations.¹¹ A diagnosis of *substance-induced anxiety disorder* is warranted when anxiety symptoms occur in relation to substance intoxication or withdrawal, or when medication use causes the symptoms. Among the medications that J.K. is taking, pseudoephedrine might be contributing to his anxiety. Other medications that can cause anxiety are listed in Table 76-2. Psychoactive substance abuse, withdrawal from CNS depressants (e.g., alcohol, barbiturates, benzodiazepines), excessive caffeine intake, and nicotine withdrawal may go unrecognized as underlying precipitants of anxiety. J.K.’s current pattern of alcohol use, although not excessive, may become problematic if he uses alcohol to self-medicate his anxiety symptoms.

Although anxiety is the hallmark characteristic of anxiety disorders, it is not unique to this diagnostic category. Virtually any psychiatric illness may present with anxiety symptoms. Major depression, schizophrenia, bipolar disorder (both depressive and manic phases), eating disorders, and dysthymia are notably associated with anxiety, and diagnostic differentiation can sometimes be difficult.¹ For example, J.K.’s difficulties with sleeping and concentrating, as well as excessive worry, may be core target symptoms of either anxiety or depression, or possibly both. If anxiety symptoms occur only in relation to another psychiatric disorder, then a separate anxiety disorder diagnosis is precluded. Anxiety in these cases may be alleviated with successful treatment of the primary psychiatric disorder. However, benzodiazepines are often used as adjunctive therapy, especially early in the course of treatment because they have a rapid onset of action.

Individuals with other psychiatric disorders can also have a primary anxiety disorder. In fact, comorbidity with anxiety disorders is the rule rather than the exception.⁶ Depression, in particular, is notably associated with anxiety disorders, and there are marked degrees of comorbidity between the two.¹² Concurrent anxiety and depression are associated with greater disability, poorer treatment outcomes, and higher suicide rates than either depression or anxiety alone.

Other factors that should be considered in J.K. are the recent changes in his life (retiring, losing his spouse). Anxiety in response to life stressors may be severe and functionally detrimental, but could be considered appropriate for the

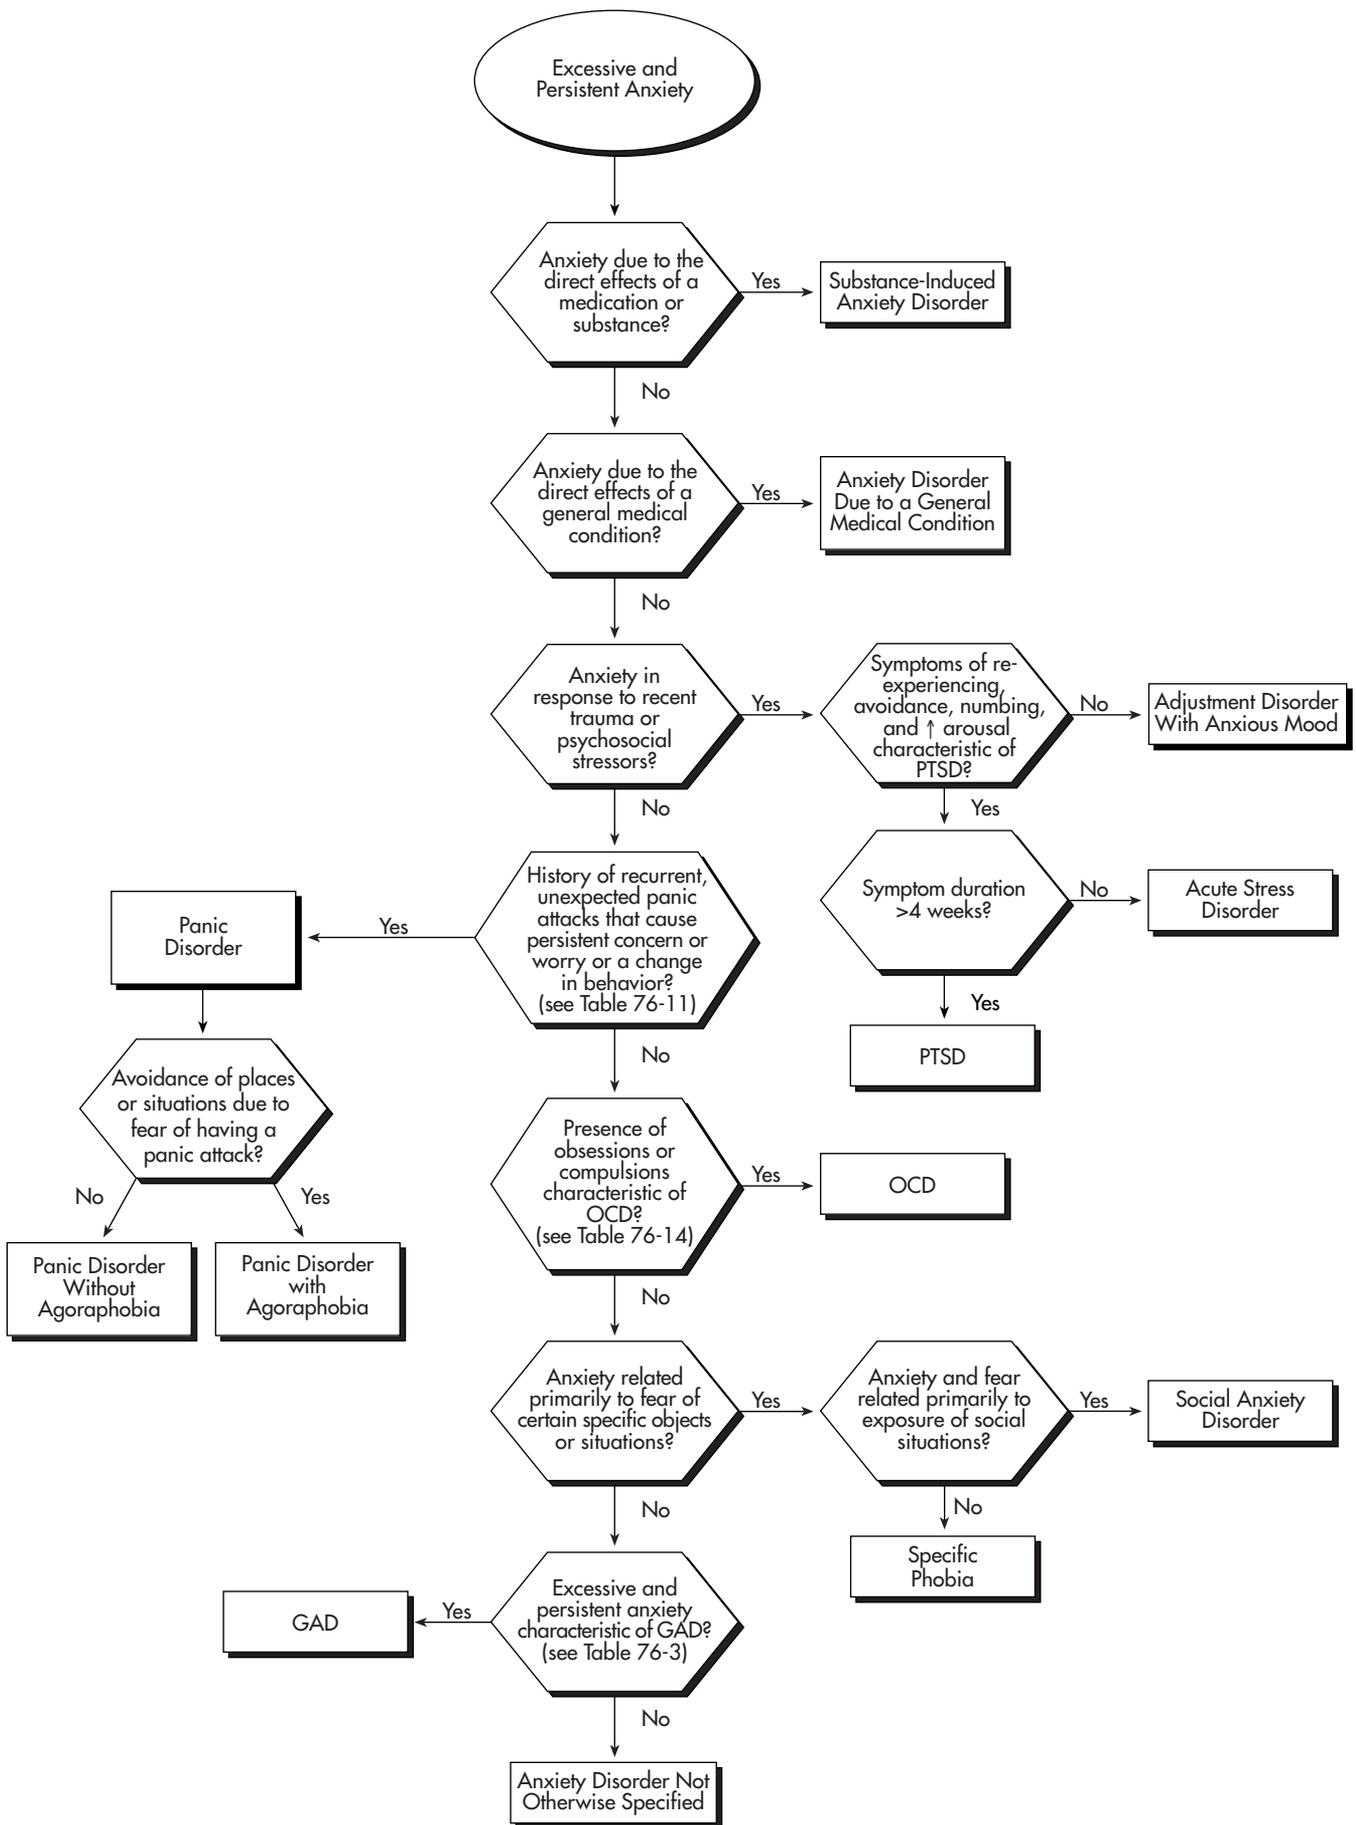

FIGURE 76-1 Diagnostic decision tree for anxiety disorders. GAD, generalized anxiety disorder; OCD, obsessive-compulsive disorder; PTSD, posttraumatic stress disorder.

Table 76-2 Secondary Causes of Anxiety**Medical Illnesses**

Endocrine and metabolic disorders: hyperthyroidism, hypoglycemia, Addison disease, Cushing disease, pheochromocytoma, PMS, electrolyte abnormalities, acute intermittent porphyria, anemia

Neurologic: seizure disorders, multiple sclerosis, chronic pain syndromes, traumatic brain injury, CNS neoplasm, migraines, myasthenia gravis, Parkinson's disease, vertigo, essential tremor

Cardiovascular: mitral valve prolapse, CHF, arrhythmias, post-MI, hyperdynamic β -adrenergic state, hypertension, angina pectoris, postcerebral infarction

GI: PUD, Crohn disease, ulcerative colitis, irritable bowel syndrome

Respiratory: COPD, asthma, pneumonia, pulmonary edema, respirator dependence, pulmonary embolus

Others: HIV infection, systemic lupus erythematosus

Psychiatric

Depression, mania, schizophrenia, adjustment disorder, personality disorders, delirium, dementia, eating disorders

Drugs

CNS stimulants: amphetamines, caffeine, cocaine, diethylpropion, ephedrine, MDMA (Ecstasy), methylphenidate, nicotine (and withdrawal), PCP, phenylephrine, pseudoephedrine

CNS depressant withdrawal: barbiturates, benzodiazepines, ethanol, opiates

Psychotropics: antipsychotics (akathisia), bupropion, buspirone, SNRIs, SSRIs, TCAs

Cardiovascular: captopril, enalapril, digoxin, disopyramide, hydralazine, procainamide, propafenone, reserpine

Others: albuterol, aminophylline, baclofen, bromocriptine, cycloserine, dapsone, dronabinol, efavirenz, fluoroquinolones, interferon- α , isoniazid, isoproterenol, levodopa, lidocaine, mefloquine, metoclopramide, monosodium glutamate, nicotinic acid, NSAIDs, pergolide, quinacrine, sibutramine, statins, steroids, theophylline, thyroid hormone, triptans, vinblastine, yohimbine

CHF, congestive heart failure; CNS, central nervous system; COPD, chronic obstructive pulmonary disease; GI, gastrointestinal; MI, myocardial infarction; MDMA, 3,4-methylenedioxymethamphetamine; NSAIDs, nonsteroidal anti-inflammatory drugs; PMS, premenstrual syndrome; PCP, phencyclidine; PUD, peptic ulcer disease; SNRIs, serotonin/norepinephrine reuptake inhibitors; SSRIs, selective serotonin reuptake inhibitors; TCAs, tricyclic antidepressants.

circumstances. Usually, this type of anxiety is self-limiting and brief, subsiding over days to weeks as the person adapts to the new situation. However, some people may have serious difficulty adjusting, with prolonged, excessive, or debilitating symptoms that progress to a primary and sometimes chronic disorder. If the person has no history of an anxiety disorder and the symptoms last only a few months, a diagnosis of *adjustment disorder with anxious mood* may be appropriate. If the symptoms are severe enough and continue for a prolonged period, a primary anxiety disorder may be present. The initial onset of a chronic anxiety disorder often occurs during a stressful time period. Short-term or intermittent therapy with anxiolytic medication or counseling can be extremely beneficial in helping persons cope during times of acute stress. In contrast, management of primary anxiety disorders usually requires more extended treatment.

In summary, the factors in J.K.'s case that warrant further investigation before a primary anxiety disorder diagnosis can be made include his medical illnesses (COPD, post-MI), his use of pseudoephedrine and caffeine, possible depression, and his adjustment to the recent changes in his life. These factors need to be addressed, and treated or corrected if possible, before a diagnosis of an anxiety disorder can be made and an appropriate treatment plan defined.

GENERALIZED ANXIETY DISORDER**Epidemiology and Clinical Course**

GAD is one of the most common anxiety disorders, with a lifetime prevalence of 3.9% to 6.6%.^{1,7} The onset of GAD

is usually gradual and may be associated with increased life stressors. Although the mean age of onset for GAD is 21 years, the high-risk period for onset ranges from the early teens to the mid-50s.⁷ GAD appears to be two times more common in females than males, and affected women often experience premenstrual exacerbation of symptoms.¹³ The typical course of GAD is often described as being chronic and recurrent, but much is unknown about the long-term course of illness. Without treatment, it appears that less than half of GAD cases undergo remission.

Most people with GAD also have at least one other psychiatric disorder, most commonly, depression or another anxiety disorder. Common comorbid disorders include panic disorder, social anxiety disorder, simple phobia, OCD, and major depression.⁶ GAD commonly precedes the development of these other disorders, and coexistence of GAD with these other conditions is associated with marked disability, high utilization of health care resources, and relatively poor treatment outcomes.⁷ Alcohol abuse and dependence are also common in GAD patients and frequently result from attempts at self-medication of anxiety symptoms.¹⁴ The observation that GAD rarely occurs in isolation has prompted debate about whether it is actually a primary anxiety disorder or merely a prodromal or residual phase of another disorder.

Diagnostic Criteria

The DSM-IV-TR criteria for GAD are presented in Table 76-3. GAD is characterized by unrealistic or excessive anxiety and worry about life issues for 6 months or longer.¹ The patient usually has great difficulty in controlling the worry, which is

Table 76-3 Diagnostic Criteria for Generalized Anxiety Disorder

1. Unrealistic or excessive anxiety and worry about life circumstances for a period of at least 6 months, during which the person has been bothered more days than not by these concerns
2. Person has difficulty controlling anxiety and worry
3. Anxiety and worry are associated with at least three of the following symptoms:
 - a. Restlessness or feeling keyed up or on edge
 - b. Easy fatigue
 - c. Difficulty concentrating or mind going blank
 - d. Irritability
 - e. Muscle tension
 - f. Sleep disturbances
4. If another psychiatric disorder is present, the focus of the anxiety and worry is unrelated to it
5. Anxiety, worry, or physical symptoms cause significant distress or impairment in social, occupational, or some other important aspect of functioning
6. Disturbance is not due to the direct effects of a substance, medication, or general medical condition and does not occur only during the course of a mood disorder, psychotic disorder, or pervasive developmental disorder

Adapted from reference 1, with permission. Copyright © 2000 American Psychiatric Association.

accompanied by at least three of the associated symptoms listed in Table 76-3. Although some types of physical symptoms are similar between GAD and other anxiety disorders, the course of the symptoms varies between disorders. If the anxiety is related solely to another anxiety disorder (e.g., obsession with germs, fear of being in social situations), a diagnosis of GAD is not warranted.

In children with GAD (also called “overanxious disorder of childhood”), the duration requirement for symptoms is only 1 month.¹ Excessive worry in this younger population typically involves performance in school or sports, punctuality, perfectionism, and the possibility of catastrophic events. Children with GAD commonly seek excessive reassurance and approval from others.

Etiology and Pathophysiology

Genetic factors play a modest, but significant role in the etiology of GAD. The genes involved in the hereditary development of GAD are believed to be the same as those in major depression, with environmental factors determining which disorder is expressed in an individual.^{5,15} Biological studies in GAD have found abnormalities in the noradrenergic, serotonergic, and CCK systems, as well as in GABA-A receptor function.⁵ Several studies report decreased α_2 -adrenergic receptors in GAD patients, and this is believed to represent downregulation of receptors in response to high catecholamine levels. Abnormally low levels of lymphocyte peripheral benzodiazepine receptors (PBRs) have been reported by several investigators. GAD patients have also shown enhanced anxiety in response to CCK-4 administration compared with normal controls, suggesting an increased sensitivity of the CCK system in GAD.

Treatment of Generalized Anxiety Disorder

Nonpharmacologic Treatments

Management of GAD can involve both nonpharmacologic and pharmacologic therapies. Nondrug treatments such as supportive psychotherapy, dynamic psychotherapy, cognitive therapy, relaxation training, and meditation exercises are often helpful in relieving anxiety and improving coping skills.¹⁶ Cognitive therapy is aimed at identifying negative thought patterns that may provoke or worsen anxiety and changing them to be more positive. Combined cognitive-behavioral therapy (CBT) has been associated with significant reductions in anxiety that are maintained over 6 to 12 months, as well as decreased psychiatric comorbidity in GAD.¹⁶ Controlled comparisons of cognitive therapies and benzodiazepine treatment have reported comparable efficacies in GAD.¹⁶ Although psychosocial treatments are commonly recommended as first-line therapy for GAD and other anxiety disorders, they are vastly underused due to cost (many insurance providers offer limited coverage for outpatient psychotherapy) and time requirements, as well as a limited availability of trained therapists. The decline in use of psychosocial therapies for anxiety disorders over the past decade also correlates with the explosion in medication options for treating anxiety disorders.

Benzodiazepines

Benzodiazepines are still widely prescribed anxiolytic agents, and their efficacy in treating GAD and many other anxiety disorders is well established.¹⁴ The benzodiazepines offer distinct clinical advantages over older agents such as barbiturates, meprobamate, paraldehyde, and alcohol. These advantages include more specific anxiolytic effects, lower fatality rates from acute toxicity and overdose (when taken alone), better side effect profiles, lower potential for abuse, and less dangerous interactions with other drugs. Currently, use of these older nonbenzodiazepine agents as anxiolytics is generally considered inappropriate because of the many advantages of benzodiazepines and other newer agents.

MECHANISM OF ACTION

In humans, benzodiazepines have four distinct effects: anxiolytic, anticonvulsant, muscle relaxant, and sedative-hypnotic. These agents are used to treat a wide variety of medical and psychiatric conditions, including muscle spasms, seizures, anxiety disorders, acute agitation, and insomnia. Benzodiazepines with a rapid onset and a short duration of action are commonly used to decrease anxiety and apprehension, as well as induce sedation before surgery and other medical procedures.

The mechanism of action of benzodiazepines involves potentiation of GABA by binding to sites on the central GABA-A receptor. There are four types of GABA-A receptors that are benzodiazepine sensitive; these are distinguished by the type of α subunit they contain (α_1 , α_2 , α_3 , or α_5).^{17,18} Benzodiazepine binding sites on α_1 -GABA-A and α_2 -GABA-A receptors were formerly called BZ-1 and BZ-2 receptors, respectively, but there is a trend away from use of the latter terminology. Receptors with an α_1 subunit are widely distributed throughout most brain areas and are the most abundant type. Benzodiazepine interaction at the α_1 -GABA-A receptors produces sedative and amnestic effects, whereas anxiolytic effects

are associated with binding to the α_2 -GABA-A receptor.^{17,19} This latter type of GABA-A receptor is localized mainly in the limbic system, cerebral cortex, and striatum. GABA-A receptors with α_3 subunits are linked with noradrenergic, serotonergic, and cholinergic neurons.

Currently available benzodiazepine anxiolytics do not have selective activity at any of the four GABA-A receptor subtypes. Research is aimed at developing benzodiazepine compounds with specific affinity for the α_2 -GABA-A receptor, which would produce anxiolytic effects without sedative and amnesic effects.²⁰ Agents that are partial agonists at α_2 -GABA-A receptors are also being studied as potential anxiolytics; these would be associated with minimal tolerance, dependence, and withdrawal.²⁰ Zolpidem (Ambien), eszopiclone (Lunesta), and zaleplon (Sonata) are examples of selective α_1 -GABA-A receptor agonists that have been introduced as selective hypnotic agents.

CLINICAL COMPARISON OF BENZODIAZEPINES

Approximately 35 benzodiazepine compounds are marketed worldwide. Of the 13 benzodiazepines commercially available in the United States, 7 are marketed as antianxiety agents, and 6 as oral sedative-hypnotics. These indications reflect the manufacturers' labeling decisions because the anxiolytics can be effective sedatives and vice versa.

Table 76-4 compares the clinical profiles of marketed oral benzodiazepines. Midazolam (Versed) is not included on Table 76-4. It is a short-acting, water-soluble benzodiazepine, indicated only for induction of sedation before surgery or for short diagnostic or endoscopic procedures. It was previously mar-

keted only in parenteral formulation, but an oral syrup form is now available. Clonazepam (Klonopin) was originally approved only as an anticonvulsant, but is now also indicated for the treatment of panic disorder. Clonazepam and most of the other benzodiazepines also have many unlabeled uses, including treatment of anxiety and agitation associated with various medical or psychiatric illnesses, GAD, and other anxiety disorders; irritable bowel syndrome; premenstrual syndrome; chemotherapy-induced nausea and vomiting; catatonia; tetanus; involuntary movement disorders (restless legs syndrome, periodic limb movements of sleep, akathisia, tardive dyskinesia, essential tremor); and spasticity associated with various neurologic disorders (cerebral palsy, paraplegia).

Antidepressant Agents

Antidepressants have now surpassed benzodiazepines as the recommended first-line treatment for most anxiety disorder patients, even though benzodiazepines are still widely prescribed. One important clinical difference between these two medication classes is that the anxiolytic effects of benzodiazepines occur almost immediately, whereas the effects of antidepressants occur gradually over several weeks. For this reason, it is common practice for short-term benzodiazepine therapy to be prescribed in combination with an antidepressant during initial treatment of many anxiety disorders.

The first indication that antidepressants might be effective in the treatment of anxiety disorders appeared in the late 1970s, when certain tricyclic antidepressants (TCAs) and monoamine oxidase inhibitors (MAOIs) were found to be useful in treating

Table 76-4 Clinical Comparison of Benzodiazepine Agents

| Drug (Trade Name, Generic) | FDA-Approved Indications | Usual Dosage Range Through 65 Years of Age | Maximum Recommended Dosage Through 65 Years of Age | Approximate Dosage Equivalencies | Year Introduced |
|--|--|---|--|----------------------------------|-----------------|
| Chlordiazepoxide (Librium, Libmitrol, ^a Librax, ^b generic) | Anxiety, preoperative anxiety, acute alcohol withdrawal | 15–100 mg/day | 40 mg/day | 50 | 1960 |
| Diazepam (Valium, generic) | Anxiety, muscle relaxant, acute alcohol withdrawal, preoperative anxiety, anticonvulsant | 4–40 mg/day | 20 mg/day | 10 | 1963 |
| Oxazepam (Serax, generic) | Anxiety, alcohol withdrawal | 30–120 mg/day | 60 mg/day | 30 | 1965 |
| Flurazepam (Dalmane, generic) | Sedative-hypnotic | 15–30 mg HS | 15 mg HS | 30 | 1970 |
| Clorazepate (Tranxene, Tranxene-SD, generic) | Anxiety, alcohol withdrawal, anticonvulsant | 15–60 mg/day | 30 mg/day | 15 | 1972 |
| Clonazepam (Klonopin, Klonopin wafer, generic) | Anticonvulsant, panic disorder | 0.5–12 mg/day | 3 mg/day | 0.5 | 1975 |
| Lorazepam (Ativan, generic) | Anxiety, anxiety associated with depression | 2–6 mg/day | 3 mg/day | 1.5–2.0 | 1977 |
| Alprazolam (Xanax, Xanax XR, Niravam orally disintegrating tablets, generic) | Anxiety, anxiety associated with depression, panic disorder | 0.5–6 mg/day (up to 10 mg/day for panic disorder) | 2 mg/day | 1.0 | 1981 |
| Temazepam (Restoril, generic) | Sedative-hypnotic | 15–30 mg HS | 15 mg HS | 30 | 1981 |
| Triazolam (Halcion, generic) | Sedative-hypnotic | 0.125–0.25 mg HS | 0.125 mg HS | 0.25 | 1983 |

^bDocumented efficacy, but not recommended for first-line treatment because of undesirable clinical properties (side effects, potential toxicity, drug interactions).

^cAdjunctive therapy only.

panic disorder. Clomipramine (Anafranil), a TCA, emerged as an effective treatment for OCD soon thereafter, and as shown in Table 76-5, selective serotonin reuptake inhibitor (SSRIs) have since gained first-line status for treating all five primary anxiety disorders.²¹ The distinction between anxiolytics and antidepressants is continually narrowing.

Early controlled studies found trazodone, doxepin, imipramine, and amitriptyline to be comparably effective or even superior to benzodiazepines in treating GAD.¹⁴ Although the benzodiazepines work more quickly, and TCA treatment is often associated with initial increases in anxiety (especially with higher dosages), continued TCA therapy is usually effective if the side effects can be tolerated. However, the TCAs are not widely used for treating anxiety disorders because attention has turned to other much safer and better tolerated antidepressants.

Paroxetine (Paxil) is the best-studied SSRI in GAD and was U.S. Food and Drug Administration (FDA) approved for this indication in 2001. Paroxetine is superior to placebo and

as effective as the TCAs in treating GAD, but it is much better tolerated. Results from a large fixed-dose study suggest that a paroxetine dosage of 20 mg/day is effective for most patients with GAD, although some may need 30 to 40 mg/day for optimal benefits.²² As with TCAs, some patients experience an initial increase in anxiety during SSRI treatment, so that lower-than-normal SSRI starting doses should be used in patients with GAD. A low paroxetine starting dose of 10 mg/day is recommended for the first week in patients with GAD to minimize initial side effects. Paroxetine maintenance therapy significantly decreases the risk of GAD relapse at 6 months.²³ The most common side effects of paroxetine in patients with GAD are sedation, nausea, dry mouth, constipation, asthenia, headache, and sexual dysfunction. With long-term therapy, weight gain may be problematic.

The combination serotonin/norepinephrine reuptake inhibitors (SNRIs), venlafaxine (Effexor XR), and duloxetine (Cymbalta) are efficacious for the treatment of GAD. Several

large controlled studies have shown venlafaxine XR to be effective in reducing anxiety associated with depression, as well as in the treatment of pure GAD.^{24–26} The recommended venlafaxine starting dose is 37.5 mg/day, and the effective dosage range for GAD is 75 to 225 mg/day.²⁶ Many patients respond to doses of 75 to 150 mg/day, although some may require up to 225 mg/day. The side effect profile of venlafaxine is similar to the SSRIs, with nausea being the most common complaint. Nausea is dose related, and usually subsides after 1 to 2 weeks of continued therapy. Other common side effects of venlafaxine include dizziness, asthenia, dry mouth, sweating, and either sedation or insomnia. Significant increases in blood pressure are not usually seen within the dosage range used for GAD (75–225 mg/day), but can occur with higher venlafaxine doses. Long-term studies report that GAD response to venlafaxine is maintained during 6 months of continued treatment.²⁵ Duloxetine recently received FDA approval for the treatment of GAD. Two 10- and one 9-week, randomized, placebo-controlled, double-blind trials in patients suffering from GAD have reported that duloxetine (60–120 mg/day) performed better than placebo.^{27–29} In the single trial with a venlafaxine XR comparison arm, both duloxetine and venlafaxine exhibited similar efficacy and tolerability.²⁷

SSRIs other than paroxetine can also be beneficial in treating GAD. Escitalopram (Lexapro) received FDA approval for GAD in late 2003, and preliminary reports suggest efficacy for citalopram (Celexa).^{21,30} Sertraline (Zoloft), fluvoxamine (Luvox), and fluoxetine (Prozac) are reportedly effective in alleviating anxiety symptoms in patients with depression.^{14,31,32} Fluoxetine may be more likely than other SSRIs to cause anxiety as an initial side effect.²¹ Fluoxetine use in depressed patients with prominent anxiety or psychomotor agitation has been associated with poor response in some studies, although others report it to be comparably effective and as well tolerated as other SSRIs in this population.^{32,33}

Mirtazapine (Remeron) is a non-SSRI antidepressant that appears promising in the treatment of GAD, but controlled studies are few.³⁴ It causes an especially low incidence of anxiety as a side effect, which is attributed to its serotonin receptor type-2 blocking activity. (See Chapter 79 for more information regarding the clinical use of various antidepressant agents.) Another non-SSRI antidepressant, nefazodone, exhibited anxiolytic effects in patients with GAD but it was associated with several cases of severe hepatotoxicity. In 2004, the trade name brand (Serzone) was voluntarily removed from the market by its manufacturer, although generic nefazodone is still available.³⁵

Although decreases in anxiety symptoms during antidepressant treatment may appear within the first 2 weeks, response is gradual and generally continues over 8 to 12 weeks or longer. Therefore, optimal trials of antidepressants in GAD should allow at least 8 weeks of adequate doses before a lack of response is determined. Continued improvements may occur over 4 to 6 months in some GAD patients treated with antidepressants.^{23,25}

Overall, advantages of antidepressants over benzodiazepines in treating GAD include their superior efficacy for cognitive symptoms such as excessive worry and their better coverage for common comorbid disorders such as depression and other anxiety disorders. Antidepressants also lack potential

for abuse and dependence, although nearly all antidepressants can cause a withdrawal syndrome on abrupt discontinuation.

Other Agents Used to Treat Generalized Anxiety Disorder

Compared with antidepressants and benzodiazepines, buspirone is effective in treating cognitive anxiety symptoms and is not associated with abuse or dependence; however, it has a delayed onset of anxiolytic effects and is not appropriate for as-needed use.

Buspirone (BuSpar) was marketed in the United States in 1986 as the first of a nonbenzodiazepine class of anxiolytics, the azapirones. This class differs pharmacologically and clinically from the benzodiazepines.^{14,36} Buspirone does not interact with GABA receptors and works as a partial agonist of the serotonin type 1A (5-hydroxytryptamine [5HT_{1A}]) receptor (i.e., it binds to the receptor but exerts a fraction of the effect of a full agonist).³⁷ This partial agonist activity results in reduced serotonin neurotransmission. In addition, buspirone enhances dopaminergic neurotransmission by blocking presynaptic dopamine receptor-2 auto receptors and also facilitates noradrenergic activity.³⁶

β -Adrenergic receptor blocking agents such as propranolol (Inderal) are very effective in reducing certain physical symptoms of anxiety (tremor, flushing, tachycardia) that result from activation of the sympathetic nervous system. These agents are especially effective in preventing performance anxiety or “stage fright” by suppressing peripheral autonomic activity, but they do not modify cognitive symptoms of anxiety. β -Blockers are not as effective as benzodiazepines in the treatment of anxiety disorders and are not recommended as a primary treatment option for GAD.

Histamine-1 (H₁) receptor blocking agents such as hydroxyzine (Vistaril) and diphenhydramine (Benadryl) have been used for years in the treatment of anxiety and insomnia. Because of their potent sedative effects, these antihistamines are generally used on an as-needed basis for insomnia or for their calming effects in a variety of patient types. Although these drugs are considered benign and diphenhydramine is available over the counter, they do possess significant anticholinergic effects, which can produce problems such as confusion, cognitive impairment, nausea, and constipation. Elderly patients, especially those who are medically ill or have dementia, are particularly vulnerable to these side effects, and diphenhydramine is considered inappropriate for use in the elderly.³⁸ There is no evidence for the efficacy of diphenhydramine in the treatment of primary anxiety disorders.

Several studies have reported hydroxyzine to be beneficial in treating GAD. A large placebo-controlled study in nonelderly patients demonstrated superiority of hydroxyzine (50 mg/day given in three divided doses) over placebo.³⁹ Hydroxyzine was as effective as benzodiazepine therapy over 3 months of treatment, although it did not work as quickly. No anticholinergic, cognitive impairment, or weight gain adverse effects were reported in hydroxyzine-treated patients, and it was very well tolerated. Minimal sedation was reported with the relatively low daily hydroxyzine dose used in this study. Abrupt discontinuation of hydroxyzine after 3 months was not associated with significant withdrawal symptoms. Hydroxyzine is an inexpensive drug and may be a treatment option for GAD in some patients, but controlled comparisons with antidepressant agents are needed to better define its current role in therapy. It is

not a good choice of therapy for elderly persons or patients with GAD and comorbid depression or other anxiety disorders.

Clinical Presentation and Assessment of Generalized Anxiety Disorder

2. N.K., a 25-year-old woman, has been employed as a bank clerk for the past 5 years. She had an excellent work record until 6 months ago, when excessive absences and a tendency to become easily upset at customers and coworkers became noticeable. On clinical assessment, N.K. complains of being tired, irritable, and tense, with frequent stomach upset and diarrhea. She has no history of mental illness; however, she admits to being stressed and worrying too much about “just little things,” which she cannot seem to control regardless of how hard she tries. N.K. denies experiencing episodic “attacks” of severe anxiety (which might be indicative of panic disorder) or of having obsessive-compulsive thoughts or behaviors.

N.K.’s physical examination is unremarkable, and she has no history of mental illness in her family, although her mother was a “nervous person.” N.K. denies any past or present use of any illicit substances or alcohol. Her mental status examination reveals the following:

- **Appearance and behavior:** N.K. is neatly groomed and dressed and speaks coherently, but she constantly fidgets and taps her right foot. She states that she often has difficulty falling asleep but generally remains asleep throughout the night.
- **Mood:** N.K. is anxious and worried about the clinician’s evaluation and admits to occasionally feeling depressed because of her anxiety.
- **Sensorium:** N.K. is oriented to person, place, and time.
- **Thoughts:** N.K. denies any auditory or visual hallucinations.

N.K. states that at times she has difficulty speaking, is unable to relax, and startles easily. She realizes that work has been difficult for her lately, and her supervisor has told her that her job is in immediate jeopardy unless she improves her performance. N.K. states that she just wants to be able to perform her job well, relax, and enjoy life. Her insight and judgment are good, and she is motivated to obtain treatment. N.K. denies any suicidal ideation. The physician’s provisional diagnosis is GAD (DSM-IV criteria). What clinical features of GAD are present in N.K., and how can her symptoms be assessed objectively?

N.K. exhibits the following target symptoms associated with GAD: excessive worry that is difficult to control, irritability, tension and inability to relax, fatigue, and sleep disturbances. Other typical symptoms of anxiety present in N.K. include gastrointestinal (GI) problems (upset stomach and diarrhea), being startled easily, difficulty speaking, and fidgeting. These target symptoms are not necessarily diagnostic of any particular disorder, but other factors in association with these symptoms are consistent with GAD. The absence of physical or other psychiatric illnesses, as well as use of any illicit substances or alcohol, excludes possible secondary causes of anxiety. The 6-month duration of symptoms is consistent with a diagnosis of GAD, and N.K. is at a common age for onset of GAD. More important, the symptoms are causing significant occupational impairment for N.K. and interfering with her quality of life; therefore, a diagnosis of GAD is appropriate in N.K.

The Hamilton Anxiety Rating Scale (HAM-A) is a useful assessment tool to evaluate clinical anxiety, and it is the standard instrument used in GAD clinical trials. A HAM-A score of >18 is generally correlated with significant anxiety, and a score of 7 to 10 is associated with remission.⁴⁰ The HAM-A can be used to assess baseline anxiety symptoms in patients such as N.K. and to monitor response throughout treatment. The Sheehan Disability Scale is a patient-rated instrument, which is commonly used to assess functional impairment due to GAD and other anxiety disorders. A score of 1 reflects mild disability.⁴⁰

Indications for and Selection of Treatment

3. Based on the information presented in N.K.’s case, how can it be determined whether treatment is indicated? What factors should be considered in choosing the most appropriate treatment for N.K.?

N.K. meets the diagnostic criteria for GAD and is suffering significant disability from her anxiety disorder. She also has insight into her illness and desires treatment that will enable her to improve her job performance and quality of life. Appropriate treatment of GAD can help achieve these goals and is therefore indicated for patients such as N.K.

Treatment options for GAD may include both pharmacologic and nondrug therapies. Psychosocial treatments such as CBT can be effective in treating GAD, but use of these therapies alone is generally reserved for patients with mild-to-moderate symptoms. In N.K.’s case, prompt treatment is needed because she feels that her job is in immediate jeopardy owing to impairments associated with her anxiety. Therefore, pharmacotherapy in combination with psychological therapy, if available, is indicated in N.K.

Among potential drug therapies, the benzodiazepines, paroxetine, duloxetine, venlafaxine, and buspirone, are all considered first-line treatments for GAD.¹⁴ A primary consideration when choosing among these options is whether any comorbid psychiatric conditions are present. Venlafaxine, duloxetine, and paroxetine are good initial choices for patients with concurrent depression, which is common in GAD patients. They are also preferred over benzodiazepines in patients with past or present alcohol or substance abuse. Other medical or psychiatric disorders may also be present, which can guide selection toward a treatment that may be dually effective.

Another important consideration when selecting treatment for GAD is how fast therapeutic effects are needed. Benzodiazepines reduce anxiety within a few hours, whereas the antidepressants and buspirone have delayed onsets of anxiolytic effects. Medication cost is another potential factor, and generic benzodiazepines are currently the least expensive anxiolytic medications.

In N.K.’s case, a benzodiazepine may be a good initial choice because of the need for quick symptom relief relating to her problems at work. N.K. is young and healthy with no past or present history of substance or alcohol use that might make benzodiazepines unsuitable for her. GAD is often chronic, and antidepressants or buspirone are usually preferred over benzodiazepines for long-term treatment. Therefore, one of these agents would also be appropriate to use in this case. Combination benzodiazepines-SSRI therapy during initial treatment of

anxiety disorders is well tolerated and may result in synergistic anxiolytic effects and quicker response.^{41,42}

Benzodiazepine Treatment

Factors Influencing Benzodiazepine Selection

4. The physician decides to treat N.K.'s GAD with venlafaxine XR and also wants to prescribe a benzodiazepine for quick control of her anxiety during the first several weeks until the onset of venlafaxine's anxiolytic effects. What factors are important in the selection of a particular benzodiazepine agent for N.K.?

Of the available benzodiazepines, none has demonstrated clear superior efficacy in the treatment of anxiety. However, certain agents have been used much more extensively than others. Alprazolam (Xanax) is the most commonly used in the United States, lorazepam (Ativan) is the next most popular, followed by clonazepam (Klonopin) and then diazepam (Valium). All four of these benzodiazepines have been successfully used in the treatment of GAD.

Because the overall anxiolytic efficacies of benzodiazepines are similar, other factors must be considered when selecting one agent over another. The one major area of clinically significant differences between benzodiazepines is their pharmacokinetic properties. These are generally the main factors considered in drug selection (Table 76-6).

Benzodiazepines can be differentiated pharmacokinetically according to their elimination half-lives and their metabolism to active or inactive compounds (Fig. 76-2; Table 76-6). Diazepam (Valium) and chlordiazepoxide (Librium) have half-lives between 10 and 40 hours but are metabolized by hepatic oxidative pathways to the active metabolite desmethyldiazepam (DMDZ), which has a half-life of at least 100 hours.⁴³ Demethylation of diazepam to DMDZ is mediated by several cytochrome P450 (CYP) isozymes, including CYP 2C19, CYP 3A4, and, to a lesser extent, CYP 2B6. CYP 2C19

appears to be the predominate pathway with usual therapeutic diazepam doses, but CYP 3A4 becomes more important with high doses, in overdose cases, and in CYP 2C19 poor metabolizers.⁴⁴ The other major active diazepam metabolite, temazepam, is formed through CYP 3A4-mediated hydroxylation.

As shown in Figure 76-2, the prodrugs quazepam (Doral) and clorazepate (Tranxene) are also metabolized to DMDZ.⁴³ Because of the long half-life of this active metabolite, chronic dosing of benzodiazepines that are converted to DMDZ can lead to drug accumulation and prolonged clinical effects. This can be especially detrimental in the elderly, those with liver disease, or persons taking other drugs that interfere with benzodiazepine metabolism. Although their long durations of action make once-daily dosing possible, small, divided daily doses are often used clinically to minimize side effects.

Clonazepam undergoes various routes of hepatic metabolism, including oxidative hydroxylation, reduction, and acetylation.⁴³ At least five metabolites have been identified, but their pharmacologic activity is uncertain. The specific enzymes responsible for clonazepam metabolism have not been confirmed, but there is evidence that it is a substrate for CYP 3A4.⁴⁵ The elimination half-life of clonazepam ranges from 20 to 50 hours, making once-daily dosing feasible. A new formulation of orally disintegrating clonazepam tablets (Klonopin wafer) has been introduced and is indicated for the treatment of panic disorder. This product dissolves quickly on the tongue and is promoted as being especially convenient because it can be taken without water.

Alprazolam (Xanax, Niravam) and lorazepam (Ativan) have intermediate half-lives of 10 to 20 hours, and oxazepam (Serax) has a short to intermediate half-life of 5 to 14 hours. Alprazolam is a triazolobenzodiazepine that is metabolized by CYP 3A4 to an active metabolite, α -hydroxy alprazolam, which has a short half-life of approximately 2 hours and is considered clinically insignificant. Alprazolam, lorazepam, and

Table 76-6 Pharmacokinetic Comparison of Benzodiazepine Agents

| Drug | Elimination Half-Life (hr) ^a | Active Metabolites | Protein Binding | Pathway of Metabolism | Rate of Onset After Oral Administration |
|------------------|---|--|-----------------|--------------------------------|---|
| Chlordiazepoxide | >100 | Desmethyldiazepam | 96% | Oxidation | Intermediate |
| Diazepam | >100 | Desmethyldiazepam | 98% | Oxidation (CYP 3A4, CYP 2C19) | Very fast |
| Oxazepam | 5–14 | None | 87% | Conjugation | Slow |
| Flurazepam | >100 | Desalkylflurazepam, hydroxyethylflurazepam | 97% | Oxidation | Fast |
| Clorazepate | >100 | Desmethyldiazepam | 98% | Oxidation | Fast |
| Lorazepam | 10–20 | None | 85%–90% | Conjugation | Intermediate |
| Alprazolam | 12–15 | Insignificant | 80% | Oxidation (CYP 3A4) | Fast |
| Temazepam | 10–20 | Insignificant | 98% | Conjugation | Intermediate |
| Triazolam | 1.5–5 | Insignificant | 90% | Oxidation (CYP 3A4) | Intermediate |
| Quazepam | 47–100 | 2-Oxoquazepam, desalkyloxoquazepam | >95% | Oxidation | Fast |
| Estazolam | 24 | Insignificant | 93% | Oxidation | Intermediate |
| Clonazepam | 20–50 | Insignificant | 85% | Oxidation, reduction (CYP 3A4) | Intermediate |
| Midazolam | 1–4 | None | 97% | Oxidation (CYP 3A4) | NA |

NA, not applicable.

^aParent drug + active metabolite.

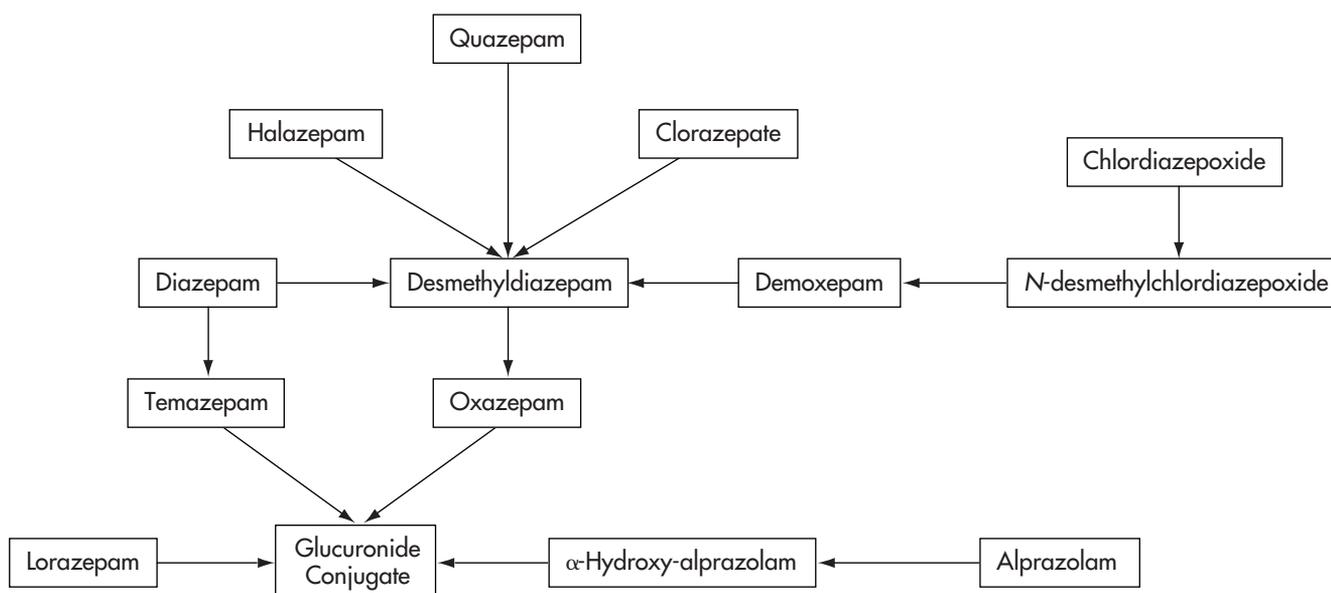

FIGURE 76-2 Metabolic pathways of benzodiazepines.

oxazepam usually need to be taken on a TID to QID dosing schedule for sustained clinical effects, but an extended-release (XR) preparation of alprazolam that allows QD or BID dosing has become available. Alprazolam XR may be associated with less CNS side effects than the immediate-release form because peak alprazolam blood levels are lower.⁴⁶ Also, a quickly dissolving tablet of alprazolam (Niravam) has been marketed. Lorazepam, temazepam (Restoril), and oxazepam undergo phase II metabolism by glucuronidation and are believed to be substrates for the uridine diphosphate-glucuronosyltransferase 2B7 isozyme.⁴⁷ These agents are free of active metabolites and are unlikely to accumulate with chronic administration; they are preferred over long-acting agents in patients with liver disease and in the elderly. Unlike phase I oxidative metabolism, phase II glucuronidation processes do not appear to decline with age.⁴⁷

Benzodiazepines are readily absorbed within 2 to 3 hours after oral administration.⁴³ They are widely distributed in the body and accumulate preferentially in lipid-rich areas such as the CNS and fat tissue. Lipid solubility varies among the agents, resulting in differences in rates of absorption and speed of onset, as well as duration of clinical effects (Table 76-6). Diazepam and clorazepate have the highest lipid solubilities and the quickest onsets of action, which can be desirable when rapid anxiolysis is needed; however, both can produce an unpleasant “drugged” or “high” feeling in some patients. Highly lipophilic benzodiazepines are also more quickly redistributed out of the brain, which decreases their duration of action. For example, even though diazepam has a very long half-life, its clinical effects last for a shorter period than lorazepam, which has a relatively short half-life.

Diazepam, lorazepam, chlordiazepoxide, and midazolam are also available for parenteral (intravenous [IV] and intramuscular [IM]) administration.⁴³ These routes are usually reserved for treatment of severe agitation or seizures or for induction of preoperative sedation and anxiolysis. IM injection of both chlordiazepoxide and diazepam can be very painful.

Lorazepam is the preferred agent when parenteral dosing is needed for quick control of anxiety or agitation because it is rapidly and completely absorbed after IM injection. The absorption of sublingual lorazepam, alprazolam, and triazolam (Halcion) is comparable to or slightly faster than oral absorption.⁴³

Cost is another important factor in benzodiazepine selection. Brand name benzodiazepines can be relatively expensive, but all are available in less costly generic versions, except the extended-release and quick-dissolving formulations. Potential drug interactions should also be considered in the selection of an agent because they can alter pharmacokinetics and clinical effects (see Question 9).

Because N.K. is young and healthy and is not taking any other medications, the clinician could choose just about any benzodiazepine. Nevertheless, most clinicians still prefer to use shorter-acting high-potency agents such as lorazepam or alprazolam for patients such as N.K. Appropriate starting doses would be lorazepam 0.5 to 1 mg TID or alprazolam 0.25 to 0.5 mg TID. Dosages can be increased every 3 to 4 days, if needed, within the dosage ranges indicated in Table 76-4. N.K. should notice a decrease in her anxiety symptoms within the first few days of treatment. Prescription of a generic formulation is recommended to reduce treatment costs.

Adverse Effects and Patient Counseling

5. Lorazepam 0.5 mg TID is prescribed for N.K. in addition to venlafaxine XR. What side effects may occur with benzodiazepine treatment, and how should N.K. be counseled regarding benzodiazepine therapy?

Overall, benzodiazepines are very safe and well-tolerated medications, and drug discontinuation due to side effects is extremely rare. Sedation and feelings of tiredness are the most common side effects of the benzodiazepines, but sedation can also be beneficial in alleviating the insomnia that often accompanies anxiety. Tolerance usually develops to the sedative

effects of benzodiazepines within 1 to 2 weeks of continued treatment; consequently, benzodiazepine sedative-hypnotics are recommended for only short-term use.⁴⁸ Fortunately, tolerance does not appear to develop to the anxiolytic or muscle relaxant effects of benzodiazepines.

Benzodiazepines can cause cognitive impairment and anterograde amnesia (decreased memory for new information after taking the drug), which is dose related and reversible on medication discontinuation. Tolerance often develops to the cognitive adverse effects, but they can also persist throughout therapy in some patients.⁴⁹ Use of alcohol during benzodiazepine therapy greatly increases the risks for memory problems and sedation, as well as for other more dangerous effects. Elderly individuals are more sensitive to the sedative, cognitive, and psychomotor effects of the benzodiazepines, and tolerance to these effects may occur more slowly than in the nonelderly.⁵⁰

Other psychomotor effects such as problems with balance and coordination and delayed reaction time also can occur during benzodiazepine treatment.⁴³ These effects are also dose related, but usually subside within a few weeks of continued treatment. However, it is important that patients starting on benzodiazepine therapy be cautioned about possible adverse psychomotor effects. Residual daytime effects after taking a long-acting benzodiazepine the previous night may even pose a hazard while driving the next day.

The link between benzodiazepine use and falls, especially in the elderly, is well documented and may result from a combination of balance impairment, sedation, and muscle relaxant effects.⁵¹ Rapid dosage escalation and use of doses that are too high (of either long-acting or short-acting agents) have been identified as major risk factors, but even use of low doses of short-acting agents greatly increases the fall risk in the elderly.^{51,52} Although tolerance can develop to the psychomotor effects of benzodiazepines, elderly individuals may experience persistent impairment. Benzodiazepines should probably be considered second-line therapy in the ambulatory older population.

Respiratory depression is another potential adverse effect of benzodiazepines, but it is usually clinically relevant only in patients with severe respiratory disease, in overdose situations (see Question 11), or when combined with alcohol or substances that depress breathing. It is recommended that benzodiazepines be avoided in patients with sleep apnea. Respiratory complications are encountered most often with IV administration. IV midazolam has been associated with a number of deaths due to cardiorespiratory arrest during its use for conscious sedation, most often in patients premedicated with narcotics or in those with chronic obstructive airways disease. Severe respiratory depression has also occurred with the concurrent use of benzodiazepines and olanzapine (Zyprexa), loxapine (Loxitane), or clozapine (Clozaril).

Paradoxical disinhibition, with increased anxiety, irritability, and agitation, can occur infrequently with benzodiazepines.^{43,53} Such effects have been mainly observed in elderly or developmentally disabled patients. Other unusual behaviors, such as increased anger, hostility, and violence, have been attributed to benzodiazepine use in a small number of cases.⁴³ Most of these reports were anecdotal and involved patients with pre-existing psychiatric disorders such as bipolar disorder, schizophrenia, or personality disorders. It is difficult

to confirm that benzodiazepines caused these paradoxical reactions because such disorders are commonly associated with behavioral problems, and benzodiazepines are often used in their treatment. Overall, there is no convincing evidence that benzodiazepines actually cause violent or suicidal behaviors, but there is some evidence to the contrary.^{43,53}

Benzodiazepines have also been associated with clinical depression, although evidence supporting a causal relationship is very limited and the use of benzodiazepines during the initial weeks of antidepressant therapy may actually improve and possibly hasten antidepressant response in depression.¹²

In summary, N.K. should be told that she may experience sedation and difficulties in thinking, concentration, or memory during the first week or so of therapy, but these side effects should resolve once she develops some tolerance to the drug. She should be extremely careful while driving or performing other tasks that require psychomotor skills, especially during the first week, and she should avoid the use of alcohol while she is taking benzodiazepines.

Benzodiazepine Abuse and Dependence

6. Two weeks later, N.K. contacts her clinician to discuss a medication concern. She reports that the medication has been extremely effective in relieving her anxiety, and she is currently taking venlafaxine XR, 150 mg Q AM, and lorazepam, 0.5 mg TID, as directed by her physician. However, her mother has told her that she will become addicted to lorazepam, and she wonders if she should stop taking it because of this concern. What potential for abuse and dependence is associated with benzodiazepines? How should N.K. be counseled regarding “becoming addicted” to lorazepam?

Concerns related to abuse and dependence are probably the major drawback to the clinical use of benzodiazepines. These agents are classified as schedule IV controlled substances, reflecting a relatively limited abuse and dependence liability. There may be differences within the class regarding abuse potential. Diazepam, alprazolam, and lorazepam are reported to be more likely to be abused than are oxazepam and chlordiazepoxide.⁵⁴ This difference in abuse potential is commonly attributed to the quicker onset of effects for drugs such as diazepam, which may be associated with a subjective euphoric sensation. The XR alprazolam formulation is reported to have a lower abuse potential than immediate-release alprazolam because of its slower onset of effects and lower maximum plasma concentrations.⁴⁶

Abuse is characterized by drug use outside the therapeutic setting and implies recreational use combined with continued use despite negative consequences, dose escalation, and loss of control over use. Patients without a history of substance abuse who take benzodiazepines for therapeutic purposes are unlikely to escalate doses or use them in ways characteristic of abuse.⁵⁴

The potential problems with benzodiazepine abuse and dependence can be avoided or minimized in several ways. First is the identification of patients who have a history of alcohol or substance abuse and using nonbenzodiazepine treatments in such cases.⁵⁴ Second, patients should be counseled about the likely duration of benzodiazepine use, the possibility of withdrawal symptoms, and the importance of gradual drug tapering when therapy is to be discontinued. The distinction between “addiction” and appropriate therapeutic use, which may be

accompanied by some degree of physical dependence, should be explained.

N.K. should be advised that as long as the medication is helping her anxiety and she is taking it according to her physician's instructions, her use of lorazepam does not constitute addiction. However, her body may develop some physiological dependence to the drug, so if she stops taking lorazepam abruptly, she could experience increased anxiety and other withdrawal symptoms. When lorazepam is to be discontinued, the dose should be decreased gradually over a sufficient period to minimize withdrawal symptoms.

Duration of Treatment

7. Two weeks later at her clinic appointment, N.K. is still doing well and has shown further improvements in her GAD symptoms. She has been taking the prescribed lorazepam and venlafaxine doses for 1 month, and her venlafaxine has been increased to the current dose of 150 mg/day during this time. How long should medication therapy continue?

GAD is a chronic disorder that can fluctuate in severity and often requires long-term treatment. Relapse after discontinuation of benzodiazepine monotherapy is reported to occur in 50% to 80% of GAD patients; however, some of these cases may actually involve benzodiazepine withdrawal.⁵⁵ These relapse rates also do not take into account the concurrent use of other medications that may prevent relapse, such as venlafaxine. Although long-term use of benzodiazepines is generally safe and effective, it is desirable to limit treatment to the shortest duration necessary because of the physical dependence potential.¹⁴ When benzodiazepines are used for acute anxiolytic effects during initiation of antidepressant treatment for GAD, they are commonly limited to short-term (2–6 weeks) therapy. N.K. has shown good response after 1 month of combined lorazepam and venlafaxine XR therapy. Because the anxiolytic effects of venlafaxine usually occur between 2 and 4 weeks of therapy and she is taking a therapeutic venlafaxine dose, it is appropriate to start discontinuing lorazepam at this time. N.K. is unlikely to experience significant withdrawal symptoms after only 1 month of treatment, but the dose should still be gradually decreased over several weeks, according to tolerability of the taper.⁵⁵

There is no consensus about the optimal duration of drug therapy for GAD. However, recent recommendations suggest that effective medication treatment be continued for at least 6 to 12 months after response.¹⁴ Continuation treatment with antidepressants significantly reduces the risk of GAD relapse over 6 months.^{23,25} Therefore, venlafaxine XR therapy should be continued for another 5 to 11 months in N.K.'s case. After that time period, gradual venlafaxine discontinuation may be considered and reinstitution of treatment is warranted if relapse occurs.

Symptoms and Management of Benzodiazepine Withdrawal

8. G.S., a 43-year-old man, has been taking diazepam 40 mg/day for 6 months for its muscle relaxant effects after sustaining a dislocated shoulder and other injuries in a car accident. Four days ago, G.S. was unable to refill his prescription for financial reasons. A brief mental status examination reveals mild confusion and irritability. Physically, G.S. is trembling and complains of overall body aching and an upset stomach. His medical history indicates

Table 76-7 Symptoms of Benzodiazepine Withdrawal

| Common | Less Common | Rare |
|-----------------------|----------------|-----------|
| Anxiety | Nausea | Confusion |
| Insomnia | Depression | Delirium |
| Irritability | Ataxia | Psychosis |
| Muscle aches/weakness | Hyperreflexia | Seizures |
| Tremor | Blurred vision | Catatonia |
| Loss of appetite | Fatigue | |

no current medical problems or psychiatric illnesses, and G.S. denies the use of tobacco, alcohol, or other drugs of abuse. How should G.S. be treated?

Because G.S. has not taken his prescribed diazepam for 4 days, it is likely that he is experiencing a withdrawal syndrome from long-term benzodiazepine use. His mental and physical symptoms are consistent with benzodiazepine withdrawal. The benzodiazepine withdrawal syndrome implies some degree of physical dependence, and its onset, duration, and severity can vary according to dose, duration of treatment, speed of withdrawal, and elimination half-life of the agent used.^{54,55} Withdrawal symptoms that follow discontinuation of agents with short half-lives usually appear within 1 to 2 days and may be more short lived, but more intense, than after discontinuation of long-acting benzodiazepines. Withdrawal symptoms usually appear 4 to 7 days after discontinuation of long-acting agents and may last several weeks. Symptoms of benzodiazepine withdrawal, which are listed in Table 76-7, are generally mild when the drug is tapered gradually during discontinuation.⁵⁵ Rarely, serious symptoms such as seizures or psychosis may occur during benzodiazepine withdrawal. Risk factors for seizures include head injury, alcohol dependence, electroencephalogram abnormalities, and use of other drugs that lower the seizure threshold.

Diazepam 10 to 20 mg orally should be administered and repeated within 1 to 2 hours if needed. Resumption of his previous diazepam dosage of 40 mg/day should effectively treat his withdrawal symptoms. However, because his acute injury occurred 6 months ago, it may be desirable to begin discontinuation of the benzodiazepine.

Various dosage reduction regimens have been proposed for benzodiazepine discontinuation. Even when managing withdrawal from low-dose benzodiazepine use, doses should be reduced slowly over 4 to 16 weeks.⁵⁵ The rate of the drug taper should be individualized to the patient, but a general recommendation is a 10% to 25% decrease in the dosage every 1 to 2 weeks. The first half of the benzodiazepine taper (down to 50% of the original dose) is generally easier and can proceed more quickly than the last half of the taper.⁵⁵ In G.S.'s case, the discontinuation period may take several months.

In general, the same benzodiazepine the patient has been taking should be used to manage withdrawal. However, because withdrawal symptoms are more severe during discontinuation of short-acting compared with long-acting benzodiazepines, a long-acting agent can be substituted at an equivalent dosage and then tapered.⁵⁵ In difficult cases, adjunctive medications have been used to ease tolerability of the gradual withdrawal. Carbamazepine (Tegretol) has been effective in attenuating the symptoms of withdrawal from both benzodiazepines and

alcohol. Propranolol decreases some physical withdrawal symptoms (tremor, tachycardia), but does not affect the associated anxiety or decrease the seizure risk.⁵⁵ CBT, combined with gradual drug taper, has also been effective in facilitating successful benzodiazepine discontinuation.

Benzodiazepine Drug Interactions

9. R.G., a 24-year-old female college student, has been taking alprazolam 1 mg TID for treatment of GAD for almost 1 year. She states that alprazolam has been very helpful for her GAD, but complains to her physician that she is feeling especially stressed

lately because she is trying to keep up with extremely difficult schoolwork while making arrangements for her upcoming wedding. She has no medical illnesses, but states that she has suffered from several episodes of vulvovaginal candidiasis since recently beginning oral contraceptives (Ortho-Novum 1/35). R.G. smokes two packs of cigarettes per day and drinks up to 6 cups of coffee per day. Itraconazole, 200 mg QD for 3 days, is prescribed for treatment of recurrent vulvovaginal candidiasis. What potential drug interactions with alprazolam are present in this case?

Reported drug interactions with benzodiazepines are summarized in Table 76-8 and can be divided into two primary

Table 76-8 Drug Interactions With Benzodiazepines

| <i>Interacting Drug(s)</i> | <i>Effect on Object Drug</i> | <i>Clinical Significance/Comments</i> |
|--|--|--|
| Hepatic enzyme inducers: carbamazepine, phenobarbital, phenytoin, and rifampin | Decreased Cps and clinical effects of benzodiazepines | Triazolam and midazolam may be ineffective in patients taking rifampin. ¹⁶³ Carbamazepine greatly decreases the Cps and clinical effects of midazolam, alprazolam, and clonazepam, possibly rendering them ineffective. ^{164,165} |
| Hepatic CYP 3A4 inhibitors: ketoconazole, itraconazole, nefazodone, fluvoxamine, fluoxetine, erythromycin, clarithromycin, cimetidine, oral contraceptives, diltiazem, nelfinavir, indinavir, ritonavir, saquinavir, verapamil | Significantly increased Cps of benzodiazepines that undergo oxidative metabolism (alprazolam, triazolam, diazepam, chlordiazepoxide, clonazepam) | Benzodiazepine dosage reductions may be required because of increased clinical effects such as sedation and psychomotor impairment; effects are greatest on alprazolam, triazolam, and midazolam. ¹⁶⁶ Ketoconazole and itraconazole should be avoided in patients taking alprazolam or triazolam. ¹⁶⁷ Benzodiazepine dosage reductions are recommended when nefazodone, fluoxetine, or fluvoxamine are added to alprazolam, diazepam, or triazolam. ¹⁶⁶ |
| Ritonavir | Initial inhibition of alprazolam and triazolam metabolism, followed by later induction of metabolism | Reduced benzodiazepine dosage is needed initially if ritonavir is added to therapy; a dosage increase may be required later. ¹⁶⁸ |
| Grapefruit juice | Increased Cps of diazepam, alprazolam, and triazolam | Increased benzodiazepine clinical effects (sedation, psychomotor impairment) are possible. ^{166,169} |
| Omeprazole | Increased diazepam Cp and prolonged half-life | Increased benzodiazepine clinical effects (sedation, psychomotor impairment) are possible. ⁵⁶ |
| Antacids, ranitidine | Decreased rate of benzodiazepine absorption | Possible delayed onset of benzodiazepine clinical effects; separation of administration times is recommended. |
| Valproic acid, probenecid Estrogen-containing oral contraceptives | Significantly decreased clearance of lorazepam Decreased Cps of benzodiazepines that undergo glucuronidation (lorazepam, oxazepam, temazepam) and increased Cps of benzodiazepines that undergo oxidative CYP 3A4 metabolism (alprazolam) | Lorazepam dosage reductions may be required. ¹⁷⁰ Decreased or increased clinical effects of benzodiazepines are possible. ^{13,47,56} |
| Central nervous system depressants (alcohol, barbiturates, and opioids) | Increased central nervous system depressant effects of benzodiazepines (sedation, psychomotor impairment) | Avoid use of alcohol with benzodiazepines; exercise caution with use of other depressants. |
| Alprazolam | Increased digoxin Cp | Digoxin toxicity is possible; monitoring of digoxin level and possible digoxin dosage reduction are recommended. ¹⁷¹ |
| Benzodiazepines | Respiratory depression and adverse cardiovascular effects reported on addition of benzodiazepines in several patients taking clozapine Possible decreased efficacy of levodopa in Parkinson disease Increased or decreased efficacy of neuromuscular blocking agents | Caution with benzodiazepine use in patients taking clozapine. Drug interaction is not well established; monitor for possible effect. Drug interaction is not well established; monitor for possible effect. |

types: pharmacodynamic and pharmacokinetic. The most significant pharmacodynamic drug interactions involve other CNS depressants such as alcohol or barbiturates. These combinations can lead to additive CNS and respiratory depressant effects that can be deadly. Important pharmacokinetic drug interactions mainly involve agents that either inhibit or induce benzodiazepine metabolism.⁵⁶ Because the benzodiazepines have a relatively wide margin of safety, elevated plasma levels and/or prolonged elimination half-lives are unlikely to cause serious toxicity. However, they can lead to increased sedative and psychomotor effects, which may be clinically significant in certain cases. Conversely, increased benzodiazepine metabolism by hepatic enzyme inducers may result in medication ineffectiveness. As indicated in Table 76-8, most pharmacokinetic drug interactions with benzodiazepines involve CYP 3A4- or CYP 2C19-mediated mechanisms.

In R.G.'s case, the most important drug interaction is between alprazolam and the newly prescribed antifungal, itraconazole, which is a potent CYP 3A4 inhibitor that can cause a 170% increase in the area under the curve of alprazolam.⁵⁷ Therefore, the dosage of alprazolam should be reduced by about one-third, over several days according to tolerability, during the 3 days R.G. is taking itraconazole.

Estrogen-containing oral contraceptives can also inhibit the CYP 3A4 metabolism of benzodiazepines such as alprazolam, potentially resulting in increased side effects.¹³ Thus, a reduction in the benzodiazepine dosage may be needed when oral contraceptives are added to ongoing benzodiazepine therapy. The clearance of benzodiazepines that undergo glucuronidation (lorazepam, oxazepam, and temazepam) can be accelerated by oral contraceptives, but this interaction is probably clinically insignificant.^{13,47}

Cigarette smoking increases the clearance of some benzodiazepines (clorazepate, lorazepam, oxazepam), but has no effect on others (diazepam, midazolam, chlordiazepoxide).⁵⁸ Overall, the effect of smoking is unpredictable and is most likely to be important in patients who either stop or start smoking while taking a benzodiazepine. R.G. should be urged to quit smoking for the sake of her general health and to prevent substantial risks for serious cardiovascular events that occur in smokers taking oral contraceptives. If R.G. does quit, careful monitoring will be needed to determine whether any alprazolam dosage reduction is necessary.

R.G. should also be encouraged to decrease her coffee consumption because caffeine can increase anxiety and possibly decrease the effectiveness of alprazolam. Caffeine has decreased diazepam concentrations by approximately 22%, but studies with other benzodiazepines are lacking.⁵⁶

Benzodiazepine Use in Pregnancy and Lactation

10. At her clinic visit 8 months later, R.G. is doing very well. She has graduated from college, is happily married, and states that she and her husband have decided to start a family. R.G.'s candida infection did not recur after a single course of itraconazole, and she has successfully quit smoking. She also has discontinued her oral contraceptive and plans to become pregnant soon. R.G. continues to take alprazolam 0.5 mg BID to TID and wonders whether she should also stop taking this drug before she becomes pregnant. What is the teratogenic potential of alprazolam? What alternative treatments are available for the management of R.G.'s anxiety?

Early reports implicated diazepam in causing several birth deformities, including cleft lip and/or cleft palate and limb and digit malformations, but later studies failed to support this association.⁵⁹ Most benzodiazepine anxiolytics are classified as pregnancy category D, indicating that there is some evidence of fetal risk but that the benefits of the medication may outweigh these risks in certain patients.⁵⁹ Available evidence suggests that benzodiazepine use during the first trimester increases the risk for oral clefts by approximately 2.4-fold, but the absolute risk is <1%. Alprazolam and lorazepam have not exhibited teratogenic effects, but it is always advisable to avoid drug use during pregnancy when possible, especially in the first trimester.⁵⁹ In patients such as R.G., the benzodiazepine should be tapered and discontinued before she becomes pregnant. Nondrug treatments for her GAD such as relaxation therapy, meditation, and biofeedback or cognitive therapy may be helpful. If necessary, single or repeated small doses of benzodiazepines during the second and third trimesters are unlikely to have important adverse effects on the baby. Alprazolam and lorazepam are the preferred agents.⁵⁹ Chronic or large doses, especially of long-acting agents, should be avoided because they may accumulate in the fetus. Perinatal sequelae reported in newborns whose mothers took benzodiazepines during pregnancy include withdrawal symptoms, sedation, muscle weakness, hypotonia, apnea, poor feeding, and impaired temperature regulation.⁵⁹

Pregnancies are sometimes unplanned, and the clinical situation of unexpected pregnancy in a woman maintained on benzodiazepines can also arise. The general course of action in such cases is often to discontinue all medications immediately. However, it is unwise to abruptly stop benzodiazepine treatment in someone who has been receiving chronic therapy because the resultant withdrawal syndromes can be detrimental to both mother and child. Benzodiazepine dosages should be tapered as quickly as possible to the lowest dosage necessary and discontinued if possible. The postpartum period is a time of heightened risk for recurrence of anxiety disorders, and new mothers should be monitored carefully for signs of relapse.⁶⁰ Benzodiazepines are excreted readily in breast milk, and it is generally recommended that they be avoided by nursing mothers.⁶¹ (Also see Chapter 46.)

Benzodiazepine Overdose and Use of Flumazenil

11. S.P. is a 17-year-old boy who is brought to the hospital by his mother. S.P. is barely conscious, and his breathing is slow and shallow. His mother states that he "took a whole bottle of diazepam" (5 mg, #30) sometime during the previous night. S.P.'s medical history is significant for a severe head injury sustained from a car accident 8 months ago. He currently takes carbamazepine (Tegretol) 200 mg TID for seizure prophylaxis. S.P.'s mother believes that diazepam is the only drug that he ingested because no other medications are missing. What signs and symptoms are consistent with benzodiazepine overdose? Why is it inappropriate to administer the benzodiazepine antagonist, flumazenil, in this case?

Benzodiazepine overdose is characterized by respiratory and CNS depression, both of which are evident in this case (S.P. is almost unconscious, with slow and shallow breathing). Overdose with benzodiazepines as the sole ingested agent is rarely life threatening, and full recovery is the usual outcome.⁶²

Flumazenil is a benzodiazepine receptor antagonist that is effective in reversing the sedation associated with benzodiazepine intoxication. Its effects on respiratory depression are inconsistent, but improved breathing may occur secondarily to increased consciousness.⁶²

The primary use of flumazenil is in reversing benzodiazepine-induced conscious sedation (primarily with midazolam) in patients who have been sedated for minor surgical or diagnostic procedures. Its use for this purpose is generally safe and effective, and facilitates patient recovery and discharge by decreasing the postprocedural monitoring period.⁶³ Flumazenil is also approved for treating benzodiazepine overdose, but this use is controversial because of potentially serious complications and questions about its cost effectiveness.⁶³ Flumazenil administration does not appear to decrease mortality or length of hospital stay in cases of benzodiazepine overdose; therefore, its use for this purpose has become limited.⁶³

There are several reports of seizures or cardiac arrhythmias (including fatalities) following the administration of flumazenil in comatose patients who had ingested multiple drugs.⁶² These overdoses often included TCAs and carbamazepine. The anticonvulsant effects of benzodiazepines may protect against TCA-induced seizures, and the rapid reversal of their effects with flumazenil removes this protection. Flumazenil is contraindicated in cases of overdose involving TCAs or carbamazepine or overdoses of any agent that decreases the seizure threshold. Toxicology screening and an electrocardiogram (ECG) should be performed before flumazenil is administered. Physical symptoms suggestive of TCA overdose include dry mucous membranes, mydriasis, and motor twitching or rigidity. Flumazenil should also be avoided in patients with increased intracranial pressure or a known history of seizures or head injury, in those who have been receiving chronic benzodiazepine therapy, and in patients with a history of recent illicit drug abuse (cocaine, heroin) because flumazenil can precipitate seizures in these situations. Administration of flumazenil should occur only when acute seizure management measures are available.

Flumazenil reverses benzodiazepine-induced sedation or coma within 1 to 2 minutes after IV administration. The most common side effects include agitation, dizziness, nausea, general discomfort, tearfulness, anxiety, and a sensation of coldness.⁶² Rapid or excessive infusion has been associated with tachycardia and hypertension. The elimination half-life of flumazenil is 41 to 79 minutes, and sedation may recur after 1 to 2 hours, especially when large doses of long-acting benzodiazepines are involved. Repeated flumazenil doses or an IV infusion may be indicated in these cases. Full recovery should be verified (3–4 hours of stable alertness) before patients are discharged after flumazenil administration, and they should be advised to avoid driving or performing other potentially hazardous activities for 24 hours. Flumazenil undergoes extensive hepatic metabolism to inactive metabolites.⁶² Dosage reductions are recommended in patients with liver dysfunction, but flumazenil pharmacokinetics are not altered significantly by gender, age, or renal impairment.

Flumazenil administration is not appropriate in S.P.'s case because of his history of head injury and seizures. Instead, management should involve general supportive measures and mechanical ventilation, if indicated. It is probably too late for use of activated charcoal or gastric lavage in this case because

the ingestion occurred the previous night. These interventions can often be beneficial in managing benzodiazepine overdose, although gastric lavage may provide no extra benefit over administration of activated charcoal alone. A psychiatric evaluation is also indicated in this case to identify and address the reasons for S.P.'s overdose.

Physiological Variables Influencing Benzodiazepines

12. B.G., a 68-year-old man, is brought to the emergency department (ED) by his wife after being involved as the driver in a minor car accident. He has no physical injuries except for several small abrasions caused by the car airbag deployment. However, B.G. appears drowsy, is mildly confused, and has an unsteady gait. A toxicology screen reveals no alcohol or other substances, except for diazepam, which his physician prescribed several months ago. B.G.'s wife states that he has been taking 1 tablet (5 mg) BID or TID and that it has been remarkably effective in improving his mood and anxiety. B.G., who is 5 feet 8 inch tall and weighs 250 lb, is a recovering alcoholic with moderate liver disease caused by years of heavy drinking. He has successfully maintained his sobriety for nearly 2 years. In addition to diazepam, B.G. also occasionally takes OTC omeprazole (Prilosec) and cimetidine (Tagamet) for heartburn. It is determined that B.G. is suffering from adverse effects of diazepam, probably caused by drug accumulation. What factors could be influencing disposition of diazepam in this patient?

Benzodiazepine pharmacokinetics can be affected by various physiological factors, including age, gender, obesity, hepatic and renal disease, and ethnicity (Table 76-9). Several of these factors are present in this case and may have contributed to the accumulation of diazepam with resulting adverse consequences.

B.G.'s age may influence diazepam disposition. Reductions in both CYP 3A4 and CYP 2C19 activity have been reported to occur with aging. The glucuronidation metabolic pathways are minimally affected with age, so no such effect is seen with lorazepam or oxazepam.⁴⁷ Although some studies indicate reduced clearance of various benzodiazepines in the elderly (especially males), others have found comparable rates of benzodiazepine clearance between young and elderly groups. Other factors that may contribute to longer benzodiazepine half-lives in the elderly include decreased hepatic blood flow and increased volumes of distribution of lipid-soluble compounds (due to decreased muscle mass and increased fat); the latter effect can increase a drug's half-life in the absence of any clearance changes. As described in Question 5, older patients are more sensitive to the sedative and psychomotor effects of benzodiazepines. For these reasons, the recommended benzodiazepine dosages for patients older than 65 years are generally one-third to one-half of those used in healthy adults (Table 76-4).

Gender also may influence benzodiazepine clearance.^{13,64} Studies examining gender effects have yielded mixed results, probably because of wide interindividual differences. In elderly patients, some investigators have found lower clearances of clorazepate, diazepam, and alprazolam in men compared with those in women.⁶⁴ Women have been reported to have higher CYP 3A4 and CYP 2C19 activities, which may partially explain these findings. The increased CYP 3A4 activity in women disappears after menopause, which may necessitate the use

Table 76-9 Physiological Factors Influencing Benzodiazepine Pharmacokinetics

| Factor | Physiological and Pharmacokinetic Effects | Clinical Significance/Comments |
|----------------|--|---|
| Aging | Increased elimination half-life due to increased Vd of all benzodiazepines ¹⁷² Decreased clearance of benzodiazepines that undergo oxidative hepatic metabolism (Table 76-6) ¹⁷³ Decreased plasma proteins may lead to increased free fraction of highly protein-bound benzodiazepines (Table 76-6) Decreased gastric acidity may lead to increased rate of benzodiazepine absorption | Lower benzodiazepine dosages, and possibly less frequent dosing intervals, recommended in the elderly Benzodiazepines that undergo glucuronidation (lorazepam, oxazepam) preferred in the elderly Possible increased clinical effects Possible faster onset of clinical effects |
| Gender | Age-related decrease in hepatic oxidative metabolism of benzodiazepines more pronounced in males Increased CYP 3A4 and CYP 2C19 activity in premenopausal women may result in higher clearance of drugs that undergo oxidative metabolism ¹³ Decreased glucuronidation in women may result in slower clearance of benzodiazepines metabolized by conjugation ¹³ Increased Vd in women due to lower lean body mass and increased adipose tissue ¹³ Lower plasma protein binding in women ¹³ | Elderly males may require especially low benzodiazepine dosages Possible decreased plasma benzodiazepine concentrations and shorter duration of clinical effects of oxidatively metabolized agents in premenopausal women Women may have longer elimination half-lives of lorazepam and temazepam and may require less frequent dosing Possible longer elimination half-lives in women, especially the elderly, and greater drug accumulation Clinical significance unknown |
| Obesity | Increased benzodiazepine elimination half-lives due to increased Vd | Increased chance of drug accumulation in obese patients; dosage reductions may be indicated |
| Liver disease | Decreased clearance and increased elimination half-lives of long-acting benzodiazepines and alprazolam in cirrhosis and hepatitis; no changes with oxazepam or triazolam ⁴⁷ Increased elimination half-life of lorazepam in cirrhosis but not acute hepatitis | Avoid long-acting benzodiazepines, or use significantly lower doses to avoid drug accumulation Decreased lorazepam dose or increased dosing interval recommended in cirrhosis |
| Kidney disease | Decreased plasma protein binding may lead to increased free fraction of highly protein-bound benzodiazepines (Table 76-6) ¹⁷⁴ | Dosage reductions may be necessary |
| Ethnicity | Decreased oxidative metabolism (via CYP 2C19) of diazepam and alprazolam in Asians ⁶⁵ | Asians may require lower doses of diazepam, alprazolam, and possibly other benzodiazepines |

CYP, cytochrome P450; Vd, volume of distribution.

of lower benzodiazepine dosages during the postmenopausal period. Women have slower glucuronidation metabolic processes than men, resulting in lower clearance of agents such as temazepam and oxazepam.^{13,47}

Obesity and liver impairment are other physiological factors that are relevant to B.G.'s case. Obesity increases the volume of distribution of benzodiazepines and the extent of accumulation of long-acting agents. Significant changes in the elimination half-lives of lorazepam and oxazepam are not observed in obese patients. Liver dysfunction can reduce benzodiazepine elimination rates and prolong their half-lives, resulting in recommendations for decreased dosages. The pharmacokinetics of oxazepam or triazolam are unaffected by liver disease.

Decreased protein binding of benzodiazepines can occur in patients with renal insufficiency, and this may lead to increased free fractions of highly protein-bound agents. However, no significant changes in clearance or volume of distribution of free drug have been noted. Regarding ethnicity, up to 20% of Asians are CYP 2C19 poor metabolizers. Decreased clearance of a variety of CYP 2C19 substrates, including diazepam, has been reported in Asian subjects.⁶⁵

In summary, the physiological factors that can alter benzodiazepine disposition in B.G. are his age, obesity, male gender, and liver disease. Accumulation of diazepam due to these combined effects probably led to his mental status changes. In addition to these factors, cimetidine and omeprazole can both

significantly impair the metabolism of diazepam, resulting in decreased clearance and increased side effects (Table 76-8).⁵⁶

If continued benzodiazepine therapy is deemed necessary for B.G., lorazepam or oxazepam would be preferred agents because they would be least affected by aging, obesity, liver disease, or drug interactions. Benzodiazepine dosage equivalencies, which are based on relative potencies, can be used to determine an equivalent dose for the selected agent (Table 76-4). However, these equivalencies are inexact, and dosing conversions should take patient variables and usual dosage ranges into consideration. For example, B.G. had been taking 10 to 15 mg/day of diazepam, so the calculated equivalent lorazepam dosage is 2 to 3 mg/day. Because of his age, a somewhat lower initial dose of 0.5 to 1.0 mg BID would be indicated, accompanied by careful monitoring for adverse effects or withdrawal symptoms. However, switching to a nonbenzodiazepine agent should be considered because this may be a better treatment option for B.G.

Buspiron Therapy

13. Several days after recovery from diazepam intoxication, B.G. expresses a desire to discontinue benzodiazepine use. He is being criticized by his fellow Alcoholics Anonymous program members for taking a drug associated with dependency. The

decision is made to switch B.G. from diazepam to buspirone. How does the clinical profile of buspirone compare with that of the benzodiazepines?

Buspirone was the first agent marketed as an anxiolytic that lacks CNS depressant effects. In contrast to the benzodiazepines, it produces no significant sedation, cognitive or psychomotor impairment, or respiratory depression, and it lacks muscle relaxant and anticonvulsant effects.³⁷ Buspirone is generally well tolerated, and side effects, when they occur, include mild nausea, dizziness, headache, and initial nervousness.⁶⁶ Some patients may experience mild drowsiness or fatigue on initiation of therapy. Low sedation potential and lack of cognitive and respiratory depressant effects make buspirone useful in older patients who may have a variety of chronic medical conditions. Unlike many antidepressants, buspirone does not adversely affect sexual functioning and has actually improved sexual functioning in some patients with GAD.³⁶ Buspirone has minimal potential for abuse and is not classified as a controlled substance. It does not produce physical dependence or withdrawal syndromes on discontinuation, even after long-term therapy.^{37,67} It also does not interact with alcohol or other CNS depressants and is relatively safe in overdose.³⁷

Buspirone is as effective as benzodiazepines such as alprazolam, oxazepam, lorazepam, diazepam, and clorazepate in the treatment of GAD.⁶⁶ Its superiority over placebo has been reported in many, but not all, trials. For example, in a controlled comparison with extended-release venlafaxine, buspirone was no more effective than placebo in treating GAD.⁶⁸ Like antidepressants, buspirone is more effective than benzodiazepines in treating the cognitive symptoms of anxiety. However, the anxiolytic effects of buspirone have a more gradual onset than that of benzodiazepines. Initial effects are observed within the first 7 to 10 days, but 3 to 4 weeks may be needed for optimal results. Buspirone must be taken on an ongoing basis if it is effective and the drug should not be taken intermittently or “as needed.”

Switching From Benzodiazepine to Buspirone Therapy

14. How should B.G. be switched from benzodiazepine to buspirone therapy?

Because buspirone has no CNS depressant effects and is not cross-tolerant with the benzodiazepines, it is not effective in preventing or treating benzodiazepine withdrawal. Thus, when patients are being converted from benzodiazepine to buspirone therapy, the benzodiazepine must be discontinued gradually. Because it takes several weeks for full therapeutic effects of buspirone to occur, it can be initiated before the benzodiazepine taper begins. This may indirectly ease benzodiazepine withdrawal by providing extra anxiolytic coverage during the benzodiazepine taper period.⁶⁹

Buspirone is completely absorbed, but it undergoes extensive first-pass metabolism, which reduces its absolute bioavailability to approximately 5%.³⁷ Administration with food may significantly increase bioavailability by decreasing the first-pass effect. Buspirone has an active metabolite, 1-pyrimidinylpiperazine (1-PP), which is present in much higher concentrations than buspirone at therapeutic doses. 1-PP acts on the noradrenergic system rather than serotonin and functions as an α_2 -adrenergic antagonist. Some of the side effects of buspirone, such as nervousness, are attributed to this active

Table 76-10 Buspirone Drug Interactions

| Interacting Drug(s) | Clinical Significance/Comments |
|--|--|
| CYP 3A4 inhibitors: nefazodone, fluoxetine, fluvoxamine, erythromycin, itraconazole, ketoconazole, diltiazem, verapamil, grapefruit juice, and ritonavir | Significant increases in buspirone Cp have been reported with these agents, but adverse clinical effects are not always apparent. |
| Rifampin | Buspirone dosage reductions are recommended when coadministered with erythromycin, fluvoxamine, nefazodone, fluoxetine, or itraconazole. |
| Haloperidol | Highly significant decreases in buspirone Cp; avoid concurrent use. Buspirone may increase haloperidol Cp, but one study found no interaction. |
| Monoamine oxidase inhibitors | Possible serotonin syndrome; avoid concurrent use. |

Cp, plasma concentration; CYP, cytochrome P450.

metabolite.^{37,70} The mean elimination half-life of buspirone is short, approximately 2 to 3 hours, but 1-PP is longer acting.

The clearance of buspirone is significantly reduced in patients with kidney or liver disease, but there is little change in side effects or tolerability.³⁷ Nevertheless, it is recommended that lower buspirone dosages be used in patients with compromised renal or hepatic function and that it be avoided in cases of severe impairment. Buspirone pharmacokinetics are not significantly affected by age or gender; therefore, no dosage adjustments are needed in the elderly.³⁷

Important drug interactions with buspirone are summarized in Table 76-10.³⁷ Buspirone is metabolized by CYP 3A4, and coadministration of CYP 3A4 inhibitors, including grapefruit juice, can result in significant increases in buspirone levels. In many cases, the half-life of buspirone remained unchanged, suggesting that these interactions are mainly due to inhibition of CYP 3A4-mediated first-pass metabolism in the gut. Because of buspirone's extremely wide margin of safety and tolerability, even very large increases in its plasma levels may be clinically insignificant. Some hepatic enzyme inducers can render buspirone ineffective due to large increases in buspirone clearance. Buspirone should be avoided in patients taking MAOIs due to the risk of serotonin syndrome. Buspirone does not appear to enhance the CNS depressant effects of alcohol.

It was previously believed that patients who had been treated with benzodiazepines in the past did not respond as well to buspirone as benzodiazepine-naive patients. It is now evident that buspirone can provide benefit in this population as long as the benzodiazepine is tapered slowly enough to prevent withdrawal.¹⁴ B.G. has been taking diazepam for several months and needs to be withdrawn gradually over a period of at least several weeks. B.G. can be started on buspirone at this time. The usual recommended starting dosage of buspirone is 15 mg/day given in two to three divided doses, but a lower dosage (10 mg/day) is indicated in B.G. because of

his liver disease. Twice-daily dosing is preferred to facilitate compliance and is comparable in efficacy and tolerability to three-times-daily dosing.⁷¹ The daily dosage may be increased in 5-mg/day increments every 3 to 4 days. Optimal anxiolytic doses generally range from 20 to 30 mg/day, with 60 mg/day being the manufacturer's recommended maximum. There are no specific guidelines for adjusting dosages in patients with liver impairment; therefore, dosage titrations in B.G. should be made slowly, according to his response and side effects. "Dividose" 15-mg tablets are available; these tablets are scored and notched, so they may be broken into 5-, 7.5-, or 10-mg doses. A 30-mg "Dividose" tablet is also available, as well as generic buspirone products.

PANIC DISORDER

Diagnostic Criteria

The DSM-IV-TR criteria for panic disorder are presented in Table 76-11.¹ The hallmark characteristic of panic disorder is the occurrence of sudden and distinct panic attacks, which are marked by a tremendous wave of symptoms and feelings listed in Table 76-11. At least four of these symptoms are required to fulfill criteria for a panic attack, and the term "limited symptom attack" refers to those events involving less than four symptoms. Three types of panic attacks have been defined with regard to the context in which they occur: unexpected or uncued panic attacks (the attack is not associated with a situational trigger); situationally bound panic attacks (the attacks invariably occur on exposure to a situational trigger); and situationally

predisposed panic attacks (the attacks are more likely to, but do not invariably, occur on exposure to a situational trigger).¹

The DSM-IV-TR criteria for panic disorder require the occurrence of at least two unexpected or uncued panic attacks that are followed by persistent worry or concern about having another panic attack or a significant change in behavior related to the attacks. Although panic attacks are the hallmark symptom of panic disorder, their occurrence does not always indicate panic disorder.¹ Depressive disorders and other anxiety disorders can also be associated with occasional panic attacks. Situationally bound panic attacks are more characteristic of specific phobias or social anxiety disorder than panic disorder, and situationally predisposed panic attacks may occur in either panic or phobic disorders. Nocturnal panic attacks, which awaken a person from sleep, are almost always indicative of panic disorder. Because panic attacks occur unpredictably, they often lead to generalized anxiety or constant fear of sudden attacks. Two subtypes of panic disorder have been identified: without agoraphobia or with agoraphobia.¹ *Agoraphobia* refers to a fear of being in situations from which escape might be difficult or embarrassing in the event of a panic attack. Mild-to-moderate agoraphobia involves selective avoidance of certain places or situations such as shopping malls, theaters, grocery stores, elevators, and driving alone. Some people may be unable to go anywhere unless accompanied by a companion. In severe cases of agoraphobia, the sufferer may become completely housebound.

Epidemiology and Clinical Course

Approximately 28% of the general population experiences a single isolated panic attack at some time in their lives.⁷² Approximately 10% to 12% of persons experience recurrent panic attacks that do not fulfill the diagnostic criteria for panic disorder; however, these persons can still be significantly affected. True panic disorder is estimated to affect 1% to 2% of Americans at some time in their lives.^{7,72} Women are affected two to three times more often than men and are more likely to develop agoraphobia.¹³ The onset of panic disorder usually occurs in the late teens to mid-30s, and it is rarely seen in the elderly.⁷ Most persons report onset of the disorder at some particularly stressful time in their life; in women, this often includes the prenatal and postpartum periods.^{13,60}

Panic disorder is accompanied by marked degrees of psychiatric comorbidity; 50% to 60% of patients suffer a major depressive episode at some point. Other common comorbid conditions include social anxiety disorder, GAD, OCD, PTSD, personality disorders, alcohol abuse, and bipolar disorder.^{1,72,73} Patients with comorbid disorders have more severe symptoms, show slower and poorer response to treatments, are less likely to experience full remission, and have a greater suicide risk (particularly when depression or substance abuse are present) than those with panic disorder alone.^{74,75} Panic disorder causes significant functional disability in areas of work, family relationships, and overall quality of life.^{7,76}

Panic disorder is associated with very high rates of health care service utilization.⁷⁵ Because of the physical manifestations of panic attacks, repeated ED visits and costly diagnostic tests are common.⁷⁷ About 25% to 32% of patients making ED visits related to chest pain actually have panic disorder. The poor recognition of panic disorder in primary care settings

Table 76-11 Diagnostic Criteria for Panic Disorder

1. Presence of at least two unexpected panic attacks, characterized by at least four of the following symptoms, which develop abruptly and reach a peak within 10 minutes:
 - a. Palpitations, pounding heart, or accelerated heart rate
 - b. Sweating
 - c. Trembling or shaking
 - d. Sensations of shortness of breath or smothering
 - e. Feeling of choking
 - f. Chest pain or discomfort
 - g. Nausea or abdominal distress
 - h. Feeling dizzy, unsteady, lightheaded, or faint
 - i. Derealization or depersonalization
 - j. Fear of losing control or going crazy
 - k. Fear of dying
 - l. Numbness or tingling sensations
 - m. Chills or hot flushes
2. At least one of the attacks has been followed by at least one of the following symptoms for a duration of at least 1 month:
 - a. Persistent concern about having another attack
 - b. Worry about the implications or consequences of the attack
 - c. Significant change in behavior because of the attack
3. Symptoms are not due to the direct effects of a medication, substance, or general medical condition
4. Panic attacks are not better accounted for by another psychiatric or anxiety disorder (e.g., phobias, obsessive-compulsive disorder)
5. May occur with or without agoraphobia (see text)

further increases use of medical services. Panic disorder is the underlying cause of symptoms in an estimated 10% to 30% of patients referred to specialty vestibular, respiratory, or neurology clinics, and up to 60% of those referred for cardiology consultation.¹ The vast majority of patients with panic disorder do not complain of feeling anxious and report only physical symptoms, such as chest pain, GI problems, headache, dizziness, and shortness of breath, which contributes to misdiagnosis.⁷⁷ It is not uncommon for patients to have been in the health care system for up to 10 years before they are correctly diagnosed.

The long-term course of panic disorder is highly variable.¹ Some patients experience episodic periods of remission and relapse, whereas others suffer almost continuously. Follow-up studies conducted several years after treatment reveal that approximately one-third of patients are still well and in remission, 40% to 50% of patients are improved but experience persistent symptoms, and another 20% to 30% are unchanged or worse.^{1,78}

Etiology and Pathophysiology

There is substantial evidence that panic disorder is biologically based. A neuroanatomical model for panic disorder has been proposed in which the anxiety and fear response to threatening stimuli are mediated through the amygdala.^{5,79} Various projections from the amygdala, including the hypothalamus and the LC, trigger autonomic and neuroendocrine responses that result in anxiety and panic attacks. Patients with panic disorder have a heightened anxiety sensitivity (fear of anxiety-related sensations), and a variety of substances and situations are capable of triggering the neural fear network that activates the anxiety and panic response.⁷⁹ Acute panic attacks are believed to be caused by dysregulated firing in the LC as described previously (see Neurobiology of Anxiety section), and hyperresponsiveness of the NE system may be an underlying cause for panic disorder.⁸⁰

Experimental provocation of panic attacks is an important component of panic disorder research. Administration of certain substances induces panic attacks rather consistently in persons with panic disorder, but not in normal healthy subjects.^{5,79} These substances include caffeine, noradrenaline, sodium lactate, hypertonic sodium chloride, high concentration carbon dioxide (CO₂), yohimbine, flumazenil, and CCK-B agonists. Administration of effective medication treatments for panic disorder blocks the effects of these panic-inducing substances. Challenge studies such as these provide evidence for possible abnormalities in GABA-A receptor, NE, 5-HT, and CCK functioning that underlie panic disorders. Decreased GABA-A benzodiazepine binding sites, abnormal regulation of neuroactive steroids that modulate GABA-A receptors, hyperactivation of the HPA axis, and CCK-B receptor gene polymorphism are among the findings associated with panic disorder.^{73,81}

Hypersensitivity to 35% CO₂ inhalation, as evidenced by precipitation of panic attacks, robustly identifies patients with panic disorder as well as those with other anxiety disorders such as OCD and GAD.⁷⁹ This association is specific enough that CO₂ hypersensitivity is considered a biological trait marker, at least for a subset of panic disorder patients. Effective treatment of panic disorder with medication significantly decreases

the sensitivity to CO₂ inhalation.⁸² Brain imaging studies also have demonstrated abnormal patterns of cerebral glucose metabolism in certain brain areas in patients with panic disorder.⁷⁹

A familial occurrence of panic disorder has been noted; first-degree relatives of individuals with panic disorder have an 8- to 21-fold greater risk of panic disorder than relatives of unaffected persons.^{1,15} Genetic and environmental influences both contribute to this familial pattern. The inherited component is believed to involve heightened anxiety sensitivity, which confers increased vulnerability for panic disorder. Heightened anxiety sensitivity in panic disorder has been associated with “catastrophic cognitions,” in which harmless normal physical sensations are misinterpreted as being dangerous and cause fear.⁷⁸ These negative cognitive patterns are often unconscious and may be integral in potentiating recurrent panic attacks in a biologically predisposed individual.

Developmental experiences may also be important in the etiology of panic disorder. Several studies have shown that distressing childhood events such as separation from parents and abuse are associated with markedly increased risks of developing panic disorder later in life.⁷⁹ Behavioral inhibition during childhood, characterized by excessive fear and avoidance of novel stimuli, is also extremely common in panic disorder patients. Obviously, no one biological abnormality can explain panic disorder, and further research is needed to define the complex interplay of the various pathophysiological, genetic, and cognitive findings in this illness.

Treatment of Panic Disorder

Approximately 70% to 90% of patients with panic disorder can experience substantial relief with currently available treatments, which include both pharmacologic therapies and CBTs.^{1,73} Medications are most beneficial for reducing panic attacks initially, and their effects on phobic avoidance generally occur later. Nonpharmacologic therapies are especially effective in reducing avoidance behaviors. The two classes of first-line medication treatments for panic disorder are the SSRIs and the benzodiazepines, and these agents are often used in combination.⁷³ Several TCA and MAOI antidepressants are also effective in treating panic disorder, but are reserved as second- or third-line options because of their clinical disadvantages compared with SSRIs. The heightened anxiety sensitivity common in panic disorder makes patients especially vulnerable to certain initial antidepressant side effects, such as anxiety and agitation. This is seen with most antidepressants, including SSRIs and TCAs, and is the reason why lower than usual starting doses of antidepressants are recommended in patients with panic disorder.

Selective Serotonin Reuptake Inhibitors

The SSRIs, paroxetine, sertraline, and fluoxetine, as well as the SNRI, venlafaxine, are FDA approved for treating panic disorder. There is strong evidence that other SSRIs (fluvoxamine, citalopram, escitalopram) are also effective.^{21,30} Several large controlled trials have demonstrated the superiority of paroxetine, sertraline, and fluoxetine over placebo in reducing the frequency of panic attacks, anticipatory anxiety, and associated depression.^{83,84} Although low starting dosages are

recommended (10 mg/day for paroxetine, 25 mg/day for sertraline, 5–10 mg/day for fluoxetine) to minimize side effects, higher doses are usually required for response. The recommended target dosage range of paroxetine for panic disorder is 20 to 40 mg/day.⁸⁵ Fixed-dose sertraline studies showed that the efficacy of 50, 100, and 200 mg/day doses was comparable; there was no consistent dose–response effect.⁸⁶ Therefore, 50 mg/day should be targeted as the minimum dose of sertraline that will be needed when treating panic disorder; higher doses may sometimes be required. The target dose of fluoxetine in panic disorder is 20 mg/day, and most patients are unlikely to require higher doses.⁸³ For citalopram, a 20- to 30-mg/day dosage range has been associated with better efficacy than 40 to 60 mg/day, whereas doses of 10 to 15 mg/day were ineffective.²⁴ The initial dose of venlafaxine XR should be 37.5 mg/day.

Response to SSRIs and other antidepressants in panic disorder occurs gradually, over the course of several weeks. Reduced frequency of panic attacks usually begins within 4 to 6 weeks. A trial period of 10 to 12 weeks should be allowed to fully assess response, and continued improvements may be seen over a treatment period of 6 months or longer.^{73,78} Overall, the SSRIs are as effective as the TCAs in treating panic disorder, but they are better tolerated and may have a slightly faster onset of therapeutic effects.^{78,87}

Benzodiazepines

The benzodiazepines, alprazolam and clonazepam, are FDA approved for treating panic disorder and are the most extensively studied agents of this class.^{77,78,88} As previously described, new formulations of these agents (Xanax XR, Klonopin wafer) have been introduced specifically for use in panic disorder. Lorazepam is another high-potency agent that appears to be as effective as alprazolam and clonazepam.⁷⁸ Other benzodiazepines such as diazepam were previously believed to be ineffective in treating panic disorder, but they can be effective if sufficiently high doses are used.⁷⁸

Optimal benzodiazepine dosing is an important issue in panic disorder because these individuals often need higher doses for response than patients with other anxiety disorders.⁸⁹ This may be related to reduced sensitivity of benzodiazepine binding sites in panic disorder.¹⁸ An alprazolam dosage range of 4 to 6 mg/day is effective for most panic disorder patients, but others may require up to 10 mg/day for optimal response. When clonazepam is used, the minimum effective dosage appears to be 1 mg/day, and most panic disorder patients do well in the range of 1 to 3 mg/day.

One problem with alprazolam use in panic disorder is that many patients experience breakthrough anxiety or panic attacks 3 to 5 hours after taking a dose because of its relatively short duration of action.⁷⁸ The total daily alprazolam dose usually needs to be taken in three or four, and sometimes five, divided doses to minimize this effect. The extended-release alprazolam formulation (Xanax XR) was developed to address this problem.⁴⁶ Xanax XR can be dosed once or twice daily and is associated with minimal interdose anxiety. It may have a lower abuse liability than immediate-release alprazolam, but it is more expensive than generic alprazolam. Clonazepam is longer acting than standard-release alprazolam, and a twice-daily dosing schedule is usually sufficient. A switch to either

clonazepam or extended-release alprazolam can be beneficial when breakthrough anxiety is a problem with immediate-release alprazolam. Extended-release alprazolam is more expensive than generic alprazolam or clonazepam and probably offers no clinical advantage in most cases. Panic disorder patients are especially sensitive to benzodiazepine withdrawal effects. For this reason, clonazepam may be preferred over alprazolam in many panic disorder patients.⁸⁹

Tricyclic Antidepressants, Monoamine Oxidase Inhibitors, and Other Antidepressants

TCAs were the first medications widely used in the treatment of panic disorder. Imipramine (Tofranil) and clomipramine (Anafranil) are as effective as alprazolam, but are less well tolerated.^{74,85} One trial with desipramine (Norpramin) found that it did not significantly differ from placebo.⁷⁸ Well-conducted studies involving other TCAs are lacking. As indicated, especially low starting dosages of TCAs (10 mg/day) are needed to minimize initial anxiety-like side effects. Even so, many patients discontinue therapy because of poor tolerability. Imipramine should be slowly titrated up to the recommended target dosage of 100 mg/day.

Clomipramine appears to be more effective than other TCAs for panic disorder, perhaps because of its greater serotonergic effects.⁹⁰ The possibility of a therapeutic dosage window for clomipramine in panic disorder has been suggested, with dosages >80 mg/day being associated with a reduced likelihood of response.^{90,91} Clomipramine seems to be most effective within the dosage range of 60 to 80 mg/day, which is relatively low but reasonably well tolerated. Patients who do not respond to clomipramine doses in this range are unlikely to benefit from further dose increases.

Among the MAOIs, phenelzine (Nardil) is often heralded as being remarkably effective in the treatment of panic disorder, but this claim is based on studies that were conducted more than two decades ago in patients who might not meet the current diagnostic criteria for panic disorder.⁷⁸ No recent MAOI studies are available to assess phenelzine's efficacy within the context of current diagnostic and treatment standards. Phenelzine may be extremely effective, but it is generally an option of last resort for treatment-refractory cases because of the many clinical disadvantages of MAOIs relative to other antidepressants (see Chapter 79). Preliminary reports suggest that other newer antidepressants, including venlafaxine, nefazodone, mirtazapine, and escitalopram, may also be beneficial in treating panic disorder.^{30,78,89} These agents may be useful in patients who do not respond to SSRI therapy.

Miscellaneous Agents

Bupropion (Wellbutrin), buspirone, and trazodone are generally ineffective for panic disorder.⁷⁸ Trials of propranolol and clonidine have yielded mixed, but largely negative results.⁷⁸ None of these agents are considered appropriate treatment options in panic disorder, although buspirone and pindolol have been effective in augmenting response to SSRI therapy.^{89,92} Other medications that are reportedly effective in treating panic disorder include the anticonvulsants carbamazepine, oxcarbazepine, tiagabine, and valproate; the calcium channel blocker verapamil; the antipsychotic agent olanzapine; the antihistamine chlorpheniramine; the serotonin-3 receptor antagonist,

ondansetron; and inositol.^{78,89} More information is needed before any of these can be recommended for the treatment of panic disorder.

Nonpharmacologic Treatments

CBTs, including exposure treatment and relaxation training, are also established as being effective in panic disorder.^{73,78} The cognitive theory of panic disorder is based on the observed heightened anxiety sensitivity in these patients and asserts that physical anxiety sensations are misinterpreted as being serious or life threatening and that these fears trigger a cycle of further worsening anxiety symptoms that finally progress to a panic attack. Reversing the cognitive component of this vicious cycle is an integral part of cognitive therapy and is important in producing lasting therapeutic effects of treatment.⁷⁸ Breathing retraining and exposure to fear cues are key components of behavioral therapy.

Some studies have found medications to be superior to CBTs in the treatment of panic disorder, whereas others report opposite results.^{73,78} CBTs reportedly result in benefits that are maintained longer after therapy is stopped and have also been effective in easing benzodiazepine discontinuation. Combining medication with CBTs can be useful, especially in patients with severe agoraphobia or those who only partially respond to either treatment modality used alone.^{89,93}

Clinical Presentation and Differential Diagnosis of Panic Disorder

15. S.K., a 24-year-old female graduate student, presents to the ED complaining of chest pain, difficulty breathing, dizziness, and nausea. She describes feeling “as if my head is going off in space and I am outside my body.” She states that she has been under extreme stress lately with examinations, working too much, and constantly fighting with her roommate. S.K. fears that she has had a heart attack or stroke brought on by her stressful life. S.K. recently visited her family physician for the same symptoms; however, a complete physical examination and laboratory workup yielded no abnormalities, and she was advised to try to relax. She states that her first “attack” occurred out of the blue about 5 months ago while she was studying in the library and that she can never predict when they will occur. Since then, her symptoms have become more severe and frequent, and she has started skipping classes for fear they will return. S.K. denies any drug or alcohol use but states that she has suffered from depression in the past and was hospitalized for one severe episode 2 years ago. An ECG is performed and found to be normal. The physician’s diagnosis is panic disorder with mild agoraphobia. What clinical features of panic disorder does S.K. display, and what are the important factors in the differential diagnosis of panic disorder?

S.K. exhibits many typical characteristics of panic disorder. As illustrated in this case, the first panic attack typically occurs without warning while the person is involved in a normal everyday activity and lasts 10 to 30 minutes. Panic attacks are extremely terrifying and usually leave the sufferer feeling anxious and convinced that something is medically wrong. As with S.K., it is not uncommon for persons to make ED visits following or during panic attacks, believing they have had a heart attack or other serious event. Unfortunately, panic disorder is often not recognized in primary care settings, and no medical

cause for the symptoms can be identified. Faced with findings that they are apparently healthy, persons may make repeated ED visits and consult different doctors and specialists in an attempt to uncover a physical explanation for their frightening symptoms.

S.K. exhibits the following target symptoms of panic disorder: chest pain, shortness of breath, dizziness, abdominal distress, and depersonalization (“my head is going off in space and I am outside my body”). Mild agoraphobia is present because she has started limiting class attendance because of her panic attacks. Other factors consistent with a diagnosis of panic disorder include her young age, female gender, lack of abnormal physical findings, and absence of possible precipitating substances. This case also illustrates the association between onset of panic disorder and stressful life events, its common association with depression, and the frequent lack of recognition of panic disorder in primary care settings.

Because different substances or medical conditions can cause severe anxiety and panic, it is necessary to rule out these potential causes for panic disorder symptoms.⁷⁷ Notable triggers of panic attacks include caffeine, alcohol, nicotine, non-prescription cold preparations, cannabis, amphetamines, and cocaine.⁷⁷ Any medication that causes anxiety as a side effect can potentially precipitate panic attacks in predisposed individuals (Table 76-2). Medical illnesses that can cause panic attacks include hyperthyroidism, hyperparathyroidism, pheochromocytoma, seizure disorders, and cardiac arrhythmias. Panic disorder is also associated with higher-than-expected comorbidities with hypertension, mitral valve prolapse, asthma, coronary artery disease, peptic ulcer disease, Parkinson disease, chronic pain syndromes, primary biliary cirrhosis, and irritable bowel syndrome.⁷⁸ In patients with comorbid medical conditions, panic disorder can worsen the physical illness.

Panic attacks can also occur in other anxiety disorders. However, in these cases, the panic attacks usually occur on exposure to a feared object or situation (in phobic disorders), an object of obsession (in OCD), or a stimulus associated with a traumatic stressor (in PTSD). S.K. reports that her panic attacks occur unexpectedly, and situationally bound or predisposed attacks are not evident; therefore, the features are consistent with panic disorder.

Treatment Selection for Panic Disorder, SSRI Dosing Issues, and Combination SSRI-Benzodiazepine Therapy

16. S.K. is referred to a psychiatrist who decides to initiate treatment with fluoxetine 20 mg Q AM. Three days later, S.K. calls the doctor complaining that her anxiety and panic attacks have greatly increased since she started taking fluoxetine. The psychiatrist prescribes alprazolam 0.5 mg (tablets) and instructs S.K. to take 1 tablet as needed for the anxiety. What factors should be considered in the selection of an initial medication treatment for panic disorder? Why is the prescribed treatment for S.K. inappropriate?

An SSRI, with or without concurrent benzodiazepine therapy, is appropriate first-line treatment for most panic disorder patients.^{88,89} In patients such as S.K. who have a history of depression, SSRIs may also help prevent depressive relapse. Patients with severe or distressing symptoms usually require

concurrent benzodiazepine therapy, which provides quick relief from anxiety and panic attacks until the therapeutic effects of SSRI occur. At that time, usually after several weeks, the benzodiazepine can be gradually discontinued. An SSRI-benzodiazepine combination is currently the most commonly prescribed initial treatment for panic disorder and is superior in efficacy to initial monotherapy.⁴² Although benzodiazepines are generally avoided in patients with a history of substance abuse, use of low doses for a limited time period may be appropriate for some such patients with disabling symptoms, as long as there is no current substance (especially alcohol) abuse.^{54,89} Because of the levels of distress and impairment caused by S.K.'s panic disorder, combined SSRI-benzodiazepine therapy would have been the preferred initial treatment. Scheduled benzodiazepine dosing is preferred over as-needed dosing schedule during initial therapy, so that panic attacks are prevented.⁸⁹ Because panic attacks generally last less than 30 minutes, they have usually passed by the time an as-needed benzodiazepine dose can take effect.

In choosing among SSRIs for the treatment of panic disorder, fluoxetine may be more likely to be anxiety provoking in some patients, and there is less published evidence to support its use than for sertraline or paroxetine.²¹ If fluoxetine is used, very low initial doses (5–10 mg/day) should be used; in S.K.'s case, the prescribed 20-mg/day starting dose was much too high. Also, scheduled versus as-needed benzodiazepine dosing would have been preferred. After 2 to 4 weeks, the benzodiazepine can be gradually discontinued while the SSRI therapy is continued and gradually titrated to the target effective dose. The potential for drug interactions must also be kept in mind when SSRI-benzodiazepine combinations are used because certain SSRIs can inhibit benzodiazepine metabolism, leading to increased benzodiazepine side effects (see Benzodiazepine Drug Interactions section and Table 76-8).

Patient Counseling Information

Patients such as S.K. who are beginning SSRI therapy for the treatment of panic disorder should be counseled about possible increased anxiety during the first 1 or 2 weeks of treatment, as well as other common SSRI side effects, including nausea, headache, and either insomnia or sedation. Because these are dose-related effects, patients should inform their clinician of any problems, and a dosage reduction may be indicated. These adverse effects usually subside after 1 to 3 weeks of continued treatment. It is also important to inform patients that it may take several weeks before beneficial effects of antidepressant treatment are seen, and 6 to 12 weeks or longer may be required for full response. Patients receiving initial benzodiazepine therapy should be counseled about their relatively quick onset of effects to provide anxiolytic coverage during the initial weeks of SSRI therapy, as well as the likely limited duration of benzodiazepine therapy. Other pertinent counseling information for benzodiazepine treatment should also be included (see Question 5). The desired goals of therapy and likely duration of treatment should also be explained (see Question 18). Providing information about the nature of panic disorder, including reassurance that panic attacks are not life threatening, is also important. Many clinicians recommend that patients keep a "panic diary" in which they record frequency of panic attacks, along with symptoms experienced during attacks.

Clinical Assessment and Goals of Therapy

17. S.K. refuses to continue taking fluoxetine, so paroxetine is prescribed instead. After 1 week of paroxetine therapy at the initial dosage of 10 mg/day, S.K. is tolerating the medication well. The plan is to gradually increase the paroxetine to 40 mg/day over the next several weeks. S.K. is also taking alprazolam, 0.5 mg BID to TID. What are the desired goals of treatment in this case, and how can S.K.'s response to treatment be assessed?

Five domains in panic disorder have been identified in which treatment outcomes should be assessed: frequency and severity of panic attacks, anticipatory anxiety, phobic avoidance behaviors, overall well-being, and illness-related disability in various areas (work, school, family).⁷⁸ The treatment goals in this case are first to stop S.K.'s panic attacks, then to reduce her anticipatory anxiety, followed by reversal of phobic avoidance.⁴⁰ These outcomes should enable her to attend class regularly and, secondarily, improve her overall functioning and quality of life.

Several different instruments have been used to assess outcomes of treatment in panic disorder.⁴⁰ In addition to the panic diary, others include the Fear Questionnaire, the Panic Appraisal Inventory, and the Panic Disorder Severity Scale. The latter is currently considered by many experts to be the most useful because it evaluates outcomes in all five identified target domains of panic disorder.^{40,78}

Course and Duration of Therapy

18. After 3 months of paroxetine therapy, S.K. reports that she has had no panic attacks in the past month and that functioning has improved dramatically. She is currently taking 40 mg/day of paroxetine (two 20-mg tablets) and gradually stopped taking the alprazolam 3 to 4 weeks ago. S.K. reveals that she is going to class, making good grades, getting along with her roommate, and dating. S.K. is experiencing no significant side effects from paroxetine but complains that it is expensive. She wonders how long she should continue taking it since she is doing so well. What is the recommended duration of treatment for panic disorder?

Long-term medication trials in panic disorder support the recommendation that treatment should continue for at least 6 to 12 months after acute response.^{78,94} The benefits of maintenance pharmacotherapy in preventing relapse are well documented. Maintenance treatment gives patients time to resume normal lifestyles and to re-establish daily activities following acute cessation of panic attacks.

In this case, S.K.'s current paroxetine dosage of 40 mg/day is appropriate because this is within the effective dosage range for panic disorder. Paroxetine therapy should be continued at the current dosage for 3 to 6 more months. Paroxetine is available as a generic and the use of a 40-mg paroxetine tablet instead of two 20-mg tablets each day can decrease the drug expense. After a successful period of full remission, a trial of medication discontinuation may be attempted to determine whether continued treatment is necessary. Medication should not be stopped in patients who are experiencing stressful life events or substantial residual problems in any of the five domains. When medication is discontinued, it should be withdrawn gradually over several months, regardless of which medication class is

involved. Because of the devastating impact that panic disorder can have, reinstatement of drug treatment is indicated if relapse occurs. Long-term treatment with antidepressants, and benzodiazepines if necessary, is generally successful in maintaining treatment benefits without detrimental effects or dosage escalations. Panic disorder is accepted as an appropriate indication for long-term benzodiazepine therapy if necessary.⁸⁸

SOCIAL ANXIETY DISORDER AND SPECIFIC PHOBIAS

Classification and Diagnosis of Phobic Disorders

The DSM-IV-TR category of phobic disorders includes two primary types: specific phobia (formerly called *simple phobia*) and social phobia (also called *social anxiety disorder*).¹ The term *social anxiety disorder* is more commonly used and is the term used in this text. These disorders involve fears that are excessive or unreasonable and lead to avoidance behavior to minimize anxiety. The DSM-IV-TR criteria for phobic disorders are presented in Table 76-12.¹ The main difference between specific phobias and social anxiety disorder is that the former involves fear and avoidance of specific objects or situations, whereas the latter involves social situations.

Social Anxiety Disorder

In social anxiety disorder, there is an intense irrational fear of scrutiny or evaluation by others because of concerns about humiliation or being made to appear ridiculous.¹ The *generalized* type of social anxiety disorder refers to cases in which fears relate to most social situations (e.g., fear of general social interactions, speaking to people, attending social gatherings, dating), whereas the *nongeneralized* type involves more specific phobias.¹ Public speaking is by far the most common

nongeneralized type; others include speaking to strangers, eating in public, and using public restrooms. A defining feature of either type is that the fears and anxiety are confined to social situations, and patients are usually symptom free when alone. The most common symptoms seen in social anxiety disorder include blushing, muscle twitching, and stuttering, in addition to other typical symptoms of anxiety. Panic attacks may also occur in either specific phobia or social anxiety disorder on exposure to the feared object or situation. However, social anxiety disorder is differentiated from panic disorder and agoraphobia in that it involves the fear of humiliation and social scrutiny, rather than the fear of having a panic attack.

The DSM-IV-TR excludes a diagnosis of social anxiety disorder if the person fears public embarrassment due to some physical or medical condition. However, this criterion is controversial because it excludes social anxiety disorder that is due to certain socially stigmatizing conditions, such as Parkinson's disease, stuttering, obesity, and physical disfigurement or deformity.¹ These cases are sometimes referred to as *secondary social anxiety disorder*.

Specific Phobias

Specific phobias are classified into five subtypes: animal type (snakes, dogs, spiders), natural environment type (heights, water, storms), blood-injection type (blood, injury, medical procedures), situational type (flying, bridges, elevators), and others.¹ Exposure to the feared circumstance produces intense anxiety, sometimes to the degree of panic attacks, and avoidance of the stimuli is common. Significant impairment of functioning or marked distress must be present for a diagnosis of specific phobia to be warranted. For example, fear of flying might constitute specific phobia in a person whose job requires airplane travel, but it would not impair functioning in someone who never has occasion to fly.

Management of specific phobias has traditionally involved mere avoidance of the stimuli. Medications generally are not considered beneficial, but CBTs involving repeated exposure to the feared situation and systemic desensitization are very effective. Computer-generated, virtual environment desensitization (virtual reality) therapy has been used successfully to reduce fears associated with flying and heights. Benzodiazepines can not only effectively reduce anxiety associated with a phobic trigger, but they can also interfere with the efficacy of exposure therapies.

Social Anxiety Disorder

Epidemiology and Clinical Course

The lifetime prevalence of social anxiety disorder is approximately 7%, which is lower than previous estimates of 13% to 14%.⁷ The male:female prevalence ratio is approximately 2:3. Social anxiety disorder usually begins early in life, with a mean onset between ages 14 and 16 years.⁹⁵ More than 50% of patients are affected before adolescence, and a history of shyness and behavioral inhibition throughout childhood is common.⁹⁵ Unless effectively treated, the clinical course is often that of a chronic, unremitting, and lifelong disorder. Only 35% of patients recovered over the 10-year follow-up in one recent study.⁹⁶

Table 76-12 Diagnostic Criteria for Phobic Disorders

Social Anxiety Disorder (Social Phobia)

1. Marked and constant fear of one or more social situations in which the person is exposed to unfamiliar people or possible scrutiny by others and the person fears humiliation or embarrassment
2. Exposure to the situation provokes an immediate anxiety response
3. Person realizes the fear is excessive or unreasonable (not required in children)
4. Feared situation is avoided or endured with intense anxiety or distress
5. Fear or avoidance significantly interferes with the person's normal routine or activities or causes marked distress
6. In individuals younger than 18 years of age, the duration of the fear is at least 6 months
7. Anxiety or phobic avoidance are not better accounted for by another psychiatric disorder (e.g., fear of having a panic attack, obsessions that accompany OCD, trauma related to PTSD)

Specific Phobia

1. Marked and persistent fear of a specific object or situation that is excessive or unreasonable
2. Other criteria (2–7) listed previously for social anxiety disorder

OCD, obsessive-compulsive disorder; PTSD, posttraumatic stress disorder.

Comorbidity and Clinical Significance

Because social anxiety disorder usually begins during the teenage years, it can seriously interfere with development of normal social skills and abilities to form interpersonal relationships.⁹⁷ This can lead to functional disabilities that may persist for a lifetime. Social anxiety disorder can interfere with achievement of full academic and career potentials and is associated with unemployment, lower levels of education, and dependence on public financial support systems.⁷ Persons with social anxiety disorder are less likely to marry, and more than half report moderate-to-severe impairments in their abilities to carry out ordinary daily activities.⁹⁷

Comorbidity in social anxiety disorder is high, with an estimated 70% to 80% of individuals having at least one other psychiatric disorder in their lifetime.^{1,95,96} Common comorbid conditions include simple phobia, major depression, GAD, panic disorder, body dysmorphic disorder, and alcohol abuse. Because of its early onset, social anxiety disorder usually precedes the development of comorbid disorders. Alcohol is commonly used to decrease anxiety in social situations. The risk of suicide attempts is very high, especially in those with both social anxiety disorder and another comorbid psychiatric illness.⁷

Etiology and Pathophysiology

Social anxiety disorder is known to be a familial disease, but the relative contributions of genetic versus environmental influences have not been differentiated.¹⁵ Early factors that may predispose to its development include anxious behavior modeling in parents and parental overprotection.¹ Shyness in children, which is associated with later development of social anxiety disorder, has been linked to a specific genetic polymorphism of the serotonin transporter promoter region.⁹⁸

Biological studies suggest that the generalized and nongeneralized types of social anxiety disorder may have different underlying pathophysiologies. Nongeneralized social anxiety disorder may mainly involve disturbances in noradrenergic system functioning, whereas there is substantial evidence for dopaminergic and serotonergic dysfunction in the generalized form.^{99,100} Abnormally low dopamine neurotransmission in generalized social anxiety disorder is supported by findings of significantly decreased dopamine-2 receptor binding; markedly reduced dopamine transporter densities; low levels of the dopamine metabolite, homovanillic acid; high rates of social anxiety disorder in persons who later develop Parkinson disease; and several reports of emergence of social anxiety disorder during antipsychotic treatment.^{99,100} Social anxiety disorder appears to be unique among the anxiety disorders in its association with dopamine system abnormalities. Pharmacologic challenge studies suggest that serotonin type-2 receptors are hypersensitive in patients with social anxiety disorder, and neuroimaging studies have found specific neural circuits to be activated in this illness.⁹⁹

Treatment of Social Anxiety Disorder

Early detection and treatment of social anxiety disorder are vital in reducing its lifelong functional consequences and may prevent development of comorbid disorders. Because of the very nature of the disorder, some sufferers are reluctant to seek treatment. Those who do seek help, even in psychiatric settings, are rarely diagnosed and treated appropriately.⁹⁵ In the

past few years, pharmacotherapy has become first-line therapy for social anxiety disorder. Nonpharmacologic treatments also can be very beneficial, and use of the two modalities may be complementary.

SELECTIVE SEROTONIN REUPTAKE INHIBITORS

As with many other anxiety disorders, SSRIs are considered the primary treatment option for most patients with social anxiety disorder.⁹⁵ Paroxetine, sertraline, and the SNRI, venlafaxine XR, have received FDA approval for this treatment indication.¹⁰¹ Fluoxetine, fluvoxamine CR, citalopram, and escitalopram have also demonstrated efficacy in controlled clinical trials.^{101–103}

Unlike patients with GAD and panic disorder, those with social anxiety disorder can usually tolerate standard antidepressant starting doses. Target effective SSRI doses for social anxiety disorder are within the normal antidepressant dosage ranges. The one fixed-dose study of paroxetine in social anxiety disorder found no overall difference in efficacy between 20, 40, and 60 mg/day.¹⁰⁴ Although some individuals may respond better to higher dosages, adequate time should be allowed at 20 mg/day before the dosage is increased. Response to SSRI treatment occurs gradually, and an adequate medication trial to assess response should last at least 8 to 10 weeks. Many who experience minimal response at week 8 may show good response at week 12, and improvements have been found to continue throughout 16 weeks of treatment.¹⁰⁵

OTHER ANTIDEPRESSANTS

The MAOIs phenelzine and tranylcypromine have also demonstrated marked efficacy for social anxiety disorder but are reserved for SSRI nonresponders.^{95,101} Before the advent of SSRIs, phenelzine was considered the mainstay of pharmacotherapy for social anxiety disorder. The typically effective dosage ranges are 60 to 90 mg/day for phenelzine and 30 to 60 mg/day for tranylcypromine.

The reversible monoamine oxidase-A inhibitors, moclobemide and brofaromine, which are currently unavailable in the United States, have shown mixed efficacy results in controlled studies.⁹⁵ Case reports and/or open studies suggest that other antidepressants, including nefazodone and bupropion, may be useful in treating social anxiety disorder, but controlled trials are needed to define their roles.⁹⁵ Imipramine is ineffective for social anxiety disorder, and TCAs are not among the recommended treatment options.^{95,101}

BENZODIAZEPINES

The high-potency benzodiazepines, clonazepam and alprazolam, may also be useful in some patients with social anxiety disorder. Clonazepam was markedly efficacious in one controlled study, whereas alprazolam showed only modest efficacy over placebo.^{95,101} The usual effective dosage ranges are 1 to 3 mg/day for clonazepam and 1 to 6 mg/day for alprazolam. In contrast to the antidepressants, benzodiazepines have a quicker onset of therapeutic effects and can also be used on an as-needed basis prior to participation in stressful social situations. However, benzodiazepines can reduce the therapeutic effects of exposure therapy. Other disadvantages of the benzodiazepines include their lack of efficacy for many common comorbid psychiatric disorders, potential for abuse and dependence, and a potentially dangerous interaction with alcohol.

Benzodiazepines are generally considered second-line therapy for social anxiety disorder, but in clinical practice they are commonly used on an as-needed basis in combination with SSRI therapy.¹⁰¹

β-BLOCKERS AND OTHER MISCELLANEOUS AGENTS

β-Adrenergic receptor blockers reduce peripheral autonomic symptoms of anxiety, but they are not effective in treating generalized social anxiety disorder.⁹⁵ However, they are useful for nongeneralized social phobia involving performance-related situations. Propranolol and atenolol are the two recommended agents and can be used on an as-needed basis to reduce performance anxiety. Small doses (10–80 mg of propranolol or 25–50 mg of atenolol) of either agent may be administered 1 to 2 hours before the performance to decrease symptoms such as tremors, palpitations, and blushing. A test dose should be tried before the actual occasion to assess medication tolerability. β-Blockers are not recommended as monotherapy for the treatment of generalized social anxiety disorder.¹⁰¹ Various other medications, including pregabalin, gabapentin, tiagabine, and levetiracetam have also been reported to be effective in the treatment of social anxiety disorder, but they are considered second-line treatment.¹⁰¹

NONPHARMACOLOGIC TREATMENTS

Several studies have demonstrated CBTs to be comparable to medications in the treatment of social anxiety disorder.¹⁰⁶ The cognitive therapy component is aimed at changing the negative thought patterns, such as expectations of performing poorly and overconcern about negative evaluation by others.¹⁰⁶ These negative expectations lead to increased apprehension and anxiety, which further impair performance abilities. The behavioral therapy component, as in other anxiety disorders, involves repeated exposure to the feared social situations and practice at performing in those situations. Cognitive-behavioral group therapies are especially beneficial in social anxiety disorder because group members can practice social interactions with one another. Although medications may work faster, CBTs are believed to result in longer-lasting treatment gains.¹⁰⁶ Social skills training can also be beneficial in improving interpersonal communication skills.

Clinical Presentation of Social Anxiety Disorder

19. S.H., an 18-year-old man, is brought for psychiatric consultation by his mother who complains that her son is extremely shy. S.H. was referred to the psychiatrist by his primary care physician, who reports that S.H. is physically healthy. S.H.'s mother states that he is a very bright young man who made straight As in high school despite frequent absenteeism, but he has no friends and has never been on a date. S.H.'s mother says that during high school, S.H. never attended any school social functions and spent all of his time in his room working on his computer. On graduation from high school, he received a full scholarship to a community college but refused to go. When questioned by the psychiatrist, S.H.'s face turns bright red, and his voice shakes when he speaks. S.H. admits that his behavior is not normal but says that he is afraid that he might “do something stupid” when he is around people and becomes extremely embarrassed when he has to talk to anyone. He has wanted to ask a certain girl for a date for 3 years but experienced severe anxiety attacks on the few occasions he has tried to approach her. S.H. is afraid of being turned down and believes that no girl would ever want to date someone

like himself. The psychiatrist's diagnosis is social anxiety disorder. What clinical features of social anxiety disorder are present in S.H.?

S.H. exhibits many characteristic features of the generalized type of social anxiety disorder. S.H. admits that he does not like being around people for fear of embarrassment, and he generally avoids social situations, which are classic traits of social anxiety disorder. His symptoms of blushing and shaking voice are also common in social anxiety disorder, as well as other typical anxiety symptoms such as palpitations, trembling, sweating, tense muscles, dry throat, hot/cold sensations, and a sinking feeling in the stomach. S.H. also displays hypersensitivity to rejection and low self-esteem, and he realizes that his behavior and fears are unreasonable. These symptoms and S.H.'s young age are consistent with a diagnosis of social anxiety disorder.

S.H.'s case illustrates the substantial disability that can result from this illness. S.H.'s anxiety disorder has deprived him of normal social development, making friends, dating, participating in social functions, and pursuit of higher education. Future impairments throughout S.H.'s life are likely to be significant unless his anxiety is treated successfully.

Treatment Selection for Social Anxiety Disorder

20. The physician decides to treat S.H. with medication and prescribes sertraline, 50 mg Q AM. Is the prescribed pharmacotherapy appropriate in this case?

Because S.H.'s generalized social anxiety disorder is severely impacting his life, medication treatment is indicated. The SSRIs are first-line therapy for treating social anxiety disorder, and sertraline is a good choice because it is FDA approved for this indication. Although not applicable in this case, sertraline is also effective for many of the other psychiatric disorders that are commonly seen in patients with social anxiety disorder. The sertraline starting dose of 50 mg/day is appropriate for S.H., and 50-mg increment dosage increases can be made every 4 weeks according to response, up to a maximum of 200 mg/day. Signs of response may be seen within 2 to 4 weeks, but 8 to 12 weeks is usually required for optimal results. If available, CBT may also be combined with pharmacotherapy for S.H.

Goals and Duration of Treatment

21. What are the goals of treatment in this case, and how can S.H.'s response to treatment be objectively assessed? How long should effective therapy be continued?

Three principle domains of treatment outcomes have been defined for social anxiety disorder: symptoms, functionality, and overall well-being.⁴⁰ It is recommended that efficacy assessments examine all three of these areas because even if all anxiety symptoms disappear, treatment is not really clinically significant unless functioning also improves. The clinician-rated Liebowitz Social Anxiety Scale (LSAS) and the patient-rated Sheehan Disability Scale can be used for measuring improvements in the symptom and functional ability domains, respectively.⁴⁰ In S.H.'s case, the desired outcomes of treatment include reducing his fear and avoidance of social situations, enabling him to comfortably interact socially and attend college, and improving his overall quality of life.

Several studies have examined relapse rates after double-blind discontinuation of effective treatment in social anxiety disorder.^{101,105,106} Based on their results, relapse appears to be very common. Long-term studies have shown that sertraline, paroxetine, escitalopram, and clonazepam prevent relapse of social anxiety disorder during continuation treatment. Therefore, pharmacotherapy should be continued for at least 1 year after response.^{95,101} After that time, a trial of gradual medication discontinuation may be attempted, accompanied by close monitoring for signs of relapse.

POSTTRAUMATIC STRESS DISORDER AND ACUTE STRESS DISORDER

Diagnostic Criteria

PTSD and acute stress disorder occur in people who have experienced a severely distressing traumatic event. These disorders are characterized by symptoms of intrusive re-experiencing, avoidance features, emotional numbing, and symptoms of autonomic hyperarousal.¹ PTSD has been recognized most commonly in war veterans and was referred to as “shell shock” after World War I. However, PTSD also occurs in persons exposed to events such as natural disasters, serious accidents, criminal assault, rape, physical or sexual abuse, and political victimization (refugees, concentration camp survivors, hostages). The trauma does not have to involve physical injury to the PTSD victim. Witnessing someone else being injured or killed, being diagnosed with a life-threatening illness, and experiencing the unexpected death of a loved one are common types of trauma that may lead to PTSD.¹

The DSM-IV-TR criteria for PTSD are presented in Table 76-13. PTSD is classified as having either an acute or delayed (after 6 months) onset in relation to the trauma; the latter is extremely rare.¹ Symptoms must persist for at least 1 month to meet the criteria for PTSD. *Acute stress disorder* is a separate diagnostic category in the DSM-IV-TR and refers to cases in which symptoms last <1 month (but at least 2 days).¹ It involves many of the same clinical features as PTSD, but there is an additional requirement of peritraumatic dissociative symptoms (numbing, derealization, depersonalization, amnesia, feeling dazed). In both PTSD and acute stress disorder, the symptoms must be severe enough to interfere with some aspect of functioning.

Epidemiology and Clinical Course

PTSD was previously believed to affect approximately 1% of the general population, but recent studies reveal a much higher lifetime prevalence of approximately 7% to 8%.¹⁰⁷ PTSD is twice as common in women than in men, although overall men are exposed to trauma more often than women.¹⁰⁷ Rates of PTSD are expected to rise as the frequency of traumatic events throughout the world continues to increase. An estimated 80% to 90% of individuals in the United States today will experience at least one event during their lifetime that is traumatic enough to lead to PTSD.¹⁰⁷

Most people who are exposed to a traumatic event do not develop PTSD; approximately 90% of individuals experience a normal acute stress response to trauma and fully recover.¹⁰⁷ Risk factors for the development of PTSD include experiencing assaultive violence, more severe and chronic traumas, a

Table 76-13 Diagnostic Criteria for Posttraumatic Stress Disorder

1. Person has experienced a traumatic event in which the individual witnessed, experienced, or was confronted with actual or threatened death, or serious injury to self or others, and to which the person responded with intense fear, helplessness, or horror
2. Traumatic event is re-experienced persistently in some way (e.g., dreams, nightmares, flashbacks, recurrent thoughts or images), or intense distress is experienced on exposure to stimuli associated with the traumatic event
3. Persistent avoidance of stimuli associated with the event and numbing of general responsiveness involving at least three of the following:
 - a. Efforts to avoid thoughts, feelings, or conversations related to the trauma
 - b. Efforts to avoid people, places, or activities that are reminders of the trauma
 - c. Impaired recall of the traumatic event
 - d. Decreased interest or participation in activities
 - e. Feelings of detachment
 - f. Restricted range of affect
 - g. Sense of foreshortened future
4. Persistent symptoms of increased arousal (not present before the event) that include at least two of the following:
 - a. Sleep disturbances
 - b. Irritability or anger outbursts
 - c. Difficulty concentrating
 - d. Hypervigilance
 - e. Exaggerated startle response
5. Duration of the disturbance (2–4) of at least 1 month
6. Disturbance causes significant impairment in some aspect of daily functioning

Adapted from reference 1, with permission. Copyright © 2000 American Psychiatric Association.

history of depressive or anxiety disorders, and experiencing dissociative or other intense symptoms during or soon after the trauma.^{107,108} Previous exposure to trauma also increases the risk of developing PTSD after later traumas, and survivors of childhood sexual or physical abuse have been found to be especially vulnerable.^{108,109} Among people exposed to various traumatic events, the overall conditional risks for PTSD are reported to be 6% for males and 13% for females.¹⁰⁷ In general, traumas involving personal assault (e.g., rape, combat) are associated with much higher conditional risks of developing PTSD than other types of trauma.

Most PTSD patients also suffer from other disorders at some point in their lifetime, including major depression, GAD, panic disorder, phobic disorders, and alcohol or other substance abuse.¹⁰⁷ Overall, 79% to 88% of those with PTSD have another lifetime psychiatric disorder, most commonly depression or substance abuse.^{109–111} High rates of substance abuse and dependence in patients with PTSD are related to attempts to self-medicate PTSD symptoms.¹¹¹ The suicide risk in PTSD is high and comparable to that seen in major depression.¹¹² PTSD causes significant functional disability and has been associated with school failure, teenage pregnancy, unemployment, marital instability, legal problems, and impaired performance in the workplace.¹¹²

The course of PTSD is highly variable. Most patients who meet criteria for PTSD 1 month after trauma show spontaneous recovery within 6 to 9 months.¹¹⁰ PTSD continues for

years in a significant minority, estimated at 10% to 25%, and some sufferers experience a lifelong course of illness. The overall median duration of PTSD is reported to be approximately 2 years, but has been found to be four times longer in women (4 years) than in men (1 year).¹¹⁰

Etiology and Pathophysiology

The effects of stress on the brain have been a topic of intensive research. Apparently, psychological trauma, especially that which occurs early in life or is chronic in duration, can cause persistent changes in various aspects of brain functioning and in neurobiological responses to stress.¹¹³ Evidence of altered NE, 5-HT, glutaminergic, GABA system, neuroendocrine, substance P, and opioid system functioning has been found in PTSD.^{114–116} Stress-induced hyperactivity of central noradrenergic systems is believed to lead to the generalized anxiety and autonomic hyperarousal associated with PTSD.¹¹⁵ These symptoms may also be related to a supersensitivity of the HPA axis system in PTSD because affected patients have a blunted ACTH response to CRH and decreased basal cortisol levels, as well as increased numbers of glucocorticoid receptors.¹¹⁴ A subset of PTSD patients appear to have an abnormally sensitized 5-HT system, and these patients may represent a neurobiologically distinct subgroup.¹¹⁶

Numerous studies have found reduced hippocampal volumes in PTSD, which is a brain area involved in learning and memory that appears to be particularly vulnerable to the damaging effects of stress.¹¹³ Neuropsychological tests show that reduced hippocampal volume is associated with cognitive and memory impairments in PTSD patients.¹¹² Functional neuroimaging studies in PTSD have found excessive activation of the amygdala and certain other brain areas in response to trauma-related stimuli.^{113,117} Thus, the neurobiological consequences of stress and trauma result in both structural and functional changes in the brain. Genetic factors may also play a role in influencing vulnerability to the damaging effects of stress.¹¹⁷

Treatment of Posttraumatic Stress Disorder

Both medications and CBTs are useful in treating PTSD. Non-pharmacologic therapies alone may be appropriate for initial treatment of mild PTSD cases, but pharmacotherapy, either alone or in combination with psychological therapies, is usually recommended for patients with moderate or severe illness.^{108,109,112} When assessing various treatment options for PTSD, it is important to consider effects on all three core symptom clusters (re-experiencing/intrusive symptoms, avoidance/emotional numbing, hyperarousal symptoms). Not all PTSD treatments are effective for these major symptom domains.

The preferred first-line medications in PTSD are the SSRIs, but various other antidepressants may also be useful. Response to pharmacotherapy occurs very gradually, over 8 to 12 weeks or longer. Partial response at 12 weeks of treatment may be followed by full remission after several more months of therapy; therefore, an adequate time period should be allowed to fully determine response to a particular medication. However, lack of improvement after 4 weeks of therapy is unlikely to be

effective with medication continuation, so alternate treatment strategies should be tried in these cases.¹¹⁸ Early treatment during the first 3 months that follow a trauma may prevent the development of chronic PTSD.¹⁰⁹

Selective Serotonin Reuptake Inhibitors

Sertraline and paroxetine are currently the only FDA-approved medications for treating PTSD. Large controlled studies have demonstrated that both agents are very effective and superior to placebo in reducing all three PTSD symptom clusters (re-experiencing, avoidance/numbing, and autonomic hyperarousal).¹¹⁸ They also have beneficial effects on depression and general anxiety symptoms and have been associated with improvements in overall functioning as well as quality of life.¹¹⁸ Fluoxetine also appears to be effective in treating PTSD in some patients, although study results have been mixed and a lack of significant effects on avoidance/numbing symptoms has been noted.¹¹⁸ Male war veterans with long-standing combat-related PTSD have been noted to respond poorly to fluoxetine, compared with females and civilians, but this observation may apply to treatment of PTSD in general.^{119,120} Citalopram, fluvoxamine, and the SNRI venlafaxine have shown efficacy in the treatment of PTSD in open trials but randomized, double-blind, placebo-controlled studies have yielded negative results, possibly due to the small numbers of subjects studied.¹¹⁸

Other Antidepressants

Several open studies and case reports suggest that nefazodone, mirtazapine, and bupropion are also effective in treating the core symptoms of PTSD.¹²¹ Although supporting evidence for these antidepressants is not as strong as for sertraline and paroxetine, they may be considered appropriate alternatives to the SSRIs in certain patients. The TCAs amitriptyline and imipramine and the MAOI phenelzine have also been found to be effective for PTSD in controlled trials, but these agents are generally not recommended because of their poor tolerability and safety profiles.¹⁰⁹ Because of the relatively high risk of suicide in PTSD, TCAs can be especially dangerous in this population.

Miscellaneous Agents

Various other medications have been used successfully in limited numbers of PTSD cases. The anticonvulsants carbamazepine, valproate, topiramate, tiagabine, gabapentin, and lamotrigine have been markedly effective in certain patients and can be particularly useful for reducing irritability, impulsivity, and angry or violent outbursts.^{121,122} Anticonvulsant therapy can also be effective for intrusive, re-experiencing, and hyperarousal symptoms. Atypical antipsychotic agents have been used effectively to treat PTSD-related psychotic symptoms (risperidone, clozapine, olanzapine) and sleep disturbances, but they do not appear to be useful for treating core PTSD symptoms.¹²¹ The α_1 -adrenergic antagonist, prazosin, and the α_2 -adrenergic agonist, clonidine, were reported to decrease nightmares and other core symptoms in patients with PTSD.¹²³ Benzodiazepines are generally ineffective in treating PTSD, although they may be useful in managing sleep disturbances during the early weeks following trauma. Their use in PTSD should be limited to short-term therapy because chronic use may have detrimental effects.¹²⁴

Nonpharmacologic Treatments

Various types of psychosocial therapies have been used in the treatment of PTSD, including anxiety management training to help patients cope with stress.¹²⁴ Cognitive therapies seem to be most effective for symptoms of demoralization, guilt, and shame, whereas exposure therapies are better for reducing intrusive thoughts, flashbacks, and avoidance behaviors. Both cognitive and exposure therapies have been shown to be markedly and comparably effective in controlled PTSD trials, but exposure is probably more critical for optimal results.^{109,112}

Clinical Presentation of Posttraumatic Stress Disorder

22. D.D. is a 42-year-old woman who was attacked and raped in the driveway of her home as she was getting out of her car 1 month ago. She did not seek medical treatment at the time and waited several days before reporting the incident to anyone, including her family. She presents to her physician complaining that she cannot sleep and that she is irritable, anxious, and depressed. When asked about any recent stressors in her life, she finally tells her doctor about the rape. D.D. has no history of psychiatric illness, admits that her symptoms have appeared since the attack, and says that she has never had any psychiatric problems until now. She states that she has nightly nightmares and becomes extremely anxious every time she comes home and gets out of her car at night (which she avoids doing when possible). She is startled when the phone rings or when someone approaches her unexpectedly, and she literally freezes if she sees a man who bears any physical resemblance to her attacker. D.D. also states that memories of the rape often flash through her mind for no reason, although she tries hard not to think about it. The assailant has not been caught, and D.D. feels extremely guilty for not promptly reporting the crime. Her symptoms are interfering significantly with her ability to work at her job and have put a strain on her marriage. What clinical features of PTSD does D.D. display?

Persons with PTSD often present with nonspecific complaints indicative of a generalized anxiety, depression, or substance use disorder. They may not realize or want to reveal an association between their symptoms and the trauma they have experienced. Careful evaluation by the clinician is required to elicit a pattern suggestive of PTSD. D.D. displays many target symptoms of PTSD, including re-experiencing (nightmares, recurrent memories), avoidance of the activity that reminds her of the trauma, and symptoms of increased arousal (sleep difficulties, irritability, exaggerated startle response). In addition, she is experiencing feelings of depression, distress, marital problems, and impairment in occupational functioning as a result of her symptoms. The lack of any previous psychiatric illness combined with the temporal relationship between the attack and her symptoms support the presence of PTSD as opposed to another anxiety or depressive disorder. Because her trauma occurred 1 month ago, her condition would be classified as acute-onset PTSD.

Treatment Selection and SSRI Dosing

23. What factors are important in the selection of an initial treatment for D.D.?

Because D.D. is exhibiting moderate-to-severe PTSD symptoms, pharmacotherapy is indicated. Medication treatment can also be combined with CBTs if they are available, but nonpharmacologic therapies alone are generally reserved for patients with mild symptoms. An SSRI is the preferred initial medication treatment for most patients.¹¹⁸ Sertraline is an appropriate choice of treatment in this case and is FDA approved for PTSD. Low initial SSRI doses are recommended in PTSD, so sertraline can be started at 25 mg/day and gradually increased to the target dosage range of 100 to 150 mg/day, according to response and tolerability.¹²¹ Regarding other SSRIs, studies suggest that a paroxetine dose of 20 to 40 mg/day is sufficient for most PTSD patients; higher doses have not been associated with better response.¹²¹ Persistent sleep complaints during the first month after a traumatic experience may predispose the patient to chronic PTSD, so management of sleep disturbances is an important component of initial PTSD treatment.¹²³ Low-dose adjunctive trazodone (25–50 mg at bedtime) would be a good choice in this case because it is a safe, effective, and an inexpensive sedative agent.

Even in the absence of formal CBTs, certain aspects of patient and family education are vital to the successful treatment of PTSD.^{108,109} Providing information about the nature and prognosis of PTSD are important. The patient should be encouraged to talk with family and friends about the trauma because repeated retelling of the traumatic event is therapeutic and can help facilitate recovery. Significant others need to understand the importance of listening and of being tolerant of the patient's emotional reaction and persistent preoccupation with his or her experience. Peer support groups are widely available and can be very beneficial in the recovery of trauma victims. Patients should be advised to try not to avoid things that remind them of the trauma, but rather to expose themselves to these situations as often as possible.

Clinical Assessment and Goals of Therapy

24. What are the goals of treatment in this case, and how can D.D.'s symptoms be objectively assessed?

The first goal of treatment of PTSD is to reduce the core symptoms of re-experiencing, avoidance, numbing, and hyperarousal. In D.D.'s case, these target symptoms include nightmares, intrusive memories, avoidance behaviors, irritability, startling easily, and sleep difficulties. Improvements should begin within the first 2 weeks and gradually continue over the course of 2 to 3 months. Secondary goals in this case include improving D.D.'s stress resilience, decreasing her work- and marriage-related disability, and improving her overall quality of life. Other general treatment goals in PTSD include decreasing detrimental behaviors (use of alcohol or substances, risky activities, violence) and treating any comorbid psychiatric conditions that may be present.

Several different rating scales have been developed to assess response to treatments in PTSD.⁴⁰ The most commonly used clinician-rated scales are the Clinician Administered PTSD Scale (CAPS) and the Treatment Outcome PTSD Scale (TOPS-8). CAPS is most often used in clinical PTSD trials, whereas TOPS-8 is shorter and easier to use in clinical practice. Patient-rated scales for evaluating PTSD symptoms include the Davidson Trauma Scale and the Impact of Events Scale. The Sheehan

Disability Scale is often used to assess functional impairment due to PTSD.

Course and Duration of Treatment

Good treatment response in PTSD is more likely to occur when treatment is begun within 3 months of the trauma.^{109,112} There is no well-established definition of response in PTSD, but a decrease in symptoms by 30% to 50%, along with substantial functional improvement, is commonly used in clinical trials. Full recovery during treatment of PTSD is fairly uncommon, and partial responders to either medication or psychosocial therapies may benefit from adding another treatment modality. When an initial SSRI trial is ineffective, the patient may be switched to another SSRI or one of the other antidepressants that have been effectively used in PTSD.¹²¹ Partial responders may benefit from the addition of a second medication, depending on which core symptoms predominate (see Pharmacotherapy of Posttraumatic Stress Disorder section).

For patients who respond, treatment should be continued for an additional 6 to 12 months for acute cases (when symptoms were present <3 months before treatment) and 12 to 24 months for chronic cases (when symptoms lasted >3 months before treatment).¹⁰⁹ Long-term SSRI treatment can prevent relapse of PTSD, especially in those who show good response during the first 3 months of therapy.¹²⁴ When pharmacotherapy is discontinued, it should be withdrawn gradually over 1 to 3 months.

OBSESSIVE-COMPULSIVE DISORDER

Diagnostic Criteria

The DSM-IV-TR criteria for OCD are presented in Table 76-14.¹ OCD is characterized by recurrent obsessions or compulsions, which are severe enough to be distressing, consume at least 1 hour a day, or significantly interfere with some aspect of functioning. An *obsession* is an intrusive or recurrent thought, image, or impulse that incites anxiety in the person and that cannot be ignored or suppressed voluntarily. The most common obsessions include germs and contamination; pathological doubt; somatic concerns; need for order and symmetry; and religious, aggressive, or sexual thoughts.^{125,126} A *compulsion* is a behavior or ritual that is performed in a repetitive or stereotypic way that is designed to reduce anxiety associated with obsessions or to prevent some future event or situation. However, the compulsions are not actually connected to the obsessions in any realistic way. Frequent compulsions include checking, cleaning, arranging symmetrically, ordering, hoarding, counting, and needing to ask questions or confess.¹²⁶ The obsessions and compulsions are unpleasant and disturbing to the sufferer and are not associated with pleasure or gratification. This feature distinguishes OCD from certain other detrimental behaviors (excessive gambling or shopping), which are often described as being “compulsive.” Adults with OCD usually realize that their rituals are senseless and excessive at some point, but children may not make this distinction.¹

OCD is a clinically heterogeneous disorder involving a wide range of symptoms. Five separate OCD symptom dimensions have been defined: symmetry obsessions and repeating, counting, and ordering compulsions; contamination obsessions and

Table 76-14 Diagnostic Criteria for Obsessive-Compulsive Disorder

1. Presence of either obsessions or compulsions:
 - Obsessions:*
 - (a) Recurrent and persistent ideas or thoughts are experienced, at some time during the disturbance, as intrusive and senseless
 - (b) Thoughts, impulses, or images are not simply excessive worries about real life problems
 - (c) Person attempts to ignore or neutralize the ideas or thoughts with some other thought or action
 - (d) Person realizes the obsessions are the product of his or her own mind
 - Compulsions:*
 - (a) Repetitive and intentional behaviors or mental acts are performed in response to the obsession or according to rigid rules
 - (b) Behavior is designed to prevent or reduce distress or to prevent some dreaded event; however, the activity is clearly excessive and unrealistic to neutralize the situation
2. At some point during the disturbance, the person realizes that the obsessions and compulsions are excessive or unreasonable (not necessary in children)
3. Obsessions or compulsions cause marked distress, are time consuming (>1 hr/day), or significantly interfere with some aspect of daily functioning
4. Content of the symptoms is not related to another psychiatric disorder, and the disturbance is not due to the direct effects of a substance, medication, or general medical illness

Adapted from reference 1, with permission. Copyright © 2000 American Psychiatric Association.

cleaning compulsions; hoarding obsessions and compulsions; aggressive obsessions and checking compulsions; and sexual/religious obsessions and related compulsions. Although specific symptoms in an individual may change over time, they usually remain within the same dimension.¹²⁶

Epidemiology and Clinical Course

OCD once was believed to be a rare disorder, but epidemiologic studies reveal that it affects between 2% and 3% of the worldwide population.^{1,127} The overall lifetime prevalence is slightly higher in women, but men tend to have an earlier onset of illness (between ages 6 and 15 years) than women (between ages 20 and 29 years).^{1,13,127} Many patients report having mild symptoms for years before full OCD emerges, and an estimated one-third to one-half of patients have onset during childhood or adolescence. Prepubertal OCD is three times more common in boys than in girls.¹³ Women with OCD often have worsening of symptoms during the premenstrual and postpartum periods, and onset or worsening of OCD during pregnancy appears to be fairly common.⁶⁰ Regardless of gender, the severity of illness usually worsens during stressful life periods.

The course and severity of OCD are highly variable and unpredictable, with some persons only mildly or intermittently affected and others suffering severely and constantly throughout their lifetime. The natural course of untreated OCD was followed for a 40-year period in a group of 144 patients.¹²⁶ Although 83% of patients were improved at the end of the follow-up period, only 20% experienced full remission. Two-thirds

of patients continued to have some OCD symptoms, and a progressive deterioration was observed in 10%. Observational studies suggest that the long-term course of OCD may be improved substantially with appropriate treatment.^{128,129} However, a portion of sufferers still experience a chronic and life-long course.

It is no surprise that OCD can have seriously detrimental effects on functional abilities and quality of life. In large-scale surveys, OCD patients report that their symptoms significantly interfere with their abilities to socialize, study, work, make friends, and maintain good relationships with family and friends.¹³⁰ It is estimated that each person with OCD loses an average of 3 years' wages over his or her lifetime.¹³⁰ Quality-of-life ratings in OCD patients indicate marked impairments and are similar to those observed in patients with depression. Fortunately, treatment of OCD can be accompanied by significant improvements in quality of life and functional abilities.

Although several effective treatments are currently available for OCD, most patients do not seek treatment until the disorder is seriously affecting their lives. One study found that OCD patients waited an average of 7.5 years after the onset of OCD before seeking medical evaluation for their disorder.¹³⁰ This may be because most OCD patients realize that their symptoms are senseless, so they attempt to hide their disorder due to embarrassment. People with OCD often carry out their rituals privately and may be very successful at concealing their symptoms from others. Initial treatment for OCD is commonly sought outside psychiatric settings, and the obsessive-compulsive symptoms are often missed.

Increased recognition that OCD is a biological disorder for which effective treatments are available is needed among the general public and health care professionals. Four simple questions are recommended for screening for potential OCD.¹²⁵ Do you have to wash your hands over and over? Do you have to check things repeatedly? Do you have recurrent distressing thoughts that you cannot get rid of? Do you have to complete actions again and again or in a certain way? Clinicians in a variety of health care settings can incorporate these screening questions into their practice to use when possible signs of OCD are present. Health care providers should be prepared to provide education about the nature and treatability of OCD to suspected sufferers and to make appropriate treatment referrals in these cases.

Psychiatric Comorbidity and Obsessive-Compulsive Spectrum Disorders

As with other anxiety disorders, OCD often is accompanied by psychiatric comorbidity. Two-thirds of those with OCD develop major depression during their lifetime.^{1,126} There is a higher-than-expected overlap of OCD with disorders such as specific and social phobias, GAD, panic disorder, schizophrenia, schizoaffective disorder, bipolar disorder, and eating disorders. Identification of comorbid conditions with OCD is important because it can influence choice of treatments. Obsessive-compulsive personality disorder, which is classified as an Axis II disorder, occurs in a small percentage of OCD patients. Despite their name similarities, obsessive-compulsive personality disorder does not involve true obsessions and compulsions (which are senseless and distressing to

the sufferer). Rather, it is a personality pattern characterized by rigid and inflexible preoccupation with rules, lists, order, and perfectionism.¹ Although these personality traits cause problems, the person with the personality disorder does not view his or her behavior as abnormal or unreasonable.

The relation between tic disorders and OCD is particularly striking. Tics occur in 20% to 30% of OCD patients, and 5% to 7% have full Tourette syndrome, whereas 35% to 50% of Tourette syndrome patients exhibit OCD symptoms.¹²⁶ Individuals with OCD plus Tourette syndrome are believed to represent a genetically and pathophysiologically distinct subtype of illness.¹²⁶ These patients are more likely to be male and tend to have an earlier age at OCD onset (before age 10 years), more severe symptoms, and poorer response to SSRIs than those with OCD alone.¹³¹

Another childhood neurologic disorder commonly associated with OCD is Sydenham chorea. This is the neurologic variant of rheumatic fever, which is an autoimmune disease triggered by infection with group A β -hemolytic streptococcal pharyngitis. Recent reports describe children who developed sudden and severe tics and obsessive-compulsive symptoms after strep throat infections.^{132,133} This condition is designated in the medical literature by the acronym PANDAS (pediatric autoimmune neuropsychiatric disorders associated with streptococcal infection), and it has been rapidly reversed by antibiotic or IV immunoglobulin treatment. The possibility of a PANDAS correlation should be considered in any child who develops abrupt onset of obsessive-compulsive symptoms, particularly those who have had pharyngitis within the past 6 months.

The term "obsessive-compulsive spectrum disorder" refers to a diverse collection of psychiatric conditions from various DSM-IV-TR categories that have overlapping characteristics with OCD and involve recurrent or distressing thoughts and/or irresistible or repetitive behaviors.¹³⁴ These include somatoform disorders (body dysmorphic disorder [preoccupation with an imagined or slight defect in appearance], hypochondriasis), eating disorders (anorexia nervosa, bulimia nervosa, binge eating disorder), and impulse control disorders (trichotillomania [recurrent impulses to pull out one's hair], pathological gambling, compulsive nail biting, kleptomania, compulsive buying). Tourette syndrome and autism are also often included in this spectrum of disorders. Some of these disorders, such as body dysmorphic disorder, have much higher comorbidities with OCD than others. Like OCD, many patients with these conditions have shown good response to treatment with serotonergic antidepressants such as clomipramine and SSRIs, sometimes preferentially over agents with mainly noradrenergic activity.¹³⁴ Examples include body dysmorphic disorder, compulsive buying, pathological gambling, trichotillomania, binge eating disorder, and bulimia nervosa.¹³⁴

Etiology and Pathophysiology

A wealth of research has attempted to identify a specific biological explanation for OCD. Because OCD displays such clinical heterogeneity, there may be several distinct etiologies for different subtypes of illness. One leading hypothesis has focused on the role of 5-HT dysfunction, which is supported by the finding that the only effective medication treatments for OCD mainly influence 5-HT transmission.¹³⁵ However, the

multitude of studies involving 5-HT challenges and other methods for assessing central 5-HT function in OCD have resulted in no conclusive answers, and the exact role of 5-HT underlying OCD still has not been determined. It is interesting that naturally occurring animal models of OCD have been observed in dogs (canine acral lick) and birds (feather picking disorder), and these conditions have been treated successfully with SSRIs.

More promising areas of OCD research involve functional brain imaging studies.¹³⁵ These techniques are used to assess regional metabolic activity in different areas of the brain. Studies in OCD patients have identified abnormal hyperactivity (when compared with normal controls) in certain frontal lobe and basal ganglia regions, specifically the orbital frontal cortex, cingulate cortex, and head of the caudate nucleus.^{135,136} Interestingly, these regional brain metabolic abnormalities normalize after successful treatment of OCD, and certain brain metabolism patterns may be associated with preferential response to SSRI versus CBTs.^{135,137} These findings have led to one current hypothesis that OCD is a neurologic disorder characterized by a hyperfunctioning circuit involving the aforementioned brain regions. In support of this hypothesis, neurosurgical techniques that interrupt this circuit are often effective in the treatment of OCD. The mechanism of efficacy of the SSRIs may be related to desensitization of terminal serotonin auto receptors in the orbitofrontal cortex, which enhances 5-HT neurotransmission in this brain region.^{135,136} Structural abnormalities have also been identified in OCD, including increased brain cortex and opercular volumes, decreased total white matter volume, and smaller pituitary gland size.^{125,135} Specific types of cognitive dysfunction have also been found, including problems with nonverbal memory, visuospatial skills, and visual attention.¹³⁵ Impairments in memory functioning have been correlated with the aforementioned structural abnormalities in OCD.

In addition to biological factors, twin and family studies support an effect of genetics on risk for OCD.¹⁵ Heredity appears to be most important in early-onset OCD cases (before age 18 years) because familial aggregation has not been observed in OCD cases with a later age at onset.¹³⁸ Several studies suggest an association between OCD and specific polymorphisms in the serotonin transporter, 5HT_{1D} β and 5HT_{2A} receptor genes, but others have failed to replicate these findings.^{139,140} Other candidate gene studies have linked OCD with functional polymorphisms in the catechol *O*-methyltransferase, dopamine D₄-receptor genes, and a high-affinity neuronal/epithelial excitatory amino acid transporter gene.^{140,141}

Treatment of Obsessive-Compulsive Disorder

Both medications and behavioral therapies are effective in the treatment of OCD. Behavioral therapy is vitally important for OCD, and the combination of drugs plus behavioral therapy provides optimal treatment. All medications consistently effective in the treatment of OCD are potent inhibitors of serotonin reuptake. These include clomipramine, and the SSRIs: fluvoxamine, fluoxetine, paroxetine, and sertraline. All five of these medications are FDA approved for the treatment of OCD in adults, and all except paroxetine are indicated for use in children with OCD.

Clomipramine

Clomipramine was the first drug with proven efficacy in treating OCD, and it was considered the standard first-line treatment for several years until the SSRIs gained popularity. Many large well-controlled studies have documented that clomipramine is far superior to placebo and significantly improves OCD symptoms in approximately 60% to 70% of patients.^{126,142} Clomipramine is unique among TCAs in its effectiveness for OCD. This distinct property is attributed to its more potent effects on 5-HT reuptake inhibition compared with other TCAs. Clomipramine is often referred to as an SRI (serotonin reuptake inhibitor), not an SSRI, because its major active metabolite, desmethylclomipramine, is a potent inhibitor of norepinephrine reuptake. Clomipramine also blocks adrenergic, histaminergic, and cholinergic receptors similarly to other TCAs, resulting in an adverse effect profile similar to that of imipramine (see Chapter 79).

Although direct comparison studies have shown clomipramine to be similar in efficacy to various SSRIs in treating OCD, several meta-analyses have concluded that clomipramine is superior to SSRIs overall.^{142,143} However, clomipramine is less well tolerated than SSRIs, and patients are more likely to discontinue clomipramine treatment because of side effects. Therefore, clomipramine is currently reserved as a second-line treatment option for patients who do not respond adequately to SSRI therapy.¹⁴² Details about the clinical use of clomipramine are discussed in Questions 32 through 34.

Selective Serotonin Reuptake Inhibitors

SSRIs are the only first-line medication treatments for OCD. Double-blind, placebo-controlled studies have documented the efficacies of fluvoxamine, fluoxetine, paroxetine, and sertraline in the treatment of OCD.¹⁴⁴ Citalopram and escitalopram also are effective but there is less evidence to support their use. There is no strong evidence that any one SSRI is more effective than the others in treating OCD, but some patients may respond to or tolerate one agent better than another.¹⁴⁴ Usual SSRI starting dosages can be used in OCD, but at least 4 weeks should be allowed before exceeding the targeted minimally effective dosages (fluvoxamine 200 mg/day, fluoxetine 40 mg/day, paroxetine 40 mg/day, and sertraline 100 mg/day).¹⁴⁴ Details about the clinical use of SSRIs in OCD are discussed in Questions 28 through 31.

Augmentation Strategies

Other than venlafaxine, none of the other miscellaneous agents studied in OCD have demonstrated impressive efficacy as monotherapy. However, several agents appear to be useful as augmentation therapy to boost response to SSRIs or clomipramine in partial responders to these agents.¹⁴⁵ The combination of an SSRI plus clomipramine is one such option for patients who show partial response, although attention must be paid to potential drug interactions, which may lead to clomipramine toxicity (see Question 34).

Antipsychotic agents are useful for augmentation therapy. They may be particularly effective in patients with comorbid tic disorders, although recent reports suggest they are equally effective in patients without tics. Older first-generation antipsychotics, such as haloperidol and pimozide, are effective in augmenting response to fluvoxamine in controlled trials

(conducted before the dangerous interaction between pimozide and CYP 3A4 inhibitors, such as fluvoxamine, was identified). Recent reports have focused on newer second-generation antipsychotics because these agents are generally preferred over first-generation antipsychotics and are better tolerated.^{145,146} Risperidone (2–4 mg/day), olanzapine (10–20 mg/day), and quetiapine (200 mg/day) have all been used successfully in treatment-resistant OCD to augment response to SSRIs.^{145,147,148} It is interesting to note that second-generation antipsychotics (risperidone, clozapine, olanzapine) have been reported to cause or worsen obsessive-compulsive symptoms in schizophrenic patients in a number of cases.¹⁴⁵ This effect is believed to be due to the 5-HT₂-receptor antagonistic activity of antipsychotics. Certain SSRI-antipsychotic combinations can increase antipsychotic plasma levels and side effects, particularly extrapyramidal symptoms. Pimozide should not be used in combination with clomipramine, fluoxetine, sertraline, or fluvoxamine because of the potential for cardiac QT interval prolongation.

Pindolol is another augmenting agent that has been shown to be effective in a placebo-controlled study.¹⁴⁹ This trial involved treatment-resistant OCD patients and found pindolol (2.5 mg TID) to be most beneficial in patients who had shown partial response to SSRI therapy.

Miscellaneous Agents

A wide variety of other medications have been tried in the treatment of OCD, with varying degrees of success. Several controlled studies support the efficacy of venlafaxine in the treatment of OCD.¹⁴² A recent trial comparing venlafaxine with clomipramine in OCD found these agents to be comparably effective, but venlafaxine was better tolerated.¹⁵⁰

Benzodiazepines are generally not beneficial in treating OCD, although there are several reports of clonazepam being effective as adjunctive therapy or monotherapy.¹²⁶ Clonazepam appears to have serotonergic effects, which may explain its potential usefulness in OCD. This agent may be helpful in patients with prominent anxiety symptoms, but it can also interfere with the effectiveness of CBT and should not be used concurrently. As discussed, fluvoxamine and fluoxetine can significantly increase serum levels of clonazepam.

The MAOI, phenelzine, was one of the first medications studied for OCD. Early case reports of its use were favorable, but more recent findings suggest that phenelzine is largely ineffective for OCD.¹²⁶

Nonpharmacologic Treatments

COGNITIVE-BEHAVIORAL THERAPIES

CBT is an extremely important component of treatment for OCD and should be incorporated into the initial treatment plan whenever possible. CBT alone may be appropriate for mild OCD or in cases in which it is desirable to avoid medication (e.g., pregnancy, medical conditions). The combination of CBT and medication is generally superior to either treatment approach used alone.^{125,126} Treatment gains achieved with CBT often are maintained long after its discontinuation, which is an advantage over pharmacotherapy.¹²⁵

The cognitive therapy component of CBT is aimed toward changing the detrimental thought patterns in OCD and is most helpful for obsessions such as scrupulosity, moral guilt, and pathological doubt. The behavioral therapy aspect, called ex-

posure plus response prevention, involves exposure to feared objects or situations followed by prevention of the usual compulsive response. This type of therapy is most beneficial for patients with contamination fears, hoarding, and rituals involving symmetry, counting, or repeating. Because exposure plus response prevention is anxiety provoking and can be very distressing, many patients refuse to participate in it.

NEUROSURGERY

Neurosurgical treatment of OCD has been practiced since the 1950s and is considered an option of last resort in treatment-refractory patients. Cingulotomy and capsulotomy are the most commonly used procedures. Indications for neurosurgery include severe disability from obsessive-compulsive symptoms and failed treatments (drugs and behavioral therapies) that have been tried systematically for at least 5 years.¹⁵¹ Reported success rates of neurosurgery in OCD range from 40% to 60% and complications, including potential infections, personality changes, cognitive impairment, and epilepsy, appear to be rare. A recent, long-term, follow-up study of patients who underwent neurosurgery during the 1970s found that therapeutic effects were maintained but that patients exhibited mild-to-moderate impairments in neuropsychological performance.¹⁵¹ Permanent cognitive sequelae from neurosurgery may be more common than previously realized. A new neurosurgical procedure using an instrument called the gamma knife (anterior gamma capsulotomy) is being used for treatment-refractory OCD. Results suggest good efficacy with improved short- and long-term safety compared with traditional neurosurgical techniques.¹⁵²

Defining Response to Therapy

Response to medication treatment in OCD is gradual and often delayed. Initial improvements usually begin to appear within the first month, but maximal response may take as long as 5 to 6 months. An adequate period to assess response at lower medication dosages should be allowed before increasing to possibly unnecessary higher dosages. Patients who show unsatisfactory response to lower SSRI dosages by weeks 4 to 9 should have their dosages gradually increased to the manufacturer's recommended maximum (see Question 28). A trial of 8 to 12 weeks at maximum medication dosages is recommended before determining response to a particular medication.

The primary goal of treatment in OCD is to decrease obsessions and compulsions to a level at which the person is able to function normally. Complete elimination of symptoms is rare with current treatments.¹⁵³ Most clinical trials in OCD define clinical response as a 25% to 35% reduction in Yale-Brown Obsessive-Compulsive Symptom Checklist (Y-BOCS) scores (see Question 27). Therefore, even those classified as responders may be left with 65% to 75% of their original symptoms, and this may or may not result in significant improvements in functioning or quality of life.

Strategies for Managing Partial Response and Nonresponse

Current estimates are that approximately 40% to 60% of patients show clinically meaningful improvements in obsessive-compulsive symptoms during an initial (SSRI or clomipramine) medication trial, but only a small percentage exhibit marked response.¹⁴² Unfortunately, a fairly large

percentage of patients derive minimal or no benefit from an initial trial and require further tactics. Approximately 20% of those who fail a first SSRI trial subsequently respond to another agent in this class; therefore, switching to a second SSRI is usually recommended as the next step before initiating a trial of clomipramine.^{125,142} However, clomipramine can be extremely effective in SSRI nonresponders, and it remains a useful treatment option despite its clinical disadvantages.

Partial responders to an initial SSRI trial may be better served by addition of one of the augmentation agents discussed in the previous section than by switching to a new medication. Also, inclusion of CBTs is important for optimizing treatment with any medication. Neurosurgery is an option for severe treatment-refractory cases. Predictors of poor response to treatment in OCD include poor insight; hoarding or sexual/religious dimension symptoms; prepubertal onset of illness; and presence of comorbid personality, mood, or eating disorders.

Clinical Presentation and Assessment

25. R.G. is a 25-year-old woman whose husband complains that she spends 1.5 hours a day cleaning the stove and takes four showers each day. The unusual behavior began about 1 year ago after the birth of their son but has continued to worsen, and R.G.'s husband states that he cannot deal with her "odd habits" any longer. R.G. recently lost her job as a secretary because of tardiness (it took her 3 hours to get ready for work) and spending too much time away from her desk in the ladies' room. R.G. admits that it is silly, but she has irresistible urges to make sure that both she and her surroundings are completely free of germs so that her child will not get sick. She also confines herself to one floor of their three-level house because she is afraid that she will fall down the stairs while carrying her son. R.G. also states that she constantly has "what if" thoughts about horrible things happening to her family, which are very disturbing. The physician's diagnosis is OCD. What clinical features of OCD does R.G. display, and how can her symptoms be objectively evaluated?

R.G. displays many characteristic symptoms of OCD. The most commonly encountered clinical presentation of OCD involves patients with excessive fear of contamination with dirt, germs, or toxins, who repeatedly wash their hands or clean objects or their surroundings. These persons also typically avoid touching possibly dirty objects (e.g., doorknobs, money) or shaking hands with people. Another common clinical presentation is the OCD patient with pathological doubt who constantly worries that something bad will happen because of his or her negligence. These people can be afraid that they have failed to lock the door, turn off the stove, shut the refrigerator door, or secure the medicine cabinet from children. As a result, they continuously check and recheck their actions.

R.G. displays obsessions of contamination and pathological doubt, and compulsions of excessive cleaning and washing. These symptoms are time consuming, cause significant distress, and have led to her unemployment and marital difficulties. As seen in this case, most persons present with a mixture of various obsessions and compulsions. R.G. also realizes that her thoughts and behaviors are "silly," which most often is the case in OCD. This case also illustrates the onset of OCD during times of stressful or significant life events. Pregnancy,

death of a relative, and marital discord have been identified as precipitating factors in the onset of OCD.^{127,153}

The aforementioned Y-BOCS is a useful tool in the initial evaluation of those who present with symptoms of OCD and may be used in the objective assessment of R.G.'s symptoms. The Y-BOCS is a 10-item scale with a maximum possible score of 40; a score of >15 is generally considered to represent clinically significant obsessive-compulsive symptoms.¹⁵⁴ This scale is a standard tool for evaluating drug efficacy in OCD clinical trials and is often used in clinical practice to assess response to treatments. Other OCD assessment instruments include the National Institute of Mental Health Obsessive-Compulsive Scale, the Leyton Obsessional Inventory, and the self-rated Maudsley Obsessional-Compulsive Inventory. Special versions for use in children have been developed for the Y-BOCS and the Leyton Obsessional Inventory.

SSRI Treatment of Obsessive-Compulsive Disorder

SSRI Selection and Dosing

26. On assessment, R.G.'s Y-BOCS score is found to be 33. Her physician prescribes fluvoxamine and instructs R.G. to take 100 mg Q am for 1 week and then 200 mg Q am thereafter. He also refers R.G. to a psychologist to receive CBT. Is this initial choice of therapy appropriate?

SSRIs such as fluvoxamine are considered the best choice of initial pharmacotherapy for OCD. The primary differences between SSRIs involve pharmacokinetic properties and potential for drug interactions (see Chapter 79). Because there are no overall differences in efficacy among the four SSRIs approved for OCD, fluvoxamine is a suitable selection for R.G. However, the prescribed dosing instructions for R.G. are not appropriate. The initial recommended dosage for fluvoxamine in adults is 50 mg/day (25 mg in children), and it is best taken in the evening because it tends to be sedating. Using higher-than-necessary dosages can increase both adverse effects and medication costs, and these factors can lead to early termination of therapy. The dosage can be increased by 50-mg increments every 3 to 4 days according to patient tolerability, up to the initial targeted dose of 200 mg/day and a maximum of 300 mg/day.¹⁴⁴ Daily doses exceeding 100 mg should be given in two divided doses, based on fluvoxamine's elimination half-life of approximately 15 hours. A controlled-release fluvoxamine formulation can be dosed once daily.¹⁵⁵ This product is reported to be better tolerated than standard-release fluvoxamine and may be associated with a faster onset of therapeutic effects.

Adjunctive Cognitive-Behavioral Therapy

The decision to include CBT in R.G.'s treatment plan is appropriate. The overall efficacy of these nonpharmacologic treatments is estimated to be 50% to 70% when used alone, and their use to complement pharmacotherapy is considered vital.¹²⁵ R.G.'s Y-BOCS score of 33 indicates a moderate-to-severe symptom severity, which provides further support for using a combined treatment approach. For R.G., exposure plus response prevention therapy might involve covering her hands with dirt and not allowing her to wash them for a certain time period. These behavioral techniques cause extreme anxiety and discomfort, which often lead to dropout from therapy or noncompliance with "homework assignments" (which

involve continuation of the therapy principles outside the clinical setting), but are highly effective if the patient can adhere to treatment.

SSRI Adverse Effects and Patient Counseling

27. What patient counseling information should be provided to R.G. in conjunction with the prescribed treatments?

All OCD patients beginning treatment should be counseled that the medication response occurs gradually and that several weeks may elapse before beneficial effects become noticeable. It is important to emphasize that maximum response may take 3 months or longer and that complete elimination of all symptoms is unlikely. It also is helpful to point out that a variety of other medication treatment options exist for those who do not respond adequately to an initial trial.

R.G. should be educated about possible fluvoxamine side effects, including nausea, sedation or insomnia, and headache. Medication should be taken with food to decrease these effects. Side effects are most common during the initial weeks of therapy, are usually dose related, and often subside with continued treatment. Other aspects of SSRI therapy, including additional adverse effects and their management and drug–drug interactions, are discussed in Chapter 79. Patients should be encouraged to report any problems to their treatment provider. The importance of adhering to prescribed therapies, both pharmacologic and behavioral, should also be stressed.

28. After 4 weeks, R.G. is taking fluvoxamine 200 mg daily and tolerating the medication well. She complains that she has not noticed much improvement, and her Y-BOCS score is slightly decreased at 30. R.G. has been to the cognitive-behavioral therapist twice but is reluctant to return because the therapy was so stressful. R.G. requests to be switched to a more effective medication, and she also asks to be given some Xanax to help calm her anxiety during behavioral therapy sessions. What is the best course of action for R.G. at this point?

Switching to another medication is not recommended at this point because not enough time has elapsed to assess fluvoxamine's efficacy. R.G. is tolerating fluvoxamine well and has shown a mild improvement, so this medication should be continued for at least another 4 weeks. Additional counseling information should be provided to R.G. to emphasize the gradual response to treatment in OCD. An increase in fluvoxamine dosage, up to 250 or 300 mg/day, may be considered after several more weeks because some patients may respond better to higher dosages. If R.G.'s symptoms continue to cause significant functional impairment after 10 to 12 weeks of higher-dose fluvoxamine therapy, a change in treatment (e.g., switching to another SSRI or augmentation therapy) will be indicated.

R.G. should be encouraged to continue CBT to optimize the chance for successful treatment. An anxiety response is integral to the therapeutic benefits of behavioral therapies; because benzodiazepines can blunt this response, they may reduce their efficacy. Therefore, alprazolam should be avoided, and a temporary reduction in the intensity of behavioral therapy may be indicated instead. Fluvoxamine can also inhibit the CYP 3A4-mediated metabolism of alprazolam, resulting in more pronounced effects from a given dose.

Course and Duration of Therapy

29. After 5 months of treatment, R.G. is happy to report that her OCD is much improved (Y-BOCS score of 11). She still has intermittent obsessions related to contamination and doubting, but they are less intense than before. She is usually able to resist urges to clean and wash excessively and is using the stairs in their home with only mild discomfort. Her previous employer has agreed to let her return to her secretarial position when she is ready, and she plans to do so soon. R.G.'s husband is extremely pleased with her progress. Their primary question at this visit is whether treatment can be discontinued now because R.G. is doing so well. What recommendations should be provided regarding the long-term course of therapy for R.G.?

This case illustrates a common outcome of OCD treatment, in which some symptoms persist (as evidenced by a Y-BOCS score of 11), but significant improvements in functioning occur. It is currently recommended that effective treatment for OCD be continued for at least 1 year after response to reduce the risk of relapse. The effectiveness of maintenance pharmacotherapy in preventing relapse of OCD is well documented.^{128,154} Therefore, continued drug treatment for at least 7 more months is indicated for R.G. Results from several studies suggest that decreased medication doses (with SSRIs and clomipramine) during maintenance therapy are comparably effective as full doses in preventing relapse.¹⁵⁴ If R.G. were experiencing any fluvoxamine-related problems, a decrease to the minimally effective dose (150 mg/day) during maintenance therapy might be recommended.

After a 1-year maintenance period, discontinuation of medication may be considered by carefully weighing the possible risks and benefits. When medication therapy for OCD is withdrawn, the dosage should be gradually decreased by approximately 25% every 1 to 2 months. Continuous monitoring for signs of relapse is required during this period. Gradual discontinuation also lessens the chance of the withdrawal syndrome that often occurs following abrupt discontinuation of SSRI or TCA therapy (see Chapter 79). Long-term or even lifelong maintenance pharmacotherapy is usually recommended after two to four severe relapses or three to four less severe relapses.

Clomipramine Treatment

Dosing Guidelines

30. K.T. is an 18-year-old Asian man who was diagnosed with OCD 2 years ago and also suffers from mild depression. His physician plans to start him on clomipramine therapy because he has failed previous trials with paroxetine and fluvoxamine. Is clomipramine an appropriate choice of therapy for this patient? What recommendations can be made regarding initiation of clomipramine treatment?

Current guidelines recommend that clomipramine be reserved for OCD patients who fail at least two SSRI trials; therefore, its choice for this patient is appropriate.¹²⁶ One precaution relevant to this case is that clomipramine, like other TCAs, is highly dangerous in overdose situations. Because K.T. is depressed, he should be evaluated carefully for any suicidal thoughts before starting clomipramine. If suicidal ideation is detected, it would be preferable to try another SSRI. This

case also illustrates the common comorbidity of depression with OCD. Fortunately, most effective treatments for OCD fall into the antidepressant category, and drug treatment can be beneficial for both conditions. Nevertheless, the responses of depression and OCD to treatment are independent of one another so that depression may respond completely to a certain medication while OCD symptoms persist.¹⁵⁴

Clomipramine should be initiated at a low dosage of 25 to 50 mg/day administered with meals. Divided daily doses are sometimes used initially to minimize side effects, but the total daily dose can be given at bedtime after dose titration. The pharmacokinetic parameters of clomipramine are comparable to other TCAs. Its average elimination half-life of approximately 24 hours makes once-daily dosing appropriate.^{144,156}

The clomipramine dosage should be increased to an initial target range of 150 to 200 mg/day over 2 to 4 weeks, guided by patient tolerability. The maximum recommended daily dosage of clomipramine is 250 mg/day because of the sharply increased risk of seizures (2.1%–3.4%) with higher dosages as compared with the risk with dosages <250 mg/day (0.24%–0.48%).¹⁵⁷ Longer duration of clomipramine therapy may also increase the risk of seizures. Clomipramine should be used with caution in persons with a history of seizures, head injury, or any other factors that might lower the seizure threshold.

Clomipramine Side Effects and Monitoring Guidelines

31. What guidelines should be recommended for monitoring the outcomes (both therapeutic and adverse) of clomipramine therapy?

Clomipramine is less well tolerated than the SSRIs and can cause a number of significant adverse effects, especially during the first few weeks of therapy. The most common side effects, reported in more than half of those taking clomipramine, include sedation, dry mouth, dizziness, and tremor.¹⁵⁷ Constipation, nausea, blurred vision, insomnia, and headache also occur frequently. K.T. should be advised that these are not serious effects and usually subside with continued treatment.

Many patients receiving long-term clomipramine (and other TCA) therapy gain substantial amounts of weight. As with the SSRIs, sexual dysfunction can be a problem in both men and women. In men, clomipramine can cause ejaculation abnormalities, which can impair fertility. Patients taking clomipramine should also be counseled about the additive CNS depressant effects with alcohol and to be cautious about the possible sedative effects while driving or performing other potentially hazardous activities.

As with other TCAs, an ECG should be performed before starting clomipramine in individuals at risk for heart disease and in pediatric patients. Elevations in liver enzymes have been observed frequently during the first 3 months of clomipramine treatment, and baseline liver function tests should also be obtained before initiating treatment. The liver enzyme changes are reversible on discontinuation of clomipramine therapy.

No therapeutic range for plasma drug concentrations has been firmly established for clomipramine in OCD, but monitoring plasma levels may be clinically useful in certain patients to guide dosing and/or minimize drug toxicity. Clomipramine metabolism is highly variable from one person to the next, and it is difficult to accurately predict the resulting clomipramine

level from any given dose. The initial hepatic metabolism of tertiary TCAs such as clomipramine involves demethylation through various isozymes, including CYP 1A2, CYP 2C19, and CYP 3A4.^{156,158} Both the parent drug (clomipramine) and the primary active metabolite (*N*-desmethylclomipramine) then undergo CYP 2D6–mediated hydroxylation. Therefore, the metabolism of clomipramine will be affected by combination with any agent that inhibits CYP 1A2, CYP 2C19, CYP 3A4, or CYP 2D6. Clinically significant drug interactions are possible with several of the SSRIs, including fluoxetine, fluvoxamine, and sertraline (see Chapter 79 Mood Disorders).

Although various studies have failed to find a correlation between clomipramine plasma level and clinical response, the ratio of clomipramine to *N*-desmethylclomipramine may be important.¹⁵⁹ Clomipramine is primarily serotonergic, whereas *N*-desmethylclomipramine is more noradrenergic; higher levels of *N*-desmethylclomipramine relative to clomipramine have been associated with poorer clinical response. Factors that impair the CYP 2D6–mediated elimination of *N*-desmethylclomipramine (concurrent medications that are potent CYP 2D6 inhibitors, CYP 2D6 poor metabolizers) may possibly decrease the efficacy of clomipramine by shifting the metabolic ratio in an undesired direction.

Asian patients such as K.T. have been found to have significantly decreased clearance of clomipramine and higher clomipramine: *N*-desmethylclomipramine ratios compared with whites, which may necessitate use of lower doses.¹⁶⁰ This is probably due to genetic polymorphism of either CYP 2C19 or CYP 2D6, which results in decreased metabolic capacity through these routes in the Asian population. Careful monitoring for possible signs of toxicity should accompany dose increases, and the clomipramine plasma level should be checked in those patients (Asian or otherwise) who show unexpected effects with usual doses. An opposite effect has been described in ultra-rapid CYP 2D6 metabolizers, in which unusually high clomipramine dosages may be required for therapeutic efficacy.

Clomipramine Augmentation

32. After 10 weeks of taking clomipramine 100 mg HS, K.T. has shown partial response. He continues to experience mild-to-moderate anticholinergic side effects and frequent daytime fatigue. His plasma clomipramine level is relatively high for the given dose at 450 ng/mL (clomipramine plus desmethylclomipramine). The physician decides to add another drug to augment treatment. Considering K.T.'s current medication regimen and the evidence supporting the different augmentation strategies, which drug would be the best choice for K.T.?

Many different agents have been used to augment response to either an SSRI or clomipramine. An SSRI could be added to clomipramine. Of the SSRIs, fluvoxamine, fluoxetine, paroxetine, and sertraline are all approved as monotherapy for OCD, and any of these would be likely to augment therapy. However, when adding an SSRI to a TCA, the potential for drug interactions should always be considered. Clomipramine is metabolized by CYP 1A2, CYP 3A4, CYP 2C19, and CYP 2D6.^{156,158,161,162} The 2D6 pathway is particularly important because it is the rate-limiting metabolic pathway for elimination of both clomipramine and

desmethylclomipramine. Fluvoxamine, paroxetine, and fluoxetine are all important inhibitors of clomipramine metabolism. Sertraline also has the potential to cause a clinically significant interaction with clomipramine. Alternatively, escitalopram and citalopram would not be likely to cause a significant drug interaction, but evidence for their efficacy as augmenting agents in combination with clomipramine is lacking. A combination less likely to be associated with a drug interaction is the combination of clomipramine and a second-generation antipsychotic. Up to 2006, ten trials comparing the effectiveness of antipsy-

chotic augmentation had been published. Three trials have been conducted using risperidone, two using olanzapine and four using quetiapine. Unfortunately, most studies are small (<30 patients). However, a meta-analysis of the available data suggested that risperidone was most effective (at a dose near 2 mg/day), and haloperidol was the next most effective agent.¹⁴⁶ Even though it might be efficacious, haloperidol would not be the optimal choice in K.T. because it inhibits clomipramine metabolism, and as a first-generation antipsychotic, it is associated with numerous side effects.

“I wake to sleep, and take my waking slow. I learn by going where I have to go.”

Theodore Roethke, *The Waking*

The human drive to sleep is strong and enduring. Most healthy people spend one-third of their lives asleep. Such a major part of life deserves full exploration and study. This chapter reviews the impact, epidemiology, and classification of disorders of the sleep-wake cycle. An overview of normal sleep physiology and neurochemistry precedes case discussions.

SOCIETAL IMPACT

The impact of sleep disorders on overall health, productivity, and quality of life has been increasingly appreciated. Untreated sleep disorders, including chronic insomnia, sleep apnea, periodic limb movements during sleep (PLMS), and narcolepsy, are all associated with diminished mental and physical functioning and poor quality of life.¹⁻⁴ Sleep research shows that chronic insomnia, for example, can predict untreated illness or may contribute to injury and illness.^{2,5,6}

Chronic insomnia is associated with immune system dysregulation and the release of proinflammatory cytokines (IL-

6 and tumor necrosis factor alpha [TNF- α]), a disruption of the hypothalamic-pituitary-adrenal (HPA) axis and a depletion of brain serotonin and other neurotransmitters.⁶ Persons with insomnia are 10 times more likely to suffer from depression and 17 times more likely to have anxiety compared with people without insomnia.⁶ Chronic insomnia is two to three times greater in individuals with high blood pressure, breathing difficulty, gastrointestinal (GI) disorders, cancer, and chronic pain, among other conditions.⁷ Insomnia and excessive daytime sleepiness in the elderly are leading predictors of institutionalization.²

In 2005, a National Institutes of Health (NIH) panel of sleep experts recommended a major shift regarding insomnia. The panel stated that insomnia is not just a symptom of a medical or psychiatric illness but a condition that contributes to the severity of that disease or disorder. Indeed, when insomnia is effectively treated, co-occurring medical and psychiatric conditions, such as chronic pain or depression, are relieved along with improvement in functioning and quality of life. The relationship between insomnia and medical or psychiatric illness is bidirectional.^{2,6} Instead of categorizing insomnia as either primary (with no other co-occurring disorder) or secondary, it should be categorized as either primary

or “comorbid” (insomnia that co-occurs with medical or psychiatric illness).⁵

Excessive sleepiness caused by a sleep disorder or sleep deprivation constitutes a serious public health hazard in health care workers, firefighters, policemen, and truck drivers.⁸ An alert mind is crucial for maximal productivity in all occupations, particularly when driving is involved. Of all drivers, 20% reportedly have fallen asleep at least once while driving.⁸ Motor vehicle accidents also tend to peak during the early morning (1 AM to 6 AM) and mid afternoon (2 PM to 4 PM) hours—times when the circadian cycle for sleepiness is maximal.⁸ College students with short sleep times (≤ 6 hrs/night) had lower grade point averages (GPA) than long sleepers (≥ 9 hours). Mid range sleepers (7–8 hours) were not significantly different than long sleepers.⁹ Medical interns made 35.9% more errors in the Medical Intensive Care Units and Cardiac Care Units when working a 24-hour shift compared with working 16 hours.¹⁰ Medical resident shifts are now limited to 12–16 hours to improve patient safety.¹⁰

EPIDEMIOLOGY

Sleep Disorders

One in seven Americans has a longstanding sleep-wake disorder.^{3–5,11,12} During the course of a year, approximately 30% of the population will experience insomnia, and approximately one-third of this group will consider the problem severe.^{2,5} Insomnia is defined as requiring >30 minutes to fall asleep, when individuals awaken throughout the night and cannot immediately return to sleep, when individuals experience early-morning awakening, or when total sleep time is decreased to <6 hours.^{2,5,13} Insomnia is the most common sleep complaint, but the resulting daytime sleepiness and fatigue are troubling after-effects. Insomnia is categorized into three general types: transient (lasting a few days), short-term (lasting <4 weeks), or chronic (persisting for ≥ 1 month). The resulting level of daytime impairment should be assessed to determine insomnia severity.^{5,6,13,14}

Major sleep disorders in order of decreasing prevalence are listed in Table 77-1.^{2,4} Nightmares, nocturnal leg cramps, and snoring are more benign sleep disorders. Nightmares occur often in 5% to 30% of children 3 to 6 years of age, and approximately 2% to 6% of adults have weekly nightmares.¹⁵ Sleep walking occurs in 1% to 2% of the population. Complex

sleep behavior disorders, such as driving or eating while still half-asleep, are uncommon to rare. These behaviors are more common in people taking hypnotic medications, and therefore, counseling is needed.^{15,16} In 2007, the U.S. Food and Drug Administration (FDA) issued a black-box warning that applies to all medications marketed for insomnia. It warns of the risk of angioedema (facial swelling), an allergic reaction, as well as complex sleep behaviors as described above.¹⁶

Hypnotic Use

Cognitive-behavioral therapy (CBT) is the preferred treatment for insomnia because of well-established efficacy, absence of drug side effects, and sustained benefit over time.^{5,14,17–20} Hypnotic medications are recommended when nondrug interventions fail, cannot be implemented, or when rapid results are essential.^{5,14,20}

Prescribing trends have shifted away from older benzodiazepine hypnotics toward sedating antidepressants, namely trazodone, sedating antipsychotics such as quetiapine, and newer benzodiazepine receptor active “Z-hypnotics” (zaleplon, zolpidem, eszopiclone).²¹ Age, gender, and socioeconomic status influence hypnotic prescribing. One study of 2,966 outpatient visits for insomnia or sleep complaint over 1996 to 2001 showed that 48% received a prescription for medication only—with no CBT. Z-hypnotics were prescribed at 25% of these visits. Factors that increased the likelihood of receiving a Z-hypnotic included female gender, co-occurring psychiatric illness, and upper socioeconomic status.

An analysis of 147,945 patient visits for sleep difficulty between 1997 and 2002 in the United States showed women were 1.5 times more likely to have insomnia-related visits. In all ages, the most frequently prescribed or recommended medications were either zaleplon or zolpidem (28.5%), and trazodone (32%). Z-hypnotics were prescribed or recommended significantly more often in patients <65 years of age compared with older patients (54.6% vs. 29.8%, respectively). Temazepam was prescribed to 18.3% of those >65 years of age compared to 15.7% of those <65 years of age. Triazolam or flurazepam was prescribed in 4.9 to 7.9% of patients from all age groups.²²

With aging, sleep typically changes in quality, partially because of sleep disruption related to chronic illnesses.^{23,24} Elderly persons consume more sleep-promoting medications than younger adults. The 2003 National Sleep Foundation’s “Sleep in America” poll found 11% of older adults take prescription medications to promote sleep compared with 6% of younger adults.²³

Table 77-1 Incidence of Major Sleep Disorders^{5,13–15,34}

| Sleep Disorder | Incidence (%) |
|----------------------------|---------------|
| Insomnia | 30–35 |
| Transient (few days) | |
| Short-term (up to 1 month) | |
| Chronic (>1 month) | |
| Sleep apnea | 5–15 |
| PLMS (nocturnal myoclonus) | 5–15 |
| RLS | 5–15 |
| Narcolepsy | 0.06 |

PLMS, periodic limb movements during sleep; RLS, restless legs syndrome.

THE SLEEP STAGES

Normal Sleep

Each sleep stage serves a physiologic function and can be monitored in sleep laboratories by polysomnography. Polysomnography is the term used to describe three electrophysiologic measures: the electroencephalogram (EEG), the electromyogram (EMG), and the electro-oculogram (EOG). The pattern of brain waves, muscle tone, and eye movements can be used to categorize sleep as rapid eye movement (REM) sleep or nonrapid eye movement (NREM) sleep.^{25,26}

Nonrapid Eye Movement Sleep

Nonrapid eye movement sleep is divided further into four stages, with different quantities of time spent in each stage. Stage 1 is a transition between sleep and wakefulness known as *relaxed wakefulness*, which generally comprises approximately 2% to 5% of sleep. Approximately 50% of total sleep time is spent in stage 2, which is rapid-wave (alpha) or lighter sleep. Stages 3 and 4 are slow-wave (delta) or deep sleep. Stage 3 occupies an average of 5% of sleep time, whereas stage 4 comprises 10% to 15% of sleep time in young, healthy adults. At sleep onset, the brain quickly passes through stage 1 and moves to stage 2. Muscle activity shuts down and brain waves become less active. After a brief REM period, the brain moves into slow-wave sleep (NREM stages 3 and 4) approximately 1 to 3 hours after a person falls asleep. The body continually moves through all of the sleep stages over the course of the night (Fig. 77-1). REM periods become longer and deep sleep lessens over the last half of the night.^{25–27}

Nonrapid eye movement sleep stages differ qualitatively as well as quantitatively. The function of stage 1 is to initiate sleep. Stage 2 provides rest for the muscles and brain through muscle atonia and low-voltage brain wave activity. Arousability from sleep is highest during stages 1 and 2. In contrast, it is difficult to awaken someone during stages 3 and 4, or delta sleep. Delta sleep, also known as *restorative sleep*, is enhanced by serotonin, adenosine, cholecystokinin, and IL-1. The ability of IL-1 to promote slow-wave sleep supports a widely held theory linking deep sleep to the augmentation of immune func-

tion. Some hormones (e.g., somatostatin, growth hormone) are released mainly during slow-wave sleep. Deep sleep is most abundant in infants and children and tends to level off at approximately 4 hours a night during adolescence.^{24,25} At age 65, deep sleep accounts for only 10% of sleep and at age 75, it often is nonexistent.^{23,25} Age-related increased awakenings, decreased deep sleep, and daytime sleepiness have been associated with increases in cortisol and the proinflammatory cytokine, IL-6.^{6,24,26}

Rapid Eye Movement Sleep

Whereas NREM sleep is necessary for rest and rejuvenation, the purpose of REM sleep remains a mystery. REM sleep also is called *paradoxical sleep* because it has aspects of both deep sleep and light sleep. Body and brainstem functions appear to be in a deep sleep state as muscle and sympathetic tone drop dramatically. In contrast, neurochemical processes and higher cortical brain function appear active. Dreaming is associated closely with REM sleep, and when a person is awakened from REM, alertness returns relatively quickly.

Numerous physiologic functions are altered during REM sleep. Breathing is irregular, consisting of sudden changes in respiratory amplitude and frequency corresponding to bursts of REM. Temperature control is lost and the body temperature typically lowers. REM sleep brings on variability in heart rate, blood pressure (BP), cerebral blood flow, and metabolism. Cardiac output and urine volume decrease. Blood may become thicker as a result of autonomic instability and temperature changes.^{26,28}

Rapid eye movement periods cycle approximately every 90 minutes throughout the night. Duration of REM increases in the last half of the night, becoming longer and more intense just after the time when body temperature is at its lowest, around 5 AM. Although the reason for the importance of REM sleep is unknown, it is clear that the human body needs REM sleep. When deprived of REM sleep, whether through poor sleep, drugs, or disease states, the brain and body try to catch up. REM rebound occurs, which may result in vivid dreams or an overall less restful sleep.^{25–27}

Abnormal Sleep

Primary insomnia (difficulty sleeping not attributable to a drug, psychiatric disorder, or medical condition) can resemble a normal sleep pattern, but may be associated with an increased time to fall asleep, multiple awakenings, or decreased total sleep time. Polysomnographic readings evaluating insomnia secondary to psychiatric disorders can be markedly different. In depressive disorders, decreased REM latency (i.e., the time from sleep onset to the appearance of REM) is a classic finding. Acute psychotic disorders feature prolonged global sleeplessness, with sleep onset latency, fragmented sleep, and decreased slow-wave sleep. Medical disorders (e.g., arthritis, cancer, infections) can be associated with significantly altered sleep-stage pattern. Uncontrolled pain can result in frequent awakenings and decreased total sleep time. Oxygen saturation is at its lowest during REM sleep; therefore, less time in REM may be advantageous for patients with cystic fibrosis and other breathing disorders.^{25,26,28}

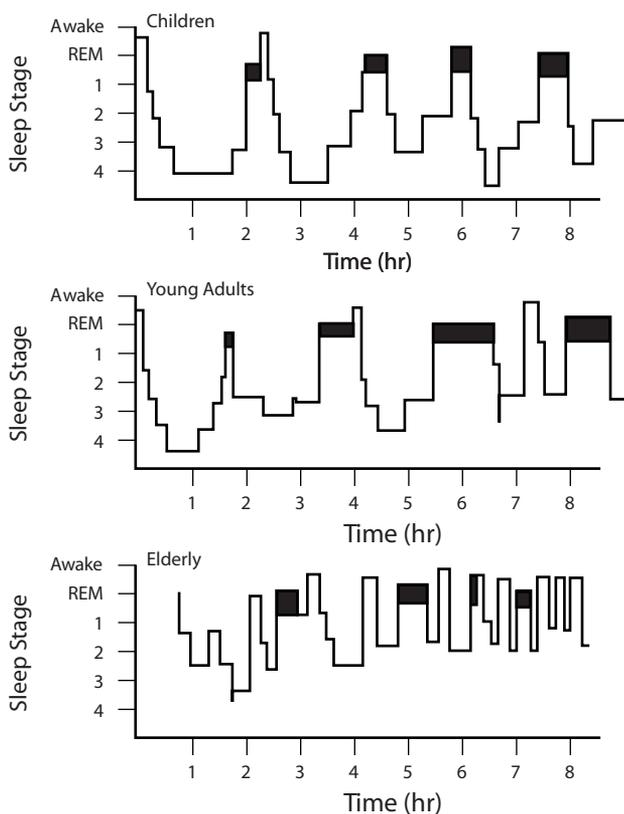

FIGURE 77-1 Normal sleep cycles.

Primary sleep disorders, including PLMS, can cause intermittent partial arousals out of stage 2 sleep and can impair the progress to slow-wave sleep. This may disrupt the quality of sleep and contribute to daytime impairment. Sleep apnea syndrome signals the brain to initiate multiple miniarousals in response to breathing cessation during sleep and, therefore, decreases the quality of sleep. Patients with narcolepsy may have the most unique pattern of sleep disruption because they fall almost immediately into REM sleep (instead of the usual 90-minute latency) and may experience an increased number of REM episodes.⁴

Although polysomnographic readings from sleep laboratories are interesting and can be useful diagnostic and assessment tools, they are neither routinely available nor are the costs routinely reimbursable by insurance companies. A thorough history of sleep problems obtained through patient interviews, along with both physical and psychiatric evaluations, are the most widely used methods of patient assessment. Although acknowledging the usefulness of clinical assessment, certain patients with more serious sleep problems, such as sleep apnea, narcolepsy, or excessive daytime impairment, should have sleep laboratory evaluations.

NEUROCHEMISTRY OF SLEEP–WAKE CYCLE

Wakefulness-and Sleep-Promoting Neurochemicals

A basic understanding of brain neurochemistry is essential in understanding sleep disorders and the clinical use of hypnotics. Hypnotics exert their effects by modulating brain neurotransmitters and neuropeptides (e.g., serotonin, norepinephrine, acetylcholine, histamine, adenosine, and γ -aminobutyric acid [GABA]). The neuronal systems where neurotransmitters and neuropeptides act to control the sleep–wake cycle lie in the brainstem, hypothalamus, and basal forebrain, with connections in the thalamus and cortex. Noradrenergic, histaminergic, and acetylcholine-containing neurons promote wakefulness as they modulate cortical and subcortical neurons. Excitatory amino acids, such as glutamate, and stimulating neuropeptides (e.g., substance P, thyrotropin-releasing factor, corticotropin-releasing factor) also promote wakefulness.²⁷ Hypocretin 1 and 2, also known as orexin a and b, are neuropeptides that modulate the sleep–wake cycle. Hypocretin 1 and 2 are deficient in people with narcolepsy and primary hypersomnia.^{29,30}

Wakefulness and sleep are antagonistic states competing for control of brain activity. Sleep takes over as the wakefulness-maintaining neuronal systems weaken and sleep-promoting neurons become active. Serotonin-containing neurons of the brainstem raphe dampen sensory input and inhibit motor activity, promoting the emergence of slow-wave sleep.^{6,25,27,31} Opiate peptides (e.g., enkephalin, endorphin) and GABA, an inhibitory neurotransmitter, also promote sleep.^{27,31–33}

Drug-Induced Effects on Neurochemicals

The neurochemistry of sleep also can be understood by considering the effect of hypnotic drugs on specific neurotransmitters. GABA is facilitated when a benzodiazepine compound attaches to the benzodiazepine-chloride-ionophore complex and causes chloride channels to open and inhibit the overexcited areas of the brain. GABA-facilitating hypnotics, such as benzodiazepines, induce sleep and decrease arousals be-

tween stages, providing more continuous stage 2 sleep. Benzodiazepines, however, also may decrease stage 4 slow-wave sleep and suppress REM, leading to REM rebound on abrupt discontinuation.^{27,31,34} Some antihistamines promote sleep by blocking histamine-containing neurons involved in maintaining wakefulness. The excitatory effects of caffeine and other methylxanthines are attributed to their antagonism of adenosine receptors. Adenosine is a sleep-promoting neurotransmitter or neuromodulator.^{27,30}

Neurotransmitter alteration may or may not affect REM sleep. Drug-induced noradrenergic and serotonergic modulation usually decreases REM sleep. An increase in dopaminergic neurotransmission can increase wakefulness but has no direct effect on REM sleep.^{27,32} In contrast, increased cholinergic neurotransmission triggers REM sleep.^{27,32} Cortisol decreases REM sleep in young and old with unpredictable effects on slow-wave sleep and increased wakefulness in the elderly.^{6,25,35,37} It is useful to think of the brain centers, neurochemicals, and neuropeptides involved as an interactive network regulating our sleep–wake cycle. Certainly, drugs or disease states that alter neurotransmission can have significant impact on the sleep–wake cycle. Sensory input (visual and acoustic) works with the internal network and signals brain centers to either wake or sleep. Thus, darkness is a visual cue that prepares the brain for sleep. Similarly, bright light serves to prepare the brain for wakefulness.^{25,38}

DYSSOMNIAS

Patient Assessment

Questions to Ask Patients

The first step in patient assessment is to determine whether the sleep problem is difficulty falling asleep, difficulty maintaining sleep, early-morning awakening, poor quality sleep, or excessive daytime sleepiness (EDS). Answers to the questions, “How long does it take you to fall asleep and how many hours do you sleep?” should be compared with the patient’s normal sleep pattern to determine how it varies. Questions such as “How do you feel during the day: well rested, sleepy, or something else?” can help assess functional impairment. Not all patients need the same amount of sleep. Approximately 7 to 9 hours of sleep is optimal for most people: too much sleep can be as problematic as too little sleep.^{13,25} The International Classification of Sleep Disorders and the Diagnostic and Statistical Manual of Mental Disorders, Fourth Edition, Text Revision (DSM-IV-TR) have categorized sleep disorders largely based on pathophysiology and presumed etiology rather than numbers of hours of sleep.^{39,40} Four main categories of sleep disorders are useful for clinical assessment (Table 77-2). The next step in patient assessment involves investigating the possible causes of the sleep disorder and any co-occurring conditions. All medical, psychiatric, drug, environmental, and social causes must be considered and treated along with the sleep disorder. The degree of functional impairment should be assessed to evaluate the severity of the disorder.

Nonpharmacologic Treatment

Cognitive-behavioral therapies are the most effective interventions for insomnia according to the American Academy of

Table 77-2 Classification of Sleep Disorders**Dyssomnias^a**

Intrinsic: idiopathic insomnia, narcolepsy, sleep apnea, periodic limb movements during sleep
 Extrinsic: inadequate sleep hygiene, substance-induced sleep disorder
 Circadian rhythm sleep disorders: jet lag, shift work, delayed sleep phase syndrome

Parasomnias^b

Arousal: confusional arousals, sleep walking, sleep terrors
 Sleep–wake transition disorders: sleep talking, nocturnal leg cramps
 Associated with REM: nightmares, sleep paralysis, impaired sleep-related penile erections
 Other: Primary snoring, sudden infant death syndrome, sleep bruxism

Medical, Psychiatric, and Substance-Induced Sleep Disorders

Associated with mental disorders: mood disorders, anxiety disorders, psychotic disorders
 Associated with neurologic disorders: Parkinson disease, Huntington disease, dementia
 Associated with other medical disorders: heart disease, renal insufficiency, pulmonary disease
 Associated with a substance: medication/substance abuse (e.g., phenylpropranolamine, cocaine)

Proposed Sleep Disorders

Menstrual-associated sleep disorder, pregnancy-associated sleep disorder, short or long sleeper

^aAny sleep pattern that is abnormal (e.g., insomnia or excessive sleepiness).

^bAny unusual behavior that emerges during sleep.

From references 6, 13, 15, with permission.

Sleep Medicine and the NIH. These interventions can take 2 to 10 weeks to successfully implement based on the individual and the severity and chronicity of that person's insomnia, however, results are long-lasting. Table 77-3 lists established cognitive and behavioral interventions with brief descriptions in addition to some sleep-hygiene tips to include in patient counseling. Sleep hygiene techniques have not been demonstrated as effective without adjunctive CBT.^{5,14}

The sleep environment should be dark and comfortable, free from noise or distractions, and not too warm or too cold. Along with creating a sleep-friendly setting, establishing regular sleep hours, particularly a regular wake time, is necessary to condition the body to sleep. Even after a poor night's sleep, it is important for healthy sleepers to avoid daytime naps and stay awake until the regular sleep time. In some cases, brief (e.g., 20-minute) naps may be refreshing without disrupting nocturnal sleep. Phototherapy, bright light exposure for 30 minutes to 1 hour on awakening in the morning, is an additional tool that can help set the circadian rhythm for regular sleep–wake cycles.^{14,21,38} Healthy sleep often can be facilitated by avoiding problem-solving activities (e.g., finances, crossword puzzles), strenuous physical exercise, or exciting movies while in bed. Exercise early in the day can improve sleep. Exercise should be completed before dinner time so that the body has a few hours to relax before it is time to sleep. Relaxation is the key to healthy sleep. If a sleeper finds himself or herself tossing,

Table 77-3 Nonpharmacologic Treatments for Insomnia

- Cognitive-behavioral therapy: most effective; can be from any trained provider.
 Cognitive: identify and stop thought patterns that interfere with sleep (e.g., “I’m never going to sleep” or allowing 15 minutes to review a worry list, then putting worries aside).
 Behavioral: stimulus control, sleep restriction, relaxation, paradoxical intention.
 - Stimulus control: train the brain to reassociate the bed and bedroom with sleep and re-establish a consistent sleep–wake schedule.
 - Sleep restriction: create “sleep-debt” by curtailing amount of time in bed, then increasing time in bed as sleep efficiency improves.
 - Relaxation therapy: progressive tensing and relaxing of muscles, yoga, stretching.
 - Paradoxical intention: encourage patient to engage in most feared behavior, “staying awake” to reduce performance anxiety associated with trying to sleep.
- Sleep hygiene: not considered effective on its own; useful adjunctive treatment.
 Avoid caffeine, stimulants, heavy meals and etoh at bedtime; exercise early in the day before dinner to relieve stress and prime brain for sleep. Turn the face of the clock away from view; establish a pre-bedtime ritual, make sure bedroom is dark, quiet, comfortable

From references 14, 20, with permission.

turning, or worrying, it is time to get out of bed and stretch, read, or listen to soft music to relax. Health care practitioners should remind patients to avoid large meals at bedtime because the digestion of heavy meals can impair sleep. Last, chemicals that can disrupt sleep (e.g., alcohol, caffeine, other stimulants) should be eliminated when possible.^{14,20,21}

Pharmacologic Treatment

When rapid relief of transient or short-term insomnia is needed or when chronic insomnia persists despite nondrug therapeutic interventions, hypnotic medication is indicated. Benzodiazepine hypnotics or newer, benzodiazepine omega-1 selective hypnotics, sometimes called “Z-hypnotics,” are first-line therapies because they offer significantly greater efficacy than over-the-counter (OTC) products; they are safer than barbiturates and are more effective compared with sedating antidepressants.^{5,21,41}

Some patients need pharmacologic treatment for insomnia but do not seek treatment from their health care providers.^{5,41} Alcohol and OTC sleep aids containing antihistamines are widely used to self-medicate insomnia, although the results are less than ideal.^{5,21}

The ideal hypnotic has a rapid onset of effect (within 20 minutes, the natural time to fall asleep), helps the patient sleep throughout the night, does not cause daytime impairment, and has no abuse potential. Currently, there are no ideal hypnotics. Hypnotics that act at benzodiazepine receptors come closest to the ideal.⁴² Available agents vary in onset, duration, and potential for daytime impairment, mostly because of their individual pharmacokinetic profiles.^{41,42} The selection of the appropriate hypnotic should consider the type of insomnia to be treated and the physiologic characteristics of the patient. For example,

if someone cannot fall asleep but has no trouble staying asleep and wants no carry-over effect into the next day, a rapid-acting hypnotic with a short half-life and no active metabolites is desirable.^{21,41,42}

Less common sleep disorders are treated with a variety of medications as well as some nondrug therapies. PLMS and restless legs syndrome (RLS) can be relieved with dopamine agonists, opioids, gabapentin, or clonazepam.⁴ Narcolepsy is best treated with planned naps, modafinil, stimulants, sodium oxybate, or some antidepressants.⁴ Both sleep apnea and primary snoring can be worsened with central nervous system (CNS) depressants but usually improve with nondrug therapies such as continuous positive airway pressure (CPAP).⁴³ Sleep disturbances associated with medical and psychiatric diagnoses require special attention because a hypnotic can either improve or worsen the problem.^{6,13}

In a Normally Healthy Patient

1. E.P., a 31-year-old woman, is requesting a medication for treatment of her insomnia. She just returned to California from Hong Kong 2 days ago and is now having difficulty getting to sleep. When she arrived in Hong Kong, she went to sleep immediately at 4 PM and awoke at 3 AM. Her sleep pattern adjusted during her 6-week visit in Hong Kong, but on returning to California, it now takes her 2 to 3 hours to fall asleep. She has difficulty awakening in the morning and, as a result, sleeps past noon. She needs to be alert during the day to fulfill her obligations as a school teacher. What information provided by E.P. is important in the assessment of her insomnia? What additional information should be obtained from E.P. to assist in the assessment of her sleep disturbance?

E.P. describes a time-zone shift or disruption in circadian rhythm, which is a common cause of transient insomnia. Her major complaint is difficulty falling asleep, because she reports no trouble staying asleep or awakening too early. It is important for E.P. not to be sedated during the day because she is a teacher. Additional information needed from E.P. includes the duration of insomnia, methods already tried to relieve insomnia and their efficacy, concurrent medications, coexisting medical or psychiatric problems, alcohol use, caffeine use, and current life stresses. E.P. should be advised that assessing all of the aforementioned information is necessary in treating her sleep problem.

2. In response to your additional questions, you learn that E.P. has no medical problems and takes no prescription medications. She has been taking pseudoephedrine at night for nasal stuffiness since returning from Hong Kong. She denies drinking alcoholic beverages and coffee but admits to recently increasing her tea intake to try to stay awake during the day. She denies a long history of insomnia, but adds, “I have not been able to sleep as well in my new apartment; I don’t know why.” What factors could be contributing to E.P.’s?

Several factors are contributing to E.P.’s type of insomnia, which can be classified as circadian rhythm sleep disorder related to jet lag. Her circadian rhythm has been disrupted because of travel, but she also takes a stimulating decongestant (i.e., pseudoephedrine) and drinks a caffeine-containing beverage (i.e., tea). In addition, she sleeps in new surroundings that may require time for adjustment. All these factors can contribute to her difficulty in falling asleep. Circadian rhythm

sleep disorder results from a mismatch between the sleep–wake schedule required by a person’s environment and the circadian sleep–wake pattern.

Nonprescription Sleep Aids

3. E.P. would like to purchase a nonprescription sleep medication. What would you recommend?

An individual risk-versus-benefit assessment is essential before recommending any medication, even OTC products. Most nonprescription sleep aids contain antihistamines such as diphenhydramine (Benadryl). Antihistamines can cause drowsiness and can help patients fall asleep. The ability to cause sedation does not necessarily lead to hypnotic efficacy. Some patients do not feel well rested the next day after taking an antihistamine, but instead feel slow, lethargic, and not mentally sharp. This “hangover effect” can be significant and may be related to the lipid solubility and central histaminic (H₁) and muscarinic blocking effects of the antihistamine.^{21,41} Antihistamines with low lipid solubility (e.g., fexofenadine, loratadine) do not cross the blood–brain barrier readily and do not cause sedation. Although diphenhydramine is the most common antihistamine found in nonprescription sleep medications, some preparations contain the antihistamines doxylamine or hydroxyzine. Tolerance can develop to the sedative effects of antihistamines after 3 to 7 days of continued use.^{21,41} Because of a high incidence of daytime sedation and risk of cognitive impairment,⁴⁴ antihistamines are a poor choice for E.P., a teacher who must stay alert and functional throughout the day. Therefore, E.P.’s insomnia should be managed with nonpharmacologic interventions before initiating any drug therapy.

Time-Zone Shift: Nonpharmacologic Treatment versus Triazolam or Z-hypnotic

4. Why is E.P. especially susceptible to the effects of time-zone shift (i.e., “jet lag”), and what counseling is needed?

Time-zone shift disrupts the natural circadian rhythm, which helps regulate sleep. E.P. traveled west, then east through multiple time zones. Symptoms and severity of jet lag are related to the direction traveled and the number of time zones crossed.³⁸ Individuals >50 years of age and those traveling eastward have more difficulty in adjusting their circadian rhythm to time-zone changes. Eastward travelers have difficulty falling asleep and westward travelers complain of difficulty staying asleep and early morning awakening.³⁸ Travelers should be made aware of the problem and should take steps to help their systems adjust. On arrival in the new time zone, travelers such as E.P. should reset their watches and participate in activities corresponding to the new time. Staying active until the new time-zone bedtime and avoiding naps and stimulants can be helpful.³⁸

E.P. should be informed about the likely causes of her insomnia (i.e., jet lag, tea, pseudoephedrine, new surroundings). She also should understand that it may take 1 to 3 weeks for her system to readjust after traveling.³⁸ The importance of nonpharmacologic interventions to improve sleep (Table 77-3) should be emphasized. For E.P., it is necessary to pay particular attention to regulating her sleep cycle by awakening at the same time each day and resisting daytime naps even after a poor night of sleep. This process, called *chronotherapy*,

Table 77-4 Pharmacokinetic Properties of Hypnotics Acting at Benzodiazepine Receptors^{22,41,54-76,111}

| Active Substance | Lipid Solubility | T _{max} (hr) | Onset (min) | Half-Life (hr) | Duration (hr) ^a |
|---------------------------|------------------|-----------------------|-------------|----------------|----------------------------|

| N-desalkyl ^b | Moderate | 10 | 30–60 | 50–100 | 10–30 |

^aTime the patient feels the effects after a single dose; usually approximates half-life with multiple doses; individual variability exists; and tolerance may develop with continued use, lessening the duration. T_{max}, time of maximum concentration.

^bFlurazepam metabolite.

regulates the internal time clock. In addition, an hour of bright light in the morning can serve as an environmental stimulus, normalizing the circadian rhythm.³⁸ If E.P.'s insomnia persists despite adhering to cognitive-behavioral interventions, a prescription hypnotic may be necessary.

5. E.P. asks if she can try one of her husband's triazolam tablets. She notes, "He is immediately out like a light when he takes it, and I worry it may be too strong for me."

Short-acting hypnotics (Table 77-4) like triazolam are effective to induce and regulate sleep if the stay will be relatively short (<5 days) and if critical activities must be accomplished during the first 48 hours after arrival at the destination.³⁸ Advantages of triazolam for E.P. include well-established efficacy, an onset of 15 to 30 minutes and no next-day impairment at recommended doses (0.25 mg, 0.125 mg for elderly). Women may be more affected from hypnotics than men, possibly because of greater oral bioavailability.^{21,41} E.P. could ask her physician to prescribe triazolam 0.125 mg in case it is needed. Triazolam is less optimal than zaleplon or zolpidem for E.P. because it can cause impairment in new learning or anterograde amnesia. These effects can be sufficiently severe to result in inability to remember new information learned on the trip. Triazolam is also associated with rebound insomnia (i.e., daytime nervousness, jitteriness, and insomnia worse than before) if abruptly stopped after >7 to 10 days of continuous use. Of the benzodiazepine hypnotics, triazolam is most commonly associated with rebound insomnia and withdrawal problems likely related to its high binding affinity to the benzodiazepine GABA-chloride-ionophore receptor complex.^{41,45} Also, triazolam's short half-life (2–5 hours), and rapid decrease in blood levels create the potential for withdrawal symptoms including anxiety and insomnia. Anterograde amnesia is not a problem with "Z"-hypnotics at recommended doses because they are selective for the Ω -1 receptor and do not have significant anxiolytic effects.⁴¹ Triazolam is highly effective in inducing sleep when used on an as-needed basis. Long-acting hypnotics, such as flurazepam (Dalmane), may prevent the traveler from awakening in the morning and should be avoided.

Melatonin

6. E.P. states she would like to try melatonin for improved sleep but wonders whether it is safe and effective. What information is

available on the safety and efficacy of melatonin for jet lag or other types of insomnia?

Melatonin is a naturally occurring hormone secreted by the pineal gland, located in the center of the brain. The pineal gland is connected to the retina via a nerve pathway that runs through the suprachiasmatic nucleus of the hypothalamus, the body's circadian clock. The pineal gland produces melatonin (a byproduct of serotonin metabolism) only during the nocturnal phase of the circadian cycle and only in relative darkness.⁴¹

Several studies show melatonin has at least mild sleep-promoting properties when administered before the period of natural increase in endogenous melatonin (~10 PM to midnight). Studies in adults show melatonin causes significantly more sleepiness when taken at 8 PM compared with 11:30 PM, theoretically because the brain's receptors are already saturated with melatonin late at night.⁴¹

Eight of ten clinical trials for jet lag found that melatonin, between 0.5 and 5 mg taken close to the target bedtime in the new time zone decreased jet lag. A systematic review of 10 clinical trials showed melatonin was more effective for travel eastward crossing multiple time zones.⁴⁶ Melatonin 0.5 to 10 mg has been found effective for entraining the circadian rhythms in blind people, for alleviating insomnia in developmentally disabled or handicapped children and adults, and treating short-term, initial insomnia in children with attention deficit hyperactivity disorder (ADHD).^{41,47} It has no established effectiveness for chronic insomnia.⁵ Consumers selecting melatonin should be advised that the safety and effectiveness of melatonin for long-term use have not been clearly established and the purity of melatonin is not regulated by the FDA. Melatonin side effects include sleepiness, headache, and nausea, although usual doses of melatonin 0.5 to 5 mg are well tolerated.^{41,48} Melatonin use has been associated with reports of depression, liver disease, and vasoconstrictive, immunologic, and contraceptive effects.^{38,41,46}

Ramelteon

7. E.P. is concerned about using melatonin because it is not regulated by FDA and the purity and product integrity cannot be guaranteed. Her doctor gave her a prescription for ramelteon (Rozerem) 8 mg at bedtime, how does ramelteon compare with melatonin?

Ramelteon is a highly selective agonist for melatonin receptors 1 and 2 (MT 1, MT 2). Melatonin receptor 1 regulates

sleepiness and MT 2 regulates phase shifts from day to night. The clinical significance of ramelteon's selectivity for MT 1 and MT 2 is not well-described.⁴⁹ Ramelteon is approved by the FDA for insomnia characterized by difficulty falling asleep. Clinical studies in primary insomnia show it decreases the time to fall asleep by 10 to 19 minutes and it increases total sleep time by 8 to 22 minutes. Its half-life ranges from 1 to 2.6 hours. Half-life of its active metabolite, M II, is 2 to 5 hours. Ramelteon undergoes hepatic metabolism by CYP1A2. Increases in serum concentration occur even with mild liver disease, so caution is recommended for patients who have at least moderate liver disease. Fluvoxamine inhibits CYP1A2, dramatically increasing the serum concentration of ramelteon, and coadministration with all potent CYP1A2 inhibitors should be avoided. The most common adverse events observed with ramelteon include headache (7%), dizziness (5%), somnolence (5%), fatigue (4%), and nausea (3%).

No evidence of cognitive impairment, rebound insomnia, withdrawal effects, or abuse potential was noted in clinical trials. Adults with a history of sedative abuse took triazolam 0.25, 0.5, 0.75 mg, and ramelteon 16, 80, 160 mg, versus placebo over 18 days. Ramelteon demonstrated no potential for abuse or motor and cognitive impairment up to 20 times the recommended therapeutic dose, whereas triazolam demonstrated potential for abuse at all doses.⁵⁰

Ramelteon is a reasonable option for initial insomnia with no abuse potential and little to no risk of next-day impairment. In the absence of published trials comparing ramelteon with other sedative-hypnotic agents, its place in therapy is unclear.

“Z-hypnotics” (Zolpidem and Zaleplon and Eszopiclone)

8. It has been a month and E.P. continues to have difficulty falling asleep. What alternative medications (aside from triazolam and ramelteon) offer rapid onset, have low risk of daytime sedation, and can be administered safely over weeks to months if necessary?

Considering their rapid onset of action, Z-hypnotics (zaleplon, zolpidem, and eszopiclone) are all potential alternatives for E.P. They have varying degrees of selectivity for Ω -1 receptor on the benzodiazepine receptor complex. This selectivity imparts hypnotic efficacy with no significant anxiolytic, muscle relaxant, or anticonvulsant effects. Consequently, Z-hypnotics have a lower risk of abuse, withdrawal, and tolerance compared with older nonselective benzodiazepines such as triazolam and temazepam. These attributes makes Z-hypnotics more desirable for the treatment of chronic insomnia. Both zolpidem controlled-release and eszopiclone are FDA approved for chronic insomnia and are effective for up to 3 to 6 months of therapy.⁵¹ Although the abuse potential of Z-hypnotics is less than for nonselective benzodiazepines, they are problematic in active substance abuse disorders, however. Z-hypnotics are C-IV controlled substances with more potential for abuse than ramelteon. Tolerance and withdrawal have been reported with abrupt discontinuation of zolpidem, particularly with self-escalation of dose, thus monitoring and counseling are needed.

Another potential advantage of Z-hypnotic's Ω -1 selectivity is little to no change in sleep architecture or sleep stages. Temazepam and flurazepam increase the percentage of stage 2 sleep but can suppress REM and stage 3 and 4 deep restorative sleep. In contrast, Z-hypnotics do not interfere with these

sleep stages and have lower rates of uncomfortable REM rebound (vivid dreams, increased autonomic instability) on discontinuation.⁵¹

The Z-hypnotics differ with respect to pharmacokinetics and adverse events. Zolpidem (Ambien), the first Z-hypnotic, marketed in the United States in 1991 is absorbed rapidly, reaches peak serum levels in 1.5 hours and is eliminated rapidly with an average half-life of approximately 2.5 hours.⁴¹ Zolpidem is metabolized by the oxidative cytochrome P450 isoenzyme CYP3A4; therefore, drug interactions should be considered when zolpidem is coadministered with CYP3A4 inhibitors such as diltiazem or fluoxetine. Zolpidem has no active metabolites and it has a low risk of residual daytime sedation in recommended doses.^{51,52} It should be taken on an empty stomach for faster absorption. The usual adult dose of zolpidem is 10 mg at bedtime; elderly or patients such as E.P., who expresses concern that a medicine may be too strong, should begin with 5 mg at bedtime. Zolpidem controlled release (CR) has no clear advantage over zolpidem, except that it may provide a slightly longer duration of sleep. Serum concentrations peak in 2 hours compared with 1.5 hours for immediate release zolpidem with an associated longer latency to effect.⁴²

Zaleplon (Sonata) offers a shorter elimination half-life (1.1 hour) and duration of effect than zolpidem. It is least likely of all hypnotic agents to cause residual daytime sedation and has the least effect on memory and psychomotor performance. An assessment of psychomotor performance, arousal, memory, and cognitive functioning with zaleplon revealed no cognitive impairment.⁵¹ The most common adverse effects with zaleplon include dizziness, headache, and somnolence. In dose escalation studies using up to 60 mg, symptoms appear at approximately 30 minutes after dosing, peak at 1 to 2 hours, and are no longer evident after 4 hours. It can be taken in the middle of the night as long as the individual has 4 hours left in bed (Table 77-4).⁴¹ Zaleplon is metabolized primarily via aldehyde oxidase, and CYP3A4 is a secondary route of metabolism, and there are no active metabolites; it has less potential for drug or food interactions compared with zolpidem or eszopiclone.⁴¹

Eszopiclone (Lunesta) maintains efficacy with no evidence of tolerance after 6 months of continuous use, resulting in an FDA approval for long-term use.⁵³ Hypnotic efficacy has been demonstrated for up to 6 months in younger patients taking 2 to 3 mg nightly, and in elderly patients taking 1 to 2 mg nightly, although only the higher range of doses significantly improved sleep maintenance. As with zolpidem and zaleplon, eszopiclone has a rapid onset of effect, but differs in that it has a longer duration of effect (Table 77-4). Time of maximum concentration (T_{max}) is delayed up to 1 hour when eszopiclone is administered after a high-fat meal, potentially delaying the onset of sleep.⁵⁴

Eszopiclone has less receptor selectivity than either zaleplon or zolpidem, potentially resulting in some anxiolytic, amnestic, and anticonvulsant activity.⁵² Among the three Z-drugs, eszopiclone has a dose-related unpleasant bitter taste in 16% to 33% of patients.⁵⁴ Headache and dizziness were reported more commonly with eszopiclone than placebo, and at higher doses, next day confusion and memory impairment have been reported in up to 3% of patients.^{51,54} Eszopiclone is primarily metabolized by CYP3A4, so drugs that induce or inhibit this isoenzyme can have an impact on metabolism and a clinical effect.⁵⁴

E.P. needs a medication that will hasten sleep onset, but does not need continued drug effect later in the night. Both zolpidem and zaleplon are useful alternatives for E.P. because of their efficacy for her sleep onset difficulty. Among the Z-hypnotics, eszopiclone has the longest half-life and the greatest risk for next-day impairment.

9. As an alternative to ramelteon, zolpidem immediate-release, 5 mg is prescribed. E.P. expresses concern over possible adverse effects owing to its labeling as a CIV controlled substance and the recent FDA warning of complex sleep behaviors such as night eating and night driving. How should E.P.'s concerns be addressed?

Patient counseling is most effective when it is interactive with both patient and practitioner actively listening to each other while exchanging information. It is best to begin by emphasizing the benefits of zolpidem to improve her sleep and daytime functioning. Next, E.P. should be reassured that zolpidem is generally well-tolerated and she will be prescribed the lowest dose to minimize the likelihood of adverse effects. Counseling should include a discussion of common and potentially serious adverse effects along with management strategies. Common possible adverse effects include headache (28.4%), drowsiness (26.2%), fatigue (16.6%), and dizziness (14.0%).⁵¹ Gastrointestinal side effects occurred in 1.7% of patients; this side effect is more common with Z-hypnotics compared with nonselective benzodiazepines. Confusion, disorientation, obsessive ideas, delirium, and psychosis occurred at a rate of 1% in postmarketing surveillance studies. Hallucinations, mostly visual, are more common in elderly patients, or in those taking high doses or patients with impaired metabolism of zolpidem.²¹ E.P. should be encouraged to report both effectiveness and all adverse effects to her clinician. Alcohol may be ingested 3 to 4 hours before taking zolpidem but they should not be taken together because it may cause excessive side effects and interfere with E.P.'s sleep.

To address E.P.'s concern about the FDA's hypnotic warning, a reasonable response would be, "rarely, individuals taking sleeping medication have been reported to be making phone calls, eating, having sex, or driving while half asleep. The risk for these potentially dangerous reactions increases if consumers take a higher than recommended dose, or drink alcohol or mix hypnotics with other sedating medications."¹⁶ Another rare allergic reaction is facial swelling (angioedema). All manufacturers of hypnotic medication are required to include this information in their package inserts.¹⁶

IN A MEDICALLY ILL PATIENT

Insomnia and Effect on Sleep Stages

10. A.T., a 42-year-old woman with a 5-year history of hypothyroidism and a 2-year history of hypertension and chronic lower back pain, was just transferred from the intensive care unit (ICU) into a medical unit. Her cardiac status is considered "stable" 2 days after a myocardial infarction (MI). She is 5 feet 9 inches tall and weighs 72 kg. She is receiving aspirin (enteric-coated), levothyroxine, and felodipine. Her main complaint is insomnia, including difficulty falling asleep, difficulty maintaining sleep, and early-morning awakenings. A.T. reports insomnia for 6 weeks be-

fore admission, which only worsened during the hospitalization. What type of insomnia does A.T. have and how might the insomnia affect her?

A.T.'s insomnia is considered chronic because she experienced it for 6 weeks before hospital admission. It is severe because it involves difficulty falling asleep, maintaining sleep, and early-morning awakening. Careful monitoring and effective treatment of A.T.'s sleep disturbance is crucial; studies show disrupted sleep can increase the risk of another adverse cardiac event owing to worsening autonomic instability and poor perfusion to the myocardium.²

Because normal sleep moves through all the stages of NREM and REM in a continuous cycle, a patient deprived of continuous sleep may not receive sufficient time in each sleep stage. When stage 2 is diminished, muscles have insufficient opportunity to rest and rejuvenate. If NREM stages 3 and 4 are eliminated, immune function and the healing process can be disrupted. If REM sleep is deprived or excessive, neurotransmitter function may be altered and physiologic homeostatic processes can be disrupted.^{6,13,25}

Drug or Disease Etiologies

11. What individual drug or disease state factors should be assessed in A.T. before developing a treatment plan?

Numerous medical disorders and primary sleep disorders are associated with difficulty falling asleep and maintaining sleep (Table 77-5 and Table 77-6).^{2,6} First, A.T.'s pain management should be assessed for optimal efficacy. Acute post-MI pain adds to A.T.'s chronic lower back pain. Of patients with lower back pain, 50% experience chronic poor sleep patterns.^{27,38} Second, A.T. was just transferred out of the ICU. Sleep deprivation in an ICU is common and is attributed to the continuous lighting, noise, and constant interventions. Sleep deprivation may prolong or worsen a disease process through diminished natural killer cell activity and decreased stages 3 and 4 of NREM sleep (when healing occurs).^{6,13,41} Medications also may be contributing to A.T.'s insomnia (Table 77-5). Levothyroxine can overstimulate the CNS if given in excessive doses.⁵⁵ A.T.'s thyroid status should be re-evaluated to ensure appropriateness of the thyroid dose, especially considering her post-MI status. Calcium channel blockers have been associated with occasional sleep disturbances; therefore, felodipine should be evaluated as a potential contributing factor.⁵⁵

Another clue to a possible cause of A.T.'s sleep problem is her description of early-morning awakening, which could be related to hospital activity during these hours or to the presence of a major depressive disorder. A.T. requires psychiatric evaluation to rule out depression, which occurs in 33% to 88% of patients after an MI.²⁸ In general, patients with chronic illnesses are at increased risk of developing major depression, which typically presents with insomnia or hypersomnia. Interestingly, medical outcome studies of other chronic illnesses (cardiovascular, pulmonary, renal, neurologic disease) show a high prevalence of sleep disturbance even in those not suffering from depression.^{2,7} Chronic insomnia related to multiple causes can be resistant to treatment; however, treatment of underlying causes increases the likelihood of insomnia resolution.

Table 77-5 Potential Causes and Contributing Factors for Each Chronic Sleep Complaint**Difficulty Falling Asleep**

Learned or conditioned activation (primary insomnia); restless legs syndrome (RLS)
 Medications: methylphenidate, modafinil, fluoxetine, bupropion, steroid, β -blocker
 Substances: caffeine, guarana, alcohol
 Psychiatric disorders: schizophrenia, depression, anxiety disorder, bipolar disorder
 Medical disorder: chronic pain, neuropathy, gastrointestinal disorder, cardiopulmonary disorders (particularly if in recumbent position).

Difficulty Maintaining Sleep

Excessive time in bed
 Psychiatric disorder: major depression, anxiety or bipolar disorder, substance abuse
 Sleep disordered breathing: sleep apnea, acute respiratory distress syndrome
 Cardiac disease: atrial fibrillation, heart failure, angina
 Neurologic disorder: dementia, Parkinson disease, multiple sclerosis

Early Morning Awakening

Major depression
 Advanced sleep phase syndrome; learned or conditioned activation (primary insomnia)
 Forced to get up because of family or work obligations

Excessive Daytime Sleepiness

Medications: clonidine, antihistamines, antipsychotic, antidepressant, benzodiazepine, chloral hydrate, opioid, anticonvulsant, α_1 -adrenergic blockers
 Obstructive sleep apnea, central sleep apnea, narcolepsy
 Chronic sleep deprivation

Based on Table 1 from reference 13.

Table 77-6 Potential Causes of Chronic Sleep Disorders^{25-69,70}**Psychiatric Disorders**

| | |
|--------------------------|----------------------|
| Anxiety disorders | Depressive disorders |
| Bipolar disorder | Psychotic disorders |
| Personality disorders | Somatiform disorders |
| Organic mental disorders | Substance abuse |

Medical and Neurologic Disorders

| | |
|--------------------|------------------------------------|
| Angina pectoris | Dementia |

| PLMS (nocturnal myoclonus) | Primary snoring |
| Circadian rhythm sleep disorder (jet lag, shift work, delayed sleep phase) | Narcolepsy |

Drugs Associated with Sleep Disturbance

| | |
|--------------------------|-------------------------------|
| Insomnia | Hypersomnia |
| Alcohol | Alcohol |
| Bupropion | Benzodiazepines |
| Fluoxetine | Antihypertensives |
| Sertraline | Clonidine |
| MAO inhibitors | α -Adrenergic blockers |
| TCA | ACE inhibitors |
| Thyroid supplements | β -Blockers |
| Calcium channel blockers | Anticonvulsants |
| Decongestants | Analgesics |
| Appetite suppressants | Chloral hydrate |
| Theophylline | Antipsychotics |
| Corticosteroids | Antihistamines |
| Dopamine agonists | Opioids |

ACE, angiotensin-converting enzyme; COAD, chronic obstructive airway disease; MAO, monoamine oxidase; PLMS, periodic limb movements during sleep; RLS, restless legs syndrome; TCA, tricyclic antidepressants.

Comparing Available Hypnotics

12. A.T.'s pain is now under control, her levothyroxine dose is appropriate, and felodipine-induced sleep disturbance, sleep-disordered breathing, RLS, and PLMS have all been ruled out. A psychiatric evaluation finds that A.T. does not have major depression, but she is anxious about "life after a heart attack." She meets criteria for primary insomnia and adjustment disorder with anxiety. She continues to have trouble falling asleep and staying asleep. She will be discharged in 2 days. The pain management team suggests an adjunctive medication with anxiolytic properties that may also help with sleep. Which hypnotic is best for A.T., considering her individual clinical characteristics?

The ideal hypnotic for A.T. should act quickly and continue working throughout the night to provide her with uninterrupted sleep. A hypnotic that is not metabolized in the liver would have a lower potential for drug interactions and lessen the opportunity for systemic accumulation. If daytime drug concentrations are needed to calm anxiety, however, a hypnotic with slowly eliminated active metabolites may be desirable. The comparable doses of the hypnotic medications are listed in Table 77-7. When considering available hypnotic medications, differences

Table 77-7 Hypnotic Dosing Comparison

| Drug | Dose (mg) | Range (mg) |
|-------------------------|-----------|------------|
| Midazolam (Versed) | 15 | 10-30 |
| Zaleplon (Sonata) | 10 | 5-10 |
| Zolpidem (Ambien) | 10 | 5-10 |
| Zolpidem ER (Ambien CR) | 12.5 | 6.25-12.5 |
| Triazolam (Halcion) | 0.25 | 0.125-0.25 |
| Temazepam (Restoril) | 15 | 7.5-30 |
| Flurazepam (Dalmane) | 15 | 15-30 |

in pharmacodynamic and pharmacokinetic properties should be considered (Table 77-4).

A nonselective benzodiazepine hypnotic is preferable in A.T. because of the need for anxiolytic properties in addition to hypnotic efficacy. Z-hypnotics are not effective anxiolytic agents. Onset of effect is related to lipophilicity, receptor binding affinity, and T_{max} .^{41,42}

The pharmacodynamic and pharmacokinetic properties of triazolam (Halcion) have already been presented. Its rapid onset is an advantage for A.T.; however, the duration of action would not be sufficient to help A.T. stay asleep. In addition, it should not be used for >7 to 10 days because of the greater potential for adverse effects with prolonged use and the possibility of significant rebound insomnia on withdrawal.⁴¹ A.T. may require a hypnotic for >7 to 10 days, which is the maximal duration for triazolam use.

Flurazepam (Dalmane) induces sleep within 15 to 45 minutes during chronic dosing. On the first night of use, however, flurazepam does not induce sleep as well as triazolam. It has intermediate fat solubility but depends on plasma concentrations of its metabolite, desalkylflurazepam, for most of its activity.⁴¹ Desalkylflurazepam concentrations take approximately 24 hours to accumulate and induce sleep. Studies show flurazepam maintains efficacy in sleep induction for at least 30 days; desalkylflurazepam has weak receptor binding affinity and a long half-life, resulting in gradual elimination and little chance for rebound insomnia.⁴¹ Desalkylflurazepam can accumulate during chronic dosing and affect daytime cognition in some patients or compete for hepatic metabolism, resulting in altered levels of other hepatically metabolized medications.^{41,56} Accumulation and daytime sedation can be therapeutic for some patients with daytime anxiety. A.T. has difficulty moving around during the day because of her chronic lower back pain, and oversedation from accumulation may impair her daytime functioning. Although flurazepam is a viable alternative, it is useful to explore other options.

Temazepam (Restoril) takes 1 to 2 hours to induce sleep. It has moderate fat solubility, similar to desalkylflurazepam, but it has a longer dissolution time. Temazepam takes 1.5 to 2 hours to reach peak plasma concentrations. Temazepam's longer dissolution time is caused by its large drug particle size in a gelatin capsule. The European product formulation, consisting of a solution in a wax matrix, induces sleep in 30 minutes.^{41,56} A potential advantage for using temazepam in A.T.'s case is its lack of hepatic oxidative metabolism and intermediate duration of action of 8 to 12 hours. It does not interfere with the metabolism of other hepatically metabolized drugs and it does not accumulate, minimizing the potential for daytime impairment.^{35,41} The long onset of action may be of concern, although A.T. could take the drug an hour before bedtime to optimize timing for sleep.

For A.T., the most appropriate choice is temazepam. Temazepam's advantages are intermediate duration of activity that would keep her asleep throughout the night, and low risk of daytime impairment owing to no known active metabolites.^{35,41}

Dependence and Tolerance

13. On further discussion with A.T., who prefers to try cognitive-behavioral interventions for anxiety reduction and sleep

induction, temazepam 15 mg at bedtime is prescribed on an as-needed basis. A.T. will be monitored regularly as an outpatient for efficacy and tolerability. As A.T. is preparing to leave the hospital, her daughter, B.T., expresses concerns about the potential for physical dependence on temazepam and the risk of A.T. becoming an addict. How would you respond to her concerns?

Fear of dependence and addiction to medications is a concern among the general public. Television station "medical experts" and popular magazine "health sections," while providing information, may increase the potential for confusion, erroneous impressions, and misinformation. For health care practitioners, it becomes even more crucial to provide sound drug information in common, easy-to-understand terms.

An example of the practitioner's response may be, "I'm glad you have expressed a concern; it gives us a chance to discuss temazepam therapy before your mother leaves the hospital. Temazepam has been prescribed for a medical reason, to improve your mother's sleep and to aid in her healing process. One therapeutic benefit of temazepam is an 8-hour duration of effect. Your mother will be able to sleep throughout the night so that she is well rested during the day. It also may decrease her anxiety over not sleeping, and that puts less stress on her heart.

"The possible side effects of temazepam include sedation, unsteadiness, and dizziness. She should let her doctor know if she experiences any adverse effects. Right now, it is unclear how long your mother will be taking temazepam. Duration of therapy needs to be assessed on an ongoing basis. If your mother takes temazepam every night for more than 4 weeks, two things could happen: (a) she may develop a tolerance and it may not help her sleep anymore, or (b) her system may develop a dependence in which she may have worse insomnia if she does not take it. These two scenarios do not always occur and are not likely because your mother will be taking it on an as-needed basis. If one or the other does happen, some other intervention may be tried to help with her sleep, or the temazepam dose can be gradually decreased to prevent withdrawal problems. It is important to advise your mother to take the medication only as directed (no more or less), avoid alcohol, and report any decrease in effectiveness or any adverse effects to her health care practitioner. Your mother, without a history of substance abuse, is not likely to become an addict. Although dependence is something to pay attention to, it is not the same as addiction and what matters is the functional ability of your mother while on and off the medication."

Epidemiologic data indicate that benzodiazepines are widely used primarily for brief periods of time, but less commonly used on a long-term basis. Dependence can occur after continued use over 2 to 4 months.³⁶ Daily users for >1 year tend to be older, medically ill, and chronically dysphoric and have panic disorder or chronic insomnia. Most chronic use appears to be medically appropriate and does not lead to dose escalation or abuse. Among chronic dysphoric patients, the indications are less clear, and dose escalation is noted sometimes without notable therapeutic benefit. Benzodiazepine hypnotics rarely are taken alone for pleasure, and generally are not likely to be abused. Among substance abusers, however, they frequently are taken as part of a polysubstance abuse pattern by alcoholics and narcotic, methadone, and cocaine users. In these groups, abuse is highly prevalent. Benzodiazepines are used to

augment euphoria (narcotics and methadone users), to decrease anxiety and withdrawal symptoms (alcoholics), and to ease the “crash” from stimulant-induced euphoria (cocaine users).³⁷

Physiologic dependence on benzodiazepines, resulting in a withdrawal and abstinence syndrome, develops usually after 2 to 4 months of daily use of the longer half-life benzodiazepines. Shorter half-life benzodiazepine use can result in physiologic dependence earlier (days to weeks) and may be associated with more withdrawal problems.^{41,45} See Table 77-4 for a comparison of pharmacokinetic properties of hypnotics.

IN PSYCHIATRIC DISORDERS

Stepwise Approach to Selecting a Hypnotic

14. P.H., a 35-year-old man, is hospitalized after a suicide attempt with an amphetamine and alcohol overdose 1 week ago. Before the overdose attempt, P.H. had been clean (i.e., abstinent) and sober for 2 years. He is diagnosed with major depression and organic mood disorder secondary to psychoactive substance abuse. His target symptoms include a 20-pound weight loss, low energy, social withdrawal, depressed mood, hopelessness, inability to experience pleasure, trouble falling asleep, and early-morning awakening. His medications include fluoxetine (Prozac), 20 mg daily; lansoprazole (Prevacid), 30 mg daily; and a multivitamin daily—all started 5 days ago. After completing an interview with P.H., you learn that he was doing well until 2 months ago when his significant other left him and he became increasingly depressed. He began to attend Alcoholics Anonymous groups more regularly, but his depression worsened. Two weeks before admission, he went on a drinking binge that led to the suicide attempt. P.H. reports feeling restless and sleeping only 3 to 4 hours a night. Use Table 77-8 to compare the clinically significant differences between available hypnotics and to demonstrate how such information can be used to develop patient-specific treatment plans. What is the best approach to solving P.H.’s sleep problem?

The stepwise approach for selecting a hypnotic outlined in Table 77-8 serves as a useful guide for applying the information to an individual patient. Once the type of insomnia is known (difficulty falling asleep, difficulty maintaining sleep, early-morning awakening), possible causes or contributing factors must be identified and treated. Cognitive-behavioral interventions can be implemented if P.H. is willing and able to participate. At step 3, if significant insomnia persists and CBT is not feasible, a medication can be considered.

Step 4 lists factors to consider in the drug selection process. For example, agents with long-acting metabolites (e.g., flurazepam) may accumulate or cause daytime hangover. Therefore, it is best to avoid flurazepam in the elderly. If the hypnotic has no hepatic metabolism, it will not be subject to drug interactions with other agents that are hepatically metabolized. If insomnia is chronic and resistant to hypnotic treatment, or if a low abuse potential agent is desired (e.g., person with existing addictive disorder), trazodone or another sedating antidepressant may be selected.

Sleep Disturbance of Depression

15. What type of insomnia does P.H. have and how is it different from other types of insomnia?

P.H. has trouble falling asleep and early-morning awakening, and sleep time has decreased to 3 or 4 hours a night. He is diagnosed with major depression, and sleep difficulty is part of the disorder. Generally, initial insomnia and early-morning awakening are associated with depression, although difficulty maintaining sleep and next-day fatigue are common as well. P.H. is most bothered by trouble falling asleep, early-morning awakening and next-day fatigue.

The insomnia of depression probably is related to a dysregulation of neurotransmitters, such as serotonin, norepinephrine and dopamine, in addition to dysregulation of the hypothalamic-pituitary axis. All are involved in regulating mood and the sleep-wake cycle.^{6,13} Neurotransmitter activity is modified by the effects of antidepressants on REM sleep. Most effective antidepressants (excluding trazodone, and bupropion) suppress REM, causing increased REM latency and decreased total REM time.^{32,57} Indeed, REM sleep deprivation can elevate mood.^{57,58} Depressed patients deliberately deprived of REM sleep have had a reduction in depressive symptoms. In addition to effects on REM, antidepressants redistribute slow-wave sleep to more physiologically natural patterns, with increased intensity in the first half of the night.⁵⁸ Sedating antidepressants with serotonin 2 (5HT-2) antagonist properties, such as trazodone and mirtazapine, alleviate insomnia and improve sleep architecture.³²

Causes: Psychiatric and Substance Abuse

16. What other factors may be contributing to insomnia in P.H.? How can his sleep problem be solved?

P.H. has been prescribed fluoxetine to treat his depression. Fluoxetine can cause insomnia in 10% to 40% of patients and thus should be dosed in the morning. P.H. also was using alcohol and stimulants before admission. Drug withdrawal and the lingering “abstinence syndromes” often are associated with insomnia, although sometimes hypersomnia is the predominant symptom.^{36,59}

Treatment

The treatment for P.H.’s insomnia should begin with patient education. P.H. should be informed that >90% of depressed patients have some sleep disturbance, either too little or too much, and his sleep should improve as depressive symptoms improve (over 2–8 weeks). Counseling on cognitive-behavioral interventions to improve sleep may be appropriate when P.H.’s depression begins to clear and he is more motivated to improve his sleep hygiene. In the meantime, the potential contribution of fluoxetine to his restlessness or insomnia should be assessed by confirming that the drug is being dosed in the early morning to minimize this effect. An alternate, less activating selective serotonin reuptake inhibitors (SSRI) such as sertraline, citalopram, paroxetine, or a sedating antidepressant such as mirtazapine may be preferred unless P.H.’s history includes a positive response with fluoxetine that would justify ongoing treatment.

Hypnotics

All antidepressants, including SSRI, such as fluoxetine, can improve sleep as the depression lifts; however, fluoxetine, bupropion, and monoamine oxidase inhibitors can all cause

Table 77-8 Stepwise Approach to Selecting a Hypnotic for Insomnia

Step 1. Determine type of insomnia: DFA, DMS, EMA; duration.
 Step 2. Consider possible causes: medical, psychiatric, drug; treat causes.
 Step 3. CBT and sleep hygiene ineffective or only partially effective; significant insomnia persists.
 Step 4. Assess type of patient: age, size, diagnosis, organ function, drug interactions, abuse potential.

| Treatment Options | Type of Insomnia | | |
|----------------------------------|--|--|--|
| | DFA | DMS | EMA |
| Antidepressants | Duration of therapy: Chronic use in depressive diagnosis Onset and duration of effects: Intermediate to long onset Pharmacokinetic considerations: See individual antidepressant Clinical considerations: Substance abuse; treatment-resistant insomnia | | Duration of therapy: Chronic use in depressive diagnosis Onset and duration of effects: Intermediate to long onset Pharmacokinetic considerations: See individual antidepressant Clinical considerations: Substance abuse; treatment-resistant insomnia |
| Chloral hydrate | Duration of therapy: Short-term use, 2–7 days Onset and duration of effects: Rapid onset; intermediate duration Pharmacokinetic considerations: Major metabolite, trichloroethanol, is active Clinical considerations: GI side effects; rapid tolerance; no EEG effects; drug interactions | Duration of therapy: Short term and chronic Onset and duration of effects: Long onset; moderate duration Clinical considerations: Hepatic metabolism | |
| Flurazepam or quazepam | Duration of therapy: Short term and chronic Onset and duration of effects: Rapid onset; long duration Pharmacokinetic considerations: Active metabolite Clinical considerations: Efficacy long term | Duration of therapy: Short term and chronic Onset and duration of effects: Rapid onset; long duration Pharmacokinetic considerations: Active metabolite Clinical considerations: Efficacy long term | |
| Temazepam | | Duration of therapy: Short term and chronic Onset and duration of effects: Long onset; moderate duration Pharmacokinetic considerations: No hepatic metabolism | |
| Zolpidem, zaleplon, or triazolam | Duration of therapy: Short-term use, 7–10 days for triazolam, 2–4 weeks for zaleplon and several months for zolpidem Onset and duration of effects: Rapid onset; short duration Pharmacokinetic considerations: Short half-life Clinical considerations: Rebound insomnia; CNS side effects | | |

CNS, central nervous system; DFA, difficulty falling asleep; DMS, difficulty maintaining sleep; EEG, electroencephalogram; EMA, early-morning awakening; GI, gastrointestinal.

insomnia as well.^{55,60} Prescribing a hypnotic short term or a sedating antidepressant is recommended for depressed patients with insomnia because a good night's sleep can improve treatment adherence and daytime functioning until antidepressant

effects become apparent.^{2,6} A study of 545 patients with major depression and insomnia taking fluoxetine in the morning were randomized to receive either eszopiclone 3 mg or placebo for 8 weeks. Eszopiclone cotherapy resulted in improved sleep

quality, faster antidepressant response, and significantly more responders and remitters at week 8 compared with placebo.⁶¹ Unpleasant taste was the only adverse effect reported significantly more in the eszopiclone group versus the placebo group (22.7 vs. 0.7%). In separate studies, zolpidem and trazodone have demonstrated efficacy for residual insomnia in depressed patients with partial antidepressant response.⁶

Hypnotics that act at benzodiazepine receptors are not recommended for P.H. because of his drug use history. Nonselective benzodiazepines can have a euphoric effect, are cross-tolerant with alcohol, and are likely to be abused by patients with substance-abuse problems.^{36,41} Abuse, dependence, and withdrawal reactions have been reported with Ω_1 selective agents Z-hypnotics (zolpidem, zaleplon, eszopiclone); therefore, neither class of drugs is appropriate for P.H.⁵¹

If the clinician determines that fluoxetine treatment is preferred over an alternate SSRI or mirtazapine, then trazodone may be added to alleviate insomnia.⁶² The addition of trazodone to fluoxetine, bupropion, or monoamine oxidase inhibitors decreased time to sleep and increased duration of sleep but caused intolerable sedation in a few patients who received fluoxetine. Tolerance did not develop to the sedative effects of trazodone in short-term studies (<6 weeks) used adjunctively for depression; however, decreased benefit over time has been reported.⁶² The 5HT-2 antagonist properties of trazodone at low dosages and its α -adrenergic blocking effects provide the rationale for its efficacy as a sedating agent.

Antidepressants

17. What is the evidence for trazodone's use in managing insomnia? What other antidepressants are used in the treatment of insomnia? Discuss the advantages and disadvantages of using sedating antidepressants for the treatment of insomnia in P.H.

Trazodone is not thought to be a highly effective antidepressant because most people cannot tolerate an effective dose (300–600 mg/day). Because of its sedating properties, trazodone has become a commonly prescribed adjunctive medication (50–200 mg/day) to induce sleep while awaiting the onset of the primary antidepressant's effect. Trazodone's half-life is approximately 6.4 hours in younger adults and 11.6 hours in the elderly. It undergoes hepatic metabolism via CYP 2D6 and 3A4, so inhibitors can increase blood levels and worsen side effects. The most common side effects of trazodone include drowsiness (29.1%), dizziness (21.9%), and dry mouth (17.7%). Cardiac arrhythmias are possible at doses >200 mg/day as is priapism, a painful prolonged erection that occurs in 1 of 1,000 to 10,000 males. Although priapism is considered rare, it can lead to impotence if untreated, therefore P.H. should be counseled about priapism.^{60,62}

In the only placebo-controlled trial of trazodone conducted in primary insomnia, investigators compared the hypnotic efficacy of trazodone and zolpidem with placebo in 306 adults (aged 21–65 years). Subjects were randomly assigned to receive trazodone 50 mg, zolpidem 10 mg, or placebo nightly for 2 weeks. Sleep parameters were assessed using a subjective sleep questionnaire that patients completed each morning and at weekly office visits. Trazodone was found as effective as

zolpidem for the first week of treatment, but during the second week, only zolpidem was more effective than placebo.⁶²

Tricyclic antidepressants (TCA) (e.g., amitriptyline, doxepin) were used to treat primary insomnia for years based on case reports describing efficacy in doses of 10 to 75 mg/night.⁴¹ TCAs, however, increase the risk of cardiovascular problems and anticholinergic side effects (see Chapter 79, Mood Disorders I: Major Depressive Disorders). TCAs have not been proven to be as effective and safe as benzodiazepine hypnotics or trazodone.

For P.H., TCAs raise additional safety concerns. P.H. has a history of substance abuse and prior suicide attempts. Both are risk factors for future suicide attempts. TCAs are more toxic in overdose when compared with trazodone, and there are multiple reports of TCA plasma levels increasing to toxic levels when administered in combination with fluoxetine (see Chapter 79).

Switching to mirtazapine as an antidepressant that offers more sedation is a reasonable consideration for P.H. Mirtazapine has 5HT-2 antagonist effects, which imparts sedation, and they are safer than TCAs in overdose.³² Mirtazapine is not associated with priapism but it can cause weight gain. Paroxetine (Paxil) is another option for treating both depression and insomnia in P.H. Paroxetine relieved insomnia for 15 primary insomnia patients in a 6-week, open, flexible-dose study.³³

IN THE ELDERLY

Patient Assessment

18. S.B., a 78-year-old woman, just moved to a skilled nursing facility from her daughter's home because her family could not take care of her. She was unable to sleep at night and paced the house. Six weeks ago, she fell and broke a hip. She had a total hip replacement and uses a walker now. S.B. takes the following medications: salsalate 750 mg BID, lorazepam 0.25 mg TID, lisinopril 10 mg daily, hydroxyzine 50 mg in the morning, and Senokot one tablet in the morning and at bedtime. Zaleplon 10 mg at bedtime has just been prescribed to treat insomnia, with the first dose to start tonight. What additional information is needed to evaluate S.B.'s sleep problem?

Thus far, it is unclear what type of insomnia S.B. has: difficulty falling asleep, difficulty staying asleep, early-morning awakening, or just overall less restful sleep. Identifying the type of insomnia helps to guide proper treatment. As discussed in previous cases, many factors can contribute to sleep problems (e.g., disease states, medications, psychosocial factors, poor sleeping habits). The usual thorough evaluation is needed to understand the etiology of S.B.'s sleep disorder, after which her medication regimen can be optimized.

19. S.B. typifies the nursing home patient, struggling with medical problems and adjusting psychologically to new life situations. On review of the progress notes in the medical record, the consultant discovers S.B.'s type of insomnia is described as difficulty falling asleep and maintaining sleep. S.B. is charted as "stable" medically, with satisfactory pain control and no dementia or major psychiatric diagnosis. The progress notes mention situational anxiety secondary to her move to the nursing home. Lorazepam (Ativan) was prescribed 3 days ago to treat the anxiety. No side

effects had been documented in the medical record, but the nursing notes describe S.B. taking 2-hour naps two to three times a day and awakening two to three times nightly to urinate. What considerations are important for the assessment and treatment of insomnia in an elderly patient such as S.B.?

Age-Related Effects on Sleep

S.B.'s age is an important consideration because sleep is qualitatively different in the elderly, despite the continued need for the same quantity of sleep. A circadian shift advance may occur in which older individuals go to bed earlier and awaken earlier.³⁸ Fewer cycles into slow-wave sleep and more frequent awakenings occur, which results in the experience of "lighter sleep."⁶³ The proportion of sleep time spent in REM does not change significantly with aging.⁶⁴ Chronic disease, depressed mood, poor perception of health, and the use of sedatives, but not age, were all associated with insomnia in one large, epidemiologic study of 6,800 individuals >65 years. Of these, 28% had insomnia at baseline, but nearly half (48%) did not report symptoms at follow-up 3 years later,⁶⁵ demonstrating that insomnia is not always persistent in the elderly. Persistent chronic medical illness (arthritis, cardiovascular disease, prostate problems) predicts persistent sleep disturbance.^{2,7} Sleep-related respiratory disturbances and periodic leg movements are more common in the elderly,^{1,3,12} and they contribute to insomnia and excessive daytime sedation. EDS occurs in 7% to 30% of those >65 years of age; cardiovascular disease, dementia, excessive night-time awakenings, and sedating medications are factors associated with EDS.^{63,64,66} All of these causes should be ruled out as contributors to poor sleep patterns in S.B.

Elderly individuals with chronic illness or social isolation report significantly more problems with sleep than those who are actively involved (e.g., club membership, religion, work) or have a close friend.^{23,64} Anxiety and depression often are associated with insomnia, and the elderly tend to be more susceptible to anxiety and depression coping with bereavement, retirement, financial security, and social and functional losses. All of the aforementioned factors contribute to poor sleep patterns.^{23,64} An often overlooked problem in the elderly is an alarmingly high rate of alcohol and drug use. Alcohol ingestion is associated with more fragmented, poor-quality sleep.⁵⁹ The observation that S.B. has several chronic medical conditions and functional impairment, and has recently changed living environments all have an impact on treatment decisions.

For S.B., several studies document success with nonpharmacologic interventions to improve sleep in the elderly.^{14,20,67} A controlled clinical trial in 78 older adults demonstrated that CBT emphasizing good sleep habits was more effective than temazepam in improving sleep as measured by sleep diaries. Polysomnography showed comparable efficacy between CBT and temazepam in improving sleep.⁶⁷ Of note is the observation that more than half of the patients screened and deemed eligible for the study (85/163) were excluded because of sleep apnea (40/163), medical or psychiatric conditions (17/163), or an inability to stop taking sedative-hypnotic agents (22/163). These exclusions exemplify the complex etiology of insomnia, the need for careful screening to rule out sleep apnea, and the reality of sedative-hypnotic dependence in a significant percentage of older adults.

Another study in 175 consecutive hospitalized elderly described how a nonpharmacologic sleep protocol (warm drink, massage, relaxation tapes) administered by nurses was effective for improving sleep and decreasing sedative-hypnotic use from 54% to 31% ($p < 0.002$). Back massage was useful in promoting sleep in a group of 24 critically ill men.^{67,68} Light therapy administered in the evening by a visor for 30 minutes at 2,000 lux to 10 elderly women in the community improved sleep efficiency and decreased fatigue.⁶⁹ These nonpharmacologic interventions should be tried for S.B. to avoid the risk of unsteady gait and excessive daytime cognitive impairment associated with any sedating medication.

AGE-RELATED EFFECTS ON HYPNOTIC DISPOSITION

Pharmacokinetic and Pharmacodynamic Differences

Small doses elicit pronounced pharmacologic effects in the elderly, and pharmacokinetic differences greatly affect the amount of drug available at the receptor site.³⁵ Absorption of benzodiazepines can be decreased by diminished gastric acidity and decreased GI motility. The volume of distribution of a hypnotic drug can be affected because the elderly may have increased or decreased plasma proteins, depending on whether they have inflammatory disease or poor nutrition. Excessive fat stores can increase the volume of tissue into which lipophilic drugs redistribute.³⁵ Bioavailability of zolpidem and eszopiclone is increased in the elderly requiring dosage reduction.⁵² Oxidative metabolism might be compromised in the elderly.⁶³ A significantly diminished metabolism is seen in individuals >75 years compared with those 65 to 75 years of age. In young elderly, hypnotic drugs that undergo oxidative biotransformation (e.g., flurazepam) may accumulate more as a result of competition for hepatic metabolism and a decline in renal function than to inherent changes in oxidative metabolism. Elderly patients typically are on multiple drugs competing for metabolism in the liver. Excretion of more hydrophilic active metabolites can be slowed in the elderly secondary to a well-documented, age-related decline in renal function.^{52,63}

Other Drugs Used as Hypnotics

20. What are the potential problems with S.B.'s current medication regimen, and what changes are needed to improve her sleep?

S.B. is receiving lorazepam three times daily and hydroxyzine every morning. The hydroxyzine can exert intense, long-lasting sedation in the elderly and cause frequent daytime naps when combined with multiple daily doses of lorazepam.^{48,70} One short nap during the day often is normal for elderly people and usually does not impair nocturnal sleep; however, in S.B., multiple naps during the day could prevent a restful sleep throughout the night.^{23,64} Although lorazepam is not marketed as a hypnotic, it possesses sedative effects as do all benzodiazepine compounds. The elderly are particularly sensitive to cognitive impairment from benzodiazepine medications so the risk versus benefit of continued lorazepam use must be considered carefully.^{23,64}

Lorazepam does not undergo oxidative hepatic metabolism and interacts only with a few drugs. It has an intermediate

elimination half-life of 10 to 20 hours, which could help S.B. maintain sleep, and it has no active metabolites.³⁵ Because S.B. currently is taking lorazepam for anxiety, a change in her dosing schedule from 0.25 mg three times daily to 0.25 mg every morning and 0.5 mg at bedtime may be useful in shifting daytime sedation more toward bedtime to help S.B. initiate and then maintain sleep throughout the night. Zaleplon can be discontinued because no need exists for it to be combined with lorazepam. In addition, the starting dose of 10 mg is too high for an elderly individual; a 5-mg dose is more appropriate (Table 77-4). Neither zaleplon nor lorazepam may be needed at bedtime if behavioral interventions are successful. The risks of hydroxyzine (i.e., cognitive impairment caused by central anticholinergic effects and excessive daytime sedation) outweigh its potential benefits for S.B. and it should be discontinued.

Rebound Insomnia and Withdrawal Symptoms

21. An attendant at a skilled nursing facility seeks assistance for one of his patients by presenting the following problem: “L.R. really has been complaining since his sleeping medication was changed. He is agitated, irritable, sweaty, and tosses and turns all night, barely sleeping. I have even noticed some BP and pulse fluctuations. He was taking flurazepam 15 mg at bedtime for many years and approximately a week ago his new doctor replaced flurazepam with zolpidem 5 mg at bedtime. Do you think this problem could be caused by the medication change?” What is causing L.R.’s symptoms?

L.R. is experiencing symptoms of benzodiazepine withdrawal. He took flurazepam every night for years and apparently developed a physical dependence. Withdrawal reactions are more common with short half-life benzodiazepines, such as triazolam, but long half-life drugs, such as flurazepam, also can elicit withdrawal responses.^{41,71} With long half-life drugs, the withdrawal symptoms typically occur 1 to 2 weeks after drug discontinuation. The lag time is caused by the slow elimination of flurazepam. Zolpidem displays cross-tolerance with benzodiazepines, including flurazepam; it could not, however, prevent the withdrawal reaction because it was given in a significantly lower relative dose. In addition, zolpidem is metabolized and eliminated rapidly.

22. What therapeutic interventions should be initiated to manage L.R.’s withdrawal symptoms and rebound insomnia?

A slow, gradual dosage reduction is tolerated better by patients than immediate benzodiazepine discontinuation. Because L.R. is experiencing withdrawal symptoms, his nightly flurazepam should be restarted. Once the withdrawal symptoms (e.g., agitation, irritability, autonomic fluctuations, insomnia) subside and L.R. is comfortable, his physician can discuss the gradual dosage reduction process with him. The gradual discontinuation of flurazepam in L.R. should begin by administering the flurazepam every other night. Subsequently, flurazepam should be administered every few nights until L.R. no longer needs the medication. The withdrawal process may require several weeks. The physical withdrawal he experienced may, however, contribute to his becoming psychologically dependent on the flurazepam. L.R. needs reassurance, and non-

pharmacologic treatment approaches, such as stimulus control, sleep restriction, and CBT.^{36,67}

SLEEP APNEA

Clinical Presentation

23. O.R., a 56-year-old man, presents to an ambulatory care clinic complaining of chronic fatigue, low energy, excessive snoring, and overall less restful sleep. He describes his sleep: “It feels like I’m just skimming the surface of sleep. I’m tired all day and my wife says my loud snoring and gasping to breathe keeps her awake.” His symptoms have worsened over the past year and a half since early retirement. He has gained weight (5 feet 10 inches, 202 pounds, body mass index [BMI] 29) and has developed hypertension. O.R.’s current BP reading is 140/90 mm Hg. Medications include hydrochlorothiazide 25 mg in the morning and aspirin 81 mg in the morning. What are the possible causes of O.R.’s sleep disorder, and why is it important for O.R. to have his problem evaluated in a sleep laboratory?

O.R. reports diminished sleep quality, excessive snoring, gasping for air, and weight gain. Although a number of causes could be responsible for O.R.’s symptoms, one of the most serious is sleep apnea. Sleep apnea is a neurologic disorder characterized by mini-episodes of cessation of breathing, which can occur 10 to 200 times an hour. If there is a reduction in airflow but no cessation of breathing, it is called *hypopnea*. The brain responds to episodes of apnea and hypopnea with “mini-arousals,” waking the individual to stimulate breathing.^{4,72,73} These frequent mini-arousals prevent the individual from obtaining quality sleep by not allowing sufficient time in deep, slow-wave sleep, or REM. Obstructive sleep apnea (OSA), the most common type, may be induced when extra body weight (note O.R.’s weight gain) places pressure on the throat and uvula, narrowing the space into which air must travel; this results in the difficulty in breathing and excessive snoring. Biochemically, proinflammatory cytokines such as C-reactive protein, TNF- α , and IL-6 have been associated with the pathogenesis of EDS and sleep apnea.^{11,12,74}

Hypertension may be contributing to O.R.’s sleep difficulty. Several studies show an increased risk of sleep apnea in patients with hypertension, coronary artery disease, and cerebrovascular disease.^{66,75} Although sleep apnea occurs in approximately 5% of women and 15% of men in the general population, it occurs in up to 40% of patients with hypertension.⁷⁵ Treatment of OSA can improve BP control and lead to more restful sleep. Of note, OSA occurs in nonobese individuals and in all ages, including infants.^{11,43,66} Sleep-disordered breathing, including snoring, is a significant risk factor for hypertension even in young individuals of normal weight.⁷⁶

Overnight evaluation by polysomnography (i.e., EEG, EOG, EMG) in a sleep laboratory would confirm or rule out sleep apnea and allow distinction between OSA and the less common, central sleep apnea.^{43,72} Patients with central sleep apnea lack respiratory effort (i.e., the diaphragm does not move in attempts to take in air); they frequently gasp for air during the night.⁷² Treatment of central sleep apnea requires continuous positive airway pressure (CPAP) as opposed to being alleviated through weight loss or anatomic manipulations. Central sleep apnea frequently occurs along with OSA.

Drug Treatment Considerations

24. Results from the sleep laboratory study clearly document O.R.'s sleep problem as OSA. He experiences an average of 56 apneic episodes per hour. O.R.'s weight gain and inactivity probably contribute to the problem. Both are serious, potentially life-threatening conditions. Why should O.R.'s sleeping difficulties not be treated with a hypnotic medication?

Hypnotics, alcohol, or any CNS depressant can be lethal for patients with sleep apnea and should not be prescribed for O.R. CNS depressants interfere with the mini-arousals required to stimulate breathing once it has stopped. In this case, the sleep laboratory study may have saved O.R. from a potential life-threatening breathing disorder that could have been exacerbated by a hypnotic with CNS depressant activity.

Obstructive sleep apnea can be treated by tracheostomy, nasal surgery, tonsillectomy, uvulopalatoplasty, and either nasal or orally administered CPAP.^{12,43,77} Weight loss and CPAP therapy are the most effective treatments and must be maintained for continued therapeutic efficacy.^{11,72} In CPAP, the patient wears a lightweight mask to bed each night and a constant flow of air is provided mechanically to prevent breathing cessation and to allow for more restful sleep. Although CPAP is effective for both obstructive and central sleep apnea, the results are short lived and apneic episodes typically reappear when CPAP therapy is stopped. Preliminary studies in individuals with nocturnal bradycardia and sleep apnea show that insertion of a permanent cardiac pacemaker significantly improved bradycardia and sleep apnea.⁷⁸ More studies are needed. At this time, the best treatment for O.R.'s hypertension and sleep apnea is weight loss and CPAP.

25. If weight loss, surgery, and CPAP are all ineffective or impractical, what drug treatments are potentially effective for O.R.'s sleep apnea?

Modafinil, an agent approved for narcolepsy, is also FDA approved to treat excessive daytime sleepiness caused by OSA or shift work sleep disorder. For O.R., it is best used as an adjunct to CPAP at doses of 200 to 400 mg in the morning.^{79,80} Protriptyline, medroxyprogesterone, theophylline, and acetazolamide have been used successfully in small numbers of patients with sleep apnea.⁸⁰ A decrease in apneic episodes is statistically significant, but not, however, clinically significant for most patients.⁸⁰ Fluoxetine and paroxetine show promise in treating sleep apnea by increasing upper-airway patency during sleep.^{80,81} To date, no clinically significant improvement has been documented with either agent.

NARCOLEPSY

Narcolepsy is an incurable neurologic disorder characterized by two main features: irrepressible sleep attacks and cataplexy. Sleep attacks can intrude at any time during the individual's waking state. Cataplexy is the loss of muscle tone in the face or limb muscles and often is induced by emotions or laughter. Cataplexy can be subtle, where the patient is limp and not moving, or dramatic, whereas persons with narcolepsy collapse to the floor.⁸² Hypnagogic hallucinations and sleep paralysis are other secondary symptoms not present in all persons with narcolepsy. Hypnagogic hallucinations are perceptual distur-

bances (i.e., auditory, visual, tactile) that occur while experiencing a sleep attack. The patient may see imaginary objects, hear sounds, or feel sensations. Sleep paralysis is a terrifying experience that can occur when falling asleep or when awakening. Patients are unable to move their limbs, to speak, or even to breathe deeply. Narcoleptics learn, however, that sleep paralysis episodes are benign and brief (lasting <10 minutes). Except for daytime sleepiness, these symptoms are thought to be expressions or partial expressions of REM sleep.^{4,15}

Symptoms of narcolepsy often begin at puberty, but patients usually are not diagnosed until years later, in their late teens or early 20s. Early symptoms consist of excessive daytime sedation and poor sleep quality. The sleep cycle becomes progressively more erratic with frequent bursts of REM and decreased regularity of deep or slow-wave sleep. Polysomnography in a sleep laboratory is necessary to confirm narcolepsy. Sleep architecture is notably different. Instead of the 90-minute delay before REM, individuals with narcolepsy progress directly into REM sleep.⁴

In the 1970s, genetic research in narcoleptic dogs (Doberman pinchers) and humans, revealed narcolepsy is associated with deficits in the hypocretin receptor-2 gene (*Hcrtr2*).^{4,29} An autoimmune response of unknown origin is thought to damage hypocretin or orexin secreting cells in the hypothalamus. Without functional hypocretin and orexin cells, the sleep-wake cycle is disrupted. Hypocretin and orexin are also involved in body weight, control of water balance and temperature.⁴

Comparing Treatments

Optimal treatment of narcolepsy involves treating both sleep attacks and cataplexy. Schedule II controlled substances, methylphenidate (Ritalin) and dextroamphetamine (Dexedrine), were the first drugs used to treat narcolepsy, with 65% to 85% of patients deriving significant improvements in wakefulness. Mixed amphetamine salts are also FDA approved for narcolepsy.⁴ The mechanism of action of methylphenidate and amphetamines is related to increasing neurotransmission of dopamine and norepinephrine. Modafinil (Provigil), a schedule IV controlled substance, is an effective treatment with less abuse potential. Its exact mode of action is not fully understood, but it is thought to increase wakefulness through noradrenergic, adrenergic, histaminergic, GABA-modulating, glutamatergic, and hypocretin or orexin stimulating mechanisms.^{4,79} In summary, these stimulating drugs decrease the number of sleep attacks, improve task performance, and increase the time to fall asleep, but cannot eliminate sleep attacks altogether. Research is under way exploring the possible use of immunosuppression at the time of narcolepsy onset. One hypothesis suggests that immunosuppression therapy during a period of pathologic immune response could prevent or reduce damage to the hypocretin system that otherwise would lead to the development of narcolepsy.^{4,83}

Cataplexy does not respond to psychostimulants or modafinil but may be lessened with low doses of antidepressants. Tricyclic antidepressants (imipramine and clomipramine) were the first antidepressants used, but protriptyline, desipramine, and SSRI (fluoxetine, sertraline, and paroxetine) are also used.⁴ SSRI and protriptyline offer the advantage of less daytime sedation, compared with tertiary TCA. The effectiveness of antidepressants for the treatment of cataplexy is thought to be

related to REM-suppressant effects. A Cochrane database review concluded insufficient evidence exists to recommend antidepressants as effective treatments for cataplexy, given that most studies are small and uncontrolled. It should be recognized, however, that large-scale studies on such a rare disorder are difficult to conduct.⁸⁴ Antidepressants are not considered effective in decreasing sleep attacks.^{4,83,84}

Sodium oxybate (Xyrem), a salt form of the CNS depressant γ -hydroxybutyrate, is the only FDA-approved treatment for cataplexy. Its therapeutic effects are related to decreased REM, improved sleep consolidation, and increased stage 3 and 4, slow-wave sleep.^{4,82} In two randomized, double-blind, placebo-controlled trials, sodium oxybate 9 g/night (i.e., 450 mg at bedtime, then 450 mg 2 to 4 hours later), but not 3 or 6 g/night, significantly reduced the median frequency of cataplexy attacks by 69% in patients with narcolepsy, whereas 4.5 to 9 g over 8 weeks significantly reduced the median frequency of cataplexy attacks by 57% to 85% in a dose-related manner. Both trials showed 6% to 30% reduction in excessive daytime sleepiness as measured on the Epworth Sleepiness Scale and 20% to 43% reduction in daytime sleep attacks.⁸²

Improved daytime wakefulness is an advantage of sodium oxybate compared with antidepressants. Adverse effects include nausea, headache, dizziness, and enuresis. Sodium oxybate can be administered safely with stimulants; however, coadministration with other CNS depressants, including hypnotic medication, is contraindicated because of the risk of respiratory depression.⁸² Individuals taking sodium oxybate should take it on an empty stomach for maximal efficacy, and it should not be given to those with sleep-disordered breathing, sleep apnea, or an alcohol or substance abuse disorder.⁸² Because of a significant abuse potential, sodium oxybate is available only through restricted distribution, the Xyrem Success Program, by calling 1-866-997-3688 Orphan Medical. It is a schedule III controlled substance.⁸²

Methylphenidate and Imipramine

26. G.B., a 23-year-old man with narcolepsy, is receiving methylphenidate long-acting (Ritalin LA) 60 mg every AM and imipramine 75 mg at bedtime to treat his narcolepsy and cataplexy. What are the potential risks of using both methylphenidate and imipramine to treat G.B.?

Anorexia, stomach pain, nervousness, irritability, insomnia, and headaches are common side effects of stimulant drugs.⁴ Psychotic reactions can occur in narcoleptic patients taking stimulants at any dose; however, these symptoms resolve when the stimulant is discontinued. Hypertension and abnormal liver function are more serious complications of long-term stimulant use. Stimulants, even at high dosages (e.g., 80 mg methylphenidate), usually do not bring a patient to a normal level of alertness, and sometimes nocturnal sleep is disrupted. To prevent stimulant-induced insomnia, doses should be taken before 3 PM. Tolerance to the therapeutic effects of stimulants may, however, develop in some patients with narcolepsy.^{4,83} Drug holidays sometimes can allow the patient to recapture therapeutic benefit; however, many patients opt for an increased stimulant dose instead. Exceeding maximal recommended doses of stimulant significantly increases the risk of psychosis, substance abuse, psychiatric hospitalization, tachy-

arrhythmia and anorexia according to a case-control study in 116 patients with narcolepsy taking stimulants.⁸⁵

Imipramine, as with all TCAs, can cause orthostatic hypotension, anticholinergic side effects, sedation, cardiac conduction changes, and periodic limb movements. In addition, G.B.'s imipramine therapy will be more complex because methylphenidate can inhibit the metabolism of imipramine, resulting in higher levels of imipramine.⁸⁶ G.B. should be monitored closely during the initiation of imipramine therapy and imipramine plasma levels should be assessed to minimize side effects and prevent toxicity. The optimal therapeutic plasma concentration of imipramine for treatment of cataplexy has not been established, but low doses may be effective and the risk of toxicity from imipramine increases when serum imipramine concentrations are >300 ng/mL.

Modafinil

27. G.B. develops intolerable nervousness, irritability, and nocturnal insomnia on methylphenidate as the dose is increased to 80 mg/day in an attempt to further decrease sleep attacks. He asks about switching to modafinil (Provigil). Does modafinil offer any advantage for G.B.?

Modafinil's efficacy relative to other CNS stimulants has not been adequately assessed in controlled clinical trials; however, it has less potential for insomnia and adverse CNS reactions at recommended dosages between 200 and 400 mg/day administered in the morning.⁴ It also has less abuse potential compared with stimulants and is a schedule IV controlled substance. Headache was the only adverse experience rated significantly higher than placebo in 283 patients taking the recommended dose of either 200 or 400 mg/day of modafinil. Anorexia, nervousness, restlessness, and pulse and BP changes are dose-related side effects to discuss during counseling. The maximal tolerable single daily dose may be 600 mg/day, because 800 mg/day produced increased BP and pulse in one tolerability study.⁸⁷ Gradual dosage titration improves tolerability. Armodafinil, an active stereoisomer of modafinil has a similar adverse effect profile as modafinil and is being studied for narcolepsy.⁴

28. What counseling should G.B. receive as he changes from methylphenidate to modafinil?

People taking modafinil should receive counseling regarding the potential for drug interactions. Modafinil induces CYP 3A4 metabolism primarily in the gut; decreased levels of triazolam and ethinyl estradiol have been associated with modafinil coadministration.⁸⁸ Enzyme inhibition may also occur. Modafinil's inhibition of CYP 2C19 is the proposed mechanism behind modafinil-associated clozapine toxicity.⁸⁹ Monitoring for drug interactions is more crucial because modafinil is increasingly used for other indications, including daytime sleepiness associated with Parkinson disease, fibromyalgia, sleep apnea, fatigue associated with multiple sclerosis, and ADHD.^{90,91,92}

Naps and Other Behavioral Interventions

29. The benefits, possible risks, and importance of regular physician assessment have been explained to G.B., and he agrees

to report efficacy and adverse effects to his primary care provider regularly. G.B.'s last imipramine level 2 weeks ago on the lower methylphenidate dose was 115 ng/mL, and G.B. is reminded to take the medicine at regular intervals along with daytime naps. Why are naps helpful in the treatment of G.B. and what other behavioral interventions are useful in treating narcolepsy?

Strategically timed 15- to 20-minute naps taken at lunch and then again at 5:30 PM can be refreshing for narcoleptics and increase their time between sleep attacks. Narcolepsy support groups are available and may help G.B. better cope with such a life-changing chronic illness. It also is important for G.B. to avoid alcohol and to regulate his bedtime and wake-up time in the attempt to normalize his sleep habits.^{4,83}

RESTLESS LEGS SYNDROME AND PERIODIC LIMB MOVEMENTS DURING SLEEP

Restless legs syndrome is a condition characterized by unpleasant leg sensations occurring at rest, worsening at night, with an irresistible urge to move. Patients use descriptors such as painful, aching, creeping, crawling, pulling, grabbing, tingling sensations relieved by movement. For some patients, RLS may also involve the arms.^{3,4} Up to 15% of the population suffers from RLS while awake, and up to 85% of these also have PLMS.³ PLMS, also known as nocturnal myoclonus, is best described as involuntary clonic-type movements of the lower extremities while sleeping that usually involve bilateral ankle dorsiflexion, knee flexion, and hip flexion. They typically last 0.5 to 5 seconds and occur every 20 to 40 seconds. Five or more movements per hour of sleep as recorded by EMG during polysomnography is considered pathologic. Depending on the severity, both RLS and PLMS contribute to insomnia and prevent restful sleep, and patients with RLS report impaired daytime functioning. Akathisia is different from RLS in that akathisia is more of a generalized urge to move which occurs throughout the day without the characteristic worsening symptoms in the evening associated with RLS.^{3,4}

Restless legs syndrome and PLMS can occur at any age, but may be most common in the elderly. Sudden remissions, which may last for months or even years, are as difficult to explain as relapses, which appear without any apparent reason. Parkinson disease, hypothyroidism, uremia, chronic bronchitis, iron deficiency, folate, B₁₂ deficiency, and pregnancy are all associated with symptomatic RLS. The pathophysiology of both conditions involves dopaminergic neurotransmission because decreased D₂ receptor binding in the striatum of patients with RLS and PLMS has been documented.⁴

Treatment

Nonpharmacologic management includes reduction in caffeine and alcohol intake, regular exercise, and cessation of smoking.⁴ Dopaminergic agents, benzodiazepines, opioids, and selected anticonvulsants have all demonstrated efficacy for RLS and PLMS. Drug selection is based on severity of symptoms, co-occurring conditions, and tolerability.⁴

L-dopa with carbidopa was the first dopaminergic agent to demonstrate efficacy for RLS. It is seldom recommended, however, because with chronic use, L-dopa treatment was associated with RLS earlier in the night (augmentation) and re-

bound RLS in the middle of the night. L-dopa may be useful on an as needed basis (i.e., when going to the movies, for example). Bromocriptine 7.5 mg/night is effective but causes excessive nausea, and CNS adverse events. Pramipexole (Mirapex) and ropinirole (Requip) both stimulate D₂ and D₃ receptors; they are FDA approved for RLS and are considered first-line therapy. Studies show they are effective in alleviating RLS and increasing total sleep time for 70% to 90% of patients.⁴ Ergot-derived dopaminergic agonists (pergolide and cabergoline) should be avoided for safety reasons. Pergolide was recently removed from the market because of the risk of cardiac valve regurgitation. A comparative study in patients with Parkinson showed pramipexole and ropinirole were not associated with clinically significant valvulopathies and are much safer than pergolide.⁹³

Pramipexole should be initiated at 0.125 mg given 2 to 3 hours before bedtime every night. The dose can be increased every 4 to 7 days based on symptoms. The usual effective dosing range is (0.375–1.5 mg/night) Ropinirole should be initiated at 0.25 mg given 1 to 3 hours before bedtime with a dosing range between 1 and 4 mg/day. Dizziness, hypotension, nausea, daytime fatigue, and somnolence can occur with both agents; therefore, careful monitoring and counseling are needed. Pramipexole is eliminated renally; ropinirole is eliminated by hepatic metabolism via the CYP 1A2 isoenzyme. Careful dosage adjustment to control symptoms with tolerable side effects is important with dopamine agonists. Insomnia is a potential problem with all dopaminergic agents and benzodiazepines are sometimes necessary in combination to alleviate this symptom.⁴

Benzodiazepines, particularly clonazepam 0.5 to 2 mg and temazepam 7.5 to 30 mg, may be effective in relieving mild to moderate RLS. Most studies, however, have shown reduction in arousals from PLMS rather than elimination of movements. These agents should not be used if sleep apnea coexists because of respiratory depressant effects. The most common adverse effect with clonazepam is excessive daytime somnolence.⁴ Agents with intermediate to long half-lives are preferred because agents with short half-lives (<5 hours) may contribute to confusional states and nocturnal wandering in patients with RLS.⁹⁴

Opioids have been demonstrated effective; however, their use is limited because of side effects (constipation, sedation, nausea), dependence, and concern over addiction. Propoxyphene (65–130 mg) or codeine 30 mg may be useful in mild cases of RLS or PLMS for intermittent symptoms. Higher-potency agents, such as oxycodone 4.5 to 5 mg or methadone 5 to 10 mg, should be reserved for severe or resistant symptoms.⁹⁴ Opioids must be used with caution in those who have sleep apnea.⁹⁴

Anticonvulsants are another potential treatment for RLS and PLMS without the insomnia of dopamine agonists or addiction potential of benzodiazepines or opioids. Carbamazepine 200 to 400 mg/day was found to be superior to placebo in one double-blind study and in small open trials.^{4,95} Several open trials and one double-blind, placebo-controlled study found gabapentin in divided doses of 900 to 3,000 mg/day to be effective, particularly when RLS occurred with pain.^{4,95}

Tramadol, a central analgesic with less abuse potential than opioids, was found effective and well tolerated in 10 of 12 patients when given over 15 to 24 months in doses of 50 to

150 mg/day.⁹⁶ Magnesium supplementation of 12.4 mmol over 4 to 6 weeks was effective in significantly improving symptoms in 7 of 10 patients with RLS or PLMS in one open trial.⁹⁷ Iron supplementation is recommended for RLS associated with iron deficiency.⁴

PEDIATRIC INSOMNIA

Typical sleep need in children varies from 12 to 14 hours in children 1 to 3 years of age to between 8.5 and 9.5 hours in adolescents.⁹⁸ All major sleep disorders can occur in youth and therefore evaluation for insomnia, RLS, PLMS, sleep apnea, and narcolepsy are needed whenever symptoms warrant. Trouble initiating and maintaining sleep are more common in children with ADHD (25%–50%) and autism spectrum disorders (44%–83%). Of infants and toddlers, 10% to 30% have bedtime sleep resistance that can be managed behaviorally with parental education. Inconsistent bedtime, falling asleep away from bed, fears, and psychiatric and medical conditions can all contribute to poor sleep in children.⁹⁸

At least 5% to 10% of high school students have delayed sleep phase syndrome, a physiologic condition where they do not fall asleep until between 1 and 3 AM and they awaken between 9 AM and noon. School schedules dictate earlier awakening resulting in chronic sleep deprivation. Recent poll data indicate that 28% of high school students fall asleep in school at least once a week and 14% are late or miss school because of oversleeping.⁹⁸

Behavioral interventions to promote good sleep habits (e.g., consistent bedtime and wake-time, prebedtime ritual) should be initiated during childhood and continued throughout adolescence to promote a lifetime of healthy sleep. No hypnotics are FDA approved for insomnia in children and adolescents and significant data are lacking to guide clinicians on medications to improve sleep in youth. Diphenhydramine, clonidine, melatonin, and chloral hydrate are commonly used in children and some adolescents; however, the use of Z-hypnotics is also increasing, although this class has not been well-studied in this population.⁹⁹

30. What is the evidence for the safety and efficacy of diphenhydramine, melatonin, clonidine, chloral hydrate, and benzodiazepine-active hypnotics in children and adolescents?

Diphenhydramine is the most commonly used sedative in children according to a survey of 800 pediatricians in four states.⁹⁹ It has been shown to decrease both time to fall asleep and awakenings in children and adults. The lowest effective dose should be given to minimize anticholinergic side effects and impaired cognition.

Melatonin at an average dose of 2 mg/night administered 1 hour before bedtime was effective and well-tolerated for 29 of 32 children age 9.6 (± 4.5 years) with chronic sleep initiation and sleep maintenance problems over an average of 2.1 months.¹⁰⁰ Melatonin 0.3 to 5 mg given 1 to 2 hours before bedtime has been effective for delayed sleep phase syndrome in adolescents.¹⁰¹

After diphenhydramine, clonidine, an α_2 -adrenergic agonist, is the most prescribed medication to improve sleep in youth despite the lack of data to support its safety and effectiveness for insomnia. Mostly, it is prescribed to treat difficulty initiating sleep. Dosing is 50 to 100 mcg at bedtime.⁹⁹ Common

side effects include sedation, dry mouth, constipation, dizziness, and bradycardia.¹⁰² Rebound hypertension is possible on abrupt discontinuation of regular use of clonidine.

Chloral hydrate is the most extensively studied sedative agent in youth,¹⁰³ and several reasons exist for its widespread use: rapid onset, moderate duration, and lack of significant effects on the EEG. Chloral hydrate induces sedation and allows brain-wave assessment without drug interference.¹⁰⁴ The most common adverse effects of chloral hydrate are nausea, vomiting, or diarrhea, which can be minimized by giving the drug diluted or with food. Tolerance to the sedative effects develops rapidly over a 5- to 14-day period of continued use.¹⁰⁴ Chloral hydrate generally is void of cardiac and respiratory toxicity at its usual dose of 50 mg/kg, but it has been linked to arrhythmias and even respiratory failure in children with compromised cardiac or respiratory systems. Therefore, it should not be used (or used only with extreme caution) in patients with severe cardiac or respiratory disorders.^{103,105} The tolerability of preprocedure chloral hydrate was evaluated in children with significant cardiac disease (<1 month to 5 years of age) undergoing echocardiograms. The drug was well-tolerated with only 10.8% of patients experiencing adverse effects; decreases in heart rate and blood pressure occurred but were not significant.¹⁰⁶

Therapeutic effects and known potential toxicities from chloral hydrate are associated with its two active metabolites: trichloroethanol and trichloroacetic acid. A single dose of trichloroethanol, the metabolite responsible for sedation, induces sedation within 30 minutes and has a usual duration of action of 4 to 8 hours, similar to its half-life of 8 to 12 hours in adults. The half-life can be longer (9–40 hours) in children, depending on the age and maturity of the patient. Trichloroacetic acid is a minor metabolite that does not achieve significant levels in most patients after a single dose. On multiple dosing, trichloroacetic acid can displace bilirubin or warfarin from albumin binding sites, potentially resulting in hyperbilirubinemia or hypoprothrombinemia.^{101,105,107} The half-life of trichloroacetic acid is much longer (2–6 days), and this metabolite can accumulate under multiple dosing conditions.

Midazolam oral syrup (0.6 mg/kg dose of a 2 mg/mL solution) is used as a premedication for children undergoing brief procedures (e.g., dental). Premedication dosing of midazolam in children is generally recommended at 0.25 to 0.5 mg/kg. Metabolism occurs via CYP3A4 isoenzyme with a half-life of 2.9 to 4.5 hours. Although more studies are needed, midazolam represents an alternative to chloral hydrate with fewer GI side effects, less potential for accumulation, and lower risk of cardiotoxicity.^{56,108} Temazepam has also been used as a premedicant in children, but the long onset of effect requires dosing 1 to 2 hours before procedures.¹⁰⁹ Clonazepam 0.25 to 0.5 mg at bedtime has a long half-life of 30 to 40 hours and has been used to prevent sleep terrors or sleep walking in children.¹⁰¹

Z-hypnotics are increasingly prescribed in youth despite a lack of data. Both zaleplon and zolpidem have been used to treat initial insomnia in older children and adolescents and delayed sleep phase syndrome in adolescents. Studies show zolpidem clearance is three times greater in children compared with young adults; therefore, usual dosing of 10 mg is recommended in children who are able to swallow tablets or capsules. Using

lower doses may result in lack of effectiveness or parasomnias including hypnagogic hallucinations.¹⁰¹

When considering the best sedative for a child, it is useful to compare the advantages and disadvantages of available agents. Barbiturates (e.g., phenobarbital, pentobarbital) are sedating, but can have a higher incidence of cardiac, respiratory, and CNS depression than chloral hydrate or benzodiazepine-active agents.¹⁰³ Benzodiazepines have not been studied systematically in children, but there are some reports of paradoxical excitatory reactions, psychomotor impairment, and excessive sedation in young age groups.¹⁰⁹ Respiratory depression and altered EEG patterns can occur secondary to benzodiazepine therapy. An analysis of adverse sedation events in pediatric patients found that 60 of 95 cases resulted in death or permanent neurologic injury. Negative outcomes were associated with drug overdose, the use of multiple sedating medications, drug interactions, prescription or transcription errors, or inadequate monitoring and resuscitation of children undergoing sedation. Among chloral hydrate, barbiturates, ketamine, or benzodiazepines, no evidence indicates that one drug or route of administration was associated with greater toxicity.¹⁰³ Any sedative should be used for the shortest period of time possible, with careful monitoring of respiratory, cardiac, and CNS functions, particularly in very young children.

FORMULARY MANAGEMENT OF HYPNOTICS

31. Balancing high-quality care with economic common sense is the responsibility of formulary managers in all health care organizations. The Pharmacy and Therapeutics Committee has decided that four hypnotics should be designated as first-line agents to promote the safe and effective treatment of insomnia. Other agents will require special permission for use. What factors should be involved in the selection of four first-line hypnotics?

Therapeutic efficacy, versatility, and patient tolerability should be foremost in identifying priority hypnotics for a health care system's core formulary. Adverse-effect profiles should be known and manageable. Another important factor is cost, which should be measured both directly (drug cost, frequency of health care utilization) and indirectly (functional ability, productivity and quality of life).¹¹⁰ When balancing the clinical therapeutics against the economic realities of the available hypnotics, five factors should be considered: onset, duration of effect, metabolism, tolerability, and cost (see Table 77-4 to review pharmacokinetic profiles).

A hypnotic with a rapid onset and short duration with no accumulation of active metabolites is best for patients who only have difficulty falling asleep and who want no risk of next-day impairment. Zaleplon (Sonata), triazolam (Halcion), and ramelteon (Rozerem) best fit this clinical profile. Compared with triazolam, zaleplon has fewer adverse reactions on discontinuation, does not affect sleep stages, and may be used for several weeks if needed. In contrast, triazolam is limited to 7 to 10 days of continuous use. Zaleplon's advantages warrant formulary status whereas triazolam does not.

Ramelteon is the only FDA-approved hypnotic without abuse potential owing to its lack of activity at the benzodiazepine receptor complex. It acts by stimulating melatonin receptors. It is rapid acting with a short duration of action and no risk of next-day impairment in its recommended 8-mg dose.

Although ramelteon has not been established as effective as benzodiazepine hypnotics, it should be included on the formulary because it has the clear advantage of no abuse potential. It is more effective at initiating sleep compared with placebo, and it is well-tolerated over 4 to 5 weeks; long-term studies are underway. It is a good option for those with trouble falling asleep who request a medication with no abuse potential.

Zolpidem and eszopiclone both have a rapid onset but there is a risk of next-day impairment. A 10-mg dose of zaleplon is free of residual hypnotic or sedative effects when administered as little as 2 hours before waking in normal subjects, whereas residual effects are still present up to 5 hours after a 10-mg zolpidem dose.¹⁹ Residual effects with eszopiclone would likely be longer than zolpidem because of its longer half-life.⁴¹ Eszopiclone offers a little longer duration of effect compared with zolpidem, but it causes more unpleasant taste, limiting patient acceptability. Zolpidem controlled release may allow for somewhat longer sleep duration compared with immediate release zolpidem, but no comparative trials have shown a distinct clinical advantage. Availability of zolpidem immediate-release generic lowers drug cost as well. For these reasons, immediate release zolpidem merits formulary status over zolpidem extended release and eszopiclone.

Temazepam (Restoril) has a long onset of action (1–2 hours) and intermediate duration (8–10 hours) of action. Temazepam offers several advantages with regard to liver metabolism. It is not oxidized in the liver and does not compete for metabolism with other hepatically metabolized drugs nor accumulate with chronic use. In addition, temazepam has been studied in both young age groups as a premedication and in older age groups as a hypnotic. Unlike Z-hypnotics, it has anxiolytic activity as well. When dosed 1 to 2 hours before bedtime, it is useful in initiating and maintaining sleep. It is an inexpensive and versatile hypnotic meriting formulary status.

Flurazepam (Dalmane) is hepatically metabolized with long-acting active metabolites. It is able to keep the patient asleep throughout the night and provide residual daytime sedation if needed for agitation or anxiety. It maintains hypnotic efficacy over at least 30 days of continuous use. Flurazepam's disadvantage includes the highest risk of next-day cognitive impairment. It does not deserve formulary status.

Chloral hydrate has a rapid onset and short-to-intermediate duration of action with no daytime hangover in patients with good hepatic function. Chloral hydrate has clinical usefulness in all age groups and, unlike other hypnotics, it is available in liquid, capsule, and suppository form, and is inexpensive. Chloral hydrate has been studied in all age groups. Disadvantages, including GI irritation, protein-binding interactions, and lack of usefulness for short-term or chronic insomnia, make it a poor choice for formulary status.

In consideration of the available clinical and cost data, zaleplon, zolpidem, temazepam, and ramelteon should be considered priority hypnotics. Zaleplon initiates sleep with the least risk of daytime hangover and can even be dosed during the night. Zolpidem initiates sleep effectively and maintains sleep longer than zaleplon for those with midnocturnal awakenings. Temazepam has a sufficient duration of action to benefit those with intolerable midnocturnal awakenings and it has an anxiolytic effect that is beneficial for many patients. Ramelteon has a rapid onset, no next-day impairment and no abuse potential.

All have been demonstrated effective and safe in the elderly. If insomnia is effectively treated with proper use of medications and nonpharmacologic interventions, costs may be decreased through decreased health care utilization, reduced work absen-

teism, and improved quality of life.^{5,41,110} A review of any formulary decision should be conducted every 6 months to determine whether these selections need to be changed based on therapeutic outcome data.

Schizophrenia is a debilitating and emotionally devastating illness with long-term impact on patients' lives. Many experts consider schizophrenia to be the most severe expression of psychopathology, encompassing significant disruptions of thinking, perception, emotion, and behavior. Schizophrenia is usually a lifelong psychiatric disability. Family relationships, social functioning, and employment are frequently affected, and periodic hospitalizations are common. The management of schizophrenia involves multiple strategies to optimize the patient's functional capacity, reduce the frequency and severity of symptom exacerbations, and reduce the overall morbidity and mortality from this disorder. Many patients require comprehensive and continuous care over the course of their lives.

The aim of this chapter is to provide a framework for the clinician to develop skills in schizophrenia management by

considering the pathophysiology, assessment, clinical course, and treatment of schizophrenia.

EPIDEMIOLOGY

In the United States, approximately 1% of the population develops schizophrenia during their lifetime. Although schizophrenia affects men and women with equal frequency, there are differences in the age of onset and course of illness. The onset of schizophrenia usually occurs during late adolescence or early adulthood. Studies have shown women have, on average, an onset of schizophrenia 3 to 5 years after men.¹ Women also have their first admission due to psychiatric illness 3 to 6 years after men on average.¹ Prevalence rates are similar throughout the world, but pockets of high prevalence have been reported in some areas. After adjusting for differences in diagnostic

criteria for schizophrenia, similar prevalence rates across cultures have been observed.

ECONOMIC BURDEN

Mental disorders constitute a large part of the global burden of disease, with schizophrenia being among the greatest causes of disability in the United States and the world.² Unlike other chronic diseases such as diabetes and hypertension, which occur late in life, schizophrenia usually affects people when they are young followed by a chronic course persisting throughout the patient's lifetime. Most people with schizophrenia experience multiple hospitalizations and generally require social assistance. Even during relatively stable phases of their illness, most people with schizophrenia require support that ranges from a family member to daytime hospitalization. As of 2002, total costs for schizophrenic patients in the United States averaged \$62.7 billion annually, taking into account direct and indirect costs, as well as unemployment costs. Direct costs include hospitalization, rehabilitation, professional services, medication, and office visits. Indirect costs include loss of productivity caused by illness, disability, premature death, and economic burden to families.³ Schizophrenia accounts for approximately 2.5% of total annual health care costs in the United States. Persons afflicted by schizophrenia represent approximately 10% of this country's permanently disabled population and consume 20% of Social Security benefit days.^{4,5} In 2004, it was estimated that 70% of patients with schizophrenia receive medications through Medicaid. Because of the advent of newer atypical antipsychotics over the past 20 years, the cost of psychotropic medications now exceeds \$10 billion annually.⁶

ETIOLOGY (NEUROBIOLOGY)

Schizophrenia is a complex disorder with multiple causes. Considering the lack of consistent neuropathology or biomarkers, current theories of the disorder have moved away from the view that it is a single entity, toward a conceptualization of schizophrenia as a collection of etiologically disparate disorders with common clinical features.^{7,8} In this section, the genetic and environmental factors, neuroanatomical, and neurochemical features of schizophrenia are considered.

Genetic and Environmental Risk Factors

First-degree biologic relatives of persons with schizophrenia have a tenfold higher risk of developing the disease than the general population.⁹ The risk is highest (40%–50%) in a monozygotic (identical) twin of a person with schizophrenia.^{10,11} There is also higher concordance for schizophrenia in monozygotic twins compared with dizygotic twins, with respective rates being approximately 50% and 15%.¹² Because the concordance rate is not 100% in monozygotic twins or 50% in dizygotic twins, other nongenetic factors must contribute to the development of the disorder. Environmental factors such as prenatal difficulties (e.g., malnutrition in the first trimester of pregnancy or influenza in the second trimester), perinatal complications, and various nonspecific stressors may also influence the development of schizophrenia. Despite the overwhelming evidence that schizophrenia is an inherited illness, a single “schizophrenia gene” has not

been found. Risk for schizophrenia is, to some extent, genetically transmitted and is probably determined by multiple genes. A review of the molecular genetics of schizophrenia cited linkage studies implicating chromosomes 6, 8, 10, 13, and 22.¹³

Neuroanatomy

Studies comparing the brains of individuals with schizophrenia with the brains of normal controls have uncovered a number of important differences. Although these studies suggest that anatomical and functional abnormalities are associated with schizophrenia, no single pathognomonic abnormality consistently has been found. In addition, localization of the site(s) responsible for the pathophysiology of schizophrenia remains elusive.

The most consistent structural finding seen with computed tomography and magnetic resonance imaging in patients with schizophrenia has been enlarged ventricles, particularly the lateral and third ventricles. In addition, there seems to be a relationship between brain asymmetry and the disease process.¹⁴ When unilateral abnormalities have been reported, they have typically involved the left hemisphere.¹⁴ As imaging technology has advanced, magnetic resonance imaging studies in schizophrenia frequently have shown morphologic abnormalities involving the temporal, frontal, and parietal lobes, and the subcortical structures.^{15–19} Findings include decreased neuronal volume and density, decreased synaptic connections, decreases in synaptophysin (a membrane protein of synaptic vesicles), and loss of microtubule associated protein and synaptosomal protein in certain regions of the cortex.^{20,21} The lack of gliosis in association with the neuroanatomical abnormalities in the brains of schizophrenia patients suggests that these changes occur neurodevelopmentally.²² Functional imaging studies, such as positron emission tomography, single photon emission computed tomography, and functional magnetic resonance imaging have demonstrated alterations in either cerebral perfusion or glucose metabolism in frontal, temporal, and basal ganglia areas of the brain.^{23–26} Additional attention has been directed toward the correlation of regional brain abnormalities with specific symptoms or subtypes of schizophrenia. Thus far, the most robust findings have been found in the relation between negative symptoms and the prefrontal cortex, positive symptoms and temporal lobes, and thought disorder and the planum temporale.²⁷

In summary, neuroimaging studies have identified anatomical and functional abnormalities that affect different areas of the brain, particularly the prefrontal and temporal areas, corresponding with the impairments observed in schizophrenia.²⁸ Medial temporal structures are important for the processing of sensory information, and abnormalities in this area may explain distortions in the interpretation of external reality that are characteristic of schizophrenia. The prefrontal cortex is responsible for some of the complex and highly evolved human functions, including the integration of information from other cortical areas. The prefrontal cortex is largely responsible for the regulation of working memory, which involves maintaining information in temporary memory while that information is used for executive functions. Hence, these abnormalities in prefrontal areas could explain the deficits in working memory and attention that are often present in schizophrenia. New theories of schizophrenia that have been proposed include the “cognitive

dysmetria” theory (implicating the thalamus and its cortical and cerebellar connections), the “disconnection model” (implicating temporolimbic and prefrontal disconnections), and the “asynchronous neural firing” model.^{29–31}

Neurochemistry

The discovery of the antipsychotic properties of chlorpromazine led to a fundamental understanding of the neurochemistry of schizophrenia. The finding that chlorpromazine and other antipsychotic drugs decrease dopamine activity by blocking specific postsynaptic receptors served as the foundation for the dopaminergic hypothesis of schizophrenia. Nearly all drugs that decrease dopamine activity decrease the positive symptoms of schizophrenia. Furthermore, the clinical efficacy of antipsychotic agents is roughly proportional to their affinity for a particular subtype of dopamine receptors, the D₂ receptor.^{32,33} Although other classes of dopamine receptors have been identified (e.g., D₁, D₃, D₄), this close relationship to clinical potency exists only for the D₂ receptor subtype.³⁴ Indirect evidence supporting the dopamine hypothesis is found in the observation that dopamine agonists such as amphetamine, levodopa, methylphenidate, and other aminergic agents can worsen schizophrenia symptoms in some patients.^{35–37} Although these observations indicate that manipulating the dopaminergic system can regulate the positive symptoms of schizophrenia, they do not directly implicate a central excess of dopamine as the sole cause of schizophrenia symptoms. This simplistic theory does not explain, for instance, cases of schizophrenia in which residual or negative symptoms predominate. The “hypofrontality theory” suggests that reduced or dysfunctional dopaminergic neurotransmission within the prefrontal cortex or mesocortical area of schizophrenic patients may be responsible for negative symptoms.^{38,39} In addition to negative symptomatology, prefrontal dopaminergic dysfunction has been correlated with cognitive dysfunction, particularly in the area of working memory. It has also been proposed that a chronically low level of striatal dopamine release causes negative symptoms (caused by low levels of dopamine in the prefrontal cortex). The diminished dopamine release leads to an upregulation of dopamine receptors, resulting in supersensitivity to phasic dopamine release in the context of environmental stressors (exhibited behaviorally as positive symptoms).⁴⁰ This theory explains why dopamine-blocking drugs improve positive symptoms, but not negative symptoms.

Serotonin also seems to play a role in schizophrenia. Alteration in monoamine activity in the limbic circuit has been proposed as a possible link to the dopamine hypothesis of schizophrenia.⁴¹ Serotonin receptors are abundant in mesocortical areas, and agonism at these receptor sites may have an inhibitory effect on dopaminergic receptors or dopamine release, possibly contributing to negative schizophrenia symptoms.

Another area of focus is the involvement of excitatory amino acids and the glutamate transmitter system in the pathogenesis of schizophrenia.⁴² Decreased activation of *N*-methyl-D-aspartic acid (NMDA) or glutamate receptors may increase cortical dopamine release and produce a syndrome resembling schizophrenia. This hypofunctional NMDA receptor theory was supported by findings of low glutamate levels in the cerebrospinal fluid of persons with schizophrenia and by the

observation that phencyclidine (PCP), an NMDA antagonist, could produce florid psychosis.⁴³ In utero exposure to excitotoxins or viruses has been proposed as a possible mechanism for destruction of NMDA receptors within the brain. The clinical effect of neuronal destruction may not be expressed until late adolescence or early adulthood (when symptoms of schizophrenia usually arise). γ -Aminobutyric acid (GABA), a major inhibitory amino acid, may act as a third link between the neuromodulation of glutamate and dopamine receptors. It has been suggested that GABA receptor function may be impaired within the prefrontal region, resulting in abnormal NMDA receptor concentrations.⁴⁴ It has also been proposed that an imbalance between NMDA, GABA, and dopamine receptors may cause the symptoms of schizophrenia. Studies examining the clinical effects of direct glycinergic agonists or inhibitors of glutamate uptake in persons with schizophrenia are needed to clarify the role of excitatory amino acid neurotransmission in this disorder.

Substantial progress has been made in neuropathological and neuroanatomical studies of schizophrenia. Insights from physiological imaging studies in living patients, studies of brain development and its genetic control, and pharmacologic studies using newer atypical antipsychotics are promising stepping stones that may lead to a better understanding of the pathogenesis of schizophrenia.

CLINICAL PRESENTATION

Historical Concept of Schizophrenia

Kraepelin⁴⁵ provided the first thorough description of the constellation of symptoms that make up schizophrenia, which he called “dementia praecox” (a syndrome of cognitive and behavioral deficits that tend to appear early in life). Kraepelin emphasized that dementia praecox generally followed a chronic course with no return to the premorbid level of functioning. Kraepelin also noted that no single pathognomonic symptom or cluster of symptoms served to characterize dementia praecox, an illness he considered so mysterious that he referred to it as a disorder whose causes were shrouded in “impenetrable darkness.” Bleuler⁴⁶ concurred with Kraepelin’s initial description of schizophrenia, although he suggested that some patients did recover and subsequently could lead productive lives. For Bleuler, the most important and fundamental feature was a fragmentation in the formulation and expression of thought, referring to it as “loosening of associations.” Bleuler described the “4 *As*” of schizophrenia, which include autism (preoccupation with internal stimuli), inappropriate affect (external manifestations of mood), loose associations (illogical or fragmented thought processes), and ambivalence (simultaneous, contradictory thinking). Thus, Bleuler focused on negative symptoms and thought disorganization rather than on the positive symptoms of schizophrenia, such as delusions and hallucinations. Another important contribution to the defining features of schizophrenia was Schneider’s “first-rank” symptoms⁴⁷ of schizophrenia that assisted the clinician in diagnosing schizophrenia. First-rank symptoms include delusions, auditory hallucinations, thought withdrawal, thought insertion, thought broadcasting, and experiencing feelings or actions that are under someone else’s control. Schneider’s first-rank symptoms provided the framework for the systematic diagnostic criteria used today in psychiatry.

Diagnosis and Differential Diagnosis

The *Diagnostic and Statistical Manual of the American Psychiatric Association*, text revision (DSM-IV-TR), is the latest edition of the guide for diagnosing and classifying schizophrenia and other psychiatric disorders. Compared with previous DSM editions, the DSM-IV-TR places a greater emphasis on negative symptoms and the social and occupational dysfunction associated with schizophrenia.¹¹ Psychosis has many causes, and all must be excluded before the diagnosis of schizophrenia is made. In addition, a diagnosis can be made only if the DSM-IV-TR criteria are met (Table 78-1). Clinicians can mis-

diagnose psychotic patients when the diagnosis is based on presenting symptoms alone without regard to the longitudinal clinical course. An accurate diagnosis is important because treatments vary for psychoses with different origins. Schizophreniform disorder is similar to schizophrenia except that it lasts for >1 month but for <6 months. Brief psychotic disorder is diagnosed when positive symptoms present suddenly and are present for ≥ 1 day but <1 month. After the episode subsides, premorbid functioning usually returns. Various personality disorders, including schizotypal, schizoid, and paranoid types also can resemble schizophrenia; however, these disorders lack the chronic thought disturbances seen in schizophrenia. Bipolar disorder, manic or depressive phase, and major depression can have psychotic features that usually are mood congruent. Negative symptoms of schizophrenia such as akinesia, anergy, apathy, and social withdrawal may resemble depression, but do not respond to antidepressant therapy. It is also important to differentiate extrapyramidal side effects of drugs, particularly akinesia seen with antipsychotic-induced parkinsonism, from the negative symptoms of schizophrenia. Common differential diagnoses are listed in Table 78-2.

Drug-induced psychosis is an important differential diagnosis when evaluating patients with schizophrenia-like symptoms. Illicit drugs may cause psychotic symptoms in any individual, but do not cause the illness of schizophrenia in persons without a predisposition to mental illness or an underlying psychiatric disorder. Drugs causing acute psychotic symptoms include amphetamines, cocaine, cannabis, phencyclidine (“angel dust”), lysergic acid diethylamide, and ketamine. In addition, anticholinergic delirium can occur if excessive doses or combinations of therapeutic agents with anticholinergic properties are prescribed. A urine toxicology screen can help to evaluate the contribution of substance abuse to psychosis, but because of the risk of false-negative results, the quality and progression of the presenting symptoms and physical findings also must be considered to make an accurate diagnosis. A particularly difficult problem is evaluating the cause of psychosis in a patient with schizophrenia and concurrent drug or alcohol abuse.

Table 78-1 DSM-IV-TR Criteria for Schizophrenia

A. Characteristic Symptoms

At least two of the following, each present for a significant portion of time during a 1-month period (or less if successfully treated):

1. Delusions
2. Hallucinations
3. Disorganized speech (e.g., frequent derailment or incoherence)
4. Grossly disorganized or catatonic behavior
5. Negative symptoms (i.e., affective flattening, alogia, or avolition)

Note: Only one “A symptom” is required if delusions are bizarre or hallucinations consist of a voice keeping up a running commentary on the person’s behavior or thought, two or more conversations with each other.

B. Social/Occupational Dysfunction

For a significant portion of the time since the onset of the disturbance, one or more major areas of functioning such as work, interpersonal relationships, or self-care is markedly below the level achieved before the onset.

C. Duration

Continuous signs of the disturbance persist for at least 6 months. This 6-month period must include at least 1 month of symptoms (or less if successfully treated) that meet criterion A (i.e., active-phase symptoms) and may include prodromal and/or residual periods when the “A criterion” is not fully met. During these periods, signs of the disturbance may be manifested by negative symptoms or by two or more symptoms listed in “criterion A” present in an attenuated form (e.g., blunted affect, unusual perceptual disturbances).

D. Schizoaffective Disorder and Mood Disorder Exclusion

Schizoaffective disorder and mood disorder with psychotic features have been ruled out because either (a) no major depressive, manic, or mixed manic episodes have occurred concurrently with the active phase symptoms or (b) if mood episodes have occurred during active phase symptoms, their total duration has been brief relative to the duration of the active and residual periods.

E. Substance/General Medical Condition Exclusion

The disturbance is not due to direct physiological effects of a substance (drug of abuse or medication) or a general medical condition.

F. Relationship to a Pervasive Development Disorder

If there is a history of autistic disorder or another pervasive development disorder, the additional diagnosis of schizophrenia is made only if prominent delusions or hallucinations also are present for at least a month (or less if successfully treated).

From reference 11.

Table 78-2 Differential Diagnosis for Schizophrenia (DSM-IV-TR)

Drug-induced Psychoses

Amphetamine
Cocaine
Cannabis (marijuana)
Phencyclidine (PCP)
Lysergic acid diethylamide (LSD)
Anticholinergics

Primary Psychiatric Disorders

Brief psychotic disorder
Schizophreniform disorder
Bipolar affective disorder, manic type
Mood disorder with psychotic features

Personality Disorders

Schizotypal
Schizoid
Paranoid

Distinguishing between the two may not be possible until the patient becomes drug free and residual symptoms are assessed. There are some differences in the presentation of drug-induced psychosis and schizophrenia. For example, chronic stimulant use usually does not present with a formal thought disorder. Cannabis psychosis may be differentiated from acute paranoid schizophrenia because patients with the former usually experience a subjective feeling of panic and retain insight into their problem.⁴⁸ Acute PCP ingestion can cause psychotic symptoms such as paranoia and acute catatonia, but other concomitant symptoms such as ataxia, hyperreflexia, nystagmus, and hypertension are not found in schizophrenia.

Target Symptoms

Schizophrenia is a complex disorder comprising different clusters of signs and symptoms. The characteristic symptoms of schizophrenia have often been conceptualized as falling into two broad categories: positive and negative (or deficit) symptoms. Positive symptoms can be further divided into two distinct groups, positive symptoms and disorganized symptoms. Positive symptoms include hallucinations (auditory, visual) and delusions (persecution, guilt, religion, mind control). Disorganized symptoms include disorganized speech, thought disorder (tangentiality, derailment, circumstantiality) and disorganized behavior (clothing, appearance, aggression, repetitive

actions). Negative symptoms include affective flattening, decreased thought and speech productivity (alogia), loss of ability to experience pleasure (anhedonia), and decreased initiation of goal-directed behavior (avolition). Most patients with schizophrenia exhibit both positive and negative symptoms, although the dominance of one type over the other usually varies throughout the course of the illness. Younger patients tend to exhibit more positive symptoms, whereas in older patients negative symptoms predominate. Table 78-3 provides a glossary of commonly used terms in schizophrenia, and Table 78-4 lists positive and negative symptoms of schizophrenia.

Cognitive deficits, including problems with attention, memory, and concentration, are another frequently cited problem for people with schizophrenia. These impairments are common, affecting as many as 70% of individuals with schizophrenia.⁴⁹ The most consistently replicated deficits are observed on tasks measuring attention, information processing speed, working memory, learning, and executive (frontal systems) functions.⁵⁰ These domains are not only commonly impaired in schizophrenia, but they are also strongly associated with functional outcomes (social and community functioning).⁵⁰ Although it is likely that the overall dysfunction observed in schizophrenia encompasses factors such as psychopathology, drug treatment, and social isolation, evidence suggests that cognitive impairments have a stronger relationship to the long-term functional outcome than positive symptoms.⁵⁰

|---|
| <p>Affect: behavior (usually an expression of an emotion) observed by the interviewer. Common types of disturbances in affect include: <i>restricted</i>—mild decrease in range and intensity of the expression of emotion; <i>blunted</i>—significant decrease in intensity of the expression of emotion; <i>flat</i>—absence of expression of emotion; <i>inappropriate</i>—incongruency between patient's affect and mood or behavior; and <i>labile</i>—abrupt shifts in expression of emotion.</p> <p>Akathisia: syndrome consisting of subjective feelings of anxiety and restlessness, and objective signs of pacing, rocking, and an inability to sit or stand still for extended periods of time.</p> <p>Akinesia: absence or decrease in voluntary movement; may be antipsychotic induced (extrapyramidal side effects) or a manifestation of negative symptoms of schizophrenia.</p> <p>Alogia: impoverished thinking usually manifested through speech and language deficits. Speech is brief and lacks spontaneity; replies to questions are very concrete (<i>poverty of speech</i>). <i>Poverty of content</i> refers to speech that is adequate in amount, but is of little substance (overly abstract), repetitive, or stereotyped.</p> <p>Energy: lack of energy.</p> <p>Anhedonia: loss of interest or pleasure.</p> <p>Avolition: an inability to initiate and sustain goal-directed activities. The patient may sit for extended periods of time and show minimal interest in participating in social or work-related activities.</p> <p>Circumstantiality: a form of disorganized speech characterized by “talking in circles” or taking an unusually long length of time in answering a question or expressing one's point of view.</p> <p>Delusions: a false belief that is firmly held despite evidence to refute the belief. The belief does not qualify as a delusion if it is a cultural or religious belief accepted by a group of individuals. Types of delusions include grandiose, persecutory, and somatic type.</p> <p>Executive function: the ability to design and carry out a solution to a plan when the solution is not obvious. Loss of executive function presents as failure to learn from past experience and failure to plan or organize life events.</p> <p>Hallucination: a sensory perception (e.g., auditory, visual, somatic, tactile) experienced in the absence of external stimuli. Hallucinations may be recognized as false sensory perceptions in some, whereas others may believe that the experiences are reality based.</p> <p>Loose associations: a form of disorganized, illogical speech characterized by unrelated words, phrases, and sentences used in a fashion that makes comprehension very difficult, if not impossible.</p> <p>Mood: a pervasive and sustained emotion that is experienced by the patient. Examples include depressed, anxious, angry, or irritable mood.</p> <p>Mood-congruent delusions or hallucinations: delusions or hallucinations that are consistent with a mood or behavior (e.g., delusions/hallucinations of death, guilt, or punishment in the presence of a depressed mood).</p> <p>Mood-incongruent delusions or hallucinations: delusions or hallucinations that are not consistent with a mood or behavior (e.g., delusions/hallucinations of death, guilt, or punishment in the presence of mania).</p> <p>Tangentiality: a form of disorganized speech in which answers are remotely or completely unrelated to questions, and patients' thoughts frequently shift in an unconnected fashion.</p> <p>Thought broadcasting: a delusion that one's thoughts are being broadcast to others (e.g., a patient feels that others can read his or her mind).</p> <p>Thought disorder: a general term often used to describe any type of abnormal thought process (e.g., delusion, loose association, conceptual disorganization).</p> <p>Thought insertion: a delusion that one's thoughts are being inserted into one's mind by others.</p> |

Table 78-4 Positive and Negative Symptoms of Schizophrenia

| Positive | Negative |
|--|---------------------------------|
| Combateness, agitation, and hostility | Psychomotor retardation |
| Tension | Affective flattening |
| Hyperactivity | Avolition |
| Hallucinations | Lack of socialization |
| Delusions | Alogia |
| Disorganized speech (loose associations, tangential, blocking) | Loss of emotional connectedness |
| Unusual behavior | Loss of executive functions |

Case Presentation

J.C., a 22-year-old, single, unemployed man, was brought into the emergency department (ED) of a mental health hospital by the police after he was found running barefoot downtown dodging cars in subzero weather. In the ED, J.C. was extremely frightened, and stated, “They won’t let me go.”

History of Present Illness: J.C. is not a poor historian. He is agitated easily and threatens the interviewer when asked questions regarding his illness. J.C. said he came to this city 5 years ago “to be the king of jazz music.” He did not complete high school, has lost touch with his family and has been living at the Salvation Army for the past 3 years. He has no close friends, and does not trust most people. He hears voices of “dead people” who tell him he is worthless and “will be killed.” He says, “The newscasters on the television are reading my mind and telling everyone my personal secrets.” These problems and insomnia have been disturbing him for the past year.

Medical History: J.C. has no history of a previous psychiatric illness and has never been hospitalized. The administrator at the Salvation Army confirms that J.C. has been living at the facility for 3 years. His behavior has always been rather “odd and unusual”; he has recently become more agitated. He does not get along with other tenants and staff and he has been unable to care for himself for the past year or so.

Psychosocial History: The hospital social worker reveals that J.C.’s mother was frequently hospitalized for unspecified psychotic episodes and his father was “never around.” J.C. admits that he was somewhat of a “rebel” as a child; he has never held steady employment and relies on Social Security income and money from strangers to survive.

Physical Examination/Laboratory Tests: J.C. was given a complete physical examination, which was noncontributory. His laboratory tests, including complete blood count (CBC) with differential, SMA-28 laboratory panel, and thyroid and liver function tests (LFTs) were within normal limits. The urine drug screen was negative, his neurologic examination was unremarkable, and no further tests were ordered.

Mental Status Examination: Appearance and Behavior: J.C. is a thin, disheveled-looking man with very poor hygiene, who appears much older than his stated age. He is extremely suspicious of the interviewer and his surroundings and continually asks, “Where am I, who are you, and what do you want?” He also is agitated easily. **Mood:** J.C. is very anxious and worried, concerned that the “dead people” are going to track him down and “bury me alive.” His affect is blunted, with a minimal range

of reactivity to his emotions. **Memory:** Remote memory seems to be intact, although his immediate and short-term memory are difficult to assess because he is uncooperative. **Sensorium:** He is oriented to person, place, time, and situation. **Thought Content:** He hears dead people talking to him. He seems to be responding to internal stimuli, mumbling to himself and answering his own questions. **Thought Process:** J.C. is very suspicious and exhibits loose associations such as “What are you doing to me? Don’t you like my hat? Jazz musicians will save us all. You are with the FBI!” **Insight and Judgment:** Both are poor as evidenced by J.C.’s denial of his illness and need for treatment, and his behavior, which precipitated this admission.

Provisional Diagnosis: Schizophrenia, Paranoid Type

1. What target symptoms of schizophrenia are present in J.C.? How are target symptoms used to monitor treatment?

J.C. exhibits many of the classic Schneider’s first-rank symptoms of schizophrenia, including auditory hallucinations (hearing voices from “dead people” telling him that he will be killed), delusions (“Jazz musicians will save us all. You are with the FBI. They will bury me alive.”), and thought broadcasting (“The newscasters on the television are reading my mind.”). Other target symptoms include agitation, suspiciousness, loose associations, poor grooming and hygiene, impaired sleep, decreased social skills, and impaired insight and judgment. These target symptoms are the basis of assessing a change in clinical status and monitoring J.C.’s response to medications.

Typical Course and Outcome

Onset of Illness

The onset of schizophrenia starts with the prodromal phase that begins with the first changes in behavior and lasts until the onset of psychosis.^{51–53} It is characterized by a slow and gradual onset of signs and symptoms that can last weeks to years, but typically persists for at least a year.⁵¹ Common prodromal signs and symptoms include anxiety, blunted affect, depression or dysphoric mood, irritability, loss of initiative, low energy, poor concentration, sleep disturbance, social isolation and withdrawal, and suspiciousness. Subthreshold or attenuated positive symptoms, and mild disorganization (digressive, vague, overly abstract, or concrete thinking) may begin during the prodrome. Gradual deterioration in functioning commonly occurs. The prodrome is difficult to recognize; however, family members may interpret the earliest subtle changes as normal adolescence, a phase, relational problems, depression, or drug use. Some researchers have viewed the prodromal phase as the optimal point to begin pharmacologic intervention. Research has shown that many patients are ill for months or even years before seeking treatment; this delay in treatment is related to outcome and level of remission. Early recognition of the prodrome could lead to interventions that delay or prevent the emergence of psychosis. Eventually, a symptom characteristic of the active phase appears (Table 78-1, criterion A), marking the disturbance as schizophrenia.

Course of Illness

In contrast with the notion of an inevitable progressive deterioration in schizophrenia as proposed by Kraepelin,

longitudinal studies of schizophrenia suggest that the course of illness is highly variable. The majority suffers from episodic exacerbations and remissions with some degree of residual symptoms.^{45,54–56} Complete remission (i.e., a return to full premorbid functioning) is not common in this disorder. Of the patients who remain ill, some seem to have a relatively stable course, whereas others show a progressive worsening associated with severe disability. Reported remission rates range from 10% to 60%, and a reasonable estimate is that 20% to 30% of all schizophrenic patients are able to lead somewhat normal lives. About 20% to 30% of patients continue to experience moderate symptoms, and 40% to 60% of patients remain significantly impaired by their disorder for their entire lives. Early in the illness, negative symptoms may manifest as prodromal features. Subsequently, positive symptoms appear. Because these positive symptoms are particularly responsive to treatment, they typically diminish, but in many individuals negative symptoms persist between episodes of positive symptoms. As patients with schizophrenia age, the frequency and severity of acute episodes may decrease; however, negative symptoms may become more prominent in some individuals, a state often referred to as burn-out.^{54,56,57}

Prognosis

Predictors of an improved long-term outcome in patients with schizophrenia include female gender, a positive family history of an affective disorder, a negative family history of schizophrenia, good premorbid functioning, higher IQ, married marital status, acute onset with precipitating stress, fewer prior episodes (both number and length), a phasic pattern of episodes and remissions (i.e., fewer residual symptoms), advancing age at onset, minimal comorbidity, paranoid subtype, and symptoms that are predominantly positive (delusions, hallucinations) and not disorganized (thought disorder, disorganized behavior).⁵⁸ Despite modern treatment advancements, schizophrenia remains a severe disease with a relatively poor outcome. Many patients experience repeated hospitalizations and exacerbations of symptoms, and suicide attempts are relatively common. Individuals with schizophrenia have a 20% shorter life expectancy than the general population.⁵⁹ This is due in part, to an increased incidence of general medical illness (such as diabetes or cardiovascular disease) and suicide.⁵⁸ Patients with schizophrenia have approximately a 50% lifetime risk for a suicide attempt and as many as 9% to 13% complete suicide.⁶⁰

2. What other factors in J.C.'s history are consistent with the diagnosis of schizophrenia, and what is his prognosis?

Other factors that are consistent with schizophrenia in J.C. include onset of illness in early adulthood (typical age of onset is late adolescence to early 30s), a positive family history of psychiatric illness, inability to maintain steady employment and establish interpersonal relationships with others, and the apparent chronicity of the illness over the past year. His acute exacerbations of psychosis are also characteristic of schizophrenia. Because of J.C.'s young age at the time of his initial psychotic episodes, a positive family history for thought disorder, an unstable home environment, and a low premorbid level of functioning, his long-term prognosis is not good.

TREATMENT

Schizophrenia is a chronic disease for which there is no cure. Pharmacotherapy can reduce symptoms to improve social and cognitive functions; however, patients have multiple relapses and experience residual symptoms throughout their lives. Treatment can decrease acute symptoms, decrease the frequency and severity of psychotic episodes, and optimize psychosocial functioning between episodes. However, many patients require comprehensive care and life-long treatment. Comprehensive care consists of pharmacologic, psychosocial, and rehabilitative treatment.

Goals of Treatment

The American Psychiatric Association Practice Guideline for the Treatment of Schizophrenia describes three phases of illness for the purpose of integrating treatment.⁵⁸ Treatment is divided into three phases—acute, stabilization, and stable—with each phase using different drug and nondrug strategies to achieve the desired therapeutic outcome. These phases are not always distinct or separate, but instead tend to overlap.

Acute Phase

During the acute phase of illness, patients suffer from floridly psychotic symptoms such as delusions and/or hallucinations, are severely disorganized, and usually require hospitalization or are placed in a supervised outpatient setting. Negative symptoms become more severe during this phase as well. The initial treatment goal is to calm agitated patients who may be physical threats to themselves or others. Medication is usually required to achieve this outcome, although nondrug interventions such as emotional support from the staff and use of quiet areas can also be helpful. An antipsychotic should be initiated as soon as feasible because prolonged psychotic episodes may be associated with a worsening of their course of illness.⁶¹

Stabilization Phase

During the stabilization phase, acute symptoms gradually decrease in severity as the patient begins to stabilize. The goals of treatment during the stabilization phase of the illness are to reduce the likelihood of symptom exacerbation and develop a plan for long-term treatment.⁵⁸ The hope is that a patient will return to his or her premorbid level of functioning, although this is unlikely. Treatment should consist of a combination of pharmacologic and nonpharmacologic strategies. Treatment guidelines recommend that patients continue the same medication and dosage from which they received benefit from during the acute phase of illness. Treatment should be continued for at least 6 months.⁵⁸ During this phase, the individual is most vulnerable to relapse. Another concern during the stabilization phase is that clinicians, patients, and families may wrongly conclude that the antipsychotic stopped working if psychotic symptoms persist during this phase. For example, a patient may have suffered from hallucinations that were loud and derogatory before initiation of treatment; after 8 weeks of treatment, the voices might remain but become quieter and less demeaning. Because antipsychotics have been shown to provide gradual improvement over a period of months after the initial episode was treated, the current regimen should be continued.⁶²

Stable Phase

During the stable phase, a level of functioning considered optimal for that individual patient is attained. Although complete resolution of symptoms is desired, many patients never achieve this goal. Negative symptoms may persist and patients may experience nonspecific symptoms such as tension, anxiety, or mood instability during the stable phase. Treatment during the stable or maintenance phase is designed to optimize functioning and minimize the risk and consequences of relapse. Antipsychotics are highly effective in preventing relapse. There are no reliable predictors of relapse for an individual patient. When developing a long-term strategy to prevent relapse and rehospitalization, the dose and type of antipsychotic, and the duration of therapy should be considered. Long-term pharmacotherapy reduces the risk of relapse in schizophrenic patients and also may reduce the risk of environment- and stress-induced relapse relative to untreated patients.^{63,64} The effectiveness of antipsychotics in remission prevention was demonstrated in studies in which stable patients were either continued on an antipsychotic or changed to placebo. In these studies, relapse rates were higher in patients who did not remain on an antipsychotic. Although results vary, approximately 70% of the patients who were switched to placebo experienced a relapse within 12 months. In contrast, only about 30% of drug-maintained patients had a relapse of their condition.⁶⁵ This supports the need for continuing antipsychotic treatment in patients after they have recovered from a psychotic episode. All patients with schizophrenia should receive maintenance therapy for at least 1 year, unless antipsychotic agents are not tolerated or the diagnosis is uncertain. If a patient has only a single episode with predominately positive symptoms and is symptom free for 1 year after the acute episode, then discontinuation of the medication with careful follow-up can be considered.⁵⁸ Patients with a history of multiple episodes may be candidates for medication discontinuation after stability has been demonstrated for 5 years.⁵⁸ Lifelong treatment is indicated in patients who present a significant risk to themselves or others when unmedicated.⁵⁸

3. What are the specific treatment goals for J.C.?

The immediate treatment goal for J.C. is to reduce his agitation because he may be a physical threat to himself and others. Intermediate goals during the stabilization phase are to attenuate, or to eliminate, if possible, symptoms of psychoses and the thought disorder. Long-term goals during the stable phase should include assisting J.C. in developing a psychosocial support system (e.g., caretakers, mental health workers, peer groups) to promote enhanced medication adherence, enable him to live semi-independently, and possibly obtain part-time employment.

Nonpharmacologic Interventions

Nonpharmacologic interventions are often combined with drug treatment and can provide additional benefits in such areas as relapse prevention, improved coping skills, better social and vocational functioning, and ability to function more independently. Interventions should be started as early as possible, even during the management of an acute episode. As a patient begins to stabilize during an acute episode, nonpharmacologic strategies can be implemented.⁵⁸ Individual therapy (e.g., supportive, insight oriented, reality oriented) can improve insight into

the illness, improve medication adherence, teach ways to cope with medication side effects and stress, and help the patient to identify early warning signs of relapse. Group therapy can enhance socialization skills. In patients who are less stable and who continue to exhibit negative symptoms, supportive therapy is generally more effective than group or other more complex, insight-oriented therapies. Family therapy is also important because family members need to learn ways to cope with such a devastating illness and how to be supportive of their loved one, while not being overly controlling. Vocational training can benefit patients who will likely need a significant amount of assistance in finding and maintaining long-term employment.⁶⁶ Evidence-based practice guidelines for psychosocial treatment of schizophrenia now include interventions such as social skills training, cognitive/cognitive-behavioral therapy, family psychoeducation, and vocational rehabilitation.⁶⁷⁻⁷¹

4. Is nonpharmacologic therapy indicated for treatment of J.C.?

J.C. should be placed in an area of the hospital ward with low amounts of noise and stimulation until his agitation subsides. He needs careful observation by staff until he is fully assessed for the cause of his symptoms and his level of dangerousness. If the treatment team determines that he is very dangerous, he may need one-to-one supervision by an individual staff member. As his behavior calms, J.C. can receive more ward privileges and should begin to attend group therapy. Initial therapy focuses on issues such as “what is schizophrenia?” and “what are the ways to treat it?” Basic issues related to medication education are also discussed. These include symptoms that are improved with medication and recognition of common acute adverse effects. Socialization with other patients and staff should also be encouraged. As J.C. improves further, therapy and education can shift toward coping skills, stress management, recognition of prodromal symptoms of relapse, long-term adverse effects, and ways to enhance adherence to treatment. Family therapy should also be considered if J.C. allows contact to occur. Family therapy focuses on decreasing family stress surrounding the illness, family problem solving, and communication. If J.C. enters a stable phase after discharge from the hospital, other strategies such as psychosocial clubhouses to improve socialization, social skills training, and vocational rehabilitation can increase his quality of life and productivity.⁵⁸

5. How should the staff and family members communicate most effectively with J.C., considering his paranoid state?

Communication should be calm and nonjudgmental in any acutely psychotic and agitated patient. Open-ended questions should be used, with a switch to closed-ended questions if J.C. is unwilling to respond. His paranoid delusions should not be challenged directly because he may feel attacked and become angry and more agitated. Instead of challenging the delusional thoughts, the clinicians should acknowledge that J.C. believes the “dead people” are real and that he is “the king of jazz,” but that they do not share his belief. Direct eye contact should also be intermittent to avoid making the patient feel threatened. If the patient is violent, they should be interviewed in the presence of another health care provider. The clinician must not react to the provocation of a threatening patient and should avoid using a loud voice or aggressive words. When interview-

ing a violent patient, questions should be focused on issues that need immediate attention, such as medication adherence before admission to the hospital, presence of medical conditions, and recent consumption of drugs and alcohol.^{72,73} As J.C. calms, he will likely be more cooperative with questions and assessments.

Assessment

Because a diagnosis of schizophrenia cannot be made or monitored by laboratory or physical tests, the clinician must use target symptoms gathered from a patient interview and historic records to assess treatment response. A complete medical, psychiatric, and medication history, physical examination, laboratory panel (electrolytes; glucose; liver, renal, and thyroid function tests; CBC with differential; urinalysis; urine toxicology screen), and electrocardiogram (ECG) should be obtained as soon as possible during the acute phase of illness or once the patient is cooperative (e.g., stable phase). A complete evaluation is needed to rule out other causes of psychosis, to identify comorbid conditions requiring treatment, and to give guidance for selecting an antipsychotic and for determining the length of treatment.

Given the lack of insight that characterizes schizophrenia patients, collateral information should be gathered from the patient's relatives, friends, and significant others. Target symptoms for schizophrenia are specific for an individual patient, and they must be clearly identified and documented before and during the course of treatment to determine response to an intervention. Both specific treatment goals and the patient's previous baseline level of functioning should be clearly established at the onset of drug therapy. These data are used to give a direction for treatment and as a way of determining whether the outcome has been achieved.

Pharmacologic Interventions

Non-Antipsychotic Agents

BENZODIAZEPINES

Benzodiazepines are commonly added to antipsychotics and have been found to be useful in some studies for anxiety, agitation, global impairment, and psychosis.⁷⁴ Adjunctive use of benzodiazepines can spare the need for higher dosages of antipsychotics. However, some studies found that the benefits of benzodiazepines were sometimes not sustained.⁵⁸ Unfortunately, it is not possible to predict who will respond to adjunctive benzodiazepine treatment, and any potential benefit must be balanced against the risks of benzodiazepines. Common side effects of benzodiazepines include sedation, ataxia, cognitive impairment, and behavioral disinhibition. This latter effect can be a serious problem in those patients who are being treated for agitation. Withdrawal reactions, including psychosis and seizures, can significantly complicate management if a patient suddenly becomes noncompliant with benzodiazepine treatment. In addition, patients with schizophrenia are vulnerable to both abuse and addiction to benzodiazepines. For these reasons, the use of benzodiazepines should be limited to short trials (2–4 weeks in duration) for the management of severe agitation and anxiety.

LITHIUM

The use of lithium in schizophrenia has been investigated as monotherapy as well as an adjunctive treatment with an-

tipsychotics. Studies evaluating the antipsychotic properties of lithium monotherapy indicate that it has limited effectiveness in schizophrenia and may be harmful for some patients.⁵⁸ In combination with antipsychotics, lithium has been observed to improve psychosis, depression, excitement, and irritability.^{58,75,76} In general, adjunctive lithium therapy may be considered in patients who have a partial or poor response to an antipsychotic agent. The dose of lithium should be sufficient to obtain a blood level in the range of 0.8 to 1.2 mEq/L. Patients should be monitored for adverse effects that are commonly associated with lithium (e.g., polyuria, tremor). Reports of increased neurotoxicity from combined use of lithium and antipsychotic agents are inconclusive, and the risk seems to be no different with either medication used alone.⁷⁷

ANTICONSULSANTS

Anticonvulsants such as carbamazepine and valproate are often prescribed in patients with schizophrenia as adjunctive treatment of psychosis, agitation, aggression, impulsivity, and mood lability.^{78,79} However, as with lithium, there is little support for the efficacy of these agents as monotherapy. In general, the evidence to support the use of carbamazepine for schizophrenia is inconsistent. Neppé⁸⁰ reviewed the literature and concluded that patients with nonresponsive psychosis and agitation, aggression, or "interpersonal difficulties" may benefit from the addition of carbamazepine. In a recent meta-analysis, Leucht et al. described a nonsignificant trend for a benefit from carbamazepine as an adjunct to antipsychotics.⁷⁸ An important consideration with carbamazepine is that the drug alters the metabolism of most antipsychotic agents, and dosage adjustment is often required. Carbamazepine should never be used concurrently with clozapine because of the additive risk of agranulocytosis.

Recent evidence indicates that valproate is being prescribed more frequently for schizophrenia and that the use of lithium and carbamazepine is declining.⁸¹ This shift in utilization may reflect a more favorable side effect profile of valproate. In a recent investigation of hospitalized patients treated with risperidone and olanzapine for an acute exacerbation of schizophrenia, concurrent administration of divalproex resulted in earlier improvements in a range of psychotic symptoms.⁸² Additional research is needed to confirm this finding. Dosages and target serum levels of carbamazepine and valproate are similar to those useful in the treatment of bipolar disorder (see Chapter 80 Mood Disorders II: Bipolar Disorders).

PROPRANOLOL

Propranolol, in combination with antipsychotic drugs, has been evaluated in nonresponders, with variable results. Potential explanations for the enhanced efficacy include a drug interaction leading to higher antipsychotic drug serum concentrations, relief of akathisia, or a primary improvement in psychosis. In addition, propranolol has improved chronic aggression in individuals with schizophrenia.⁸³ When used to treat aggression or to enhance the response to antipsychotic agents, high doses are needed. Propranolol is started at 40 to 80 mg twice a day and is increased every other day until intolerable adverse effects occur (systolic blood pressure [BP] of <90 mm Hg or a heart rate <50 beats/minute). Dosages as low as 160 mg and as high as 1,920 mg have been effective; however, a reasonable trial usually is considered to be 240 mg/day for 2 months.^{83,84}

Antipsychotics

CLASSIFICATION AND NOMENCLATURE OF THE ANTIPSYCHOTICS

Antipsychotics have been broadly classified into two groups. The older agents (i.e., those introduced in the United States before 1990) are referred to as *typical* or *conventional* antipsychotics or dopamine receptor antagonists, with pharmacologic activity attributed to the blockade of central dopamine receptors, particularly the D₂ receptor subtype. These agents have also been referred to as *major tranquilizers* and *neuroleptics*. The term major tranquilizer is inaccurate, because these agents, particularly the high-potency agents, can improve psychosis without associated sedation. *Neuroleptic* refers to the tendency of these drugs to cause neurologic side effects, particularly extrapyramidal symptoms (EPS). Typical antipsychotics are further classified as high- or low-potency agents, based on their relative ability to block dopamine receptors. They can also be classed by chemical structure (phenothiazine and nonphenothiazine) and potential for common adverse effects (EPS, sedation, anticholinergic, and cardiovascular effects).^{66,85} Examples of typical agents include haloperidol, fluphenazine, thiothixene, chlorpromazine and thioridazine.

Newer agents, *atypical* or *serotonin-dopamine antagonists*, consist of clozapine, risperidone, olanzapine, quetiapine, ziprasidone, aripiprazole, and paliperidone. These agents demonstrate postsynaptic effects at 5-HT_{2A} and D₂ receptors. Some of the general characteristics that may be considered as features of atypical antipsychotic include an absence or decreased incidence of EPS and tardive dyskinesia (TD), lack of effect on serum prolactin, greater efficacy for refractory schizophrenia, and greater activity against negative symptoms.⁸⁶ However, currently there are no widely accepted characteristics that define an “atypical” antipsychotic, and clozapine is actually the only atypical agent which fulfills *all* of the criteria stated above. Recently, the term *second-generation antipsychotic* has also been proposed to describe this class of medications, although there is no consensus on the nomenclature at the present time.⁸⁷

MECHANISM OF DRUG ACTION

Although the specific mechanism of action of antipsychotics has not been elucidated, the focus is postsynaptic blockade at dopamine D₂ and serotonin 5-HT_{2A} receptor sites. It is generally accepted that D₂ receptor antagonism plays a key role in the treatment of positive symptoms of schizophrenia as well as in the production of EPS and hyperprolactinemia-related side effects. Knowledge of the central dopamine pathways in the brain can be used as a model to understand the therapeutic and side effects of the antipsychotics. The central dopamine system is composed of four tracts: mesolimbic, mesocortical, nigrostriatal, and tuberoinfundibular (Fig. 78-1). Drug action can be predicted if a clinician understands the function of each tract, along with the binding affinity of an agent for receptors located in the tract (Tables 78-5 and 78-6). Blockade of dopamine receptors in the mesolimbic tract is likely responsible for the reduction of positive symptoms of schizophrenia. Blockade of the other dopamine tracts is largely responsible for the adverse effects of antipsychotic treatment. The mesocortical tract is responsible for higher-order thinking and executive functions. Dopamine hypofunctioning in this area, either from the schizophrenia itself or by antipsychotic action, may be responsible for negative symptoms. The nigrostriatal tract

modulates body movement. Antipsychotic-induced blockade in this area causes EPS. Lastly, antipsychotic-induced blockade of the dopamine tract in the tuberoinfundibular area of the anterior pituitary leads to hyperprolactinemia.³⁹ Ideally, selective dopaminergic blockade of the mesolimbic tract would be preferred. Unfortunately, typical antipsychotics block all four of these dopaminergic pathways. Studies have demonstrated that antipsychotic effects require a striatal D₂ receptor occupancy of 65% to 70%; D₂ receptor occupancy greater than 80% significantly increases the risk of EPS.^{88,89} During chronic treatment with typical antipsychotic agents, between 70% and 90% of D₂ receptors in the striatum are usually occupied.⁹⁰ Not surprisingly, all the typical antipsychotic agents have been observed to be effective in reducing positive symptoms of schizophrenia and they all can cause EPS and TD.

In contrast with typical antipsychotic agents that affect all four dopamine tracts, atypical antipsychotics primarily affect dopamine tracts in the limbic system and have been termed *limbic specific*.³⁹ For example, therapeutic doses of risperidone, olanzapine, and ziprasidone produce >70% occupancy at D₂ receptors.^{91,92} However, attributing antipsychotic efficacy solely to D₂ receptor effects is an oversimplification because many patients do not respond to medication despite adequate D₂ occupancy.⁸⁸ Furthermore, low levels of D₂ striatal receptor occupancy (<70%) have been observed with therapeutic doses of clozapine and quetiapine. This may explain the low propensity of these agents to produce EPS, but also calls into question the minimum receptor occupancy necessary for antipsychotic efficacy as proposed for typical agents.^{92,93}

Blockade of the 5-HT_{2A} receptors, a shared property of the atypical agents, has been investigated with regard to its significance in mediating antipsychotic effects.⁹⁴ At therapeutic doses, most atypical agents occupy more than 80% of cortical 5-HT_{2A} receptors.^{92,95,96} Blockade of 5-HT_{2A} receptors, independent of D₂ antagonism, has not been demonstrated to produce antipsychotic effects. However, it is postulated that a high 5-HT_{2A} to D₂ receptor affinity ratio may underlie the enhanced therapeutic efficacy and low propensity for EPS observed with atypical antipsychotics.³⁹ Serotonin is known to exert a regulatory effect on dopaminergic receptors or dopamine release, but the degree of control may vary depending on the pathway. Specifically, serotonin tonically inhibits dopamine release. Therefore, 5-HT_{2A} antagonism should enhance dopaminergic transmission. It has been proposed that the atypical properties of antipsychotics (efficacy against negative symptoms and low propensity to produce EPS) are due in part to augmentation of dopaminergic function via 5-HT_{2A} blockade in the mesocortical and nigrostriatal pathways and limbic specificity.^{39,97} Aripiprazole is an antipsychotic agent with unique effects at D₂ and 5-HT receptors. Specifically, this agent has partial agonist activity at D₂ and 5-HT_{1A} receptors and antagonist activity at serotonin 5-HT_{2A} receptors. Aripiprazole is a functional antagonist at D₂ receptors under hyperdopaminergic conditions but exhibits functional agonist properties under hypodopaminergic conditions.⁹⁸ Paliperidone (Invega) is the newest atypical agent approved by the U.S. Food and Drug Administration (FDA). Because paliperidone is the primary active metabolite of risperidone, 9-hydroxyrisperidone, we should expect the mechanism of action of paliperidone to be similar to that of risperidone.^{99,100}

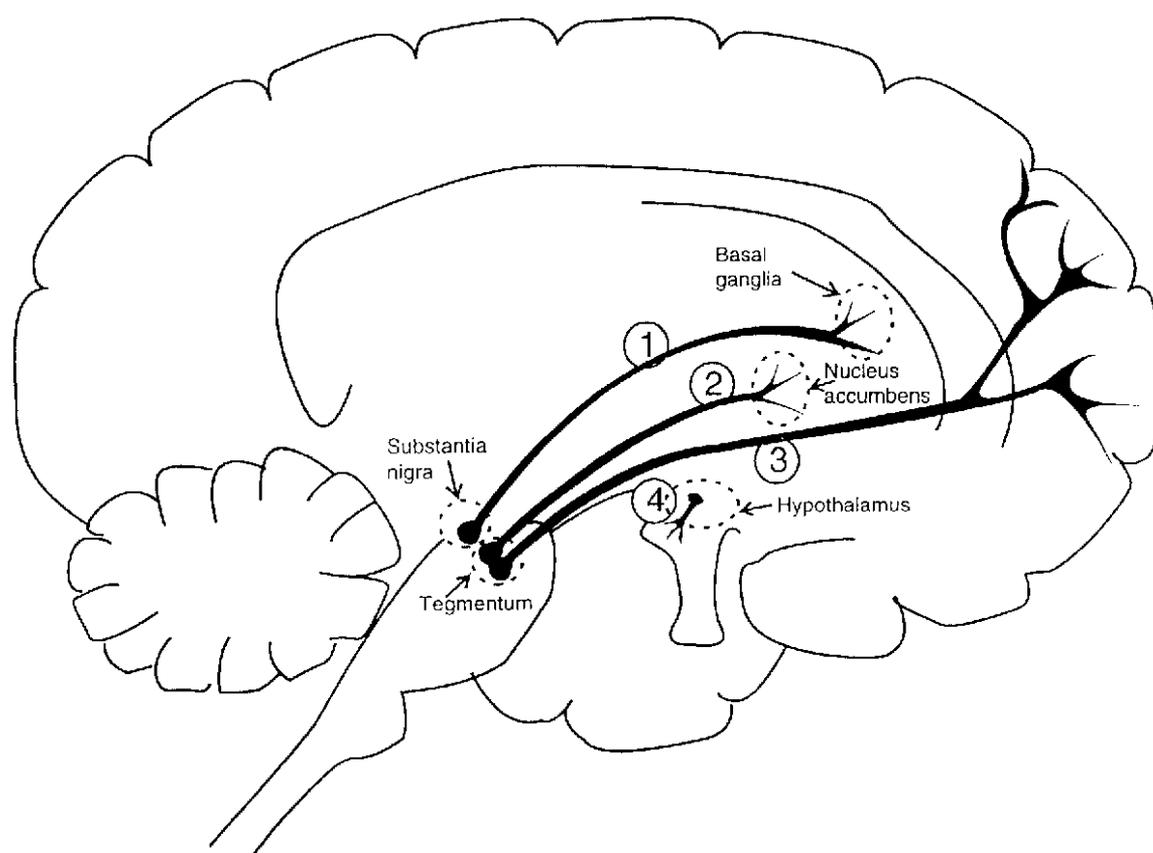

FIGURE 78-1 Four dopamine pathways in the brain. The neuroanatomy of dopamine neuronal pathways in the brain can explain both the therapeutic effects and the side effects of the known antipsychotic agents. (1) The nigrostriatal dopamine pathway projects from the substantia nigra to the basal ganglia, and is thought to control movements. (2) The mesolimbic dopamine pathway projects from the midbrain ventral tegmental area to the nucleus accumbens, a part of the limbic system of the brain thought to be involved in many behaviors, such as pleasurable sensations, the powerful euphoria of drugs of abuse, as well as delusions and hallucinations of psychosis. (3) A pathway related to the mesolimbic dopamine pathway is the mesocortical dopamine pathway. It also projects from the midbrain ventral tegmental area, but sends its axons to the limbic cortex, where it may have a role in mediating positive and negative psychotic symptoms or cognitive side effects of neuroleptic antipsychotic medications. (4) The fourth dopamine pathway of interest is the one that controls prolactin secretion, called the tuberoinfundibular dopamine pathway. It projects from the hypothalamus to the anterior pituitary gland.

Table 78-5 Neurotransmitter Tract Function and Effect of Typical Versus Atypical Antipsychotics

| <i>Neurotransmitter Tract</i> | <i>Clinical Function</i> | <i>Typical Agent Effects</i> | <i>Atypical Agent Effects</i> |
|-----------------------------------|--|--|--|
| Dopamine-nigrostriatal | Modulates EPS | Potent D ₂ blockade causes EPS | Minimal EPS owing to greater specificity for mesolimbic system |
| Dopamine-mesolimbic | Modulates arousal, memory, behavior | Effectively treats positive symptoms | Effectively treats positive symptoms |
| Dopamine-mesocortical | Modulates cognition, socialization, and other negative symptoms | Less effective for negative symptoms | Clozapine (possibly others) greater efficacy for negative symptoms; clozapine, risperidone (others?) may improve cognition |
| Dopamine-tuberoinfundibular | Regulates prolactin release | Increases prolactin release (dose related) | No increase in prolactin with clozapine, dose-related with risperidone, no significant increase with others |
| Serotonergic (5-HT ₂) | 5-HT ₂ blockade reduces EPS, improves negative symptoms | Minimal affinity for 5-HT ₂ receptors | Greater affinity for 5-HT ₂ receptors |

EPS, extrapyramidal side effects.

Antipsychotic drugs also affect other receptors, usually resulting in adverse effects rather than enhanced therapeutic response. For example, histamine-1 (H₁) blockade is responsible for sedation and possibly weight gain. Blockade of 5-HT_{2C} receptors may also play a role in the weight gain associated with some atypical agents. α₁-Adrenergic blockade causes orthostatic hypotension and plays a role in sexual dysfunction.

Muscarinic receptor blockade causes the classical anticholinergic effects such as dry mouth, blurred vision, constipation, and urinary retention. An understanding of the receptor-binding properties of the typical and atypical agents is helpful to predict their adverse effects profiles.^{66,85,101} Properties of typical and atypical antipsychotics are listed in Tables 78-6 and 78-7.

Selection of an Antipsychotic

In all patients, the selection of a specific antipsychotic agent should be individualized. The choice of a specific medication is usually based on a number of factors and is frequently more art than science. Important factors include prior experience (efficacy and side effects), the ease of attaining a therapeutic dose, available dosage forms, and formulary or cost considerations. One of the best predictors of response is the patient's previous response to a specific antipsychotic, or a positive response in a first-degree relative. If a patient responded poorly to an antipsychotic in the past, an agent from a different chemical class should be prescribed. Also, if a patient has a particular aversion to an antipsychotic side effect, an appreciation for differences among the available antipsychotics in this regard would be helpful. Drugs with a similar side effect profile should be avoided. Although all the antipsychotic agents have been shown to be efficacious during the acute phase of schizophrenia, atypical antipsychotics (with the exception of clozapine) have become the agents of first choice for the treatment of schizophrenia. The rationale for this practice is based on the lower risk of EPS and TD with the atypical agents.

Efficacy

Typical antipsychotics are effective in reducing positive symptoms of schizophrenia during acute psychotic episodes and in preventing recurrence in many patients.¹⁰² These agents are less effective for treating negative symptoms. In fact, there is concern that typical agents may exacerbate negative symptoms by causing drug-induced akinesia. In general, all typical antipsychotic agents are believed to be equally effective when used in equivalent doses.

Clinical trials demonstrate that the atypical agents—clozapine, risperidone, olanzapine, quetiapine, ziprasidone, aripiprazole, and paliperidone—are superior to placebo, and are at least as effective as typical antipsychotics for treatment of the positive and negative symptoms of schizophrenia.^{98,103–113} In a meta-analysis of 52 randomized clinical trials comparing atypical agents (including clozapine, risperidone, quetiapine) with typical agents (haloperidol or chlorpromazine), Geddes et al.¹¹⁴ found no difference in efficacy between these two drug classes if the dose of the typical agent was considered. The apparent superiority of atypical antipsychotics (in terms of efficacy and drop-out rates) could be attributed to the use of excessive doses of typical agents (> 12 mg/day haloperidol or equivalent). In contrast, two other meta-analyses concluded that the atypical agents have efficacy and tolerability advantages over typical agents independent of haloperidol dosage.^{115,116} Davis et al.¹¹⁶ concluded that available evidence demonstrates an efficacy advantage for some (clozapine, risperidone, olanzapine) but not all atypicals (quetiapine, ziprasidone, and aripiprazole) when compared with typical agents. These authors suggest that the atypical agents are at least as efficacious as typical agents for positive symptoms, and that atypical agents are likely more efficacious with negative and cognitive symptoms. This potential advantage of the atypical agents continues to be a source of much debate. On one hand, there are some who believe that atypical agents have a unique therapeutic effect on the primary negative symptoms, whereas others contend that this finding is actually a secondary impact upon other related symp-

toms and disease manifestations.¹¹⁷ Data on risperidone and olanzapine suggest a direct effect on primary negative symptoms independent of their effect on psychotic, depressive, or EPS.^{118,119}

The National Institute of Mental Health Clinical Antipsychotic Trials of Intervention Effectiveness trial (CATIE) was a real-world trial evaluating schizophrenic patients. The trial compared the effectiveness of atypical antipsychotics (quetiapine, risperidone, clozapine, olanzapine, and, later, ziprasidone) to that of perphenazine, a midpotency typical antipsychotic.¹²⁰ Perphenazine was chosen owing to a lower incidence of EPS compared with high and other midpotency typical antipsychotics, as well as decreased sedation when compared with low-potency typical antipsychotics. In this study, 1,460 patients were included from 57 sites in 24 states. The results indicated olanzapine was least likely to be discontinued; however, it (and clozapine) had the most metabolic side effects. Perphenazine was as effective as the atypical agents, however, it had the highest incidence of EPS, even after patients with TD were excluded from receiving the medication.^{121,122}

Dosage Forms

ORAL DISINTEGRATING TABLET

Pharmacotherapy during the acute phase is administered orally (as tablets or liquid concentrate) or intramuscularly (IM), depending on the patient's willingness to take medication, the risk of imminent harm, and dosage form availability. Usually, antipsychotic therapy is administered orally. The newest technology available is the oral disintegrating tablet (ODT). ODT can be in the form of a compressed tablet, compression molded tablets, and freeze-dried (lyophilized) wafers that dissolve or disintegrate within a matter of seconds when placed on the tongue. Of the atypical agents, risperidone, olanzapine, and aripiprazole are available as ODT.

SHORT-ACTING INJECTABLES

Although all of the antipsychotics are available in oral formulations, only a few are available as injectables. Short-acting IM preparations of an antipsychotic may be preferred over oral medication if a patient is agitated and not likely to be cooperative. IM preparations bypass the gastrointestinal tract and first-pass metabolism and have a faster onset of action. For example, most IM antipsychotics reach a maximum plasma level within 30 to 60 minutes and patients usually experience substantial calming within 15 minutes.¹²³ Of the short-acting agents available for IM use, most clinical experience has been with high-potency typical antipsychotic medications such as haloperidol or fluphenazine. Haloperidol and fluphenazine have the advantage of being calming without being sedating, but they can cause severe EPS. Some clinicians prefer low-potency agents such as chlorpromazine, because they are more sedating. Low-potency agents can also cause severe hypotension. High-potency agents can be given in larger doses because they have a lower risk of anticholinergic and cardiovascular complications than low-potency agents. In general, the use of oral typical agents has declined because of the neurologic risks. Studies have shown that the FDA-approved IM formulations of the atypical agents (olanzapine, aripiprazole, and ziprasidone) seem to be better tolerated than typical agents and are equally effective as haloperidol in the acute treatment of psychoses in patients with schizophrenia.^{124,125}

Agitation is a problem that many mental health providers face. It can affect whether or not a patient can be treated at any point in time. A patient who is acutely agitated may behave in a way that may result in harm of self, others, or property. In these cases, medication is needed to calm the patient. In the past, sleep was thought to be essential in the treatment of acute agitation. This is no longer true, though, some facilities may still use this as an endpoint or goal.¹²⁶ If rapid tranquilization is required for a patient who is acutely agitated and exhibiting dangerous behavior, the combination of IM haloperidol and IM lorazepam appears more effective than either alone.¹²⁷ However, rapid tranquilization is not necessarily more effective than traditional dosing methods, and is associated with a greater incidence of acute side effects such as dystonic reactions.^{128,129} Rapid tranquilization can be achieved when repeated IM injections of high-potency antipsychotics or benzodiazepines are given until the patient is either adequately calmed, a maximum recommended daily dose is reached, or dose-limiting adverse effects such as acute dystonia (antipsychotics), ataxia, or slurred speech (benzodiazepines) occur. The most commonly used regimen is haloperidol 2 to 5 mg combined with lorazepam 2 mg injected IM every 30 to 60 minutes to a maximum of three doses.¹³⁰ Patients should be monitored for severe adverse events, particularly those patients with underlying medical or neurologic problems. Vital signs should be monitored and the dose should be held if clinically significant adverse effects occur.^{129,131} The concept of rapid tranquilization should not be confused with rapid neuroleptization, which implies the use of very high loading dosages of antipsychotics (e.g., administering a series of closely spaced IM doses over a period of hours) to produce a more rapid remission of psychotic symptoms.¹³⁰ The practice of rapid neuroleptization leads to a higher incidence of EPS without advantages of efficacy when compared with the administration of lower doses of the same drugs. Rapid neuroleptization is no longer recommended.¹²⁸ Most recently, with the advent of IM and fast-acting oral formulations of atypical antipsychotics, the combination has changed to decrease the incidence of EPS. Clinical trials have shown that risperidone, ziprasidone, aripiprazole, and olanzapine are at least as effective as haloperidol and lorazepam (Table 78-8).^{125,126,132–139}

6. How should pharmacotherapy be used to treat the acute phase of schizophrenia in J.C., and what should be done first to manage his acute symptoms?

Aripiprazole 9.75 mg IM injection can be given to J.C. so further assessment can be completed. Aripiprazole for any a typical IM agent is a good choice because it has efficacy in calming rather than sedating the patient, it has a lower propensity for EPS and TD, and is available in a short-acting IM formulation. These are important features because J.C. is likely to refuse oral medications because of his paranoid symptoms. Also, aripiprazole IM has limited cardiovascular problems such as hypotension, bradycardia with or without hypotension, tachycardia, and syncope as compared with olanzapine IM.^{132,139} Lorazepam 0.5 to 1 mg PO or IM every 4 to 6 hours as needed may be given to J.C. to control ongoing agitation, however, greater sedation and orthostatic hypotension have been observed with the combination of lorazepam and aripiprazole as compared to aripiprazole alone.¹³² Subsequent doses of aripiprazole IM can be given every 2 hours if needed for agitation, up to a maximum of 30 mg/day.

7. J.C. was given a single dose of aripiprazole 9.75 mg IM. His agitation resolved after the first injection but you are later informed that this medication is not covered by J.C.'s healthplan. What is the next medication you would recommend for J.C., and what factors should be considered when selecting an antipsychotic for the acute and stabilization phases?

An antipsychotic prescribed at a dose reflective of the needs during the stabilization phase should be started now. Olanzapine, 10 mg at bedtime, is an appropriate choice for pharmacologic treatment of schizophrenia in the acute phase. With the exception of clozapine, any of the other atypical agents would also be appropriate choices.

Past experience with antipsychotics predicts therapeutic success in the selection of a regimen. J.C. does not have a past psychotropic medication history to guide drug selection. He also does not have a history of nonadherence, which would direct the choice toward a depot product. A common starting dose for olanzapine is 10 mg/day.

Table 78-8 Agents to Treat Acute Agitation

| Medication | Dosage Form | Dose | Onset | Half-life | Duration of Action |
|--------------------------------|--------------------------|---------|-----------|-----------|--------------------|
| Lorazepam | PO (tablet), IM, IV | 1–2 mg | 60–90 min | 12–15 hr | 8–10 hr |
| Typical Antipsychotics | | | | | |
| Haloperidol | PO (tablet), IM, IV | 5–10 mg | 30–60 min | 12–36 hr | up to 24 hr |
| Droperidol | IM, IV | 5–10 mg | 15–30 min | 2–4 hr | 6–8 hr |
| Atypical Antipsychotics | | | | | |
| Olanzapine | PO (tablet), IM, ODT | 10 mg | 15–45 min | 30 hr | 24 hr |
| Risperidone | PO (tablet, liquid), ODT | 2 mg | 60 min | 20 hr | Not available |
| Ziprasidone | PO (tablet), IM | 20 mg | 30–60 min | 2–5 hr | 4 hr |
| Aripiprazole | PO (tablet, liquid), IM | 9.75 mg | 1–3 hr | 75–94 hr | Not available |

IM, intramuscularly; IV, intravenously; ODT, oral disintegrating tablet; PO, orally.
Compiled from references 125, 126, and 132–139.

8. When should J.C.'s target symptoms start to respond to olanzapine?

During the first week, often known as the medicated co-operation stage, J.C. should respond to the calming properties of the antipsychotic, and his symptoms of hostility, agitation, and insomnia should improve. During the next 2 to 6 weeks, the improved socialization stage, J.C. should begin to obey hospital rules, attend ward meetings, and generally become more sociable. Severely ill schizophrenic patients with chronic disease may never reach this stage. The elimination of the thought disorder stage can occur within any time frame, but usually takes at least 2 to 3 weeks and up to several months to occur. During this stage, the core symptoms of schizophrenia such as delusions, hallucinations, and thought disturbance improve. If no improvement of J.C.'s core symptoms is observed after 3 weeks of olanzapine 10 mg/day, then the dose should be increased slowly to 15 or 20 mg/day and the patient should be observed for another 3 to 4 weeks.

9. It is 6 months later. Most of J.C.'s symptoms have improved, he is residing in assisted living housing and working part-time at Goodwill Industries. Although he is not troubled by any side effects, he sees no point in continuing his medication. Should olanzapine be discontinued? What are the current practice guidelines regarding long-term treatment?

J.C. clearly is responding well to olanzapine and has no side effects. To minimize risk of relapse, he should continue his current regimen for at least another 6 months. If his symptoms remain stable and he maintains good psychosocial functioning (e.g., continues work, keeps close contact with social workers, attends medication groups), discontinuation of therapy can be considered.

When J.C. has been stabilized for a total of approximately 1 year on olanzapine 10 mg/day, then the dose can be reduced by 20% every 3 to 6 months until it is discontinued or relapse occurs. If he exhibits recurrent target symptoms of schizophrenia or decompensation, then the dose should be increased to the previous effective dose (or medication restarted if it was discontinued). Because it is likely that J.C. will require long-acting antipsychotics, it is important to determine the minimal effective dose to prevent recurrence, while minimizing the risk of adverse effects. J.C. is not a candidate for intermittent therapy during the stable phase. He is not a decanoate candidate because he is compliant with treatment.

LONG-ACTING DEPOT INJECTABLES

Long-acting depot medications are not recommended for acute psychotic episodes because these medications take months to reach a steady-state concentration and are eliminated very slowly.⁵⁸ Hence, it is difficult to correlate clinical effect with dosage, and it is extremely difficult to make dosage adjustments to manage side effects. However, long-acting depot medications can be useful for maintenance therapy in patients with a history of nonadherence to their oral medication and in those who prefer the convenience of long-acting or depot injections. In these situations, the oral form of available depot medications should be initiated first. If the oral form has been shown to be safe and effective, the patient can be converted to the depot form. Fluphenazine, haloperidol,

and risperidone are available as long-acting decanoate injections. Long-acting injectable risperidone appears to combine the most valuable features of an atypical antipsychotic (broadly efficacious and well tolerated) with those of injectable long-acting antipsychotics (improved bioavailability and assured medication delivery).^{141,142}

Pharmacokinetics and Drug Interactions

Dosing considerations also have a major influence on safe and effective antipsychotic selections. Specific factors include the number of times a day a medication needs to be administered, the difference between a starting dose and a "target" therapeutic dose (i.e., titration required), and the risk for drug–drug interactions. The long half-life (12–24 hours) and active metabolites of most oral antipsychotic drugs allow for once- to twice-daily dosing.¹⁴³ Most antipsychotics, with the exception of clozapine and ziprasidone, can be safely given once a day. Most antipsychotics achieve a steady-state concentration in 4 to 7 days, but it is important to understand that the onset of antipsychotic effect is not related to achieving steady state. Pharmacologic effects often persist for longer than pharmacokinetics would imply. In some instances, treatment is initiated at a subtherapeutic dose and gradually titrated upward to an effective dose. This approach is taken to allow the patient to develop tolerance to adverse events such as sedation or orthostatic hypotension. In the case of acute agitation, antipsychotic doses are also often divided, despite the long half-lives of these drugs, such that the sedative effects are maintained over the day. Once a patient has been stabilized or has become tolerant to the adverse effects, the goal is to give medication once a day, usually at bedtime. Bedtime dosing enhances medication adherence and concentrates ongoing adverse effects such as sedation at night.

Both pharmacokinetic and pharmacodynamic drug interactions can occur with antipsychotic agents. Cytochrome P450 enzymes, especially the 1A2, 2D6, and 3A4 isoenzymes, are responsible for the metabolism of many antipsychotics.¹⁴⁴ Induction or inhibition of these enzymes by other drugs may result in clinically important drug interactions. Table 78-9 summarizes the metabolic pathways for commonly used antipsychotic drugs. In the case of clozapine, serious complications such as seizures can occur when drug interactions cause serum concentrations of clozapine to rise significantly. Examples of drugs that have the potential to cause serious interactions with antipsychotics include fluvoxamine (CYP 1A2 inhibitor), erythromycin, ketoconazole, and ritonavir (CYP 3A4 inhibitors), quinidine, risperidone, fluoxetine, and paroxetine (CYP 2D6 inhibitors), and cimetidine (multiple enzyme inhibition).¹⁴⁵ Conversely, inducers of drug metabolism such as carbamazepine (induces multiple enzymes) or cigarette smoking (induces CYP 1A2) can reduce the plasma concentrations of antipsychotic drugs. For example, carbamazepine has been shown to reduce plasma concentrations of haloperidol by 50%.¹⁴⁶ Cigarette smoking has been shown to increase the metabolism of clozapine and olanzapine.¹⁴⁴ Pharmacodynamic interactions may occur when medications with similar unwanted properties are concurrently prescribed. For example, concomitant use of low-potency typical agents or clozapine along with diphenhydramine or hydroxyzine may cause augmentation of anticholinergic effects. Pharmacodynamic drug interactions of greatest concern are those that can cause

significant orthostatic hypotensive, anticholinergic effects, and sedation. Pharmacokinetic and dosing information for the antipsychotics are provided in Tables 78-9 and 78-10.

Pharmacoeconomic Considerations

Although medication expenditures represent only a small portion of total resource utilization associated with the management of schizophrenia, concern exists about the cost of atypical antipsychotics and whether their relative advantages over typical agents are worth their increased cost.¹⁴⁷ Drug acquisition costs for atypical antipsychotics can be 100-fold higher than typical antipsychotics. Most pharmacoeconomic studies with atypical antipsychotics show that these agents are at least cost neutral and may offer cost advantages compared with traditional agents when total mental health costs are considered.¹⁴⁸ Depending on the individual study, the higher costs associated with atypical antipsychotics are offset by decreased number of hospital admissions, length of inpatient stay, and number of outpatient visits. Hence, drug costs should not be the sole factor considered when selecting an antipsychotic. The selection of a medication should be individualized and factors such as efficacy, side effects, patient acceptance, and total health care costs should be considered.

Adverse Effects

An important factor in the selection of an antipsychotic is the potential risk for adverse events. Key adverse effects that differentiate the antipsychotics include EPS, anticholinergic side effects, cardiac effects, hyperprolactinemia, metabolic effects and sedation. Table 78-7 compares antipsychotic agents with regard to the risk of these adverse effects.

EXTRAPYRAMIDAL SIDE EFFECTS AND TARDIVE SYNDROMES

EPS is a broad term that describes several types of acute and chronic drug-induced movement disorders. Acute dystonia, parkinsonism, and akathisia all occur early in treatment, whereas TD, tardive dystonia, and tardive akathisia have a late onset, usually after years of treatment. The acute forms of EPS

usually develop soon after the initiation of antipsychotics, are dose dependent, and are generally reversible soon after discontinuation of the offending agent.¹⁴⁹ It has been estimated that 60% of patients who receive typical antipsychotics develop some form of EPS acutely.⁵⁸ In general, typical agents are more likely to cause EPS than atypical agents when these medications are used at usual therapeutic doses. Among the seven currently available atypical agents, clozapine and quetiapine are associated with the lowest risk for EPS. The rising prescription rate of atypical antipsychotics (and decrease in use of the typical agents) have substantially reduced the problem of EPS. Similarly, the risk of antipsychotic-induced TD is suggested to be lower with atypical agents compared with typical agents. Most of the evidence documenting a decreased incidence of TD with atypical agents is derived from data and clinical experience with clozapine, risperidone, olanzapine, and quetiapine.^{150–153}

Acute Dystonia

Acute dystonia has the earliest onset of all the EPS symptoms. Most cases occur within the first few hours or days after initiation or dose increase of antipsychotic medication. Dystonia is characterized by sustained muscle contractions. Common presentations of antipsychotic-induced dystonia include a sudden onset of brief or sustained abnormal postures, including tongue protrusion, oculogyric crisis (eyes rolling back into head), trismus (spasm of the jaw), torticollis (torsion of the neck); opisthotonos (arching of back), and unusual positions in the trunk, limbs, and toes. Laryngeal dystonias are the most serious dystonias and are potentially fatal. Risk factors for acute dystonia include younger age, male gender, high dosage of high-potency typical antipsychotics, and previous history of dystonia.⁵⁸

The exact pathophysiology of acute dystonia is uncertain. Conflicting theories describe either a hypodopaminergic or hyperdopaminergic state after an antipsychotic-induced blockade of postsynaptic dopamine receptors. Acute dystonia likely is caused by dysregulation of the dopamine system and

imbalance between neurotransmitter systems after acute antipsychotic administration.¹⁵⁴

10. J.P., a 19-year-old man, was brought to the psychiatric ED because of assaultive behavior toward his mother. J.P. states he struck her because the devil told him to do it. Trifluoperazine 5 mg IM Q 4 to 6 hr PRN was started to control his assaultive behavior. He received four IM injections over 24 hours and was converted to 15 mg PO HS. On day 2 of the admission he complained of a stiff neck and protruding tongue. J.P. became very upset and wanted to leave the hospital and never take these medications again. No other medical conditions were noted. What evidence suggests that J.P. is experiencing an acute dystonia reaction?

The sudden appearance of a stiff neck and a protruding tongue in J.P. is consistent with acute dystonia. In addition, J.P.'s young age, male gender, and use of a high-potency typical antipsychotic agent also place him at high risk for experiencing a dystonic reaction.

11. How should acute dystonia be treated in J.P.?

Acute dystonic reactions are sudden in onset, dramatic in appearance, and can cause patients great distress. It requires immediate treatment. The initial goal of treatment is to relieve

symptoms as soon as possible with either benztropine 1 to 2 mg or diphenhydramine 25 to 50 mg by IM injection. Although the IV route has a faster onset of action, it is not needed in J.P. because his reaction is not severe. If symptoms do not resolve within 15 to 30 minutes, then the dose should be repeated. If there are contraindications to the use of anticholinergic drugs, lorazepam 1 to 2 mg IM can be used. J.P. must be reassured that this is a temporary condition that can be prevented and treated. To prevent another reaction, J.P. should be given oral anticholinergic drugs in doses commonly used for pseudoparkinsonism for 2 weeks after this dystonic reaction.¹⁵⁴

Parkinsonism

The clinical presentation of antipsychotic-induced parkinsonism includes bradykinesia or akinesia, which may be associated with decreased arm swinging, a masklike face, drooling, decreased eye blinking, and soft, monotonous speech, tremor, which is most commonly a rhythmic, resting tremor, and rigidity of the extremities, neck or trunk (most identifiable in the limbs as a “cogwheel” rigidity during passive motion).¹⁵⁴ Antipsychotic-induced parkinsonism occurs in approximately 20% of patients treated with antipsychotic agents.⁵⁸ Symptoms can occur at any time, but usually develop within 4 weeks after antipsychotic initiation or a dose increase. Advanced age,

antipsychotic dose and potency, and preexisting EPS are the major risk factors for antipsychotic-induced parkinsonism.¹⁵⁵ The Simpson Angus Rating Scale is used commonly to assess the presence and severity of EPS (Table 78-11).¹⁵⁶

Antipsychotic-induced parkinsonism (as well as idiopathic Parkinson's disease) is thought to be due to postsynaptic dopamine receptor blockade in the nigrostriatal system, leading to an imbalance between the dopaminergic and cholinergic systems. Reasons for the delay in onset between receptor blockade, which occurs within hours after initiating an antipsychotic, and development of symptoms are not well understood.¹⁵⁴

Atypical antipsychotics are the mainstay of the pharmacologic management of psychosis in patients vulnerable to developing antipsychotic-induced parkinsonism. The reduced parkinsonian liability of atypical antipsychotics has been associated with their limbic specificity, 5-HT_{2A} blocking effects and in some cases less D₂ receptor blockade.^{89,92,97}

12. S.B., a 46-year-old man, has a diagnosis of chronic undifferentiated schizophrenia and was treated with loxapine 50 mg TID with inadequate response. The dose cannot be increased due to oversedation. Because of the incomplete response, S.B. was switched to haloperidol 5 mg Q AM and 10 mg QHS. One week after the switch, S.B. returns to the clinic complaining of feeling “real slow.” He has a bilateral hand tremor that improves when he picks up his coffee cup. Physical examination detected cogwheel rigidity in both arms, although it was worse on the right side. S.B. wants to be taken off this “bad” medication. What evidence suggests that S.B. has antipsychotic-induced parkinsonism?

The onset of symptoms within 1 week of starting a new, high-potency typical antipsychotic is the first clue to the presence of EPS. The “slow feeling” possibly is indicative of akinesia, and S.B.'s bilateral tremor and cogwheel rigidity also are features of antipsychotic-induced parkinsonism.

13. What antiparkinsonian drug could be selected for S.B., if any?

In mild cases of antipsychotic-induced parkinsonism, immediate intervention may not be required if the movement disorder is not bothersome to the patient. For troublesome cases, as experienced by S.B., the simplest intervention is to reduce the

^aOral dose or IM injection can be used.

antipsychotic (haloperidol) dose to the lowest effective level. If dose reduction is not possible, then an antiparkinsonian agent can be added (Table 78-12).¹⁵⁴

All anticholinergic antiparkinsonian agents are equally effective for antipsychotic-induced parkinsonism, although there are differences in adverse effects and duration of action. Trihexyphenidyl is the least sedating but more prone to abuse, whereas diphenhydramine is the most sedating. Benztropine has the longest duration and can be used once or twice a day if needed, whereas the others have to be used three to four times a day. Benztropine 1 mg twice a day orally could be initiated for S.B. because he is likely too psychiatrically unstable to tolerate a reduction in the haloperidol dose. The tremor, rigidity, and akinesia should begin to resolve within the first few days of treatment. Alternatively, a switch to an atypical antipsychotic may negate the need for an antiparkinsonian drug in S.B.

14. Benztropine 1 mg BID is started one week later, all of S.B.'s acute symptoms of parkinsonism have disappeared. How long should benztropine be continued in S.B. now that his EPS are resolved?

The long-term treatment of antipsychotic-induced parkinsonism with antiparkinsonian medication is controversial.¹⁵⁴ The World Health Organization published a consensus statement recommending that the prophylactic use of anticholinergic medication in patients receiving antipsychotics should be avoided or used only in cases where alternative strategies have failed.¹⁵⁷ For S.B., an attempt to taper and discontinue the antiparkinsonian treatment should be initiated 6 weeks to 3 months after symptoms resolve. Unfortunately, as many as 30% of patients chronically treated with typical antipsychotics continue to experience parkinsonian symptoms.⁹⁰ If that should occur with S.B., he should be switched to an atypical agent.

15. What risks are associated with long-term anticholinergic treatment?

The risks of anticholinergics include constipation, dry mouth leading to dental caries, and blurred vision. They can also impair memory, especially in older patients. Some patients develop tolerance to these adverse effects, but others do not, even with chronic use. Patients sometimes abuse anticholinergic medications for their mood-elevating and hallucinogenic effects. Abuse may be confused with reluctance to discontinue antiparkinsonian medication because of the fear of recurrent EPS or ongoing symptoms.

16. One week after the benztropine was started, S.B.'s psychiatric symptoms began to respond to the haloperidol, but he developed acute urinary retention. Reduction of the benztropine dose to 1 mg/day did not improve his urinary retention. What alternative treatments without anticholinergic effects are available to manage S.B.'s pseudo-parkinsonian symptoms?

S.B. is just beginning to gain benefit from his haloperidol; therefore, the haloperidol dose should not be reduced. Amantadine, an antiparkinsonian medication that directly stimulates postsynaptic dopamine receptors and restores the cholinergic and dopaminergic balance in the nigrostriatum, would be a reasonable alternative to benztropine in S.B. Amantadine is an option for patients who cannot tolerate or who respond poorly to anticholinergic drugs. It often is preferred in the elderly because of the lower incidence of cognitive impairment. The parkinsonian symptoms usually respond within 24 hours.

S.B. should be started on amantadine 100 mg twice a day and benztropine should be discontinued. He should be monitored to determine whether EPS reappear and his urinary retention problem is corrected. S.B. also should be monitored for the appearance of amantadine-associated, dose-related adverse effects such as tremor, slurred speech, ataxia, depression, hallucinations, rash, orthostatic hypotension, and insomnia. If he cannot tolerate amantadine, or if amantadine does not control his EPS, an atypical antipsychotic agent can be considered.

Akathisia

Akathisia is a syndrome consisting of subjective feelings of restlessness or the urge to move and an objective motor component expressed as a semipurposeful movement most often involving the lower extremities (pacing, rocking, and an inability to sit or stand in one place for extended periods of time). Akathisia is observed in up to 50% of patients treated with typical antipsychotics and ranges from 5% to 15% of patients treated with atypical agents.^{58,158} Akathisia is often extremely distressing to patients, is a common cause of medication non-adherence and, if allowed to persist, can produce dysphoria and possibly aggressive or suicidal behavior.⁵⁸ It is often difficult to distinguish from psychomotor agitation and worsening psychosis. Hence, the clinician must take care not to misdiagnose akathisia because an increase in antipsychotic dose could worsen this adverse event. It usually develops within days to weeks after initiating antipsychotic therapy.

The pathophysiology of akathisia is unclear, but much attention has focused on two theories.¹⁵⁴ One theory states that the mesocortical postsynaptic dopamine blockade leads to increased locomotor activity. An alternate theory claims that akathisia is caused by dopamine antagonist-induced dysregula-

tion of noradrenergic tracts that project from the locus ceruleus to the limbic system.

17. J.P. was diagnosed with paranoid schizophrenia. His acute episode improved with trifluoperazine 15 mg HS, and he had no other dystonic reactions. Two weeks later he became increasingly agitated, began pacing the floor, was unable to sit or lie down for longer than 10 minutes at a time, and subjectively had a feeling that he described as "I have ants in my pants." J.P. is observed rocking back and forth from one foot to the other while standing in line for his dinner. He has no symptoms of antipsychotic-induced parkinsonism. Should the dose of trifluoperazine be increased?

J.P.'s symptoms of rocking, pacing, agitation, and the inability to sit still are consistent with akathisia. Because his psychiatric symptoms have improved and the new symptoms developed within 2 weeks after the initiation of trifluoperazine, a diagnosis of akathisia is more probable than unresponsiveness to the antipsychotic medication. Therefore, the trifluoperazine dose should not be increased because it can worsen the akathisia.

18. How should J.P.'s akathisia be managed?

Akathisia is less responsive to treatment than are antipsychotic-induced parkinsonism and dystonia.⁵⁸ As an initial approach to manage his akathisia, a small reduction (5 mg/day) in his trifluoperazine dosage should be attempted. If symptoms of his psychosis return or if the akathisia persists, the addition of a β -blocking agent, an anticholinergic drug, or a benzodiazepine can be considered.^{58,154} Propranolol would be a recommended agent because there is a suggestion that its efficacy and safety profile may be preferable compared with other agents.¹⁵⁹ Anticholinergic drugs are appropriate alternatives if antipsychotic-induced parkinsonism is present. If his symptoms do not improve in response to a dosage reduction of his trifluoperazine within 1 week, J.P. should be started on propranolol 20 mg three times a day, and the dose should be increased by 20 mg every other day to a maximum of 120 mg, if necessary.¹⁵⁹ He has no contraindications to β -blocker therapy and does not have antipsychotic-induced parkinsonism; therefore, antiparkinsonian agents (Table 78-12) are not preferred over propranolol. If the akathisia persists after a trial of propranolol 120 mg/day therapy for 1 week, benzodiazepines should be tried or he should be switched to an atypical antipsychotic.

Tardive Dyskinesia (TD)

TD is a syndrome characterized by involuntary choreoathetoid movements that occurs in individuals taking long-term antipsychotics. The face (tics, blinking, grimacing), tongue (chewing, protrusion, tremor, writhing), lips (smacking, pursing, puckering), neck and trunk (torsion and torticollis), and limbs (toe tapping, pill rolling, and writhing) are commonly involved. The movements may be choreiform (rapid, jerky, nonrepetitive), athetoid (slow, sinuous, continual), or rhythmic (stereotypic) in nature.

TD occurs in approximately 20% of patients who receive long-term treatment with typical agents.¹⁴⁹ The cumulative annual incidence is approximately 5% through the first 4 years of treatment in an adult who receives typical antipsychotic treatment.¹⁶⁰ Advancing age is the most consistently observed risk factor for the development of TD.¹⁶¹ The annual incidence rates of developing TD are three- to fivefold higher in older

patients compared with younger adults.^{162,163} Other risk factors include higher mean daily and cumulative antipsychotic doses, and presence of extrapyramidal signs early in treatment.^{162,163} Although there is some indication that the risk of TD may be higher in women, nonwhites, patients with affective psychiatric disorders, and patients taking concomitant anticholinergic agents, these findings have not been consistently observed.¹⁶¹

For most patients, TD does not seem to be progressive or irreversible; it can be reversed with discontinuation of the antipsychotic agent. The onset of symptoms tends to be subtle with a fluctuating course.¹⁶¹ Most TD cases are relatively mild. However, a portion of patients (5%–10%) may develop a form of TD that is severe enough to impair functioning.¹⁶⁴ Severe oral dyskinesia may result in dental and denture problems that can progress to ulceration and infection of the mouth as well as muffled or unintelligible speech. Severe orofacial TD can impair eating and swallowing, which in turn could produce significant health problems. Gait disturbances owing to limb dyskinesia may leave patients vulnerable to falls and injuries.

Although the exact cause of TD is unknown, dopaminergic hypersensitivity, disturbed balance between dopamine and cholinergic systems, dysfunction of GABAergic and noradrenergic systems and neurotoxicity via free radicals have been proposed.¹⁴⁹

19. C.M., a 31-year-old woman, was diagnosed with chronic paranoid schizophrenia 9 years ago. She responds to antipsychotic drugs, but has been hospitalized six times because of nonadherence to her medications. She has taken loxapine, haloperidol, and fluphenazine in the past and currently is being treated with trifluoperazine 25 mg HS (decreased from 30 mg 1 month ago). C.M. also has been taking trihexyphenidyl 2 mg TID for the past 5 years. Involuntary movements (including tongue protrusion, frequent blinking, and writhing movements of her legs) were noted during a recent evaluation. What data in C.M.'s history are consistent with TD?

The 9 years of antipsychotic treatment and the symptoms of tongue protrusion, blinking, and writhing leg movements are consistent with TD. Long-term anticholinergic treatment (trihexyphenidyl) also may contribute to the development of C.M.'s abnormal movements.

20. C.M. has no history of abnormal movements and currently has no EPS. What disorders or medications can produce symptoms similar to those of TD?

Tourette syndrome, dental problems, Huntington's or Sydenham's chorea, chorea of pregnancy, and systemic lupus erythematosus are among the disorders that have been associated with dyskinesic movements. Medications such as metoclopramide, amoxapine, bromocriptine, levodopa/carbidopa, and pramipexole¹⁶⁵ also can cause TD. Spontaneous dyskinesia resembles TD but can occur in patients without previous exposure to antipsychotic medications.¹⁶¹ This form of abnormal movement is noticeably more common in elderly patients. A baseline dyskinesia rating is essential before treating elderly patients with antipsychotic medications to avoid the potential diagnostic dilemma of differentiating spontaneous dyskinesia from antipsychotic-induced TD.

TD varies in severity and presentation and is reversible in many cases; therefore, rating scales are needed to standardize assessments (Table 78-11). A temporal relationship between

an antipsychotic dose change and movement severity should be evaluated when performing assessments. An increase in the antipsychotic dose can clinically suppress the symptoms, whereas a decrease in dose can transiently unmask the movements often called "withdrawal dyskinesia."¹⁶⁵ For example, the movements C.M. is exhibiting may have worsened as a result of the recent dose reduction in trifluoperazine. On the other hand, a dose increase may produce a temporary lessening of movement severity. Patients taking long-term antipsychotics should be evaluated for TD every 3 to 6 months using a standardized rating scale (Table 78-11). Findings always should be documented in patient records to ensure continuity of care.

21. C.M. is diagnosed with antipsychotic-induced TD. How should C.M.'s TD be managed?

Management of TD should focus first on prevention. That is, antipsychotic drugs must be reserved to treat conditions known to respond (e.g., psychotic disorders such as schizophrenia, major depression with psychotic features, schizoaffective disorder), and the total dose and duration of treatment should be minimized. Because C.M.'s long-term exposure to antipsychotics is the likely cause of her TD, discontinuation of her trifluoperazine would be the ideal treatment. Unfortunately, she has experienced multiple recurrent psychotic episodes and requires lifetime treatment with antipsychotics. Because of the reduced TD liability with atypicals, C.M. should be switched to an atypical agent.^{150–153} It has been recommended that an atypical antipsychotic be used for mild TD symptoms, and that clozapine be considered when TD is severe or distressing to the patient.^{150,166} Rapid reduction in the dose of trifluoperazine must be avoided to prevent severe withdrawal dyskinesias, but her dose should be slowly reduced as an atypical antipsychotic is titrated to the lowest effective dose. This minimizes both her exposure to antipsychotic medications and her corresponding dyskinesia risk. Trihexyphenidyl should also be discontinued because of its possible contribution to TD. Because C.M. has already been diagnosed with TD, an evaluation of the risks and benefits of continued antipsychotic treatment must be discussed with her and documented in the chart.

22. Are there other medications for treating T.D.?

A number of other agents have been studied for their potential therapeutic effects on TD. Drugs that augment GABA neurotransmission (e.g., diazepam, clonazepam, valproic acid), adrenergic drugs (propranolol, clonidine) and free-radical scavengers (vitamin E) have all been used, with limited or inconsistent results.^{160,167,168} These agents may be useful as adjunctive treatments when TD persists despite the use of atypical agents.

ANTICHOLINERGIC EFFECTS

Anticholinergic effects are more significant with low-potency typical antipsychotics, and with the atypical agents, clozapine and olanzapine. Clinically, patients complain of constipation, urinary retention, and dry eyes, mouth, and throat. Dry mouth and throat can cause several additional problems, including dental caries and weight gain if thirst is satisfied with high-sugar drinks. Oral fungal infections can also occur if gum or liquids with high sugar content are regularly consumed. The most serious complications from medications with

anticholinergic properties are delirium and adynamic ileus.^{169,170} Interestingly, clozapine causes significant hypersalivation despite its anticholinergic effects. The mechanism is unknown, but it may be caused by clozapine's augmentation of the adrenergic receptors that control salivation.¹⁷¹ Drug therapy with benztropine, amitriptyline, and clonidine may alleviate hypersalivation; however, these agents are not effective in all patients and when they are beneficial tolerance may develop. Although anticholinergic effects are a minor problem with high-potency typical agents, some patients may still have problems when anticholinergic antiparkinsonian agents are added to treat EPS.

CARDIOVASCULAR EFFECTS

Orthostatic Hypotension

Antipsychotic drugs can cause a variety of cardiovascular complications, but the most common problem is orthostasis from α_1 -adrenergic blockade. Low-potency typical agents and atypical antipsychotics pose the greatest risk for producing orthostatic hypotension. Orthostasis is most likely to occur during the first few days of treatment or when increasing the dose of medication. Although tolerance usually occurs within 2 to 3 weeks, orthostasis necessitates slow dose titration early in treatment for patients who are particularly prone to this side effect (e.g., the elderly).

Tachycardia

Tachycardia may occur as a result of the anticholinergic effects of antipsychotic medications on vagal inhibition, or secondary to orthostatic hypotension.⁵⁸ Clozapine produces the most pronounced tachycardia. If tachycardia is sustained or becomes symptomatic, low doses of a β -blocker such as atenolol or propranolol can be useful once an ECG has ruled out other medical causes.

Electrocardiographic Changes

ECG changes such as prolongation of the QT and PR intervals, ST-segment depression and T-wave flattening have been observed with antipsychotics.¹⁷² The most clinically important of these potential changes is prolongation of the QTc interval (which is the QT interval adjusted for heart rate) and has drawn the attention of the FDA. QTc prolongation may lead to the development of ventricular tachyarrhythmias such as torsades de pointes and ventricular fibrillation, which can cause syncope, cardiac arrest, or sudden cardiac death. All antipsychotics have the potential to prolong the QTc interval to varying degrees. In 2000, Pfizer in consultation with the FDA, completed a study in which the QTc intervals of patients taking several antipsychotics, at usual therapeutic dosages and in the presence of a metabolic inhibitor, was compared (Fig. 78-2).¹⁷³ Thioridazine was shown to prolong the QTc interval at least 20 msec longer than haloperidol, risperidone, olanzapine, or quetiapine. This led to a boxed warning on the FDA-approved product labeling stating that thioridazine has been shown to prolong the QTc interval in a dose-related manner and its use should be limited to patients who cannot be managed on other antipsychotics. In the same study, ziprasidone prolonged the QTc interval 5 to 15 msec longer than did haloperidol, risperidone, olanzapine, or quetiapine. Unlike thioridazine, the ziprasidone effects were not dose related. The exact point at which QTc prolongation becomes clinically dangerous is unclear. Because most reported cases of torsades de pointes have appeared in individuals with a QT interval >500 msec, discontinuation of the suspected offending agent has been recommended if the interval consistently exceeds 500 msec. It is important to note that no patients in this study had QTc intervals exceeding 500 msec or arrhythmias. Despite the fact that no increased risk of arrhythmia or sudden death has been demonstrated with ziprasidone, caution is warranted in patients with some types

Mean Change in QTc from Baseline (steady state)

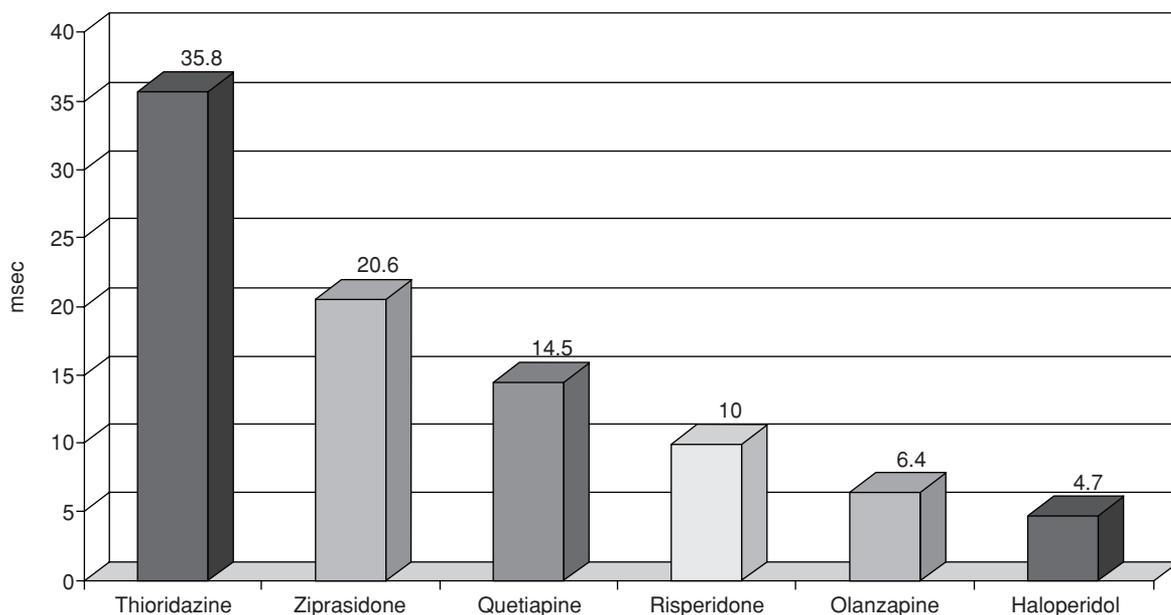

FIGURE 78-2 Comparison of QTc changes with antipsychotics. (Adapted from reference 173.)

of cardiac disease and with an uncontrolled electrolyte disturbance. The coprescription of ziprasidone with other drugs that prolong the QT interval should be avoided. Under most clinical circumstances, however, ziprasidone may be safely used without ECG monitoring or other special precautions.

METABOLIC EFFECTS

Hyperprolactinemia

Antipsychotic-induced hyperprolactinemia has come to the forefront because of differences found among the atypical agents. Before the introduction of the atypical agents, prolactin elevation was unavoidable because all typical antipsychotics elevate serum prolactin by blocking the tonic inhibitory actions of dopamine in the tuberoinfundibular tract.¹⁷⁴ Among the atypical agents, risperidone and, to a lesser extent, olanzapine produce a dose-related increase in prolactin levels that is equal to or greater than that seen with typical antipsychotics.^{175,176} The remaining atypical agents have little impact on serum prolactin levels.¹⁷⁵ Hyperprolactinemia is of clinical importance because it may lead to galactorrhea, gynecomastia, amenorrhea, anovulation, impaired spermatogenesis, decreased libido and sexual arousal, and anorgasmia.¹⁷⁷ Interestingly the hyperprolactinemia is not always associated with clinical symptoms. For example, Kleinberg et al.¹⁷⁶ failed to find an association between sexual dysfunction and risperidone-associated hyperprolactinemia. This may be a product of the multifactorial nature of sexual dysfunction or methodologic limitations in data collection. Patients often do not spontaneously report symptoms of sexual dysfunction and clinicians must remember to ask about these potential side effects.¹⁷⁵

Weight Gain

Weight gain is emerging as one of the most significant concerns associated with the use of antipsychotics, particularly among the atypical agents. The mechanism of antipsychotic-induced weight gain is unclear, but antagonism of histamine H₁ and serotonin 5-HT_{2C} receptors has been implicated.¹⁷⁸ A genetic

predisposition exists for weight gain; a mutation in the 5-HT_{2C} receptor gene may increase risk for weight gain from atypical antipsychotics. No genetic tests exist to predict which patients will gain weight from the atypical antipsychotics.^{179,180} Another theory is the potential decreased signaling of two serotonin receptors, 2A and 2C, increased calorie intake and appetite, and/or decreased metabolic rate.^{180,181} The higher the binding affinity to the histaminergic receptor, the more that agent is likely to be associated weight gain.¹⁸⁰ Among the atypical agents, weight gain is most common with clozapine and olanzapine, lowest with ziprasidone and aripiprazole, and intermediate with risperidone and quetiapine.¹⁸² In a meta-analysis, Allison et al.¹⁸³ found that the estimated weight gain at 10 weeks of therapy was greater with clozapine (4.45 kg) and olanzapine (4.15 kg) relative to risperidone (2.1 kg) and ziprasidone (0.04 kg), as illustrated in Figure 78-3. Moderate short-term weight gain has been demonstrated with quetiapine and is minimal with aripiprazole.^{98,184} Similarly, clozapine and olanzapine have the largest associated weight gain with long-term treatment.¹⁸⁴ The weight gain observed with clozapine and olanzapine is not dose dependent and plateaus 6 to 12 months after treatment initiation.^{185,186} However, other authors suggest that antipsychotic-associated weight gain plateaus within the first several months of treatment with risperidone, quetiapine, and ziprasidone can continue over several years for clozapine and olanzapine.¹⁷⁵ The issue of weight gain has important clinical implications in light of the link with impaired glucose tolerance and type II diabetes, hyperlipidemia, and increased mortality.^{58,187-190} Patients who had no weight gain due to atypical antipsychotics can still develop diabetes mellitus. In a case review of 45 patients who developed or had worsening of their diabetes, nearly 50% had no weight gain. Atypical antipsychotics may impair insulin sensitivity or glucose regulation independent of weight gain, although the true reason for diabetes is still unknown.^{179,181}

Cardiovascular disease is the leading cause of death among patients with schizophrenia.¹⁹¹ On average, patients with

schizophrenia live 20% shorter than the general population. They commit suicide up to 20 times more than the general population; and patients with schizophrenia specifically aged 25 to 44 years old, are three times more likely to die compared with the general population. This number has continued to increase as patients are no longer institutionalized.¹⁷⁹

23. L.A., a 45-year-old woman with chronic paranoid schizophrenia, had been managed successfully with haloperidol for many years. She subsequently developed TD and was switched to olanzapine 20 mg HS. Before initiation of olanzapine 4 months ago, L.A. was 54 and weighed 132 lb. She has responded well to the olanzapine; however, she now weighs 148 lb. Can L.A.'s weight gain be attributed to olanzapine?

Weight gain has been reported with typical antipsychotics, but even greater weight gain has been seen with atypical agents such as clozapine and olanzapine, and to a lesser extent, risperidone and quetiapine.^{182–184} The cause of antipsychotic-induced weight gain is multifactorial and may include a change in food preferences, increased food or fluid intake, carbohydrate craving, or a lack of activity. Blockade of the histamine and 5-HT_{2C} receptors are also contributory. H₁ blockade causes sedation that may produce inactivity. H₁ blockade may also increase weight by interfering with normal satiety signals from the gut, resulting in overeating. Evidence for a role of 5-HT_{2C} antagonism is derived indirectly from appetite-suppressing drugs, such as fenfluramine, which are thought to act via 5-HT agonism.¹⁹²

L.A.'s weight gain should be taken seriously because it may contribute to medical conditions such as diabetes, hyperlipidemia, coronary artery disease, gastrointestinal disorders, cancer, and hypertension.^{193,194} A significant weight gain may cause her to have a poor self-image, which may lead to treatment nonadherence. Obese patients with schizophrenia are 2.5 times more likely to discontinue their medication than nonobese patients.¹⁹⁴ She should be enrolled in a weight management program. If a patient gains 5% or more of their pretreatment body weight, switching to another antipsychotic should be considered.¹⁹⁵ For L.A., switching to another antipsychotic with lower weight gain liability may be considered; however, this decision must be balanced against her current positive response to olanzapine.

24. How should the potential metabolic complications associated with antipsychotics be monitored?

Although the risk of TD seems to be significantly reduced with the use of atypical antipsychotics, there is con-

cern regarding other long-term side effects with these agents including impaired glucose tolerance, type 2 diabetes, and hyperlipidemia.^{175,187}

L.A. should be informed about these potential complications. The routine monitoring of weight, fasting glucose levels, and lipid panels have been recommended and appropriate therapeutic options should be initiated if abnormalities are observed.^{175,187} Guidelines have been created for the monitoring of metabolic issues associated with atypical antipsychotic use (Table 78-13). At baseline, a personal and family medical history should be obtained, as well as height and weight (to determine body mass index), waist circumference, BP, fasting plasma glucose, and a fasting lipid panel.^{195,196} Fasting blood glucose and lipid levels, as well as BP measurements, should be completed 3 months after drug initiation, then every year if the patient is within normal limits.^{195,196} Weight should be reassessed at weeks 4, 8, and 12, then quarterly, after drug initiation.^{195,196} L.A. should be encouraged to self-monitor her weight and report any significant weight fluctuations. Subjective evidence of a weight change may include a change in clothes or belt size. In addition, she should be routinely monitored for the presence of diabetic symptoms (e.g., polyuria, polydipsia) at every clinic visit.

NEUROLEPTIC MALIGNANT SYNDROME

25. C.B., a 25 year-old man, was hospitalized with the diagnosis of schizophrenia, paranoid type, and was started on loxapine 25 mg HS. After 2 days of therapy, C.B. became rigid, seemed confused at times, and had a fever of 41°C. A diagnosis of neuroleptic malignant syndrome (NMS) was made. What features of this syndrome does C.B. have and how should it be treated?

NMS is a rare but potentially lethal adverse effect of antipsychotic therapy. The risk of NMS seems to be lower for atypical agents than for typical agents.¹⁴³ However, cases of NMS have been linked to treatment with clozapine, risperidone, olanzapine, quetiapine, ziprasidone, and aripiprazole.^{197–203}

NMS can occur hours to months after the initial drug exposure, and the mortality rate is reported to be as high as 20%.⁵⁸ The incidence is estimated at between 0.02% and 3.23% of patients taking typical antipsychotic drugs.²⁰⁴ The cardinal features include muscular rigidity, hyperthermia, autonomic dysfunction, and altered consciousness. Extrapyramidal dysfunction (e.g., rigidity) and akinesia usually develop initially or concomitantly with a temperature elevation as high as 41°C. Autonomic dysfunction includes tachycardia, labile BP, profuse diaphoresis, dyspnea, and urinary incontinence. The

patient's level of consciousness may vary from alert to mutism, stupor, and coma. Other neurologic findings include sialorrhea, dyskinesia, and dysphagia. Symptoms usually develop rapidly over 24 to 72 hours. Creatine kinase, CBC, and LFTs are usually increased.

C.B.'s fever of 41°C, rigidity, and confusion are consistent with NMS. C.B.'s loxapine should be discontinued and supportive measures initiated to treat hyperthermia and prevent dehydration (e.g., antipyretics, a cooling blanket, and IV fluids).²⁰⁵ Secondary complications such as pneumonia and renal failure should be managed as they develop.

If C.B.'s condition does not show a trend toward improvement or worsens after 1 to 3 days of observation and supportive therapy, a number of additional pharmacologic interventions should be considered.²⁰⁵ NMS has been attributed to dopamine depletion caused by neuroleptic drug blockade of dopamine pathways in the basal ganglia and hypothalamus. For that reason, dopamine agonists such as amantadine or bromocriptine sometimes are beneficial. Dantrolene relaxes skeletal muscle and is specifically recommended for severe hyperthermia. C.B. should be started on dantrolene 50 mg four times daily and either bromocriptine 2.5 mg three times daily or amantadine 100 mg three times daily to accelerate reversal of his condition.²⁰⁶ If he is unable to take oral medications, 1.25 to 1.5 mg/kg IV dantrolene should be used.

NMS is self-limiting and usually lasts 2 to 14 days after the oral antipsychotic is discontinued, or longer after discontinuation of depot medications. C.B.'s response to therapy can be assessed by frequently monitoring his vital signs and by measuring creatine kinase daily. After several weeks of recovery, treatment may be cautiously resumed with another atypical antipsychotic.^{205,207}

SEDATION

Sedation can occur with any antipsychotic agent; however, it is most pronounced with the low-potency typical agents and with clozapine and quetiapine. Sedation at the beginning of treatment may be desirable for anxious or aggressive patients. However, persistent sedation during long-term treatment may adversely affect daily functioning and quality of life. Most patients develop some tolerance to these sedating effects over time, but it can be minimized by reducing the dose or shifting administration to bedtime.

HEPATIC DYSFUNCTION

26. A.S., a 24-year-old woman, is brought to the hospital because of unusual behavior and violence toward her mother. A.S. is diagnosed with schizophrenia, paranoid type, acute exacerbation. Quetiapine 25 mg BID was prescribed initially and the dose gradually increased until 200 mg TID was achieved. Her baseline laboratory tests (CBC with differential, a chemistry profile that included LFTs, and serum electrolytes) were within normal limits. The same tests were repeated 10 days after her psychosis was under evaluation. The aspartate aminotransferase and alanine aminotransferase are now 2.5 times normal, but she has no GI complaints or medical problems. Should quetiapine be discontinued at this time?

Benign elevations in LFTs (i.e., increases in aspartate aminotransferase or alanine aminotransferase less than two to three times normal) have long been reported early in the course of therapy with most antipsychotic drugs.^{34,66,85} Such

increases are rarely problematic; thus, no routine assessment of liver function is mandated by the FDA.

A more specific hepatic complication, cholestatic jaundice, has been associated with certain antipsychotic agents. The phenothiazines, especially chlorpromazine, have been implicated. Most cases develop within the first month of therapy and usually are preceded by prodromal symptoms of fever, chills, nausea, upper gastric pain, malaise, and pruritus. Discontinuation of the phenothiazine and symptomatic care are the primary modes of treatment because the cholestatic jaundice generally is self-limiting and usually resolves within 2 to 8 weeks. Occasionally, a more chronic course may develop. Once the signs and symptoms have resolved, an alternate class of antipsychotic, preferably a nonphenothiazine, should be prescribed.

The LFTs in A.S. are only modestly abnormal, and she is not experiencing symptoms of hepatotoxicity or cholestatic jaundice. Therefore, quetiapine should be continued. Routine laboratory monitoring of LFTs does not prevent drug-induced cholestatic jaundice; thus, no follow-up laboratory tests are required unless symptoms of hepatic dysfunction develop. Awareness and evaluation of A.S. for prodromal symptoms is the most appropriate action at this time.

OCULAR EFFECTS

27. Are there any additional baseline tests that should have been performed on A.S. before starting quetiapine?

The ocular effects of antipsychotic agents are well recognized and are generally of minor clinical consequence. Corneal and lens changes have been reported with several phenothiazines and thiothixene. Chlorpromazine is the most commonly implicated, with the risk being greatest with long-term, high-dose exposure (1–3 kg lifetime dose).²⁰⁸

If A.S. has not yet had a slit-lamp evaluation, an ophthalmologist should evaluate her as soon as possible. A 6-month follow-up examination is also indicated. Quetiapine should probably be discontinued if lens changes were noted on any of the examinations.

TEMPERATURE DYSREGULATION AND DERMATOLOGIC EFFECTS

28. N.M., a 27-year-old man, recently was diagnosed with undifferentiated schizophrenia and was stabilized with chlorpromazine 400 mg HS during a 3-month stay in an inpatient unit. N.M. has continued chlorpromazine 400 mg HS as an outpatient and has done so well that he is ready to return to work as a laborer at a construction site. What precautions should he take when working outside?

N.M. should be advised to wear a hat when working outside, drink fluids, stay in the shade as much as possible, and seek a cooler environment if he feels hot. Antipsychotics can cause temperature dysregulation, likely by inhibiting hypothalamic temperature regulation. The net result is poikilothermia (the normal body temperature cannot respond to heat or cold, and patients become hypothermic or hyperthermic, depending on the surrounding temperature).²⁰⁹ The strong anticholinergic effects of N.M.'s chlorpromazine can impair cutaneous heat elimination and further exacerbate the problem. Olanzapine and clozapine also have strong anticholinergic properties, necessitating caution for patients exposed to excessive heat.

N.M. should also be advised to use a sunscreen with maximum sun protection factor, along with protective clothing because chlorpromazine-induced photosensitivity can predispose him to severe sunburns. The tricyclic structure of some antipsychotic drugs absorbs ultraviolet rays, producing free radicals that damage skin. Chlorpromazine is the most common cause of photosensitivity, but it can occur with all phenothiazines and with thiothixene.²⁰⁹

Other dermatologic reactions can occur with antipsychotics, and N.M. should be advised to report any skin abnormalities to his physician. Dermatitis, presenting with a maculopapular rash on the face, neck, and upper chest, occurs in approximately 5% of patients shortly after starting chlorpromazine. Localized or generalized urticaria also can develop. Antihistamines usually provide adequate relief, but the antipsychotic agent may have to be discontinued in severe cases. The rash rarely reappears after resumption of treatment.

SEIZURES

29. R.A., a 26-year-old woman recently diagnosed with chronic paranoid schizophrenia, is brought to the hospital after assaulting a neighbor. She presents in an acute psychotic state and has not calmed down since entering the hospital. She has struck two staff members on the psychiatric unit. R.A. has had generalized tonic-clonic seizures since age 14 and currently is taking carbamazepine 300 mg TID (serum concentration on admission is 8.2 mg/mL). R.A. has not been taking any antipsychotic medications and has been seizure free for 1 year. She needs acute treatment with an antipsychotic because of her dangerous behavior. How should an antipsychotic be initiated to treat her schizophrenia in light of her seizure disorder?

Antipsychotic drugs can lower the seizure threshold, producing seizures in patients who previously were seizure free. Seizures are most common with low-potency typical antipsychotics and clozapine.⁵⁸ Clozapine-induced seizures are dose related. The seizure rate is approximately 1% at doses below 300 mg/day, 2.7% at doses between 300 and 600 mg/day, and 4.4% at doses above 600 mg/day.²¹⁰ Because R.A. is currently a danger to herself and to others, the benefits of antipsychotic treatment outweigh the risks. Strategies to minimize the risk of seizures should be employed and include slow dose titration, use of lowest effective doses, and possible concurrent administration of an antiepileptic drug (e.g. carbamazepine).²¹¹

Haloperidol, an agent with a low risk for causing seizures, is a good selection. An initial dose of 5 mg PO or 2.5 mg IM should be given immediately, and additional dosages should be carefully administered until the psychosis resolves or she is no longer dangerous. The decision to use scheduled or as-needed medications should be based on whether she remains dangerous after a few immediate doses and the underlying cause of the psychosis. Supplemental benzodiazepines may be used to avoid high doses of haloperidol. If necessary, R.A.'s carbamazepine dose should be adjusted to maintain good seizure control and serum concentrations should be monitored. Carbamazepine (and other enzyme-inducing antiepileptic drugs) can influence the hepatic metabolism of antipsychotic agents. R.A. should be monitored for recurrent symptoms of schizophrenia if her carbamazepine dosage is increased.

SEXUAL DYSFUNCTION

30. K.J., a 24-year-old man with chronic paranoid schizophrenia, was rehospitalized for an acute exacerbation secondary to nonadherence with thioridazine 400 mg HS. During the medication history, it is discovered that he stopped taking thioridazine because he lost his interest in sex. When he tries to have intercourse, he experiences delayed ejaculation. About a week after stopping the thioridazine he is able to have a normal ejaculation. How does thioridazine contribute to K.J.'s sexual dysfunction?

Thioridazine is recognized as the most common cause of antipsychotic-induced sexual dysfunction.²¹² Sexual side effects such as diminished libido, impaired arousal, and erectile and orgasmic dysfunction, however, have also been reported with both other typical agents and atypical agents.¹⁷⁵ The causes of antipsychotic-induced sexual dysfunction are related to a number of factors including hyperprolactinemia via dopamine blockade, α -adrenergic blockade, and anticholinergic and sedative effects.²¹³ Impaired sexual function has also been observed in untreated patients with schizophrenia, making the distinction between drug-induced and disease-induced symptoms difficult.²¹⁴ K.J.'s sexual dysfunction likely is related to the thioridazine because the symptoms resolved after he stopped the medication. Lowering the dose of thioridazine or converting him to another antipsychotic with less influence on sexual function may be helpful, although no reliable evidence is available to indicate which drugs are least likely to cause sexual dysfunction.

Predictors of Medication Response

As a general rule, antipsychotic agents should be initiated and titrated over the first few days to an average effective "target" therapeutic dose unless the patient's physiological status or history indicates that this dose may result in unacceptable adverse events.²¹⁵ After 1 week on the "target" dose, a modest dosage increase (within the recognized therapeutic range) may be considered if minimal or no improvement has been observed. In instances in which symptoms improve after the dose is increased, it may be difficult to know whether the response resulted from the dose change or from additional days on the drug. The duration of a therapeutic trial is 3 to 8 weeks in patients with little to no response, and 5 to 12 weeks in patients with a partial response.^{166,215} Dosing recommendations for the antipsychotics are provided in Table 78-10.

Factors to Consider When Evaluating a Poor Response

A large proportion of patients with schizophrenia do not have an adequate response to antipsychotic therapy. Inadequate response may be caused by inadequate dosing, poor adherence, or true resistance to antipsychotic treatment.²¹⁶ Some of these factors can be addressed. In some patients, the therapeutic antipsychotic dose cannot be reached because of intolerable side effects. As mentioned, a therapeutic trial of 3 to 12 weeks at an optimal dosage may be necessary to determine the full benefit from an antipsychotic agent. Nonadherence with medications is a common obstacle in the management of schizophrenia, even in supervised settings. Blood level monitoring may be helpful to identify nonadherent patients as well as those in whom a pharmacokinetic factor may account for a poor response (e.g., poor drug bioavailability, rapid metabolizer,

concomitant use of a metabolism-inducing agent). Therapeutic ranges of some antipsychotics are provided in Table 78-9.

A single definition of treatment resistance does not exist, but factors to consider in this definition include chronic or repeated hospitalizations, persistent positive symptoms, lack of improvement in negative symptoms, and breakthrough symptoms despite adherence to treatment.²¹⁶ Guidelines for determining treatment resistance have been proposed and include at least two prior drug trials of 4 to 6 weeks duration at 400 to 600 mg chlorpromazine (or equivalent, i.e., 8–12 mg of risperidone) with no clinical improvement, >5 years without a sustained period of good social or occupational functioning, and persistent psychotic symptoms.^{216,217}

Several strategies have been proposed if a change in antipsychotic medication is necessitated by side effects or insufficient efficacy.¹⁴⁰ These include an abrupt switch (abrupt cessation of the current drug, with abrupt introduction of the new one at the expected therapeutic dose), a gradual switch (slow downward adjustment of the dosage of the current medication, with slow upward adjustment of the dosage of the new drug) or an overlapping switch (abrupt introduction of the new medication overlapping with the current medication, followed by downward adjustment of the dosage of the previous medication). None of these strategies has been demonstrated to be superior to another in terms of efficacy or safety, and the switch strategy depends on the clinical presentation.

31. M.S., a 24-year-old man, was brought to the ED by the police because voices told him to strike his mother. His medical workup and urine drug screen were negative. M.S. has a diagnosis of schizophrenia, undifferentiated type, and has been hospitalized four times in the last 2 years secondary to poor adherence to his prescribed medication. He has had the same presentation on all previous hospitalizations. During his last hospitalization, M.S. was stabilized on thiothixene (Navane) 20 mg orally at bedtime without any signs of adverse effects. How can IM depot therapy decrease readmissions, and how do we determine if M.S. is a good candidate for IM depot therapy?

M.S.'s history suggests that he is a good candidate for depot therapy. He responds to typical antipsychotics, but relapses owing to nonadherence. He should be able to tolerate higher potency antipsychotics because he has tolerated moderate doses of thiothixene. The patient should also be asked whether he is willing to take injections before proceeding with this strategy.

Conversion From Oral to Depot Therapy

32. How could M.S. be converted from oral therapy to depot therapy?

For patients such as M.S. who have never taken risperidone, haloperidol, or fluphenazine (the currently available long-acting depot forms of antipsychotics), an oral trial lasting several days to weeks is needed before conversion. The trial is necessary to ensure tolerability, evaluate response, and, when possible, determine the minimum effective dose.

Various formulas to convert from oral formulations to the decanoates have been proposed, but no method has been proved clinically superior. Clinicians should strive to use the longest dosing interval between injections and minimize the duration of combination oral and depot therapy. Careful evaluation of

both tolerance and response is required for several months after initiating depot therapy.

FLUPHENAZINE DECANOATE CONVERSION

After stabilizing the patient on oral fluphenazine, multiply the total daily fluphenazine oral dose by 1.2 and administer as fluphenazine decanoate IM every 1 to 2 weeks.²¹⁸ Alternatively, 12.5 mg of fluphenazine decanoate can be administered IM every 1 to 2 weeks for every 10 mg (rounding to the nearest 10-mg increment) of oral fluphenazine per day (e.g., 25 mg/day PO rounded to 30 mg/day and given as 37.5 mg of decanoate).²¹⁹ The decanoate dosing interval may be increased to every 3 weeks after 4 to 6 weeks of therapy because of fluphenazine accumulation. There are no specific guidelines for the continuation of oral therapy after initiating the depot formulation; however, combination oral and IM therapy should be limited to the initiation period (1–4 weeks) or during times of decompensation.

HALOPERIDOL DECANOATE CONVERSION

Elderly patients or those stabilized on <10 mg of oral haloperidol per day should receive haloperidol decanoate in an IM dose that is 10 to 15 times the oral daily dose every 4 weeks. If higher oral doses are needed for stabilization, then the first decanoate dose should be 15 to 20 times the oral daily dose to a maximum of 450 mg.²²⁰ The first injection of haloperidol decanoate should not exceed 100 mg. If more is required, the balance of the dose can be given in an additional one to two injections (provided that there are no EPS) over 3 to 7 days. Because haloperidol accumulates, the monthly decanoate dose should be decreased every 3 to 4 months by 25% until a minimum effective dose is achieved. Most patients can be effectively managed with a maintenance dose of 50 to 200 mg every 4 weeks.¹⁶⁶ Guidelines for concomitant oral therapy remain unclear and should be based on response and adverse effects, with the goal of depot alone after the first month of treatment if the aforementioned strategy is used.²¹⁸

Using these guidelines, M.S. should be converted from thiothixene 20 to 10 mg of oral haloperidol per day (Table 78-10). Oral haloperidol should be continued alone for at least 1 week, until M.S. is stabilized. Once stabilization with oral haloperidol has occurred, haloperidol decanoate 100 mg IM can be administered. This can be followed with 50 mg IM 3 days later if no adverse effects are noted after the first injection. The total initial dose is 150 mg every 4 weeks (15 times the oral dose). A 200-mg total dose is also acceptable if the clinician believes the patient needs more drug. No oral medication is needed after the second injection and should only be given if M.S. shows signs of decompensation. M.S. should be monitored carefully for extrapyramidal side effects and response. M.S. should receive haloperidol decanoate 150 mg IM every 4 weeks with the dose adjusted according to response and tolerance; the dose can be decreased after 3 to 4 months because of drug accumulation.

LONG-ACTING RISPERIDONE FORMULATION

It is recommended that patients establish tolerability with oral risperidone prior to initiating treatment with Risperdone CONSTA. In published clinical trials, IM doses of 25, 50, or 75 mg have been administered at 2-week intervals.^{141,142} The

recommended dose is 25 mg IM every 2 weeks. Oral therapy of risperidone should be continued for 2 to 3 weeks after the first IM injection and then discontinued.

Inadequate Response

33. J.H., a 33-year-old man, was diagnosed with chronic paranoid schizophrenia at age 21 and has been hospitalized 15 times because of his illness. He repeatedly presents in a paranoid and hostile state complaining of auditory hallucinations and paranoid delusions in which the police and the people in his apartment building are trying to kill him. His symptoms have prevented him from obtaining employment, and he has no close friends. He has been treated with fluphenazine 20 mg HS and perphenazine 48 mg HS, but has had only a partial response to each medication. After each discharge, J.H. stays out of the hospital for approximately 6 months, then relapses, even with good adherence. He currently is taking haloperidol 15 mg HS with only minimal improvement after 2 months of treatment. What can be done to improve his response?

J.H. meets criteria for treatment-resistant schizophrenia, and clozapine is the “gold standard” for the treatment of this type of patient.²¹⁶ However, considering the risk of agranulocytosis, the burden of side effects, and the requirement of white blood cell (WBC) monitoring associated with clozapine therapy, one of the other atypicals should be tried before proceeding to clozapine.^{166,216}

Clozapine

INDICATIONS

34. J.H. did not respond to an adequate trial of quetiapine 400 mg BID and was just admitted to the hospital again. He is becoming increasingly isolated and paranoid. He has no other medical conditions and is taking only lorazepam 1 to 2 mg Q 4 to 6 hr PRN. His last dose of quetiapine was 2 days ago. Because of his refractory illness, J.H. is being considered for clozapine therapy. What are the advantages and disadvantages of clozapine therapy? What makes him a good candidate for clozapine?

Clozapine is approved by the FDA for treatment of resistant schizophrenia or when adverse effects such as TD and EPS preclude use of other antipsychotics. Clozapine is contraindicated in patients with a history of a myeloproliferative disorder, uncontrolled epilepsy, paralytic ileus, clozapine-induced agranulocytosis or granulocytopenia a current WBC count below 3,500 mm³ or ANC count below 2,000/mm³. Clozapine also should be used with caution in patients who cannot tolerate anticholinergic effects, in those at risk for drug-induced orthostasis, or in patients with significant renal or hepatic disease.²²¹ Because of J.H.’s progressive decline in social functioning and inadequate response to haloperidol, fluphenazine, perphenazine, and quetiapine, clozapine should be considered.

Clozapine has clearly demonstrated superiority to typical agents in treating refractory schizophrenia. In the pivotal study by Kane et al.,²²² 30% of clozapine-treated subjects versus 4% of chlorpromazine-treated subjects met criteria for response at 6 weeks. A review and meta-analysis of seven controlled trials compared clozapine with typical antipsychotics in treatment-resistant schizophrenia and found that clozapine was superior in terms of overall therapeutic response, EPS, and adherence rate.²²³ However, similarly favorable response rates have

not yet been seen with other atypical agents in treatment-resistant schizophrenia. Risperidone and olanzapine have been most often studied in this regard. In a double-blind trial comparing risperidone with haloperidol in treatment-refractory schizophrenia, a significantly higher response rate favoring risperidone was observed at week 4 but not at week 8.²²⁴ In a 6-week clinical trial, only 7% of patients prospectively determined to be resistant to haloperidol responded to olanzapine, a rate that did not differ from chlorpromazine.²²⁵ In general, atypical agents other than clozapine have not been consistently found to be as effective in treatment-resistant schizophrenia.²²⁶ Nevertheless, given the problems associated with clozapine (risk of agranulocytosis, burden of other side effects, and the requirement for hematologic monitoring), atypical agents should be tried before proceeding to clozapine in most patients.²¹⁶ However, some patients do not respond to clozapine after an adequate trial of at least 6 months at a therapeutic dose. In such situations, it is reasonable to prescribe the antipsychotic to which they had the historic best response. Augmentation strategies, such as the addition of mood stabilizers (lithium and valproate), benzodiazepines, propranolol, antidepressants, or another antipsychotic agent, may be attempted. However, evidence for this approach is lacking.²²⁶ Treatment guidelines recommend reserving augmentation strategies for patients who fail or cannot tolerate clozapine, although in practice these strategies are often tried before a trial of clozapine.^{58,227}

INITIATION OF THERAPY

35. How should clozapine be initiated in J.H.? What are its side effects and how should he be monitored?

Whenever possible, clozapine should be initiated when a patient is medication free. However, if the patient is too ill to be taken off all antipsychotic drugs before adding clozapine, the current medication can be discontinued after a therapeutic clozapine dose has been achieved. Alternatively, clozapine can be titrated upward while the first antipsychotic is slowly tapered downward. Whenever possible, high-potency antipsychotics should be the concurrent agent used during the clozapine titration to minimize additive adverse effects such as sedation, anticholinergic effects, and orthostasis. Benzodiazepines should not be used for early behavioral and anxiety control, because their combined use with clozapine can lead to respiratory or cardiac arrest.⁵⁸

Clozapine can be started in an outpatient setting if patients are carefully monitored for tolerability, especially orthostasis. The starting dose is 12.5 to 25 mg once or twice a day with increases of 25 to 50 mg/day until a target dose is reached. Clozapine is given in divided doses. The optimal dose has not been specifically delineated although an initial target of 300 to 450 mg/day is reasonable based on clinical experience. The maximum daily dose is 900 mg, but titration should proceed slowly to such high doses, and only after adequate trials at lower doses. Response is based on improvement of individual target symptoms and can be monitored by psychometric rating scales (Table 78-11). In addition, the overall ability of a patient to function and care for oneself during clozapine therapy also should be considered.²²⁸ Most patients improve significantly during the first 6 weeks, but some take longer. Although the exact length of an appropriate trial is unclear, 12 weeks is

adequate for most clients; however, improvement may continue for 6 to 12 months after initiating therapy.^{58,229,230}

Clozapine has been issued five blackbox warnings from the FDA. These included agranulocytosis, seizures, myocarditis, increased mortality in elderly patients with dementia-related psychosis, and other adverse cardiovascular and respiratory effects.²³¹ The risk of seizures is dose dependent. The risk of fatal myocarditis is most frequent in the first month of treatment with clozapine. Other adverse cardiovascular and respiratory effects indicates orthostatic hypotension that may or may not be accompanied by syncope. Rarely, collapse with respiratory or cardiac arrest may occur. This is why it is essential to start patients on 12.5 mg once or twice daily, whether it is initiation of treatment, or the patient has been off of clozapine for 2 or more days.²³¹

Clozapine causes agranulocytosis in approximately 1% of patients; therefore, baseline and weekly CBCs are required during treatment. Clozapine is automatically discontinued if a patient is noncompliant with the blood work. After 6 months of continuous, stable treatment, patients can be changed to biweekly WBC monitoring if their WBC counts are acceptable ($\geq 3,500$ mm³ and the absolute neutrophil count [ANC] is $\geq 2,000$ mm³). After an additional 6 months on a continuous, stable regimen, the patient may be changed to WBC monitoring every 4 weeks.²³¹ If a patient takes clozapine for <6 months with no problems, but stops the drug for <1 month, WBC monitoring can restart where it was left off for a total of 6 months. If the break is >1 month, then an additional 6 months of weekly testing are needed.

If baseline laboratory work is within normal limits and an informed consent is obtained, J.H. can start on clozapine 25 mg at bedtime. His clozapine dose should be increased by 25 to 50 mg every day until the dose is 300 mg/day, the minimum dose at which most patients respond. The doses should be split and given as 150 mg twice a day. Subsequently, clozapine should be increased incrementally according to the guidelines described. If J.H. has no response to 300 mg after 4 to 8 weeks (based on a reduction in Brief Psychiatric Rating Scale scores and global improvement), then the dose can be increased to 450 mg (150 mg TID). If response still is inadequate, then the dose can be increased slowly to a maximum of 900 mg/day. Careful monitoring for orthostasis, hyperthermia, and over sedation is needed, especially during early titration. Serum concentration monitoring can also help to guide dose increases.

Clozapine may also cause sialorrhea, or hypersalivation. This is most often worst at night, and may lead to social withdrawal, choking, or aspiration pneumonia.²³² The incidence ranges from 31% of patients (premarket studies) to up to 80% in several clinical trials.²³³ Several case reports have indicated that the scopolamine patch (1.5 mg/72 hour), ipratropium sublingual spray (0.03% or 0.06% given 2 sprays up to three times daily), atropine 1% ophthalmic solution (2 drops swish and swallow twice daily), botulinum toxin (150 IU injected into each parotid gland), and guanfacine (1 mg every morning) are effective in reducing, if not eliminating, sialorrhea.^{232–236} Other medications commonly used are clonidine, anticholinergics (biperiden, benztropine, and diphenhydramine), amitriptyline, terazosin, and propranolol.^{235,237}

36. Four weeks after starting clozapine, J.H.'s WBC count drops to 4,000/mm³ from a baseline of 6,800/mm³. Two weeks

later, he has a WBC count of 2,100/mm³ and an ANC of 980/mm³. What action, if any, should be taken?

[SI unit: WBC count, 4.0 and $2.1 \times 10^9/L$, respectively]

The hematologic adverse effect profile for clozapine is very different from that of other antipsychotic agents. The incidence of clozapine-induced agranulocytosis is at least 10 to 20 times greater than the incidence with typical antipsychotic medications.²²¹ The incidence increases with age and is higher among women.²³⁸ Analysis of data from 150,409 patients followed by the Clozaril National Registry found agranulocytosis in 585 patients resulting in 19 deaths.²³⁸ The risk of agranulocytosis is greatest early in treatment with most cases appearing during the first 3 months of treatment. After 6 months, the risk for agranulocytosis decreases substantially but may occur in rare instances up to 5 years into treatment.^{228,231} Trends in the weekly tests showing a continual decline in WBC count, even if it remains $>3,000/mm^3$, require careful attention. Guidelines for responding to reduction in WBC are described in Table 78-14.

Clozapine should be discontinued immediately, J.H. should be hospitalized, and hematology and infectious disease

Table 78-14 Guidelines for Response to Clozapine-Induced White Blood Cell Abnormalities

Do Not Initiate Clozapine

Initial WBC count $<3,500/mm^3$
Initial ANC $<2,000/mm^3$
History of myeloproliferative disorder
History of agranulocytosis or granulocytopenia related to clozapine

WBC $<2,000/mm^3$ and/or ANC $<1,000/mm^3$

Discontinue clozapine immediately
Do not rechallenge patient
Monitor WBC and differential: until normal and for at least 4 weeks:
—Daily until WBC $>3,000/mm^3$ and ANC $>1,500/mm^3$
—Twice weekly until WBC $>3,500/mm^3$ and ANC $>2,000/mm^3$
—Weekly after WBC $>3,500/mm^3$
Consider bone marrow aspiration
Protective isolation initiated if deficient granulopoiesis

WBC 2,000–3,000/mm³ or ANC 1,000–1,500/mm³

Discontinue clozapine
Monitor WBC and differential:
—Daily until WBC $>3,000/mm^3$ and ANC $>1,500/mm^3$
—Twice weekly until WBC $>3,500/mm^3$ and ANC $>2,000/mm^3$
May restart clozapine when:
—if no symptoms of infection present
—WBC $>3,500/mm^3$ and ANC $>2,000/mm^3$

WBC Drops to 3,000–3,500/mm³; $>3,000/mm^3$ Over 1–3 Weeks; Immature WBCs Present

Repeat WBC with differential
If repeated WBC between 3,000 and 3,500/mm³ and ANC $<2,000/mm^3$
—repeat WBC with differential until WBC $>3,500/mm^3$ and ANC $>2,000/mm^3$

ANC, absolute neutrophil count; WBC, white blood cell.
Compiled from references 58 and 231.

specialists should manage his care. Granulocyte colony-stimulating factor has been used successfully to manage clozapine-induced agranulocytosis.²³⁹ Clozapine should not be reinstated in J.H. because he has a very low ANC. However, it should be noted that agranulocytosis can be reversible upon discontinuation of clozapine, in most cases, with no persisting hematologic sequelae.²³⁸

37. What pharmacotherapy options could be tried to improve J.H.'s response now that clozapine is contraindicated?

Sequential monotherapy trials with other atypical agents that he had not been previously exposed to may be initiated. Alternatively, strategies such as the combination of an antipsychotic and a mood stabilizer or another antipsychotic have been attempted. Because J.H. has no precautions or contraindications to an adjunctive trial of lithium, he is a candidate for a 1-month lithium trial along with an antipsychotic medication other than clozapine. The antipsychotic is selected after reviewing his medication history and choosing the agent to which he had the best previous response. Lithium should be given at doses to achieve a target level of 0.8 to 1.2 mEq/L and continued for 1 month to allow the best chance for response. If the patient is unchanged at the end of 1 month, the lithium should be discontinued and another adjunctive agent tried for a 1-month trial.

Serum Concentration Monitoring

38. E.H., a 68-year-old woman who was diagnosed with chronic undifferentiated schizophrenia >30 years ago. She requires maintenance therapy with antipsychotic drugs because she relapsed when her haloperidol dose was decreased to 10 mg/day. Currently, she is responding poorly to haloperidol 15 mg HS for 6 weeks despite good adherence to her therapy. She has moderate pseudoparkinsonism controlled by benztropine 1 mg BID. Why should a serum concentration of haloperidol be obtained before increasing E.H.'s dose of this drug?

Antipsychotic drug serum concentrations are not part of routine clinical care, but can be considered under the following circumstances²⁴⁰:

- Poor response to moderate doses after an adequate trial (dose and duration)
- Serious or unexpected adverse effects at moderate dosages
- Deterioration in a compliant and previously stable patient
- Use of higher than usual dosages
- Evaluating whether the lowest effective dose is used in maintenance therapy
- Children, elderly, and medically compromised patients with potentially altered pharmacokinetics

It is unnecessary and not cost effective to obtain serum concentrations for antipsychotic drugs that do not have defined therapeutic ranges. Most studies describe haloperidol's therapeutic range to be between 4 and 12 ng/mL.^{241,242} The recommended ranges for fluphenazine and thiothixene are 0.2 to 2.8 ng/mL and 2 to 15 ng/mL, respectively.^{243–245} Evaluation of clozapine trials suggest an optimal range of 350 to 420 ng/mL.^{246,247} Greater response rates were observed in olanzapine-treated patients whose plasma concentrations were >23.2 ng/mL in blood samples collected 12 hours after the dose.²⁴⁸ Samples should be collected 5 to 7 days after a fixed

dose and 10 to 12 hours after the last dose for oral preparations. Two to three months should elapse before samples are collected in patients taking depot preparations.²⁴⁰

E.H. has received an adequate trial of haloperidol and has moderate antipsychotic-induced parkinsonism. To prevent exposure to higher than necessary doses, a serum haloperidol concentration is warranted before increasing the dose. The target serum concentration should be between 4 and 12 ng/mL.

Treatment Adherence

Poor adherence with prescribed antipsychotic therapy is a significant problem in the long-term management of schizophrenia. Comprehensive reviews suggest that deviation (primarily underuse) from prescribed regimens occurs in about 50% of patients with schizophrenia.^{249,250} Recent advances in medication treatments with atypical agents have produced fewer side effects, which some studies have shown has increased adherence.^{251,252} During any phase of illness, nonadherence with maintenance antipsychotic therapy places patients at risk for exacerbation of psychosis, increased clinic and emergency room visits, and rehospitalization.^{253,254} Nonadherence to prescribed regimens can also compromise patients' daily functioning and quality of life. Long-acting depot antipsychotics should be strongly considered for patients who have a history of nonadherence. In addition to assured medication delivery, another benefit of depot preparations is avoidance of potential bioavailability problems. Clinicians should suspect poor absorption if serum concentrations are much lower than expected for a given oral dose; however, factors such as nonadherence or drug–drug interactions must also be ruled out. Disadvantages of long-acting depot formulations include the time required to reach optimal dosing and the inability to immediately withdraw the drug if unpleasant side effects develop.^{58,255} Because of this, patients should be converted to a depot form after confirmation that the oral dosage form is safe and effective.

CONSIDERATIONS IN SPECIFIC POPULATIONS

Pregnancy

39. D.M., a 26-year-old woman, has a 6-year history of chronic undifferentiated schizophrenia that has been treated with chlorpromazine 400 mg HS. She is psychiatrically stable and was last hospitalized 2 years ago. When D.M. decompensates, she isolates herself, is unable to care for herself, does not eat properly, and does not maintain her grooming and hygiene. She just found out that she is 8 weeks pregnant. Should her chlorpromazine be continued and what are the risks if the medication is continued?

Most of the available evidence regarding the use of antipsychotics during pregnancy has focused on typical antipsychotics. Among the typical antipsychotics, pooled results of large retrospective and small prospective controlled studies suggest an increased risk of congenital anomalies in patients treated with low-potency phenothiazines, particularly when treated during the first trimester.²⁵⁶ Guidelines have recommended that the use of antipsychotic medication during the first trimester should be minimized or avoided if possible, especially between weeks 6 and 10.⁵⁸ If an antipsychotic is necessary during this period, high-potency typical antipsychotics

may be safer.⁵⁸ In addition to their teratogenic effects, there are other reasons to avoid low-potency antipsychotics. Low-potency agents can worsen constipation and cause orthostatic hypotension and uteroplacental insufficiency. Guidelines have also recommended that medications should be tapered 1 week before delivery to minimize neonatal complications such as dystonia, withdrawal dyskinesias, temperature dysregulation, and irritability.⁵⁸

Medication management should balance the needs of D.M. against those of her unborn child. D.M.'s schizophrenia has been stable for 2 years. Chlorpromazine should be discontinued because it is a low-potency phenothiazine and D.M. is currently in her first trimester. Because she is a danger to herself when ill, it is critical that treatment be initiated at the first evidence of decompensation. D.M. should be monitored by her clinician, family members, and caseworker at frequent intervals for reemergence of psychotic symptoms. If D.M. decompensates, treatment should be restarted with a nonphenothiazine, high-potency agent at the lowest possible dose (e.g., haloperidol or fluphenazine 2–5 mg at night). If D.M. does not respond to low-dose haloperidol or fluphenazine, or if she develops intolerable extrapyramidal side effects, then a lower potency antipsychotic drug or an atypical agent can be selected. D.M.'s chart should include the following documentation: specific behaviors that necessitate treatment (danger to self, fetus, or others), goals of therapy (acute control of dangerous behavior or remission), dose, route of administration, schedule, and projected duration of treatment, obstetric history and other medications used during pregnancy, alcohol or illegal drug use; regular progress notes on response and need for continued treatment; and informed consent from the patient or guardian.

Children

40. M.J. is the 5-year-old son of a close friend of the family who was diagnosed with autism. His mother, R.J., knows you are a

psychiatric pharmacist and asks your opinion about the use of atypical antipsychotics in children with autism. What can you tell her?

Risperidone is the only atypical antipsychotic agent that is approved by the FDA for the symptomatic treatment of irritability in autistic children and adolescents.⁹⁹ In a study of 5- to 17-year-old children with autism accompanied by severe tantrums, aggression, or self-injurious behavior, the children were randomly assigned to flexible doses of either placebo or risperidone treatment (dose range, 0.5–3.5 mg/day) for 8 weeks.²⁵⁷ A significantly greater percentage of children receiving risperidone responded to treatment than those receiving placebo (56.9% vs. 14.1% respectively, $p < 0.001$); 69% of the risperidone group had at least a 25% improvement on the irritability subscale of the Aberrant Behavioral Checklist as rated by a parent or primary caretaker and confirmed by a clinician and a rating of much or very much improved on a global improvement scale compared with only 12% in the placebo group ($p < 0.001$). The benefit from risperidone treatment was maintained for six months in two-thirds of the risperidone responders. The overall reduction in the level of irritability was 57% at 8 weeks of risperidone in comparison with a reduction of only 14% with placebo ($p < 0.001$). Troost et al.²⁵⁸ evaluated the long-term effects of risperidone for an additional 24 weeks after the initial 8-week open-label trial. Risperidone was effective in reducing disruptive behavior in about one-half of the children, although considerable weight gain was observed.

Data with other atypical antipsychotics for the treatment of autism are limited. Olanzapine has the most data to date with open-label trials suggesting efficacy; quetiapine, ziprasidone, and aniprazole may also be effective.^{259–265} Hollander et al.¹²⁰ found olanzapine to be a potential alternative to risperidone for improving global functioning of pervasive developmental disorders but the risk of significant weight gain may limit its use in children/adolescents. In contrast, ziprasidone was not associated with significant weight gain.²⁶⁴

We who squander our sorrows
How we look beyond them
into the mournful passage of time
To see whether they might end

—*Rainer Marie Rilke*

INTRODUCTION

Depression is a common, chronic, and potentially debilitating illness that has tempered the human condition since the beginning of recorded history. The ancient Egyptians, for instance, wrote about depression more than 3,000 years ago. In the First Book of Samuel (dated about 700 BC), Saul, the King of Israel, is overcome by an “evil spirit” that causes him to feel “incapacitated, guilt-ridden and hopeless,” leading ultimately to his suicide.¹

Cultures throughout history have speculated on the origin of depression. The ancient Greeks believed that depression was caused by an excess of bile. Hippocrates thoroughly described the condition as a somatic illness and is believed to have coined the term “melancholia,” which literally translates to “black bile.” During the Middle Ages, depression and other psychiatric illnesses were considered to be punishment or afflictions from a vengeful God rather than actual illness. At that time, the church and society believed depression to be the result of being weak minded or sinful. Even today, many people suffering from a depressive episode carry the stigma of “having a nervous breakdown,” and medications are viewed as a “crutch” to help cope with daily life. Throughout history, depression has affected the lives of many famous people, including Lud-

wig Van Beethoven, Meriwether Lewis, Abraham Lincoln, Charles Dickens, Winston Churchill, Ernest Hemingway, and Marilyn Monroe.¹

Although many people experience “the blues” on occasion, the term “depression” is reserved in psychiatry to define a specific medical condition with distinctive biological and pharmacologic implications. Similarly, the term “clinical depression” is liberally applied in popular culture to a condition that approximates the psychiatric diagnosis of major depression. In general, depressive disorders are enormous health concerns that are often misdiagnosed or undertreated. The physical and social dysfunction associated with depression is profound and is believed to outweigh many other chronic medical conditions, including hypertension, diabetes, and arthritis.² The Medical Outcomes Study, for instance, determined that the degree of impairment in depressed individuals is comparable to that seen in patients with chronic heart disease.³ The financial ramifications of depression are tremendous and place an overwhelming burden on our society. In 2000, the estimated cost of depression in the United States was \$83.1 billion annually, with most of these costs (\$51.5 billion) attributed to lost productivity and absenteeism in the workplace.⁴

Epidemiology

Since World War II, the lifetime incidence of depression has been rising steadily in studied populations. A recent investigation concluded that the annual incidence of mood disorders is approximately 10% in the adult population, and 1 in 15 adults (6.7%) will suffer from an episode of major depression during

any 12-month period.⁵ Various studies from Europe and the United States have estimated the lifetime prevalence to be 5% to 12% in adult males and 9% to 26% in females.⁶ Although the incidence of depression is remarkably similar across various races and ethnic groups, the illness may be slightly more common in lower socioeconomic classes.⁷

The onset of depression occurs most commonly in the late 20s, but there is a wide range, and the first episode may actually present at any age. One prevailing misconception is that depression is more common among elderly individuals.⁸ Epidemiologic evidence suggests that the incidence is slightly lower in older persons than in the general population, but certain subtypes may be more common (e.g., melancholia, depression with psychotic features), and new-onset depression that initially presents during geriatric years may carry a worse prognosis.

Genetic factors appear to play a major role in the cause of depression. The offspring of depressed individuals are 2.7 times more likely to have depression if one parent is afflicted, and 3.0 times more likely if both parents suffer from depression.⁹ Concordance rates for monozygotic (identical) twins range from 54% to 65%, whereas dizygotic (fraternal) twins range from 14% to 24%.¹⁰ Genetic factors may also predispose individuals to an earlier onset of depression (younger than 30 years of age).¹¹

Alternatively, there is clear evidence that depression may occur as a result of stressful events (i.e., environmental factors) in one's life. These factors include a difficult childhood, physical or verbal abuse, pervasive low self-esteem, death of a loved one, loss of a job, and the end of a serious relationship. Acute depressive episodes are often attributed to a combination or diatheses of environmental or genetic factors. For instance, individuals carrying a genetic predisposition to mood disorders may undergo a traumatic experience that ultimately triggers the manifestation of depressive symptomatology. Depression may also occur spontaneously, however, among people who appear to lack any obvious genetic or environmental factors.

Diagnosis and Classification

Both the diagnosis and the classification of depression have undergone many transformations since Emil Kraepelin's biological model of the late 19th century. Kraepelin separated the functional psychoses into two groups: manic-depressive insanity and dementia praecox. Kraepelin's detailed descriptions of these two mental illnesses laid the foundation for modern psychiatry.¹² In 2000, the American Psychiatric Association (APA) published refined, standardized criteria for diagnosing depressive disorders in the *Diagnostic and Statistical Manual of Mental Disorders*, Fourth Edition, Text Revision (DSM-IV-TR).¹³ Depressive disorders are classified under Mood Disorders in DSM-IV-TR and include major depressive disorder; single-episode or recurrent, dysthymic disorder; and depressive disorder, not otherwise specified. See Table 79-1 for the classification of mood disorders.

As previously stated, a major depressive disorder may occur as a single episode, but it is more commonly a recurrent event and looked on, therefore, as a chronic illness.⁶ The frequency of recurrent episodes is highly variable, with some people experiencing discrete episodes separated by many years of relatively normal mood (i.e., euthymia), and others experiencing residual

From reference 13.

symptoms between episodes that may never completely remit. The risk of future episodes appears to increase disproportionately with the chronicity of the illness. For instance, after the first episode there is a 50% likelihood of a second. After the second, there is a 70% chance of a third, and with the third episode comes nearly a 90% incidence of a fourth.

Depressive disorders may be subclassified using cross-sectional symptom features, or specifiers, according to DSM-IV-TR.¹³ For example, the phrase "with melancholic features" is used when patients possess primary neurovegetative symptoms, early morning awakening, marked psychomotor agitation or retardation, and significant anorexia or weight loss. Melancholia is often a more severe form of depression, and the cause is rather autonomous (i.e., lacking apparent environmental triggers).¹⁴ It may also be less likely than other forms of depression to remit spontaneously. The phrase "with atypical features" is used when depressive symptoms include weight gain, hypersomnia, leaden paralysis, or rejection sensitivity. When hallucinations or delusions occur in patients who are primarily depressed, the phrase "with psychotic features" is applicable to the mood disorder. Other diagnostic specifiers used in DSM-IV-TR include "chronic," "with catatonic features," and "with postpartum onset."

Dysthymic disorder is a type of depressive illness characterized by fewer symptoms than major depression, but the course is much more chronic with symptoms being present most of the time for at least 2 years. In practice, the distinction of major depression from dysthymia may be difficult to make and requires a detailed psychiatric history. Some patients may experience an episode of major depression superimposed on a history of dysthymia, a condition commonly known as *dou-ble depression*. The treatment for dysthymia has traditionally focused on psychotherapy, but recent evidence suggests that antidepressant medications may also be effective.¹⁵

Differential Diagnosis

Symptoms of depression may be induced or exacerbated by numerous medical illnesses or medications (Tables 79-2 and 79-3). Consequently, DSM-IV-TR specifies that whenever an "organic cause" is temporally related to the onset of depressive symptoms, the patient does not fit the criteria for major depression, even if all other criteria are met.¹³ The rationale for this

Table 79-2 Selected Medical Conditions That May Mimic Depression

| Central Nervous System | Women's Health |
|--|--|
| Alzheimer disease Cerebrovascular accident Epilepsy Multiple sclerosis Parkinson disease | Premenstrual dysphoric disorder Antepartum/postpartum Perimenopause |
| Cardiovascular | Other |
| Cerebral arteriosclerosis Congestive heart failure Myocardial infarction | Chronic fatigue syndrome Chronic pain syndrome(s) Fibromyalgia Irritable bowel syndrome Malignancies (various) Migraine headaches Rheumatoid arthritis Systemic lupus erythematosus |
| Endocrine | |
| Addison disease Diabetes mellitus (types I and II) Hypothyroidism | |

stipulation is that if the medical illness is successfully treated or the offending agent is discontinued, the depressive illness will spontaneously resolve, eliminating the need for somatic intervention. Although lists of medical illnesses or medications are helpful, the clinician should be aware that the actual evidence demonstrating an association between depression and specific organic causes is often very limited and anecdotal. If a medication or condition is suspected of causing depression, the chronologic association should be investigated rigorously before other action is taken.

Clinical Presentation

For a diagnosis of major depressive disorder to be made, symptoms must be present for at least 2 weeks and must not be precipitated or influenced by a medical illness or medication (according to DSM-IV-TR criteria). Individuals must possess at least five symptoms, one of which is either depressed mood *OR* anhedonia (diminished interest or pleasure in activities). The other seven symptoms are as follows:

1. Change in appetite
2. Change in sleep
3. Low energy
4. Poor concentration (or difficulty making decisions)
5. Feelings of worthlessness or inappropriate guilt
6. Psychomotor agitation or retardation
7. Recurrent thoughts of suicide

The diagnostic criteria also stipulate that the mood disturbance must cause marked distress or result in clinically significant impairment of social or occupational functioning. To distinguish depression from grief reactions or bereavement, it is also stipulated that the symptoms of major depression must persist for at least 2 months after the precipitating event. Table 79-4 lists the specific criteria for a diagnosis of major depressive disorder.

Although low energy and changes in sleep or appetite are present in most depressed patients, the clinical presentation of depression can be highly variable. Many patients, for example, will readily express profound sadness or hopelessness, but others can project a more anxious or irritable appearance. Psychomotor agitation may be apparent, featuring wringing of the hands, grimacing, pacing, or cursing. Conversely, psychomotor retardation can be evident, with slowed speech or thinking, soft monotone voice, or minimal facial expression. On occasion, psychotic symptoms (e.g., auditory hallucinations, persecutory delusions, somatic delusions of serious medical illness) may also occur.

Although the criteria for detecting major depression are exactly the same in the elderly population as in the general population, the presentation may be slightly different than in younger individuals. Elderly patients may be less likely to acknowledge sadness or melancholy and choose to dwell instead on somatic complaints such as headache, insomnia, joint pain, dizziness, or constipation.¹⁶ As a result, clinicians are advised to consider the possibility of depression whenever a person presents with vague, chronic symptoms of physical illness and unclear etiology.

Table 79-3 Selected Medications That May Induce Depression

| Cardiovascular Agents | Hormonal Agents |
|---|---|
| β -blockers (?) Clonidine Methyldopa Reserpine | Anabolic steroids Corticosteroids Gonadotropin-releasing hormone Progestins Tamoxifen |
| Central Nervous System Agents | Others |
| Barbiturates Benzodiazepines (?) Chloral hydrate Ecstasy (MDMA) Ethanol | Efavirenz Interferon Isotretinoin Mefloquine Levetiracetam |

Table 79-4 Diagnostic Criteria for Major Depressive Disorder

- At least five of the following symptoms have been present during the same 2-week period and represent a change from previous functioning. One of the symptoms must be either depressed mood or loss of interest/pleasure.
 - Depressed mood most of the day, nearly every day
 - Loss of interest in pleasurable activities most of the day, nearly every day
 - Change in weight or appetite (increase or decrease) when not dieting
 - Insomnia or hypersomnia nearly every day
 - Fatigue or loss of energy nearly every day
 - Diminished ability to think or concentrate, or indecisiveness
 - Feelings of worthlessness or excessive or inappropriate guilt nearly every day
 - Psychomotor agitation or retardation nearly every day
 - Recurrent thoughts of death or suicidal ideation
- Symptoms cause clinically significant distress or impairment in social, occupational, or other important areas of functioning.
- Symptoms are not caused by an underlying medical condition or substance (e.g., medications or recreational drugs).

Pathophysiology

Our understanding of the biological basis for depressive disorders has come a long way since Hippocrates first identified bile as a possible cause. Several modern theories addressing the origin of depression have evolved over the past three decades, focusing on neurotransmitter systems, including norepinephrine, serotonin, and dopamine. As unique antidepressant medications are developed and our understanding of the mechanisms of pharmacologic action improve, other cogent theories of depression will undoubtedly evolve.

In the past, the *monoamine hypothesis* proposed that decreased synaptic concentrations of norepinephrine and/or serotonin caused depression. The norepinephrine depletion theory was originally based on the observation that reserpine, which depleted catecholamine stores in the central nervous system (CNS), was capable of causing depression.^{17,18} This theory evolved into the *permissive hypothesis*, which emphasized a greater role for serotonin in promoting or “permitting” a decline in norepinephrine function. Specifically, this hypothesis suggests that low concentrations of serotonin or norepinephrine in the CNS precipitated depressive symptoms, while low levels of serotonin and increased activity of norepinephrine resulted in manic symptoms. Antidepressants were believed to relieve depression by inhibiting the reuptake of norepinephrine and/or serotonin from the synapse back up into the neuron, and effectively increasing neurotransmitter concentrations in the synaptic cleft.¹⁹

Although these theories were initially helpful in enhancing our understanding of how antidepressants worked, there were multiple reasons to suspect that other mechanisms and systems were involved. First, antidepressants were capable of blocking the reuptake of neurotransmitters almost immediately after administration, yet several weeks lapsed before therapeutic effects were evident (i.e., delayed onset).²⁰ Second, synaptic concentrations of biogenic amines are not always decreased in depressed individuals and can actually be higher than those seen in normal controls.²¹ Last, antidepressants in development can work via other mechanisms, which do not involve relative increases in synaptic neurotransmitter concentrations (e.g., can block substance P, or can antagonize corticotropin-releasing factor or corticosteroid receptors).^{22–24}

The *dysregulation hypothesis* has evolved more recently and suggests that depression, as well as other psychiatric disorders, is the result of a dysregulated neurotransmitter system. Specific criteria for dysregulation have been proposed as follows: (a) an impairment in the regulatory or homeostatic mechanisms, (b) an erratic basal output of the neurotransmitter system, (c) a disruption in normal periodicities (circadian rhythm), (d) a less selective response to environmental stimuli, (e) perturbation of the system resulting in a delayed return to baseline, and (f) restoration to efficient regulation through the use of pharmacologic agents.²⁵

Regardless of the antidepressant mechanism of action, changes in the presynaptic and postsynaptic receptor densities (or sensitivities) have been described as being “downregulated.”²⁶ Changes include a decrease in postsynaptic alpha-adrenergic receptor sensitivity, along with alterations in the sensitivities of the alpha-adrenergic, dopaminergic (D2) and serotonin receptor subtypes (5-HT_{1A} and 5HT_{2A}). For example, selective serotonin reuptake inhibitors (SSRIs) can in-

crease the efficiency of serotonergic neurotransmission acutely (through reuptake blockade), but their therapeutic effects are linked temporally with increased release of serotonin through downregulation of presynaptic autoreceptors (5-HT_{1A}).²⁷

Today, emphasis continues to be placed on serotonin, norepinephrine, and dopamine neurotransmitters, and additional attention is also being paid to their differential effects on specific depressive symptoms. For instance, appetite, sleep, libido, motor function, anxiety, and aggression all appear to be strongly influenced by serotonin transmission. Research evidence for serotonergic influence has demonstrated that the concentration of serotonin’s primary metabolite (5-hydroxyindoleacetic acid [5-HIAA]) is decreased in the cerebrospinal fluid (CSF) of depressed patients.²⁷ Low 5-HIAA concentrations have also been found in the CSF of patients attempting suicide and may have a role in triggering other violent activities.²⁸ Dietary depletion of L-tryptophan, a serotonin precursor, has induced relapse in depressed patients previously responsive to SSRIs, and symptoms such as irritability and disrupted sleep/appetite appear to return preferentially²⁹ (Fig. 79-1).

Alternatively, deficiencies in norepinephrine (and dopamine to some extent) are believed to mediate depressive symptoms such as anhedonia, decreased energy, memory impairments, and executive dysfunction.³⁰ Administration of α -methyl paratyrosine (which inhibits the synthesis of norepinephrine) has resulted in the return of these depressive symptoms among patients previously treated successfully with noradrenergic antidepressants.³¹ The role of dopamine in mediating this constellation of symptoms has been implied through postmortem studies, neuroimaging results, and the demonstrated effectiveness of pure dopamine agonists (e.g., amantadine, pramipexole) in relieving depression.³² Ultimately, it is still believed that a common circuitry is influenced by the different neurotransmitters, resulting in the clinical manifestation of depression.³¹

Neuroendocrine Findings

Along with dysregulated neurotransmitter systems, neuroendocrine abnormalities may contribute to the development of depression. Depressed patients often have abnormal thyroid function tests (including low triiodothyronine [T₃] and/or thyroxine [T₄] levels).³³ They also may exhibit an abnormal response to challenge with thyroid-releasing hormone (TRH), consisting of a blunted or exaggerated thyroid-stimulating hormone (TSH) response.³⁴ Clinical hypothyroidism can also induce depressive symptoms, and thyroid supplementation can reverse this pathology, suggesting an indirect association between mood disorders and thyroid homeostasis.³⁵

The hypothalamic-pituitary-adrenal (HPA) axis may also influence the manifestation of depression, with a relative hyperactivity of this system commonly reported in depressed individuals. Pituitary and adrenal glands are often enlarged in depressed patients, and concentrations of corticotropin-releasing factor (CRF) are often elevated during depressive episodes and decline with the administration of antidepressant medications or electroconvulsive therapy (ECT).^{24,36} Exogenous administration of CRF has elicited classic symptoms of depression in laboratory animals (including decreased appetite, anxiety, insomnia, and decreased libido).³⁷ In humans, medications that block postsynaptic corticosteroid receptors have also displayed antidepressant properties, as demonstrated with

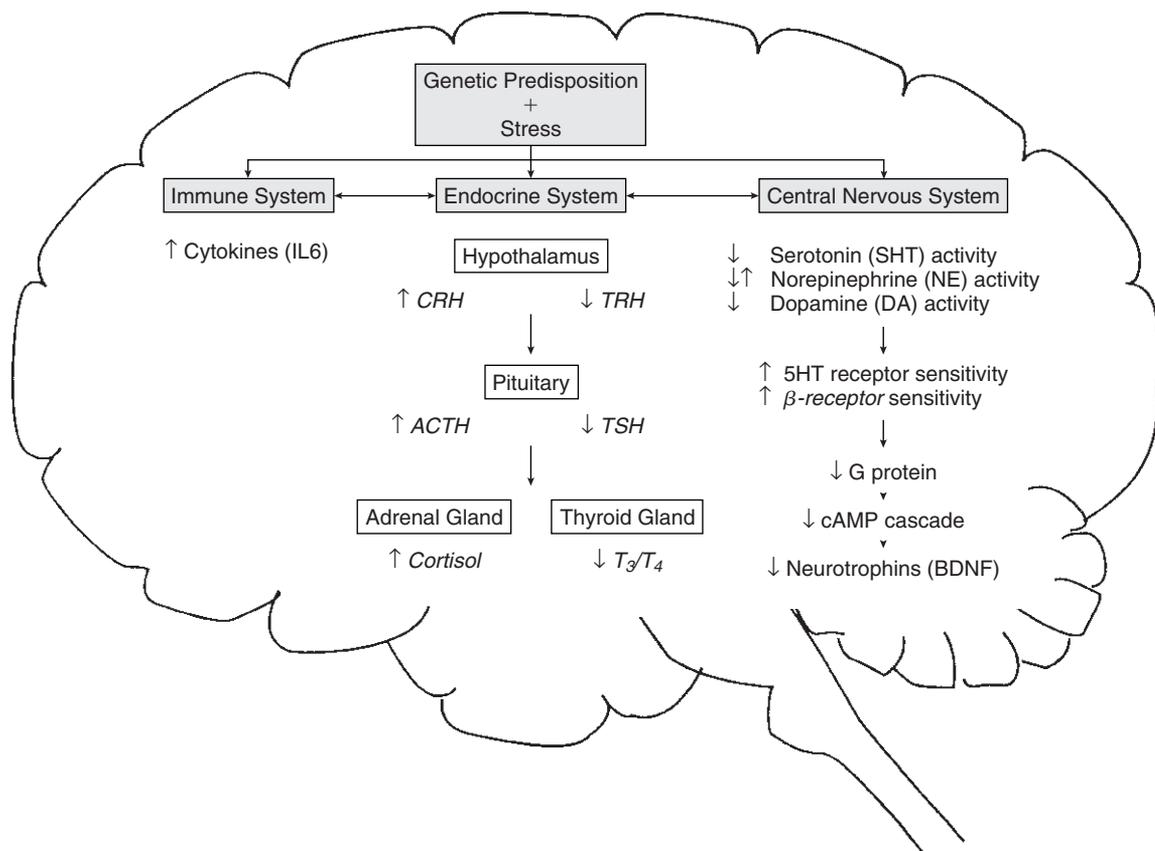

FIGURE 79-1 Influence of genetic and environmental factors on the immune system, endocrine system, and central nervous system. CRH, corticotropin-releasing hormone (also known as corticotropin-releasing factor [CRF]); TRH, thyrotrophin-releasing hormone; ACTH, adrenocorticotropic hormone; TSH, thyroid-stimulating hormone; T_3/T_4 , thyroxine/triiodothyronine. (Copyright JL Corbitt, PR Finley 2003.)

ketoconazole and mifepristone.^{38,39} Interestingly, serotonin exerts a strong influence on the HPA axis (and vice versa). Activation of the postsynaptic serotonin receptors (5-HT₂) along the hypothalamic paraventricular nucleus can stimulate corticotropin-releasing hormone-secreting neurons. Corticosteroids can also modulate serotonin synthesis, metabolism, and reuptake.²⁴

Not all of the evidence, however, supports a causative role of HPA overactivity in the manifestation of depression. The acute administration of high-dose corticosteroids, for instance, is more commonly associated with mood elevation (e.g., euphoria or hypomania), leading some to suggest that the exaggerated HPA response seen with depression is actually the body's attempt to overcome this mood disorder. Furthermore, HPA overactivity has not been observed in certain populations of depressed patients, such as adolescents and young adults. Given the strong association of depression with chronic inflammatory conditions, further exploration of the relationship of the HPA axis to depressive symptoms is imperative.

Imaging Studies

Imaging studies (including computed tomography, magnetic resonance imaging, positron emission tomography [PET], and single-photon emission computed tomography) suggest that patients with depression have regional brain dysfunction, most

often affecting the limbic structures and prefrontal cortex. Alterations in cerebral blood flow and/or metabolism in the frontal-temporal cortex and caudate nucleus are associated with common depressive symptoms such as dysphoria, anhedonia, hopelessness, and flat affect.⁴⁰ Increased firing of the amygdala in the left hemisphere has been linked in PET studies with the future development of depression.⁴¹ Because subtypes of depression have been linked to different regional dysfunctions, a network hypothesis has begun to emerge that may lead to improvements in depression diagnosis and targeted treatments.⁴²

Patient Assessment Tools

Pharmaceutical care in the depressed patient requires specialized knowledge of the illness and treatments, as well as refined interviewing skills. To obtain specific information about the target symptoms of depression and to assess the therapeutic impact of psychotropic medications, effective and productive interpersonal communication is vital. The structured mental status examination is an established systematic way of assessing a patient's mental health (Table 79-5). Many functional domains are assessed in a mental status examination. Through this structured interview, the clinician has an observational basis for evaluating a patient's appearance, behavior, speech, mood, affect (i.e., outer manifestation of inner emotional states),

Table 79-5 Mental Status Exam**General Appearance, Behavior, Speech**

- Apparent age; appear ill or in distress?
- Dress
- General reaction to examination, negativism
- Posture and gait
- Unusual movements
- Facial expression
- Signs of anxiety
- General level of activity
- Repetitious activities (stereotypy, mannerisms, compulsions)
- Disturbances of attention: distractibility
- Speech: mute, word salad, echolalia, klang, neologisms

Mood and Affect

- Quality of prevailing mood; intensity and depth
- Constancy of mood, patient-stated mood
- Affect: range, appropriateness, lability, flatness

Sensorium

- Orientation for time, place, person, situation
- Memory: recent and remote, immediate recall

Level of Intellectual Functioning

- An estimate of current intellectual functioning, not an estimate of original intellectual potential
- General fund of information: presidents, oceans, governor, large cities, current events. Why does the moon appear larger than the stars?
- Vocabulary
- Serial 7 subtractions (also tests attention and sensorium)

Thought Processes

- Pattern of associations (tempo, rhythm, organization, distortions, excesses, deficiencies)
- False perceptions (hallucinations, illusions, delusions, distortions of body image, depersonalization)
- Thought content (what patient tells, main concerns, obsessive ideation)
- Abstracting ability (tests by similarities, proverbs)
- Judgment and insight

sensorium, memory, and intellectual function. For a more detailed discussion of the mental status examination and specific psychiatric interviewing techniques, readers should refer to other sources.^{43,44}

Behavioral rating scales have been used for many years in drug efficacy studies and are being used routinely in the clinical arena today. Rating scales can be helpful in assessing the severity of mental illness, quantifying changes in target symptoms, and determining treatment efficacy, but they are not necessarily diagnostic. Rating scales can vary in length, content, and format, and can be completed by providers, patients, researchers, family members, or conservators. Numerous depression scales have been developed over the years, including the Hamilton Rating Scale for Depression (HAM-D), the Beck Depression Inventory, the Zung Depression Scale, the Hopkins Symptom Checklist, the Montgomery Asberg Depression Rating Scale, the Center for Epidemiological Studies Depression (CES-D) Scale, the Patient Health Questionnaire, and the Quick Inventory of Depressive Symptoms (QIDS).^{45–52} The HAM-D was initially designed to measure the efficacy of antidepressant medications given to severely depressed individuals in controlled clinical trials (Table 79-6).⁴⁵ Over the years, this instrument emerged as the gold standard of depression rating scales, although many clinicians are unaware of its limitations. For instance, the HAM-D was never designed for routine use in the general ambulatory care patient population and fails to address a number of target symptoms required for a DSM-IV-TR diagnosis of major depression (e.g., low energy, poor concentration, reverse neurovegetative symptoms). The QIDS has emerged recently as a more valuable instrument in the hands of primary care providers. It contains a total of 16 items, can be completed within 10 to 15 minutes, and is available at no cost to clinicians. It has been validated and used extensively in clinical and research settings and is available in a clinician-rated or patient-rated format. The CES-D is also available in an abbreviated format and has served as a useful

screening instrument among elderly populations (Tables 79-7 and 79-8).⁵³

Although depression symptoms are clearly associated with many biochemical and endocrine anomalies, there are currently no useful laboratory tests that are routinely administered to aid the clinician in establishing a diagnosis of depression. For many years, the dexamethasone suppression test (DST) was used to confirm the diagnosis of depression, but now it is rarely indicated. The rationale for this test lies in the apparent inability of depressed patients to suppress cortisol concentrations after dexamethasone administration. The standard protocol consists of administering a 1-mg dose of dexamethasone at 11 PM and obtaining blood samples at 4 PM and 11 PM on the following day for the purpose of measuring subsequent cortisol concentrations. The results are considered abnormal (positive) if either of the two samples are >5 mcg/dL. Studies have demonstrated that the DST is often more abnormal in older depressed subjects, and a meta-analysis concluded that a positive baseline DST was predictive of worse treatment outcomes.⁵⁴ Unfortunately, many medical conditions and medications may augment the cortisol response, resulting in a greater likelihood of false-positive findings. Furthermore, as many as half of depressed subjects may have a normal DST (i.e., manifesting in false-negative findings). The APA Task Force on Laboratory Tests in Psychiatry has outlined some of the potential indications for the DST, and it may, in fact, be useful in certain clinical situations to confirm a diagnosis of depression.⁵⁵ However, in general, the DST is not recommended as a routine screening instrument at present.

Nondrug Therapies for Depression

The successful treatment of depression provides a most formidable challenge to modern medicine. In addition to the emotional turmoil and social disability that a depressed individual endures, the illness can have an affect on other disease

Table 79-6 Hamilton Depression Scale (HAM-D 17)

For Each Item, Check the Box Next to the Response That Best Characterizes the Patient

| | | |
|--|--|--|
| 1. Depressed mood (sadness, hopeless, helpless, worthless) | 0 <input type="checkbox"/> Absent | |
| | 1 <input type="checkbox"/> These feeling states indicated only on questioning | |
| | 2 <input type="checkbox"/> These feeling states spontaneously reported verbally | |
| | 3 <input type="checkbox"/> Communicates feeling states nonverbally (i.e., through facial expression, posture, voice, and tendency to weep) | |
| | 4 <input type="checkbox"/> Patient reports VIRTUALLY ONLY these feeling states in his or her spontaneous verbal and nonverbal communication | |
| 2. Feelings of guilt | 0 <input type="checkbox"/> Absent | |
| | 1 <input type="checkbox"/> Self-reproach, feels he or she has let people down | |
| | 2 <input type="checkbox"/> Ideas of guilt or rumination over past errors or sinful deeds | |
| | 3 <input type="checkbox"/> Presents illness as a punishment; delusions of guilt | |
| | 4 <input type="checkbox"/> Hears accusatory or denunciatory voices and/or experiences threatening visual hallucinations | |
| 3. Suicide | 0 <input type="checkbox"/> Absent | |
| | 1 <input type="checkbox"/> Feels life is not worth living | |
| | 2 <input type="checkbox"/> Wishes he or she were dead or any thoughts of possible death to self | |
| | 3 <input type="checkbox"/> Suicide ideas or gesture | |
| | 4 <input type="checkbox"/> Attempts at suicide (only serious attempt rates 4) | |
| 4. Insomnia early | 0 <input type="checkbox"/> No difficulty | |
| | 1 <input type="checkbox"/> Complains of occasional difficulty falling asleep (i.e., more than one-half hour) | |
| | 2 <input type="checkbox"/> Complains of nightly difficulty falling asleep | |
| 5. Insomnia middle | 0 <input type="checkbox"/> No difficulty | |
| | 1 <input type="checkbox"/> Patient complains of being restless and disturbed during the night | |
| | 2 <input type="checkbox"/> Waking during the night—any getting out of bed rates 2 (except for purposes of voiding) | |
| 6. Insomnia late | 0 <input type="checkbox"/> No difficulty | |
| | 1 <input type="checkbox"/> Waking in early hours of the morning but goes back to sleep | |
| | 2 <input type="checkbox"/> Unable to fall asleep again if gets out of bed | |
| 7. Work and activities | 0 <input type="checkbox"/> No difficulty | |
| | 1 <input type="checkbox"/> Thoughts and feeling of incapacity, fatigue, or weakness related to activities, work, or hobbies | |
| | 2 <input type="checkbox"/> Loss of interest in activities, work, or hobbies—either directly reported by patients, or indirect in listlessness, indecision, and vacillation (feels he or she has to push self) | |
| | 3 <input type="checkbox"/> Decrease in actual time spent in activities or decrease in productivity, in hospital, rate 3 if patient does not spend at least 3 hours a day in activities or decrease in productivity, in hospital, rate 3 if patient does not spend at least 3 hours a day in activities (hospital job or hobbies), exclusive of ward chores | |
| | 4 <input type="checkbox"/> Stopped working because of present illness, in hospital, rate 4 if patient engages in no activities except ward chores, or if patients fails to perform ward chores unassisted | |
| 8. Retardation (slowness of thought and speech, impaired ability to concentrate, decreased motor activity) | 0 <input type="checkbox"/> Normal speech and thought | |
| | 1 <input type="checkbox"/> Slight retardation at interview | |
| | 2 <input type="checkbox"/> Obvious retardation at interview | |
| | 3 <input type="checkbox"/> Interview difficult | |
| | 4 <input type="checkbox"/> Complete stupor | |
| 9. Agitation | 0 <input type="checkbox"/> None | |
| | 1 <input type="checkbox"/> “Playing with” hands, hair, etc. | |
| | 2 <input type="checkbox"/> Hand wringing, nail biting, hair pulling, biting of lips | |
| 10. Anxiety psychic | 0 <input type="checkbox"/> No difficulty | |
| | 1 <input type="checkbox"/> Slight retardation at interview | |
| | 2 <input type="checkbox"/> Obvious retardation at interview | |
| | 3 <input type="checkbox"/> Interview difficult | |
| | 4 <input type="checkbox"/> Complete stupor | |
| 11. Anxiety somatic | 0 <input type="checkbox"/> Absent | Physiological concomitants of anxiety, such as |
| | 1 <input type="checkbox"/> Mild | Gastrointestinal (GI)—dry mouth, wind, indigestion, diarrhea, cramps, belching |
| | 2 <input type="checkbox"/> Moderate | Cardiovascular—palpitations, headaches |
| | 3 <input type="checkbox"/> Severe | Respiratory—hyperventilation, sighing |
| | 4 <input type="checkbox"/> Incapacitating | Sweating |
| 12. Somatic symptoms—GI | 0 <input type="checkbox"/> None | |
| | 1 <input type="checkbox"/> Loss of appetite but eating without staff encouragement; heavy feelings in abdomen | |
| | 2 <input type="checkbox"/> Difficulty eating without staff urging; requests or requires laxatives or medication for bowels or medication for GI symptoms | |
| 13. Somatic symptoms—general | 0 <input type="checkbox"/> None | |
| | 1 <input type="checkbox"/> Heaviness in limbs, back, or head; backaches, headache, muscle aches; loss of energy or fatigability | |
| | 2 <input type="checkbox"/> Any clear-cut symptoms rates 2 | |

states, slow the recovery process, or even promote complications. Furthermore, the likelihood of future depressive episodes increases with each recurrence, dampening the patient's prognosis over time.

Although pharmacologic intervention has become the primary treatment modality for relieving depressive symptoms, the efficacy and suitability of other therapeutic options should not be overlooked. Most experts now advocate a three-pronged approach to relieving and preventing depressive symptoms, involving (a) psychotherapy, (b) somatic interventions, and (c) lifestyle adjustments. Because these interventions address different aspects of the illness at different stages in the recovery process, they work synergistically together, and a brief summary of these approaches can be found later in this chapter. (*Note:* Because discussion of medications comprises the bulk of this chapter; readers are advised to refer to the "Drug Management" section for information specific to pharmacotherapy.)

Psychotherapy

For the treatment of mild to moderate depression, psychotherapy has proved to be comparable to pharmacologic intervention and may actually be preferred by some patients. For the acute treatment of severe depression, antidepressants appear to be more effective than psychotherapy alone and have a more rapid onset of therapeutic action.⁵⁶ The beneficial effects of psychotherapy, however, may persist longer than medication-related benefits after the interventions have been formally discontinued. In addition, psychotherapy may be particularly beneficial for preventing relapse among patients who previously demonstrated a therapeutic response to antidepressants.⁵⁷ Overall, the combination of treatments is superior to either intervention alone, although the routine use of both modalities is often not feasible in today's health care environment.⁵⁶

Several forms of psychotherapy are available, including cognitive-behavioral therapy (CBT), interpersonal therapy, and psychoanalytic and psychodynamic therapies. CBT, in particular, often focuses on identifying and reversing negative thought patterns that perpetuate depressed emotions. It has been studied extensively in the depression field and is now available in a manual-driven, evidence-based format. A more precise explanation and description of psychotherapeutic alternatives is beyond the scope of this textbook. However, clinicians in the field are strongly encouraged to develop familiarity with these approaches, as well as general supportive counseling techniques, which can serve to promote the recovery process and decrease the likelihood of future episodes.⁵⁸

Somatic Interventions

ECT is a safe, rapid-acting, and highly effective therapeutic intervention that continues to suffer, ostensibly, from a poor public image. ECT was enormously popular during the 1940s and 1950s and was used without discretion to treat a wide variety of psychiatric conditions. This practice waned with the advent of effective psychotropic medications, and with the accumulation of case reports describing fractures and severe cognitive impairment in treated patients. Since the 1950s, the ECT procedure has undergone considerable transformation and refinement.⁵⁹ Adjunctive medications are now routinely administered to prevent adverse effects and reduce morbidity (e.g., a short-acting barbiturate for general anesthesia, an anticholinergic agent to prevent bradycardia and dry excessive airway secretions, succinylcholine to prevent fractures from tonic-clonic contractions). The electric stimulus itself is no longer applied in one steady current but now consists of a series of brief pulses that have been shown to decrease the severity of postictal headaches and memory impairment.

Fundamentally, ECT features the induction of generalized seizures through an electric current delivered by bilateral or

Table 79-7 Quick Inventory for Depressive Symptomatology (Clinician-Rated) (QIDS-C16)

NAME: _____

TODAY'S DATE: _____

Please circle the one response to each item that best describes the patient for the past 7 days.

1. Sleep Onset Insomnia:
 - a. Never takes longer than 30 minutes to fall asleep.
 - b. Takes at least 30 minutes to fall asleep, less than half the time.
 - c. Takes at least 30 minutes to fall asleep, more than half the time.
 - d. Takes more than 60 minutes to fall asleep, more than half the time.
2. Midnocturnal Insomnia:
 - a. Does not wake up at night.
 - b. Restless, light sleep with few awakenings
 - c. Wakes up at least once at night
 - d. Awakens more than once at night and stays awake for 20 minutes or more, more than half the time.
3. Feeling Anxious or Tense:
 - a. I do not feel anxious or tense.
 - b. I feel anxious (tense) less than half the time.
 - c. I feel anxious (tense) more than half the time.
 - d. I feel extremely anxious (tense) nearly all of the time.
4. The Quality of Your Mood:
 - a. The mood (internal feelings) that I experience is very much a normal mood.
 - b. My mood is sad, but this sadness is pretty much like the sad mood I would feel if someone close to me died or left.
 - c. My mood is sad, but this sadness has a rather different quality to it than the sadness I would feel if someone close to me died or left.
 - d. My mood is sad, but this sadness is different from the type of sadness associated with grief or loss.
5. Sleep During the Night:
 - a. I do not wake up at night.
 - b. I have a restless, light sleep with a few brief awakenings each night.
 - c. I wake up at least once a night, but I go back to sleep easily.
 - d. I awaken more than once a night and stay awake for 20 minutes or more, more than half the time.

Please complete *either 6 or 7* (not both)
6. Decreased Appetite:
 - a. There is no change in my usual appetite.
 - b. I eat somewhat less often or lesser amounts of food than usual.
 - c. I eat much less than usual and only with personal effort.
 - d. I rarely eat within a 24-hour period, and only with extreme personal effort or when others persuade me to eat.
7. Increased Appetite:
 - a. There is no change from my usual appetite.
 - b. I feel a need to eat more frequently than usual.
 - c. I regularly eat more often and/or greater amounts of food than usual.
 - d. I feel driven to overeat both at mealtime and between meals.
8. Aches and Pains:
 - a. I don't have any feeling of heaviness in my arms or legs or any aches or pains.
 - b. Sometimes I get headaches or pains in my stomach, back, or joints, but these pains are only sometime present and don't stop me from doing what I need to do.
 - c. I have these sorts of pains most of the time.
 - d. These pains are so bad they force me to stop what I am doing.
9. Concentration/Decision Making:
 - a. There is no change in my usual capacity to concentrate or make decisions.
 - b. I occasionally feel indecisive or find that my attention wanders.
 - c. Most of the time, I struggle to focus my attention or to make decisions.
 - d. I cannot concentrate well enough to read and cannot make even minor decisions.
10. Energy Level:
 - a. There is no change in my usual level of energy.
 - b. I get tired more easily than usual.
 - c. I have to make a big effort to start or finish my usual daily activities (e.g., shopping, homework, cooking, or going to work).
 - d. I really cannot carry out most of my usual daily activities because I just don't have the energy.
11. General Interest:
 - a. There is no change from usual in how interested I am in other people or activities.
 - b. I notice that I am less interested in people or activities.
 - c. I find I have interest in only one or two of my formerly pursued activities.
 - d. I have virtually no interest in formerly pursued activities.
12. Capacity for Pleasure or Enjoyment (excluding sex):
 - a. I enjoy pleasurable activities just as much as usual.
 - b. I do not feel my usual sense of enjoyment from pleasurable activities.
 - c. I rarely get a feeling of pleasure from any activity.
 - d. I am unable to get any pleasure or enjoyment from anything.
13. View of Myself:
 - a. I see myself as equally worthwhile and deserving as other people.
 - b. I am more self-blaming than usual.
 - c. I largely believe that I cause problems for others.
 - d. I think almost constantly about major and minor defects in myself.
14. View of My Future:
 - a. I have an optimistic view of my future.
 - b. I am occasionally pessimistic about my future, but for the most part I believe things will get better.
 - c. I'm pretty certain that my immediate future (1–2 months) does not hold much promise of good things for me.
 - d. I see no hope of anything good happening to me anytime in the future.
15. Thoughts of Death or Suicide:
 - a. I do not think of suicide or death.
 - b. I feel that life is empty or wonder if it's worth living.
 - c. I think of suicide or death several times a week for several minutes.
 - d. I think of suicide or death several times a day in some detail, or I have made specific plans for suicide or have actually tried to take my life.

Please review this test and write in this space _____ the numbers of the three items that were the most difficult to understand.

unilateral electrode placement. Certain medications may raise seizure thresholds (benzodiazepines) or promote cognitive impairment (lithium) and should be discontinued before the procedure. Adverse effects are generally minimal and consist mainly of transient anterograde amnesia (i.e., difficulty remembering events around the time of the procedure), retrograde amnesia, confusion, headaches, and muscle aches. Cardiovascular effects (e.g., ventricular arrhythmias, myocardial infarction [MI]) are the most ominous sequelae, but these events are actually quite rare.

Many years of clinical experience have enabled clinicians to identify patient populations most likely to benefit from this intervention. Today, ECT is recommended for patients with treatment-resistant depression, severe vegetative depression, psychotic depression, and depression in pregnancy. Overall response rates are rather impressive, ranging from 70% to 90%, and ECT has the distinct advantage of inducing a therapeutic response within the first week or two of treatments.⁶⁰ The recommended frequency of ECT treatments is variable. Most institutions have used three sessions weekly to induce a therapeutic response acutely, although evidence suggests that twice-weekly sessions are better tolerated and more cost effective.⁶¹ The frequency of treatments thereafter (i.e., maintenance therapy) is unknown, although recent evidence suggests that ECT administered weekly for 1 month and less frequently thereafter may be as effective as aggressive pharmacotherapy in preventing relapse.⁶²

Other somatic interventions have also been used successfully to treat depression. Transcranial magnetic stimulation (TMS) is a noninvasive procedure involving the application of an electrical stimulus across the scalp, which ultimately generates an electrical field in the cerebral cortex.⁶³ Unlike ECT, TMS does not generate an actual seizure and is very well tolerated. Evidence of efficacy has been demonstrated in several investigations using repetitive high-frequency techniques, and imaging studies have shown functional improvements consistent with antidepressant properties. However, it is not currently U.S. Food and Drug Administration (FDA) approved for the treatment of depression. Vagal nerve stimulation (VNS) involves the surgical implantation of an electrical device in the subcutaneous tissue below the clavicle, which sends an impulse along the left vagal nerve into the cerebral cortex.⁶⁴ This intervention has proven to be effective for intractable seizures. It is currently FDA approved for the management of treatment-resistant depression as well, although the safety and cost effec-

tiveness of this expensive procedure have not been extensively studied.

Light therapy or phototherapy is particularly effective for relieving the irritability and malaise associated with seasonal affective disorder, a milder form of depression that has been attributed to decreases in natural sunlight found with seasonal variation.⁶⁵ Phototherapy is administered in the form of a light box delivering 1,500 to 10,000 lux over a period of 1 to 2 hours daily. It is generally very well tolerated, although case reports of mania have surfaced as with any other somatic intervention used for depression. Sleep deprivation may be an effective adjuvant to antidepressants and has also been studied as a remedy for premenstrual dysphoric disorder. The goal of sleep deprivation is to gradually advance sleep cycles by altering wake schedules, ultimately minimizing the duration of rapid eye movement (REM) sleep.⁶⁶

Lifestyle Adjustments

Any therapeutic approach to mood disorders should seek to reverse unhealthy or destructive lifestyle habits and consider other activities that may relieve stress and facilitate well-being. Alcohol, recreational drug use, and excessive caffeine consumption should be minimized (if not prohibited) in patients suffering from depression or anxiety disorders. Sleep habits should be evaluated and improved to ensure optimal rest. This also promotes the restoration of normal physiological and immunologic processes that can ward off chronic illness. Dietary factors should be modified to promote diverse, balanced, and nutritional eating habits.

Increased physical activity and sustained cardiovascular exertion can impart a variety of health benefits, as well as relief from mood disorders. Although investigations examining the effectiveness of exercise for clinical depression have met with mixed results, exercise can certainly regulate appetite, improve sleep patterns, increase energy, enhance self-esteem, and indicate a return to euthymic status.⁶⁷ Exercise has been shown to increase circulating concentrations of serotonin in the periphery and enhance neurogenesis in the hippocampus.⁶⁸ Other activities may also serve to relieve stress and help patients develop insights into their emotional well-being. These pursuits can range from daily journal writing (or “journaling”), to prayer or meditation, to yoga and tai chi. Classes in mindfulness-based meditation, in particular, are now being offered at many medical centers, and the health benefits of this approach have been

demonstrated in a wide range of medical conditions (e.g., cancer, chronic pain syndromes, HIV illness).⁶⁹ Certain herbal remedies may also be effective and are discussed in Chapter 3.

MAJOR DEPRESSIVE DISORDER

Diagnosis

1. A.R. is a 25-year-old woman who presents to the student health clinic for a routine physical examination. During her visit, A.R. states, “I’ve been feeling pretty down lately and just want to give up.” Her physical examination is unremarkable, and all laboratory tests (complete blood count with differential, chemistry panel, and thyroid function tests) are within normal limits. A human chorionic gonadotropin test is negative. Her medical history is noncontributory, the only prescription medication she has received is an oral contraceptive (which she has taken faithfully for the past 6 months), and she denies drinking alcohol or using other recreational substances.

When asked, A.R. states that she has had increasing periods of depressed mood over the past few months and often finds herself crying in the morning for no particular reason. She reports that she has no interest in her old hobbies (playing the piano, mountain biking, gardening). She is engaged to be married in 3 months but feels that she does not deserve to be a wife. Over the past 2 months, her appetite has decreased, and she has lost 15 lb. She feels overwhelmed about all of the plans that she needs to make for her wedding (“I don’t even deserve a wedding this nice”) and has difficulty sleeping, often waking in the middle of the night and being unable to fall back asleep. She has no energy during the day and finds it difficult to concentrate or make decisions. This is a major concern because she is a graduate student at the local university.

The mental status examination reveals an appropriately dressed female who appears sad but who is alert, coherent, and logical. Her affect is constricted, apprehensive, and sad. Mood is depressed, and she admits having suicidal ideation but no specific plans. She is oriented to person, place, and time but shows some recent memory deficits. Her intelligence is estimated to be above average. Concentration and abstractions (e.g., “don’t cry over spilled milk,” “a rolling stone gathers no moss”) are satisfactory. She denies hearing voices or other hallucinations. She has good insight and judgment into her illness. What signs and symptoms does A.R. have that support the diagnosis of major depressive disorder?

The target symptoms of depression are listed in Table 79-9 and can be recalled by the mnemonic D-SIG-E-CAPS or DIG-SPACES. Based on A.R.’s history, she describes a dysphoric or depressed mood as well as anhedonia (lack of interest in hob-

bies or pleasurable activities). In addition, she demonstrates frequent episodes of crying, decreased appetite (with an unintentional 15-lb weight loss), poor concentration, low energy, suicidal ideation, worthlessness, and inappropriate guilt. Her mental status examination is consistent with these target symptoms, revealing a constricted, sad affect (physical manifestation of inner emotional states) and frequent crying episodes during the interview.

Based on the DSM-IV-TR criteria, A.R. has major depressive disorder. Over the past 2 weeks, she has consistently exhibited at least five of the associated symptoms, one of which is depression or anhedonia. It does not appear that her symptoms are the result of any medical condition, medication, thought disorder, or uncomplicated bereavement. The anhedonia and vegetative symptoms (e.g., midnocturnal insomnia, decreased appetite, weight loss) are consistent with the depressive subtype of melancholia.

Suicide Assessment

2. What is the risk of A.R. hurting herself? How should suicidal ideation be assessed?

Patients with major depression should always be assessed for the presence of suicidal thoughts (e.g., “Do you ever feel like giving up?”, “Are you thinking about hurting yourself?”). Suicide is viewed by the depressed patient as a remedy to insurmountable problems when all other options appear hopeless. Comments made by the patients alluding to suicide (e.g., “Life is not worth living anymore,” “I am leaving and may never see you again”) should be taken seriously. Misunderstandings about suicidal ideation abound in the general public. Common myths include the ideas that people are more likely to commit suicide if asked about it, that people who attempt suicide are just looking for attention, or that suicide is usually attempted after a sudden traumatic event.

Several factors may place a person at greater risk for a suicide attempt. A detailed plan, for instance, suggests a serious intent and a higher risk for successful suicide. The clinician should be concerned if a change takes place in A.R.’s personality (e.g., giving away possessions, making a will, purchasing a firearm, asking about the lethal dose of medications). Other risks for suicide include living alone, having a physical illness, being unemployed, being 15 to 24 years of age or older than 65 years of age, having a history of alcohol/drug abuse, or having a family history of suicide.⁷⁰ Gender plays a role as well, with women much more likely to attempt suicide, while men are more often successful.

The management of patients who are potentially suicidal depends on the attendant risk, incorporating many of the

Table 79-9 Depressive Disorder Target Symptom Mnemonic

| D | SIG | E | CAPS |
|----------------|--|-------------|---|
| Depressed mood | Sleep (insomnia or hypersomnia) Interest (loss of, including libido) Guilt | Energy loss | Concentration (loss) Appetite (loss or gain) Psychomotor (agitation or retardation) Suicide (ideation) |

From ref. 67.

factors just cited. For patients who are actively suicidal, hospitalization is often necessary and may even be facilitated against the patient's will in high-risk settings. Other life-saving interventions include establishing close contact with the patient's family and health care provider, convincing the patient to contract for his or her safety, ensuring that firearms and other lethal means are removed from the home, and avoiding antidepressants with a narrow therapeutic index (e.g., tricyclic antidepressants [TCAs]) or limiting the dispensed quantity to <10 days. Depressed patients surface in any health care environment, so all clinicians should have an emergency hotline or crisis telephone number at their disposal.

A.R. is at some risk for suicide, although she does not have a detailed plan at present. She should be monitored closely during the first few weeks of therapy by friends or family members. If her suicidal ideation becomes severe, A.R. should be admitted to a facility for her own safety. Unfortunately, it is not always possible to predict whether A.R. (or any depressed patient) will attempt to commit suicide. Even with the most conservative precautions, a small percentage of patients succeed in their suicide attempts.

DRUG MANAGEMENT

Drug Selection: General Considerations

3. A.R. is diagnosed as follows: Axis I—major depressive disorder, single episode, with melancholic features; Axis II—none; and Axis III—none. What drug options are available for A.R.'s depressive symptoms? What considerations should be made when selecting antidepressant therapy?

At present, 23 medications have received FDA approval in the United States for the treatment of depression. They can be conveniently grouped into six categories:

1. SSRIs
2. Serotonin norepinephrine reuptake inhibitors (SNRIs)
3. Norepinephrine reuptake inhibitors (NRIs)
4. TCAs
5. Monoamine oxidase inhibitors (MAOIs)
6. Miscellaneous (e.g., trazodone, mirtazapine)

All available antidepressants are equally effective in the general depressed patient population, and all appear to have the same delayed onset of therapeutic effects. Historically, it has been reported that 65% to 70% of patients given a therapeutic trial of an antidepressant will have a positive response (therapeutic response traditionally defined as a $\geq 50\%$ drop in depression rating scores), and 35% to 40% achieving remission (i.e., virtual absence of symptoms).⁷¹ These treatment effects, however, were usually measured in randomized controlled trials (RCTs) among patients with minimal comorbidity who were exhibiting moderate-to-severe psychopathology. Recent efforts have been made to examine these response patterns under less rigidly controlled conditions (i.e., more naturalistic studies). Most notably, a series of investigations that came to be known as the STAR*D (Sequenced Treatment Alternatives to Relieve Depression) trials enrolled nearly 3,000 patients from primary care clinics and mental health centers across the United States in an effort to determine the effectiveness of first-line treatments, as well as second-line agents and augmentation

Table 79-10 Factors to Consider in Selecting an Antidepressant

- History of prior response (personal or family member)
- Safety in overdose
- Adverse effect profiles
- Patient age
- Concurrent medical/psychiatric conditions
- Concurrent medications (e.g., potential for drug interactions)
- Convenience (e.g., minimal titration, once-daily dosing)
- Cost
- Patient preference

strategies.⁷² All eligible patients received a relatively rigorous course of citalopram (average dose = 41.8 mg daily), and the results suggested that response rates are closer to 50% and remission is achieved in 30% of patients treated under “real world” conditions.

Because the response rates for all currently available antidepressants are comparable, other important considerations should influence decision making (Tables 79-10–79-13). The first factor to consider is the patient's history of previous response. If this history is unavailable (or the patient has never received an antidepressant before), the clinician should inquire about family history. If a first-degree relative had a successful course of antidepressant treatment with minimal adverse effects, that specific medication (or another from the same antidepressant class) would be a prudent choice for initiating therapy.

The potential impact of an antidepressant on concurrent medical conditions or disease states is often considered next. For example, certain antidepressants (e.g., TCA, paroxetine, mirtazapine) are associated with significant weight gain and would not be desirable choices for obese patients. Similarly, bupropion should be avoided in patients with a history of seizures, and venlafaxine may not be ideal for patients with hypertension.

Many clinicians select an antidepressant by matching the patient's presenting symptoms to the side effect profile of antidepressant medications. For example, if a depressed patient is sleeping and eating excessively, and possesses little energy or motivation, the clinician may choose an agent that will address these baseline symptoms, perhaps through the enhancement of noradrenergic transmission (e.g., bupropion). Patients with substantial anxiety or irritability may benefit preferentially from antidepressants that facilitate serotonergic transmission (e.g., SSRI) because nearly 50% of patients with major depression are believed to be suffering from a concurrent anxiety disorder. Conversely, some clinicians argue that if an antidepressant is clinically effective, it will relieve all target symptoms eventually, regardless of the adverse effect profile. Nonetheless, tailoring antidepressant medications to a patient's presentation is a common practice that may minimize the initial side effect burden and promote adherence.

Other important patient-specific factors to consider in the selection of an agent include safety in overdose, potential for drug interactions, ease of administration (once daily vs. divided doses), necessity of titration practices, cost (to the patient/institution), and patient preference.

Because A.R. is a student, the clinician may want to select an antidepressant that has minimal effects on alertness or cognitive function, such as an SSRI or bupropion. Of these

Table 79-11 Pharmacology of Antidepressant Medications

| Medication | Serotonin | Norepinephrine | Dopamine | Bioavailability (Oral) | Protein Binding | Half-Life (in hours) (Active Metabolite) |

0, negligible; +, very low; ++, low; +++, moderate; +++++, high.

two options, an SSRI may be preferred for A.R. because she is experiencing a significant decrease in appetite and insomnia, which may be exacerbated with bupropion.

Response Rates of Target Symptoms

4. A.R. is given a prescription for sertraline 50-mg tablets. She is instructed to take a half tablet (25 mg) for the first week and increase to a whole tablet daily thereafter. She is also asked to return to the clinic in 4 weeks for follow-up. How soon should A.R.'s target symptoms begin to resolve?

A similar delayed pattern of therapeutic response has been observed with all antidepressant medications. Traditionally, patients have been informed that approximately 4 to 6 weeks must elapse before they will experience any therapeutic benefit from medication. However, researchers in the field consider this a conservative estimate, gleaned from standard drug efficacy studies ill suited to answer this question.⁷³ In such studies, patients will begin to show signs of clinical response during the first 1 or 2 weeks of active treatment, but because the difference from placebo is assessed every 7 days and will not ordinarily achieve statistical significance until the third or fourth week, these early response patterns are misinterpreted to suggest that it may take a month or more for patients to improve. Some experts have contended, in fact, that trials uniquely designed to investigate the onset of therapeutic effect will conclusively

show that patients exhibit substantial improvement during the first 2 weeks of treatment, and *maximum* improvement may not be evident for 4 weeks or more.⁷⁴

The *pattern* of patient response can also be generalized, with neurovegetative symptoms often the first to subside (e.g., altered sleep or appetite, decreased energy, excessive worrying and irritability). The cognitive symptoms are slower to respond, and 3 to 4 weeks or more may elapse before improvements are evident. These symptoms include excessive guilt or pessimism, poor concentration, hopelessness or sadness, and decreased libido.

A.R. should be counseled concerning this anticipated delay in therapeutic response and advised that optimal improvement may take at least 4 weeks. If she is not aware of this time frame, she may stop the medication prematurely, prolonging her distress and further delaying the recovery process.

Selective Serotonin Reuptake Inhibitors

Adverse Effects

5. What are the most common side effects reported with SSRIs, and how should they be managed?

Although it is not accurate to say that SSRIs (or SNRIs) cause fewer side effects than TCAs, the adverse effects associated with these newer antidepressant classes are generally milder and less likely to lead to discontinuation.⁷⁵ There are

Table 79-12 Adverse Effects of Antidepressant Medications

also generally fewer concerns with SSRI (or SNRI) and comorbid illnesses than one encounters with TCAs, suggesting that SSRIs may often be a better choice in medically complex patients.

As clinical experience accumulates with the SSRI (and SNRI) agents, a distinct side effect profile has emerged, consisting of gastrointestinal (GI) complaints, CNS disturbances, and sexual dysfunction. All these medications may induce nausea, but this tends to be a transient effect that diminishes after the first week of treatment. Typically, the SSRI can cause some local GI irritation 1 to 2 hours after oral administration. For this reason, patients should always be advised to take the medication after a meal or snack, particularly during the first week of therapy. Nausea with SSRIs may also be mediated centrally through the stimulation of certain serotonin receptors (5-HT_{3C}) that activate the chemoreceptor trigger zone.⁷⁶ Nausea triggered by this mechanism has a more delayed onset, corresponding to the accumulation of medication until steady-state dynamics are reached, and often persists throughout the dosing interval. Patients who experience nausea mediated by CNS stimulation may be unable to tolerate this effect and often require dosage reduction or drug discontinuation.

SSRIs may also have transient and bothersome effects on bowel function. Unlike nausea, there does appear to be clinically relevant differences among SSRIs in this regard. Sertraline, fluoxetine, and citalopram have been associated with a 15% to 20% incidence of diarrhea.⁷⁷ Fortunately, the diar-

rhea often remits after 1 week or so of continued therapy and rarely requires an interruption of treatment. In contrast, paroxetine possesses a mild affinity for blocking muscarinic receptors that can manifest as anticholinergic side effects, such as constipation, dry mouth, or urinary hesitancy. This may discourage the use of paroxetine in patients with pre-existing constipation or those receiving other medications with anticholinergic potential.

SSRIs can have myriad effects on the CNS, with disturbances in sleep or disposition being a primary concern. Overall, the SSRIs appear to have significant but highly variable effects on sleep architecture. For example, in sleep studies, SSRIs have been shown to increase sleep latency and decrease sleep efficiency, often resulting in morning sleepiness or malaise. Many patients also notice that their dreams become more vivid and memorable, which is not always a desirable experience, and may prolong the REM stage, resulting in less fitful sleep.⁷⁸ It should be emphasized, however, that sleep may actually improve once the antidepressant properties of the medications are apparent and baseline depressive symptoms are relieved (e.g., midnocturnal insomnia).

Compared with older antidepressants, SSRIs are generally considered activating compounds, and there does appear to be a hierarchy among the individual agents. Fluoxetine, for example, is widely regarded as the most activating of the SSRIs, a property that may be desirable in anergic patients or undesirable in those who are agitated or have difficulty falling asleep.⁷⁹

Table 79-13 Dosage Ranges and Costs of Antidepressant Medications

| Medication | Brand Name | Starting Dose (mg/day) | Maximum Dosage (mg/day) | Usual Dosage (mg/day) | Relative Cost ^a |

For this reason, fluoxetine is usually administered in the morning after breakfast. However, it should be noted that fluoxetine is not necessarily activating for all patients. In fact, some find it to be slightly sedating or numbing. Daytime drowsiness can be experienced with fluoxetine, perhaps as a result of light, restless sleep. Sertraline, escitalopram, and citalopram have also been associated with comparatively more insomnia than sedation, but they are generally considered to be less activating than fluoxetine in this regard. The effects of paroxetine appear to be somewhat mixed, with approximately equal proportions of patients complaining of sedation and insomnia, respectively.

Another type of CNS side effect reported with SSRIs involves the extrapyramidal system. SSRIs have been associated with extrapyramidal side effects (EPS), consisting of akathisia, dystonias, and parkinsonian symptoms that are qualitatively identical to those commonly seen with high-potency antipsychotics. Fortunately, the reported incidence of EPS effects is much lower than with antipsychotic agents.⁸⁰ Although EPS reactions have been documented with all SSRIs, most case reports have featured paroxetine. Because paroxetine has the highest affinity for serotonin receptors, this may lend support to the theory that these EPS effects are mediated through the indirect influence of serotonergic neurons on dopaminergic activity. In certain areas of the brain, serotonin and dopamine appear to have an inverse relationship, whereby central stimulation of serotonin receptors results in a net decline in dopaminergic transmission. Therefore, management of EPS effects induced

by SSRI is identical with that of those precipitated by antipsychotics. Dystonias and parkinsonian side effects can be treated with anticholinergic agents and subsequent dosage reduction. Akathisia usually responds to a dosage decrease and/or administration of low-dose β -blockers.

The deleterious effects of SSRI on sexual function were overlooked in early clinical trials, but it is now widely recognized that these adverse effects are very common and potentially profound consequences of SSRI treatment that can often lead to medication nonadherence.⁸¹ In the medical literature, the reported incidence of sexual dysfunction ranges from 1.9% to 75%, reflecting the diversity of research methods (or lack thereof) used to detect this occurrence.^{82,83} The actual incidence of SSRI-induced sexual dysfunction is approximately 30% to 50%, and it appears to be slightly more common in men, but the severity may be worse in women. Delayed orgasm is the most common sexual complaint attributed to SSRIs or SNRIs, and should be distinguished from decreases in desire or libido, which are considered to be an aspect of the psychopathology of depression itself. This iatrogenic effect on orgasms has actually been used to clinical advantage in men reporting premature ejaculation, but most patients find it undesirable.⁸⁴ All SSRIs are commonly implicated with sexual dysfunction, but there are several indirect lines of evidence suggesting that paroxetine and fluoxetine are the worst in this regard.^{85,86} It also appears that this is a dose-dependent phenomenon, which may respond favorably to a decrease in daily dosage. Unlike the GI

and CNS side effects reported with SSRIs, sexual dysfunction is not usually a transient adverse effect and must be addressed by clinicians if patients are to complete a full course of therapy.

6. Are there any other adverse effects of SSRIs about which A.R. should be aware?

In addition to GI, CNS, and sexual side effects, a variety of other, less common, adverse sequelae may jeopardize treatment. Dry mouth and headache occur with many antidepressants, and, although these somatic complaints are prevalent in the general population, placebo-adjusted rates suggest that SSRIs may induce this phenomenon.⁷⁷ Increased sweating has also been reported with SSRIs and can be particularly uncomfortable or embarrassing.⁸⁷ Dosage reduction may help relieve this adverse effect, and alpha-blockers (e.g., terazosin, prazosin) and anticholinergic antidotes have been used as well (e.g., benztropine or low-dose TCA at bedtime).^{88,89} Bruxism, or teeth grinding, can also be an unfortunate consequence of SSRI treatment, leading to chipped or cracked teeth and generally poor dentition.⁹⁰ Often, patients may not be aware of this nocturnal effect and complain merely of a dull, persistent headache during the morning hours. This, too, may be a dose-dependent side effect of all SSRIs, and several antidotes have been prescribed (e.g., buspirone, benzodiazepines, gabapentin).^{91,92} In small retrospective studies and several case reports, SSRIs have been linked to dilutional hyponatremia or syndrome of inappropriate antidiuretic hormone.^{93,94} All SSRIs (and venlafaxine) have been associated with this phenomenon, and elderly patients appear to be uniquely at risk.

The long-term effects of SSRIs on body weight are more variable and difficult to predict. It is worthwhile to recall that decreased appetite is one of the most common depressive symptoms and that a small weight gain after an antidepressant course may actually be viewed as a therapeutic effect of successful treatment. Early reports of weight loss with fluoxetine generated much optimism for the use of SSRI in obesity, but longitudinal studies found this to be a brief, transient phenomenon.⁹⁵ All SSRIs have been implicated with significant weight gain after long-term use, but it is relatively rare phenomenon believed to be mediated by genetic markers that have not been conclusively identified. The exception is with paroxetine, which has been implicated much more often than other SSRIs. One long-term RCT compared the effects of fluoxetine, sertraline, and paroxetine on total body weight.⁹⁶ After 7 months of SSRI use, 25% of the patients receiving paroxetine gained a clinically significant amount of weight (defined as a >7% increase in total body weight) compared with 7% with fluoxetine and 4% with sertraline. Long-term studies with citalopram and escitalopram suggest that 3% to 5% of patients will experience a significant weight gain. Because weight gain may occur with any SSRI, it is best to monitor weight changes closely during long-term treatment and respond accordingly.

Retrospective studies have also linked SSRI with an increased risk for severe GI bleeds.⁹⁷ This has been attributed to the SSRI effects on decreasing platelet activation and aggregation. Interestingly, these pharmacologic properties may also confer a therapeutic advantage, as longitudinal studies have suggested that SSRI may be cardioprotective and prevent future MI. Because the bulk of evidence addressing SSRI effects on GI bleeds and MI has been inferred from nonrandomized

retrospective studies that may be strongly influenced by other confounding factors (e.g., lifestyle habits, depression itself), future prospective trials are clearly indicated.

Dosage Titration

7. A.R. calls the clinic 2 weeks later requesting a dosage increase. She reports that she has been taking 50 mg of sertraline every morning for the past week and has noticed considerable improvement in her sleep, appetite, and outlook (“Little things don’t bother me so much anymore”), but believes she could be doing better. She still feels as though her mood and concentration could improve, and admits that she has yet to resume her exercise regimen (“I still don’t have the energy”). She asks you if she could increase her dosage. What changes would you make to her antidepressant regimen at this time?

It is very important to establish realistic expectations for treatment with antidepressants from the very beginning of therapy. Patients need to be informed of the anticipated course of antidepressant treatment and should be advised, for instance, that the onset of side effects usually precedes that of therapeutic effects. Also, patients should be advised that, although antidepressants may relieve their acute symptoms and prevent relapse, they do not abolish environmental stressors, increase self-esteem, or reverse negative perceptions and emotions.

Dosing and prescribing patterns with SSRI have changed since the first SSRI (fluoxetine) was introduced in the United States in 1988. In general, clinicians have come to realize that “one size fits all” prescribing philosophies and early aggressive dosing practices were largely unnecessary and often compromised medication adherence. Providers have found, in fact, that lower dosages of SSRIs may actually suffice (e.g., 10 mg/day of fluoxetine, paroxetine, or citalopram) if patients are informed of the delayed onset of therapeutic effects and are closely monitored for tolerance and response. Because preclinical fixed-dose studies were rarely conducted with these lower dosages, it is difficult to endorse this practice empirically. However, there is experimental evidence demonstrating that daily doses as small as 5 mg of fluoxetine are more effective than placebo and comparable to 20 mg in a significant segment of the depressed populace.⁹⁸

For A.R., many factors must be considered before increasing her dosage. She has been receiving the medication for only 2 weeks (25 mg daily for 1 week, 50 mg daily thereafter), and the improvement she is exhibiting in neurovegetative symptoms may suggest that the resolution of cognitive symptoms is soon to follow. She should be reminded that the optimal effects of antidepressants may not be evident for 4 to 6 weeks. Furthermore, it is possible that the lack of improvement in her concentration and energy may be largely situational as the day of her wedding approaches. An increase in medication at this time would not necessarily address these environmental factors and would serve only to increase the side effect burden. Therefore, a reasonable recommendation would be to continue with the current daily dose of 50 mg and to re-evaluate the medication’s effects when she returns to clinic in 2 weeks.

8. At the end of 4 weeks of treatment, A.R. is seen in the clinic and asked about side effects she has experienced. She recalls some mild nausea during the first week of treatment but continued to take the medication after breakfast (as directed) and noticed that

Table 79-14 Management of SSRI-Induced Sexual Dysfunction

- Patience (may improve after 2–4 weeks)
- Reduced dosage (if possible)
- Drug holidays (sertraline, paroxetine, citalopram, escitalopram *only*)
- Antidotes
 - Bupropion SR 150 mg QD–BID
 - Sildenafil 50–100 mg QD PRN
 - Mirtazapine 7.5–15 mg HS
 - Cyproheptadine 4–12 mg PRN (1 hour prior)
 - Methylphenidate 2.5–5.0 mg QD
 - Others: yohimbine, amantadine, buspirone, ginkgo
- Change of antidepressants (e.g., bupropion, mirtazapine)

this effect went away after approximately 3 or 4 days of therapy. She denies diarrhea, insomnia, or headache. Before leaving, she reluctantly admits that the only side effect she is experiencing is sexual. (“I love my fiancée, but sex isn’t as enjoyable anymore.”) How should this side effect be managed at this time?

From a clinician’s standpoint, the detection and proper management of SSRI-induced sexual dysfunction can be one of the most important factors in ensuring medication adherence (Table 79-14). Clinicians may be uncomfortable asking patients about their sexual activities and satisfaction, but the high incidence of this side effect (and low likelihood of patients volunteering information) necessitates a thoughtful and direct approach. Some patients acknowledge sexual dysfunction but decide that the improvement in their mood and overall health outweighs limitations in sexual performance; however, many others simply stop the medication if the side effect is never addressed.

It may be wise to advise patients that sexual function may change over time, depending on the type and etiology of sexual dysfunction experienced. Depression itself is associated with a decreased libido in 70% to 90% of untreated patients.⁹⁹ This symptom will most likely subside with a successful course of antidepressant treatment. Delayed ejaculation or anorgasmia, however, is usually an iatrogenic phenomenon with SSRIs and SNRIs, often persisting and jeopardizing treatment. Because A.R. has been taking the medication faithfully for the first 4 weeks and the time course is consistent with the SSRI effects, it is unlikely that the condition will spontaneously remit now, and some action must be taken.

Ordinarily, one of the first options in managing sexual dysfunction is to reduce the dosage, but this may precipitate a recrudescence of the original depressive symptoms in some patients. In A.R.’s case, she is taking a relatively low therapeutic dosage of sertraline, and a further decrease may be a risky proposition. An alternative solution for A.R.’s problem may be to recommend drug holidays. Small open-label studies with short-acting SSRIs (e.g., sertraline, paroxetine) suggested that if patients skipped their doses on Friday and Saturday, sexual function would return to normal on the weekends.^{100,101} Although this method was reported to be successful, it may also promote nonadherence with medication and lead to increased risk of relapse or withdrawal symptoms.

If the patient has had a therapeutic response to the antidepressant, the next option in this setting is to consider antidotes to SSRI-induced sexual dysfunction, and the most popular treatment at present is bupropion. Clinical reports and

controlled investigations suggest that the addition of this antidepressant can be helpful for restoring sexual desire and may relieve delayed orgasm or anorgasmia in approximately 50% of patients.^{102–104} This therapeutic effect has been demonstrated in depressed and nondepressed patients alike. A common dosing technique is to start with 150 mg of bupropion daily. If unsuccessful, the dose can be increased to 150 mg SR twice daily after several days (or 300 mg of the XL preparation).

From a mechanistic standpoint, sexual arousal and orgasm constitute a complex physiological process, and it is not well understood how SSRIs induce adverse effects or how bupropion may provide relief. Some researchers have theorized that delayed ejaculation or orgasm is mediated by a stimulation of postsynaptic 5-HT₂ or 5-HT₃ receptors, whereas others suggest that the indirect effects of SSRIs on dopamine may be involved.¹⁰⁵ Additional theories point to the inhibitory effects of SSRIs on prolactin or nitric oxide synthetase.¹⁰⁵

Other remedies have been prescribed for SSRI-induced sexual dysfunction. A large randomized, controlled trial examined the impact of sildenafil on male patients suffering from this side effect.¹⁰⁶ Overall, 54% of patients randomized to sildenafil found it to be effective compared with a 4% response rate with placebo. Open-label trials of sildenafil in women experiencing SSRI-induced anorgasmia have also reported improvements, suggesting that controlled trials in this population are warranted.

Cyproheptadine is an obscure antihistamine with potent antiserotonergic properties, which has also received some attention as a potential antidote. It has been used successfully for the treatment of SSRI-induced sexual dysfunction in doses of 4 to 12 mg just before intercourse.¹⁰⁷ Unfortunately, cyproheptadine is sedating and appears to have a limited role in this capacity. If it is used, one should never administer the medication on a routine or daily basis because reports of relapse in depressed patients have surfaced. Amantadine, buspirone, and yohimbine have also been used successfully to reverse delayed ejaculation or decreased libido, but the evidence for efficacy is rather limited.^{108–110} One small double-blind study compared the effects of amantadine with buspirone or placebo among depressed patients developing sexual dysfunction on antidepressants.¹¹¹ All three treatments improved sexual dysfunction to a comparable extent, and the only statistically significant finding was related to an increase in energy reported among patients receiving amantadine (vs. placebo). An open-label trial of *Ginkgo biloba* in men and women with sexual dysfunction reported very high success rates, but mixed results have been experienced in actual practice.¹¹² Mirtazapine is capable of blocking postsynaptic 5-HT₂ receptors and theoretically may relieve ejaculatory difficulties, but controlled trials have not been conducted. Finally, stimulants such as methylphenidate or dextroamphetamine may increase libido in SSRI-treated patients, but the potential for dependence and abuse discourages their routine administration.¹¹³

The onset of A.R.’s sexual dysfunction is consistent with the introduction of sertraline, and it appears, at this time, that her situation will not improve if she continues to take the SSRI. Because she is exhibiting some evidence of a therapeutic response, one would prefer to continue sertraline and discuss possible antidotes for sexual dysfunction with her. A.R. states that she would prefer to not start another prescription medication to treat her problem, but she will “think about it.”

Table 79-15 Duration of Antidepressant Treatment

| | |
|-------------------------------|----------|
| Acute treatment phase: | 3 mo |
| Continuation treatment phase: | 4–9 mo |
| Maintenance treatment phase: | Variable |

- Acute and continuation treatment recommended for all patients with major depressive disorder (i.e., minimal duration of treatment = 7 mo)
- Decision to prescribe maintenance treatment is based on the following.
 - Number of previous episodes
 - Severity of previous episodes
 - Family history of depression
 - Patient age (worse prognosis if elderly)
 - Response to antidepressant
 - Persistence of environmental stressors
- Indefinite maintenance treatment is recommended if any one of the following criteria are met.
 1. Three or more previous episodes (regardless of age)
 2. Two or more previous episodes and age older than 50 yr
 3. One or more and age older than 60 yr

Duration of Treatment

9. At 6 weeks, A.R. reports that her depressive symptoms are effectively in remission (“I feel like I have my old life back!”). Her energy has improved, and she is doing well in her studies and looks forward, once again, to her wedding day. How long should A.R. continue taking the antidepressant?

According to the guidelines issued by the Agency for Health Research and Quality (formerly known as the Agency for Health Care Policy and Research), antidepressant treatment can be broken down into three stages (Table 79-15).¹¹⁴ The first stage, *acute treatment*, lasts approximately 12 weeks; during this time, the clinician attempts to resolve the presenting symptoms and induce remission. The second stage is commonly called *continuation treatment* because the patient continues to receive the same antidepressant regimen that induced the initial treatment response, and the clinician attempts to keep the acute symptoms in remission. The duration of continuation treatment is variable (4–9 months after initial treatment or response), but it is recommended that all patients suffering from major depression complete these first two stages. Therefore, the minimum duration of treatment is 7 months. Alternatively, others have advocated that the minimum duration of treatment should be for 6 months after the complete resolution of symptoms.

The third stage of treatment, *maintenance treatment* or prophylaxis, is not indicated for all patients, and the necessity of continuing medication beyond the first 6 to 7 months depends on many patient-specific factors. One must consider the number of previous episodes, family history of depression, patient’s age, severity of presenting symptoms, response to therapy, and persistence or anticipation of environmental stressors. There are specific populations for whom indefinite pharmacologic treatment is advocated: (a) individuals with three or more previous episodes of major depression, (b) individuals older than 50 years with two or more previous episodes, and (c) individuals older than 60 years with one or more previous episodes.¹¹⁴ Many experts believe that pharmacotherapy should also be continued indefinitely in all elderly people (older than 65 years) suffering from major depression, but research evi-

Table 79-16 Discontinuation of Antidepressants

| |
|---|
| Withdrawal syndrome |
| • Worse with paroxetine, venlafaxine |
| • Symptoms: dizziness, nausea, paresthesias, anxiety/insomnia, flulike symptoms |
| • Onset: 36–72 hr |
| • Duration: 3–7 days |
| Taper schedule (for patients receiving long-term treatment) |
| • Fluoxetine: generally unnecessary |
| • Sertraline: decrease by 25–50 mg every 1–2 wk |
| • Paroxetine: decrease by 5–10 mg every 1–2 wk |
| • Citalopram: decrease by 5–10 mg every 1–2 wk |
| • Escitalopram: decrease by 5 mg every 1–2 wk |
| • Venlafaxine: decrease by 25–50 mg every 1–2 wk |
| • Nefazodone: decrease by 50–100 mg every 1–2 wk |
| • Bupropion: generally unnecessary |
| • Tricyclics: decrease by 10%–25% every 1–2 wk |

Note: Risk of relapse greatest 1 to 6 months after discontinuation.

dence to conclusively support this recommendation is currently lacking.¹¹⁵

Because A.R. is exhibiting a full therapeutic response to sertraline, the recommendation would be for her to continue with the effective dosage (50 mg/day) for at least 7 consecutive months. At the end of this time frame, the clinician should sit down with the patient and review the considerations that enter into the decision to continue treatment. Ultimately, the decision to continue antidepressant medications is left to the patient’s judgment, and he or she should be well informed of the potential consequences of stopping treatment.

In the future, if A.R. decides to discontinue her antidepressant, she should be advised of potential withdrawal symptoms (Table 79-16). Abrupt discontinuation of chronic SSRI treatment (e.g., treatment >2 months) has been associated with dizziness, headache, anxiety, flulike symptoms, and paresthesias.¹¹⁶ The onset of these symptoms is generally within 48 to 72 hours of stopping treatment, and effects may persist for at least 1 week. Withdrawal symptoms generally are mild and self-limiting but can be uncomfortable and alarming. Because of their relatively short half-life (and absence of long-acting metabolites), paroxetine, fluvoxamine, and venlafaxine have been associated with a more profound withdrawal presentation than other SSRIs and SNRIs. Due to its long-half life (and that of its active metabolite), fluoxetine has not been commonly associated with withdrawal symptoms. Nonetheless, one is best advised to taper slowly off all antidepressant medications after an extended treatment course.

After A.R. has completed a full course of pharmacotherapy, it is advisable to taper her sertraline over several weeks to minimize the risk of withdrawal, as well as to monitor for signs and symptoms of relapse (e.g., decrease to 25 mg daily for 2–4 weeks, then discontinue). The risk of relapse is relatively low during the first month off medication, and depressive symptoms often return during the second or third months. The risk of relapse is highest during the first 6 months overall.¹¹⁷

Antidepressants in Pregnancy and Lactation

10. Eight months after starting her antidepressant, A.R. reports that she has continued to be symptom free and is now living

happily with her husband. She has taken the sertraline faithfully each morning and is willing to do so for as long as it is prescribed (“I don’t ever want to go through that again!”). She also reveals that she and her husband are thinking of stopping her birth control pills for the purpose of starting a family. She asks if it is necessary to continue the antidepressant through her pregnancy. How should A.R. and her husband be counseled at this time?

The risk for depression is substantial during pregnancy and during the postpartum period.¹¹⁸ Historically, patients have been informed that pregnancy is relatively protective in regard to depression, but more recent evidence does not support this perception.¹¹⁹ A recent prospective investigation reported that women who discontinued their antidepressant on learning they were pregnant were much more likely to relapse prior to delivery (68% relapse rate vs. 26% who continued treatment; hazard ratio = 5.0).¹²⁰

Before deciding to treat with an antidepressant during pregnancy, one should make a careful inventory of the benefits and risks. The consequences of maternal depression on the mother and fetus must be compared with the potential risks of in utero medication exposure (i.e., teratogenicity, growth impairment, other adverse birth outcomes). From the mother’s perspective, untreated depression carries with it a great deal of distress during an emotional time. Sleep and appetite may be compromised at a time when these functions are most important for the baby’s development. Mothers may also be tempted to drink alcohol or abuse substances, and studies have also shown that depressed mothers are much less likely to attend prenatal clinic visits. Depression during pregnancy is a very strong risk factor for postpartum depression as well. Neonatal studies have shown that infants of mothers who became depressed during pregnancy were smaller at birth, had lower Apgar scores, and experienced more irritability and emotional problems.¹²¹ Abnormal activation along the HPA axis has also been demonstrated among infants born to mothers who were depressed during pregnancy, and other factors suggesting enhanced susceptibility to depression later in life may be engendered as well.

The attendant effects of antidepressants on the developing fetus have been difficult to predict or quantify. For obvious reasons, RCTs of potential teratogens are seldom conducted in expectant mothers, so study methods to assess fetal risk are less than ideal, and recommendations may change in coming years with subsequent investigations.

At the present time, it is believed that most of the SSRIs and newer antidepressants pose little risk for the development of serious fetal malformations, and they have been subsequently categorized as Class C by the FDA (suggesting that the risk to the fetus is not definitively known). Their relative safety has been corroborated recently by two large case-control studies published in the *New England Journal of Medicine*, where a very small increase in risks was reported.^{122,123} One notable exception to the SSRI safety profile can be found with paroxetine, which was recently reclassified as Class D by the FDA following the demonstration of a sixfold increase in the risk of persistent pulmonary hypertension in newborns.¹²⁴ Interestingly, the FDA also speculated that the benefits of paroxetine to the mother may still outweigh the risks to the developing fetus.

An additional concern with SSRIs and SNRIs in pregnancy can be found in the risk for neonatal withdrawal symptoms im-

mediately after delivery. This has been reported with TCA in the distant past as well. A small controlled investigation ($n = 40$) examined the effects of fluoxetine and citalopram on CNS effects in newborns and found a significant increase in restlessness, tremor, shivering, and hyperreflexia during the first 4 days of life (vs. controls) that spontaneously remitted shortly thereafter.¹²⁵ Although some clinicians have interpreted these findings to suggest that antidepressants should be tapered and discontinued prior to delivery, others have argued that delivery and the postpartum period constitute major stressors for the new mother and the risk of relapse during this time would be unacceptably high if the medication is withdrawn. This same study did not find any substantial difference in birthweight or preterm deliveries, but there was a significant decline in Apgar scores on average. Other studies have also reported a small but significant decrease in birthweight among babies exposed in utero to SSRI (vs. TCA).

The safety of bupropion in pregnancy has also not been extensively studied. A recent review of animal studies uncovered an increased risk of congenital abnormalities, but retrospective reviews in humans have failed to identify an enhanced risk of fetal malformation or spontaneous abortions. Due to these findings in animal trials, however, the FDA recently changed bupropion to a Class C rating. Data are even more sparse with mirtazapine, venlafaxine, or duloxetine, but again no cause for alarm has been identified among infants exposed to these antidepressants in utero. Similarly, fetal malformations have been rarely reported with TCA and they are generally regarded as safe in pregnant women. MAOIs, however, should be avoided due to increased risks for hypertensive crises.

For A.R., it is important to assess her risk for depression if she stops taking her antidepressant. This was her first episode of depression (which occurred under stressful circumstances), and she does not have a strong genetic predisposition to mood disorders. If she is committed to starting a family, she may want to consider being tapered off the sertraline over several weeks just before conception. If she becomes pregnant and her depression returns, the risk to the fetus appears to be quite low with most SSRIs, including sertraline. Theoretically, this risk can be reduced further if the antidepressant is started after the first trimester (when most major fetal development occurs), and lower doses would be prudent as well to minimize fetal exposure.

11. What are the risks of continuing antidepressant medications during breast-feeding?

Approximately 70% of mothers report sadness or anxiety during the first few days after delivery (“baby blues”), but these feelings will usually resolve within 1 to 2 weeks. Approximately 10% of women will develop unremitting symptoms that ultimately satisfy criteria for major depressive disorder. Although psychotherapy may be appealing and obviate the need for medication exposure via breast milk, it is often inconvenient and impractical for new mothers to leave the house on a weekly basis without their infants. Antidepressant medications, therefore, are frequently prescribed to manage postpartum mood disorders.

Because breast-feeding is widely advocated in contemporary medical circles, the passive transfer of medication from mother to infant must be considered. Studies with TCAs and

SSRIs suggest that concentrations of antidepressants in breast milk are *not* negligible. However, subsequent concentrations in the infant's bloodstream are relatively low, and the sequelae from this exposure have been limited to scattered case reports of increased infant irritability. Among the available agents, doxepin and fluoxetine have been associated with the highest concentrations in infants, and although the clinical or developmental consequences of this finding have not been elucidated, it has been recommended that these medications be avoided.¹²⁶ Recent studies with SSRIs suggest that the concentrations achieved in breast milk are lowest with sertraline and that paroxetine, citalopram, and escitalopram are somewhere between the extremes of fluoxetine and sertraline.^{126,127} If an antidepressant is to be continued in a mother who is breast-feeding, the lowest dosage should be prescribed, and the mother may want to take the medication just before the infant's longest sleep period. It may also be useful to note that the concentration of SSRI in breast milk will generally peak approximately 4 to 8 hours after oral administration. If a new mother is particularly concerned about breast milk exposure, she can be advised to pump and save breast milk immediately prior to taking their antidepressant, and pump and dump breast milk (if possible) between the 4- and 8-hour postadministration period.

Drug Interactions

12. A.R. was recently diagnosed with an uncomplicated urinary tract infection and given a prescription for a short course of oral antibiotics. She is not yet pregnant, but has called to ask if there are any drug interactions to be concerned with in regard to her antidepressant (sertraline). What can you tell her?

There is a growing awareness of the potential for certain antidepressants (e.g., certain SSRIs, duloxetine) to inhibit the metabolism of other medications that are cleared through the cytochrome P450 system of isoenzymes (Table 79-17). In general, these drug interactions are concentration dependent and most clinically relevant when the affected medication has a narrow therapeutic index, requires conversion to an active metabolite, or cannot be eliminated through other metabolic routes.¹²⁸ Important examples of affected medications include TCAs, calcium channel blockers, estrogen, theophylline, phenytoin, warfarin, triazolobenzodiazepines, and cisapride.

The SSRIs are potent inhibitors of the cytochrome P450 isoenzymes, but important differences exist among the individual agents in their affinity for the isoenzymes and for the specific metabolic pathways involved (Table 79-17). For instance, the cytochrome P450 1A2 isoenzyme (or CYP 1A2) is most sensitive to the inhibitory effects of fluvoxamine, whereas fluoxetine and paroxetine have the highest affinity for CYP 2D6.¹²⁸ Fluoxetine's active metabolite has moderate inhibitory effects on the CYP 3A4 isoenzyme. In comparison, sertraline, citalopram, and escitalopram have a lower potential for drug interactions but may still inhibit the metabolism of various medications based on the individual circumstances (e.g., high dose, genetic predisposition).^{128–130}

Although *in vitro* affinities of antidepressants for the respective isoenzymes can be very helpful for predicting potentially dangerous drug combinations, there is wide interpatient variability in the susceptibility for these interactions. Much of this

variability can be attributed to genetic polymorphism. With CYP 2D6, for example, approximately 5% to 10% of whites and 1% to 2% of Asians are considered poor metabolizers via this isoenzyme (i.e., possess a nonfunctional variant of the enzyme); and the rest of these respective populations are regarded as extensive metabolizers.¹³¹ However, genetic variation does not explain the unpredictable nature of the situation entirely.

One of the best examples of this variability can be found with desipramine, a secondary amine of the TCAs, which is metabolized almost exclusively through the CYP 2D6 pathway. *In vitro* affinities suggest that paroxetine would have the greatest impact on metabolism occurring via this route, but controlled investigations discovered that fluoxetine increased the plasma desipramine concentrations of adult volunteers by 350%, paroxetine by 125%, and sertraline by 20%.^{132–134} One plausible explanation for this unexpected finding may be that therapeutic doses of fluoxetine are associated with much higher plasma concentrations than other SSRIs because of a smaller first-pass effect. Levels may also be higher at steady state because of the longer plasma half-life of fluoxetine and norfluoxetine compared with other SSRIs. It is also worth mentioning that even though sertraline had less of an impact on desipramine concentrations, two patients experienced a doubling of steady-state desipramine levels, emphasizing the wide variability in patient response.¹³⁴ Other investigations have reported that bupropion increased the area under the curve for desipramine by 500%, duloxetine by 300%, and escitalopram by 100%, respectively.

The CYP 3A4 isoenzyme is actually the most abundant CYP enzyme found in the human body, and it has been estimated that nearly half of all medications prescribed will ultimately undergo metabolic degradation via this isoenzyme. Fortunately, the only two antidepressants that can have significant inhibitory effects on this enzyme are norfluoxetine and fluvoxamine. Serious drug interactions have been mediated through this pathway, the most notable involving cardiotoxicity and malignant ventricular arrhythmias precipitated by elevated concentrations of several medications that have subsequently been withdrawn from the market (terfenadine, astemizole, and cisapride). Another clinically significant interaction may occur when fluoxetine is coadministered with the triazolobenzodiazepines (triazolam, alprazolam, and midazolam). Because these psychotropic medications are occasionally combined to manage anxiety disorders or depression, clinicians are advised to empirically reduce the initial dosage of the triazolobenzodiazepines (75% with triazolam, 50% with alprazolam) in patients currently receiving these SSRIs.

Serotonin Syndrome

13. What is serotonin syndrome, and is A.R. at risk for this interaction?

Serotonin syndrome is a rare but potentially fatal interaction that has been precipitated by the combination of two or more drugs that enhance serotonin transmission.¹³⁵ The syndrome consists of a constellation of associated symptoms, including anxiety, shivering, diaphoresis, tremor, hyperreflexia, and autonomic instability (increased/decreased blood pressure and pulse rate).¹³⁶ Fatalities have been attributed to malignant hyperthermia.

Table 79-17 Drug Interactions of the Cytochrome P450 System

| Relative Rank | CYP1A2 | CYP2C9/19 | CYP2D6 | CYP3A4 |
|---|---|---|--|---|
| Offending Agent (inhibits enzyme) | | | | |
| High | Fluvoxamine | <i>Cyp2C9</i> Fluoxetine Fluvoxamine <i>Cyp2C19</i> Fluvoxamine | Paroxetine Fluoxetine Duloxetine Bupropion | Fluoxetine (norfluoxetine) Fluvoxamine |
| Moderate | Fluoxetine Paroxetine | <i>Cyp2C19</i> Fluoxetine Sertraline | Citalopram Escitalopram Sertraline | |
| Low | Citalopram Escitalopram Sertraline Venlafaxine Duloxetine Bupropion | <i>Cyp2C9/19</i> Citalopram Escitalopram Paroxetine Sertraline Venlafaxine | Venlafaxine Mirtazapine | Citalopram Escitalopram Paroxetine Sertraline Venlafaxine Duloxetine |
| Other Inhibitors | | | | |
| | Quinolones (ciprofloxacin, enoxacin, etc.) Macrolides (erythromycin, clarithromycin) Grapefruit juice | Modafinil (2C9, 2C19) Cimetidine (2C19) Omeprazole (2C19) Imidazoles (2C9, 2C19) (ketoconazole, fluconazole) | Fenfluramine Yohimbine Methadone Quinidine Celecoxib | Macrolides (Erythro, Clarith) Cimetidine CCB (verapamil, diltiazem) Imidazoles (ketoconazole, fluconazole) Protease inhibitors Grapefruit juice |
| Other Inducers | | | | |
| | Cigarettes Caffeine St. John's wort | St. John's wort | Modafinil Phenytoin and phenobarbital Carbamazepine Rifampin Prednisone Testosterone | St. John's wort |
| Affected Agent (increased concentration) | | | | |
| | TCA-tertiary amines (imipramine, amitriptyline) Phenothiazines (chlorpromazine) Thiothixene Haloperidol Clozapine Olanzapine Caffeine Theophylline Propranolol Tacrine | <i>Cyp2C9</i> Phenytoin Tolbutamide Warfarin NSAIDs <i>Cyp2C19</i> TCA-tertiary amines (imipramine, amitriptyline) Citalopram Barbiturates Propranolol Omeprazole | TCA-secondary amines (desipramine, nortriptyline) Fluoxetine Paroxetine Venlafaxine Duloxetine Amphetamines Atomoxetine Risperidone Donepezil Codeine Hydrocodone Tramadol Dextromethorphan Chlorpheniramine Beta-Blockers (propranolol, metoprolol) | Fluoxetine Sertraline Venlafaxine Modafinil Quetiapine Ziprasidone Aripiprazole Buspirone Benzodiazepines (triazolam, alprazolam) Zolpidem Carbamazepine Donepezil CCB (verapamil, diltiazem, nifedipine) Sex hormones (estrogen) Corticosteroids Statins (lovastatin, simvastatin) Protease inhibitors Sildenafil |

mcpp, 1-(m-chlorophenyl) piperazine; NSAIDs, nonsteroidal anti-inflammatory drugs; TCA, tricyclic antidepressant; CCB, calcium channel blockers.

With mild cases of serotonin syndrome, the symptoms ordinarily resolve 24 to 48 hours after the serotonergic agents have been discontinued. Supportive treatment is usually not necessary. For more severe reactions, various serotonergic antagonists, such as cyproheptadine, methysergide, and propranolol, have been used.^{137–139} Dantrolene has been administered successfully to manage hyperthermia.¹⁴⁰

Most case reports of serotonin syndrome (and most fatalities) have occurred with a combination of an MAOI and an SSRI, which is now considered an absolute contraindication. Other case reports involve the combination of an MAOI (or SSRI) and tryptophan, meperidine, SNRI, tricyclics, dextromethorphan, linezolid, and tramadol.¹³⁵ One case of serotonin syndrome was reportedly induced by the combination of clomipramine with S-adenosylmethionine.¹⁴¹ Serotonin syndrome has also been reported with concurrent administration of multiple SSRIs. Theoretically, the combination of an SSRI with St. John's Wort may also precipitate this pharmacodynamic interaction, but more recent evidence has suggested that the MAOI properties of the herbal preparation are minimal with therapeutic doses. Nonetheless, a case series of five older patients who developed symptoms reminiscent of serotonin syndrome has appeared in the literature, and, given the degree of uncertainty that persists, this combination of antidepressant agents is best avoided.¹⁴² The safety of combining an SSRI with certain migraine medications (e.g., sumatriptan) has not been elucidated, and clinicians are advised to avoid this combination if possible as well.

The combination of a phenylpiperazine (e.g., trazodone) with an SSRI may pose some concern because both classes of antidepressants augment serotonin activity in the CNS. Trazodone has been associated with serotonin syndrome in two incidences, one involving the coadministration of buspirone and the other associated with a concomitant MAOI.¹³⁶ However, in practice, trazodone has been commonly prescribed to patients receiving an SSRI for the treatment of insomnia, and no confirmed cases of serotonin syndrome have surfaced in the medical literature.¹⁴³

Refractory Depression

14. F.H. is a 55-year-old postmenopausal woman presenting to the women's health clinic who has suffered from multiple depressive episodes since the age of 30 years. She reports that she has been hospitalized on three different occasions. Although F.H. is unable to recall details of any specific antidepressant trials, her prescription record reveals treatment with imipramine (100 mg/day), nortriptyline (75 mg/day), diazepam (10 mg/day), and fluoxetine (20 mg/day for the past 8 weeks). Eventually, she recalls that imipramine made her "dizzy and left a strange taste in my mouth" and that diazepam made her "even more depressed." She says that the fluoxetine may be "helping a little bit but I feel so jumpy and irritable that no one can stand me." F.H. has grown rather despondent over her situation ("I almost feel like giving up"). What would be the next reasonable step for managing F.H.'s depressive illness?

Pooled results of clinical trials suggest that the majority of patients with major depression receiving an adequate trial of any antidepressant will have a therapeutic response, traditionally defined as at least a 50% reduction in depressive symp-

toms. However, for a patient who is severely depressed, a 50% reduction in symptoms still leaves him or her with significant psychopathology and associated disability. Consequently, there has been a strong movement in recent years to consider full remission as the preferred therapeutic end point.⁷¹ Scientific support for this ideologic shift comes from long-term studies demonstrating that patients achieving remission are much less likely to suffer relapse. One longitudinal investigation found that patients with residual symptoms were three times more likely to suffer relapse during the 12 months after treatment than those who had remitted.¹⁴⁴ Although remission can be generally defined as the virtual absence of residual depressive symptoms, it can also be quantified with a corresponding threshold value on a depression rating scale (e.g., QIDS <6; 17-item HAM-D <7).⁷¹ As more clinical trials use these rigorous standards, it has become evident that approximately only 30% to 40% of patients receiving an adequate trial of an antidepressant actually achieve remission. Therefore, strident efforts are being made to make patients feel well and not merely better, and providers must undertake a thorough, rational, and perhaps aggressive approach to optimize treatment and achieve this goal.

For F.H., the first step would be to confirm her diagnosis and rule out potential medical explanations for her distress. Iatrogenic causes should also be explored, such as recent changes in her hormone replacement therapy. Persistent stressors or substance abuse patterns may be hindering her sustained recovery and should be addressed.

An assessment of F.H.'s attitude toward medication adherence is also vital, and her complete medical records should be obtained to verify the dose, duration, and results of previous antidepressant trials. It is critical to confirm that she received full therapeutic trials of the antidepressants that she was prescribed before seeking other therapeutic options. A full therapeutic trial for the treatment of depression is considered to be a minimum of 4 weeks receiving a clinically effective dosage of medication. Although some improvement may be noted during the first 1 or 2 weeks of treatment, maximal response is rarely evident until 4 weeks of medication have been received. An open-label study with fluoxetine, for instance, randomized patients who were not fully responsive after 3 weeks of treatment (20 mg/day) to either continue with the original regimen or receive an increased dosage (60 mg/day) for 5 additional weeks.¹⁴⁵ At the end of the study period, 49% of the patients receiving 20 mg converted to full responders, suggesting that 3 weeks is an inadequate period to confidently assess patient response. Because 50% of the patients receiving 60 mg/day converted to full responders, it may also be inferred that dosage increases are not necessary in many patients.

Drug Selection

Serotonin Norepinephrine Reuptake Inhibitors

15. After a careful interview and workup, it was determined that F.H. is suffering from an acute episode of major depression with a probable history of dysthymia as well (i.e., double depression). She denies substance abuse, which is supported by a subsequent toxicology screen. From her medical chart and interview, it is confirmed that she received a therapeutic trial of nortriptyline and fluoxetine with inadequate clinical benefit. She is not interested in psychotherapy. Her provider decides to start

venlafaxine (37.5 mg SR preparation daily). Is this a reasonable choice?

Because 30% to 40% of patients will effectively achieve remission and about 20% to 25% of patients will stop an antidepressant because of side effects, it is safe to say that *most* patients started on a given antidepressant ultimately need a significant adjustment or change to their original regimen.¹⁴⁶ Clinicians, therefore, are obligated to have a thorough understanding of several antidepressant medications and classes if they are to facilitate successful outcomes.

In F.H.'s case, she has previously failed a therapeutic trial of nortriptyline and is currently expressing vague suicidality, so an additional TCA would not be a reasonable choice (see full discussion of TCAs in the text that follows). Although she has also failed a fluoxetine trial, open-label studies and large controlled investigations suggest that 50% to 70% of patients who are unresponsive or intolerant of one SSRI will experience a therapeutic response to a different SSRI.^{145,147,148} For example, in the STAR*D trials patients failing an initial course of citalopram were just as likely to respond if they were randomized to a subsequent trial of a different SSRI (sertraline) as they were to other antidepressant classes (venlafaxine and bupropion, specifically).¹⁴⁹ If a different SSRI is to be initiated, it may be wise to opt for one with less activating properties than fluoxetine (e.g., sertraline, paroxetine, citalopram, escitalopram). Alternatively, a medication from a different antidepressant class would possess the hypothetical benefit of a unique mechanism of action (e.g., venlafaxine, bupropion). Because F.H. is evidently experiencing much torment and despair, a sense of urgency may be perceived, justifying a different pharmacologic approach altogether.

Venlafaxine is the first member of a relatively new class of antidepressants known as SNRIs. Duloxetine (Cymbalta), which possesses a very similar mechanism of action, is the only other SNRI that is approved in the United States for the treatment of depression at the present time.¹⁵⁰ Studies in severe melancholic depression and treatment-resistant depression suggest that venlafaxine is at least as effective as other antidepressants in these populations, and it has emerged as a valuable alternative agent.^{151–153} At dosages <150 mg/day, venlafaxine's therapeutic effects are mediated exclusively from the blockade of serotonin reuptake. Therefore, associated adverse effects at low dosages are qualitatively and quantitatively very similar to those found with SSRIs: GI distress, sleep disturbances, and sexual dysfunction. At higher dosages, effects on norepinephrine are observed, which distinguish venlafaxine from an SSRI in terms of adverse effects (e.g., causes hypertension) but may also confer additional therapeutic benefit. Duloxetine does not appear to exhibit a dose-dependent differential effect on neurotransmitters.

Venlafaxine has a relatively brief plasma half-life (5–8 hours) and is demethylated to an active metabolite (*O*-desmethyl-venlafaxine) that has a short half-life as well (11 hours). This metabolite was recently approved by the FDA for the treatment of depression. Duloxetine also has a relatively short half-life (12 hours) and, as with the SSRI, withdrawal reactions may occur when the SNRI are abruptly discontinued after chronic administration. Venlafaxine is not a potent inhibitor of cytochrome P450 isoenzymes, so drug interactions are less of a concern than with certain SSRIs, but duloxetine is

a moderate inhibitor of the CYP 2D6 isoenzyme. Both SNRIs have been associated with serotonin syndrome, so clinicians should be aware of the potentially dangerous drug combinations that can occur with these antidepressants.¹⁵⁴

For F.H., the choice of venlafaxine seems to be prudent. It is fairly safe in overdose, possesses a unique mechanism of action, and is generally less activating than fluoxetine (which had provoked some irritability in her). In comparison to SSRIs, venlafaxine possesses a wide therapeutic range and ordinarily requires more dosage titration (which can increase resource utilization). A starting dose of 37.5 mg (XR) is reasonable, but baseline vitals should be recorded for F.H. with every dosage change in order to monitor the effect of this SNRI on her blood pressure and heart rate. Most patients respond to daily doses between 150 and 225 mg. Because F.H. is suffering from a relatively severe depression, it may be wise to increase her daily dose to 75 mg once she has exhibited good tolerance (i.e., after 4–7 days). In the event that F.H. has not exhibited a satisfactory response to 75 mg/day after 4 weeks, the dosage may be increased in increments of 37.5 to 75 mg every few weeks to a daily maximum of 225 mg. Although daily doses of the XL preparation above 225 mg are not recommended by the manufacturer, anecdotal success and relative safety have been reported for doses as high as 300 mg daily.¹⁵⁵

Other Agents: Bupropion and Mirtazapine

16. Are there any other antidepressants to consider if F.H. fails her venlafaxine trial?

Bupropion is an aminoketone with a mechanism of action that is clearly different from that of any other antidepressant that has received FDA approval. The direct effects of bupropion on serotonin transmission are negligible, but it may act by enhancing dopamine and/or norepinephrine activity.¹⁵⁶ At therapeutic dosages, bupropion has an attractive adverse effect profile, limited to occasional nausea and insomnia or jitteriness. Seizures, which were reported shortly after it was released in 1985, appear to be very unlikely with therapeutic dosing of bupropion, provided that patients are not predisposed (e.g., history of epilepsy, bulimia, or recent history of heavy drinking). Bupropion is one of the few antidepressants that may actually decrease appetite. A recent randomized, placebo-controlled investigation of bupropion in depressed obese patients observing caloric restriction found that bupropion was much more likely to induce significant weight loss than placebo.¹⁵⁷ After 26 weeks of treatment, 40% of the bupropion-treated patients lost >5% of their total body weight versus 16% with placebo. This weight loss was positively correlated with an improvement in depressive symptoms.

Bupropion is converted via the cytochrome P450 2B6 isoenzyme to an active metabolite (9 hydroxy-bupropion). Bupropion (or its metabolite) appears to have a moderate affinity for inhibiting the CYP 2D6 isoenzyme, and significant elevations of venlafaxine and metoprolol have been demonstrated to occur with concurrent administration. Because of its short half-life (approximately 8 hours for the parent compound and 12 hours for the active metabolite), bupropion has historically been administered in divided doses, although a once-daily preparation is now available (Wellbutrin XL, or generic). For the regular-release product, the recommended starting dose is 100 mg BID, increasing to 100 mg TID after at least 3 days. Individual doses

must not exceed 150 mg and should be given at least 6 hours apart. With the SR formulation, initial daily doses are 150 mg QD, increased to 150 mg BID by the fourth day at the earliest. Individual doses of bupropion SR can be as large as 200 mg, and divided doses should be given at least 8 hours apart. For the XL formulation, the package insert recommends initiating at 150 mg QD and increasing to 300 mg QD as early as the fourth day. Maximum daily doses are 450 mg for regular and XL products and 400 mg for SR products.

Mirtazapine is a novel antidepressant capable of modulating serotonin and norepinephrine activity through a complex mechanism of action. In vitro studies reveal that mirtazapine is an antagonist at presynaptic α_2 -autoreceptors and postsynaptic 5-HT₂ and 5-HT₃ receptors.¹⁵⁸ In addition, it appears to possess some mild inhibitory properties at serotonin reuptake transporters. Therefore, the net effect of mirtazapine is to enhance serotonin and norepinephrine in a manner that is clearly distinct from any other antidepressants. In a comparative randomized trial with fluoxetine for moderate to severe depression, mirtazapine appeared to be much more effective than the SSRI after 4 weeks of treatment (58% responders vs. 30% with the SSRI; $p < 0.05$), but the differences were no longer significant at 6 weeks (63% vs. 54%; $p = 0.67$).¹⁵⁹

The most common adverse effects experienced with mirtazapine are sedation and weight gain. Because mirtazapine has potent antihistaminergic effects, it is considered to be quite sedating. Anecdotally, it has been reported that higher daily doses of mirtazapine (>30 mg) are less sedating than lower doses owing to an increase in noradrenergic effects. In addition to the substantial risk of increasing appetite and total body weight, mirtazapine has also been associated with significant increases in total cholesterol and triglycerides.¹⁶⁰ The recommended starting dosage is 15 mg at bedtime, and the therapeutic dosage ranges from 15 to 45 mg/day.¹⁶⁰ Data from controlled trials have demonstrated safety and efficacy in doses up to 60 mg daily.^{159,161}

Irreversible MAOIs (e.g., phenelzine, tranylepromine) may also be an alternative for patients who have failed multiple antidepressant trials. Like venlafaxine, TCAs, and mirtazapine, MAOIs are believed to relieve depressive symptoms by enhancing the activity of multiple neurotransmitters, which may be desirable for refractory cases. Because serious drug and dietary interactions are encountered with MAOIs, candidates for treatment should be chosen carefully; a full discussion of the clinical usefulness of MAOIs can be found in the “Depression With Atypical Features” section at the end of this chapter.

Antidepressant Augmentation

17. Three months later, F.H. reports that she feels less hopeless on venlafaxine XL (150 mg/day) and that her appetite has improved as well. However, she is still somewhat depressed and lethargic and attempts to increase her dosage have been limited by nausea and recurring insomnia. What pharmacologic options remain to help manage her refractory depression?

Because F.H. has obtained considerable relief from her venlafaxine trial but is experiencing dose-limiting side effects, one would prefer to add a second medication (i.e., augmentation therapy) rather than changing antidepressants at this time (Table 79-18). A reasonable next step would be to augment

Table 79-18 Partial Response to Antidepressant Treatment Augmentation Strategies (With SSRIs)

Ensure completion of full therapeutic trial (4–6 wk).

Ensure optimal dose of antidepressant.

Consider augmentation therapies:

- Bupropion
- Lithium
- Thyroid supplements
- Pindolol (?)
- Buspirone
- Atypical antipsychotics
- Modafinil
- Lamotrigine

her current venlafaxine regimen with another medication such as lithium, thyroid hormone, or bupropion. Lithium's antidepressant properties appear to apply to both unipolar and bipolar patients. Seven of nine antidepressant augmentation trials with lithium have reported positive therapeutic effects, usually within 1 week of achieving steady-state dynamics (i.e., 3–7 days of daily dosing).¹⁶² Effective lithium blood levels are generally within the range used to treat bipolar disorder (0.5–1.2 mEq/L). As with the use of lithium therapy in bipolar disorder, all appropriate clinical monitoring parameters should be followed carefully (see Chapter 80).

T₃ also has a long history of use in psychiatric circles for patients exhibiting partial or suboptimal responses to antidepressant monotherapy. Five of six RCTs support the use of T₃ supplementation for antidepressant augmentation, with an average effect size of 0.58 reported.¹⁶³ Triiodothyronine (Cytomel), at a dosage of 25 mg/day can accelerate as well as augment antidepressant response, and superior effects have been reported in female patients, in particular. The response to the thyroid supplementation should be noticeable within 1 to 2 weeks, much like that found when lithium is used to augment therapy. Thyroxine (T₄) has also been administered successfully in a dose of 0.1 mcg daily. Whether T₃ is superior to T₄ has not been resolved, although one study seemed to indicate that more patients respond to the former (T₃) than to the latter (T₄).¹⁶³ In the recently concluded STAR*D trials, T₃ was compared to lithium for antidepressant augmentation in patients with two previous treatment failures.¹⁶⁴ Remission rates were modest for both agents in this challenging population (24.7% with T₃ vs. 15.9% with lithium, NS).

Bupropion has also been used successfully as an augmenting agent for many years in several open-label trials and one RCT.^{165,166} Patients receiving SSRI or SNRI who continue to complain of fatigue, hypersomnia, or executive dysfunction are excellent candidates, and the combination treatment is usually well tolerated. With F.H., one should be mindful that bupropion may increase her venlafaxine levels and hasten the return of GI and CNS effects.¹⁰⁴ Although the stimulating properties of bupropion may help relieve her lethargy, it may also exacerbate her insomnia.

Lamotrigine is FDA approved for the treatment of bipolar depression. Like lithium, its clinical utility has also extended to the treatment of unipolar disorder, but the evidence supporting lamotrigine in this capacity is currently preliminary. If indicated, lamotrigine should be initiated at a low dose of 25 mg at bedtime and slowly advanced to a target of 150 mg

daily over a period of 6 to 8 weeks to minimize the potential for serious life-threatening rashes (e.g., 25 mg daily × 2 weeks, 50 mg daily × 2 weeks, 100 mg daily × 2 weeks, 150 mg daily thereafter). CNS side effects such as sedation, dizziness, and ataxia have also been commonly reported.

Buspirone augmentation has been supported by multiple open-label studies and one large RCT. Unfortunately, an additional RCT failed to find a statistically significant benefit from buspirone augmentation due, primarily, to an inexplicably high placebo response rate. Theoretically, buspirone may be of benefit to patients with residual symptoms of anxiety, in particular, and titration up to daily doses of 30 to 45 mg daily are often required.

Among other options, pindolol is a unique alpha-blocker with intrinsic sympathomimetic properties that has received some attention as an augmenting agent.¹⁶⁷ Early open-label studies and one double-blind, controlled trial suggested that pindolol may enhance or accelerate the therapeutic effects of other antidepressants.^{167–169} These benefits were attributed, in part, to the inhibitory effects that pindolol has on the 5-HT_{1A} autoreceptor.¹⁷⁰ A more recent double-blind placebo-controlled investigation enrolled 86 depressed patients, and, after 6 weeks of treatment, there was no statistical advantage to pindolol augmentation in terms of the onset or extent of antidepressant effect.¹⁶⁹ A 3-week, single-blind, crossover followed the initial study phase, and again no benefits from the alpha-blocker were evident. Given the obvious discrepancies in study results, further research appears warranted to adequately assess whether pindolol enhances response to SSRIs or other antidepressant medications.

Modafinil is FDA approved for the treatment of narcolepsy, but it has been used extensively to increase energy and alertness, particularly among depressed patients. A large placebo-controlled RCT was conducted among 311 subjects exhibiting a partial response to an SSRI.¹⁷¹ Significant improvements were seen on sleepiness and fatigue scales, as well as overall depression scores, among patients randomized to a fixed dose of 200 mg daily.

The use of atypical or second-generation antipsychotics (SGAs) for the management of treatment-resistant depression has become relatively common among mental health providers but definitive well-controlled trials are currently lacking. Although a wide variety of anecdotal evidence suggests that SGAs may be effective for unipolar, bipolar, or psychotic depression, most investigations have featured an open-label design or a limited number of subjects. One common finding in these reports, however, has been a very rapid therapeutic response to relatively low doses (e.g., 1–2 mg of risperidone, 5–10 mg of olanzapine). Given the high acquisition costs of these medications, and the significant metabolic effects that have been demonstrated, it is hoped that additional trials will be conducted to examine the wisdom of this practice in the near future.

The Elderly

18. R.M., a 71-year-old man, is brought in to see a primary care provider by his daughter with whom he has been living since the death of his wife 6 months ago. His daughter reports that R.M. had been in good health until his wife's death and that since then

he has been keeping to himself, showing little interest in social activities. She reports that he used to be a happy, outgoing person but is now very irritable and becomes agitated over insignificant things. Over the past 4 months, he has lost approximately 12 lb and has trouble falling asleep. He used to be a voracious reader but seems uninterested in current events now. He appears to be confused or preoccupied at times and is incapable of understanding new concepts. His only documented medical problem is benign prostatic hypertrophy (BPH), and current medications consist of a stool softener and bulk laxative. Today's physical examination is normal, and the laboratory examination is significant only for a mildly elevated prostate-specific antigen (PSA) of 10.0 ng/mL.

On mental status examination, R.M. is perceived to be a thin, nervous, sad-appearing elderly man. He is oriented × 3. His response to questions is slow, and his volume of speech is reduced. Affect is sad. Mood is dysthymic. He shows mild impairments in his ability to think through problems and perform simple mathematical exercises. There is no evidence of delusions, hallucinations, or paranoia. He denies suicidal thoughts but feels hopeless at present and admits “there's no reason to live anymore.” How does a depressive episode in late life, such as that in R.M., differ from an episode earlier in life?

Depression in late life is typically more difficult to recognize than depression in younger adults. Clinicians and patients may inappropriately attribute depressive symptoms to the “aging process” and minimize their significance. In addition, functional expectations are often lowered after retirement, making the degree of impairment difficult to evaluate. Because medical comorbidities are also more common in the elderly, depressive symptoms may be overlooked or misinterpreted in the workup as well.¹⁷²

In general, the elderly present with the same depressive target symptoms as younger adults, which is reflected in the fact that DSM-IV-TR diagnosis for major depression in adults is not specific for age. However, qualitatively, the presentation of depression among the elderly may be quite different.¹⁷³ For instance, older patients are more likely to present with psychomotor retardation and are less likely to acknowledge “depression” per se, preferring instead to dwell on somatic concerns (e.g., poor sleep, low energy, changes in bowel function, bodily aches and pains). They are also much less likely to share or admit suicidal thoughts, and because elderly men have the highest suicide success rate, an accurate assessment of depression and attendant risks is critical (see “Drug Selection” section).¹⁷⁴

19. What is R.M.'s differential diagnosis? Should he receive antidepressant therapy?

In assessing nonspecific behavioral and cognitive symptoms in the elderly, a careful differential diagnosis between medical and other psychiatric disorders is essential because numerous medical illnesses can mimic depressive symptoms. Anemia, malignancies, congestive heart failure (CHF), and endocrine abnormalities may all present in a manner similar to that in depressive illness and can be ruled out only with a careful line of questioning and systematic physical workup.

One of the more difficult differential diagnoses in this setting involves the distinction of depression from dementia.^{175,176} Like depression, patients with dementia may present with apathy, poor memory or concentration, reduced

facial expression, and lack of spontaneous interaction. The illnesses are often comorbid, as 30% to 70% of patients with dementia also suffer from major depression.¹⁷⁶ Some experts have suggested, in fact, that new-onset depression in elderly patients may actually be part of a prodrome toward the manifestation of Alzheimer Dementia (AD).^{176,177} A longitudinal cohort study found that, among elderly patients suffering from an acute episode of major depression, 57% were ultimately diagnosed with AD within the next 3 years.¹⁷⁵ Diagnostically, there are three notable differences between dementia and depression: (a) the symptoms (slow and subtle changes with dementia, rapid with depression), (b) orientation (markedly impaired with dementia, intact with depression), and (c) principal CNS impairment (short-term memory with dementia, concentration with depression).

Drug Selection

A therapeutic trial of an antidepressant in a depressed individual with cognitive impairment may reverse the symptoms of the affective illness and restore functional capacity. Cognitive function may also improve to some degree. Moreover, because primary degenerative dementia is largely a diagnosis of exclusion, a successful trial of an antidepressant may help clarify the underlying pathological condition and is strongly recommended in patients with a positive personal or family history of mood disorders. Patients with dementia, in fact, may benefit from antidepressant therapy, even if they do not present with a major mood disorder.¹⁷⁸ Overlapping pathophysiology and neuroanatomical dysfunction in these two disorders might explain the efficacy of antidepressants for selected symptoms of degenerative dementia. Although R.M.'s physical examination and laboratory workup were normal, a therapeutic trial of an antidepressant is warranted based on his current depressive target symptoms.

The overall efficacy of antidepressants in elderly patients is believed to be comparable to that observed in younger subjects, although the response to treatment is somewhat slower (i.e., 6-week therapeutic trial usually warranted). Similarly, the comparative therapeutic effects of individual antidepressants do not appear to differ qualitatively between elderly patients and the general population. The selection of antidepressants for geriatric depression, therefore, is quite similar to the process recommended for younger patients, although the presence of medical comorbidities and current medications will often have a greater influence on treatment plans due to the higher overall disease burden found in older patients. For example, the anticholinergic effects of certain antidepressants (TCA, paroxetine) may discourage their use in elderly patients suffering from narrow angle glaucoma, chronic constipation, or urinary hesitancy. The cognitive effects of antidepressants may also be more pronounced in elderly people due to differences in pharmacokinetic disposition (prolonged half-life) and pharmacodynamic properties (compromised integrity of blood–brain barrier). Although sedating antidepressants such as mirtazapine may serve to promote sleep in depressed patients suffering from insomnia, other geriatric clients may be candidates for more activating medications that can increase energy or enhance alertness (e.g., bupropion).

In the case of R.H., mirtazapine might be a judicious choice due to the fact that his appetite and sleep have diminished considerably over the past several months. A conservative starting

dose of 7.5 mg at bedtime might be considered to ensure his tolerability of a new medication, although it is quite possible that eventual dosage increases might be required to achieve a therapeutic response.

Tricyclic Antidepressants

20. B.H. is an obese 52-year-old man suffering from his first episode of major depressive disorder, melancholic subtype. He has an 8-year history of CHF (New York Heart Association functional class II) with an ejection fraction of 35% and atrial fibrillation. He is currently taking digoxin 0.25 mg PO QD and enalapril 10 mg PO BID. His CHF has been well controlled on this regimen, and he remains asymptomatic with regard to the CHF. His atrial fibrillation occurs about once every 6 months. All other laboratory parameters are within normal limits. His cardiologist believes that TCA are the most effective antidepressants for melancholic depression. Are there any safety concerns in starting a TCA in this patient?

For many years, the TCAs were the most popular class of medications used to treat depression. The acquisition cost for TCAs was quite low, we had several decades of experience using them, and there continue to be providers who prefer antidepressant medications that enhance serotonin and norepinephrine for the treatment of severe or melancholic depression (i.e., dual-action antidepressants).¹⁷⁹ TCAs continue to be prescribed for other indications that are comorbid with depression as well (e.g., migraine prophylaxis, chronic pain). Unfortunately, TCAs possess a variety of adverse effects, ranging from bothersome (dry mouth, sedation, constipation) to serious (cardiovascular effects), which often prevent patients from receiving therapeutic doses of medication.¹⁸⁰ Patient adherence with prescribed medication may also be compromised with TCAs.¹⁸¹

The SSRIs are widely regarded as a major breakthrough in the pharmacologic management of depressive symptoms and have largely supplanted the TCA in their role as preferred agents for the treatment of mood disorders. Their popularity can be attributed to numerous advantages over older compounds, including a lower side effect burden, safety in overdose, less dosage titration, once-daily administration, and patient preference. Results of a meta-analysis concluded that, although the overall efficacy of the two antidepressant classes was comparable, primary care patients receiving an SSRI were much less likely to discontinue therapy prematurely due to side effects.¹⁸² Although SSRIs were once more expensive than TCAs, most are now available in generic formulations and are relatively inexpensive.

Side Effects

21. B.H.'s cardiologist is concerned about the effect of a TCA on his cardiac status. What are the major adverse effects and toxicities of the TCAs, and how should these be managed?

The most common adverse effects of the TCAs are listed in Table 79-12. Anticholinergic effects are commonly encountered with the TCAs and may adversely affect adherence.¹⁸³ These side effects include dry mouth, blurred vision, constipation, and urinary retention. Although patients may develop tolerance to these effects, they may never disappear completely. Clinicians should be prepared to counsel patients about the

appropriate way to manage these problems. Patients with dry mouth, for instance, may tend to drink excessive fluids to relieve discomfort. To minimize the inherent potential for weight gain with TCAs, patients should be advised to avoid caloric beverages and drink water or dietetic fluids instead. Sugarless gum or hard candy is often recommended as well.

TCAs also can be very sedating and are usually administered at bedtime to minimize functional impairments. Confusion or memory deficits may also occur with TCAs and can be particularly onerous in elderly patients. The secondary amines may be more tolerable in this regard, but all TCAs can impair concentration or alertness to some extent.

The impact of TCAs on cardiovascular function is a legitimate and serious concern. The most potentially dangerous adverse effect of the TCAs is their quinidinelike properties (type IA) on prolonging cardiac conduction through the His-Purkinje system. This, in conjunction with positive chronotropic and adrenergic-blocking properties of the TCAs, can lead to re-entry arrhythmias (e.g., torsades de pointes and other ventricular arrhythmias). In patients with pre-existing conduction defects and in overdose, there is a greater risk for cardiac arrhythmias.¹⁸⁴ Therefore, B.H. should receive a baseline electrocardiogram (ECG) before therapy.

Orthostatic hypotension is the most common and troublesome cardiovascular effect of the TCAs and MAOIs because it can result in significant morbidity and mortality.^{185,186} Major clinical consequences of orthostatic hypotension include falls leading to bone fractures, lacerations, and even MI. Patients with CHF, such as B.H., are at greatest risk for developing orthostatic hypotension.

Imipramine and nortriptyline have been best studied with respect to their association with orthostatic hypotension. Amitriptyline, desipramine, doxepin, and clomipramine are also capable of producing it to varying degrees. Although systematic comparisons of the propensity of the TCAs to cause orthostatic hypotension are generally lacking, the tertiary amines (e.g., imipramine) may cause more severe orthostatic hypotension than the secondary amines (e.g., nortriptyline), and research evidence supports the contention that nortriptyline has the lowest risk for causing orthostatic hypotension among TCAs.^{184,187}

Antidepressants and Cardiac Disease

22. Will the choice of antidepressant affect B.H.'s arrhythmia?

There are substantial differences among antidepressants (and antidepressant classes) in regard to overall cardiac safety and arrhythmogenic effects in particular. The SSRIs, in general, appear to be relatively safe in patients with a history of arrhythmias or recent MI.¹⁸⁸ In a placebo-controlled investigation, hospitalized patients with unstable cardiac disease were randomized to either sertraline or placebo.¹⁸⁹ Overall, both treatment arms were very well tolerated, and there was actually a lower risk of severe cardiac events reported in the sertraline group (vs. placebo). Retrospective data suggest that SSRIs may be somewhat cardioprotective in depressed patients with heart disease, a benefit that might be explained by their ability to decrease platelet activation.^{190,191}

TCAs increase heart rate, probably via intrinsic anticholinergic properties that increase sinus node activity. Clinically,

this effect is generally not significant, especially in medically healthy, depressed patients.¹⁹² However, it may be important in those with underlying conduction disease, coronary artery disease, or CHF. TCAs, when used at therapeutic dosages for the treatment of depression, decrease premature atrial and ventricular contractions in both depressed and nondepressed patients.^{193,194} Antidepressants with class IA antiarrhythmic activity (e.g., TCAs) may also have arrhythmogenic activity and thus increase the chances of ventricular arrhythmias and sometimes of sudden death. This effect on rhythm and conduction is believed to be related to the inhibitory effects of TCAs on the fast sodium channels and a decrease in Purkinje fiber action potential amplitude, membrane responsiveness, and slowed conduction.¹⁹⁴ Even nortriptyline, which is believed to be one of the safer TCAs in patients with heart disease, was associated with a greater risk for adverse cardiac events than paroxetine in an RCT.¹⁹⁵

Bupropion and mirtazapine appear unlikely to affect cardiac rhythm or induce arrhythmias in susceptible patients.¹⁸⁸ Bupropion, however, should be used with caution in patients with pre-existing hypertension because of potential increases in BP.¹⁹⁶ Its safety has not been well studied in patients with heart disease. Similarly, venlafaxine does not appear to be arrhythmogenic, but increases in BP may be seen with higher dosages (>150 mg daily) limiting its usefulness in certain patient populations.¹⁵⁵ The nonselective MAOIs do not seem to affect rhythm significantly, although they generally do slow heart rate and can cause or worsen orthostatic hypotension.¹⁹⁷ Trazodone was associated with ventricular aggravation in the past, but this risk has not been further elucidated, and its widespread use as a sedative hypnotic in institutional settings has generally been well tolerated.¹⁸⁸

Plasma Concentration Monitoring

23. Are plasma concentrations clinically useful in monitoring antidepressant therapy? When should plasma antidepressant concentrations be obtained?

Attempts to demonstrate an association between plasma concentrations and therapeutic response for SSRIs, venlafaxine, and bupropion have been largely unsuccessful. In contrast to the newer agents, the serum concentration of some TCAs correlates well with clinical response. Nortriptyline exhibits a curvilinear effect, whereas imipramine demonstrates a sigmoidal relationship between serum levels and clinical response.^{198,199} Maximum benefit of imipramine is usually associated with serum levels of imipramine plus its demethylated metabolite, desipramine, in excess of 250 ng/mL. The relationship between plasma concentration of desipramine and clinical response is less clear, but it appears that a linear relationship is likely.²⁰⁰ The most controversy surrounds amitriptyline; studies have shown a linear relationship, a curvilinear relationship, and no relationship between serum concentration and outcome.^{201–203}

The APA Task Force on the Use of Laboratory Tests in Psychiatry recommends plasma concentration monitoring of TCA when patients are elderly, not responding to therapy, nonadherent, experiencing adverse effects, or on multiple medications that may result in a possible drug interaction.²⁰⁴ Plasma concentrations of imipramine, nortriptyline, and desipramine

should be obtained after at least 1 week of a constant dosage when steady state has been achieved. Samples should be drawn 12 hours after the last dose has been administered. Routine therapeutic blood monitoring of other antidepressants is not recommended because information concerning their usefulness is limited; however, serum levels may be useful for evaluating adherence in some patients or ruling out serious toxicities.²⁰⁵

Other Medical Comorbidities

Diabetes

24. B.L. is a 43-year-old woman who has become increasingly depressed over the past 4 months after the unexpected death of her father. She mentions that she was very upset immediately following his death, unable to sleep at night, and frequently crying at work. These symptoms have not abated over the past few months. She is slightly obese and has always been “borderline diabetic,” but her blood sugar control has worsened since her father’s death, and she has subsequently gained 30 lb ($HbA_{1c} = 8.2$ last week, up from 6.1, 4 months ago). She is very upset that she has recently been diagnosed with type 2 diabetes and does not believe that she is capable of following the lifestyle modifications recommended. How strong is the association between depression and diabetes? Would an antidepressant be an appropriate treatment for her symptoms at this time, and, if so, which agent(s) would be recommended?

The potential association of depression with diabetes has been discussed in the medical literature for more than 300 years.²⁰⁶ Results of a meta-analysis confirmed that diabetic patients are twice as likely to be suffering from depression than the general population, an association that appears to hold true for type 1 and type 2 diabetic illness.²⁰⁷ Theories abound as to why diabetic patients become depressed, citing complex physiological, psychological, and social factors, and a precise explanation has not been elucidated. Conversely, longitudinal studies have shown that depressed patients are twice as likely to develop type 2 diabetes with time, and in 80% to 90% of cases, the mood disorder preceded the metabolic condition.²⁰⁸ It has also been established that depressed diabetic patients are much more likely to suffer long-term complications with this metabolic disorder, and successful treatment of depression has been demonstrated to improve glycemic indices.^{209–211}

Successful treatment of mood disorders in patients with diabetes is important for several reasons. Patients with depression or diabetes are at risk for cardiovascular illness, and successful antidepressant treatment, therefore, may substantially decrease morbidity and mortality. Depressed patients are also much less likely to comply with treatment recommendations in general because of their hopelessness, cognitive impairment, and social isolation. As a result, they are three times more likely to stop taking their medications, leading to a worsening of diabetes and other medical conditions.²¹² Most depressed patients also report a change in their appetite at baseline, which may lead to a compromise in blood sugar control. Moreover, decreases in energy and motivation may also sabotage diabetes treatment plans.

Although the number of clinical studies conducted with depressed diabetic patients is limited, antidepressants appear to possess the same efficacy rates for this particular comorbid-

ity as previously found in the general population.²¹¹ Currently, there is no evidence to suggest that one class of antidepressant is more efficacious than another. Selection of an antidepressant in the diabetic population, therefore, rests largely on differences in adverse effect profiles, potential impact on diabetes complications, and potential for drug interactions.

One important consideration in selecting an antidepressant is the potential impact of the agent on appetite, blood sugar control, and total body weight. Although research on the effects of antidepressants on glycemic control is limited primarily to rat populations, important differences appear to exist among antidepressants in regard to weight gain potential.²¹³ As discussed previously, the risk of clinically significant weight gain appears to be highest with mirtazapine, TCAs, and MAOIs, and these medications should be avoided. Although SSRI and SNRI may occasionally induce weight gain in susceptible patients (estimated incidence of 3%–5%), this adverse effect appears to be of greatest concern with paroxetine (25% incidence). Bupropion may cause appetite suppression in some patients, which may be beneficial for the obese but may also pose a theoretical concern about hypoglycemia in diabetic patients.

Because one of the long-term complications of diabetes is sexual dysfunction, this potential side effect of antidepressants may also be worth considering. It should be emphasized, however, that erectile dysfunction and impotence are the sexual side effects most commonly encountered by male diabetics. Thus, although the SSRI may impair sexual performance by delaying or preventing orgasm, this impairment occurs at a different stage of the sexual process and would not necessarily discourage use of SSRIs. Diabetic neuropathies may also influence antidepressant selection. SNRIs have proven quite effective for the management of neuropathic pain, but clinicians should also be aware that venlafaxine and duloxetine may increase blood pressure and heart rate as well.

Pharmacokinetic drug interactions may also be a concern for certain antidepressants in diabetic patients. For instance, many of the oral antidiabetic agents are substrates for metabolism by the cytochrome P450 isoenzyme system. Inhibition of this metabolic step may precipitate a serious drug interaction by increasing plasma concentrations of the antidiabetic agents and enhancing hypoglycemic effects. Several of these agents are metabolized via the CYP 2C9 isoenzyme (e.g., tolbutamide, glyburide, glipizide, rosiglitazone), and the administration of certain SSRIs (e.g., fluoxetine or fluvoxamine) may potentiate their effects. Repaglinide and some of the sulfonylureas are metabolized via the CYP 3A4 isoenzyme, which may also be inhibited by fluoxetine or fluvoxamine.

For B.L., the depressive symptoms she experienced after her father’s death may be considered a natural response to this serious loss. Because her symptoms have persisted for longer than 2 months, her psychiatric illness would no longer be categorized as a grief reaction (or bereavement) and should be managed medically as an acute episode of major depression. Thus, it is advisable that her depression receive serious attention (i.e., thorough assessment of psychiatric condition) and necessary treatment. Medical history, previous antidepressant trials, and concurrent use of other prescription medications should also be investigated. If B.L. is amenable to an antidepressant, an SSRI that is unlikely to induce weight gain or potentiate drug interactions may be a prudent choice. Such agents would include sertraline, citalopram, or escitalopram.

Epilepsy

25. C.B., a 20-year-old woman, was recently diagnosed with major depressive disorder, single episode. Since the age of 8, she has also experienced complex partial seizures. Her seizures have been difficult to control in the past (at least six seizures per month), but her condition has improved recently (none for 8 months) on a combination of carbamazepine and gabapentin. Are there any special considerations with regard to antidepressant selection in this patient?

Although seizures are a relatively uncommon effect of antidepressant medications, they are frightening and serious when they occur. The overall risk of seizures with most antidepressants is quite low at therapeutic dosages, and, as a result, the precise risk is difficult to quantify with any statistical certainty.²¹⁴ Furthermore, the risk of new-onset seizures in the general population (i.e., not necessarily receiving antidepressants) is approximately 0.073% to 0.086% annually, suggesting the likelihood of occasional coincidental case reports.²¹⁵ Among the antidepressants marketed in the United States, imipramine may be the best studied, and the frequency of seizures was reported to be 0.1% among patients prescribed therapeutic dosages (–200 mg/day).²¹⁶

Generally, it is believed that iatrogenic seizures are a dose-related phenomenon, so it is not surprising that most case reports of antidepressant seizures have involved overdose ingestions, most commonly with the TCAs. Seizures have been correlated to peak plasma concentrations of tricyclics (e.g., levels >1,000 ng/mL) and typically occur within 6 hours after the overdose.²¹⁷

The specific antidepressant may also be of some importance, but one may want to recall the methodologic difficulties inherent in estimating accurate figures. An older review cited amoxapine with the highest risk of seizures in overdose, followed by maprotiline and the TCAs (collectively).²¹⁸ Bupropion was withdrawn from the market in 1986 after the appearance of new-onset seizures in bulimic patients receiving the antidepressant as part of a placebo-controlled trial (4 of 69 subjects).²¹⁹ After a re-examination of the original dosing recommendations, bupropion was released again in 1989, and a new SR preparation appeared in 1998. Among the 3,100 patients to receive the new preparation for up to 1 year, the cumulative seizure risk was 0.15%.²²⁰ Although SSRIs have been associated with seizures in acute overdose, the comparative risk encountered with dosages in the therapeutic range has not been determined.

Because of C.B.'s seizure history, choosing a medication with a low risk of seizures is prudent. Bupropion, for instance, is contraindicated in patients with a pre-existing seizure disorder. Because carbamazepine has a narrow therapeutic index and is metabolized by multiple isoenzymes within the cytochrome P450 system, antidepressants that may inhibit its clearance and raise plasma levels, such as duloxetine (CYP 2D6), fluoxetine (CYP 2D6 and 3A4), and paroxetine (CYP 2D6), should be avoided. Similarly, carbamazepine may induce the metabolism of certain TCAs, and it also possesses some of the cardiotoxic effects of these antidepressants (e.g., slowed conduction) further discouraging its use. Among the remaining alternatives, one may opt for an SSRI less likely to inhibit metabolic pathways (e.g., sertraline, citalopram) or venlafaxine.

AIDS

26. K.H., a 33-year-old HIV-positive woman, has been reasonably healthy over the past 2 years but recently developed AIDS after an episode of oral candidiasis. During the past few months, she has noticed a loss of interest in life, accompanied by decreased energy, easy fatigability, and difficulty concentrating (she has to read a sentence several times before she can comprehend its meaning). She also reports a depressed mood but denies suicidal ideation. Her current medications are zidovudine (Retrovir), lamivudine (Epivir), ritonavir (Norvir), and oral clotrimazole troche (Mycelex). After a thorough medical workup, other opportunistic infections have been ruled out. What precipitating factors may be contributing to K.H.'s current symptoms of depression?

Patients with serious illnesses such as HIV/AIDS or certain cancers are faced with an extreme psychosocial stressor that can precipitate a depressive episode. Research evaluating the severity of emotional distress in persons with HIV has shown elevated anxiety, depression, social isolation, and suicidal ideation.²²¹ Chronic depression in AIDS patients has, in fact, been associated with an acceleration of the disease progression, as well as a significant reduction in the perceived quality of life (vs. nondepressed HIV-infected controls).^{222,223} K.H. currently is, or will be, confronted with a number of psychological issues, including fear of developing an opportunistic infection, chronic somatic preoccupations, debilitation, anger, possible death at a young age, and reactive depression.^{224,225}

Although K.H.'s target symptoms (fatigue, decreased concentration, and depressed mood) may represent a depressive episode secondary to psychosocial stressors, her differential diagnosis also includes HIV-1–associated cognitive/motor complex or dementia resulting from HIV disease (formally known as *AIDS dementia complex*).²²⁶ HIV-associated dementia closely resembles the symptoms of a depressive disorder and is part of the Centers for Disease Control and Prevention classification system for HIV infection (category C).²²⁷ Neoplasms and opportunistic infections of the CNS secondary to AIDS can also alter mental status. However, a thorough medical workup ruled out opportunistic infection in K.H.

27. Based on K.H.'s target symptoms, is she a candidate for antidepressant therapy? What considerations should be made when selecting antidepressant therapy for K.H.?

K.H. would benefit from antidepressant therapy to help ameliorate her target symptoms of decreased energy, lack of concentration, and depressed mood, regardless of whether it is a major depressive episode or direct HIV involvement within the CNS. Although antidepressant trials in the general HIV population are lacking (and particularly scarce among populations of women or underrepresented minorities), several factors should be taken into account when selecting antidepressant medication in an HIV/AIDS patient.^{228,229} In general, comparative trials with conventional agents have been associated with high dropout rates because of adverse effects, suggesting that HIV/AIDS patients may be more vulnerable to toxic effects, or that lower doses of antidepressant medications should be considered.^{230,231}

Drug interactions can be a primary concern because several of the protease inhibitors undergo metabolic transformation via the cytochrome P450 system, primarily through the

CYP 3A4 and CYP 2B6 isoenzymes. Therefore, fluoxetine and fluvoxamine are best avoided. Among the alternatives, SSRIs and TCAs have demonstrated comparable efficacy in the depressed HIV/AIDS population, but the side effect burden of SSRIs may be more tolerable to these patients. Bupropion has become increasingly popular in depressed HIV/AIDS patients, and the activating properties may be attractive in this particular patient.²³² Inhibition of bupropion metabolism has been demonstrated with concurrent administration of ritonavir, efavirenz, and nelfinavir, however, which may complicate its use under certain circumstances.²³³ Low-dose psychostimulants (e.g., methylphenidate, dextroamphetamine) or modafinil may also be helpful because some limited evidence has demonstrated improved cognition and mood in AIDS patients.²³⁴ For appetite stimulation, mirtazapine would be a reasonable option in some AIDS patients, although the sedating potential should be carefully considered. An additional option may be ECT, which has been administered safely and effectively to the depressed AIDS population as well.²³⁵

Depression With Atypical Features (Atypical Depression)

Monoamine Oxidase Inhibitors

28. G.R., a 38-year-old, 73-kg woman, presents at the university outpatient psychiatric clinic with a chief complaint of extreme lethargy and depressed mood more days than not for the past 6 weeks. During this period, she has also been sleeping too much and overeating (she says she has gained at least 10 lb in this time frame). On interview, she also reports an intense fear of heights and consequently does not travel if it involves driving over a bridge or flying in an airplane. She reports that this episode seems to have started around the time of the break-up with her boyfriend, and she becomes extremely anxious and tearful in revealing this piece of her history. Her psychiatric history is consistent with at least two other similar depressive episodes, the first when she was 18 years old and the second occurring around age 25 years. She currently weighs 73 kg, and her physical examination and laboratory assessments are within normal limits. In the past, she has exhibited a poor response to trials of fluoxetine and nortriptyline. During her last episode, she is noted to have responded to phenelzine 60 mg/day.

G.R.'s depressive illness manifests differently from that expected in most cases of depression. How is this depression of G.R. different from melancholic depression?

G.R. suffers from hysteroid dysphoria, more commonly known as atypical depression (Table 79-19). DSM-IV-TR now refers to it as depression with atypical features.¹³ Clinically, atypical depression has generally been regarded as a fairly heterogeneous group of depressive symptoms that represent a specific form of depressive illness. Traditionally, atypical depression has been regarded as a more persistent, debilitating, and treatment-resistant mood disorder. Patients with this disorder tend to respond better to MAOIs than other antidepressant classes.²³⁶

The term “atypical depression” was first used to describe patients with symptoms of depression, such as a worsening of mood in the evening, lethargy, phobic and somatic anxiety, and emotional overreactivity to environmental events. In studying atypical depression, one group of investigators has identified a set of explicit operational criteria for atypical de-

Table 79-19 A Comparison of Atypical Depression and Melancholia

| Feature | Atypical Depression | Melancholia |
|-----------------------|---------------------------|-------------------|
| Onset | Teens (or younger) | Thirties (avg) |
| Gender | Females > males | Females > males |
| Course | Chronic | Episodic |
| Phenomenology | | |
| Appetite/weight | Increased | Decreased |
| Sleep | Increased | Decreased |
| Energy | Low with leaden paralysis | Low |
| Reaction to rejection | Very sensitive | Indifferent |
| Treatment response | MAOI = SSRI = TCA | MAOI = TCA = SSRI |

MAOI, monoamine oxidase inhibitor; SSRI, selective serotonin reuptake inhibitor; TCA, tricyclic antidepressant.

pression (the “Columbia” criteria) based on the literature and their own clinical experience.²³⁷ Briefly, the requirements are as follows: patients must meet criteria for DSM depressive disorder; however, they are excluded if they have pervasive anhedonia (i.e., they have a mood reactivity or enjoy some activities or daily experiences). Furthermore, they must have at least two of the following: (a) hypersomnia, (b) leaden paralysis (profound lethargy), (c) hyperphagia, or (d) pathological sensitivity to interpersonal rejection (rejection sensitivity). The features of atypical depression and melancholia are compared in Table 79-19.

G.R. reports a depressed mood, extreme lethargy, phobic avoidance of bridges or high places, and a recent problem with hypersomnia and hyperphagia with subsequent weight gain. She also seems to have a prominent rejection sensitivity regarding the relationship with her boyfriend.

INITIATION

29. What role do MAOIs have in the management of depression today? Would this class of antidepressant be appropriate for G.R.? Outline a dosage titration and treatment plan.

For the treatment of depression, the modern pharmacologic era was ushered in by the discovery of iproniazid, an antitubercular medication and potent inhibitor of MAO.²³⁸ Subsequent research with this MAOI ultimately led to the formulation of the biogenic amine hypothesis of depression, and it influenced antidepressant drug development for the next 20 years.

Although the MAOIs, most notably phenelzine and tranylcypromine, were commonly prescribed for the treatment of depression in the 1970s and 1980s, their popularity has waned in recent years primarily because of the risks of serious drug–drug and drug–food interactions.²³⁹ However, for the treatment of atypical depression, the MAOIs are among the most effective pharmacologic agents available and are still prescribed for patients with this depressive subtype usually after failing an SSRI. Double-blind trials featuring MAOIs versus TCAs have consistently demonstrated a superior response to the MAOIs, and a controlled trial comparing moclobemide with fluoxetine reported that the MAOI was superior as well.^{240–242} Limited data comparing TCAs with SSRIs for atypical depression

suggest that the two classes are comparable in efficacy, and both were superior to placebo.²⁴³

Because of G.R.'s positive response to phenelzine in the past, this choice of an antidepressant would be reasonable, but one should ask about the patient's previous experience with this medication (therapeutic effects, side effects, adherence, duration of treatment, and reason for discontinuation). If the dietary restrictions were difficult for G.R. to follow, she may be a good candidate for an MAOI transdermal patch (selegiline, Emsam). This transdermal agent is available in 6, 9, and 12 mg strengths, but only the 6 mg patch was approved by the FDA as safe without the need for dietary restrictions. She should remain wary, however, of the variety of drug interactions that may occur with concurrent MAOI use.

ADVERSE EFFECTS

30. G.R.'s insurance company is not willing to approve the non-formulary use of the MAOI patch, and she is unable to afford its monthly cost. Phenelzine is restarted at a dose of 30 mg daily (15 mg in the morning and at lunchtime). G.R. is being monitored closely for suicidal ideation, especially because the MAOIs are potentially lethal when taken in overdose. What other adverse effects of the nonselective MAOIs should be looked for in G.R. while she is being treated with phenelzine?

Orthostatic hypotension, weight gain, edema, and sexual dysfunction are common during MAOI therapy.²⁴⁴ As is the case with the TCAs, the nonselective MAOIs can cause clinically significant postural decreases in BP. However, with the MAOIs, the mechanism is believed to be a direct sympatholytic effect because both the lying and the standing systolic BP readings are decreased.^{245,246} Phenelzine seems to cause orthostatic hypotension more commonly than does tranlycypromine.²⁴⁷ Because the orthostatic hypotension appears to be dose related, a reduction in dosage may be helpful.²⁴⁸ For more difficult cases, orthostatic hypotension has been managed pharmacologically by the addition of 25 mg/day of triiodothyronine or initiation of fludrocortisone 0.025 to 0.05 mg once to twice a day.²⁴⁹ Monitoring for BP changes, as well as edema and serum electrolyte changes (e.g., hypokalemia), is paramount if these pharmacologic interventions are used. MAOI-induced weight gain may be managed by monitoring carbohydrate and fat intake. Edema can be treated by elevating the affected limbs and/or using a thiazide diuretic (e.g., hydrochlorothiazide 25–50 mg BID), with careful monitoring of other medications (e.g., serum lithium levels) for potential drug interactions.²⁴⁹ Sexual dysfunction occurs in up to 20% of patients taking MAOIs but may diminish and disappear spontaneously over time.^{250,251} If necessary, it can be managed with bethanechol (Urecholine) at dosages up to 50 mg/day in both men and women.²⁴⁴

A switch into mania has been reported in up to 10% of patients with a history of bipolar disorder. Therefore, MAOIs should be avoided in this population.²⁴⁴ Although MAOIs are not known as antimuscarinic medications, some patients complain of anticholinergic-like side effects, including blurred near vision and urinary retention. Dosage reduction may be helpful, but these effects may also diminish over time. Paresthesias have also been reported with the MAOIs and can be treated with pyridoxine 50 to 150 mg/day.²⁵² The nonselective MAOIs are not associated with proarrhythmic, antiarrhythmic, or contractility effects when used in therapeutic dosages. Rash is by

far the most common side effect reported with the selegiline patch, with an approximate incidence of 30% to 40%. Like other MAOI, selegiline can be quite activating, and insomnia is frequently reported.

DRUG-FOOD INTERACTIONS

31. G.R. states that what she most fears is the “cheese reaction.” What steps can be taken to avoid it?

The “cheese reaction,” which can manifest as a hypertensive crisis, is so named because it occurred in patients who were taking nonselective MAOIs and ingested foods high in tyramine, a byproduct of tyrosine metabolism that is found in certain foods and beverages, such as aged cheese or Chianti wine (Table 79-20). When tyramine is ingested in the absence of an MAOI, it is rapidly metabolized by MAO in the GI tract before systemic absorption. In the presence of an MAOI, more tyramine is absorbed and relatively high concentrations of tyramine may be achieved in circulation, resulting in the displacement of norepinephrine (and other catecholamines) from presynaptic storage granules. Norepinephrine surges out into the synapse, and as metabolic degradation is inhibited by the MAOI, a profound pressor response is triggered.²⁵³ The transdermal application of low-dose selegiline (i.e., 6 mg patch) does not cause appreciable MAOI activity in the GI tract, so normal tyramine degradation continues to occur locally, and dietary restrictions are unnecessary with this strength.

Hypertensive crisis can occur at any time after ingesting the tyramine-containing food and is probably not related to the duration of MAOI therapy.²⁴⁴ Reports of hypertensive crisis are sporadic and difficult to quantify. About 8% of phenelzine

Table 79-20 Foods Containing Tyramine

High Amounts of Tyramine^a

Smoked, aged, or pickled meat or fish
Sauerkraut
Aged cheeses (e.g., Stilton, blue cheese)
Yeast extracts (e.g., Marmite)
Fava beans

Moderate Amounts of Tyramine^b

Beer (microbrewed > commercial)
Avocados
Meat extracts
Red wines such as Chianti

Low Amounts of Tyramine^c

Caffeine-containing beverages
Distilled spirits
Chocolate
Soy sauce
Cottage and cream cheese
Yogurt and sour cream

^a May not consume.

^b May consume in moderation.

^c May consume.

Adapted from Shulman KI et al. Dietary restriction, tyramine, and the use of monoamine oxidase inhibitors. *J Clin Psychopharmacol* 1989;9:397.

patients and 2% of tranylcypromine patients reported hypertensive reactions based on a chart review of 198 patients taking MAOIs.²⁴⁴ However, it is a relatively rare event and is certainly found less often than MAOI-induced orthostatic hypotension.

Patients who are to receive nonselective MAOIs should be reliable and willing to comply with food and medication restrictions. This adverse event can be minimized with a low-tyramine diet that begins several days before starting the MAOI and continues for 3 to 4 weeks after stopping the MAOI. The severity of the cheese reaction is related to the amount of tyramine in any given food (i.e., 20 mg of tyramine can produce a severe hypertensive reaction), and the amount of tyramine can vary greatly in “high-tyramine food items.”^{254,255} Foods that absolutely should not be consumed with nonselective MAOIs include aged cheeses, concentrated yeast extracts, fava beans, and sauerkraut.²⁵⁶ Microbrewed beers have much higher tyramine content than large, commercially produced varieties and are best avoided. Likewise, consumption of any food that has spoiled, is overripe, or has fermented, even if it is not found in the restricted list, should be avoided. Foods that typically contain tyramine and therefore should be avoided or consumed with caution when taking an MAOI are listed in Table 79-20.

32. How should an MAOI-induced hypertensive crisis be managed in G.R.?

A hypertensive crisis should be considered a medical emergency. In a hospital setting, general supportive measures are used, with attention to respiratory, metabolic, and cardiovascular systems. The urine should be acidified (e.g., with vitamin C), and IV beta-blockers are often given (e.g., phentolamine [Regitine] 5 mg IV followed by 0.25–0.50 mg IV every 4–6 hours). On occasion, patients have also received prescriptions for nifedipine with instructions to carry the medication with them and administer a 10-mg sublingual dose (if necessary).²⁵⁷

DRUG–DRUG INTERACTIONS

33. What common drug–drug interactions are associated with the nonselective MAOIs?

Several potentially fatal drug–drug interactions occur with this group of antidepressants. Like the reaction with tyramine, indirect sympathomimetics such as phenylpropanolamine and pseudoephedrine (common ingredients in over-the-counter cold preparations and diet pills) can cause a precipitous rise in BP that can result in cerebrovascular accident.

The potential for inducing serotonin syndrome with the combination of SSRIs and MAOIs has been well chronicled. A washout period of at least 14 days should separate the use of an SSRI and an MAOI. Because fluoxetine (and its primary active metabolite norfluoxetine) has a much longer half-life, the recommended washout period is at least 5 weeks after discontinuing this particular SSRI. Caution is advised when other serotonergic medications are prescribed (see “Serotonin Syndrome” section). In addition, patients should avoid medications such as carbamazepine and cyclobenzaprine, which are structurally related to the TCAs.²⁵⁸ Meperidine (Demerol) can cause a life-threatening interaction with MAOIs that is somewhat reminiscent of serotonin syndrome. This reaction is a result, in part, of the MAOI interfering with the degradation of the meperidine and is manifested by agitation, hyperthermia, and circulatory collapse.²⁵⁹ Other narcotic analgesics such as

meperidine, methadone, and tramadol may also trigger this reaction. Codeine and hydrocodone do not appear to have this effect when combined with MAOIs.

Depression With Psychotic Features (Psychotic Depression)

34. R.S., a 41-year-old man, is brought to the crisis stabilization unit (CSU) by the police because of extremely agitated behavior. His wife had called the police because R.S. was on the roof of their home with a gun shooting into the shingles. R.S. had worried for some time that the mortgage balance on the house was too large; now he was yelling that the house was “killing his spirit” and that he could not handle it any longer. He had told his wife that he was “inadequate as a provider” for her and their two children. In your interview with him at the CSU, he tells you that for the past week he has been hearing the voice of his deceased father telling him to kill himself after destroying the house. This has distressed him greatly. Of note, he was fired from his job as a computer analyst 6 weeks ago. His sleep is reported by his wife to be poor over the past month, with difficulties in falling asleep as well as waking up during the night and being unable to resume sleeping. His mood is depressed, and he has lost 15 lb in the past 2 weeks as a result of decreased appetite. His psychiatric history is positive for two past episodes of depression, one at age 22 and the other at age 35. Both episodes resolved after 8-week courses of imipramine 250 mg/day. He is diagnosed with major depressive disorder, recurrent, with psychotic features, and is admitted to the adjacent hospital for treatment. What features of psychotic depression are evident with R.S.?

Psychotic depression, also known as *delusional depression* or *depression with psychotic features*, is a type of affective illness in which the individual manifests with primary mood symptoms found in major depression and also demonstrates secondary psychotic features, such as delusions (fixed, false beliefs) and/or hallucinations (generally auditory). This disorder may be regarded as an extreme form of depression in which the individual’s mood is so disturbed that perception is significantly impaired or distorted. Endocrine abnormalities and imaging studies strongly suggest that depression with psychotic features is distinct from unipolar depression, and there is evidence that it more closely resembles bipolar illness. Psychotic depression has been estimated to occur in at least 5% of the depression admissions to acute care hospitals in the United States, and it may be comparatively more common in the geriatric population.²⁶⁰

The delusions and hallucinations encountered with psychotic depression can be classified as either mood congruent or mood incongruent. Mood-congruent psychotic features imply that the psychosis is consistent with the depressive illness. In depression, mood-congruent delusions might include self-deprecatory thoughts as well as extreme feelings of guilt, sinfulness, or nihilistic ideation. Mood-incongruent psychotic features imply that the psychotic content is not consistent with the overall mood but, rather, is bizarre, much like that seen in schizophrenia. An example of mood-incongruent features may be a giggle or grin as a patient describes his or her misery and desire to commit suicide.

R.S. described mood-congruent hallucinations when he spoke of his dead father commanding him to kill himself. His

ideas of being inadequate and not a good provider are also consistent with a mood-congruent delusion.

35. Why is it critical to resolve R.S.'s psychotic depression promptly? What treatment options are available for R.S.?

Psychotic depression is associated with much greater morbidity and mortality than other forms of major depression and also carries a higher risk of suicide than other types of depressive illness. This factor is currently a major concern in R.S.'s case because he has reported suicidal ideation.

Psychotic depression is often refractory to antidepressant monotherapy.^{261,262} If pharmacotherapy is used in R.S., the historical approach has been to prescribe an antipsychotic medication in addition to an antidepressant medication. The combination of an antipsychotic and an antidepressant has proved to be superior to either component alone in psychotic depression. Several combination products are available that contain both an antipsychotic and an antidepressant (e.g., Symbyax contains fluoxetine and olanzapine). Although these combination products may appear to be convenient, they are fixed-dose combinations, and it is impossible to titrate the dosages of the individual agents independently. In psychotic depression, as the psychosis lifts, it is often prudent to taper and discontinue the antipsychotic agent while maintaining the antidepressant medication for a full course of treatment. If the antipsychotic drug is continued after the psychosis has lifted, the patient may be at greater risk for the neurotoxic effects of the antipsychotic (e.g., pseudoparkinsonism, tardive dyskinesia) as well as an increased side effect burden overall.

Atypical or second-generation antipsychotics, such as risperidone and olanzapine, are believed to possess some antidepressant properties, leading researchers to consider their usefulness as monotherapy for this disorder.²⁶³ There is still some controversy as to whether the atypical agents are relieving depressive symptoms or the negative symptoms of schizophrenia; however, their ability to block postsynaptic 5-HT₂ receptors and facilitate dopamine transmission in certain areas of the brain suggests genuine antidepressant properties. Furthermore, their proven efficacy in treating bipolar disorder (both mania and depression) may suggest some clinical benefit in managing refractory depression or depression with psychotic features. At present, evidence supporting their use in psychotic

Table 79-21 Seven Things That Everyone Should Know About Depression

- **Depression is NOT a personality flaw or a weakness of character.** Depression has been associated with a chemical imbalance in the nervous system, which can be easily corrected with antidepressant medications and associated counseling.
- **All antidepressants are equally effective.** Approximately 65% of patients receiving a therapeutic trial of any antidepressant medication will have a beneficial response.
- **Most patients receiving antidepressants will experience some side effect(s) initially.** Identify an accessible health professional who can answer your questions.
- **Antidepressants should be taken at the same time daily.** This will make it easier for you to remember to take the medication and may also minimize side effects.
- **The response to antidepressants is delayed.** Several weeks may pass before you begin to feel better, and it may take 4 to 6 weeks before maximal benefits are evident.
- **Antidepressants must be taken for at least 6 to 9 months.** Even if you are feeling completely better, studies have shown that people who stop their medication during the first 6 months are much more likely to become depressed again.
- **Antidepressants are NOT addictive substances.** Antidepressants may elevate the moods of depressed individuals, but they do not act as stimulants and are not associated with craving or other abuse patterns. However, if certain antidepressants are discontinued abruptly, mild withdrawal reactions may occur.

depression is preliminary. The most rigorous trial compared the effects of risperidone with combination therapy with haloperidol and amitriptyline.²⁶⁴ Although combination treatment did appear to be more efficacious, risperidone produced substantial declines in depression and general psychopathology. Several other case reports suggest that the atypical antipsychotics are worthy of additional study.

If pharmacotherapy is unsuccessful, ECT has proven to be a particularly effective remedy for this psychotic depression. ECT has a reported success rate of 80% to 85% in this population, and the onset of effect is quite rapid. The ideal frequency of maintenance treatments, however, has not been established.

In summary, Table 79-21 offers seven points that everyone should know about depression.

- Lithium 80-16
- Lithium Refractoriness 80-16
- Anticonvulsants 80-16
- Atypical Antipsychotics 80-17

Manic-depression distorts moods and thoughts, incites dreadful behaviors, destroys the basis of rational thought, and too often erodes the desire and will to live. It is an illness that is biological in its origins, yet one feels psychological in the experience of it; an illness that is unique in conferring advantage and pleasure, yet one that brings in its wake almost unendurable suffering and, not infrequently, suicide.

Kay Redfield Jamison¹

INTRODUCTION

Bipolar disorder (formerly known as *manic-depression*) is a chronic and progressive illness that disrupts and disables the lives of those afflicted. Impairment in day-to-day functioning continues even when mood symptoms have dissipated.² Based upon a report from the National Institute of Mental Health patients typically spend one-fourth of their adult lives in the hospital and half of their lives disabled.³ In fact, the burden of bipolar disorder exceeds many severe illnesses such as human immunodeficiency virus, diabetes mellitus, and asthma.⁴

Diagnosis and Classification

Mood disorders are diagnosed using the criteria established in the *Diagnostic and Statistical Manual of Mental Disorders*, Fourth edition, Text Revision (DSM-IV-TR).⁵ Discrete periods of mood disturbance are defined as *major depressive episodes*, *manic episodes*, *hypomanic episodes*, or *mixed episodes*.

Manic or hypomanic episodes (Table 80-1) are periods of abnormally and persistently elevated, expansive, or irritable

mood.⁵ Hypomanic episodes are less intense than manic episodes, which are severe enough to impair functioning (self-care, occupational, social), complicate a medical condition, result in psychotic features, or require hospitalization.⁵ Although manic and hypomanic episodes are characteristic symptoms of bipolar disorder, it is depressive episodes that predominate. Depressed mood is ordinarily the initial presenting symptom.^{6,7} Bipolar disorder and major depressive disorder share the same criteria with major depressive episodes (Table 79-4).⁵ A mixed episode is diagnosed when a patient meets criteria for both a major depressive episode and a manic episode concurrently for at least a 1-week period.⁵ Associated symptoms with mixed episodes include agitation, insomnia, changes in appetite, psychosis, and suicidality.

A person who has experienced one or more manic or mixed episodes with or without a depressive episode is diagnosed as having *bipolar I disorder*. An individual who has experienced one or more episodes of both hypomania and depression (without a history of manic or mixed episodes) is diagnosed as having *bipolar II disorder*.⁵

The diagnosis of a *cyclothymic disorder* is used for a person who has experienced at least 2 years of mood cycling characterized by numerous periods with hypomanic symptoms and separate periods with depressive symptoms that do not meet the criteria for a major depressive episode. *Bipolar disorder, not otherwise specified* (NOS), refers to disorders with features of mania or hypomania that do not meet the criteria for a specific bipolar disorder.⁵

The DSM-IV-TR also uses a series of descriptors called *specifiers* to further characterize the course of illness and the

Table 80-1 DSM-IV-TR Criteria for a Manic Episode^a

1. A distinct period of abnormally and persistently elevated, expansive, or irritable mood, lasting ≥ 1 week (or of any duration if hospitalization is necessary).
2. During the period of mood disturbance, ≥ 3 of the following symptoms have persisted (4 if the mood is only irritable) and have been present to a significant degree:
 - Inflated self-esteem or grandiosity
 - Decreased need for sleep (e.g., feels rested after only 3 hours of sleep)
 - More talkative than usual or pressure to keep talking
 - Flight of ideas or subjective experience that thoughts are racing
 - Distractibility (i.e., attention too easily drawn to unimportant or irrelevant external stimuli)
 - Increase in goal-directed activity (either social, at work, at school, or sexually) or psychomotor agitation
 - Excessive involvement in pleasurable activities that have a high potential for painful consequences (e.g., the person engages in unrestrained buying sprees, sexual indiscretions, or foolish business investing)
3. The symptoms do not meet the criteria for a Mixed Episode.
4. The mood disturbance is sufficiently severe to cause marked impairment in occupational functioning or in usual social activities or relationships with others, or to necessitate hospitalization to prevent harm to self or others, or there are psychotic features.
5. The symptoms are not due to the direct physiologic effects of a substance (e.g., a drug of abuse, a medication, or other treatment) or a general medical condition (e.g., hyperthyroidism).

^aCriteria for a hypomanic episode are identical to a manic episode however the symptoms need only be present for 4 days and are not severe enough to cause marked impairment in occupational functioning or in usual social activities or relationships with others, or to necessitate hospitalization to prevent harm to self or others, or for psychotic features to be present. Manic-like episodes that are clearly caused by somatic antidepressant treatment (e.g., medication, electroconvulsive therapy, light therapy) should not count toward a diagnosis of bipolar I disorder.

Reprinted with permission from American Psychiatric Association. Mood Disorders. In: Diagnostic and Statistical Manual of Mental Disorders. Fourth Ed. Text Revision. Washington, DC: American Psychiatric Association; 2000;362:368.

most recent type of episode experienced by the individual. Recent episodes are first classified as hypomanic, manic, mixed, or depressed. They may be described further in terms of severity (mild, moderate, severe), the presence of psychotic features (in partial or full remission), with or without catatonic features, or with onset during the postpartum period. Other specifiers convey information regarding the pattern of illness. For example, some individuals experience major depressive episodes at a characteristic time of the year (usually the winter) or switch from depression to mania during a particular season. The specifier “with seasonal pattern” applies only to the pattern of major depressive episodes. Other specifiers describe whether full recovery between episodes (i.e., with or without full interepisode recovery) occurs and whether individuals experience rapid cycling (four or more mood episodes/year).⁵

Epidemiology and Cost Burden

Using DSM-IV criteria, the lifetime prevalence of bipolar I disorder is estimated to be 1.0%; bipolar II disorder is slightly more common at 1.1%.⁸ The prevalence rate for the bipolar spectrum of illnesses which includes bipolar I, bipolar II, and subthreshold bipolar disorder (mood symptoms present but not

meeting full diagnostic criteria) is 4.4%.⁸ Bipolar I and II are more common in females than in males, whereas subthreshold illness predominates in males.⁸ The familial nature of bipolar disorder has been well established. The estimated relative risk of bipolar disorder in first-degree relatives of probands has been estimated to be 10.7.⁹ Twin studies add further support to the genetic linkage of bipolar disorder. Goodwin and Jamison report a 63% concordance rate (rate of illness in co-twin of affected proband) for monozygotic twins compared with 13% for dizygotic twins.⁹ The cost of bipolar illness in 1991 was reported to be \$45 billion.¹⁰ Direct costs accounted for 17% of the total, whereas the remaining 83% was owing to indirect costs such as lost wages, suicide, institutional care, and caregiver burden.

Clinical Signs and Symptoms

A manic episode usually begins with a change in sleep patterns along with mood elevation. Target symptoms typically include increased talkativeness, staying awake all night, and bursts of energy during which projects are begun but rarely completed. Mania often is characterized by thought disturbances. Patients may exhibit “flight of ideas” (rapid speech that switches among multiple ideas or topics) and delusions of grandeur (false beliefs of special powers, knowledge, abilities, importance, or identity). The behavior of manic patients is characterized as being intrusive, loud, intense, irritable, suspicious, and challenging. They often exercise poor judgment. For example, they may spend large sums of money in business deals that ultimately fail, become sexually promiscuous, take excessive risks, or fail to obey laws.

These symptoms usually develop gradually over several days to more than a week in three stages. *Stage I* is characterized by euphoria, irritability, labile affect, grandiosity, overconfidence, racing thoughts, increased psychomotor activity, and an increase in the rate and amount of speech. This stage corresponds to an episode of hypomania. *Stage II* features increased dysphoria (a feeling of extreme discomfort and unrest), hostility, anger, delusions, and cognitive disorganization without apparent cause. This stage corresponds to acute mania. Many patients progress no further than this stage. Others may proceed to *stage III*, in which the manic episode progresses to an undifferentiated psychotic state. Individuals in stage III experience terror and panic. Their behavior is bizarre and psychomotor activity is frenzied. They may experience hallucinations. They progress from disorganized thought patterns to incoherence and disorientation. Just as the manic episode gradually builds, it often declines in a gradual manner. Psychotic symptoms usually resolve first, whereas irritability, paranoia, and excessive behavior continue. Slowly, remaining symptoms such as hyperverboosity, seductiveness, and dysphoria decrease.¹¹

Course of Illness

The mean age of onset for the bipolar spectrum of illnesses is 21 years.⁸ Bipolar I is the earliest in onset at 18 years, compared with bipolar II at 20 years and subthreshold bipolar disorder at 22 years.⁸ Approximately 20% to 30% of new cases occur in children between 10 and 15 years old.^{12,13} Patients may present initially with mania, hypomania, depression, or a mixed episode. However, 75% of patients report

having had multiple episodes of depression before the development of a manic episode.¹² Misdiagnosis is common early in the illness with a startling 69% of patients reporting being misdiagnosed.¹² Furthermore, up to 26% reported visiting as many as five physicians before an accurate diagnosis was made. Interestingly, although 70% of patients reported having at least one symptom of mania before, only about 40% reported these symptoms to a physician.¹² After 60 years of age, there is a significant decrease in the new onset of bipolar disorder.¹⁴ Therefore, a presentation of mania later in life should alert the clinician to an underlying medical problem as the possible cause.

Bipolar disorder is a recurrent illness; single episodes of mania occur in fewer than 10%.⁵ Most suffer multiple episodes of mania, hypomania, or depression separated by periods of euthymia (normal mood) throughout the course of their lives. In the majority, mania occurs just before or immediately after a depressive episode.⁵ There may be a 5- to 10-year period from the onset of illness until the first hospitalization or diagnosis.¹⁴

The course of illness is characterized by episode, length duration of euthymic intervals, frequency of relapse, severity of episodes, and predominant syndrome (mania, hypomania, or depression). These factors do not remain fixed throughout an individual's illness. For instance, individuals may experience episodes of dysphoria and depression before ever experiencing hypomania or mania. Often, the euthymic interval and cycle length decrease with additional episodes. Over time, a course of alternating manic and depressive episodes without intervening euthymic periods can develop.

People diagnosed with either bipolar I or II disorder who experience shorter cycle lengths and who suffer from four or more episodes of depression, hypomania, mania, or a mixed episode in a year are identified as "rapid cyclers." Rapid cycling occurs in 20% of cases; women are more often affected than men.¹⁵ Individuals with rapid cycling bipolar disorder often are refractory to conventional treatment and suffer significant morbidity and mortality because of their rapid changes in mood. They may have little or no euthymic period between manic and depressive episodes. This can have drastic family, social, and occupational consequences.

Unfortunately, despite adequate treatment, 73% of individuals with bipolar disorder relapse within 5 years. Furthermore, nearly half continue to experience significant mood symptoms between episodes, and fewer than 20% are euthymic or have minimal symptoms.¹⁶

Complications of Bipolar Illness

Patients with bipolar illness have higher rates of mortality from both natural and unnatural causes. Higher rates of natural mortality largely result from cardiovascular disease.¹⁷ Suicide (primarily in depressive and mixed episodes) and excessive risk-taking behaviors (primarily during manic or hypomanic episodes) also contribute to the high mortality rate. Significant risk factors for suicide in bipolar patients include drug abuse, hospitalization for depression, age younger than 35 years, a recent (within 2 years) hospitalization, previous suicide attempts, and a family history of affective disorders.^{18,19} Overall mortality as well as deaths owing to suicide or cardiovascular causes are significantly reduced in bipolar patients who are adequately treated.¹⁶

Bipolar patients are especially prone to substance abuse. Approximately 42% have comorbid substance use disorders.⁸ Rapid cyclers and those with dysphoric mania have the highest rates of concomitant substance abuse.¹⁹ Individuals in a manic phase may engage in sexual indiscretions or risky sexual practices that expose them to sexually transmitted diseases.

The World Health Organization recently identified the top ten causes of disability-adjusted life-years in the world; bipolar disorder ranked sixth.²⁰ Individuals with bipolar disorder are likely to experience stress and upheaval in many areas of their lives, including relationships, employment, and finances. Of bipolar patients, 88% have been hospitalized once and 66% at least two times.²⁰ Patients with manic and depressive episodes have divorce rates that are two- to threefold higher than those found in nonaffected populations. Patients often report having poor relationships with family members, and nearly 75% report that their family members have a limited understanding of bipolar disorder.¹² Employment problems may result from bizarre, inappropriate, or unreliable behavior. In one study, 60% of patients reported being unemployed, 88% felt the disease affected how well they performed at work, and 63% felt that they were treated differently from their peers.¹² Financial and legal problems may result from excessive spending, involvement in schemes, substance abuse, and risk-taking behavior. Caregivers and family members may also suffer significant distress in caring for a relative with bipolar illness.²⁰

Treatment Overview

Several North American guidelines for the treatment of bipolar disorder exist.^{14,21–24} The most recent guidelines to be updated are from the Texas Implementation of Medication Algorithms and the Canadian Network for Mood and Anxiety Treatments.^{21,23} The goals of treatment across the phases of illness include the control of acute symptoms, symptom remission, return to normal level of functioning, prevention of relapses, and reduction of suicide.¹⁴ Both the acute treatment of manic and depressive episodes and maintenance treatment for prevention of future episodes require individualization of therapy; treatment decisions should take into account presenting symptoms, history of response, patient preference, and comorbid medical or substance use conditions.

Initial treatment strategies for hypomanic/manic episodes includes the preferred and well established antimanic agents lithium, valproate, or an atypical antipsychotic (AAP). Mixed episodes are more likely to respond to valproate or an AAP than lithium. Carbamazepine (CBZ) and the AAP olanzapine are effective in manic or mixed episodes; however, safety concerns preclude their use as first-line agents.^{21,25} Short-term use of benzodiazepines may be needed, particularly for severely ill or agitated patients.¹⁴ In the case of severe manic symptoms or in those only partially responsive to an adequate trial (generally 1–2 weeks) of monotherapy, a two-drug combination of lithium, valproate, or an AAP is recommended.²¹ CBZ, oxcarbazepine, or a typical antipsychotic alone or in combination with a preferred antimanic drug are potential alternatives. For treatment-resistant cases, electroconvulsive therapy (ECT), clozapine, or a three-drug combination of lithium plus an anti-convulsant (CBZ, oxcarbazepine, valproate) plus an AAP are recommended. When drug combinations are used, the individual agents should employ different mechanisms of action.

The treatment of acute depressive episodes emphasizes the use of drugs that target the depressed phase without inducing mania or cycle acceleration. Lithium or lamotrigine are preferred treatments for bipolar depression.^{14,21,23,24} For patients with a history of severe, recent, or recurrent mania, lamotrigine should only be used in combination with an antimanic agent.²¹ Despite being the only U.S. Food and Drug Administration (FDA)-approved treatments for bipolar depression, quetiapine and the olanzapine/fluoxetine combination (OFC), should be reserved for second-line use because of the risk of side effects such as metabolic complications.²⁵ After failure of these second-line options, a two-drug combination of lithium, lamotrigine, quetiapine, or OFC is appropriate.²¹ Subsequent medication trials can include antidepressants, such as selective serotonin reuptake inhibitors (SSRIs), bupropion, or serotonin and norepinephrine reuptake inhibitors (SNRIs), but only when used in combination with an antimanic agent.²¹ The use of antidepressants at this stage in treatment has been hotly debated.^{21,26} Because of concerns of undertreated depression, some authors have suggested earlier use of antidepressants; however, others advocate for an “antidepressant-sparing” strategy because of the risks of inducing mania and cycle acceleration. Owing to an increased risk of switching into mania and side effects, the use of monoamine oxidase inhibitors and tricyclic antidepressants (TCA) should be reserved for refractory cases.

Maintenance treatment of bipolar disorder should include continuing the acute phase treatment while periodically simplifying and moving toward monotherapy with lithium, valproate, or lamotrigine. Although several AAPs are effective in preventing relapse, they are considered alternative treatments owing to safety concerns.²¹ Patient and family education to improve medication adherence are vital to promote long term recovery. Causes of nonadherence that should be considered include ambivalence, side effects, lack of insight, and a reluctance to surrender the “high” of the manic episode.¹⁴ Patients should also be advised to maintain regular patterns of daily activities, a consistent sleep–wake cycle, meals, exercise routines, and other schedules.

CLINICAL ASSESSMENT

Clinical Presentation and Diagnosis

1. H.M., is a 23-year-old man, accompanied to the clinic by his wife, A.M. She called the clinic before bringing H.M. in and reported much of the following information. A.M. says that he was doing well until about 3 weeks ago, when his niece was killed in an automobile accident. At the funeral, he borrowed some “nerve pills” from his cousin. Since then, H.M. has been acting increasingly “wild.” He has been staying up later and later at night and often bursts into the bedroom at 2 or 3 A.M. and loudly awakens A.M. Sometimes, he presents her with expensive gifts, which they cannot afford. He often jumps on the bed and starts singing her love songs in a loud voice. A.M. notes that H.M. then almost always demands sex, after which he sleeps for a few hours and then loudly gets up and leaves the house.

H.M. recently has experienced problems at work, where he is a snack delivery truck driver. Over the last several weeks, he was noted to be loading his truck in a rapid and reckless manner. His boss received several reports that H.M. was driving unsafe and at high speeds. Store owners called to complain that he was giving

away free cases of snacks to customers. He often did not complete deliveries to the stores at the end of his route.

Last week, when his boss called to express concern over his behavior, H.M. said he was quitting his job. He wrote an illegible resignation note, which was at least 10 pages long, called an overnight air delivery service to deliver the note to his employer (who is located only 3 miles from his home), and then left the house before the driver arrived to pick it up. H.M. returned several hours later driving a brand new foreign car and wearing an expensive new suit, red cowboy boots, and a bright green hat with a large feather. He told A.M. that he had a new job, which was going to make him a millionaire.

Last night, she found a large sum of money in his pants pocket when emptying the clothes hamper. He did not come home at all, but he called her at 4 A.M. to tell her to pack for Dallas, where he was going to become the new head coach of the professional football team.

Upon arriving at the clinic, H.M. insists, “I don’t need no doc. I am supercalifragilistic!” He then bursts into song. He is dressed flamboyantly but needs a shave and shower. He gives the examiner (a stranger) a bear hug and has trouble sitting still, listening, or allowing others to talk. His speech is pressured and loud; he often fails to complete sentences or communicate entire ideas, and he is rhyming and punning. His mood obviously is elevated, but he becomes increasingly irritable throughout the examination. He insists he must get to Texas to sing the national anthem at a football game before the CIA can stop him; he then breaks down in tears. Within moments, he is again smiling and talking of money-making schemes. He is oriented to person and place, but thinks it is tomorrow. Intelligence seems average. When asked to interpret a proverb, H.M. becomes angry, throws a chair across the room, and yells, “Enough of this! Air Force One is waiting for me!” He then storms out of the office. How is H.M.’s presentation consistent with the diagnosis of a manic episode?

The hallmark of a manic episode is changes in mood, behavior, cognition, and perception (Table 80-1).¹¹ H.M. first demonstrates an elevated mood. He is exuberant and notes how great he feels. However, manic patients often demonstrate lability in their mood, and they may become irritable and easily frustrated, especially when challenged. In this case, H.M. becomes irritable and resentful when questioned by the examiner. His quick displays of sadness and anger further demonstrate the volatility of his mood.

H.M. displays behavior and speech typical of acute mania. He has a reduced need for sleep, behaves recklessly, and is overactive. His speech is pressured, loud, and full of rhymes and puns, and he sings to express his emotion. As illustrated by H.M., speech may skip from topic to topic in a “flight of ideas.” Behavior often is characterized as being excessive and expansive. H.M. dresses flamboyantly, hugs his examiner, writes an unnecessarily lengthy letter of resignation, seeks an overnight courier service for local delivery, presents his wife with lavish gifts, and distributes merchandise to strangers.

Delusions are often present in acute mania and are grandiose in nature and deal with inflated abilities, self-importance, wealth, or special missions in life. H.M. makes unrealistic comments about his money-making schemes, his singing ability, his position as the coach of a professional football team, and his intended use of the presidential plane. Persecutory delusions may also be present such as H.M.’s fear that the CIA is going to stop him.

Patients with acute mania are often disorganized and do not complete tasks. They tend to skip from idea to idea and scheme to scheme. In this case, H.M. neglects his hygiene, fails to complete his deliveries, and neglects sending out his resignation letter.

Precipitating Factors

2. What factors make H.M. vulnerable to the occurrence of a manic episode at this time?

The mean age of onset for bipolar disorder is 21 years of age.⁸ Thus, H.M. is at the age in which his disorder would be likely to first manifest itself. In addition, manic episodes are often precipitated by psychosocial stressors.²⁷ The death of H.M.'s niece may have served as a predisposing factor for the development of a manic episode.

A variety of medications and clinical states can induce or precipitate manic episodes (Table 80-2). The most common drug causes of mania involve medications that affect monoamine neurotransmitters,²⁸ such as antidepressants and stimulants. Corticosteroids, anabolic steroids, isoniazid, levodopa, caffeine, and over-the-counter stimulants can induce or aggravate mania. Sleep loss also can be a significant cause of mania.²⁷ A reduction in sleep after the death of his niece could have contributed to the development of H.M.'s manic episode.

3. If the “nerve pills” borrowed by H.M. were antidepressants, could they have contributed to the development of his manic episode?

All major classes of antidepressants including monoamine oxidase inhibitors, TCAs, SSRIs, and SNRIs may precipitate mania in an estimated 20% to 40% of patients with bipolar disorder.²⁹ Despite the purported risk, up to 78% of patients

with bipolar disorder are treated with antidepressants, but only 56% receive mood stabilizers.²⁶ There are numerous case reports of induction of mania or hypomania with antidepressant treatment, but few controlled studies making it difficult to make comparisons across antidepressant classes. A comparison of the monoamine oxidase inhibitor, tranylcypromine, and the TCA, imipramine, found a similar rate of treatment emergent mania between groups (21% and 25%, respectively).³⁰ A meta-analysis found a higher switch rate for TCAs (11.2%) than for SSRIs (3.7%), which approximated placebo (4.2%).³¹ A controlled trial with bupropion, sertraline, and venlafaxine (in combination with a mood stabilizer) found an overall switch rate of 19% during acute treatment and 37% during the continuation phase of the study with no significant difference between agents.³² Antidepressants may also cause cycle acceleration in bipolar disorder, which effectively decreases the time between mood episodes. The risk for cycle acceleration may be heightened for patients who develop manic or hypomanic symptoms on antidepressants despite receiving antimanic treatment concurrently.³³ In the case of H.M., an antidepressant may have precipitated the manic episode or shortened his cycle, moving him into an episode of mania from a preexisting state of depression or euthymic mood.³⁴

TREATMENT OF ACUTE MANIA

4. Why does H.M. require treatment?

Manic episodes have a number of severe complications. Left untreated, severe mania can result in confusion, fever, exhaustion, and even death. The impairment in judgment, the excesses, and the risk-taking that occur during manic episodes may devastate relationships, careers, and finances, and lead to physical harm and loss of life. Manic individuals may engage in illegal activities or behave in a manner that results in a violation of the law. H.M. drives recklessly, may have lost his job, spends excessive amounts of money on gifts, clothing, and automobiles; and plans to participate in a variety of money-making schemes. He has acquired a great deal of cash suddenly, perhaps from withdrawing all of his family's savings or from some type of illegal enterprise. Manic patients also may engage in risky sexual encounters, leading to infection with sexually transmitted diseases or human immunodeficiency virus. Alcohol and drug abuse are common. Irritability, such as that demonstrated by H.M., can lead to episodes of violence, resulting in potential harm to the patient or to others. The goals of treatment are to reduce the severity and duration of the current mood episode as well as to prevent recurrence of future episodes.

Valproate (Divalproex, Valproic Acid)

5. What is the appropriate treatment for H.M.'s acute manic episode?

Depending on the type and severity of mania, first-line treatment includes lithium, valproate, AAPs (aripiprazole, quetiapine, risperidone, ziprasidone), or a combination of these agents.^{14,21–24} Table 80-3 lists the treatment recommendations as summarized by North American Treatment Guidelines. Considering H.M.'s presentation, monotherapy with a first-line agent is appropriate.^{14,21–24} In the past, lithium was the preferred first-line agent for mania, but its use is limited by a

Table 80-2 Selected Drugs Reported to Induce Mania

| | |
|--------------------------------|---|
| <i>Anticonvulsants</i> | Gabapentin, lamotrigine, topiramate |
| <i>Antidepressants</i> | Monoamine oxidase inhibitors, TCAs, SSRIs, SNRIs, bupropion, nefazodone, trazodone, mirtazapine |
| <i>Antimicrobials</i> | Clarithromycin, ofloxacin, cotrimoxazole, erythromycin, isoniazid, metronidazole, zidovudine, efavirenz |
| <i>Anti-Parkinsonian Drugs</i> | Levodopa, amantadine, bromocriptine |
| <i>Anxiolytics/hypnotics</i> | Buspirone, alprazolam, triazolam |
| <i>AAPs</i> | Aripiprazole, olanzapine, quetiapine, risperidone, ziprasidone |
| <i>CNS stimulants</i> | Caffeine, cocaine, methylphenidate, amphetamine, |

narrow therapeutic index, drug interactions, and bothersome side effects. However, some experts indicate that lithium remains the preferred mood stabilizer in euphoric mania. The efficacy of valproate in acute mania has been shown to be comparable with lithium; approximately one-half of patients will demonstrate at least a 50% reduction on the Mania Rating Scale derived from the Schedule for Affective Disorders and Schizophrenia.³⁵ Valproate may also be preferred in patients who have characteristics that predict a poor response to lithium, such as substance abuse, rapid cycling, mixed states, or multiple prior episodes.²²

Dosing and Monitoring

6. Valproate was chosen for the management of H.M.'s mania because of comparable efficacy to lithium as well as the more rapid onset of effect.¹⁴ How should valproate therapy be initiated, and what baseline tests are necessary? How will H.M.'s response to therapy be monitored?

The initial dose of valproate for H.M. should be 250 mg three times per day.¹⁴ The dosage should then be increased by 250 to 500 mg every 2 to 3 days to obtain steady-state serum valproate levels between 45 and 125 mcg/mL or a maximum dosage of 60 mg/kg/day.³⁶ An alternative strategy is to use an oral loading regimen of 20 to 30 mg/kg/day given on a TID schedule during an acute episode of mania. This approach has been used during inpatient management, and may result in a more rapid onset of effect.³⁷ The correlation between serum concentration and efficacy is not well established with valproate levels of 45 mcg/mL being a minimum threshold and higher concentrations offering greater benefit. In fact, those achieving a serum concentration of 80 mcg/mL by day 3 had greater symptom improvement at days 3 and 5 of treatment.³⁷ A pooled analysis demonstrated a linear relationship between serum concentration and efficacy with the greatest improvement found in patients with valproate levels >94 mcg/mL.³⁸ Above valproate levels of 125mcg/mL, the risk of side effects increases.³⁹

Before valproate is initiated, baseline laboratory tests, including a complete blood count (CBC) with differential and platelets, and liver function tests should be obtained. H.M.'s baseline weight and neurologic status should be recorded. In premenopausal women who have not undergone surgical sterilization, a baseline pregnancy test is warranted. Attention should be given to any medications that might be administered concurrently with valproate because interactions with

aspirin, phenytoin, phenobarbital, lamotrigine, rifampin, warfarin, felbamate and carbamazepine are cited frequently (also see Chapter 54).

Valproate should decrease the severity and duration of H.M.'s current manic episode, decrease the frequency of subsequent episodes, and increase the euthymic period between episodes. Once treatment has started, H.M. should be monitored for response of his initial target symptoms, including grandiosity, decreased need for sleep, pressured speech, distractibility, and impulsivity. Symptom improvement with valproate can be expected in approximately 5 days.⁴⁰

SIDE EFFECTS

7. What are the potential side effects of valproate therapy? How should H.M. be monitored for these possible effects?

H.M. should be monitored for potential dose-related adverse reactions of valproate including various gastrointestinal (GI) complaints (nausea, diarrhea, dyspepsia, anorexia), sedation, ataxia, tremor, benign hepatic transaminase elevations, and thrombocytopenia. GI complaints may be mitigated by reducing the dosage, changing to an extended-release preparation, or administering an antacid or H₂-antagonist. Central nervous system (CNS) effects such as ataxia and sedation may respond to dosage reduction, although sedation may resolve with continued treatment. If tremor is bothersome or interferes with the patient's functioning, dosage reduction or change to the extended-release preparation may provide relief.⁴¹ Alopecia occurs in 0.5% to 12% of patients and may improve with dose reduction.⁴² Small elevations in transaminases are considered benign; however, valproate should be discontinued if elevations are more than two to three times the upper limit of normal.

Weight gain occurs in up to 20% of patients receiving valproate.³⁹ The increase in body weight is particularly distressing to some patients and may contribute to medication nonadherence. Weight gain has been associated with valproate serum concentrations >125 mcg/mL; therefore, dosage reduction may be helpful.³⁹ Valproate also has been associated with the development of polycystic ovary syndrome in women.⁴³ Core features of polycystic ovary syndrome include oligomenorrhea and hyperandrogenism, which develop concurrently in about 10% of women with bipolar disorder after taking valproate. The clinical features associated with polycystic ovary syndrome include menstrual irregularities, infertility, hirsutism, alopecia, insulin resistance, hyperlipidemia, and obesity.

There are several reports of valproate-induced hyperammonemic encephalopathy in psychiatric patients.^{44,45} Patients presenting with coma or mental status changes should have serum ammonia and liver functions tests ordered. If valproate-induced hyperammonemic encephalopathy is suspected, then valproate should be discontinued. Other serious adverse events with valproate include fulminant hepatic failure, agranulocytosis, and pancreatitis, all of which require discontinuation of therapy as well.

Once valproate therapy is initiated, liver function tests, valproate serum levels, and CBCs with differential and platelets should be monitored at least monthly for the first 3 months and every 3 to 6 months thereafter.¹⁴ Body weight should also be determined at baseline and monitored monthly during therapy.

8. H.M. was titrated to a total daily valproate dosage of 2,500 mg/day and a steady-state plasma concentration of 95 mcg/mL was reported after 1 month of treatment. A routine CBC with differential and platelet count was ordered at this time and the following data were reported: white blood cell (WBC) count, $8.5 \times 10^3/\text{mm}^3$; hemoglobin, 14.5 g/dL; hematocrit, 43%; red blood cells, $5.2 \times 10^6/\text{mm}^3$; neutrophils, 59%; lymphocytes, 27%; monocytes, 6%; eosinophils, 2%; basophils, 0.5%; and platelets, $75 \times 10^3/\text{mcL}$. How should H.M.'s valproate-induced thrombocytopenia be managed?

[SI units: WBC count, $8.5 \times 10^9/\text{L}$ (normal, 3.2–9.8); hemoglobin, 145 g/L (normal [male], 115–155); hematocrit, 0.43 L (normal [male], 0.39–0.49); red blood cells, $5.2 \times 10^{12}/\text{L}$ (normal [male], 4.3–5.9); neutrophils, 0.59 L (normal, 0.54–0.62); lymphocytes 0.27 L (normal, 0.25–0.33); monocytes, 0.06 L (normal, 0.03–0.07); eosinophils, 0.02 L (normal, 0.01–0.03); basophils, 0.005 L (normal, 0–0.0075); platelets, $75 \times 10^9/\text{L}$ (normal, 130–400)]

Valproate-induced thrombocytopenia occurs rarely and is associated with higher serum levels.³⁹ Nevertheless, clinicians should educate patients to look for signs such as easy bruising or bleeding. In most patients, thrombocytopenia is asymptomatic and responds to a lowering of the valproate dosage; complete discontinuation of the drug is often unnecessary.⁴⁶ H.M.'s dosage should be reduced, and his platelet count should be monitored closely. In addition, he should be observed for reemerging symptoms of mania.

Lithium

PRELITHIUM WORKUP

9. C.N., a 21-year-old woman, was diagnosed with her first episode of mania 3 weeks ago. At that time, she was hospitalized and treated with lithium at a dose of 1,200 mg/day (serum level, 0.8 mEq/L). C.N.'s manic episode was stabilized, and after 10 days she was discharged from the hospital. She was scheduled to see her outpatient psychiatrist for follow-up 1 week later, but failed to keep the appointment. Today, C.N. arrives at the emergency department at the request of her mother. C.N. is pulling her mom's hair and kicking wildly as she is pulled from the car. She can be heard screaming "The FBI is after me, Mom! You want them to find me, don't you? I would have made it out of the country if you hadn't gotten in the way! I was going to marry Prince Charles and become the new queen of England." Upon evaluation, C.N.'s mood is irritable, and she is pacing around the interviewer. She is dressed in a short skirt and high heels and is wearing an excessive amount of makeup and costume jewelry. During the interview, she interrupts the examiner, smiles, and says in a loud, provocative voice "Let's you and me get out of here!" Her mother states that after C.N. was discharged from the hospital, she lost her prescription and within several days, stopped attending her classes at the local community college. She began staying out late, playing her radio loudly, and driving recklessly, finally hitting the side of the garage while parking early this morning. What laboratory tests are required before initiating lithium therapy for C.N.?

Because lithium can affect many organ systems, baseline laboratory values must be evaluated before therapy is initiated. These values will serve to determine whether future abnormal values are lithium related. Furthermore, various physiologic states may affect lithium's excretion or predispose one to lithium toxicity. In these cases, baseline laboratory tests are useful in determining the presence of factors that contraindicate the use of lithium or require an adjustment in dosage. As a young, healthy female, C.N.'s prescreening laboratory battery should include electrolytes, blood urea nitrogen, creatinine, urine-specific gravity, thyroid-stimulating hormone (TSH), thyroxine (T_4), and a CBC (Table 80-4). Also, a pregnancy test should be obtained before starting therapy.

Table 80-4 Lithium Monitoring

| | Baseline | Weekly \times 4 Weeks | Monthly \times 3 Months | Quarterly | Yearly | If Symptoms Arise |
|-------------------------------|----------|-------------------------|---------------------------|-----------|--------|-------------------|
| Pregnancy ^a | x | | | | | x |
| CBC | x | | | | | x |
| Electrolytes | x | | | | x | x |
| Kidney (BUN/SCr) ^b | x | | | | x | x |
| ECG ^c | x | | | | x | x |
| Urine | x | | | | | x |
| Thyroid function | x | | | | x | |
| Lithium level | | x | x | x | | x |
| Weight/BMI/waist size | x | | | | x | |

^a Women of childbearing potential.

DOSING

10. C.N.'s baseline laboratory parameters were normal. How should lithium treatment for C.N. be initiated?

Because C.N. has previously responded to lithium and does not have rapid cycling or mixed bipolar disorder, she is likely to respond to lithium again. Although there are many strategies for calculating lithium dosage requirements, it is simplest to begin C.N. at a dosage of 300 mg two times a day. This is a common starting dose for a healthy adult patient.

Patients experiencing an acute manic episode require higher lithium levels than are required during maintenance therapy. The goal for the acute management of C.N. is a serum level between 0.5 and 1.2 mEq/L.¹⁴ Because lithium is not immediately effective, C.N.'s lithium dosage can be adjusted based on the results of lithium serum levels checked twice weekly until the manic episode resolves. As she recovers and enters the maintenance phase of treatment, both C.N.'s lithium dosage and her lithium levels will require reevaluation (see Question 25).

11. How long will it take to get the full effect of lithium?

The half-life of lithium is approximately 24 hours; therefore, steady-state concentrations are achieved in approximately 5 days. The onset of action is slow taking as long as 1 to 2 weeks to fully exert its therapeutic effects.¹⁴ Because of the delay in onset, it is appropriate to use an adjunctive medication to help reduce C.N.'s acute symptoms. Both benzodiazepines and antipsychotics have been used in this manner.¹⁴ AAPs (see Chapter 78) are preferred over typical antipsychotics and have

been demonstrated to enhance efficacy and accelerate time to response when used in combination with lithium.²¹ Benzodiazepines reduce agitation, anxiety, and insomnia.⁴⁷

SIDE EFFECTS

12. After 3 weeks of therapy, C.N. is demonstrating significant improvement in her sleep, impulsivity, delusions, and activity level. She has achieved her previous lithium carbonate dose of 1,200 mg/day and her lithium level is 0.8 mEq/L. However, today she is complaining to the nursing staff that she has developed a hand tremor. Soon after her physician arrives to evaluate her, she asks to be excused so that she can go to the bathroom. How might C.N.'s presentation be related to her medication?

[SI unit, lithium, 0.8 mmol/L]

When considering side effect management early in lithium therapy, it becomes important to monitor lithium levels closely. When patients start to recover from acute mania, the rate of lithium clearance may decrease and patients may demonstrate an increase in lithium levels and worsening side effects (Table 80-5). This does not seem to be the case with C.N. because her lithium level is within the accepted range for the management of acute mania.

C.N. is complaining of a hand tremor. She should be interviewed and examined to determine its origin. In this case, the likely medication-related cause for the tremor would be lithium. Lithium-induced tremor occurs in 10% to 65% of patients treated and is characteristically rapid, regular, and fine in amplitude (8–12 cycles/sec).^{47,48} Often, this tremor occurs early in therapy and improves over time. Caffeine, personal or

Table 80-5 Lithium Adverse Effects

| Organ System | Clinical Presentation | Comments |
|---------------------|--|--|
| Cardiovascular | ECG changes | T-wave suppression, delayed or irregular rhythm, increase in PVCs; SSNS; myocarditis |
| | Edema | Primarily ankles and feet; transient or intermittent; secondary to effects on sodium/carbohydrate metabolism; caution about diuretics and sodium restriction to avoid lithium toxicity |
| Dermatologic | Acne | Worsens |
| | Psoriasis | Treatment-refractory worsening |
| Endocrine | Rashes | Maculopapular and follicular |
| | Hypothyroidism | About 5% goiter; about 30% clinically significant hypothyroidism; may diminish sex drive |
| Fetus (teratogenic) | Hyperparathyroidism | Clinically nonsignificant |
| | Tricuspid valve malformation, atrial septal defect | Ebstein anomaly |
| Gastrointestinal | Anorexia, nausea (10%–30%) | Usually early in treatment and usually transient; may be early sign of toxicity |
| | Diarrhea (5%–20%) | Slow-release preparations may help |
| Hematologic | Leukocytosis | May be useful in disorders such as Felty syndrome, iatrogenic neutropenia. May counter CBZ-induced leukopenia |
| | Tremor (10%–65%) | Dose-related; men > women; worse with antidepressants/antipsychotics; reduce dose or use β -blocker |
| Neurologic | Cognitive disruption (10%) | Worsens compliance; perceived as “mental dulling” |
| | Poor concentration/memory; fatigue/weakness | May be early toxicity; may mimic depression |
| Renal | Polyuria-polydipsia (nephrogenic diabetes insipidus) | May be an indication of morphological changes; requires adequate hydration |

CBZ, carbamazepine; ECG, electrocardiogram; PVC, premature ventricular contraction; SSNS, sick sinus node syndrome.

family history of tremor, alcoholism, anxiety, antidepressants, antipsychotics, and possibly increased age enhance the risk of lithium-induced tremor.⁴⁸ The tremor is more common in patients with higher serum concentrations and may be worse at times of peak serum levels.¹⁴ If C.N. is not bothered by the tremor and suffers no impairment, treatment is not necessary. If the tremor becomes problematic, her lithium dosage may be reduced or a β -adrenergic blocking agent can be added. Switching to a sustained-release lithium preparation may reduce peak serum levels and ameliorate tremors associated with the peak of absorption.¹⁴ Because it is fairly early in treatment and C.N. has only a moderate lithium level, it is more reasonable to add propranolol 10 mg three times a day rather than to reduce the lithium dosage if an intervention is required. Propranolol usually is effective at dosages <160 mg/day.⁴⁸ C.N. also should be educated about her tremor and instructed to reduce her caffeine consumption.

In addition, C.N. should be asked about her trip to the bathroom during this clinic visit, because lithium may cause both diarrhea and polyuria. Polyuria and polydipsia are common, occurring in up to 60% of patients.⁴⁹ Nephrogenic diabetes insipidus is present in 12% of patients on long-term treatment.⁵⁰ With the lower serum levels of lithium commonly used today, the actual increase in urine volume may be as low as 20%; thus, a decrease in C.N.'s lithium dosage may help to reduce polyuria if this is a problem. Urine output also has been correlated with trough lithium levels.⁵¹ Although the advantages of once-daily administration of lithium are not universally accepted, switching a stabilized patient to this schedule with its lower trough levels may help to reduce urine volume.¹⁴ If C.N. were to fail to respond to either of these interventions, amiloride could be prescribed concurrently.¹⁴ Amiloride seems to antagonize the effect of lithium on free water clearance by reducing the ion entry into renal epithelial cells.

If C.N.'s trip to the bathroom was because of diarrhea, lithium should be evaluated as a possible cause; up to 20% of patients started on lithium experience diarrhea, epigastric bloating, and sometimes pain early in therapy.⁵¹ Diarrhea from lithium is associated with high serum levels, once-daily dosing, and rapidly absorbed preparations; therefore, divided doses may help to alleviate the problem. Use of lower doses and switching to sustained-release preparations are alternative strategies that could be used. Sustained-release preparations can potentially lead to lower lithium levels in patients with rapid GI motility because the product must be present in the small intestine for several hours to achieve maximal absorption. If C.N. has diarrhea or polyuria, her fluid status and lithium levels should be monitored carefully. Dehydration leads to increased lithium reabsorption in the proximal tubule and could result in accumulation to toxic levels.

13. Should C.N. be switched to a sustained-release preparation of lithium?

Sustained-release dosage forms have often been used to aid in medication adherence and reduce side effects. Although standard lithium preparations are often administered three or four times per day, many clinicians prescribe them for once- or twice-daily administration. Sustained-release lithium is usually administered once or twice daily, results in lower peak levels, and may decrease side effects associated with high peak concentrations. Both lithium-induced tremor and gas-

tric symptoms may respond to a change to sustained-release preparations.¹⁴ If C.N. is no longer experiencing problems with tremor or GI side effects, she should be maintained on a standard preparation of lithium carbonate.

14. What should C.N. be told regarding potential renal damage from lithium?

C.N. should be informed that lithium can cause renal side effects; however, cases of irreversible kidney damage are relatively rare and have occurred mainly when patients have pre-existing renal disease, have experienced episodes of lithium intoxication, or have been poorly monitored with regard to lithium levels.⁵² Communication with her physician regarding situations that increase the risk of lithium toxicity (see Question 16) and cooperation with regular lithium and renal function monitoring can vastly reduce the risk of renal disease secondary to lithium therapy. Finally, C.N. must be informed that polyuria is not related to any of the more serious renal side effects.

PATIENT EDUCATION

15. What does C.N. need to know about lithium before she is discharged?

As with all drugs, C.N. should be instructed to disclose the medications she is taking to all of her health care providers. She should be informed that dehydration, fever, vomiting, or sodium-restricted diets could lead to increases in her lithium level. Therefore, she needs to drink plenty of fluids and eat a diet consistent in the amount of sodium. C.N. should be instructed to contact her physician if she starts to experience any symptoms of lithium toxicity, including worsening tremor, slurred speech, muscle weakness or twitches, or difficulty walking.

C.N. also should be told to use caution in selecting over-the-counter medications. Specifically, she should be warned to avoid the use of preparations containing any of the nonsteroidal anti-inflammatory drugs, which can increase lithium levels.⁵³ C.N. should know that caffeine can sometimes be troublesome in patients taking lithium. On a short-term basis, caffeine can worsen lithium tremor; on a longer term basis, it may lower lithium levels.⁵³ With regard to serum lithium level monitoring, C.N. needs to know that lithium levels usually are drawn approximately 12 hours after a dose of lithium. If she is taking lithium in the evening and the morning, she should take her evening dose and then report for a blood sample to be drawn in the morning before taking her morning dose.

TOXICITY

16. One day, C.N.'s mother calls, concerned that C.N. has been complaining of nausea, vomiting, and diarrhea for several days. Over the past few hours, C.N. has become confused and has developed a coarse tremor and slurred speech. It has been 4 months since C.N.'s lithium level has been checked. The only change is that C.N. started taking ibuprofen recently for headaches. What action should be taken?

There is a strong possibility that C.N. is suffering from lithium toxicity, which can occur acutely from an overdose or insidiously if lithium excretion is reduced. *Mild toxicity*

at levels <1.5 mEq/L usually includes feelings of apathy, lethargy, and muscle weakness accompanied by nausea and irritability. *Moderate toxicity* occurs between 1.5 and 2.5 mEq/L with symptoms progressing to coarse tremor, slurred speech, unsteady gait, drowsiness, confusion, muscle twitches, and blurred vision. *Severe toxicity* at levels >2.5 mEq/L can result in seizures, stupor, coma, renal failure, and cardiovascular collapse. C.N. seems to be experiencing moderate lithium toxicity. She should be taken to the emergency department immediately, where stat laboratory tests, including a lithium level, electrolytes, and renal function tests, should be ordered. Intravenous solutions should be started to ensure that C.N. is hydrated adequately, and electrolyte abnormalities should be corrected promptly. Depending on the results of physical examination and laboratory tests, cardiac monitoring should be instituted. Her ibuprofen should be discontinued.

Lithium levels must be interpreted with caution if they were drawn within 12 hours of lithium ingestion, because levels drawn sooner than 12 hours may be falsely elevated. In contrast, levels that are drawn too soon may be falsely low in individuals who have ingested large quantities of a sustained-release lithium formulation. Twelve-hour serum lithium levels >2.5 mEq/L, coma, shock, further deterioration, and failure to improve with conservative management are indications for dialysis. Although peritoneal dialysis has been instituted in cases of lithium intoxication, hemodialysis is preferred.¹⁴

HYPOTHYROIDISM

17. After receiving lithium at 1,200 mg/day for 1 year, C.N. returns complaining that the lithium is slowing her down. She is tired and has gained weight in recent weeks and thinks that she is becoming depressed. In the examining room, C.N. complains that the temperature is too cold. What is the most likely cause of C.N.'s complaints? What treatment should be instituted?

C.N.'s symptoms are consistent with those of hypothyroidism. Lithium affects the incorporation of iodine into thyroid hormone, interferes with secretion of thyroid hormones, and may interfere with the peripheral degradation of T_4 to T_3 (tri-iodothyronine).⁵⁴ Using laboratory indices, the incidence of hypothyroidism in lithium-free bipolar patients ranges from 6% to 11% as compared with 28% to 32% in lithium-treated patients.⁵⁵ Subclinical hypothyroidism with elevated levels of TSH may be present in an even larger number of patients taking lithium. Risk factors for developing lithium-induced hypothyroidism include female gender, family history of hypothyroidism or thyroid illness in first-degree relatives, weight gain, elevated baseline TSH, preexisting autoantibodies, an iodine-deficient diet, rapid cycling, and elevated lithium levels.⁵⁶ For women, the first 2 years of treatment may be a period of heightened risk as well for any patient starting lithium in middle age.⁵⁶

Thyroid function tests should be ordered to evaluate C.N.'s current symptoms. If she is found to be hypothyroid, discontinuation of therapy is *not* necessary. She should receive levothyroxine in doses that normalize her thyroid function tests. Even if she has an elevated TSH with normal levels of T_3 and T_4 , low-dose thyroid supplementation may help to resolve her symptoms, and prevent breakthrough depressive symptoms.⁵⁴

DRUG AND DIETARY INTERACTIONS

18. T.J., a 35-year-old man, is hospitalized and treated with lithium for a severe manic episode. He had a stable lithium level of around 0.80 mEq/L for several weeks, but his last two levels have dropped to 0.65 and 0.61 mEq/L without any change in his drug therapy. T.J. insists that he is taking the medication as prescribed. The nursing staff believes that he is compliant with his medication but notes that he is spending more time off the ward and in the cafeteria. What factors could contribute to a decrease in T.J.'s lithium levels?

[SI units: lithium, 0.80, 0.65, and 0.61 mmol/L]

Drug interactions are a common cause of changes in lithium levels, but there have been no changes in T.J.'s regimen (Table 80-6 provides a list of clinically significant drug interactions). Changes in formulation or brand may sometimes have an impact on lithium levels. However, lithium is relatively well absorbed and has a long elimination half-life, so this usually does not result in large changes in the 12-hour postdose lithium level. Occasionally, patients switched from lithium citrate to solid dosage forms experience small changes in lithium levels.

T.J. should be questioned regarding his visits to the cafeteria because diet can have a major influence on lithium excretion. If T.J. is consuming large amounts of caffeinated beverages or salty snacks, a reduction in lithium levels could occur. Increases in dietary sodium intake and the ingestion of methylxanthines (e.g., caffeine, theophylline) can increase lithium clearance.⁵³

Finally, acute mania can increase lithium clearance.⁵⁷ If T.J. was showing signs of a relapse, his decrease in lithium levels might be attributable to his return to a manic state.

LITHIUM IN PREGNANCY

19. A.J., a 36-year-old woman, has been maintained successfully on lithium therapy for 5 years for bipolar disorder. She asks whether she should stay on lithium because she plans to become pregnant in the near future.

Lithium has been associated with a variety of congenital malformations, including the rare cardiac malformation, Ebstein anomaly.⁵⁸ There is considerable disagreement about the importance of lithium as a teratogen. Lithium was originally thought to increase the risk of the Ebstein anomaly 400 times; however, the risk is more likely 20 to 40 times higher than in the general population.⁵⁹ The estimated overall risk for congenital malformations is approximately 4% to 12% compared with 2% to 4% in controls.⁶⁰ Still, lithium is a pregnancy category D drug because of evidence of the risk to the human fetus. Because malformations of this type are most likely to occur in the first trimester of pregnancy, it is advisable for patients to discontinue lithium therapy, when possible, during the first trimester.

In addition to cardiac malformations, infants exposed to lithium have been reported to develop hypotonia, nephrogenic diabetes insipidus, and thyroid abnormalities.⁵⁸ Lithium administration during pregnancy increases the risk of premature delivery by a factor of two to three.⁶¹ Unfortunately, the relative safety of other psychotropics commonly used in bipolar disorder is either not ideal or is unknown. Valproate and CBZ are categorized as FDA category D during pregnancy and the general consensus is that these medications are genuine teratogens and should be avoided.⁶² Lamotrigine has not been

Table 80-6 Lithium Drug Interactions of Clinical Significance**Drugs That May Increase Lithium Levels***NSAIDs*

Many NSAIDs have been reported to increase lithium levels as much as 50%–60%. This probably is due to an enhanced reabsorption of sodium and lithium secondary to inhibition of prostaglandin synthesis.

Diuretics

All diuretics can contribute to sodium depletion. Sodium depletion can result in an increased proximal tubular reabsorption of sodium and lithium.

Thiazidelike diuretics cause the greatest increase in lithium levels, whereas loop diuretics and potassium-sparing diuretics seem to be somewhat safer.

ACE inhibitors

ACE inhibitors and lithium both result in volume depletion and a reduction in glomerular filtration rate. This results in reduced lithium excretion.

Drugs That May Decrease Lithium Levels*Theophylline, caffeine*

Theophylline and caffeine may increase renal clearance of lithium and result in a decrease in levels in the range of 20%.

Acetazolamide

Acetazolamide may impair proximal tubular reabsorption of lithium ions.

Sodium

High dietary sodium intake promotes the renal clearance of lithium.

Drugs That Increase Lithium Toxicity*Methyl dopa*

Cases of sedation, dysphoria, and confusion owing to the combined use of lithium and methyl dopa have been reported.

Carbamazepine

Cases of neurotoxicity involving the combined use of lithium and carbamazepine have been reported in patients with normal lithium levels.

Calcium channel antagonists

Cases of neurotoxicity involving the combined use of lithium and the calcium channel blockers verapamil and diltiazem have been reported. Lithium does interfere with calcium transport across cells.

Antipsychotics

Cases of neurotoxicity (encephalopathic syndrome, extrapyramidal effects, cerebellar effect, EEG abnormalities) have been reported due to the combined use of lithium and various antipsychotics. The interaction may be related to increase in phenothiazine levels, changes in tissue uptake of lithium, and/or dopamine-blocking effects of lithium. Studies attempting to demonstrate this effect have yielded differing results.

Serotonin-selective reuptake inhibitors

Fluvoxamine and fluoxetine have been reported to result in toxicity when added to lithium. Sertraline has been reported to cause nausea and tremor in lithium recipients.

ACE, angiotensin-converting enzyme; EEG, electroencephalogram; NSAIDs, nonsteroidal anti-inflammatory drugs.

associated with fetal anomalies thus far in available surveys but the data is best regarded as preliminary at the present time. Typical antipsychotics are classified as pregnancy category C, suggesting that adverse morphologic outcomes are less likely to occur (in comparison with mood stabilizers), although this is not necessarily predictive. Data on AAPs are also preliminary, but it is worth noting that, in a recent comparison of placental passage, olanzapine was associated with the highest exposure (72% ratio of umbilical cord-to-maternal plasma concentrations), followed by haloperidol (65%), risperidone (49%), and quetiapine (24%).⁶³ Olanzapine was also associated with the highest rates of low birth weight and neonatal intensive care unit admissions. For additional information on the safety of psychotropic medications see Chapters 54, 76, 78, and 79.

A.J. and her physician should discuss her individual risks related to lithium treatment. In addition to the risks of teratogenicity, they must consider the harm that could result from the possible recurrence of episodes of mania or depression and the risks inherent in discontinuing lithium or switching to another antimanic agent. Also, A.J. should be actively involved in the decision-making process.

If A.J. and her physician decide that she is to remain on lithium, her levels must be monitored closely during pregnancy and her dosage adjusted periodically. Lithium clearance

increases during the third trimester by 30% to 50%, resulting in a reduction in lithium levels and a need for dosage adjustment.⁵⁹ Approximately 16 to 18 weeks after conception, screening tests, high-resolution ultrasound, and fetal echocardiography can be used to determine whether cardiac defects have developed.⁵⁹ If possible, A.J.'s physician should consider decreasing the lithium dose before delivery to minimize lithium levels in the newborn and to offset the reduction in lithium excretion that occurs after delivery.⁵⁹

If A.J. and her physician decide that she is to discontinue lithium, they must be prepared to deal with the risks of lithium discontinuation. Several cases of what are thought to be rebound manic episodes have resulted from the abrupt cessation of lithium therapy. If lithium is to be discontinued in A.J., it should be gradually reduced over 4 weeks.

20. A.J. did not use lithium throughout her pregnancy. After delivery, A.J. and her physician decide to restart lithium. How soon can this take place?

Lithium can be restarted as soon as A.J.'s urine output is established and she is fully hydrated. However, this decision also may be affected by whether or not A.J. chooses to breast-feed her child because lithium passes into breast milk and is

present in concentrations up to 72% of that found in the maternal blood.⁵⁸ Risks to the newborn include hypothyroidism, cyanosis, hypotonia, lethargy, and cardiac dysrhythmias. Hydration status must be closely monitored because lithium toxicity may develop during infantile illnesses. Thus, A.J. and her physician must discuss the advantages of breast-feeding versus the risks of exposing the newborn to lithium or withholding lithium during the postpartum period. A.J. should be informed that approximately 40% to 70% of bipolar women experience affective episodes after delivery.⁵⁸

If A.J. chooses to breast-feed while taking lithium, she should consider using infant formula when the child becomes ill because febrile illness, vomiting, and diarrhea can increase the risk of lithium toxicity. She also should be instructed to contact her pediatrician if the infant experiences diarrhea, vomiting, hypotonia, poor sucking, muscle twitches, restlessness, or other unexplained changes in behavior or status.

Atypical Antipsychotics

21. D.W., a 34-year-old female singer and musician, recently experienced her fourth hospital admission for a manic episode. She also suffers from psoriasis and asthma. A trial of lithium led to worsening of her psoriasis and unacceptable tremor, which interfered with her guitar playing. Use of β -blockers was not considered because of her asthma. She was subsequently switched to valproate monotherapy. However, tremor has again become problematic. Furthermore, she is concerned about her appearance because she has begun to experience weight gain and hair loss from the valproate. What other drugs are available for the treatment of acute mania?

AAPs are acceptable first-line choices for the treatment of acute mania (Table 80-3) and aripiprazole, olanzapine, quetiapine, risperidone, and ziprasidone are FDA approved for this indication (Table 80-7). Three recent systematic reviews and meta-analyses support the efficacy of AAPs as a class.^{64–66} Perlis et al.⁶⁴ reviewed data from 12 randomized, placebo-controlled, monotherapy studies and 6 adjunctive studies finding a collective response rate of 53% for AAPs compared with 30% for placebo. There was no difference in response between the individual AAPs. In adjunctive studies, the mean odds ratio was 2.4 for a 50% improvement with the addition of an AAP to a mood stabilizer (primarily lithium or valproate). Scherk et al.⁶⁵ conducted a meta-analysis of 24 randomized controlled trials and found superiority of AAPs for acute mania in com-

parison to placebo and equal efficacy to lithium, valproate, and the typical antipsychotic haloperidol. In this analysis, the addition of an AAP to lithium, valproate, or CBZ was found to be more effective in reducing manic symptoms and lead to less treatment discontinuation than lithium or the anticonvulsant alone. The results of a different meta-analysis specifically designed to evaluate combination treatment of AAPs with lithium or an anticonvulsant also found greater efficacy for the combined regimen.⁶⁶ In most combination therapy studies, AAPs were limited to patients having no response or only a partial response to lithium or an anticonvulsant. Thus, the utility of drug combinations as initial therapy cannot be addressed.

Although the AAPs seem to be equally effective for the treatment of acute mania, these agents differ in their adverse effect profiles. A significant concern regarding the use of AAPs is the risk of metabolic complications, including weight gain, glucose dysregulation, and dyslipidemia. Clozapine and olanzapine have the highest risk for metabolic complications, quetiapine and risperidone are associated with an intermediate risk, and ziprasidone and aripiprazole seem to have the lowest risk.^{25,21} Clozapine is also associated with significant safety concerns, including agranulocytosis, seizures, sialorrhea, anticholinergic side effects, and orthostasis. The requirement for frequent monitoring of WBC count is also a deterrent to its use. Efficacy data with clozapine are limited compared with the other AAPs, but clozapine seems to be effective in treatment-resistant mania and in long-term mood stabilization.^{67–69}

Sedation is common with clozapine, olanzapine, and quetiapine and this effect may be beneficial in the treatment of acute mania. However, sedation can also lead to nonadherence with long-term use.⁷⁰ Aripiprazole and ziprasidone are less sedating, and the adjunctive use of a benzodiazepine is often necessary in the acute management of mania. The use of adjunctive benzodiazepines may also benefit treatment emergent akathisia, which occurs in 11% to 18% of patients treated with aripiprazole.^{71,72} Ziprasidone may cause activation; however, this effect is attenuated at doses of 120 mg/day or more. Results of the Clinical Antipsychotic Trials of Intervention Effectiveness study in schizophrenia suggest that risperidone may overall be the best tolerated of the AAPs; however, this drug carries a higher risk for serum prolactin elevation and extrapyramidal symptoms.⁷³

D.W.'s concern over her weight gain makes aripiprazole or ziprasidone rational choices for her manic episode. Aripiprazole should be started at 30 mg/day with the option to decrease the dose to 15 mg/day. If ziprasidone is selected, it should be started at 40 mg BID with food and increased to 60 to 80 mg BID with food on the second day of therapy. In addition to symptom response, D.W. should be monitored for metabolic complications of AAP therapy. If D.W. fails to respond to the initially selected AAP, a switch to a different AAP may prove beneficial given the variability in individual response.²¹ Table 80-8 provides dosing information for AAPs in acute mania.

22. What alternative agents are available for acute mania if lithium, valproate, or an AAP fail?

Alternative and Adjunctive Therapies

ANTICONVULSANTS

CBZ represents an alternative treatment for the management of acute mania when lithium, valproate and AAPs fail.^{14,21,23,24}

Table 80-7 FDA-Approved Medications for Bipolar Disorder

| Drug | Mania | Mixed | Depression | Maintenance |
|--|-------|-------|------------|-------------|
| Carbamazepine (extended-release capsule) | X | X | | |
| Lamotrigine | | | | X |
| Lithium | X | | | X |
| Valproate (divalproex sodium) | X | X | | |
| Aripiprazole | X | X | | X |
| Olanzapine | X | X | | X |
| Olanzapine/fluoxetine | | | X | |
| Quetiapine | X | | X | |
| Risperidone | X | X | | |
| Ziprasidone | X | X | | |

Table 80-8 Atypical Antipsychotic Dosing in Acute Mania

| Atypical Antipsychotic | Initial Dose | Titration | Effective Dose Range |
|------------------------|--------------|--------------|----------------------|
| Aripiprazole | 30 mg/day | Not required | 15–30 mg/day |
| Olanzapine | 10–15 mg/day | 5 mg/day | 5–20 mg/day |
| Quetiapine | 50 mg BID | 50 mg BID | 200–400 mg BID |
| Risperidone | 2–3 mg/day | 1 mg/day | 1–6 mg/day |
| Ziprasidone | 40 mg BID | 20–40 mg BID | 40–80 mg BID |

Initial interest with CBZ in affective disorders dates back to the early 1970s with expanding clinical use in the 1980s.⁷⁴ In 2005, the FDA approved the extended-release CBZ capsule for the treatment of acute manic and mixed episodes based on the results of two double-blind, randomized, placebo-controlled trials.⁷⁴ To enhance power, a pooled analysis of these two studies has been conducted.⁷⁵ The primary endpoint, reduction in manic symptoms, was superior to placebo at days 7, 14, and 21 with a mean decrease in the Young Mania Rating Scale (YMRS) of 12 points compared with a 6-point reduction with placebo. The response rates at study endpoint were 52% for CBZ-treated patients and 26% for placebo-treated patients. Significant reductions in the YMRS were achieved in both manic and mixed episodes. The mean final dose of extended release CBZ was 707 mg/day.

CBZ should be started at 100 to 200 mg twice daily. The dose should be increased by 200 mg every 3 to 4 days until adequate serum levels have been reached.¹⁴ Although no correlation between CBZ serum levels and response in bipolar disorder has been established, serum levels > 12 mcg/mL are associated with sedation and ataxia. The recommended target serum level is from 4 to 12 mcg/mL.¹⁴ Average daily doses for maintenance therapy range from 200 to 1,600 mg/day.

Adverse effects occur in up to 50% of patients receiving CBZ.¹⁴ Neurologic adverse effects, including ataxia, blurred vision, diplopia, and fatigue, are most frequently reported. CBZ can cause adverse hematologic effects, including transient leukopenia, and more rarely, agranulocytosis, thrombocytopenia, and aplastic anemia. CBZ therapy may also cause hyponatremia, skin rashes, elevation of liver enzymes, weight gain, and GI complaints. Women of child-bearing potential should be tested for pregnancy because CBZ is classified as pregnancy category D and has the potential to cause teratogenic effects, especially neural tube defects.

Before receiving CBZ, patients should undergo baseline laboratory testing, including a CBC with differential and platelets, and liver function tests. Subsequent hematologic and liver function monitoring should occur every 2 weeks during the first 2 months of treatment and every 3 months thereafter (see Chapter 54).¹⁴ During therapy, patients should be monitored for abnormal bleeding or petechiae, skin rashes, signs and symptoms of infection, and signs of hyponatremia such as mental status changes.

CBZ can induce the metabolism and, thereby, reduce the effect of a number of drugs, including oral contraceptives, war-

farin, theophylline, haloperidol, lamotrigine, and TCAs. The concurrent use of erythromycin, cimetidine, fluoxetine, or calcium channel blockers may lead to increased levels of CBZ and unanticipated toxicity (see Chapter 54). CBZ has a complex pharmacokinetic interaction with valproate. CBZ can increase the metabolism of valproate, resulting in reduced serum concentrations and efficacy. Conversely, valproate may inhibit the metabolism of CBZ, leading to increased serum concentrations and adverse effects. The combination of CBZ and lithium may increase the risk of neurotoxicity, particularly in patients with preexisting neurologic diseases. Therefore, the combination should be avoided in these patients. CBZ also has the ability to induce its own metabolism. This autoinduction effect may cause CBZ levels to decrease for up to 1 month after a dose adjustment is made; thus, dose increases may be needed to maintain a therapeutic effect.

Oxcarbazepine, a structural analog of CBZ, may be an option for the treatment of bipolar disorder. Oxcarbazepine has some advantages over CBZ, including improved tolerability and fewer drug interactions. However, there is a paucity of well-designed clinical trials of oxcarbazepine in bipolar disorder.⁷⁶ Case reports, retrospective chart reviews, open-label trials, and small double-blind studies have found oxcarbazepine monotherapy or adjunctive treatment to be effective in acute mania.⁷⁶ The only study of oxcarbazepine in bipolar disorder with adequate statistical power to detect an effect did not report a significant difference between placebo and oxcarbazepine for the primary endpoint (mean reduction in YMRS). This study included 116 children and adolescents (the majority of patients were between ages 7 and 12 years old) with a manic or mixed episode.⁷⁷

Other anticonvulsants studied in mania include lamotrigine, gabapentin, topiramate, tiagabine, zonisamide, and levetiracetam. Initial open-label studies of lamotrigine in mania were promising, and there is one published double-blind trial to date that showed a similar response between lamotrigine, lithium, and olanzapine.^{78,79} However, there are two unpublished trials of lamotrigine in mania, both of which are negative.⁷⁸ Currently, experts doubt that lamotrigine has any significant effect in acute bipolar mania.

Another anticonvulsant, gabapentin, has been studied in bipolar disorder. Open trials and case reports suggested that adjunctive treatment with gabapentin was effective in manic, hypomanic, and depressive states of bipolar disorder.^{80–82} A more recent controlled trial found no benefit of gabapentin.⁸³ In this double-blind, placebo-controlled trial, gabapentin dosed flexibly between 900 and 3,600 mg/day was administered as an adjunct to lithium, valproate, or lithium plus valproate in patients with bipolar I disorder whose current episode was manic, hypomanic, or mixed. At 12 weeks, gabapentin failed to show any significant benefit over placebo. In fact, the placebo group did significantly better than the gabapentin-treated patients.

Topiramate was also originally suspected to have antimanic effects based largely on open add-on studies.⁸⁴ However, in four double-blind, placebo-controlled trials, topiramate did not separate from placebo and was less effective than lithium in the treatment of acute mania.⁸⁵ Tiagabine has not been evaluated in randomized, controlled trials in the treatment of bipolar disorder. In the two open trials conducted, no benefit on manic or hypomanic symptoms was demonstrated and some patients

experienced serious side effects such as seizures.^{86,87} Two separate, open-label adjunctive trials with levetiracetam and zonisamide in treatment-resistant bipolar patients have shown reductions in manic symptoms; however, these studies included patients in a variety of bipolar mood states (depression, mania, cycling, euthymia), not just acute mania.^{88,89} Caution is warranted; zonisamide was discontinued in 32% of patients for worsening mood symptoms. Also, 7 out of 16 levetiracetam-treated patients with manic symptoms dropped out and 6 of the remaining patients developed an exacerbation of manic symptoms.

Despite the array of treatments available for the management of acute mania, large numbers of patients fail to respond to monotherapy, and combination therapy is becoming increasingly common.⁹⁰ Potentially useful combinations include lithium plus AAPs, valproate plus AAPs, and lithium plus valproate.^{22,23} A combination to be avoided is CBZ and clozapine owing to the increased risk of hematologic adverse effects.

Benzodiazepines and Antipsychotics for Acute Agitation

23. M.B. is a 39-year-old man hospitalized for an acute manic episode but refusing all medications, reporting “I will be robbed of my superpowers.” He is found pacing around the inpatient unit shouting orders for his release. When asked to return to his room by the nursing staff, he becomes agitated, picks up a chair, and begins swinging it wildly at anyone who approaches him. In the past M.B. developed an acute dystonic reaction to haloperidol. M.B. has a medical history of diabetes mellitus and hypertension. What is an appropriate pharmacologic intervention for M.B.?

Benzodiazepines and antipsychotics are useful in treating agitation, irritability, and hyperactivity associated with acute manic episodes. Oral formulations are preferred and are favored by patients in psychiatric emergencies.⁹¹ Oral dose delivery can be facilitated with liquid concentrates and orally disintegrating tablets. Uncooperative patients may require intramuscular (IM) injections of benzodiazepines or antipsychotics.⁹² Traditionally, the combination of IM haloperidol and IM lorazepam has been used; however, the rapid-acting IM AAPs are becoming increasingly popular with improved tolerability over typical antipsychotics. Currently, ziprasidone, aripiprazole, and olanzapine are available in rapid-acting IM dosage forms. IM ziprasidone at doses of 10 and 20 mg is effective in psychotic agitation.^{93,94} IM aripiprazole is effective at doses of 9.75 and 15 mg for manic or mixed-state agitation (however, oversedation is more common with a 15-mg dose).⁹⁵ Olanzapine 10 mg IM is effective for manic or mixed-state agitation.⁹⁶ Repeat doses of IM ziprasidone, aripiprazole, and olanzapine can be administered 2 to 4 hours after the first dose, if needed. The concurrent use of a benzodiazepine with an antipsychotic is generally safe and potentially more effective than either agent alone; however, IM olanzapine should not be used with benzodiazepines owing to concern regarding excessive sedation and cardiorespiratory depression.^{97,98}

Lorazepam is the preferred benzodiazepine for acute manic agitation. Benefits of lorazepam include availability of both IM and oral formulations (tablet and concentrate), lack of active metabolites, and safety in hepatic and renal impairment. The Expert Consensus Guideline recommends dosing lorazepam

at 1 to 3 mg orally or 0.5 mg to 3 mg IM, with repeated doses at least 60 minutes apart and a maximum dose of 10 to 12 mg in the first 24 hours.⁹⁹ The primary concerns regarding the use of benzodiazepines for agitated mania are sedation and potential for abuse and addiction. Because adjunctive therapy with benzodiazepines is usually administered on an inpatient basis for a short time period, abuse and addiction are unlikely to be important considerations.

M.B. is uncooperative and an immediate danger to others, thus warranting IM administration. Because of M.B.’s history of acute dystonia to haloperidol, an IM AAP (such as olanzapine, ziprasidone, or aripiprazole) should be used. The combination of ziprasidone 10 mg IM and lorazepam 2 mg IM is an appropriate intervention. IM administration of aripiprazole and lorazepam may also be used. As M.B. becomes calmer and more receptive to treatment, he should be transitioned to oral therapy. Adjunctive benzodiazepine treatment may be necessary during M.B.’s hospitalization to control his manic symptoms.

TREATMENT OF ACUTE BIPOLAR DEPRESSION

24. H.C., a 31-year-old woman, was hospitalized for treatment of an acute manic episode 3 months ago. She was discharged on valproate 1,750 mg/day with a favorable response. Recently, her parents have become concerned because H.C. has been in bed most of the day for the last 2 weeks. When out of bed, H.C. sits on the couch without moving for hours. She only nibbles at the food her parents offer her. She has no other signs or symptoms of physical illness and has not taken any additional medications, alcohol, or drugs of abuse to her parents’ knowledge. On further questioning, they admit that she is intermittently tearful and expresses remorse for her behavior when she was manic. They also quote her as saying that she is “as low as I can go and I just want to die.” They suspect she is suicidal. H.C.’s parents report that she is taking valproate as prescribed and that the last time she was this depressed lithium did not seem to help even in combination with valproate. Her valproate level on discharge was 80 mcg/mL. What change in H.C.’s treatment should be instituted at this time?

Lithium

Acute bipolar depression is a recurring and chronic problem for many patients. The depression is often difficult to control and puts patients at significant risk for suicide. Until recently, little attention was paid to bipolar depression and few data are available regarding the best treatment options for these patients. Remission of depressive symptoms should be the primary goal for bipolar depression. Ideal treatment for bipolar depression should target acute depressive symptoms, decrease suicide risk, prevent future mood episodes (both manic and depressive), and not precipitate mania or mood cycling.¹⁰⁰ A logical first step in the management of bipolar depression is to optimize the dose of the current mood stabilizer.²¹ Although most studies of lithium for acute bipolar depression are nearly two decades old, this agent remains one of the drugs of choice.¹⁴ Seven of eight placebo-controlled cross-over studies demonstrated the benefit of lithium in bipolar depression with a mean response rate of 76%.¹⁰⁰ Higher serum lithium concentrations (≥ 0.8 mEq/L) may be required and are associated with antidepressant activity in bipolar depression.¹⁰¹

Lamotrigine

Lamotrigine is considered a first-line agent for bipolar depression by all North American guidelines.^{14,21–24} A double-blind, placebo-controlled trial of lamotrigine monotherapy in bipolar depression found that 51% of patients receiving lamotrigine 200 mg/day met criteria for response on the Hamilton Rating Scale for Depression (HAM-D), compared with 45% of those treated with lamotrigine 50 mg/day, and 37% of placebo-treated patients.¹⁰² The difference in response rates among the three groups did not reach statistical significance. However, a significant difference between both treatment groups and placebo was noted on the Montgomery-Asberg Depression Rating Scale (MADRS). A cross-over study of lamotrigine, gabapentin, and placebo reported response rates of 45%, 26%, and 19%, respectively.¹⁰³ Lamotrigine was recently compared with OFC in a large 7-week trial of bipolar I depression.¹⁰⁴ Improvement from baseline on the Clinical Global Impressions-Severity of Illness Scale was significantly greater with OFC (−1.85) than for lamotrigine (−1.62), the response and remission rates did not differ between groups. Also, patients receiving lamotrigine did not achieve the 200 mg/day target dose until week 5 (leaving only 2 weeks of study treatment at the target dose). Patients treated with OFC experienced more adverse effects than those treated with lamotrigine.

Because H.C. did not respond to lithium in combination with valproate during her past depressive episode, lamotrigine is a reasonable alternative treatment for the current episode. Lamotrigine metabolism is affected by the concomitant use of enzyme-inducing (e.g., CBZ) and enzyme-inhibiting drugs (e.g., valproate). Thus, the initial dose and titration schedule for lamotrigine must be adjusted for patients taking these and other interacting drugs. For patients receiving no enzyme inducers or inhibitors, the initial dose is 25 mg/day for weeks 1 and 2, followed by 50 mg/day for weeks 3 and 4, 100 mg/day for week 5, and then increased to 200 mg/day at the beginning of week 6. Patients receiving enzyme inducers should begin lamotrigine treatment with 50 mg/day for weeks 1 and 2, then 100 mg/day in divided doses for weeks 3 and 4. Thereafter, the dose can be increased by 100 mg/day each week to a target dose of 400 mg/day in divided doses (usually BID). In this case H.C. is taking valproate, which is known to inhibit the metabolism of lamotrigine. Therefore, the initial dose for H.C. is 25 mg every other day for weeks 1 and 2 followed by an increase to 25 mg/day for weeks 3 and 4. The dose can be increased to 50 mg/day for week 5, and then increased to the maximum recommended dose of 100 mg/day beginning at week 6. For some patients, doses higher than the target dose may be useful. Dizziness, headache, ataxia, sedation, blurred vision, and GI disturbances are the most common side effects. Lamotrigine may cause a skin rash, especially when dosages are increased quickly and in patients receiving concomitant valproate. Lamotrigine-induced rash may progress to the life-threatening Stevens-Johnson syndrome. H.C. should be instructed to contact her physician immediately at the first sign of a skin rash.

Atypical Antipsychotics

AAPs offer another option for the treatment of bipolar depression. Quetiapine has been studied in two identical, double-blind, placebo-controlled studies for patients with bipolar I or II depression. In both studies, patient were randomized to

quetiapine 300 or 600 mg/day, or placebo for 8 weeks. The primary efficacy outcome was mean reduction in MADRS from baseline to week 8. The first study (BOLDER I) randomized 542 patients.¹⁰⁵ The mean change in MADRS from baseline to study endpoint was similar in the 300 and 600 mg/day treatment groups and both were superior to placebo. Discontinuation due to adverse effects was most common in the 600 mg/day group. The second study (BOLDER II) randomized 509 patients.¹⁰⁶ In both active treatment groups, the reduction in MADRS was again superior to placebo. Discontinuation owing to adverse effects (most commonly dry mouth, sedation, somnolence, dizziness) was most common in the 600 mg/day group. Based on these two studies, the target dose of quetiapine for bipolar depression should be 300 mg/day.

Olanzapine and olanzapine–fluoxetine combination have been studied in patients with bipolar I depression. In the first published study, patients were randomized to olanzapine ($n = 370$), placebo ($n = 377$), or olanzapine–fluoxetine combination ($n = 86$).¹⁰⁷ The 4:4:1 ratio of treatment allocation was explained by the authors: “the primary objective of this 8-week, randomized, double-blind, parallel study was to compare the efficacy and safety of olanzapine monotherapy and placebo in the treatment of bipolar I disorder, depressed. An olanzapine–fluoxetine combination treatment arm was also included concurrently for exploratory purposes.” Thus, the primary objective was to compare olanzapine with placebo in bipolar depression. Both the olanzapine and the olanzapine–fluoxetine combination groups had greater improvement in MADRS than placebo throughout the study. This benefit was evident as early as week 1 of the study. Additionally, the olanzapine–fluoxetine combination was superior to treatment with olanzapine alone from weeks 4 through 8. As mentioned, olanzapine–fluoxetine combination therapy was statistically superior to lamotrigine in bipolar depression; however, the clinical significance of this difference remains to be established.¹⁰⁴ A prominent concern with the use of olanzapine–fluoxetine combination or quetiapine is the substantial risk of metabolic complications. Because of these risks, quetiapine and olanzapine–fluoxetine combination are reserved for second-line use in bipolar depression, despite being the only FDA-approved drugs for this indication.²¹

Antidepressants

Antidepressant use in bipolar depression is controversial and current guidelines suggest that they should be used only when other preferred treatments such as lithium, lamotrigine, quetiapine, or olanzapine–fluoxetine combination have failed (either alone or in combination).²¹ Antidepressant monotherapy should be avoided in bipolar disorder at all times.^{14,21} However, there is conflicting evidence regarding the protective role of antimanic agents against the development of mania triggered by antidepressants.^{26,108–110} The largest controlled trial of antidepressant augmentation in bipolar depression was conducted as part of the Systematic Treatment Enhancement Program for Bipolar Disorder (STEP-BD) study. This study was a 26-week, double-blind, placebo-controlled trial comparing antidepressants (bupropion or paroxetine) with placebo as adjunctive treatment to a mood stabilizer (any FDA-approved antimanic agent).¹¹¹ The primary endpoint of durable recovery (euthymia for 8 weeks) was achieved in 24% of antidepressant treated subjects compared with 27% of subjects receiving placebo. There was no significant difference between groups

in treatment emergent mood switch. These findings suggest that there is no advantage of adjunctive treatment with an antidepressant in patients with bipolar depression receiving a FDA-approved antimanic agent.

MAINTENANCE THERAPY OF BIPOLAR DISORDER

25. R.L., a 33-year-old man, has been treated for an episode of acute mania with lithium 600 mg BID for 3 weeks. He is no longer overtly manic. However, because R.L. may have had past episodes of depression and mania, his physician decides to institute prophylactic (maintenance) lithium therapy. What are the goals of maintenance lithium therapy for R.L.? How should he be monitored during this maintenance phase? How long should R.L. be maintained on lithium?

Lithium

Appropriate goals for maintenance therapy include an increase in the interval between episodes, a decrease in the frequency of episodes, and a reduction in the duration and severity of single episodes. Maintenance therapy with lithium clearly reduces the frequency and severity of mood episodes in patients with bipolar disorder. Goodwin and Jamison¹¹² have shown that in patients receiving maintenance lithium, only 34% relapsed, compared with 81% of patients receiving placebo. However, some studies indicate that lithium's effectiveness may be much lower. Naturalistic studies that followed patients on maintenance lithium indicate an episodic recurrence rate of 43% to 55%.^{113,114} It is possible that these studies failed to identify patients with rapid cycling disorder who may have done poorly on lithium. Beyond preventing mood relapses, lithium therapy may have the added benefit of reducing mortality from suicide.¹¹⁵ Conflicting results have been published recently regarding lithium's effectiveness for prevention of any mood episode in patients with bipolar I disorder.^{116,117}

Target levels for maintenance therapy with lithium should be in the range of 0.5 to 0.8 mEq/L.¹⁴ However, one study found that patients with lithium levels ranging from 0.4 to 0.6 mEq/L had relapse rates 2.6 times higher than patients with levels ranging from 0.8 to 1.0 mEq/L. Although these higher levels reduced the number of relapses, they also resulted in a higher incidence of side effects.¹¹⁸

In addition to determining appropriate maintenance lithium levels for R.L., it is appropriate to consider whether once-daily administration of lithium can improve adherence or side effects. During periods of dosage readjustment, R.L. will require monitoring of his lithium serum level more frequently. Once stabilized, the monitoring frequency can be reduced to quarterly. See Table 80-4 for recommended lithium monitoring parameters.

The decision to institute maintenance lithium therapy usually is made because of the severity of affective episodes and the belief that they will recur in the future. A period of successful maintenance therapy means that the individual is controlled, not cured, because most patients who are withdrawn from lithium eventually relapse. With each recurrent manic episode, the risk of experiencing subsequent and more frequent manic episodes increases. Furthermore, as individuals experience successive episodes, they tend to recover less completely and function at a diminished level between occurrences.¹¹² Be-

cause the goal is to prevent the trauma of repeated episodes and the deterioration that may accompany them, R.L. may require lithium for the remainder of his life.

Lithium Refractoriness

26. P.B. is a 42-year-old woman with five previous hospitalizations for manic and/or depressive episodes. She has experienced approximately six severe mood swings in the past year, including episodes of depression and hypomania. Despite adequate plasma levels, she has not responded to a regimen that includes lithium and paroxetine. She now presents as depressed, with expressions of suicidal hopelessness about her condition, sleep disturbances, and poor appetite. Why is P.B. failing to respond to lithium?

There are several potential reasons for P.B.'s poor response. Poor adherence always must be considered as a potential reason for lithium failure; however, P.B. has an adequate level of lithium. If P.B. had been intermittently compliant in the past or if her therapy had been stopped, she might have developed a syndrome called *lithium discontinuation-induced refractoriness*. This phenomenon occurs in patients who once responded to lithium and then had their lithium discontinued. When an affective episode recurs, they fail to fully respond to lithium reintroduction. However, there is conflicting evidence regarding lithium refractoriness, and it is unclear how often this phenomenon occurs.^{119,120} If P.B. had been having more and more breakthrough affective episodes gradually, she simply could have become tolerant to lithium. Thus, a careful review of P.B.'s history of adherence and the pattern of her affective episodes is necessary.

P.B. has another potential reason for nonresponse. She has had at least six affective episodes in the past year. Therefore, she meets criteria for rapid cycling. Approximately 70% to 80% of rapid cyclers have a poor response to lithium.¹⁴ P.B.'s trough lithium level should be assessed to ensure that it exceeds the lower limit of the usual therapeutic range. Potential causes of rapid cycling such as the paroxetine should be discontinued. Medical etiologies (e.g., hypothyroidism) and substance abuse should also be evaluated. The addition of valproate or lamotrigine may be warranted.¹⁴

27. What other maintenance treatments for bipolar disorder are available?

Anticonvulsants

Because of the side effects of lithium, many patients become intolerant or unwilling to continue lithium therapy. Valproate and lamotrigine are reasonable alternatives that have shown efficacy in bipolar maintenance therapy. The first controlled trial of valproate in the maintenance treatment of bipolar disorder randomized 372 patients with a recent manic episode to valproate, lithium, or placebo.¹¹⁷ Patients were followed for 52 weeks. The primary outcome of time to any mood episode did not differ between groups. However a lower percentage of patients discontinued treatment for any reason in the valproate group (62%) than lithium (76%) or placebo (75%) and patients on valproate remained in the study longer (198 days) than patients on lithium (152 days) but not placebo (165 days). The mean valproate serum concentration was 85 mcg/mL.

Lamotrigine has been studied rigorously in the maintenance treatment of bipolar I disorder. A pooled analysis of two placebo-controlled studies involving 638 patients found that lamotrigine and lithium more than doubled the time to intervention (e.g., addition of pharmacotherapy or ECT) for any mood episode compared with placebo.¹²¹ The time to intervention was 197 days for lamotrigine, 187 days for lithium, and 86 days for placebo. Interestingly, lamotrigine was also superior to placebo in delaying the time to an intervention for a depressive episode, making it an attractive agent for patients with frequent depressive relapses.

Limited evidence supports the role of CBZ in the maintenance treatment of bipolar disorder. In a 2-year study of 94 patients randomized to lithium or CBZ, more patients had a mood relapse on CBZ (42%) than lithium (27%).¹²² Mean drug blood levels were within the predefined range for both CBZ (6.8 mcg/mL) and lithium (0.75 mmol/L). Another study compared CBZ and lithium as prophylactic therapies for patients with bipolar I disorder ($n = 114$), bipolar II disorder, or bipolar disorder NOS ($n = 57$).¹²³ For bipolar I patients, CBZ failed more often than lithium with regard to all criteria (hospitalization, recurrence, concomitant medication, side effects, and subclinical recurrence). In contrast, the failure rate for lithium and CBZ in bipolar II or bipolar NOS was dependent on the failure criterion used. The authors summarize that CBZ was equally as effective as lithium in this population. In a separate analysis, patients were stratified into classical (bipolar I disorder without mood incongruent delusions or comorbidity; $n = 67$) and nonclassical (all other patients; $n = 104$) bipolar subtypes. The rate of hospitalization was significantly lower for lithium than for CBZ (26% vs. 62%, respectively) in the subgroup of patients with classical bipolar disorder. No significant difference was found in the subgroup of patients with nonclassical bipolar disorder subtype.

Atypical Antipsychotics

AAPs have become increasingly popular alternatives and adjunctive treatments for maintenance therapy of bipolar disorder. To date aripiprazole and olanzapine have received FDA approval for the maintenance treatment of bipolar disorder; however, the mood-stabilizing properties of the AAPs may be shared among all agents in the class. A 26-week, double-blind, placebo-controlled relapse prevention study of aripiprazole was conducted in 161 patients with a recent manic or mixed episode.¹²⁴ After patients met stabilization criteria (YMRS ≤ 10 and MADRS ≤ 13) during an aripiprazole open-label phase they were randomized to aripiprazole (mean, 24 mg/day) or placebo. On the primary outcome of time to a mood episode, aripiprazole was superior with a hazard ratio of 0.52 for relapse on aripiprazole relative to placebo. An extension phase of this study found that aripiprazole was superior to placebo in delaying time to mood episode for an additional 74 weeks; however, only 12 patients completed the study.

Olanzapine and lithium were compared in an open-label relapse prevention study of 431 patients with a recent manic or mixed episode who met remission criteria (YMRS ≤ 12 and HAM-D ≤ 8) on an open-label combination therapy of lithium and olanzapine.¹²⁵ Patients were then randomized to lithium (mean serum level, 0.7 mEq/L) or olanzapine (mean dose, 13.5 mg/day) monotherapy for 52 weeks of follow-up. Mood relapse

occurred in 30% of olanzapine-treated patients and in 39% of lithium-treated patients. This result met the authors predefined criteria for statistical noninferiority of olanzapine relative to lithium. In a more recent study, 361 patients achieving remission (YMRS ≤ 12 and HAM-D ≤ 8) during open-label treatment with olanzapine were randomized to placebo or olanzapine (mean 12.5 mg/day) for 48 weeks of follow-up.¹²⁶ Time to any mood episode was significantly longer with olanzapine (174 days) than with placebo (22 days). Despite strong evidence of efficacy for olanzapine, the risk of metabolic complications limits the use of this drug in the long-term treatment of bipolar disorder (see Question 21).

28. What is the role of psychotherapy in bipolar disorder?

Psychotherapy can have a profound effect on the prevention of acute illness, as well as a sustained effect on maintenance treatments. Excessive stress, for example, is often implicated in the onset of affective episodes, particularly early in the lifetime course of bipolar illness.²⁷ If individuals and their families can learn to avoid these triggers or to develop coping skills, the acute impact can be minimized and future episodes averted.

Therapy may also help the family to cope with the extreme emotions and disruption that are the hallmark of acute manic and depressive episodes. Violent outbursts, infidelity, financial debts, and loss of self-esteem may all be a byproduct of relapse, and family members must come to terms with such calamities, as well as fears surrounding future episodes. Improvements in sleep hygiene may be encouraged in these sessions, because regular sleep-wake cycles seem vital to the maintenance of euthymic states. Last, sustained medication adherence must also be emphasized; individuals with bipolar disorder will often stop their mood stabilizers in an effort to resume the “highs” of mania. Many other patients also find the cumulative side effect burden of complex psychotropic regimens to be prohibitive.

The specific psychotherapeutic approach to bipolar disorder is generally quite similar to interventions offered to individuals with schizophrenia. Family-focused therapy seems to be quite effective, as are cognitive-behavioral, interpersonal, and social rhythm therapy. Collaborative care models have been extensively studied for unipolar depression in primary care settings, but the effectiveness of collaborative care models for bipolar illness is less clear. In the STEP-BD trials, subjects were randomized to one of four therapy approaches and collaborative care was the least effective.¹²⁷ Reported response rates were 77% with family-focused therapy, 64% with interpersonal and social rhythm therapy, 60% with cognitive-behavioral therapy, and 54% with collaborative care. However, some authorities contend that the collaborative care intervention was comparatively less intensive than the other three treatment modalities in this report.

29. Are there other treatment options for bipolar disorder?

Although most experts advocate for regular physical activity to prevent bipolar mood swings, the body of literature supporting such an approach is very limited. Lifestyle surveys have demonstrated that people afflicted with bipolar disorder are less likely to exercise and more likely to exhibit poor dietary habits than those without a serious mental illness.¹²⁸ Theoretically, exercise may improve dietary habits, regulate sleep, increase energy, and promote euthymic moods. Because all of

these factors would be expected to improve the prognosis of bipolar illness, exercise should be encouraged.

A wide variety of herbal preparations and dietary supplements have been studied for the treatment of bipolar disorder. There has been considerable interest in the benefits of omega-3 fatty acid supplementation. A meta-analysis of double-blind, placebo-controlled trials of combined bipolar and unipolar depression found significant benefit of omega-3 fatty acid supplementation over placebo in patients with bipolar and unipolar depression.¹²⁹ In most cases, omega-3 fatty acid supplementation was used as adjunctive treatment and included eicosapentaenoic acid (EPA) alone or a combination of EPA and docosahexaenoic acid (DHA). The doses studied ranged from 1 gm/day of EPA all the way up to 9.6 g/day of combined EPA and DHA. Frangou et al.¹³⁰ compared 1- and 2-g/day doses of ethyl-EPA with placebo. Although both doses were superior to placebo, there was no difference between the 1- and 2-g/day doses. In a separate dose-ranging study for unipolar depression, results demonstrated a difference in response between the 1-g/day group and the placebo group; however, the 2- and 4-g/day treatment results did not differ from placebo.¹³¹ Both of these studies suggest that 1 g/day of EPA may be adequate; but, the optimal dose of DHA and the optimal ratio of EPA to DHA remains unknown. The value of omega-3 fatty acids in the treatment and prevention of future manic episodes has been less clear. In fact, in one small randomized trial, 3 of 14 subjects treated with omega-3 fatty acids withdrew from the study due to the occurrence of manic or hypomanic symptoms.¹³²

Among the other options, inositol was recently compared with lamotrigine and risperidone in an augmentation trial for

bipolar depression.¹³³ The three treatments were equivalent with regard to recovery from depression; however, the study was open label and the sample size was small ($n = 66$). St. John's wort and *S*-adenosyl-*L*-methionine may be effective for depressive episodes; however, these agents should generally be avoided in bipolar disorder owing to the risk of switching to mania.^{134,135} Chromium shows some promise for the treatment of acute depressive episodes. In one study, approximately one-third of bipolar patients with treatment-resistant rapid cycling bipolar disorder had a positive response.¹³⁶ The number of affective episodes also decreased for those patients remaining in the study; however, only 23% of patients were available for follow-up evaluation at 1 year. The adjunctive use of intravenous magnesium has been found to be beneficial for treatment resistant acute mania.¹³⁷

ECT has been shown to have benefit in acute mania, mixed states, depression, and as a therapy to prevent relapse.¹⁴ The rapid onset of effect of ECT in acute mania has been well documented. This therapy is also well tolerated, when used with a pretreatment regimen that includes a short-acting barbiturate, a skeletal muscle depolarizing agent, and atropine. The optimal placement of ECT electrodes (unilateral versus bilateral placement of electrodes) and the optimal frequency of ECT treatments to prevent a relapse are still unknown. The influence of concurrent psychotropic medications on ECT treatment success also should be considered.¹³⁸ Anticonvulsants and benzodiazepines may raise the seizure threshold and interfere with seizure induction. Lithium may increase confusion and memory impairment after ECT. Antipsychotics agents seem to be relatively safe in patients receiving ECT.

The popular culture book *Ritalin Nation* suggests that modern Western society's high-speed lifestyle and rapid-fire culture have significant consequences for children.¹ Because children are being continuously bombarded with sophisticated sensory stimuli via television and video games, many never learn to concentrate on free-play activities. By the time they reach school age, they have not learned the skills necessary to attend to activities such as reading, writing, and arithmetic. It is hypothesized that children become "addicted to" and "dependent" on continuous sensory stimulation. DeGrandpre hypothesizes that the symptoms of attention deficit hyperactivity disorder (ADHD)—hyperactivity and an inability to attend to low-stimulation activities—reflect an escape behavior used by children to maintain sensory stimulation.¹ In this theory, methylphenidate is effective only because it provides stimulation in this case, pharmacologic stimulation as opposed to auditory or visual stimulation. This minority opinion contends that ADHD is a diagnosis invented by 20th-century psychiatrists and pharmaceutical companies. In the well-known European children's story of Fidgety Phillip written in the 1863 book, *Struwwelpeter*, by Heinrich Hoffmann² "Phil stop acting like a worm, the table is no place to squirm. Thus speaks the father to his son severely say it, not in fun. Mother frowns and looks around, although she doesn't make a sound. But Phillip will not take advice, he'll have his way at any price. He turns and churns, he wriggles and jiggles. Here and there on the chair, Phil, these twists I cannot bear." Today, Phil may have been diagnosed with ADHD.

Among the vocal critics of ADHD are included the Church of Scientology, newspaper reporters, talk show hosts, Drug Enforcement Agency officials, conservative legislators, and a small number of physicians and psychologists. Safer categorized the objections of the ADHD faultfinders into seven criticisms: (a) physicians are haphazard in their diagnosis and treatment of ADHD; (b) school alternative programs for treating ADHD are neglected or ignored because of stimulant treatment; (c) ADHD is caused by 20th- and 21st-century social and cultural pressures and is not really a legitimate diagnosis; (d) stimulant treatment has profound limitations; (e) stimulants are

harmful and abused by ADHD patients; (f) methylphenidate is overprescribed; and (g) pharmaceutical companies influence the "pro-Ritalin" parent support groups excessively to legitimize the acceptance of Ritalin as the treatment of choice in ADHD.³ However, the data do not support these assertions. These claims are countered by the following data: (a) on average, a physician requires an hour to make the initial ADHD diagnosis; (b) 25% of ADHD children do not receive a prescription; (c) most pediatricians offer nonmedical treatment alternatives for ADHD; (d) 45% of methylphenidate-treated ADHD diagnosed children are in special education classes because of learning disabilities; (e) genetic determinants are the major causative factor in explaining the etiology of ADHD; (f) stimulants are clearly more effective than behavioral therapy for the treatment of ADHD; (g) stimulants are safe, well tolerated, and rarely abused by ADHD youth; (g) because of diversion, pharmaceutical company production quotas cannot be used to determine or estimate the number of treated ADHD individuals; (h) in reality, stimulants may be underprescribed for ADHD children and adolescents because of the social stigma associated with taking methylphenidate or amphetamines; and (i) parents have the same attitudes toward ADHD, regardless of whether they are members of a pro-Ritalin parent support group.³

DIAGNOSTIC CRITERIA

The effectiveness of stimulants in improving academic performance is often misunderstood. On occasion parents may pressure clinicians into writing stimulant prescriptions for a "let's see if it helps" trial. If the drug does help, they may assume that the diagnosis of ADHD is validated. However, stimulant medications improve vigilance performance (attention/concentration) in both normal and hyperactive children.⁴ Other commonly used dopamine agonists such as caffeine and nicotine also benefit concentration and the ability to study. Table 81-1 presents the *Diagnostic and Statistical Manual of Mental Disorders*, Fourth Edition, Text Revision (DSM-IV-TR) criteria required to make a diagnosis of ADHD.

Table 81-1 DSM-IV-TR Diagnostic Criteria for Attention Deficit Hyperactivity Disorder**Inattention Factor**

(Six or more of the following nine behaviors need to be present for ≥ 6 months in two or more settings, such as home, school, or physician's office.)

1. Careless mistakes or inattention to detail
2. Reduced attention span
3. Poor listener
4. Cannot follow instructions and does not complete tasks
5. Difficulty organizing tasks and activities
6. Avoids and/or dislikes chores or homework
7. Loses things needed for tasks and activities
8. Easily distracted by extraneous stimuli
9. Forgetful in daily activities

Hyperactivity/Impulsivity Factor

(Six or more of the following nine behaviors need to be present for ≥ 6 months in two or more settings, such as home, school, or physician's office.)

Hyperactivity

1. Fidgets with hands/feet or squirms in chair
2. Cannot remain seated in the classroom
3. Uncontrollable/inappropriate restlessness
4. Difficulty in engaging in play or leisure activities quietly
5. Often on the go and appearing driven by a motor
6. Excessive talking

Impulsivity

7. Blurts out answer prior to completion of question
8. Difficulty waiting turn
9. Interrupts or intrudes on others

Reprinted with permission from reference 73.

ADHD impacts the child and his or her family, the child's social interactions, and the child's self-esteem. Often children are aware of these difficulties and resist doing their normal day-to-day tasks. Establishing a diagnosis of ADHD in an adult who has never been treated for the disorder during childhood is difficult. Symptoms tend to be more subjective, with less overt hyperactivity. Unlike teachers who are often familiar with the symptoms associated with ADHD in children, spouses, coworkers and employers are often unfamiliar with ADHD as a disorder that can also affect adults. They may attribute the individual's difficulties to being lazy or to "underachievement". Symptoms of ADHD in adulthood often interfere with social relationships and employment.

PREVALENCE

ADHD is classified into three subtypes depending upon the hallmark clinical features: hyperactive-impulsive, inattentive, or combined. The Centers for Disease Control and Prevention analyzed data from the 2003 National Survey of Children's Health.⁵ In 2003, approximately 7.8% (4,418,000; 95% confidence interval = 4,234,000–4,602,000) of U.S. children ages 4 to 17 years were diagnosed with ADHD. ADHD diagnosis

was reported approximately 2.5 times more frequently among males than females.

COMORBIDITY

There is a high rate of comorbidity between ADHD and other psychiatric conditions including conduct disorder, oppositional defiant disorder, depression, major affective disorder, and anxiety disorders, including obsessive-compulsive disorder and Tourette syndrome (TS). Family histories from first-degree relatives of probands with ADHD reveal increased rates of ADHD (25% concordance rate), polysubstance dependence, antisocial personality disorder, depression, and anxiety disorders.⁶ Children with ADHD are at an increased risk of having antisocial behavior, depression, and polysubstance abuse problems as adults. ADHD symptoms persist into adulthood in approximately 10% to 60% of patients.⁷ Adults with ADHD are usually self-sufficient, but they have poorer academic performance, poorer job performance, and lower socioeconomic status than do their siblings. They also have more frequent divorces, job changes, changes of residence, and car accidents. Most adults with ADHD report a high level of subjective distress (79%) and interpersonal problems (75%).⁸

DIFFERENTIAL DIAGNOSIS

ADHD should not be diagnosed until head injuries, absence seizures, cerebral infection, substance abuse, hyperthyroidism, anxiety disorders, and mood disorders have been excluded. Of these conditions, anxiety disorders and mood disorders are most commonly misdiagnosed as ADHD. The ADHD workup should include teacher and parent-child ratings using an accepted rating scale such as the Iowa Connors Rating Scale for ADHD; a physical examination; lead screening; a neurological examination; antenatal, perinatal, social, family, school, and medical history; developmental milestones; cognitive testing that includes an IQ test and a reading test; and psychometric tests that quantify errors of omission (inattention) and errors of commission (hyperactivity/impulsivity).

SIGNS AND SYMPTOMS

1. C.B., a 6-year-old boy, was brought into a child psychiatry clinic after his mother attended his first-grade school conference and was told that her son was having difficulty adjusting to first grade. C.B.'s mother reported that C.B. had always been a somewhat difficult child. He showed disruptive behavior and did not respond well to direction to put toys away, and he never seemed to be able to keep track of what was going on around him. As an infant, he was irritable and overactive. At 7 months, when he began crawling, he would disrupt the entire house. He was unable to follow through with parental instructions to keep his feet off the furniture, not walk on the tops of tables, and not walk through the living room carrying melting chocolate popsicles. When he learned to talk, he talked incessantly and continuously. Attempts to ignore his attention-seeking behavior seemed to have little effect on him. He was disruptive and impulsive in preschool, with noisy, attention-seeking behaviors that continued through first grade. He was oblivious to the pleas of teachers and teaching assistants to get him to sit still and pay attention. He would not sit in his seat.

Often he would get up and run around the room. He could not stay on task on assignments for more than 5 minutes without becoming distracted. Before he even started his assignments, looking for his lost pencil would distract him. His partially completed class assignments would be incomplete and filled with careless errors. He would talk to his classmates when they were working, pointing out to them what was going on outside. He was in constant motion, moving his legs and arms and wiggling in his seat. It was difficult for C.B. to participate in school activities/games because he interrupted others or participated out of turn, which made other kids not like him. During the clinic evaluation, C.B. was quite active. He jumped on his chair rather than sitting on it. When he eventually did sit, he remained in his chair for only 2 to 3 minutes. He then began pulling books off the shelves. When he was told to leave them alone, he threw two books onto the floor and then headed toward the doctor's desk to examine the pens, pencils, and paperweights. C.B. had trouble attempting to put a puzzle together (a five-piece puzzle); he would put one piece in place, lose interest, and throw the remaining pieces across the room. He would reverse letters when asked to write the letters of the alphabet, and he reversed the letter *r* when writing his name. His physical exam was otherwise within normal limits. What symptoms of ADHD does C.B. present? For which of the three diagnostic subtypes of ADHD does he meet the criteria?

Based on his history, C.B. exhibits the symptoms of ADHD, combined subtype. C.B. represents a child with ADHD who is more likely to present to a child psychiatry clinic rather than a pediatrician or family doctor. If his medical history was explored, C.B. would likely be a risk taker, having more accidents requiring stitches and involving broken bones than other children his age. It is likely that his parents and perhaps C.B. himself would say that he has trouble making and maintaining friendships or that his friends were more likely to be children who themselves have behavior difficulties. Finally, it appears that C.B. has comorbid oppositional defiant disorder. Although establishing a learning disorder diagnosis at his current age is unlikely, as C.B. ages the probability of this occurring is likely to increase, and he should be monitored and tested for a learning disorder.

NEUROBIOLOGY

Various abnormal neurochemical and genomic abnormalities are associated with ADHD. A decrease in 3-methoxy-4-hydroxyphenylglycol (MHPG), the major metabolite of norepinephrine, supports a norepinephrine deficiency hypothesis, whereas low levels of homovanillic acid, the major metabolite of dopamine, is postulated to support a dopamine deficiency hypothesis.⁹ In addition, an excess of platelet monoamine oxidase (MAO) has been observed in children with ADHD. Normally, there is an age-related decrease in MAO in the platelets of children.¹⁰ However, this decrease in MAO activity was not observed in children with ADHD. The computerized electroencephalogram brain mapping of ADHD children show an excess of theta (slow wave) activity in the frontal lobe, which may relate to a decrease in glucose metabolism in this area and suggest dysregulation of arousal and attention.¹¹ The neurochemical changes are also hypothesized to have a genetic basis. Candidate genes associated with ADHD can be grouped into four categories: (a) genes coding for various neurotrans-

mitter functions (i.e., dopamine-transporter receptor [DAT1], dopamine-4 receptor [DRD4], dopamine-5 receptor [DRD5], synaptosome-associated protein of 25 kDA [SNAP25]); (b) genes coding for enzymes involved in dopamine biosynthesis (i.e., tyrosine hydroxylase [chromosome 11p15.5], dihydroxyphenylalanine [DOPA], decarboxylase [chromosome 7p11], dopamine-beta-hydroxylase [chromosome 9q34]); (c) genes coding for enzymes involved in the metabolism of catecholamines (i.e., catechol-*O*-methyltransferase [COMT], MAO); and (d) other genes (i.e., glutamate receptor inotropic N-methyl-D-aspartate [NMDA] 2A [GRIN2A] [chromosome 16p13], serotonin transporter gene).¹²

PHARMACOTHERAPY

Although central nervous system (CNS) stimulant or psychostimulant medications are currently the drugs of choice, tricyclic antidepressants (TCAs), atomoxetine, bupropion, and clonidine are also useful medications in the treatment of patients with ADHD. Stimulants that are norepinephrine and/or dopamine agonists benefit the symptoms of ADHD. Patients, teachers, and clinicians rate 75% of children with ADHD to be improved on stimulants, compared to 18% of placebo-treated children.¹³ Approximately 20% to 25% of those who respond poorly to one medication will respond positively to another.¹⁴

Central Nervous System Stimulants

The short- and long-term effectiveness and safety of pharmacological and nonpharmacological interventions for ADHD in children and adults was suggested in a meta-analysis based on 77 randomized controlled trials.¹⁵ There were no obvious differences in effectiveness among the stimulants methylphenidate, dextroamphetamine, and pemoline. However, the six randomized controlled trials that compared drugs with nondrug interventions consistently showed that stimulants, particularly methylphenidate, were more effective than nonpharmacologic interventions. The 20 combined therapy (stimulants plus psychotherapy) randomized controlled trials were unable to identify any additional benefit from the nonpharmacologic interventions. The analysis concluded that psychostimulants are first-line drugs in the treatment of ADHD, and the stimulants methylphenidate, dextroamphetamine, mixed amphetamine salts, and pemoline are equivalent in efficacy. ADHD symptoms that should improve with treatment include hyperactivity; attention span; impulsivity and self-control; compliance; physical and verbal aggression; social interactions with peers, teachers, and parents; and academic productivity. ADHD symptoms that may or may not improve include reading skills, social skills, learning (less improvement in this area than behavior), academic achievement, antisocial behavior, and arrest rates.¹⁶ Although stimulants are more effective for improving behavioral symptoms than academic performance, these agents can improve classroom learning. Methylphenidate 0.3 mg/kg per dose improves performance on arithmetical and language tasks.¹⁷ In addition, aggressive behavior, including stealing and vandalism, is improved by standard doses of methylphenidate 0.3 to 0.6 mg/kg. Stimulants decrease friction between siblings and peers and improve maternal-child interactions. Patients most likely to respond are characterized

as having low ADHD severity, low anxiety, higher IQs, being younger, and being highly inattentive. The response from a single stimulant dose predicts the home and school behavioral response at 4 weeks.¹⁸ Finally, patient adherence to stimulant medication correlates with greater improvement on teacher-reported symptoms, an effect that is stable for up to 5 years.¹⁹

2. C.B. and his mother come to the local pharmacy with a prescription for Concerta 18 mg, #30 tablets, one tablet in the morning with zero refills. The mother is upset with the cost of the medication. Her assumption was that methylphenidate was inexpensive. What relevant patient/caregiver counseling points can you make with respect to the cost of the immediate- and extended-release medications presented in Table 81-2? Suggest to the mother a simple quantitative method whereby she can monitor whether C.B. is responding to the medication. She is also concerned about potential side effects of psychostimulants that she has read about, such as drug addiction, tics, growth retardation, and other adverse effects. What counseling points would you make to her regarding these issues?

According to Table 81-2, generic formulations of short- and intermediate-acting psychostimulants are available. The intermediate-acting formulations of methylphenidate are effective for 6 to 8 hours. If the rationale for nonimmediate-release formulations is to spare the child the embarrassment of taking the medication at school, one of these less expensive products would be suitable.

The Iowa Connors Teacher's Scale—Revised is an example of an ADHD monitoring tool that is used by teachers for monitoring of children and adolescents at school. The scale consists of ten items scored as *not at all* (0), *a little bit* (1), *pretty much* (2), or *very much* (3). They are divided into two symptom clusters: the Attention Factor and the Conduct Factor. The five items of the Attention Factor consist of (a) fidgeting, (b) hums and makes other odd noises, (c) excitable (impulsive), (d) inattentive (easily distracted), and (e) fails to finish thing he starts. The

five items of the Conduct Factor consist of (a) quarrelsome, (b) acts smart, (c) temper outburst (explosive, unpredictable behavior), (d) defiant, and (e) uncooperative. This scale has been updated such that normative data exist by both gender²⁰ and ethnicity.²¹ Typically, children with untreated ADHD typically score 2 standard deviations above the mean for their comparison group. Following successful treatment, their score should decrease to <1 standard deviation above the mean.

Adverse drug reactions (ADRs) are relatively infrequent with the therapeutic use of psychostimulants for ADHD. According to a parental survey, the only side effect of methylphenidate more severe than at baseline was appetite suppression, whereas dextroamphetamine caused more severe insomnia and appetite suppression. Methylphenidate was better tolerated than dextroamphetamine because of more severe insomnia, appetite suppression, irritability, proneness to crying, anxiety, dysphoria, and nightmares. Only four of 125 subjects (3.2%) discontinued the medication because of side effects.²² The association between psychostimulant use and growth retardation is controversial. Some authors contend that growth retardation occurs as a function of the disease rather than a result of psychostimulant use.²³ Others suggest that it is indeed possible for stimulants to cause growth retardation, but that this effect is reversible with drug holidays such as on the weekends or during the summer.²⁴ However, drug holidays have the risk of disruption of the psychosocial development of the child during the medication-free intervals. Stimulants have been alleged to precipitate or exacerbate tics in children in approximately 1.3% to 60% of ADHD patients.²⁵ Multiple randomized controlled trials have challenged the veracity of this adverse effect. As an example, the Tourette's Syndrome Study Group contrasted the effect of methylphenidate, clonidine, and the combination of the two to placebo in the treatment of 136 children (7–14 years old) diagnosed with ADHD and Tourette's Syndrome. The group concluded that prior recommendations to avoid methylphenidate in these children because of concerns of worsening tics were unsupported.²⁶

Table 81-2 Characteristics of Psychostimulants

| Product | Maximum Dose (mg/d) | Peak Concentration (hr) | Duration of Action (hr) |
|---|---------------------|--------------------------------|-------------------------|
| Short-acting psychostimulants (IR) | | | |
| Methylphenidate (Ritalin, Methylin, generic) | 60 | 1–2 | 3–4 |
| d-Methylphenidate (Focalin) | 20 | 1–2 | 4–5 |
| Dextroamphetamine (generic) | 40 | 3 | 3–5 |
| Intermediate-acting psychostimulants | | | |
| Methylphenidate (Ritalin SR, Methylin ER, Metadate ER, generic) | 60 | 4–5 | 6–8 |
| Dextroamphetamine (Dexedrine Spansules) | 40 | 1st peak, 3; 2nd peak, 8 | 5–8 |
| Mixed amphetamine salts (Adderall, generic) | 30 | 3 | 3–7 |
| Long-acting psychostimulants | | | |
| Methylphenidate (Metadate CD) 30:70 ratio of IR:ER product | 60 | 1st peak, 1.5–3; 2nd peak, 4–6 | 6–9 |
| Methylphenidate (Ritalin LA) 50:50 ratio of IR:ER product | 60 | 1st peak, 1–2; 2nd peak, 5–7 | 8–10 |
| Methylphenidate (Concerta) | 54 | 1st peak, 1–2; 2nd peak, 6–8 | 12 |
| Mixed amphetamine salts (Adderall XR) | 30 | 1st peak, 3; 2nd peak, 7 | 10–12 |

CD, controlled dose; ER, extended release; IR, immediate release; LA, long acting; SR, sustained release; XR, extended release.

C.B.'s mother concerned about stimulant treatment increasing risk of her child becoming a substance abuser. This concern is probably unfounded. A meta-analysis of epidemiologic literature led to the conclusion that stimulant-treated patients with a diagnosis of ADHD were less likely to be diagnosed with substance use disorder than those not treated with stimulants.²⁷ However, C.B.'s mother's concerns are not completely without merit. In 2005, the U.S. Food and Drug Administration (FDA) added a warning to amphetamine package prescribing inserts to note that misuse of amphetamine may cause sudden death and serious cardiovascular adverse events.²⁸ Amphetamines should not be used in patients with structural cardiac abnormalities because of the risk of sudden unexplained death. In addition, there are a small number of cases of sudden unexplained death in children without cardiac abnormalities taking Adderall.

Tricyclic Antidepressants

3. Because of economic issues, C.B. has been treated with generic immediate-release methylphenidate for several years. He has two bottles of medication, one he keeps at home, while the other is held by the school nurse. When C.B. started junior high school, his mother noticed his home supply was gone before it needed refilling. It was discovered that C.B. was selling the methylphenidate to his friends at school. At this time, it was decided to treat C.B. with another class of drugs than the psychostimulants. His primary care practitioner asks for your recommendation regarding an alternative agent to treat C.B.'s ADHD. What alternatives would be recommended for C.B.?

TCAs have been used in the treatment of patients diagnosed with ADHD for nearly 30 years. There may be an ADHD subgroup that responds better to the TCAs than to stimulants. Because TCAs may be effective for the treatment of major depression and anxiety disorders in children and adolescents, this class of drugs might best be reserved for patients diagnosed with ADHD accompanied by major depression or any of the anxiety disorders such as obsessive-compulsive disorder. Six randomized controlled trials in ADHD have established the efficacy of amitriptyline,²⁹ imipramine,^{30,31} desipramine,^{32,33} and nortriptyline.³⁴ TCAs are more effective than placebo in treating ADHD, but they are less effective than methylphenidate. TCAs such as imipramine and clomipramine can also cause significant daytime sedation. This sedation is likely to adversely affect cognition in children diagnosed with ADHD. An additional concern that limits the utility of the TCAs in this patient population is their potential adverse effects on cardiac conduction. Six fatalities have been associated with desipramine administration in children; therefore, careful cardiac monitoring is imperative.³⁵ A baseline electrocardiogram (ECG) should be obtained, and then repeated when dosages reach 1.5 mg/kg/day, 3.0 mg/kg/day (typical maintenance dose), and 5 mg/kg/day (the maximum dose). With respect to the use of TCA in children and adolescents, the American Heart Association recommends a baseline history and physical, a current medication history, and a baseline ECG within the following parameters of PR interval = 200 milliseconds, QRS duration = 120 milliseconds, and QTc = 460 milliseconds.³⁶ Follow-up ECG and history are indicated after steady state is achieved and at the dosage thresholds listed

above. Nortriptyline, because it is twice as potent, is dosed at 1.5 to 2.5 mg/kg/day and requires ECG monitoring at doses that reflect the difference in potency.

Bupropion

Six randomized controlled trials have established the effectiveness of bupropion as an alternative medication to the psychostimulants in the treatment of ADHD among children, adolescents, and adults.^{37,38} One of the studies found bupropion at an average dose of approximately 3 mg/kg/day to be as effective as methylphenidate in the treatment of adolescents with ADHD.³⁹ The two most common adverse effects encountered with bupropion in ADHD studies were dermatologic reactions and seizures. Dermatologic reactions occurred twice as often as the placebo with severe bupropion-induced urticaria requiring discontinuation in 5.5% (4/72) of the patients in one study.⁴⁰ In adults, the risk of seizures increases by about fourfold if bupropion doses of >450 mg/day are exceeded.⁴¹ Although there are no case reports of seizures in children receiving therapeutic doses of bupropion, it is recommended to confine the dose range for treating ADHD to less than 6 mg/kg/day.

Atomoxetine

Atomoxetine inhibits the presynaptic norepinephrine transporter and is not classified as a psychostimulant. Clinical trials have shown that atomoxetine is superior to placebo in reducing the symptoms of ADHD in children, adolescents, and adults.^{42,43} However, a trial comparing atomoxetine to the mixed amphetamine salt product, Adderall, found atomoxetine to be less effective than the psychostimulant.⁴⁴ Atomoxetine requires a 10- to 14-day titration to the therapeutic dose of 1 to 1.5 mg/kg/day. The slow titration is necessitated by the high rates of nausea (12%), vomiting (15%), and asthenia (11%).⁴⁵ In addition, atomoxetine can raise blood pressure and heart rate. Two or more episodes of high systolic and diastolic blood pressures occurred in 8.6% and 5.2% of pediatric subjects, respectively. Heart rate increases of >110 beats/minute and more than 25 beats/minute over baseline were observed in 3.6% of patients.⁴⁵

An additional concern regarding the use of TCAs, atomoxetine, and bupropion is the prescribing insert warning regarding an increase in suicidal thinking and behavior. Pooled analyses of short-term (4–16 weeks) placebo-controlled trials of nine antidepressant drugs in children and adolescents with major depressive disorder, obsessive-compulsive disorder, or other psychiatric disorders (a total of 24 trials involving more than 4,400 patients) revealed a greater risk of suicidal thinking or behavior during the first few months of treatment in those receiving antidepressants. The average risk of such events on drug was 4%, twice the placebo risk of 2%.⁴⁶ The seriousness of this warning has been questioned because no suicides occurred in these trials, and because the suicide rates for the 15- to 24-year-old age group in the United States decreased from 13.2/100,000 in 1990 to 9.9/100,000 in 2001.⁴⁷ The FDA has authored a patient information handout for pharmacists to give to parents whose children are receiving antidepressant prescriptions entitled *Medication Guide—Antidepressant Medicines, Depression, and Other Serious Mental Illnesses and Suicide Thoughts or Actions*.⁴⁸ Thus, this information packet should be given to

the parents for patients receiving a TCA, bupropion, or atomoxetine prescription, even though they are being treated for ADHD.

Modafinil

Modafinil, at single daily doses ranging from 170 to 425 mg/day, has been found to be effective in the treatment of ADHD-diagnosed prepubescent, adolescent, and adult patients.^{49,50} One small preliminary study found it to be as effective as dextroamphetamine in the treatment of adults with ADHD.⁵¹ Common adverse effects include insomnia, headache, and decreased appetite, although discontinuation rates are similar to placebo.⁵²

Because C.B. was selling a short-acting methylphenidate, considering a change to a different medication is reasonable. After discussion with C.B. and his parents, the treating physician may believe that C.B. is aware of the seriousness of this act and thus may elect to continue treatment with the stimulant medication. Conversely, a long-acting stimulant medication with less abuse potential could be considered. However, most clinicians would elect to change the patient's medication to a class without known abuse potential. Based on the available literature, both atomoxetine and bupropion would be reasonable alternatives. Both medications have the disadvantage of taking several days to weeks to become effective. Atomoxetine is not available in generic form; bupropion, even though it is available as a generic product, would be more expensive than methylphenidate. However, the safety margin for misuse of atomoxetine is greater than for bupropion and thus atomoxetine would be preferred by some providers as an alternative to C.B.'s use of methylphenidate.

4. A.D., a 6-year-old first grader, has responded well to his methylphenidate (Concerta) treatment during the school year. His mother sends him off to his father and stepmother for his annual summer visit, with explicit directions for the parents regarding how to use the medication. One month later, he returns home with a full bottle of medication. As he bounces around the room, A.D. reports that his father and stepmother said he did not need these "poison pills". A.D.'s mother phones the stepmother to find that they put A.D. on the Feingold diet along with sugar restriction to control his behavior. What are the roles of diet and alternative therapies in the treatment of ADHD?

The Feingold diet is the most widely known dietary intervention associated with the treatment of ADHD.⁵³ It is based on the theory that many children are sensitive to dietary salicylates and artificially added colors, flavors, and preservatives. The elimination of these substances from the diet has been proposed to improve learning and behavioral problems associated with ADHD. However, most randomized controlled trials do not support this hypothesis. In addition, the prevalence who have food sensitivities consistent with the Feingold diet among children with ADHD is very small.⁵³ Another dietary intervention hypothesis is that the elimination of all dietary sugars will reverse the hyperactivity associated with ADHD. However, the claims of an association between sugar intake and hyperactivity have not been supported, even in those children who are reportedly sensitive to the effects of sugar.⁵⁴ The use of very high doses of vitamins and/or minerals, known as megavitamin therapy, to treat ADHD is another intervention that lacks

data to support its claim. All randomized controlled trials conducted to evaluate the effectiveness of megavitamin therapy in ADHD are negative. The American Psychiatric Association and American Academy of Pediatrics concluded that the use of megavitamin therapy to treat behavioral and learning problems is unjustified.⁵⁵

5. G.S. is a 6-year-old boy referred to the Tourette Syndrome clinic by his pediatrician because of worsening motor (blinking, grimacing) and vocal (throat clearing, coprolalia, grunting) tics. He is treated successfully with clonidine 250 mcg/day. However, his behavior and performance in school is still so poor that his teacher refers him to the school psychologist, who diagnoses ADHD, combined type. A trial of stimulant treatment is considered. The parents are concerned about treating his two disorders simultaneously with the clonidine and a stimulant. Can stimulants be used in children with both disorders?

The two commonly prescribed alpha-2-adrenergic agonists in child-adolescent psychiatry, clonidine and guanfacine, are not approved by the FDA for any psychiatric indication. However, a large randomized controlled trial supports the use of clonidine in the treatment of comorbid Tourette Syndrome and ADHD.⁵⁶ The Tourette Syndrome Study Group compared the effect of methylphenidate (mean, 26 mg/day), clonidine (mean, 250 mcg/day), and the combination (methylphenidate ~26 mg/day + clonidine mean, 280 mcg/day) to placebo in the treatment of 136 children (7–14 year olds) diagnosed with ADHD and Tourette Syndrome. Teacher ratings showed that both clonidine and methylphenidate used as individual treatments were more effective than placebo. However, the greatest improvement was seen with the combination therapy. Clonidine primarily benefited the symptoms of impulsivity and hyperactivity, while methylphenidate primarily benefited inattention. A meta-analysis of trials evaluating the efficacy of the clonidine for the treatment of children and adolescents with ADHD concluded that the effect size of the drug was modest (0.58) and less than that of the psychostimulants.⁵⁷ Despite its widespread use, there is just one randomized controlled trial that documents the effectiveness of guanfacine in the treatment of patients diagnosed with ADHD and/or a tic disorder. Thirty-four medication-free elementary school-age children with ADHD and a tic disorder participated.⁵⁸ After 8 weeks of treatment with a modal dose of 1 mg guanfacine TID, the children had a mean improvement of 37% in their total score on the teacher-rated ADHD Rating Scale, compared to 8% improvement for placebo. Continuous Performance Test commission errors decreased by 22% and omission errors by 17% in the treated group, compared with increases of 29% in commission errors and of 31% in omission errors in the placebo group. However, the parent-rated hyperactivity on dextroamphetamine improved by 27% in the guanfacine group and 21% in the placebo group, a nonsignificant difference.

6. G.S.'s mother places a call to the clinic asking to talk to his physician. She tells the physician that the school psychologist recommended a complicated behavioral modification program that the parents were to institute for G.S. The mother instituted the program, but after two weeks, she was exhausted. In her opinion, the behavioral modification provided no benefit after one month. She asks the physician whether behavioral modification benefits the symptoms of ADHD.

The Multimodal Treatment Study of Children with ADHD (MTA) Cooperative Group was designed to compare long-term medication and behavioral treatments with respect to efficacy. A group of 579 children between 7 and 10 years of age with ADHD combined type were recruited and randomized to four different treatment groups.²⁴ The children were included even if they had comorbid diagnoses, including conduct disorder, oppositional defiant disorder, or a learning disability. The treatment groups included drug treatment regimen, behavioral treatment, drug treatment regimen plus behavioral treatment, or typical community treatment. Behavioral interventions were delivered in a group-based recreational setting and included an 8-week, 5-days-per-week, 9-hours-per-day, intensive program administered by a counselor/aid. Once school started, the subjects in this arm of the study received 60 school days of a part-time, behaviorally trained, paraprofessional aid who worked directly with the child. In addition, the child's teacher received 10 to 16 sessions of biweekly consultation that focused on classroom behavior management strategies. Daily behavior report cards were sent home to parents. At the same time, families were involved in 27 group therapy meetings plus 8 individual family meetings. The goal of this behavioral management treatment was to train the parents to administer appropriate techniques so they could continue the treatment on their own. Of the children receiving medication, 75% received methylphenidate; 10% received dextroamphetamine; and 15% received pemoline, imipramine, clonidine, guanfacine, or bupropion. It was concluded that drug treatment was more effective than behavioral treatment according to parents' and teachers' ratings of inattention, and teachers' ratings of hyperactivity-impulsivity. Combined treatment (drug treatment plus behavioral modification) was equally effective as medication management only and more effective than behavioral treatment and community care according to parent- and teacher-reported ADHD symptoms. A regimented drug treatment protocol for ADHD appears to be both beneficial and cost effective. However, the study did confirm that if comorbid disorders such as conduct, oppositional defiant, anxiety, or affective were present, then behavior management with or without drug treatment was beneficial for these comorbid conditions. The behavioral management techniques used in this study were costly and highly labor-intensive.

7. G.S. returns to clinic 3 months later for a follow-up appointment. He is doing quite well receiving a combination of methylphenidate and clonidine but no behavioral therapy. His mother has been using the Iowa Connors Rating Scale for ADHD which she was taught to use as a way to monitor her son's behavior. Her observational scores show him to have an approximate average score of 8 for the past week. This score is significantly decreased from a score of 24 at his initial workup. The teacher's scores on the rating scale are similar to the mothers' scores. The mother asks the physician if they could talk privately for a few minutes. She relates to the physician that out of curiosity, she has been sporadically scoring the test for her husband, G.S.'s biological father, for several weeks. Although the conduct factor was normal, she reports that he scores about a 12 on the attention factor. She inquires whether her husband would be a candidate for psychostimulant therapy for ADHD. He was treated for 2 years as a child for hyperactivity, but then his parents stopped the treatment when his hyperactive behavior improved. What is the

natural course of ADHD through adulthood? Are the effective treatments for adolescents and children diagnosed with ADHD effective in adults as well?

The experience of G.S.'s father is similar to that of many adults who were diagnosed with ADHD as children. Thus, in a series of 128 boys, hyperactivity and impulsivity symptoms were seen to decline at a higher rate than inattention symptoms.⁵⁹ Among 18 to 20 years olds with ADHD who were followed up over 4 years, 40% continued to meet the *Diagnostic and Statistical Manual of Mental Disorders*, Third Edition, Revised (DSM-III-R) criteria for ADHD. Importantly more than 90% of the 18 to 20 year olds continued to experience functional problems with inattention.⁵⁹ Other researchers have followed children with ADHD to adulthood by comparing the academic records of controls and ADHD adults. The latter had significantly higher rates of repeated grades, tutoring, placement in special classes, and reading disability.^{60,61} Adults with ADHD have been found to achieve lower socioeconomic status and experience more work difficulties and more frequent job changes.⁶² In a study comparing 172 ADHD adults to 30 non-ADHD adults, the adults with ADHD reported more psychological maladjustment, more speeding violations, and more frequent changes in employment.⁶³ More adults with ADHD had their driver's licenses suspended, had performed poorer at work, and had quit or been fired from their job. Adults with ADHD also were more likely to have had multiple marriages.

Numerous studies have documented the effectiveness of methylphenidate,⁶⁴ desmethylphenidate,⁶⁵ mixed amphetamines,⁶⁶ desipramine,⁶⁷ bupropion,³⁸ atomoxetine,^{68,69} and modafinil⁵⁰ in the treatment of adults with ADHD. All of the trials were similar in that the experimental drug was compared with placebo with the exception of modafinil, where an amphetamine comparator was used along with placebo. A notable finding is that the effect sizes for improvement relative to placebo were lower with atomoxetine (0.35 and 0.40 in two studies) than with methylphenidate and amphetamine (effect sizes of 0.8 to 1.0). This indirect evidence suggests that atomoxetine may be less effective than the stimulants for ADHD treatment. Doses for immediate-release methylphenidate are more conservative (0.3 mg/kg per dose in adults) when inattention is the predominate feature. In contrast, doses of up to 0.6 mg/kg immediate-release methylphenidate are often necessary to optimally control the behavioral feature of the disorder.⁷⁰ These methylphenidate doses are consistent with 0.5 to 1.0 mg/kg/day doses found to be effective in adults.⁶⁴ Mixed amphetamine salts are effective in doses of 20 to 60 mg/day.⁶⁶ The effective dose of desipramine is approximately 150 mg/day. Bupropion is generally dosed at 3 mg/kg/day.⁴¹ The two large studies of atomoxetine used doses that ranged from 60 to 120 mg/day.⁶⁹ The mean effective dose for modafinil was 207 mg/day.⁵⁰

8. An editorial by a community newspaper criticized the local school district for the widespread prescribing of psychostimulants by school psychologists. The editorial provided the stimulus for a review by the school board of the clinical practices of the psychologist staff. A regional expert on ADHD pharmacotherapy was contacted by the board and asked to present a rational set of medication prescribing guidelines for the treatment of children and adolescents diagnosed with ADHD. The expert decided that the

most straightforward approach to this issue would be to present the Texas Medication Algorithm Project (TMAP) guidelines for the treatment of ADHD in children and adolescents. Describe the TMAP algorithm for the treatment of children and adolescents diagnosed with ADHD.

The goal of the TMAP algorithm is to provide systematic guidance and structure regarding the potential array of therapeutic options for the ADHD population. There are five algorithms for ADHD treatment; one each for the following diagnoses: (a) ADHD, (b) ADHD with major depressive disorder, (c) ADHD with any anxiety disorder, (d) ADHD with a tic disorder such as Tourette Syndrome, and (e) ADHD with aggression.⁷¹ The algorithms and the details of their use can be found on the Texas Department of State Health Services website (<http://www.dshs.state.tx.us/mhprograms/CMAP.shtm>).⁷³ For patients with ADHD only, it is recommended to initiate treatment with either methylphenidate or an amphetamine. Patients who fail the first psychostimulant can then be treated with the alternate psychostimulant. For patients that fail the stimulants, a trial of atomoxetine is warranted. If atomoxetine fails, a TCA or bupropion can be tried. If these drugs both fail, the alpha-adrenergic agonists, clonidine and guanfacine, should

be considered. Patients diagnosed with comorbid ADHD and major depressive disorder can be treated according to both the TMAP ADHD and Major Depressive Disorder algorithms. In patients with comorbid ADHD and an anxiety disorder, initial treatment with atomoxetine or a psychostimulant is recommended. If these treatments fail, the combination of atomoxetine with a psychostimulant, or a psychostimulant with a selective serotonin reuptake inhibitor should be considered. Patients with ADHD and a tic disorder can be treated similarly to those with ADHD only. However, if the tics worsen, an alpha-adrenergic agonist, atypical antipsychotic haloperidol, or pimozide can be tried individually until the patient responds. For patients with significant comorbid aggression, the standard ADHD algorithm should be used; behavioral interventions are added if the patient's behavior does not improve. If behavioral modification fails, an atypical antipsychotic, lithium, or valproate should be considered. Clinicians should not follow the algorithm blindly. It should be emphasized that algorithms integrate available research and clinical consensus into user-friendly, hierarchical decision trees of medication options. The algorithms are not intended to serve as a substitute for clinician judgment.

Control of eating and maintenance of normal body weight are common problems in our society. Despite the public and medical pressure to “stay fit,” the incidence of obesity has doubled over the past two decades, particularly among children and adolescents.¹ A review of eating disorders and obesity, as well as recommendations for self-help books and websites related to eating disorders, can be found in the *Clinical Manual of Eating Disorders*² and the second edition of *Eating Disorders and Obesity: A Comprehensive Handbook*.¹ The third edition of the American Psychiatric Association *Practice Guidelines for the Treatment of Patients with Eating Disorders* provides the most recent diagnostic and treatment guidelines for anorexia nervosa, bulimia nervosa, and binge-eating disorder.³ Although effective therapies for eating disorders exist, many people do not seek treatment and many cases are not recognized in clinical settings.

DEFINITIONS: EATING AND RELATED DISORDERS**Eating Disorders**

Eating disorders should be considered a syndrome characterized by a cluster of symptoms that define the condition.¹⁻⁴ Anorexia nervosa, bulimia nervosa, binge-eating, and obesity

are examples of eating or metabolic disorders that evolve as a result of weight loss behaviors and/or by a complex interaction of social, developmental, and biological factors. Diagnosis of eating disorders is based on weight, engagement in weight loss behaviors (e.g., restricting or avoiding food, vomiting, laxative and diuretic abuse, use of appetite suppressants, overexercising), binge-eating behaviors, abnormal attitudes and preoccupation with weight, shape, and food, and medical consequences.⁴ Preoccupations with body weight and shape, food avoidance, and overeating are relatively “modern” clinical disorders. In Western societies, men have less pressure to be slim and to diet compared with young females (e.g., less media influences on dieting and exposure to abnormally thin body images). It is estimated that up to two-thirds of teenage girls and one in six adult women in the United States diet each year.^{1,2,5} Compared with men, women are twice as likely to report current dieting or a history of dieting. Adolescent girls often start dieting around 12 to 13 years and the rates increase between the ages of 12 and 16.¹ Dieting in males is more likely to be associated with participation in sports, gender identity conflicts, past obesity, and fear of medical complications than from any sociocultural pressures for dieting. Many “fad” diets provide inadequate nutrition, are medically dangerous, and result in

Table 82-1 Body Mass Index and Guidelines for Weight Classes

Metric Conversion Formula Using Kilograms and Meters

$$\text{BMI} = \frac{\text{Weight in kilograms}}{\text{Height in meters}^2}$$

Nonmetric Conversion Formula Using Pounds and Inches

$$\text{BMI} = \frac{\text{Weight in pounds}}{\text{Height in inches}^2} \times 703$$

| Weight Status | BMI | Obesity Class |
|------------------|-----------|---------------|
| Anorexia nervosa | ≤17.5 | |
| Underweight | <18.5 | |
| Normal | 18.5–24.9 | |

rebound weight gain after dieting owing to starvation-induced reduction in metabolic rate. Starvation or the lack of regular intake of food produces both physiologic and psychological symptoms (i.e., anxiety, irritability, and distractibility), a preoccupation with food, a drive to eat, and binge-eating behaviors.¹

People without eating disorders seem to integrate cultural, behavioral, and chemical changes (release of chemicals from the stomach, intestine, and brain) to produce an appropriate perception of hunger or satiation and are more likely to maintain an ideal weight. Ideal body weight can be measured by a number of calculations, but the body mass index (BMI) is most commonly used for assessing weight based on age and gender norms.^{6,7} For calculations of BMI and guidelines for weight classes, see Table 82-1. Behaviors associated with each eating disorder are unique, but may overlap and occur throughout the individual's lifetime (Table 82-2 compares eating disorders).

Anorexia Nervosa

The term *anorexia* (the medical term for loss of appetite) was first used in 1873 by an English physician, Sir William Gull, who described a young woman with restrictive dieting and amenorrhea. When the focus on weight and thinness becomes pathological and detrimental to the person's health (e.g., deficiency in essential amino acids, vitamins, minerals, and electrolytes; bone loss; depression; and cardiac changes) it is called *anorexia nervosa*. Criteria from the *Diagnostic and Statistical Manual of Mental Disorders*, Fourth Edition-Text Revision (DSM-IV-TR) are listed in Table 82-3.⁴ Anorexia nervosa is defined by a BMI ≤17.5 kg/m². Because linear growth may be impaired in people with anorexia nervosa owing to poor nutrition, adjustments to height and weight calculations must be made based on expected values for the age range.¹ Weight loss, a refusal to maintain a minimal normal weight for age and height, and amenorrhea are characteristic features of the disorder. Classic symptoms and attitudes include persistent and irrational fear of becoming overweight, a distorted perception of body image, and denial of the seriousness of the illness.⁸

Anorexia nervosa is divided into two subtypes: restricting and binge-eating/purging.⁴ Weight loss is accomplished primarily by the reduction in total food intake (restriction), although most eventually try purging (misuse of laxatives and diuretics or self-induced vomiting) and use of excessive exercise to lose weight. Approximately 50% of women with anorexia nervosa develop bulimic symptoms; some women who initially have bulimic symptoms later develop anorexic symptoms.³ Patients with anorexia can alternate between restricting and bulimic subtypes throughout their illness. Individuals with the binge-eating/purging type are likely to exhibit more impulse control behaviors such as suicidal and self-harm behaviors, drug and alcohol abuse, mood lability, and increased sexual activity.^{3,8}

Bulimia Nervosa

Bulimia, or binge eating (consuming a large amount of food over a short period of time), was first described in 1979 by

Table 82-2 Comparison of Eating Disorders

| | Anorexia Nervosa | Bulimia Nervosa | Binge-Eating Disorder |
|---|--|--|--|
| Lifetime prevalence | 0.5%–1% females | 1%–4% females | Unknown |
| Prevalence rates | | | 0.7%–4% (community) 20%–30% (weight control programs) |
| Female:male | 10:1 | 10:1 | 1.5:1 |
| Onset | Mid to late adolescence (14–18 years) | Late adolescence or early adulthood | Late adolescence or early 20s |
| Cross-over from AN to BN or vice versa | 15% | ~1% | NA |
| Subthreshold eating disorder | 15% | 20% | Unknown |
| Persistent disorder | 10% | 10% | Unknown |
| No clinical eating disorder after long-term follow-up (10 yr after referral) | 50% | 70% | Unknown |
| Death | <10% | ~1% | Unknown |

Table 82-3 DSM-IV-TR Diagnostic Criteria for Anorexia Nervosa⁴

- A. Refusal to maintain body weight at or above a minimally normal weight for age and height (e.g., weight loss leading to maintenance of body weight <85% of that expected; or failure to make expected weight gain during period of growth, leading to body weight <85% of that expected).
- B. Intense fear of gaining weight or becoming fat, even though underweight.
- C. Disturbances in the way that one's body weight or shape is experienced, undue influence of body weight or shape on self-evaluation, or denial of the seriousness of the current low body weight.
- D. In postmenarchal females, amenorrhea (the absence of at least three consecutive menstrual cycles). (A woman is considered to have amenorrhea if her periods occur only following hormone [e.g., estrogen] administration.)

Specify types:

Restricting type: During the current episode of anorexia nervosa, the person has not regularly engaged in binge eating or purging behavior (i.e., self-induced vomiting or the misuse of laxatives, diuretics, or enemas).

Binge eating/purging type: During the current episode of anorexia nervosa, the person has regularly engaged in binge eating or purging behavior (i.e., self-induced vomiting or the misuse of laxatives, diuretics, or enemas).

Table 82-4 DSM-IV-TR Diagnostic Criteria for Bulimia Nervosa⁴

- A. Recurrent episodes of binge eating. An episode of binge eating is characterized by both of the following:
 1. Eating, in a discrete period of time (e.g., within any 2-hour period), an amount of food that is definitely larger than most people would eat during a similar period of time and under similar circumstances
 2. A sense of lack of control over eating during the episode (e.g., a feeling that one cannot stop eating or control what or how much one is eating)
- B. Recurrent inappropriate compensatory behavior to prevent weight gain, such as self-induced vomiting; misuse of laxatives, diuretics, enemas, or other medications; fasting; or excessive exercise
- C. The binge-eating and inappropriate compensatory behaviors both occur, on average, at least twice a week for 3 months
- D. Self-evaluation is unduly influenced by body shape and weight
- E. The disturbance does not occur exclusively during episodes of anorexia nervosa

Specify types:

Purging type: During the current episode of bulimia nervosa, the person has regularly engaged in self-induced vomiting or the misuse of laxatives, diuretics, or enemas

Nonpurging type: During the current episode of bulimia nervosa, the person has used other inappropriate compensatory behaviors, such as fasting or excessive exercise, but has not regularly engaged in self-induced vomiting or the misuse of laxatives, diuretics, or enemas

Gerald Russell, a London psychiatrist, who observed that several of his anorectic patients went on eating binges. Bulimia was first recognized as a separate disorder from anorexia nervosa in 1980 in the DSM-III. Originally, the criteria emphasized binge-eating behaviors without the associated features of self-induced vomiting, laxative abuse, and preoccupation with shape and weight. Individuals with bulimia have a powerful urge to overeat in combination with a fear of becoming fat; thus, they induce vomiting or abuse purgatives or both to get rid of ingested foods. One essential distinction from anorexia is that patients with bulimia nervosa usually maintain a normal weight, although a few patients are overweight or obese.²

The diagnostic criteria for bulimia nervosa have evolved over time to the most current DSM-IV-TR criteria (Table 82-4).⁴ The characteristics of bulimia nervosa include binge-eating along with inappropriate compensatory behaviors and methods to prevent weight gain that occur, on average, at least twice weekly for 3 months. Patients must satisfy all five criteria (Table 82-4) to be diagnosed with bulimia nervosa and may be further classified as either the purging or nonpurging type. Individuals with bulimia nervosa may use several methods to compensate for binge-eating. Vomiting after binge-eating (or purging) is the most common technique and is used by 80% to 90% of individuals with bulimia nervosa.³ In comparison with nonpurging bulimics, those with purging behaviors have more anxiety about eating, a greater disturbance in body image, more self-injurious behaviors, and a higher incidence of comorbid anxiety, depression, and alcohol abuse.¹ Nonpurging forms of bulimia nervosa may include excessive

exercise or fasting, taking appetite suppressants or stimulants, and use of insulin for weight control in patients with diabetes mellitus.¹

Eating Disorder Not Otherwise Specified

A subset of individuals may have characteristics of anorexia nervosa and bulimia nervosa, but do not meet the complete diagnostic criteria of the disorder.² In the DSM-IV-TR, these individuals are classified as having an "Eating Disorder Not Otherwise Specified" (ED-NOS), which also has been called an *atypical eating disorder*.⁴ Subsyndromal or subclinical eating disorders have been found in 7% to 10% of young women. Up to 50% of individuals presenting to eating disorder programs are given the diagnosis of ED-NOS because they fail to meet one DSM-IV-TR criteria (e.g., <2 eating binges per week for 3 months, <3 months of amenorrhea).³ Individuals who abuse weight reduction medications, take anabolic steroids, or use excessive exercise to lose weight and those with binge-eating behaviors are diagnosed with ED-NOS. Extreme vegetarians or vegans may be a type of eating disorder due to their obsessive aversion to ingesting meat or animal byproducts and strict avoidance of animal-derived foods. Cases of food refusal and undernutrition secondary to hypochondriasis may be an atypical eating disorder.¹ Individuals with a subsyndromal eating disorder are at risk for developing anorexia nervosa and bulimia nervosa and need professional help to reduce abnormal eating habits, food restriction, body image distortion, and compulsive exercising.³

Binge-Eating Disorder

Binge-eating disorder is a proposed diagnostic entity in the DSM-IV-TR and is characterized by recurrent binge-eating episodes unaccompanied by behaviors to prevent the weight gain, such as self-induced vomiting or laxative abuse.²⁻⁴ The diagnostic criteria requires binge-eating episodes that are associated with three (or more) of the following: eating very rapidly; eating until feeling uncomfortable; eating large amounts of food when not physically hungry; eating alone because of embarrassment about how much is eaten; and feeling disgusted, guilty, or depressed about overeating.^{2,4} Binge-eating episodes must occur at least 2 days a week for 6 months and cause significant distress about binge-eating. In some individuals, binge-eating may be triggered by dysphoric moods such as anxiety and depression, whereas others may feel “numb” or “spaced out” during the eating episode.^{2,4} Binge-eating patients are more likely to overeat in response to negative emotional states, and obese binge-eaters often eat in response to emotional stress.² A night eating syndrome characterized by insomnia with evening hyperphagia has been recognized as a type of binge-eating disorder.¹ Nighttime eaters suffer from frequent awakenings and their snack intake is usually high carbohydrate-to-protein foods. During the night, they can consume more than 50% of their normal daily caloric intake.

Approximately 15% to 50% (average, 30%) of people in weight control programs fit the criteria for a binge-eating disorder; approximately one-third of these individuals are male.^{3,4} Binge-eating disorder may be a type of nonpurging bulimia nervosa or an overeating disorder, because this pattern of eating is found in both bulimia nervosa and obesity.⁹ Chronic, recurrent binge-eating and dieting are associated with obesity, which leads to significant morbidity and mortality.⁸ Comorbid psychiatric disorders associated with binge-eating disorder include anxiety, depression, obsessive-compulsive disorder, impulsive behaviors, substance-related disorders, and personality disorders.^{4,8}

Obesity

Obesity is not recognized as a psychiatric or eating disorder in the DSM-IV-TR, although individuals often have comorbid anxiety and depression, a history of “yo-yo” dieting (weight loss attempts followed by weight gain), binge-eating behaviors, and obsessions about food and body weight.⁹ Obesity is a chronic metabolic disorder that is determined by multiple biological and environmental factors, a sedentary lifestyle, and a genetic predisposition. The current worldwide epidemic of obesity may be secondary to overconsumption of high-fat, energy-rich foods; unhealthy snacking between meals; more food choices at restaurants, snack bars, and grocery stores; readily available inexpensive food 24 hours a day; larger sized portions of food and drinks; increased advertising of high-fat/high-carbohydrate foods and drinks; and the lack of physical activity and sleep. The addition of 20 to 30 kcal/day over a number of years can lead to significant weight gain; thus, energy intake and energy output through physical activity must be balanced for weight control.¹ The increase in the prevalence of obesity and negative health outcomes (diabetes, hyperlipidemia, cardiovascular disease) are major public health problems in industrialized countries. Despite the improvements in treatment for cardiovascular disorders over the last decade, a study has shown that obesity has significant impact on activi-

ties of daily living and functional impairment as people age.¹⁰ In addition, obesity has been shown to be associated with a 25% increased risk of mood and anxiety disorder, although a causal relationship has not been established.¹¹

Obesity is defined as a BMI ≥ 30 kg/m² and obese patients have an estimated 50% to 100% increased mortality rate compared with patients with BMI in the range of 20 to 25 kg/m² (Table 82-1).^{7,12-15} People with a BMI range of 25 to 29.9 kg/m² are considered overweight and those >28 have an increased risk of developing chronic illnesses (e.g., musculoskeletal disorders, cardiovascular disease, diabetes).

EPIDEMIOLOGY

The prevalence of anorexia nervosa, bulimia nervosa, binge-eating, and obesity have increased over the past 50 years.^{1,5} An estimated 5 million Americans have an eating disorder (anorexia nervosa, bulimia nervosa, binge-eating disorder, and variations of disturbances in eating). Eating disorders are more common in women (90%–95% of cases are women, and lifetime male:female prevalence ratios range from 1:6–1:10).³ Overall lifetime prevalence rates of eating disorders (including any binge eating) ranged from 0.6% to 4.5% in adults surveyed in 2003.⁸ Homosexual orientation and premorbid obesity are risk factors for eating disorders among males.^{1,3}

Anorexia Nervosa

The prevalence of anorexia nervosa has increased in industrialized societies where there is an abundance of food and where being thin is linked with attractiveness and success.^{1,3} Patients with anorexia nervosa are predominantly female (90%–95% of cases), typically middle to upper-middle class, and white. Prevalence rates among late adolescent and early adulthood females is 0.5% for narrowly defined and up to 4.1% for more broadly defined anorexia nervosa.^{3,4} The incidence and prevalence of childhood-onset anorexia nervosa is not known. It is estimated that 19% to 30% of preadolescent patients with anorexia nervosa are male.¹⁻³ Common comorbid conditions associated with anorexia nervosa in both men and women include poor self-esteem, mood disorders (major depression, dysthymia, and bipolar), anxiety disorders (especially obsessive-compulsive disorders and social phobia), substance abuse, and personality disorders (cluster C spectrum, particularly avoidant personality disorder and obsessive-compulsive personality disorder).¹⁻³ Women who have recovered from anorexia nervosa are likely to have perfectionism, inflexible thinking, overly compliant behavior, social introversion, as well as a continued drive for thinness and rigid eating habits.^{1,2}

Bulimia Nervosa

The true prevalence of bulimia nervosa is not known because most patients seem to be within the standards of a healthy weight and are secretive about their eating habits. Furthermore, estimates of lifetime prevalence among women vary widely (1%–4%) because most studies have examined selected populations such as high school or college students.³ Male cases of bulimia nervosa are uncommon, whereas the ratio of binge-eating disorder is more equivalent between genders.¹ Bulimia nervosa is four to six times more common than

anorexia nervosa. Comorbid disorders associated with bulimia nervosa and binge-eating include obesity, substance (alcohol, cocaine, nicotine) use disorders, personality disorders (cluster B and C spectrum, particularly borderline personality disorder and avoidant personality disorder, impulsive, and narcissistic personality), anxiety disorders (obsessive-compulsive disorder, panic disorder, and social phobia), mood disorders (major depression, dysthymia, and bipolar disorder), and impulse control disorders (compulsive buying, kleptomania, and self-mutilation).^{2,3,8} Individuals who have recovered from bulimia nervosa often continue to have obsessional symptoms, abnormal eating behaviors, overconcern with body image, dysphoric mood, and low self-esteem.^{1,16}

Binge-Eating Disorder

The onset of binge-eating usually first occurs in late adolescence or in the early 20s and after significant weight loss from dieting.⁴ Binge-eating is more common in women than men (~1.5 times) and its estimated prevalence rate in the United States is between 2% and 5% of adult women.^{4,16} The prevalence of binge-eating disorder is between 0.7% and 4.0% in community samples; 20% to 30% in individuals participating in weight loss programs; and up to 50% in patients seeking bariatric surgery.^{2,4} Approximately 1.5% of the general population has night eating syndrome, which is characterized by morning anorexia, evening hyperphagia, insomnia, and occurs more often in obese individuals during periods of high stress.¹⁷ The prevalence of night eating disorder ranges from 9% to 14% of patients being treated at obesity clinics and between 8% and 42% among bariatric surgery patients.¹⁷

Obesity

Obesity is a major public health concern worldwide and is the leading cause of numerous medical conditions (e.g., cardiovascular disease, hypertension, dyslipidemia, diabetes, sleep apnea) and premature death.^{7,14,18} Approximately 97 million adults in the United States are overweight or obese.¹⁴ Adult obesity usually results from a steady weight gain from the mid-20s to between ages 50 and 59, when the prevalence of obesity peaks.¹⁹ The increased prevalence of obesity with increasing age may be secondary to continued consumption of calories that are not expended because of reduction in daily exercise, reduction in the amount of energy the body needs for daily functions, and smoking cessation.¹⁹ In 2003 and 2004, 66% of adults were considered overweight or obese and 32% of patients had BMI ≥ 30 kg/m².¹⁹ Obesity is more common in women (with higher rates in low socioeconomic status groups) and in those with diabetes mellitus.³ In the recent National Health and Nutrition Examination Survey (NHANES) report, obesity and overweight were more prevalent among non-Hispanic black women consistent with previous years.¹⁹ The rate of extreme obesity (BMI ≥ 40) was also highest among black women (14.7% versus 6.9% among all U.S. adults).¹⁹ The economic impact of obesity in the United States in 1994 was estimated to be \$68 billion for medical expenses and loss of income and more than \$30 billion for diet programs and products.^{20,21} Future research is needed to assess the impact of obesity and weight loss on direct/indirect costs of medical care and lost productivity outcomes.²²

In recent years, the incidence of obesity (BMI ≥ 30 kg/m²) and severe obesity (BMI >40 kg/m²) has been rising in industrialized countries, particularly among children and adolescents.²³ According to the latest report from the NHANES taken from data collected during 2003 and 2004, 17% of children in the United States were overweight and the prevalence of overweight increased 2.2% and 4.2% in females and males, respectively.¹⁹ From 1999 to 2000 to 2003 to 2004, non-Hispanic black female children/adolescents had the highest prevalence (2.8%) of overweight. Childhood obesity is unfortunate because typical weight reduction methods may not be successful and there is a greater negative psychological impact on the child secondary to comments by his or her peers. It is known that children who are overweight often remain overweight as adults.²⁴ Although the cause for the increased prevalence of overweight among children is unclear, poor diet, lack of physical activity, and sleep deprivation have been shown to be potential contributors.²⁵⁻²⁷ As in adults, type 2 diabetes mellitus is a significant concern in overweight children.²⁸ The weighted prevalence of type 2 diabetes mellitus in adolescents was recently estimated to be 29% of all adolescents who had diabetes; in addition, 11% of all U.S. adolescents were estimated to have impaired fasting glucose.²⁸ Furthermore, the prevalence of metabolic syndrome in adolescents was estimated to be 4.5% from the NHANES 1999 to 2004 study.²⁹ Treatment of childhood obesity should always be initiated as early as possible; most programs recommend a reduction in weight gain rather than weight loss.

ETIOLOGY AND PATHOPHYSIOLOGY

Eating behavior reflects an interaction between the individual's genetic makeup, physiologic state (e.g., balance of neurotransmitters and neuropeptides, metabolic state and rate, sensory receptors for smell and taste, condition of the gastrointestinal [GI] tract), and environmental factors (e.g., sight of the food, accessibility of food, ambient temperature, stress, social gatherings).^{1,30,31} Cultural and religious beliefs and traditions about food also affect eating behaviors. Medical conditions, psychiatric disorders, medications, and substances (e.g., nicotine, central nervous system [CNS] stimulants) may influence appetite and eating behaviors as well (see Table 82-5 for a list of medications and medical conditions that may cause weight gain and loss). Normally when a person has eaten an adequate amount of food, neurotransmitters or peptides in the brain signal the satiety centers in the hypothalamus and there is a reduced desire to eat. Because more bulimia patients starve themselves or use strict dieting between binges, their bodies may sense a "food-deprived state" and this changes brain chemistry to stimulate appetite.³¹ When the "starving" person begins to eat, the brain neurotransmitters (e.g., serotonin) that normally turn off appetite may fail to work; thus, the person eats excessive amounts of food. Studies in patients with eating disorders have shown that the perceptions of hunger and satiety are abnormal in patients who binge and purge.³¹

The exact etiology and pathogenesis of anorexia nervosa are unknown, but are likely a combination of familial, psychological, sociocultural, and biological factors.^{1,30} Fluctuations in serotonin, dopamine, norepinephrine, leptin, neuropeptide Y (NPY), and cortisol levels modulate appetite, satiety, and eating behavior.^{1,32} The neuropeptide, neurotransmitter, and

hormonal disturbances found in anorexia nervosa are secondary to malnutrition and weight loss and seem to normalize after weight normalization and long-term recovery.^{30,32}

There are many possible causes for obesity, such as genetic predisposition, disturbances of hunger and satiety centers in the brain, endocrine abnormalities, environmental and cultural influences, socioeconomic status, medical conditions such as hypothyroidism, medications that stimulate appetite, and inactivity.^{14,31} Obese individuals tend to have more restrained eating (dieting with chronic caloric restriction) and lower levels of activity compared with persons with normal weight. This behavior can lead to lowered basal metabolic rates, less energy expenditure, and increased weight gain secondary to periodic overeating and binge-eating.⁹ Recently, there have been several association studies linking short sleep duration and metabolic changes such as obesity, insulin resistance, and diabetes.³³ One study showed that children aged 30 months and younger who lacked sleep were at risk of developing obesity at 7 years.³⁴ Alteration of the hypothalamic regulation of appetite and energy expenditure owing to sleep loss has been one explanation. Sleep loss has also been shown to be associated with low leptin levels and high ghrelin levels; both factors contribute to signaling of energy deficit and hunger, which may contribute to overeating and obesity.³⁵

Individuals with mental illness are especially prone to developing obesity. Psychotropic medications including chlorpromazine, clozapine, and olanzapine cause significant weight gain.² Associated physiological changes may increase the risk

of type 2 diabetes mellitus. Of patients with severe chronic mental illness, 40% to 62% are overweight before initiation of medication.³⁶ Contributing factors may include reduced access to medical care, lifestyle habits (decreased physical activity, poor diet), and economic issues that restrict participation in healthy living regimens.

Psychological, psychodynamic, and cognitive theories have attempted to explain the emotional, perceptual, and phobic fears of eating disorders, but there are few studies evaluating these hypotheses.^{1,3} Examples of psychological and familial factors associated with anorexia nervosa include the fear and avoidance of sexuality and growth, failure of parents to encourage independence and self-expression, rigidity and overinvolvement of parents, and premorbid perfectionism and high-achieving characteristics.³ Childhood sexual abuse or early sexual trauma may be a contributing factor in the etiology of eating disorders.¹

Genetics

There is a genetic risk for anorexia nervosa, with higher rates among first-degree biological relatives and higher concordance rates for monozygotic twins (~55%) compared with dizygotic twins (~5%).^{1-3,37,38} A large epidemiologic twin study found a strong genetic association between anorexia nervosa and bulimia nervosa; thus, these eating disorders share a familial risk.^{30,39} Comorbid mood disorders and an increased risk of mood disorders have been found among first-degree

biological relatives of individuals with the binge-eating/purging type of eating disorder.³⁰ Eating disorders and excessive exercising have been linked to obsessive-compulsive personality disorder and to obsessive-compulsive disorder.^{30,40} There is an increased frequency of bulimia nervosa, mood disorders, obsessive-compulsive disorders, and substance abuse and dependence among first-degree biological relatives of patients with bulimia nervosa.³⁹ Genetic studies show that 80% of children with two obese parents are obese compared with 40% of children with one obese parent, and 10% of children with two normal-weight parents.³¹ Genetic risks for obesity are associated with a higher “set-point” for appetite and food intake, which causes individuals to eat more before feeling full. Recently, investigators have found a variant in the fat mass and obesity associated gene that may be linked to BMI and obesity.⁴¹

Hypothalamus Dysregulation

Neurobiological theories of eating disorders have focused on dysregulation of the hypothalamic–pituitary–adrenal, hypothalamic–pituitary–gonadal, and hypothalamic–pituitary–thyroid axes as well as dysregulation of neurotransmitters, neuropeptides, endogenous opioids, growth hormone, insulin, and leptin.^{1,30,31,42} Alterations in hypothalamic functioning are associated with appetite changes, mood disorders, and neuroendocrine disturbances.^{1,30} The hypothalamus is the major appetite and eating control center in the brain and is sensitive to a variety of facilitatory and inhibitory neurotransmitters and polypeptide neurohormones from the brain and GI tract.^{1,31} Disruption of the ventromedial hypothalamus produces hyperphagia and obesity, whereas lesions of the lateral hypothalamus cause hypophagia and weight loss. This suggests that there is a ventromedial “satiety” and lateral “feeding” center in the hypothalamus. The hypothalamus receives input from peripheral satiety sites (e.g., gastric and pancreatic peptides released secondary to food passing through the GI tract), from leptin that is produced by fat cells, and from the catecholamine and indoleamine neurotransmitter system in the brain.^{1,30,43}

Neurotransmitter Dysregulation

Serotonin

Serotonin plays an important role in postprandial satiety, anxiety, sleep, mood, obsessive-compulsive, and impulse control disorders.^{1,30} Serotonin is synthesized from the essential amino acid, *L*-tryptophan, which must come from the diet.⁴⁴ Under the influence of darkness, serotonin is metabolized in the pineal gland to melatonin, a major neuromodulator of sleep and reproductive function. Serotonin activity in the region of the medial hypothalamus has an inhibitory effect on appetite and is responsible for satiety or the feeling of fullness after food intake.^{40,44,45} Pharmacologic treatments that increase intrasynaptic serotonin or those that directly activate serotonin receptors cause satiety and reduce food consumption.⁴⁰ Serotonin has an inhibitory effect on dopamine activity and its release is increased with motor activity. Excessive exercising and hyperactivity are found in many patients with eating disorders, particularly anorexia nervosa.⁴⁶ Physical exertion increases

central serotonin synthesis and turnover, which perpetuates reduced food intake and body weight.

Conversely, reduction of serotonergic activity in the CNS is associated with eating disorders, depression, anxiety disorders, and obsessive-compulsive disorder.^{30,40,45} Low cerebrospinal (CSF) fluid levels of 5-hydroxyindoleacetic acid, the major metabolite of serotonin, are associated with aggressive, impulsive, and suicidal behavior and have been found in low-weight patients with anorexia nervosa and in patients with more frequent bingeing.⁴⁰ Diminished serotonin activity (either by tryptophan depletion or serotonin antagonists) can contribute to increased food intake and carbohydrate craving.^{16,45} Dietary restriction of tryptophan has been shown to reduce brain serotonin synthesis, causing a deficiency state. The reduction in serotonin activity may upregulate the appetite or satiety centers in the brain, thereby increasing the amount of food a person wants to eat. Agents that block postsynaptic serotonin activity (e.g., clozapine, olanzapine, risperidone, quetiapine, cyproheptadine, mirtazapine) can stimulate appetite and may cause weight gain.

Dopamine

Disturbances in dopamine activity and feedback regulation at different receptors have been postulated as a cause of anorexia nervosa.⁴⁰ Agents that increase dopamine activity (e.g., apomorphine, a dopamine agonist; levodopa, a metabolic precursor of dopamine; and amphetamine, a releaser of dopamine from presynaptic stores) have been shown to have anorexic effects.⁴⁷ Dopamine agonists increase dopaminergic transmission and motor activity, which causes loss of appetite and hyperactivity; at higher doses, these agents may cause psychosis (hallucinations and delusions) and repetitive/stereotypical behaviors.⁴⁷ The CNS effects of dopaminergic agents occur in the cerebral cortex, in the reticular-activating system, and in the hypothalamic feeding center. The mesolimbic–mesocortical dopaminergic circuits are important for behavior reward and reinforcement, and are involved with “addictive” behaviors.⁴⁷ Dopamine-augmenting agents such as amphetamines are used for the treatment of exogenous obesity and may produce tolerance, dependence, and withdrawal reactions. Conversely, dopamine receptor antagonists such as clozapine, pimozide, and chlorpromazine may cause dysphoria and are often associated with weight gain.

Norepinephrine

The hypothalamus is innervated by noradrenergic pathways; thus, norepinephrine is involved in the regulation of eating behavior, the hypothalamic control of thyrotropin-releasing hormone secretion, corticotropin-releasing hormone (CRH) release, and gonadotropin secretion.⁴⁷ *D*-Amphetamine, which inhibits the reuptake of norepinephrine, decreases hunger sensations and food intake. Abnormalities in leptin and β_3 -adrenergic activity have been associated with obesity and diabetes.^{18,48} The human β_3 -adrenoceptor is involved in a feedback loop with leptin to regulate energy balance, lipolysis in adipocytes, serum insulin levels, and food intake.⁴⁹ People with hereditary obesity or non–insulin-dependent diabetes mellitus may have abnormalities in the β_3 -adrenoceptor or in leptin activity, signaling, or receptors.⁴⁸ A genetic variant of the β_3 -adrenoceptor in humans has been associated with morbid obesity and non–insulin-dependent diabetes. It is possible

that some cases of obesity may be secondary to failure of the β_3 -adrenoreceptor on brown adipocytes to respond appropriately to leptin-induced sympathetic activity.⁵⁰ β_3 -Adrenergic receptor agonists are being studied to induce thermogenic activity and promote weight loss when combined with a calorie-restricted diet.⁴⁹

Neuropeptide and Leptin Dysregulation

Leptin

Leptin is thought to act as an afferent satiety signal in the brain to regulate body fat mass.^{1,51,52} Leptin reduces food intake, decreases serum glucose and insulin levels, increases metabolic rate, and reduces body fat mass and weight by reducing NPY activity.^{51,53} Leptin serum levels are highly correlated with BMI and body fat,⁵² and its secretion has a circadian rhythm and an oscillatory pattern similar to other hormones.^{48,54} Leptin is supposed to signal the brain to stop eating, but the signal may not get through properly in some overweight people.⁵¹ It has been postulated that some obese individuals may have partially resistant hypothalamic receptors or that there is a defect in the blood-brain barrier transport system for bringing leptin into the brain.^{51,54,55} CSF leptin levels in some obese humans have been found to be much lower than expected compared with serum leptin levels which suggests that the brain uptake of leptin may be defective.¹ Leptin and leptinlike products currently are being investigated for weight reduction in obese patients and in overweight patients with non-insulin-dependent diabetes mellitus.⁵¹

Malnourished or underweight individuals with anorexia nervosa have reduced plasma and CSF leptin compared with normal weight controls.^{52,56,57} In anorexic patients, CSF leptin levels return to normal before full weight restoration and may contribute to difficulties in patients achieving and maintaining a normal weight.³⁰ In women with bulimia, serum leptin levels are correlated with body weight and are similar to normal controls.³⁰

Neuropeptides

NPY and peptide YY are chemically related, 36-amino-acid peptides and are two of the most potent stimulators of appetite.^{1,45} Both enhance food intake in animals, possibly by causing hunger.⁵⁸ Peptide YY is three times more potent in stimulating food intake than NPY.³⁰ Injection of NPY into the brain causes all of the features of leptin deficiency (e.g., hyperphagia and obesity).⁵⁵ Many of leptin's effects on food intake and energy expenditure are centrally mediated in the hypothalamus by neurotransmitters such as NPY.^{51,53} NPY levels are high in the CSF of anorectic patients but are ineffective in overriding the appetite suppressant neurotransmitters and neuropeptides.^{31,59} Plasma leptin and CSF levels of NPY and peptide YY return to normal concentrations in women who have recovered from anorexia nervosa or bulimia nervosa.⁴⁵ Regardless, a recent study of 497 obese patients showed that NPY Y5 receptor antagonism did not produce increased weight loss when added to 6 months of either orlistat or sibutramine therapy.⁶⁰

Opioid Peptides/Endorphins

Endogenous opiates play a role in food reward. Altered opioid activity may contribute to changes in feeding behavior,

reproductive activity, and cortisol release.³⁰ β -Endorphin, an endogenous opiate peptide, stimulates feeding behavior in animals and humans, and levels are highly correlated with body weight.⁵⁸ Underweight anorexic and some bulimic patients have reduced CSF β -endorphin concentrations that may contribute to changes in feeding behavior.³⁰ Dynorphin, an endogenous opioid receptor ligand, enhances feeding behavior and acts at the paraventricular nucleus in the hypothalamus.³¹ Opioid agonists stimulate feeding, whereas opioid antagonists inhibit feeding; however, there have been few data to support a therapeutic role opioid antagonists in weight loss.⁶¹

Miscellaneous Neurohormones and Peptides

Food intake and gastric emptying are regulated by the peripheral release of GI peptides such as cholecystokinin, glucagon, calcitonin, bombesin, and somatostatin, all of which inhibit feeding.^{1,62} Other hormones, neurotransmitters, and peptides involved in the regulation of hunger and satiety (e.g., histamine, oxytocin, vasopressin, galanin, CRH, melanocyte-stimulating hormone, hypocretin, and orexin) and lipotic action (e.g., growth hormone and dehydroepiandrosterone) are being investigated. Histamine is involved in the regulation of appetite, and histamine₁-blocking agents (e.g., tricyclic antidepressants [TCAs], antipsychotics, antihistamines) cause sedation and increased appetite in animals and humans.⁶³ Growth hormone, a lipolytic hormone that acts at adipose tissue, reduces and redistributes body fat by releasing glycerol and free fatty acids into the circulation.⁶⁴ Growth hormone secretion is significantly lower in obese individuals and lipolysis is, therefore, reduced. As people age, the secretion of growth hormone declines (it is estimated that 50% of people >65 years have growth hormone deficit).⁶⁴ Replacement doses of growth hormone have been suggested to treat obesity and to reverse body changes associated with aging.

Brain Changes

Once malnutrition occurs, the normal mechanisms for regulating eating behavior change and anorexia is perpetuated because of neurochemical dysregulation and, possibly, brain atrophy. Brain imaging studies have found generalized atrophy and/or ventricular dilation in patients with anorexia nervosa that reverse with weight gain.³⁰ Reduced regional cerebral blood flow in the temporal lobe has been reported in childhood-onset anorexia, indicating a possible functional abnormality of the brain.⁶⁵ Electroencephalograms of anorexic patients often show generalized abnormalities secondary to electrolyte, glucose, and fluid changes in the brain.³⁰ Morphologic brain changes (e.g., sulcal widening, enlarged ventricles) have been found on brain positron emission tomography and computed tomography scans in some bulimic patients. Electroencephalographic changes (e.g., paroxysmal spike pattern) have been reported in some patients with bulimia nervosa, but brain wave changes usually are more disturbed with anorexia nervosa.³⁰

INITIAL ASSESSMENT

A comprehensive evaluation of patients with eating disorders is essential in determining the diagnosis and selecting treatment options (Table 82-6).^{2-4,66} A psychiatric assessment is

Table 82-6 Assessment and Management of Eating Disorders

| <i>Assessment</i> | <i>Examples</i> |
|---|--|
| Develop a therapeutic alliance with the patient | Other physicians, dietitians, mental health professionals, school personnel |
| Collaborate with other clinicians and providers | DSM-IV-TR criteria, structured interviews, rating scales, screening tools |
| Assess and monitor eating disorder symptoms and behaviors | Binge-eating, purging behaviors, laxative abuse, excessive exercise, food restrictions |
| Determine diagnosis and target behaviors | Vital signs, weight and height, BMI, cardiovascular status, dental exam, comorbid medical disorders, laboratory tests (Tables 82-7 and 82-8) |
| Assess and monitor medical status | Anxiety, obsessions/compulsions, insomnia, depression, suicidal ideation or plan, substance abuse, impulsive behaviors, personality disorders |
| Assess and monitor for psychiatric disorders | History of eating disorders, family dynamics and support, family attitudes toward eating, exercise, appearance |
| Assess family issues | |
| Management | |
| Provide education about eating disorder, management, and treatment approaches | |
| Provide appropriate treatment setting | Inpatient hospitalization, residential treatment, partial hospitalization, or intensive outpatient care depending on medical or psychiatric conditions |
| Provide psychosocial treatments | Individual, group, family and couples therapy, self-help, online resources, 12-step programs |
| Restore or maintain a healthy weight | Monitor weight, growth, and individual characteristics |
| Nutritional rehabilitation for anorexia nervosa | Resume eating and weight gain for seriously underweight, normalize eating patterns and normal perceptions of hunger and satiety |
| Minimize target behaviors | Food restrictions, binge-eating, purging, and excessive exercising |
| Treat physical and medical complications | |
| Treat associated psychiatric conditions | |
| Prevent relapse | |

BMI, body mass index; DSM-IV-TR, Diagnostic and Statistical Manual of Mental Disorders, Fourth Edition, Text Revision.
Adapted from references 2 and 3.

required to establish the diagnosis, identify any comorbid psychiatric disorders, determine the risk of suicide, and evaluate psychosocial stressors.³ Concurrent mood, anxiety, obsessive-compulsive, personality, and substance abuse disorders often accompany anorexia and bulimia nervosa and need to be identified. Medical complications are numerous with eating disorders (Table 82-7) and require a multi-system assessment and laboratory monitoring (Table 82-8). An interdisciplinary treatment team consisting of physicians, nurses, dietitians, and mental health professionals is recommended for the management of children and adolescents with eating disorders.¹⁻³

A detailed weight history and growth chart are needed to detect the onset of an eating disorder.³ Evaluation of eating behaviors, and purging helps to identify patterns and factors that precede binge-eating. Determining the frequency, type, and length of exercising identifies pathological or excessive physical activity. Assessing body image beliefs and distortions, cultural attitudes about size and shape, and family attitudes toward appearance are important in determining perceptions and attitudes about appropriate weight. Menstrual cycle history and duration of amenorrhea identifies women with increased risk of osteopenia and osteoporosis. Males also develop osteopenia and osteoporosis and may have a lower bone density compared with females with anorexia nervosa.¹ Lowered libido and infertility are common owing to diminished sex hormones, cessation of menstruation, and gonadal atrophy.¹ Diagnosis of comorbid psychiatric disorders (e.g., affective, anxiety, substance abuse, and personality disorders) and medical conditions (e.g., diabetes, thyroid abnormalities, inflammatory bowel disease)

helps to determine which management strategies should be used to correct an underlying condition.^{2,3}

TREATMENT APPROACHES

A multifaceted treatment approach that addresses medical, dental, nutritional, psychiatric, and family needs is recommended for anorectic, bulimic, or obese patients.^{1-3,31,67} Guidelines for the medical and psychiatric assessment and management of eating disorders have been published (Tables 82-6 and 82-7).^{3,66} Because patients may be resistant or disinterested in treatment, family members or friends may initiate medical attention.³¹ Interventions include education about the disorder, exercise, nutritional counseling, modification of eating behavior, psychotherapy, and pharmacotherapy. Obtaining the patient's cooperation in the program to establish healthy eating patterns is vital.³ Most patients receive weekly outpatient assessments and therapy to monitor progress toward treatment goals over several months. Hospitalization is recommended for patients with severe anorexia nervosa who require life-saving intensive medical management, including refeeding.³ Caloric intake, weight, urine output, serum electrolytes, heart rate, and blood pressure are monitored daily.^{1,2} Indications for inpatient treatment include a 75% or less expected body weight, intractable purging, rapid weight loss, cardiac disturbances, severe electrolyte imbalances, psychosis, or suicidal ideation.³ Residential eating disorder programs that specialize in the long-term treatment of eating disorders for those individuals who need more intensive therapy are available.³

Table 82-7 Medical Complications of Eating Disorders

| <i>Organ System</i> | <i>Signs and Symptoms</i> | <i>Associated Laboratory Abnormalities</i> |
|-------------------------|---|--|
| Cardiac | Acrocyanosis; arrhythmias; bradycardia; chest pain; cold extremities; dizziness or lightheadedness; faintness; orthostatic hypotension; palpitations; peripheral edema; syncope; tachycardia; weakness | Electrocardiogram changes (e.g., QTc prolongation, ST-segment depression, T-wave inversion); mitral valve prolapse; left ventricular changes (e.g., decreased mass and cavity size); cardiomyopathy (emetine toxicity from ipecac) |
| Central nervous system | Anxiety; apathy; cognitive impairment; decreased attention and concentration; depression; fatigue; headache; irritable mood; lethargy; neuropathies; obsessional thinking; peripheral neuropathy; seizures (large fluid shifts or electrolyte disturbances); weakness | Brain imaging changes (e.g., cortical atrophy, decreased gray and white matter, increased ventricular:brain ratio, ventricular enlargement); electroencephalogram changes (e.g., diffuse abnormalities, metabolic encephalopathy); abnormal cerebral blood flow and metabolism |
| Dental | Dental caries (from acidic vomitus); dental enamel erosion (from acidic vomitus); gingivitis; swollen cheeks/neck; enlarged salivary glands | Increased serum amylase (benign parotid hyperplasia); erosion of dental enamel |
| Dermatologic | <i>Anorexia nervosa</i> : acne, alopecia, brittle nails, dry skin and hair, hair thinning, lanugo (fine body hair), yellow skin (hypercarotenemia) <i>Vomitters</i> : scarring or calluses on dorsum of hand (Russell's sign); petechiae | Increased serum carotene (in anorexia nervosa); vitamin deficiencies |
| Endocrine/metabolic | Cold intolerance; diuresis; fatigue; low body temperature; pitting edema; poor skin turgor; impaired temperature regulation; weakness | Carbohydrate intolerance; dehydration (e.g., increased urine specific gravity, osmolality); electrolyte abnormalities (e.g., hypokalemia, hypomagnesemia, hypophosphatemia); hyperamylasemia; hypercholesterolemia in anorexia nervosa; hypercortisolism; hypoglycemia; hypothermia; hypothyroidism (e.g., low T ₃ , elevated TSH); lipid abnormalities; low basal metabolic rate |
| Fluid/electrolyte/renal | Decreased or increased urinary volume; dehydration; diuresis; peripheral edema (cessation of laxative and diuretic abuse); pitting edema | Decreased glomerular filtration rate; decreased serum creatinine; hypochloremia; hypokalemia; hypomagnesemia; hyponatremia; hypophosphatemia (especially on refeeding); hypozincemia; increased blood urea nitrogen; ketonuria; metabolic acidosis (laxative abuse); metabolic alkalosis (vomiting); renal calculi; renal failure |
| Gastrointestinal | <i>Anorexia nervosa</i> : abdominal pain, abnormal bowel sounds; abnormal taste sensation (zinc deficiency); bloating (abdominal distension with meals); constipation; dehydration; delayed gastric emptying; gastric dilation (rapid feeding); parotitis; vomiting <i>Laxative abuse</i> : constipation; decreased intestinal motility; diarrhea <i>Vomitters</i> : dental caries; esophagitis; gastroesophageal erosions; gastric tears; gastritis; gastroesophageal reflux; heartburn; parotid hyperplasia | Abnormal liver function tests; increased serum amylase (in purging); gallstones; increased pancreatic amylase; pancreatitis Gastric motility: delayed emptying Endoscopy: Barrett esophagus or inflammation; Mallory-Weiss (esophageal) or gastric tears or perforation Stool guaiac: positive for purging or laxative abuse |
| Hematologic | Fatigue; cold intolerance; bruising; clotting abnormalities | Anemia (normocytic, microcytic, or macrocytic); leukopenia; neutropenia; thrombocytopenia |
| Musculoskeletal | Bone pain with exercise; delayed linear growth; fractures (from bone loss); muscle wasting, weakness, and aches; myopathy | Osteopenia or osteoporosis (decreased bone density); short stature (arrested skeletal growth); stress fractures |
| Nutrition | Low body weight; cachexia; dehydration; hypothermia; weakness; vitamin and mineral deficiencies (stomatitis, glossitis, diarrhea) | Hypoalbuminemia; low weight and BMI; low body fat percentage; anemia; hypercholesterolemia; decreased serum calcium, ferritin, B ₁₂ , folate, niacin, thiamine, zinc |
| Reproductive | <i>Anorexia nervosa</i> : amenorrhea; arrested sexual development (atrophy of breasts, delayed puberty, ovarian/uterine regression, regression in secondary sexual characteristics); loss of libido; infertility; oligomenorrhea; pregnancy complications and neonatal complications (low weight gain and low-birth-weight infant) | Decreased serum estradiol (women); follicle-stimulating hormone and luteinizing hormone (prepubertal levels); decreased serum testosterone (men) |

BMI, body mass index; T₃, tri-iodothyronine; TSH, thyroid-stimulating hormone.

Relapse prevention requires long-term outpatient psychotherapy as well as psychopharmacologic agents when appropriate.

Treatment of obesity generally does not involve hospitalization, although the patient's degree of overweight/obesity and its impact on quality of life is an important consideration. Before recommending treatment, assessment of the BMI, waist circumference, presence of obesity-related diseases, risk factors for cardiovascular disease and related conditions, and patient's motivation to lose weight should be assessed.¹⁴ Patients should also be screened for medical conditions and/or medications that can increase the risk for obesity, and these underlying factors should be corrected before recommending treatment.

ANOREXIA NERVOSA

Clinical Features

1. S.B., a 16-year-old girl, is referred to her physician because of a 30-lb weight loss over the past 6 months and amenorrhea for the past 9 months. She had a normal menarche at age 12 years and reached her maximum weight of 140 lb at age 11. S.B. is a star player on her high school tennis team and previously was involved in gymnastics as a child. Her current weight is 98 lb and height is 5 feet 5 inches. S.B. feels that her weight is perfect, because it helps her move better on the tennis court, an opinion she believes is reinforced by her coach. S.B. rarely eats three meals a day and is on an extreme no-fat diet. She runs an average of 8 miles/day and practices tennis 2 to 3 hours/day after school. Despite her parents' concern about her weight, S.B. feels that if she gains weight, she will be fat and unable to play competitive tennis.

Upon further questioning, S.B. admits to a previous weight loss at around age 13 from 140 to 100 lb, which resulted in amenorrhea for 6 months. At that time, she was involved in gymnastics and was told she needed to lose weight to stay on the team. S.B. started exercising to burn off calories and skipping breakfast to lower her caloric intake. At times, she became dehydrated and had episodes of hypotension that resulted in dizzy spells. She also took "diet pills" that a friend gave her, which made her heart beat fast and caused insomnia. At times she had difficulty controlling her diet and would binge on foods that were "bad"; this usually only happened when she was under more stress at school and at home. During this time, S.B. was on the honor roll and involved in competitive gymnastics and tennis at her school. S.B. was referred by her school nurse to the school psychologist because of the noticeable weight loss. The psychologist recommended that she be evaluated by her pediatrician to receive treatment for an eating disorder. What characteristics does S.B. have that are related to anorexia nervosa?

Anorexia nervosa, a condition of self-induced weight loss, is characterized by a BMI ≤ 17.5 , weight loss of at least 15% of ideal body weight, a preoccupation with body weight and food, behaviors directed toward weight loss, intense fear of gaining weight, disturbances of body image, and amenorrhea (Table 82-3).⁴ S.B.'s BMI is 16.3 ($98 \text{ lb} \div [65 \text{ in}]^2 \times 703$), which fits the criteria for anorexia nervosa. The main clinical feature of anorexia nervosa is a morbid fear of becoming fat and losing control over eating.⁴ Anorectic behaviors include restrictive dieting (e.g., drastically reducing the amount of food ingested, minimizing foods high in fat and carbohydrates, and vegetarianism), purging behaviors (e.g., self-induced vomiting and excessive use of laxatives or diuretics), and strenuous exercise. The anorectic person often has a starved appearance that is caused by loss of subcutaneous fat tissue.³⁰ Associated behaviors include looking in mirrors to check for thinness, expressing concern about being fat, and preoccupation with food (e.g., collecting recipes, preparing elaborate meals, hiding or hoarding carbohydrate-rich foods, throwing away food, cutting food into small pieces, eating slowly). Personality traits include low self-esteem, sensitivity to rejection, perfectionism, competitiveness, an extreme sense of responsibility, excessive conformity, guilt, and an intolerance of angry feelings.² Sleep disturbances, depression, anxiety, phobias, social isolation, and sexual disinterest are commonly associated with anorexia nervosa. Anorexia nervosa has been considered a type of obsessive-compulsive disorder with obsessive thoughts about food and weight and compulsive acts or rituals to alleviate the thoughts or fears of being "fat."^{1,30}

Course and Prognosis

2. How does S.B.'s clinical course resemble others with anorexia nervosa and what is her prognosis?

As illustrated by S.B., anorexia nervosa typically begins in adolescent girls between the ages of 13 and 18 years (mean, 17) and rarely occurs after age 40.² However, the incidence of anorexia nervosa has increased in prepubertal children owing to overconcern and obsession about weight and dieting.^{1,68} The onset of anorexia nervosa frequently is associated with a major change in life (e.g., leaving home for college) or after a stressful life event. Anorexia usually begins with significant

food deprivation (e.g., related to dieting, stress, or severe illness) along with strenuous physical exercising.³ Most patients with anorexia nervosa are extremely overactive and obsessive about exercise routines to burn off calories and induce weight loss. Exercise is typically solitary and rigid, and patients feel guilty if they do not exercise. Individuals like S.B., who have occupational or athletic pressures to be thin (e.g., gymnasts, figure skaters, long distance runners, ballet dancers, and models) are at increased risk for developing anorexia nervosa.^{2,3} Among males, wrestlers, body builders, and runners seem to be at greatest risk for developing an eating disorder and for abusing anabolic steroids.³

The course and prognosis for anorexia nervosa is variable and individuals may only have a single episode, recurring cycles of weight loss and weight gain, or a chronic deteriorating course that may result in death.^{1,2} Some individuals may be overweight initially, then develop anorexia nervosa when they start dieting, and later develop bulimia nervosa or obesity. Approximately 30% to 50% of patients with anorexia nervosa develop symptoms of bulimia during the course of their illness.³ Approximately 45% to 50% of people with anorexia nervosa or bulimia nervosa recover completely, approximately 30% achieve a partial recovery, 20% to 25% are plagued with a long-term illness with no substantial change in symptoms, and fewer than 10% of persons with anorexia nervosa die.^{1,3,30,69} Patients with anorexia nervosa may have extreme anxiety, restlessness, and insomnia owing to food deprivation. Many patients who have recovered from anorexia nervosa continue to suffer from social phobias and generalized anxiety, obsessional thinking, compulsive behaviors, perfectionism, dysthymia, and depression.^{3,30}

In severe weight loss cases, hospitalization is required to restore weight and correct electrolyte and fluid abnormalities. Those who require hospitalization have higher rates of mortality (~6%–10%) secondary to suicide or from the physical effects of starvation.⁷⁰ The mortality rate of anorexia nervosa is approximately 0.56%/year, which is 12 times higher than the mortality rate of young women in the general population.^{3,71} Recurrent depressive episodes and suicide have been reported in up to 5% of patients with chronic anorexia nervosa.¹ A follow-up study of women with eating disorders reported a 7.4% mortality rate with 4 out of 10 deaths due to suicide in women with anorexia.⁷² Mortality rates among women with anorexia are higher in those with low weight at intake, low serum albumin levels, longer duration of illness, bingeing and purging, poor social functioning, and comorbid substance abuse and affective disorders.⁷³

Medical Complications

3. The physician treating S.B. is concerned about possible medical complications caused by her anorexia nervosa. What laboratory and other medical tests should be ordered when assessing S.B. for her anorexia nervosa? What are the most common laboratory abnormalities that you would expect to see and why do they occur?

Starvation can affect all major organ systems and result in serious laboratory, cardiac, bone, and brain abnormalities.^{1–3} Self-induced vomiting and the use of laxatives, diuretics, and

enemas also can cause physiologic changes and abnormal laboratory tests (Tables 82-7 and 82-8). Appropriate laboratory tests for evaluation of patients with anorexia nervosa include the following: complete blood count, urinalysis, electrolytes, lipid profile, serum albumin, amylase, renal function, liver function, thyroid function, electrocardiogram (ECG), and a bone density scan.³ Follicle-stimulating hormone, luteinizing hormone, prolactin, and estradiol levels should be assessed in females and testosterone levels should be evaluated in males.

In anorectic patients, the metabolic rate declines due to a loss of body mass that causes a reduction of tri-iodothyronine. Other abnormalities include elevated liver enzymes, increased lipid metabolism resulting in increased free fatty acids, hypoalbuminemia, fasting hypoglycemia, and glucose intolerance. Hypokalemia from emesis or chronic diarrhea after laxative abuse can cause skeletal and smooth muscle weakness, cardiac conduction abnormalities, arrhythmias, and possibly, cardiac arrest.³⁰ Amenorrhea may occur early in the illness before significant weight loss has occurred (i.e., when BMI is between 17 and 19) and can persist after weight gain, leading to infertility and bone loss. The decrease in bone density correlates with the duration of amenorrhea in women with anorexia nervosa.⁷⁴ Bone loss and inadequate bone formation (osteopenia and osteoporosis) may be caused by calcium, vitamin, and micronutrient deficiencies; estrogen and testosterone deficiency; hypercortisolemia; insulinlike growth factor-I deficiency; and excessive exercise.^{74,75} Bone density is correlated with caloric intake, fat mass, leptin levels, and BMI. Studies have reported that young women with anorexia nervosa may have a bone density similar to menopausal women in their 70s and 80s.⁷⁴ Although body density may increase with weight recovery, osteopenia may be a permanent consequence of the disease, resulting in significant morbidity from bone fractures.⁷⁴ In males, weight restoration leads to increased testosterone levels, but 10% to 20% of men may have some type of testicular abnormality secondary to prolonged starvation.¹

Treatment

Medical Management

4. The laboratory tests for S.B. indicate that she has a low tri-iodothyronine level, mild anemia, an elevated blood urea nitrogen (BUN), hypokalemia, and hyponatremia. T-wave inversions and bradycardia are found on the ECG. Low estradiol and luteinizing hormone levels and reduced bone density on the bone scan are reported. S.B. has orthostatic hypotension from dehydration and is severely constipated. Physical examination reveals lanugo (fine body hair), dry skin and hair, and atrophy of the breasts. The physician recommends that S.B. be admitted to an inpatient program that specializes in eating disorders. Based on S.B.'s presentation, does this patient require hospitalization? What is the usual approach for correcting and monitoring these complications from anorexia nervosa?

Patients should be hospitalized for any of the following conditions: rapid weight loss of >15% of body weight, hypotension with a systolic blood pressure <90 mmHg, bradycardia (heart rate, <50 beats/minute), core body temperature <97°F, suicidal ideation, medical complications, and

nonresponsiveness to outpatient treatment (after 3–4 months).³ S.B. should be hospitalized because of her medical complications of anorexia nervosa. Because the majority of medical complications associated with anorexia nervosa improve with nutritional rehabilitation, the first step in most eating disorder programs is to restore weight, rehydrate, and correct serum electrolytes under close medical supervision.^{1–3} Vitamin and mineral deficiencies secondary to restricted dieting require supplementation of vitamins, minerals, and electrolytes (potassium, magnesium) along with nutritional refeeding.

The primary treatment for anorexia nervosa is to improve overall nutritional status, restore weight, restore gonadal function, and establish normal eating patterns (Table 82-6).³ Weight gain reduces the core symptoms of anorexia nervosa and improves dysphoric mood and obsessive-compulsive behaviors.¹⁶ A minimum goal weight is approximately 90% of ideal weight for height using standard tables, but a final “healthy” goal weight is the weight at which normal ovulation and menstruation occur.³ Inpatient weight restoration programs can increase weight at a rate of 2 to 3 lb/week, whereas outpatient programs usually have lower weight goals of 0.5 to 1 lb/week. Guidelines for calorie intake and monitoring during refeeding can be found in the American Psychiatric Association’s Practice Guideline for the Treatment of Patients with Eating Disorders.³ Parenteral or enteral nutrition is used for patients with severe undernutrition who are refractory to other methods of weight gain.³ Rapid refeeding and weight gain are not recommended because they increase the risk of a “refeeding syndrome,” characterized by gastric bloating, edema, cardiac changes, and congestive heart failure.⁷¹ Initial caloric intake of 30 to 40 kcal/kg/day (1,000–1,600 kcal/day) with progressive increase up to 70 to 100 kcal/kg/day during the weight gain phase are usual standards for nutritional rehabilitation.³ For the weight maintenance phase, intake of 40 to 60 kcal/kg/day is required to maintain growth in children and adolescents.³

Weight gain results in improvement in psychological and medical complications associated with starvation and patients are more likely to participate and benefit from psychosocial treatments. Treatment should continue for at least 3 to 6 months after achieving the goal weight and until menstrual periods resume.¹⁶ Cognitive and physiological abnormalities may persist for months after achieving the goal weight, thus abnormal eating behaviors and body image distortions may return without a comprehensive treatment approach.¹⁶

Routine monitoring of laboratory tests (e.g., complete blood count and platelets, renal and hepatic function tests, electrolytes, BUN, urinalysis, ECG), weight, and vital signs is required to assess medical status (see Table 82-8).^{2,3,76,77} Patients who are emaciated often have cognitive difficulties and psychological changes that can interfere with their participation in behavioral and cognitive therapies.³¹ Patients with a history of vomiting must be watched closely to prevent this compensatory behavior during hospitalization. Cardiac monitoring (e.g., blood pressure, pulse, ECG) is indicated to assess cardiac arrhythmias, ventricular tachycardia, or prolonged QT interval.³

Bone density studies at baseline and at 6- to 12-month intervals are recommended to assess lumbar spine bone density and to determine the risk of compression fractures.⁷⁴ Weight restoration has been shown to be important in reversing men-

strual irregularities, pubertal delay, and bone loss that may result in fractures.⁷⁸ Prolonged amenorrhea (>6 months) has been associated with irreversible osteopenia (loss of bone density), greater risk of osteoporosis, a higher rate of spine and hip fractures, and infertility.⁷⁴

Cognitive–Behavioral Therapy, Behavioral Therapy, and Family Therapy

5. S.B. and her family meet with a psychologist from the eating disorder’s program to receive education about anorexia nervosa and to review treatment goals. At first, S.B. refuses to be admitted, but her parents strongly support a structured program because they argue about her eating behaviors and excessive exercising. Because of the seriousness of her medical status, S.B. finally agrees to participate in therapy. What are the standard therapeutic approaches for patients with anorexia nervosa?

Anorexia responds to a variety of psychotherapeutic approaches that include individual, group, and family therapy.^{1,3,31} Behavioral positive reinforcement programs (i.e., operant conditioning) and response–prevention techniques are very helpful in reducing destructive eating behaviors. Positive rewards, such as increasing social activities, visitations, and physical exercise, can be used when preset weight gain goals are met. Those who use self-induced vomiting after eating can be observed for several hours after meals to prevent purging behavior. These techniques can be modified for both inpatient and outpatient programs to monitor progress toward treatment goals.

Cognitive–behavioral therapy (CBT) helps patients to identify false thinking, distortions in processing and interpreting events, and their relationship to mood and behavior.² Patients are encouraged to evaluate thoughts and feelings related to eating, fears, anxiety, and control issues. Cognitive techniques are taught to help the person restructure his or her thought process, to improve problem solving skills, and to better cope with life stresses. Cognitive therapy can help the person to better understand his or her overvaluation of being thin and obsession with food.

Family counseling or therapy may be helpful in younger adolescents, particularly if family dynamics or unfair parental expectations are issues that increase stress.³ Individual and family therapy provide opportunities to help patients understand themselves and their relationships with others.

Pharmacotherapy

6. S.B.’s mother asks the attending psychiatrist in the eating disorders program about medications used for anorexia nervosa. The mother is also worried about S.B.’s depressed mood and hopelessness about the future. The physician explains that psychotropic medications usually are not effective in treating the primary symptoms of anorexia nervosa until the person has gained at least 85% of their expected body weight. Are there any effective medications for anorexia nervosa? Which agent should be recommended for S.B.?

Many pharmacologic agents have been tried in the acute treatment of anorexia nervosa, but none have been shown to be more effective than placebo. Malnourished patients may be prone to side effects of medications, and some antidepressant agents (e.g., TCAs) can increase the risk of dehydration,

hypotension, arrhythmias, and seizures.³ The pharmacokinetics of medications also can be altered in patients with anorexia nervosa owing to changes in body fat and protein. For example, hypoalbuminemia can result in more free (unbound) drug and a decrease in body fat can reduce the volume of distribution of fat-soluble drugs, resulting in increased steady-state plasma levels.⁷⁹ Because of the increased risk of drug toxicity, any drug therapy should be started with very low doses that are titrated gradually based on adverse effects. In one systematic review, the literature on the efficacy of medications and behavioral interventions for anorexia nervosa in adults and children was weak or nonexistent.⁸⁰

Serotonin-augmenting agents such as *selective serotonin reuptake inhibitors* (SSRIs) are more effective in the treatment of bulimia nervosa than in underweight patients with anorexia nervosa.^{2,3} Patients with reduced dietary tryptophan have low CSF serotonin levels; therefore, SSRIs may not work owing to low serotonin production and release.^{2,16} After weight gain and adequate protein intake, SSRIs are more likely to have a therapeutic effect in weight-restored anorexic patients. SSRIs such as fluoxetine may have a potential role in preventing relapse in weight-restored individuals with anorexia.² Antidepressants generally are reserved for patients with prominent depressive or obsessive-compulsive symptoms that persist after weight has been regained.³ SSRIs are considered the safest class of antidepressants and are the drugs of choice for comorbid anxiety, obsessive-compulsive-impulsive behaviors, social phobia, and depression.² SSRIs are better tolerated than other classes of antidepressants (e.g., TCAs, monoamine oxidase inhibitors [MAOIs]).³ Serotonin-norepinephrine reuptake inhibitors such as duloxetine and venlafaxine have not been adequately studied. Bupropion, a norepinephrine-dopamine reuptake inhibitor is contraindicated in patients with anorexia because of an increased risk of seizures.²

Antipsychotics, such as chlorpromazine and pimozide, were initially used to treat psychotic-like obsessional thinking, but there is no evidence that they are effective in anorexia nervosa.^{2,16} Atypical antipsychotic agents with serotonin antagonist effects (i.e., olanzapine, quetiapine, risperidone) may exacerbate obsessive-compulsive disorder, worsen binge-eating, and cause weight gain due to blockade of serotonin receptors.¹⁶ Cyproheptadine (serotonin antagonist with antihistamine effects that increases appetite and promote weight gain) has been tried in anorexia nervosa with mixed results.² There is no evidence that mood stabilizers or anticonvulsants help with the treatment of anorexia. Lithium carbonate has been tried, but has a narrow therapeutic range and may cause neurotoxicity at high plasma levels; it does not seem to be effective in increasing weight gain.¹⁶

Estrogen replacement is inadequate to increase bone density in patients with anorexia nervosa, particularly without weight restoration and normalization of body fat composition.^{74,75} Oral contraceptives may cause weight gain, but have no effect on bone density.² Calcium supplementation alone has not been shown to increase bone density in anorexia nervosa.⁷⁵ Controlled trials of zinc supplementation have been conducted but results are mixed.¹ Adequate nutrition, weight gain, calcium and vitamin D supplementation, restoration of the regular menstrual cycle, and moderate weight-bearing aerobic exercise are currently the treatments of choice to maintain bone density.^{74,75}

Other agents have been used to treat anorexia nervosa. Benzodiazepines (e.g., lorazepam 0.5–1 mg or oxazepam 15–30 mg) have been given before feeding to reduce anxiety symptoms, but these agents may cause CNS depression, dependence, and withdrawal reactions. Clonidine has not been found to increase weight or have therapeutic effects.¹⁶ Metoclopramide and domperidone (dopamine antagonists) have been investigated for increasing gastric emptying and reducing abdominal distension and bloating, but there is concern about extrapyramidal reactions when these agents are used in high doses.²

BULIMIA NERVOSA

Clinical Features

7. S.B., now a 21-year-old woman, still struggles to maintain her normal weight despite several relapses of her anorexia nervosa. Since starting college, she has started gaining weight when living in the dorms with a self-serve cafeteria. Over the past year, rather than exercising excessively to keep the weight off, she sometimes binge-eats at fast food restaurants late at night. The binge-eating episodes have become very expensive and S.B. has started shoplifting and stealing money to support her “habit.” Currently, S.B. has been binge-eating at least three times a week over several months. She is beginning to gain weight even though she restricts food between bingeing episodes and induces vomiting afterward to help control her weight. S.B. is very secretive about her binge-eating and purging despite living in a sorority house at college. She plans the episodes late at night and often drives into the country to consume the food and to vomit. S.B. is scared of gaining weight, so she often does not eat for several days between the binge-eating episodes and is thinking about using laxatives to lose weight. What characteristics and behaviors of S.B. suggest that she may be suffering from bulimia nervosa?

Many aspects of S.B.’s history are consistent with bulimia nervosa with compensatory mechanisms (Table 82-4). She has a long history of secretive bingeing and purging. Bulimia nervosa is often a chronic disorder with multiple episodes of relapse and remission that begins in late adolescence or in early adult life between the ages of 15 and 24 years.^{1,3} Bulimia may occur in normal weight, obese, or anorexic individuals, as is the case with S.B. Binge-eating usually is preceded by emotional factors (e.g., anxiety, depression, boredom, relationship or family problems) or a stressful life event.³ Younger women tend to have family problems or are seeking independence from parents, whereas women older than age 20 are more likely to have marital or relationship difficulties preceding the onset of bulimia nervosa. Before the onset of the disorder, individuals may be overweight and report periods of severely restricting food intake, fasting, and using “fad” diets to lose weight.¹ Binge-eating occurs when the person loses his or her control over food restriction and becomes “out of control” when consuming food. Before starting to binge-eat, women can become sweaty, tachycardic, anxious, and tense, all of which may be related to starvation from dieting. During the bingeing episode, a sense of freedom and a reduction in anxiety or negative thoughts often is reported. Afterward, the person may feel depressed, guilty, and anxious about gaining weight and try to reduce these negative emotions with the act of vomiting.

Course and Prognosis

8. How does the clinical course of S.B. resemble others with bulimia nervosa and what is her prognosis?

The course of the disorder may be intermittent, with periods of remission and recurrences of binge-eating, or it may be chronic.¹⁻³ Between binges, individuals often diet rigorously, try to resist the urge to eat, and are fearful of weight gain. Over time, the frequency and severity of the binge-eating increases and bulimia nervosa develops. Low self-esteem, anxiety, guilt about binge-eating, depression, impulsive behaviors, sexual conflicts, and problems with intimacy are commonly found in women with bulimia nervosa.³ In one sample of women with eating disorders, 35% of women had relapse of bulimia nervosa at the 9-year follow-up period; in addition, relapse was associated with greater body image disturbances and psychosocial dysfunction.⁸¹ Approximately 5% of those with bulimia nervosa develop anorexia nervosa.³⁰

9. In addition to bingeing, S.B. now admits to using laxatives several times a day. She has also recently started smoking cigarettes and occasionally uses cocaine for its euphoric and appetite suppressant effects. How are these common compensatory mechanisms used to prevent weight gain in patients with bulimia nervosa?

Most binge eaters end the episode because they become nauseated, full, or have discomfort.^{3,4,31} Several strategies are used to reduce the fear of gaining weight. The most popular is to reduce the amount of calories absorbed from the food they have eaten by inducing vomiting or restricting food between binges.³¹ As many as 80% to 90% of bulimic patients have induced vomiting after an episode of binge-eating to decrease abdominal discomfort and to reduce the chance of gaining weight, and approximately 60% of patients regularly use self-induced vomiting. Initially, individuals may use a variety of methods to induce vomiting, such as gagging themselves with their fingers, a toothbrush, or a spoon. Later, individuals may be able to vomit without self-induction techniques.

Between 75% and 90% of binge eaters have abused laxatives during their illness but this method is less effective in controlling body weight. Laxatives act primarily on the large bowel to empty, but this occurs after food already has been absorbed in the small intestine. Excessive laxative intake may lead to electrolyte disturbances, particularly potassium deficiency. Approximately 60% have used over-the-counter (OTC) diet pills that may contain some form of laxative.

Some individuals may restrict food or starve between eating binges, use excessive exercise, and ingest appetite-suppressant products in an attempt to compensate for binge-eating. A number of appetite-suppressing medications with sympathomimetic effects have addictive properties. Approximately 40% of binge eaters have used diuretics to lose weight, but this only loses fluid weight and is ineffective for reducing energy from food. Approximately 10% use prescription anorectic medications and at least 20% of bulimic patients abuse alcohol or drugs.

Misuse of diuretics and enemas, consuming syrup of ipecac to induce vomiting, or taking thyroid hormones are less frequently used methods to reverse binge eating effects. Women

with eating disorders, especially in those who binge and purge, seem to be at higher risk of smoking than controls.⁸²

Medical Complications

10. S.B. has been experiencing constant headaches, muscle cramps, and fatigue for several days and feels that she has the flu. She makes an appointment at the student health clinic and is evaluated by a nurse practitioner in a walk-in clinic. During the physical examination, the nurse notes abrasions on the top of her hand, hypertrophy of the salivary and parotid glands, and enamel loss on her teeth. S.B. is dehydrated and complains of chronic constipation. What signs and symptoms of bulimia nervosa are present on S.B.'s physical examination? What laboratory screening tests are recommended to rule out a medical diagnosis or medical complications from bulimia nervosa?

Individuals with bulimia nervosa are usually within their normal weight range; thus, medical complications, morbidity, and mortality associated with weight loss or obesity are less of a problem.³ Common physiologic changes and abnormal laboratory tests associated with purging are listed in Table 82-7. Baseline laboratory tests often include serum electrolytes, a complete blood count, liver and renal function tests, thyroid function tests, and an ECG (Table 82-8).³

Purging behavior can produce electrolyte abnormalities (e.g., hypochloremia, hypokalemia, hyponatremia), fluid disturbances, and dehydration.^{3,31} Metabolic alkalosis (elevated serum bicarbonate) is associated with loss of stomach acid through vomiting; metabolic acidosis may occur secondary to diarrhea through laxative abuse. Hypokalemia occurs secondary to aldosterone secretion and increased potassium excretion from the kidneys, and through self-induced vomiting.³¹ Electrolyte disturbances can cause lethargy, weakness, and possibly, cardiac arrhythmias.

Permanent loss of dental enamel, especially on the front teeth, and dental cavities are common secondary to the effects of stomach acid.³¹ Enlargement or inflammation of salivary glands (sialadenitis), particularly the parotid glands, from recurrent vomiting often is reported. Elevated serum amylase owing to increases in salivary isoenzymes often results. Calluses or scars on the dorsal part of the hand secondary to trauma by the teeth (known as the *Russell sign*) is caused by repeated self-induction of vomiting.⁸³ Individuals who chronically abuse syrup of ipecac to induce vomiting may develop myopathy (e.g., muscle weakness, aching, hyporeflexia, slurred speech) and/or cardiotoxicity (e.g., atrial premature contractions, supraventricular tachycardia, ventricular tachycardia, flattened or inverted T waves, prolonged QT and P-R intervals, changes in the QRS complex, decreased contractility, and cardiac arrest).³¹ Ipecac contains a cardiotoxin that, in high doses, may cause permanent necrosis of heart fibers and interstitial edema.

Laxative abuse initially causes diarrhea, but continued use may result in rebound fluid retention and electrolyte disturbances. A withdrawal syndrome associated with discontinuation of laxatives is characterized by constipation, abdominal bloating and cramping, agitation, and feeling "sick." Diuretics or OTC slimming tablets cause electrolyte disturbances, particularly potassium deficiency. Fluid retention may result when long-term diuretic use is discontinued.

Approximately 40% of women with bulimia nervosa have irregular menstruation and 20% have amenorrhea. Menstrual disturbances usually cease when body weight is stabilized and when dangerous methods of weight control, including excessive exercise and intermittent starvation, are stopped.

Treatment

Medical Management

11. The nurse practitioner feels that S.B. has bulimia nervosa based on the physical examination and laboratory tests (serum potassium, 3.0 mEq/L; BUN:creatinine ratio, >30; volume depletion; scarring on the dorsum of the hand; and severe dental caries and enamel erosion). She confronts S.B. about her eating habits and recommends referral to a therapist and psychiatrist who have experience in eating disorders. S.B. finally confesses about how horrible she feels and asks for help. A plan is established that includes a psychiatrist, therapist, and nutritionist to manage the medical, psychological, and nutritional aspects of treatment. How should physiologic complications be monitored and assessed in SB?

Individuals who seek medical help may not tell their physician about their eating habits; thus, bulimia nervosa may be missed. Most patients with bulimia nervosa do not require hospitalization unless there is a medical or psychiatric indication such as severe depression with suicidal thoughts, severe concurrent drug or alcohol abuse, or a life-endangering medical problem (e.g., severe hypokalemia, metabolic alkalosis/acidosis, severe dehydration, acute pancreatitis, cardiomyopathy, cardiac arrhythmia).^{3,16} Common medical complaints include GI problems (irritable bowel syndrome, spastic colon), menstrual irregularities, depression, or panic attacks. Those who seek treatment for bulimia nervosa have usually started inducing vomiting or taking purgatives, or both. Patients with self-induced vomiting should be monitored for esophageal tears, dehydration, metabolic alkalosis (hypochloremia and hypokalemia), elevated serum amylase, weakness and lethargy, cardiac arrhythmias, erosion of dental enamel or dental caries, and vitamin, electrolyte, and mineral deficiencies.³ Correcting serum electrolyte abnormalities helps to reduce the risk of medical complications such as cardiac arrhythmias. Individuals who abuse ipecac require monitoring of blood pressure (hypotension), heart rate (tachycardia), ECG to assess cardiac failure, and liver enzymes. An echocardiogram may be needed to diagnose cardiomyopathy.

Cognitive–Behavioral Therapy and Interpersonal Therapy

12. S.B. agrees to participate in an intensive outpatient eating disorder treatment program that is coordinated through the student health clinic. Her team feels that she will need help with self-esteem development, coping skills, and adherence with treatment, so they develop biweekly sessions to work on goals. What are the standard nonpharmacologic therapies for patients with bulimia nervosa or binge eating disorder?

Psychoeducational groups, nutritional counseling, self-help manuals, and self-monitoring have all been used as treatments for bulimia nervosa. However, the literature suggests that individuals who receive CBT have higher remission rates; thus, this treatment should be considered the first-line treatment of choice for most patients.² Most patients benefit more from structured CBT approaches, requiring an average of 20 ses-

sions over a 4- to 6-month period.^{3,16} Beside CBT, interpersonal psychotherapy may be useful in treating bulimia nervosa and binge-eating disorder.² Time-limited interpersonal psychotherapy, up to 16 weeks, also has been shown to improve interpersonal problems and role transitions and reduces bulimic behaviors over the long term. Reviews of psychological and pharmacotherapy comparative studies for bulimia nervosa and binge-eating disorders can be found elsewhere.¹

Behavioral and cognitive techniques help individuals to self-monitor their binge-eating and purging episodes and document changes in mood and circumstances related to the binge-purge behavior.² CBT helps the person to examine distortions in his or her thought processing and interpretation of events, and uses cognitive restructuring to change the way he or she thinks and reacts. Several studies have reported that CBT or CBT in combination with antidepressants is more effective in reducing bulimic symptoms than giving antidepressant medications alone.^{2,3,16,84} CBT has been reported to be more effective than supportive psychotherapy and the addition of an antidepressant may significantly improve depression and binge-eating behaviors.⁸⁵ Psychoeducational approaches along with individual and group therapy are commonly used for CBT. Behavioral therapy is used to stop the binge-eating and purging behaviors by restricting exposure to situations or cues that trigger a binge-purge episode, by finding alternative behaviors that are less destructive, and by delaying the purging response to eating. Response prevention techniques are used to prevent vomiting by placing an individual in a more restrictive environment or situation where it is very difficult to vomit.

Pharmacotherapy

13. The psychiatrist has several individual sessions with S.B. to assess the severity of the eating disorder and to rule out other psychiatric or medical disorders. S.B. has mild symptoms of depression that do not meet the criteria for a major depressive episode. Nicotine and cocaine help her mood, so S.B. wonders if an antidepressant would help her feel less anxious and reduce the urge to binge and purge. The psychiatrist agrees that the comorbid substance abuse, mild depression, anxiety symptoms, and obsessive-compulsive behaviors may respond to an antidepressant. What medications have been used to treat bulimia nervosa? How safe and effective are these agents, and how long should patients be maintained on treatment?

If medications are required, antidepressants are considered the drugs of choice for bulimia nervosa.^{1-3,16} Bulimic patients do not need to be clinically depressed to benefit from treatment. Several short-term, double-blind, placebo-controlled studies have demonstrated that antidepressants are effective for reducing binge-eating and vomiting episodes, although some classes such as TCAs and MAOIs have more adverse effects and may not be tolerated.^{86,87} Serotonin-augmenting agents are the most commonly prescribed antidepressants for bulimia nervosa and binge-eating disorder and have a more favorable side effect profile in comparison with other classes.¹⁶ Nutritional counseling has been shown to be effective in bulimia nervosa and may have beneficial effects when combined with SSRI treatment.⁸⁸ Few long-term controlled studies have been done with antidepressants to evaluate if modifications in eating behaviors and weight are maintained over time. Fluoxetine and fluvoxamine combined with CBT was shown to be more effective than drug therapy alone in the treatment of binge eating disorder at 1-year

follow-up based on BMI and eating disorder rating scales.⁸⁴ A summary of randomized controlled trials of antidepressants versus placebo for bulimia nervosa can be found elsewhere.²

Fluoxetine was approved by the U.S. Food and Drug Administration (FDA) in 1996 for the treatment of bulimia nervosa. Higher daily doses of fluoxetine (60 mg/day) may be superior to the standard antidepressant dose of 20 mg/day.¹⁶ Other serotonin-augmenting agents (e.g., citalopram, escitalopram, fluvoxamine, paroxetine, sertraline, and venlafaxine) are alternative treatments for bulimia nervosa or binge-eating disorder.^{2,16} The efficacy and ideal dose of SSRIs other than fluoxetine have not been established.¹⁶ Common side effects reported with SSRIs include diarrhea, nausea, headache, insomnia, and sexual dysfunction. Bradycardia and hyponatremia have been reported with SSRIs; thus, monitoring of heart rate, blood pressure, and serum electrolytes is recommended, particularly for patients who use diuretics or have purging behaviors.

In a review of double- and single-blind, placebo-controlled studies, TCAs, MAOIs, topiramate, ondansetron, and inositol have shown some benefit in bulimia nervosa.^{2,89} Bupropion is not recommended for the treatment of eating disorder patients owing due to reported risks of seizures in patients with bulimia nervosa.² Topiramate, a novel antiepileptic agent, has been reported to decrease binge-eating episodes and improve quality of life in patients with bulimia nervosa in several double-blind, placebo-controlled studies.²

Duration of antidepressant therapy is an important issue because patients treated for at least 6 months have a better long-term outcome than patients who receive shorter antidepressant trials.⁸⁶ Only 50% of patients achieve a complete remission after antidepressant treatment and a majority have relapses after the initial intervention has stopped.¹⁶ Approximately one-third of patients may relapse with prophylactic antidepressant treatment.¹⁶ A rapid relapse of binge-eating behaviors has been reported when antidepressants are withdrawn in both bulimia nervosa and binge-eating disorder.⁸⁶ In general, antidepressants should be prescribed for at least 6 months, and some patients may require long-term prophylactic antidepressant treatment.¹⁶ Daily recordings of mood and binge-eating behaviors, weekly weighings, and close monitoring may have their own therapeutic benefits as well.

OBESITY

Clinical Features

14. S.B., now 50 years old, is married and has 3 children. She has been treated successfully for her eating disorders that she suffered as a young woman and has lived without any complications for several decades. Unfortunately, after 3 children, she has noticed a slow but progressive increase in her weight over the past few years. She is currently being evaluated at a chronic pain clinic for lower back and knee pain secondary to degenerative joint disease. Her current height is 5 feet 6 inches tall; she weighs 250 lb, has a waist circumference of 40 inches, and is unable to move without significant joint and back pain. In the past 15 years, she has developed diabetes, hypertension, and hyperlipidemia. S.B. is currently being treated for depression and perimenopausal symptoms. S.B.'s current medications include metformin, atenolol, atorvastatin, and paroxetine. How is obesity defined and assessed in a patient like S.B.? What common clinical features of obesity and risk factors are useful for determining the need for treatment in S.B.?

Obesity is an excessive accumulation of body fat secondary to poor appetite regulation and decreased energy metabolism. Appropriate treatment of the overweight/obese patient requires assessment of the degree of overweight and overall risk status. The best method to determine the degree of overweight/obesity is to measure the BMI, which is associated with total body fat content.¹⁴ The waist circumference is an independent predictor of risk factors and morbidity and correlates to abdominal fat content.^{7,14} High relative health risks are seen in patients with waist circumference >102 cm (40 inches) in men and >88 cm (35 inches) in women compared with patients with normal weight. Fat deposited around the waist seems to be more likely than fat on the hips or thighs to lead to health risks such as cardiovascular disease, insulin resistance, type 2 diabetes, hyperlipidemia, and increased blood pressure. The waist circumference may not be as predictive or helpful in patients with BMI >35 kg/m² and height <5 ft.¹⁴ Waist:hip ratio indicates regional fat distribution and increased health risk is seen in patients with high intra-abdominal fat (waist:hip ratio >1 in men and >0.8 in women).⁷ Skin-fold thickness can be used to assess body fat at various sites, but measurements may vary between observers and it does not provide information about intramuscular or abdominal fat.⁷ S.B.'s BMI is 40.3 (250 lb ÷ [66 in]² × 703), which is in obesity class III (extreme obesity). To determine absolute risk and need for treatment of overweight/obesity, clinicians should be familiar with related diseases and other risk factors (Table 82-9).

Patients who are overweight/obese need to be monitored for other cardiovascular risk factors as recommended by the guidelines published by the National Cholesterol Education

Table 82-9 Conditions That Increase the Risk Status in Overweight/Obese Patients

| <i>Disease Conditions</i> | <i>Risk for Disease Complications, Mortality</i> |
|---|--|
| Coronary heart disease Atherosclerotic disease Type 2 diabetes mellitus Sleep apnea | Very high |
| Other obesity-related diseases | |
| Gynecologic abnormalities Osteoarthritis Gallstones and complications Stress incontinence | High |
| Cardiovascular risk factors | |
| Cigarette smoking Hypertension Increased LDL cholesterol Low HDL cholesterol Impaired fasting blood glucose Family history of premature CHD Age (men >45, women >55 or postmenopausal) Physical inactivity High serum triglycerides | Very high if ≥2 risk factors |

CHD, coronary heart disease; HDL, high-density lipoprotein; LDL, low-density lipoprotein.

Adapted from reference 14.

Program and the Joint National Committee on Prevention, Detection, Evaluation and Treatment of High Blood Pressure. The impact of S.B.'s current medications for her various chronic conditions and her limited mobility to participate in exercise regimens should be taken into consideration. Patients' motivation to lose weight is a significant predictor of success or failure in the weight management program. The willingness to participate in a regimen may depend on past history of diets, social support at home and workplace, patient's understanding of the illness, time, and financial burden.¹⁴ Obesity is considered a chronic medical condition because it causes multiple physical complications.⁷ The greater the degree of obesity, the harder it is for a person to lose weight permanently without medical and behavioral interventions. Major depressive disorder, anxiety disorders, and low self-esteem are common in obese patients owing to social prejudice and discrimination in the work force.⁹

Course and Prognosis

15. S.B. has steadily gained weight since her early 30s after the birth of her first child. She has always struggled with her weight and has three other siblings who are obese. She has tried more than 15 diets to lose weight, but each time she stops the diet she regains even more weight. S.B. admits to overeating and, at times, uses laxatives and OTC diet pills to help her control her weight and appetite. What is the typical course and prognosis of obesity?

Obesity is a chronic disease that can begin in childhood or adolescence and can be characterized by a slow and steady increase in body weight during adult life. In a retrospective cohort study comparing long-term mortality of people undergoing bariatric surgery with obese patients in the control group, the rate of death from any cause was 40% lower in the surgical group.⁹⁰

Overeating or binge-eating along with restrictive dieting is a common occurrence among Americans and may be a chronic lifelong problem that leads to obesity. Recent studies have shown that 10% to 25% of obese people regularly engage in binge-eating behavior and that the greater their weight, the more likely they are to be binge eaters¹⁶; at least 25% to 45% of obese individuals have symptoms that meet the criteria for binge-eating disorder.^{9,16,83} Unlike individuals with bulimia nervosa, obese binge-eaters usually do not vomit or purge and may or may not restrict food intake between binge-eating episodes. Obese binge-eaters often have a preoccupation with their body shape and weight, but they have poor control of their eating habits. Women tend to be more concerned about their body shape and weight and are more likely to diet than men. More than 80% of people who lose weight gradually regain it; patients who continue on weight maintenance programs consisting of dietary, physical, and behavioral therapy have a better chance of not regaining weight than those who discontinue weight maintenance programs.¹⁴

Medical Complications

16. The physician in the pain management clinic is very concerned about S.B.'s weight because of her current medical con-

ditions and the likelihood of further complications during her lifetime. What are the most common medical conditions associated with obesity?

Obesity has a tremendous impact on physiologic functioning and medical illnesses. Obese people tend to die young, and the more abdominal body fat, the greater the mortality. Obesity-related medical conditions in the United States result in 300,000 deaths per year and cost approximately \$70 billion in health care costs.⁹¹ Obesity is linked with many disabling diseases such as diabetes mellitus (non-insulin-dependent and insulin-resistant), pulmonary impairment (hypoventilation, hypoxia, hypercapnia, and sleep apnea), gallbladder disease (gallstones and cholecystitis), cancers (colorectal, prostate, breast, cervical, endometrial, uterine, and ovarian), osteoarthritis (hips, knees, and back), gout, cardiac disease (hypertension, stroke, congestive heart failure, and coronary heart disease), increased cholesterol and triglycerides (TG) (increased low-density lipoproteins and decreased high-density lipoproteins), dermatologic problems (intertrigo and stretching of skin), and menstrual irregularities.^{14,31} The Nurses Health Study showed that the risk of developing diabetes in women with BMI >35 was 60 times higher than the lowest risk group (BMI <22 kg/m²).⁹² It is estimated that >60% of type 2 diabetes mellitus cases are due to obesity.²⁰ Weight loss helps to control diseases associated with obesity and may even help prevent development of these diseases. Weight loss has been shown to be beneficial in lowering blood pressure, total cholesterol, low-density lipoproteins, TG, blood glucose in patients with diabetes mellitus type 2, and increasing high-density lipoproteins.¹⁴

Treatment

Medical Management

17. The physician recommends that S.B. reduce her weight over the next 12 months to help improve the quality of her life, reduce the associated morbidity from related medical conditions, and prolong her life. What would be appropriate goals for weight loss with F.W.? What type of nutritional and exercise plan should be recommended?

According to the National Heart, Lung, and Blood Institute guidelines, weight loss treatment should be initiated for patients who are overweight, who have increased waist circumference plus two or more risk factors, or are obese (BMI ≥ 30).¹⁴ The general goals of weight loss and management are to prevent weight gain, reduce body weight, and maintain weight loss over a long period.¹⁴ Treatment options to facilitate weight loss include moderate caloric restriction, medications (e.g., appetite suppressants, lipase inhibitors), physical activity, and behavior therapy. Obese patients (like S.B.) should strive to lose 10% of baseline weight at a rate of 1 to 2 lb/week with an energy deficit of 500 kcal/day over 6 months. Overweight patients should ideally lose 0.5 lb/week with an energy deficit of 300 to 500 kcal/day over 6 months. A low-calorie diet consistent with National Cholesterol Education Program Step 1 or Step 2 diet has been shown to be most effective. A low-fat diet does not decrease weight unless total caloric intake is decreased. Total fat intake should account for 30% or less of total calories consumed per day.¹⁴ Drastic caloric restriction is difficult to maintain and may lead to reduced metabolism and

overeating due to hunger. Severe caloric restriction and rapid weight loss can be harmful and result in rebound binge-eating behavior and weight gain.⁹³

Increased physical activity can facilitate weight loss and is essential in preventing weight gain. Overweight children and adults should have at least 30 minutes of moderate-intensity physical exercise daily (with a gradual increment of increasing exercise by several minutes each day up to 30 minutes per day). It has recently been shown that moderate exercise (e.g. 4 kcal/g per week) can improve physiologic variables.⁹⁴ Modest weight loss is beneficial, because even a small amount of weight loss, as little as 5%, is associated with significant improvements in health status.

Obese patients should be evaluated for hypothyroidism because it is a potential cause of weight gain. However, use of thyroid hormones to cause weight reduction in patients with normal thyroid function is not recommended.

Nonpharmacologic Therapy

18. S.B. has never participated in a behavior modification weight reduction or maintenance program. The physician recommends that she attend weekly social support meetings and learn more desirable behaviors for self-monitoring her diet and exercise. What types of nonpharmacologic therapies or programs are available for weight reduction and relapse prevention?

Behavioral modification programs using support groups, a balanced diet, and exercise are most effective for mild obesity (20%–40% overweight).³¹ Behavioral modification programs (e.g., nutritional education, exercise, cognitive restructuring, self-monitoring) are the most effective for overweight children and help to motivate parents and children to alter their lifestyles.¹⁴ Supportive family therapy is desirable, particularly for obese children. Obesity may be related to cultural attitudes, family eating behaviors, and social events involving food. Relapse prevention should identify high-risk situations or events that may cause weight gain so that the person can learn new coping strategies to avoid overeating.

Because of the high demand by consumers, there are numerous types of weight loss programs, diets, and products that may or may not be effective. Individuals who want to lose weight frequently seek out popular structured programs (e.g., Jenny Craig, Weight Watchers). Other weight loss programs include low-fat, low-sodium, vegetarian, soy, Atkins, and Zone diets. Regardless of which weight loss program is chosen, patients should select a program that emphasizes the following: (a) counseling for lifestyle changes, (b) trained staff, (c) coping strategies for stressful times, (d) weight loss maintenance, and (e) flexible and appropriate food choices.⁹⁵

Overall, a combination of low-calorie diet, behavioral modifications, and increased physical activity are most effective for reducing and maintaining weight loss. These measures must be attempted and maintained for at least 6 months before considering pharmacotherapy.¹⁴

Pharmacotherapy

19. S.B. asks the physician about medications that can help with weight loss. What is the current status of pharmacologic agents for obesity therapy? What are their mechanisms of action, efficacy, and potential adverse effects?

A comprehensive treatment approach to obesity includes a weight loss diet, exercise, supportive psychotherapy, and behavioral modification techniques. If indicated, medications such as an anorectic agent (to suppress hunger and appetite) or a GI lipase inhibitor (to reduce fat absorption) may be prescribed.⁹⁶ Weight loss is possible for most patients, but the main problem is that the vast majority of people regain the weight over time.² Obesity is a chronic, lifelong illness that may require long-term medication therapy. Medication should be considered only for patients with a BMI >30 kg/m² without risk factors or >27 kg/m² with an obesity-related risk factor (Table 82-9).¹⁴ Anorectic medications or lipase inhibitors should not be considered a replacement for diet, behavioral modification, and exercise, but rather as add-on therapy.

Medications used for the treatment of obesity in the United States are found in Table 82-10. Although there are many medications with varying mechanisms of action that have been theorized to be effective for weight loss, currently marketed drugs for weight loss do so by suppressing the appetite or decreasing the absorption of fat.⁹⁶ According to recent meta-analyses and critical reviews, sibutramine and orlistat have been shown to have consistent and sustained, albeit modest, weight loss effects over other pharmacologic classes of drugs up to 1 year.^{97,98}

AMPHETAMINES AND SYMPATHOMIMETICS

Amphetamines, dextroamphetamine, and sympathomimetics have been used as appetite suppressants and thermogenic agents for several decades.⁹⁹ The enhancement of dopaminergic activity is believed to be responsible for amphetamine's rewarding, reinforcing, and addictive properties.¹⁰⁰ Because of their euphoric properties and risks of drug abuse, amphetamines are schedule II controlled agents and are not routinely used for weight loss.¹⁰¹ Additional concerns with sympathomimetics are the potential for rebound binge-eating, weight gain, lethargy, and depression when the medication is discontinued.³¹ Other centrally active appetite suppressants that augment catecholamines (e.g., phentermine, mazindol, phendimetrazine, and diethylpropion) were developed for the treatment of obesity and may have a lower incidence and severity of CNS side effects compared with the amphetamines.⁹⁹

Although amphetamines and sympathomimetics may be quite effective for weight loss, they are not without significant risks. Fenfluramine and dexfenfluramine were voluntarily removed from the United States market in 1997 due to studies linking their usage to valvular heart disease and primary pulmonary hypertension.¹⁰² As of April 2004, the FDA has prohibited the sale of dietary supplements containing ephedrine alkaloids (ephedra) owing to the many reports of serious adverse effects (e.g., stroke, seizures, and death).¹⁰³ Ephedrine (found in ephedra and ma huang) was included in several OTC and herbal products that promoted their ability to increase energy expenditure, thus causing weight loss. Phenylpropanolamine (PPA), a popular synthetic catecholamine that was widely found in OTC weight-loss products and decongestants, was also voluntarily withdrawn in 2000.¹⁰⁴ PPA increased satiety by stimulating norepinephrine and dopamine release in the hypothalamic feeding center, but studies found an increased risk of hemorrhagic stroke in women who took appetite suppressants containing more than 32 mg/day PPA.¹⁰⁵ Because of significant adverse effects of sympathomimetics, these agents are no longer recommended for weight loss.

Table 82-10 Medications Marketed or Used for the Treatment of Obesity

| Generic Name | Trade Name | Dosage | DEA Schedule or Class |
|-------------------------------|--------------------------------------|-----------------------------------|-----------------------|
| Amphetamine/dextroamphetamine | Adderall | 5–30 mg/day | II ^a |
| | Biphedamine | 12.5–20 mg/day | II ^a |
| Benzphetamine hydrochloride | Didrex | 25–50 mg one to three times daily | III |
| Dextroamphetamine | | | |
| Immediate release | Dexedrine | 5–10 mg before meals | II ^a |
| Extended release | Dexedrine | 10–30 mg | II ^a |
| Diethylpropion hydrochloride | | | |
| Immediate release | Tenuate | 25 mg TID; 75 mg AM | IV |
| Controlled release | Tenuate Dospan | 75 mg AM | IV |
| Ephedrine | Various products | 20–60 mg/day | OTC |
| Mazindol | Sanorex | 1 mg TID; 2 mg AM | IV |
| Methamphetamine hydrochloride | | | |
| Immediate release | Desoxyn | 2.5–5 mg before meals | II ^a |
| Orlistat | Xenical, Alli | 120 mg TID, 60 mg TID | Prescription, OTC |
| Phendimetrazine tartrate | Bontril, Plegine, Prelu-2, X-Trozine | 35 mg TID; 105 mg AM | III |
| Phenmetrazine | Preludin | 25 mg BID–TID | II ^a |
| Phentermine | | | |
| Hydrochloride | Adipex-P, Fastin, Oby-Cap, Phentride | 8 mg TID; 30–37.5 mg AM | IV |
| Resin | Ionamin | 15–30 mg AM | IV |
| Sibutramine | Meridia | 5–15 mg/day | IV |

^aHigh abuse potential, not recommended for routine or long-term use.

BID, twice a day; OTC, over the counter; TID, three times a day.

Adapted from references 53 and 125.

ANTIDEPRESSANTS

Serotonin- and/or norepinephrine-augmenting agents (e.g., serotonin or norepinephrine reuptake inhibitors) are the most effective agents for suppressing appetite drive and reducing weight. For obese binge-eating patients, SSRI antidepressants such as fluoxetine have been used successfully to reduce binge-eating behavior, but this is not always associated with weight loss.⁶⁵ The reason for the weight regain is unclear, but may relate to the development of tolerance or the lack of frequent follow-up visits.¹⁰⁶ In a recent meta-analysis, high-dose fluoxetine was shown to produce a pooled weight loss of 4.74 kg at 6 months and 3.15 kg at 12 months.⁹⁸ Studies with other SSRIs are either lacking, limited by small sample size or have shown nonsignificant results.⁹⁸ Bupropion, an antidepressant that inhibits dopamine reuptake, has been shown to have some weight loss (2.77 kg) effects at 6 and 12 months when combined with other weight loss measures (diet, exercise).⁹⁸ Antidepressants that have histamine-antagonist effects (i.e., TCAs) or block serotonin receptors (e.g., mirtazapine) cause sedation and increase appetite and weight, and thus should not be used in obese patients.⁶³

SEROTONIN/NOREPINEPHRINE REUPTAKE INHIBITORS

Sibutramine (Meridia), a prescription medication marketed for weight loss, is structurally related to amphetamines (β -phenylethylamine) and is classified as a schedule IV controlled agent.¹⁰⁷ Sibutramine and its two active metabolites inhibit the reuptake of serotonin and norepinephrine and, to a lesser extent, dopamine, thereby increasing concentrations of these neurotransmitters in the brain.^{107–109} By increasing serotonin and norepinephrine activity, α -adrenergic, β -adrenergic,

and serotonin_{2A/2C} receptors are stimulated, which in turn causes a downregulation of α - and β -adrenergic and serotonin receptors.^{44,107} This promotes a sense of satiety and thus decreases appetite. A synergistic interaction between norepinephrine and serotonin has been shown to maximize reduction in food intake.^{100,110} When a norepinephrine or serotonin reuptake inhibitor is given alone, food intake generally is not altered unless these agents are given in significantly higher dosages. Sibutramine also is thought to cause a sympathetic stimulation of brown adipose tissue (thermogenesis to increase glucose utilization) via the β_3 -adrenoceptors.^{100,110}

In a recent meta-analysis for long-term administration of sibutramine, including 10 trials and more than 2,600 patients, sibutramine reduced weight by 4.3% over those taking placebo and increased the percentage of patients achieving successful weight maintenance.⁹⁷ In addition, cardiovascular risk profiles also improved with sibutramine (increased high-density lipoprotein cholesterol and lower TG concentrations). It should be noted that sibutramine was associated with elevations in diastolic and systolic blood pressure as well as heart rate.

In a 1-year trial, 224 obese patients were randomized to receive sibutramine alone, lifestyle modification counseling alone (in group sessions), sibutramine plus group sessions of lifestyle modification, or sibutramine plus brief lifestyle modification counseling by a primary care provider. All patients were restricted to a 1,200 to 1,500 kcal/day diet and similar exercise regimen.¹¹¹ Patients who received the drug and group sessions of lifestyle modification lost the most weight (an average of 12.1 kg) versus those in the other groups, who only lost about half the average weight. It should be stressed that

sibutramine should always be combined with lifestyle modifications.

Common adverse effects of sibutramine include headache, decreased appetite, dry mouth, constipation, and insomnia.^{108,112} Other less common side effects include sweating, irritability, excitation, dizziness, insomnia, and increases in blood pressure and heart rate (increase in blood pressure by 1–3 mmHg and in heart rate by 4 to 5 beats/minute). Frequent blood pressure and pulse rate monitoring is recommended because these cardiovascular effects are believed to be dose related. Sibutramine must be used cautiously in patients with high blood pressure and its use is not recommended in patients with heart disease, congestive heart failure, conduction disorders (arrhythmias), or stroke. Sibutramine is absolutely contraindicated in patients taking certain CNS medications that increase levels of norepinephrine or serotonin (e.g., MAOIs) and other centrally acting appetite suppressants. Precautions should be taken in patients who are coadministered lithium, antimigraine agents (e.g., sumatriptan, dihydroergotamine), and some opioid analgesics (e.g., tramadol, dextromethorphan). Drugs that inhibit liver enzymes (cytochrome P450 3A4), such as ketoconazole and erythromycin, can increase serum concentrations of sibutramine. Sibutramine is well absorbed and has high first-pass liver metabolism to produce two active metabolites, both with long elimination half-lives of 14 to 16 hours.¹⁰⁸ Initial dosing of sibutramine is 10 mg once daily with or without food (typically in the morning) and the dose can be increased to 15 mg once daily if needed. A 5-mg dose is available for patients who do not tolerate the recommended starting dose.

LIPASE INHIBITORS

Orlistat (Xenical), an FDA-approved weight loss medication, works to reduce dietary fat absorption by inhibiting GI (stomach and pancreas) lipase activity.^{113,114} In February 2007, the FDA approved the OTC marketing of orlistat under the trade name, Alli.¹¹⁵ Orlistat is a hydrogenated derivative of lipstatin (a naturally occurring lipase inhibitor produced by *Streptomyces toxytricini*) that is a potent inhibitor of lipases and weak inhibitor of other intestinal hydrolases.¹¹⁴ Gastric and pancreatic lipase are enzymes that play a pivotal role in the digestion of dietary fat (TG). Before digestion and absorption of dietary fat is possible, each TG molecule must be hydrolyzed by lipase enzymes into absorbable products—two fatty acid molecules and one 2-monoacylglycerol molecule. Orlistat inhibits lipase by binding to and inactivating the enzyme. Subsequently, TG cannot be absorbed, and approximately 30% of ingested fat is excreted in the feces.¹¹⁴ The therapeutic activity of orlistat takes place in the stomach and small intestine and effects are seen as soon as 24 to 48 hours after dosing.

Orlistat does not exert appetite suppressant effects, has no CNS effects, and has no systemic absorption.¹¹⁴ It is most effective if combined with a reduced fat and calorie diet¹¹³ and is indicated to reduce the risk of weight regain after prior weight loss. It also is indicated for obese patients with an initial BMI ≥ 30 kg/m² or ≥ 27 kg/m² in the presence of other obesity-related risk factors. In a recent meta-analysis, orlistat was shown to produce less weight loss (2.9 kg) than sibutramine; orlistat also improved blood pressure, low-density and high-density lipoprotein concentrations.⁹⁷ GI adverse events were common, although there was no report of vitamin deficiencies. Orlistat may also reduce the risk of related diseases;

in a 4-year study, orlistat plus lifestyle changes was associated with a 37% risk reduction of diabetes in over 3,300 obese patients.¹¹⁶

The most common adverse effects associated with orlistat include GI problems (loose stools, oily spotting, flatus with discharge, fecal urgency, fatty/oily stools, increased defecation, fecal incontinence, bloating, and cramping).¹¹⁷ The most common adverse events reported are fatty/oily stool, fecal urgency, and oily spotting. The most common non-GI adverse effect was headache (6%). Side effects usually develop early in treatment and persist for 1 to 4 weeks, but occasionally last longer than 6 months. Because GI adverse effects are worse with a high-fat diet, orlistat may enhance dietary compliance with a low-fat diet.

Orlistat may reduce the absorption of fat-soluble vitamins (A, D, E, and K) and patients should take a multivitamin supplement that contains these vitamins.¹¹⁷ The supplement should be taken once a day at least 2 hours before or after the administration of orlistat, such as at bedtime. Orlistat may interfere with vitamin K absorption and potentiate the bleeding effects of warfarin. Orlistat may also reduce the absorption of amiodarone and cyclosporine. When used in diabetic patients, weight loss may be accompanied by improved control of diabetes, which requires a reduction in doses of diabetic medications, including insulin. Orlistat has additive effects when combined with lipid (cholesterol)-lowering agents such as pravastatin; thus, the dose of statins may be reduced.¹¹⁴ The dosage of prescription orlistat in adults is 120 mg three times daily (OTC dose is 60 mg three times daily), during (or up to 1 hour after) each main meal containing fat. If a meal occasionally is missed or contains no fat, the dose may be omitted. Dosages exceeding 120 mg three times daily do not provide additional benefit.

MISCELLANEOUS AGENTS

Topiramate is a second-generation antiepileptic agent which acts as an agonist at γ -aminobutyric acid (GABA_A) receptors and as an antagonist at non-*N*-methyl-D-aspartic acid glutamate receptors. It has been shown to produce a dose-dependent weight loss between 1 and 8 kg and may also produce weight loss in patients with bipolar affective disorder.¹¹⁸ In a pooled analysis of 6 studies with wide range of dosages, topiramate produced a 6.5% weight loss compared with placebo at 6 months.⁹⁸ Paresthesia, CNS, and GI effects were commonly seen at higher doses. Zonisamide has been recently studied in randomized controlled trials for weight loss in obese patients with and without binge-eating.^{119,120} One double-blind, placebo-controlled study showed that the active treatment group lost an average of 6% of baseline body weight compared with the placebo group at the end of 4 months.¹¹⁹ In the binge-eating population, tolerability was low for zonisamide and resulted in a 20% dropout rate.¹²⁰

20. S.B. is willing to try a pharmacologic interventions along with behavioral modification, but she has heard about the use of surgery to reduce the size of her stomach. When should surgical intervention be used? What are potential complications related to surgery and postsurgical precautions?

Surgery

Surgery should be used only for morbidly obese individuals (BMI ≥ 40 or ≥ 35 kg/m² with comorbid conditions) in whom

behavioral or pharmacologic treatments have failed.¹²¹ For severely obese patients (>100% over normal weight), the most effective treatment is a surgical procedure to reduce the size of the stomach. Surgical procedures either reduce the absorptive surface of the GI tract resulting in malabsorption, or reduce the stomach volume so that the person feels full after a smaller meal. According to recent guidelines, gastric banding, vertical banded gastroplasty, Roux-en-Y gastric bypass, and biliopancreatic diversion are effective options, although the degree of weight loss and complications may differ.¹²² Gastric bypass has been shown to produce a greater weight loss compared with gastroplasty procedures.¹²³ In addition, laparoscopic (vs. open surgical approaches) may be preferred for reducing postoperative complications and hospital stay.¹²² The mortality rate from bariatric surgery is estimated to be 0.3% to 1.9% and literature has shown that centers who perform surgeries at high volume have better outcomes.⁹⁶

Some of the complications of bariatric surgery include nausea, stomach ulceration, stenosis, anemia, and cholelithiasis. Postsurgical precautions include careful evaluation of meal sizes and timing along with meal content, especially immediately after surgery. Patients should be aware that they will not be able to resume their normal eating habits and they should be properly educated on lifestyle modifications for maintenance of weight loss. In addition, medications and adequate intake of necessary nutrients are important considerations after surgery. Medication such as nonsteroidal anti-inflammatory drugs, salicylates, and bisphosphonates may cause ulcerations and medications that are delayed- or extended-release may not be absorbed owing to changes in gastric size.¹²⁴ Medications may need to be administered using liquid formulation and other dosage routes. Transdermal formulations need to be carefully dosed to account for changes in body surface area postsurgically.¹²⁴

SUBSTANCE ABUSE

CHAPTER 83

Drug Abuse

Wendy O. Zizzo and Paolo V. Zizzo

DEFINITIONS 83-1**DRUG CULTURE 83-2****URINE SCREENING 83-2****OPIOIDS 83-3**

- Heroin 83-3
- Heroin Addiction 83-3
 - Opioid Withdrawal 83-3
 - Withdrawal From Different Opioids 83-4
- Iatrogenic Dependence 83-4
- Medical Complications 83-4
- Heroin Overdose 83-5
- Treatment of Opioid Dependence 83-5
- Substitution Pharmacotherapies for Opioid Dependence 83-5
 - Methadone Detoxification 83-5
 - Buprenorphine Detoxification 83-6
 - Maintenance Therapy 83-7
- Pain Management 83-7
- Methadone in Pregnancy 83-8
 - Withdrawal During Pregnancy 83-8
 - Neonatal Addiction 83-8
 - Breast-Feeding 83-8

- Opiate Antagonist Treatments 83-8
- Ultrarapid Opiate Detoxification 83-9
- Symptomatic Therapy of Opioid Withdrawal 83-9

SEDATIVE-HYPNOTICS 83-10

- Abstinence Syndromes Associated with Sedative-Hypnotic Dependence 83-10
- Treatment of Sedative Withdrawal 83-11
- γ -Hydroxybutyric acid 83-11

CENTRAL NERVOUS SYSTEM**STIMULANTS 83-12**

- Cocaine 83-12
 - Dosage Forms and Routes of Administration 83-12
 - Pharmacokinetics and Effects 83-12
 - Adverse Effects 83-13
 - Cocaine Addiction 83-13
 - Treatment of Addiction 83-13
- Amphetamines 83-14
 - Physical and Psychological Effects 83-14
 - Adverse Effects and Toxicities 83-14
 - Withdrawal and Treatment 83-15

DISSOCIATIVE DRUGS: PHENCYCLIDINE, KETAMINE, AND DEXTROMETHORPHAN 83-15

- Phencyclidine 83-15
 - Phencyclidine Intoxication 83-15
 - Medical Management of Intoxication 83-16
 - Psychological and Prolonged Effects 83-16

HALLUCINOGENS 83-16

- LSD 83-16
 - Effects 83-16
 - Adverse Effects 83-17
 - Flashbacks and Long-Term Effects 83-17
- MDMA 83-17
 - Effects 83-17
 - Adverse Effects 83-18
 - Long-Term Effects 83-18

MARIJUANA 83-19

- Effects 83-19
- Adverse Effects 83-19
- Long-Term Effects 83-20

INHALANTS 83-20

- Effects of Inhalants 83-21
- Acute Complications of Inhalants 83-21
- Toxicities of Inhalants 83-21
- Inhalant Abuse and Dependence 83-22

DEFINITIONS

Physical addiction or dependence occurs when repeated administration of a drug causes an altered physiologic state (neuroadaptation). Following neuroadaptation, a characteristic set of withdrawal symptoms occurs when the drug is abruptly discontinued. Psychological addiction or psychological dependence refers to a “maladaptive pattern of substance use leading to clinically significant impairment or distress.”¹ Habituation is a state of either chronic or periodic drug use characterized by a desire (but not a compulsion) to continue using the drug, no tendency to increase the dose, and an absence of physical addiction despite some degree of psychological dependence.

These conditions collectively are now thought of as addictive disease. A different clinical syndrome is associated with

each drug, but all involve a chronic process with progressive deterioration of psychological and physiologic activity secondary to the habitual use of a drug. Although the neurochemistry of the addictive process is possibly the same for all drugs, the psychosocial and pharmacokinetic aspects vary from drug to drug. Evidence, consistent with models established for alcoholism, indicates that genetically inherited traits may result in expression of addictive disease when the person is exposed to certain drugs and other habituating psychic stimuli.²

The *Diagnostic and Statistical Manual of Mental Disorders*, fourth edition (*DSM-IV*) cites criteria for substance-related disorders and divides them into two groups: the substance use disorders (including criteria for distinguishing between substance

dependence and substance abuse) and the substance-induced disorders (intoxication, withdrawal, and others).¹

DRUG CULTURE

The drug-using population has developed colloquialisms referring to specific drugs as well as many of the aspects of their drug-using lives. Clinicians encountering unfamiliar expressions should simply ask the patient to explain any terms that are not mutually understood. Most patients are surprisingly willing to describe their drug use if they trust the clinician's ability to help them.
