Level of severity is determined by both impairment and risk. Assess impairment domain by caregiver's recall of previous 2–4 weeks. Assign severity to the most severe category in which any feature occurs.

At present, there are inadequate data to correspond frequencies of exacerbations with different levels of asthma severity. For treatment purposes, patients who had ≥2 exacerbations requiring oral corticosteroids in the past 6 months, or ≥4 wheezing episodes in the past year, and who have risk factors for persistent asthma may be considered the same as patients who have persistent asthma, even in the absence of impairment levels consistent with persistent asthma.

be useful in identifying triggering allergens, but it is only of supportive value in the diagnosis of asthma.

Pulmonary Function Tests

The diagnosis of asthma is based in part on demonstration of reversible airway obstruction. A brief discussion of tests to detect reversibility of airway obstruction is important. Furthermore, a short summary of arterial blood gases (ABGs) is pertinent here in assessing the severity of asthma exacerbations.

SPIROMETRY

Lung volumes often are measured to obtain information about the size of the patient’s lungs, because pulmonary diseases can affect the volume of air that can be inhaled and exhaled. The tidal volume is the volume of air inspired or expired during normal breathing. The volume of air blown off

after maximal inspiration to full expiration is defined as the vital capacity (VC). The residual volume (RV) is the volume of air left in the lung after maximal expiration. The volume of air left after a normal expiration is the functional residual capacity (FRC). Total lung capacity (TLC) is the VC plus the RV. Patients with obstructive lung disease have difficulty with expiration; therefore, they tend to have a decreased VC, an increased RV, and a normal TLC. Classic restrictive lung diseases (e.g., sarcoidosis, idiopathic pulmonary fibrosis) present with decrements in all lung volumes.¹⁸ Patients also may have mixed lesion diseases, in which case the classic findings are not apparent until the disease has advanced considerably.

The spirometer also can be used to evaluate the performance of the patient’s lungs, thorax, and respiratory muscles in moving air into and out of the lungs. Forced expiratory maneuvers amplify the ventilation abnormalities produced. The single

most useful test for ventilatory dysfunction is the FEV. The FEV is measured by having the patient exhale into the spirometer as forcefully and completely as possible after maximal inspiration. The resulting volume curve is plotted against time (Fig. 22-3) so that expiratory flow can be estimated.

Standard spirometers contain pneumotachographs in the mouthpieces that can measure airflow directly. A number of important measures of lung function are made from the resulting flow-volume curves (Fig. 22-4). The advantages of this technique include a display of simultaneous flows at any lung volume, visual estimation of patient effort and cooperation, high reproducibility within as well as across individuals, and an analysis of the distribution of flow limitation.^{18,19} The FEV₁

of the forced vital capacity (FVC, the maximum volume of air exhaled with maximally forced effort from a position of maximal inspiration) commonly is measured to determine the dynamic performance of the lung in moving air. The FEV₁ usually is expressed as a percentage of the total volume of air exhaled and is reported as the FEV₁ to FVC ratio. Healthy persons generally can exhale at least 75% to 80% of their VC in 1 second and almost all of it in 3 seconds. Thus, the FEV₁ normally is 80% of the FVC. The patient's breathing ability is compared against "predicted normal" values for patients with similar physiologic characteristics, because lung volumes depend on age, race, gender, height, and weight. For example, an average-sized young adult male may have an FVC of 4 to

Table 22-4 Sample Questions for the Diagnosis and Initial Assessment of Asthma^a

A “yes” answer to any question suggests that an asthma diagnosis is likely.

In the past 12 months . . .

- Have you had a sudden severe episode or recurrent episodes of coughing, wheezing (high-pitched whistling sounds when breathing out), chest tightness, or shortness of breath?
- Have you had colds that “go to the chest” or take more than 10 days to get over?
- Have you had coughing, wheezing, or shortness of breath during a particular season or time of the year?
- Have you had coughing, wheezing, or shortness of breath in certain places or when exposed to certain things (e.g., animals, tobacco smoke, perfumes)?
- Have you used any medications that help you breathe better? How often?
- Are your symptoms relieved when the medications are used?

In the past 4 weeks, have you had coughing, wheezing, or shortness of breath . . .

- At night that has awakened you?
- On awakening?
- After running, moderate exercise, or other physical activity?

^aThese questions are examples and do not represent a standardized assessment or diagnostic instrument. The validity and reliability of these questions have not been assessed.

5 L and a corresponding FEV₁ of 3.2 to 4 L. The FEV₁ and the FVC are the most reproducible of the pulmonary function tests.

PEAK EXPIRATORY FLOW

The PEF is the maximal flow that can be produced during the forced expiration. The PEF can be measured easily with various

handheld peak flow meters and commonly is used in emergency departments (EDs) and clinics to quickly and objectively assess the effectiveness of bronchodilators in the treatment of acute asthma attacks. Peak flow meters also can be used at home by patients with asthma to assess chronic therapy. The changes in PEF generally parallel those of the FEV₁; however, the PEF is a less reproducible measure than the FEV₁.⁵ A healthy, average-sized young adult male typically has a PEF of 550 to 700 L/minute. Commercial peak flow meters come with a chart for patients to determine their predicted normal PEFs based on their gender, age, and height.

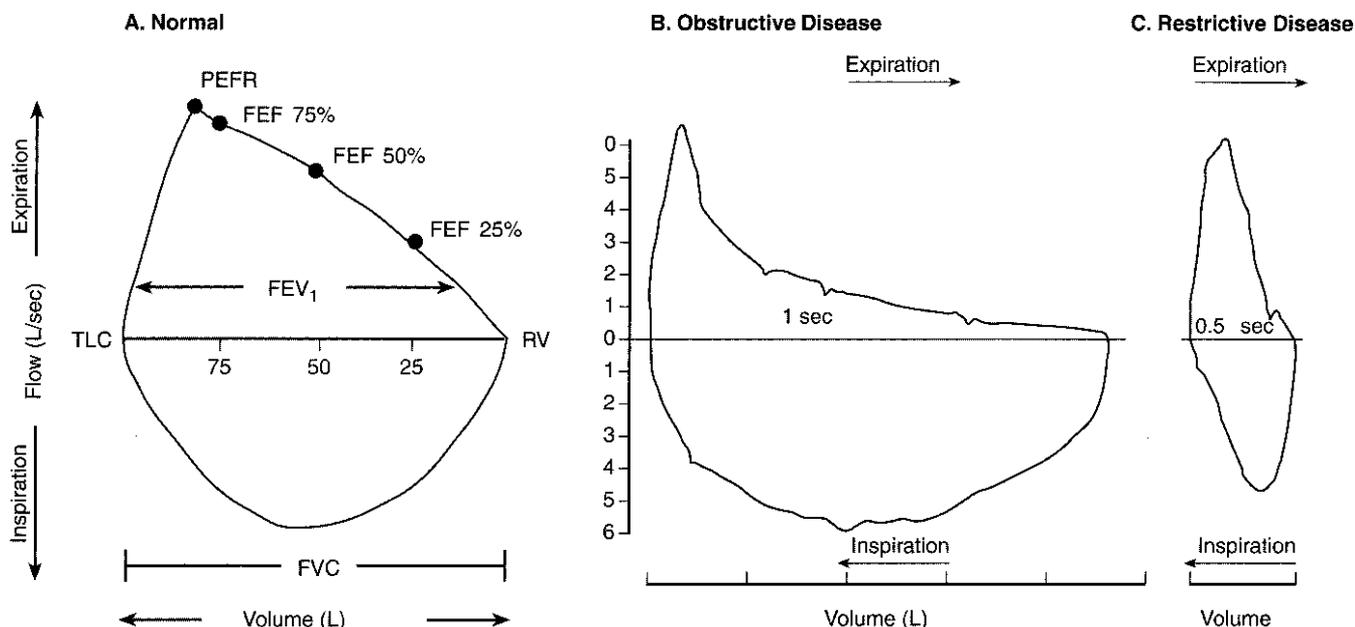

FIGURE 22-4 Flow-volume curves resulting from a forced expiratory maneuver. **A:** Normal flow-volume curve. **B:** Typical pattern for obstructive disease. **C:** Typical pattern for restrictive disease.

Obstructive versus Restrictive Airway Disease

Generally, pulmonary disorders fall into two categories: those that restrict the lungs and thorax and those that obstruct them. In simplest terms, restrictive disease limits airflow during inspiration, and obstructive disease limits airflow during expiration. Restrictive disease results from a loss of elasticity (e.g., fibrosis, pneumonia) or physical deformities of the chest (e.g., kyphoscoliosis), with a consequent inability to expand the lung and a reduced TLC. Therefore, a typical flow-volume curve (Fig. 22-4C) for a patient with restrictive disease shows markedly depressed volumes with increased flow rates (when corrected for the volume).

Whereas restrictive airway diseases limit lung expansion, obstructive airway diseases (e.g., bronchitis, asthma) narrow air passages, create air turbulence, and increase resistance to airflow. In obstructive diseases, maximal expiration may begin at higher-than-normal lung volumes, and the expiratory flow is depressed (Fig. 22-4B). Resistance to flow is increased at lower lung volumes, giving the characteristic scooped-out appearance of the obstructive flow-volume curve (Fig. 22-4B).

Reversible Airway Obstruction

Spirometry often is used to determine the reversibility of airway disease. Although many generally associate reversibility with bronchospasm, therapy can improve airflow by reversing any of the causative pathologic processes of asthma described previously. Significant clinical reversibility produced from bronchodilators is determined by the tests outlined in Figure 22-5. The FEV₁ is considered the gold standard test for determining reversibility of airway disease and bronchodilator efficacy. Significant clinical reversibility is defined as a 12% improvement in FEV₁ following administration of a short-acting bronchodilator.¹ An improvement of 20% in FEV₁ provides noticeable subjective relief of respiratory symptoms in most patients. For patients with a very low baseline FEV₁ (e.g., <1 L), an absolute improvement of 250 mL sometimes is considered a better indicator of therapeutic benefit than assessing percentage of change. In either case, the patient's subjective clinical impression also should be considered when using pulmonary function testing and drug challenges as predictors for future therapy.

LIMITATIONS OF SPIROMETRY

Because the FEV₁ and the PEF are both highly effort dependent, complete patient cooperation is required for reliable results. Therefore, spirometric tests often are unobtainable in patients who are severely ill as well as in patients who are very old or very young. The FEV₁ and PEF also are relatively insensitive to small airway changes and are therefore unable to detect early mucous plugging and inflammation in small bronchioles. Although the forced expiratory flow (FEF)_{25%-75%} is a more sensitive test of small airway obstruction, it is also much more variable, requiring larger changes (30%–40%) to be clinically significant.

Spirometric pulmonary function tests before and after administration of an inhaled bronchodilator can be useful in assessing the reversibility of airway obstruction. If significantly depressed pulmonary function tests are not reversed by the administration of a bronchodilator acutely, a 2- to 3-week trial of oral corticosteroid treatment followed by retesting might detect reversibility.¹

If pulmonary function is normal or near normal at the time of spirometric assessment, the patient can be challenged by exercise or drugs that are known to produce bronchospasm in asthmatics (e.g., aerosolized methacholine).

Blood Gas Measurements

The best indicators of overall lung function (ventilation and diffusion) are the ABGs (i.e., PaO₂, PaCO₂, and pH). Although ABG measurements also are dependent on the patient's cardiovascular status, they are indispensable in assessing both acute and chronic changes in pulmonary patients. (See Chapter 10 Acid-Base Disorders for a review of ABGs.) Another means of assessing the patient's ability to oxygenate tissues adequately is to measure oxygen saturation, which is described by the following equation:

$$\text{O}_2 \text{ saturation} = \frac{\text{Quantity of O}_2 \text{ actually bound to hemoglobin}}{\text{Quantity of O}_2 \text{ that can be bound to hemoglobin}} \times 100$$

According to this equation, oxygen saturation is the ratio between the actual amount of oxygen bound to hemoglobin

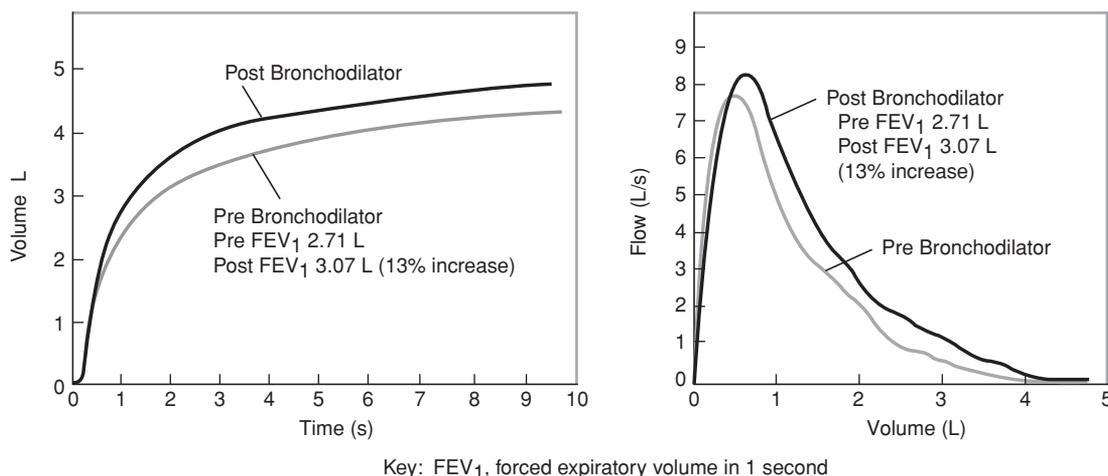

FIGURE 22-5 Interpretation of results of spirometry. The graphs depicted are for illustration only. The Interpretation of flow rates may vary with the age of the patient. (Reprinted with permission from reference 2.)

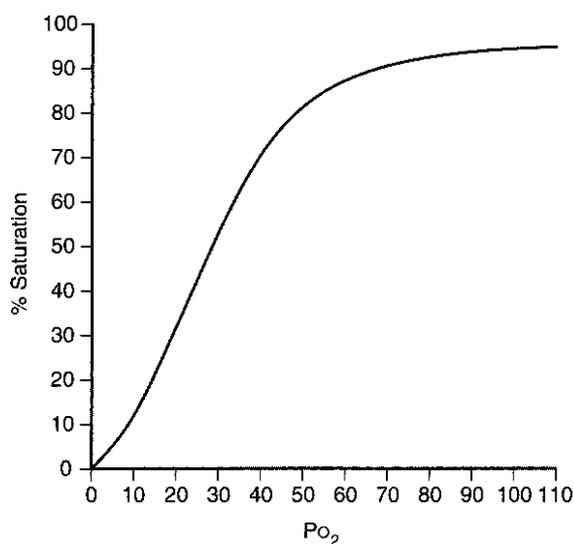

FIGURE 22-6 The oxygen dissociation curve reveals that the percent saturation of hemoglobin increases almost linearly with increases in the arterial O₂ tension until a PaO₂ of 55 to 65 mmHg is reached. At PaO₂ values above this, the increase in hemoglobin saturation becomes proportionately less and relatively little additional oxygen is added to the hemoglobin despite large increases in PaO₂. (Reproduced with permission from Guenther CA, Welch MH. *Pulmonary Medicine*. 2nd ed. Philadelphia: JB Lippincott; 1982.)

and the potential amount of oxygen that could be bound to hemoglobin at a given pressure. The denominator in the preceding equation is the oxygen capacity. The normal oxygen saturation of arterial blood at a PaO₂ of 100 mmHg is 97.5%; that of mixed venous blood at a PO₂ of 40 mmHg is about 75%.¹⁸

Oxygen saturations can be measured continuously with transcutaneous monitors. This type of monitoring (pulse oximetry) is extremely helpful in determining whether supplemental oxygen therapy is indicated in patients with various chronic respiratory diseases. At a PaO₂ of <60 mmHg, oxygen saturation begins to drop precipitously (Fig. 22-6)

Goals of Therapy

The EPR-3¹ established the following goals of therapy to achieve control of asthma:

Reduce Impairment: (a) Prevent chronic and troublesome symptoms (e.g., coughing or breathlessness in the night, in the early morning, or after exertion), (b) maintain (near) “normal” pulmonary function, (c) maintain normal activity levels (including exercise, other physical activities, and attendance at work or school), (d) require infrequent use of short-acting inhaled β₂-agonist ([SABAs], ≤2 days a week for quick relief of symptoms), and (e) meet patients’ and families’ expectations of and satisfaction with asthma care.

Reduce Risk: (a) Prevent recurrent exacerbations of asthma and minimize the need for ED visits or hospitalizations; (b) prevent progressive loss of lung function—for children, prevent reduced lung growth; and (c) provide optimal pharmacotherapy with minimal or no adverse effects.

Major Components of Long-Term Management

To achieve these goals of therapy, EPR-3¹ also outlines some general treatment principles. Asthma management has four major components, including (a) measures of asthma assessment and monitoring, (b) education for a partnership in asthma care, (c) control of environmental factors and comorbid conditions that affect asthma, and (d) medications. Optimal long-term management requires a continuous care approach, including each of these four major components, to prevent exacerbations and decrease airway inflammation. Early therapeutic interventions in managing acute exacerbations are very important in decreasing the chance of severe narrowing of the airways. Achieving the goals of asthma therapy also involves individualizing each patient’s therapy. In addition, optimal care involves establishing a “partnership” between the patient, the patient’s family, and the clinician.

For most patients with asthma, the condition can be extremely well controlled by using the step-care approach recommended by EPR-3¹ (Figs. 22-7–22-9). A concerted effort in patient education as an integral part of state-of-the-art long-term management has been demonstrated to improve outcomes, including quality of life in patients with asthma. Because of the excellent outcomes associated with optimal long-term management, if a patient requires an ED visit or hospitalization, great care should be given to determining how the acute-care visit could have been prevented.

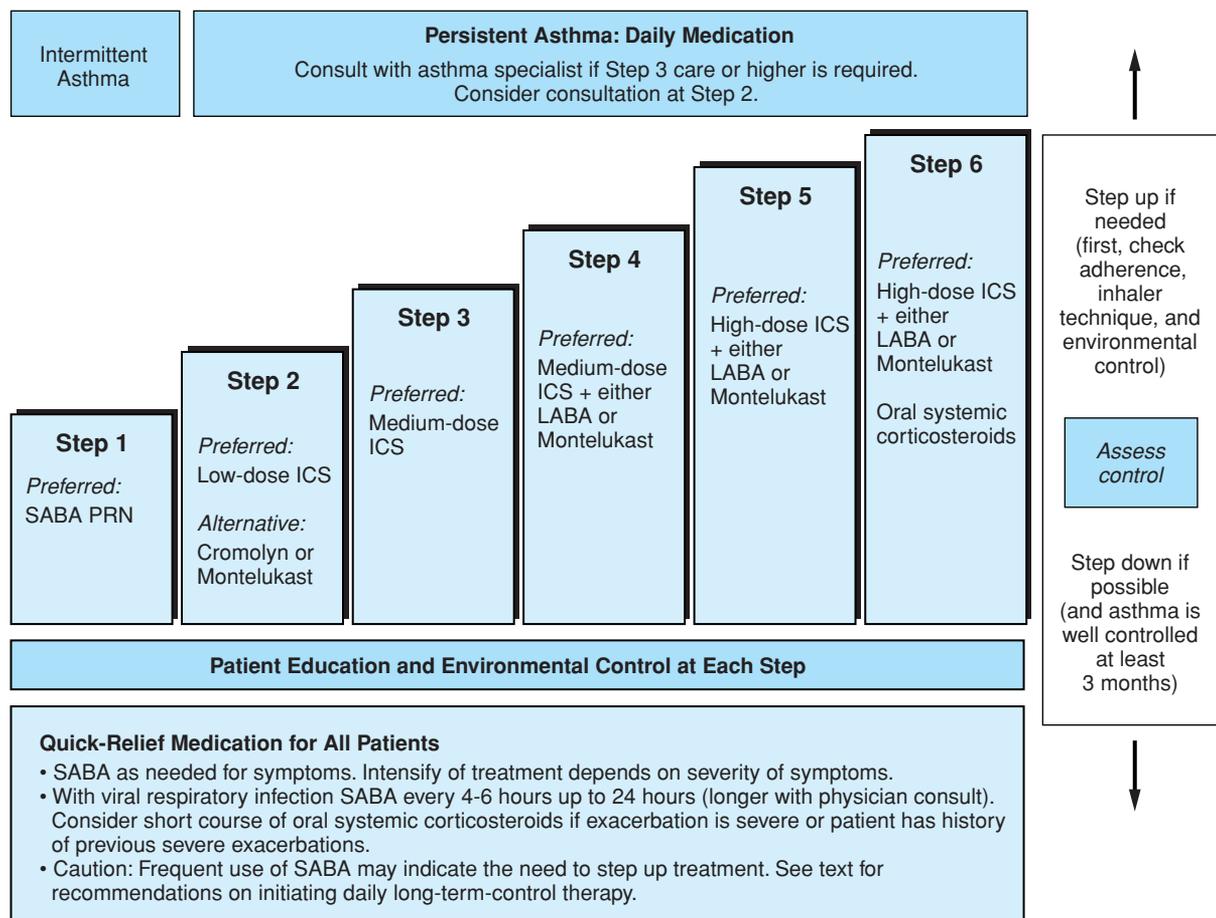

ACUTE ASTHMA

Assessment

Signs and Symptoms

1. Q.C., a 6-year-old, 20-kg girl, presents to the ED with complaints of dyspnea and coughing that have progressively worsened over the past 2 days. These symptoms were preceded by 3 days of symptoms of a viral upper respiratory tract infection (sore throat, rhinorrhea, and coughing). She has experienced several bouts of bronchitis in the last 2 years and was hospitalized for pneumonia 3 months ago. Q.C. is not being treated with any medications at present. Physical examination reveals an anxious-appearing young girl in moderate respiratory distress with audible expiratory wheezes; occasional coughing; a prolonged expiratory phase; a hyperinflated chest; and suprasternal, supraclavicular, and intercostal retractions. Bilateral inspiratory and expiratory wheezes with decreased breath sounds on the left side are heard on auscultation. Q.C.’s vital signs are as follows: respiratory rate (RR), 30 breaths/minute; blood pressure (BP), 110/83 mmHg; heart rate, 130 beats/minute; temperature, 37.8°C; and pulsus paradoxus, 18 mmHg. Her arterial oxygen saturation (SaO₂) by pulse oximetry is 90%. Q.C. is given O₂ to maintain SaO₂ >90% and 2.5 mg of albuterol by nebulizer Q 20 minutes for three doses. After the initial treatment, Q.C. claims some subjective improvement and appears to be more comfortable; however, wheezing on auscultation becomes louder. What signs and symptoms in Q.C. are consistent with acute bronchial obstruction? Does increased wheezing after albuterol indicate failure of the medication?

Asthma is an obstructive lung disease; therefore, the primary limitation to airflow occurs during expiration. This outflow obstruction leads to the classic findings of dyspnea, expiratory wheezes, and a prolonged expiratory phase during the

Key: Alphabetical order is used when more than one treatment option is listed within either preferred or alternative therapy. ICS, inhaled corticosteroid; LABA, inhaled long-acting β_2 -agonist; SABA, inhaled short-acting β_2 -agonist.

Notes:

- The stepwise approach is meant to assist, not replace, the clinical decisionmaking required to meet individual patient needs.
- If alternative treatment is used and response is inadequate, discontinue it and use the preferred treatment before stepping up.
- If clear benefit is not observed within 4–6 weeks and patient/family medication technique and adherence are satisfactory, consider adjusting therapy or alternative diagnosis.
- Studies on children 0–4 years of age are limited. Step 2 preferred therapy is based on Evidence A. All other recommendations are based on expert opinion and extrapolation from studies in older children.

FIGURE 22-7 Stepwise approach for managing asthma in children 0–4 years of age. (Reproduced with permission from reference 1.)

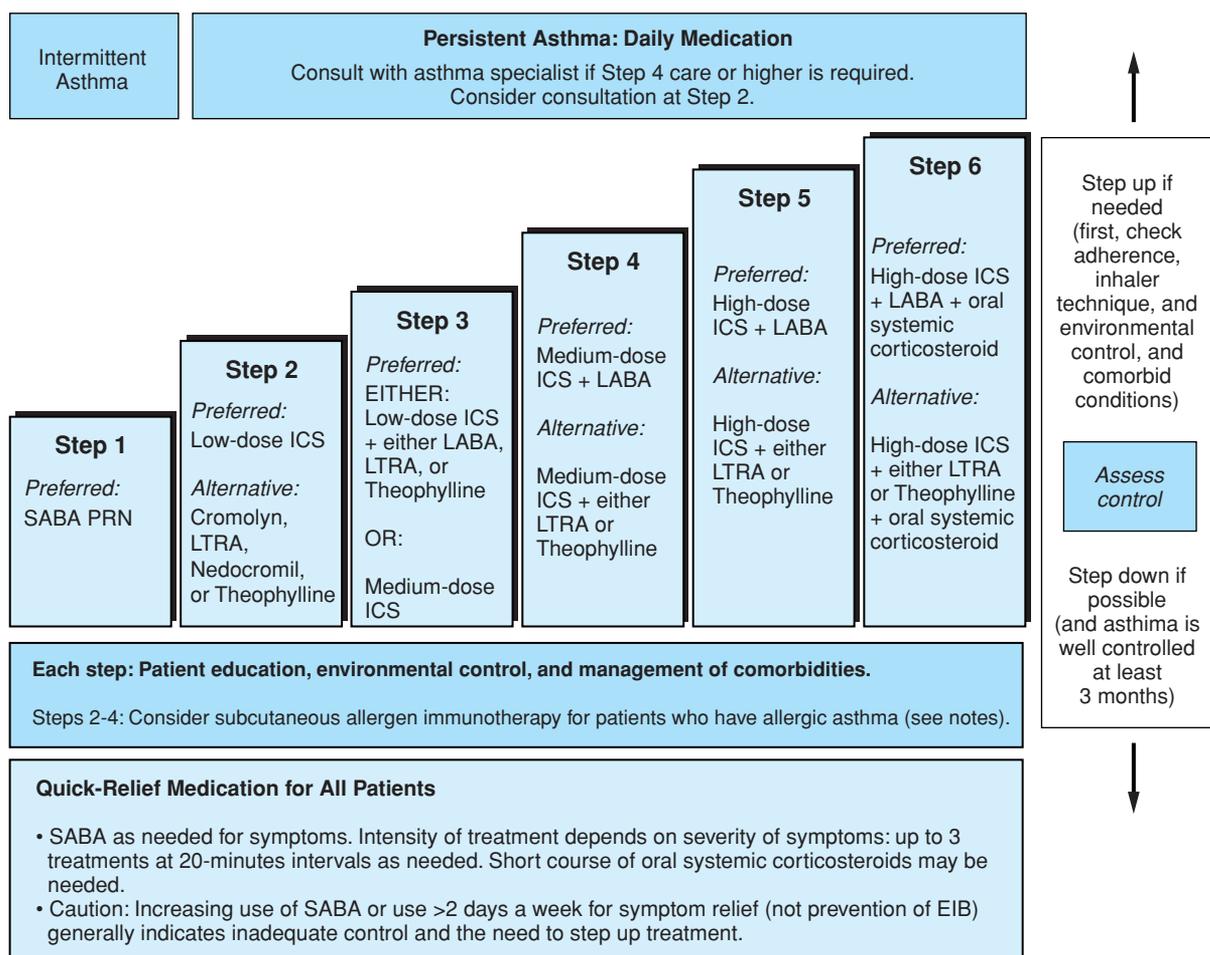

ventilatory cycle.¹ Wheezing is a whistling sound produced by turbulent airflow through a constricted opening and usually is more prominent on expiration. Thus, the audible expiratory wheezing in Q.C. is compatible with bronchial obstruction. In fact, Q.C.'s obstruction is so severe that even inspiratory wheezes and decreased air movement were detected on auscultation. It is important to realize that the classic symptom of wheezing requires turbulent airflow; therefore, effective therapy of acute asthma actually may result in increased wheezing initially as airflow increases throughout the lung. As a result, Q.C.'s increased wheezing on auscultation is compatible with her clinical improvement following the albuterol nebulizer treatments.

The coughing experienced by Q.C. is another common finding associated with acute asthma attacks. The coughing may be due to stimulation of "irritant receptors" in the bronchi by the

chemical mediators of inflammation (e.g., leukotrienes) that are released from mast cells or to the mechanics of smooth muscle contraction.

In the progression of an asthma attack, the small airways become completely occluded during expiration, and air can be trapped behind the occlusion; therefore, the patient has to breathe at higher-than-normal lung volumes.¹ Consequently, the thoracic cavity becomes hyperexpanded, and the diaphragm is lowered. As a result, the patient must use the accessory muscles of respiration to expand the chest wall. Q.C.'s hyperinflated chest and her use of suprasternal, supraclavicular, and intercostal muscles to assist in breathing also are compatible with obstructive airway diseases.

Occlusion of the small airways, air trapping, and resorption of air distal to the obstruction can lead to atelectasis (incomplete expansion or collapse of pulmonary alveoli or

Key: **Alphabetical order is used when more than one treatment option is listed within either preferred or alternative therapy.** ICS, inhaled corticosteroid; LABA, inhaled long-acting β_2 -agonist, LTRA, leukotriene receptor antagonist; SABA, inhaled short-acting β_2 -agonist

Notes:

- The stepwise approach is meant to assist, not replace, the clinical decisionmaking required to meet individual patient needs.
- If alternative treatment is used and response is inadequate, discontinue it and use the preferred treatment before stepping up.
- Theophylline is a less desirable alternative due to the need to monitor serum concentration levels.

FIGURE 22-8 Stepwise approach for managing asthma in children 5–11 years of age. (Reproduced with permission from reference 1.)

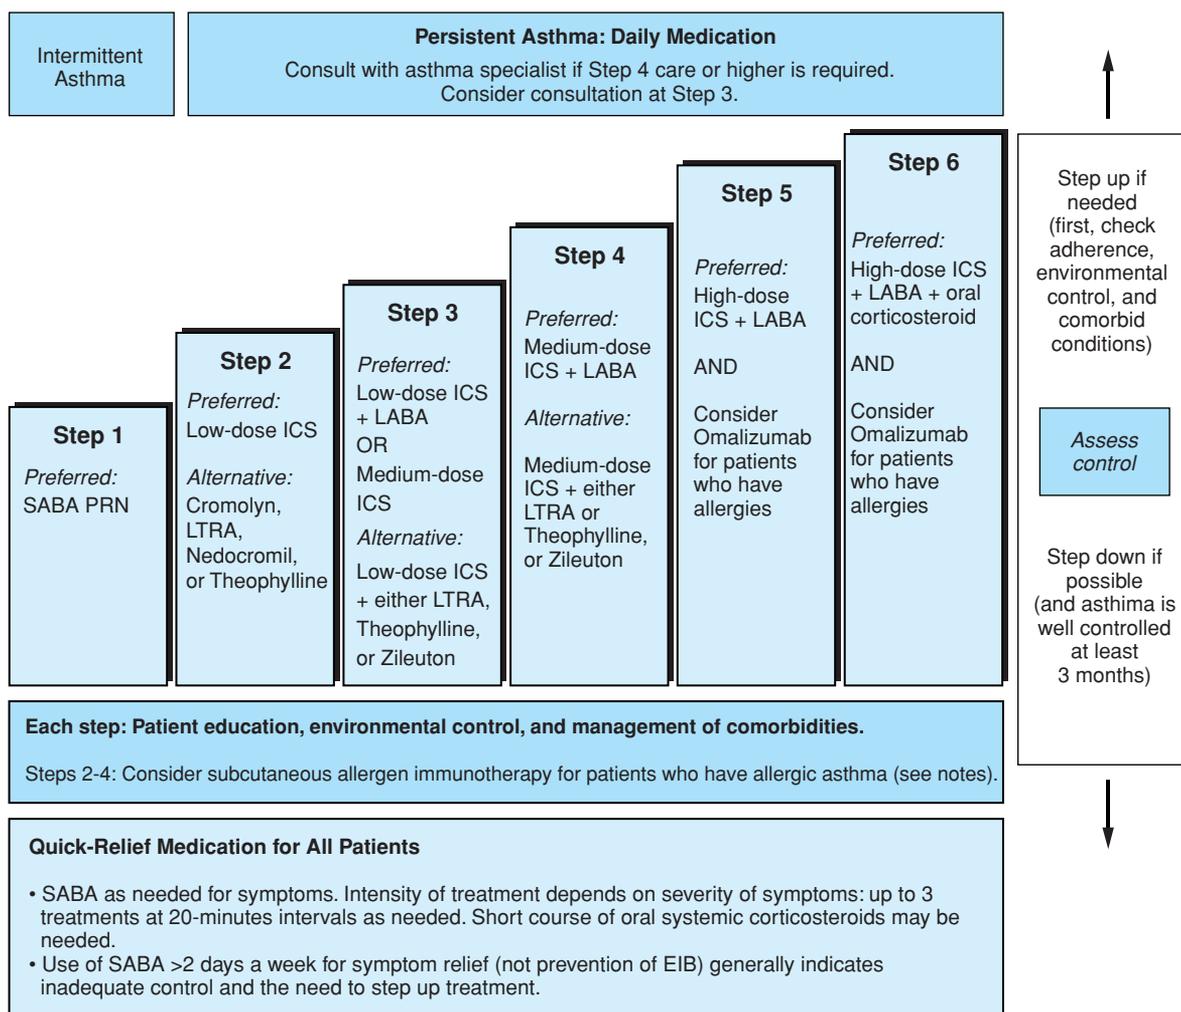

of a segment of lobe of the lung). Localized areas of atelectasis often are difficult to distinguish from infiltrates on a chest radiograph, and atelectasis can be mistaken for pneumonia.

Q.C.'s history of multiple bouts of "bronchitis" is significant and typical of many young asthmatics. In any patient with recurring episodes of bronchial symptoms (i.e., bronchitis, pneumonia), the possible diagnosis of asthma should be investigated.

The increased pulse, RR, and anxiety experienced by Q.C. can be attributed both to hypoxemia and the feeling of suffocation. The hypoxemia in acute asthma is due principally to an imbalance between alveolar ventilation and pulmonary capillary blood flow, also known as ventilation-perfusion (\dot{V}/\dot{Q}) mismatching.²⁰ Each alveolus of the lung is supplied with capillaries from the pulmonary artery for gas exchange. When ventilation is decreased to an area of the lung, the alveoli in

that area become hypoxic, and the pulmonary artery to that region constricts as a normal physiologic response. As a result, blood flow is shunted to the well-ventilated portions of the lung because of the need to preserve adequate oxygenation of the blood. The pulmonary arteries, however, are not constricted completely, and when a small amount of blood flows to the poorly ventilated alveoli, mismatching is the result. Conditions of diffuse bronchial obstruction (i.e., acute asthma) increase the amount of mismatching. In addition, some mediators of acute bronchospasm (e.g., histamine) further worsen mismatching by constricting bronchial smooth muscle while concurrently relaxing vascular smooth muscle.

Q.C. also demonstrated a significant pulsus paradoxus. *Pulsus paradoxus* is defined as a drop in systolic BP of > 10 mmHg with inspiration. In general, pulsus paradoxus correlates with the severity of bronchial obstruction; however, it is not always present.²⁰

Key: **Alphabetical order is used when more than one treatment option is listed within either preferred or alternative therapy.** EIB, exercise-induced bronchospasm; ICS, inhaled corticosteroid; LABA, long-acting inhaled β_2 -agonist; LTRA, leukotriene receptor antagonist; SABA, inhaled short-acting β_2 -agonist

Notes:

- The stepwise approach is meant to assist, not replace, the clinical decisionmaking required to meet individual patient needs.
- If alternative treatment is used and response is inadequate, discontinue it and use the preferred treatment before stepping up.
- Zileuton is a less desirable alternative due to limited studies as adjunctive therapy and the need to monitor liver function. Theophylline requires monitoring of serum concentration levels.
- In step 6, before oral systemic corticosteroids are introduced, a trial of high-dose ICS + LABA + either LTRA, theophylline, or zileuton may be considered, although this approach has not been studied in clinical trials.

FIGURE 22-9 Stepwise approach for managing asthma in youth ≥ 12 years of age and adults. (Reproduced with permission from reference 1.)

Extent of Obstruction

2. What additional tests would be helpful in assessing the extent of pulmonary obstruction in Q.C.?

Chest radiographs are not recommended routinely but should be obtained in patients who are suspected of a complication (e.g., pneumonia).¹ Hyperinflated lungs and areas of atelectasis can be seen on a chest x-ray film; however, chest x-ray studies usually are negative and of little value in evaluating acute asthma attacks. The finding of a local decrease in breath sounds in Q.C.'s left lung may justify the need for a chest x-ray study, particularly if a significant differential in air movement persists after initial therapy. A local decrease in

breath sounds may indicate pneumonia, aspiration of a foreign object, pneumothorax, or merely thickened mucous plugging of a large bronchus.

Pulmonary function testing (e.g., FEV₁, PEF) provides objective measurement of the degree of airway obstruction. Peak flow meters are helpful in the ED for assessing both the severity of airway obstruction and the response to bronchodilator therapy. Unfortunately, infants and many young children do not have the cognitive or motor skills necessary to perform pulmonary function tests. EPR-3 points out that in one study, only 65% of children 5 to 16 years of age could complete either FEV₁ or PEF during an acute exacerbation. Because of Q.C.'s initial anxiety, the PEF should be measured after

bronchodilator therapy has been initiated when she may be calmer. One disadvantage of pulmonary function tests in acute asthma is that the forced expiratory maneuver commonly triggers coughing. ABG measurements are the gold standard for assessing very severe airway obstruction.²¹ EPR-3¹ suggests ABGs for evaluation of PCO₂ in patients who have suspected hypoventilation, severe distress, or FEV₁ or PEF <25% of predicted after initial treatment. However, in less severe exacerbations, ABG measurements are unnecessary if other objective measures of airway obstruction (e.g., pulmonary function tests) have been monitored.¹ In acute asthma, ABG determinations usually indicate hypoxemia because of mismatching and hypocapnia with respiratory alkalosis because of hyperventilation.²¹ The degree of hypoxemia correlates with the severity of obstruction. Severe hypoxemia (PO₂ <50 mmHg) that is associated with an FEV₁ <15% of predicted represents very severe airway obstruction.^{20,21} Likewise, when the FEV₁ is <25% of the predicted value, carbon dioxide increasingly is retained and the PCO₂ begins to rise into the usual normal range.¹ Because of mismatching and the ease of correction of hypoxemia with oxygen therapy, the PCO₂ is the more sensitive indicator of ventilation abnormalities in acute asthma with prolonged or chronic airway obstruction; carbon dioxide retention (hypercapnia) and respiratory acidosis are prominent. ABG measurements are indicated in patients who fail to respond adequately to initial therapy or in patients requiring hospitalization; they are not indicated at this time for Q.C. A repeat pulse oximetry at 1 hour after treatment initiation is warranted in Q.C. to ensure adequate arterial oxygen saturation.

Need for Hospitalization

3. Q.C. may require hospitalization. Which clinical test is predictive of the need for admission or whether Q.C. will relapse if sent home from the ED? Are Q.C.'s signs and symptoms predictive of whether she will relapse and return to the ED if not hospitalized?

The most useful predictive tool is the FEV₁ or PEF response to initial treatment. Patients who do not improve to at least 40% of predicted FEV₁ or PEF after initial intensive therapy are more likely to require hospitalization.¹ Although Q.C. is not able to perform spirometry, she is able to execute the PEF maneuver, and the plan is to check her PEF after 1 hour of therapy. Signs and symptom scores alone are not adequate to predict outcome of ED treatment of asthma, but scores along with pulse oximetry and PEF or FEV₁ are helpful predictors.¹

Short-Acting Inhaled β -Adrenergic Agonist Therapy

Short-Acting Inhaled β -Agonists Compared With Other Bronchodilators

4. Why was a SABA selected as the bronchodilator of first choice in preference to other bronchodilators such as aminophylline or ipratropium for Q.C.?

Because of their potency and rapidity of action, inhaled β_2 -agonists are considered the first choice for the treatment of acute asthma.¹⁻⁵ The bronchodilatory properties of SABAs are particularly effective in reversing early-phase asthma responses. Aminophylline (a theophylline salt) is not as efficacious and has more risks for serious adverse effects than inhaled albuterol.¹⁻⁵ Similarly, the bronchodilation from the anti-

cholinergic drug ipratropium is of smaller magnitude than with short-acting inhaled β_2 -agonists.¹⁻⁵ However, two double-blind pediatric trials found that the sickest children had a reduced rate of hospitalization if given ipratropium with albuterol in the ED.^{22,23} In one trial,²² children with baseline FEV₁ <30% of predicted value had a reduced rate of admission with ipratropium, and in the other trial,²³ children with baseline PEF <50% had a reduced rate of hospital admission. Consequently, although early addition of inhaled ipratropium in adequate doses to SABAs will improve pulmonary function tests and reduce the rate of hospitalization in severely ill patients, Q.C.'s physician chose to use only inhaled short-acting β_2 -agonists initially because Q.C. was not severely ill.

Preferred Routes of Administration

5. What is the preferred route of administration for short-acting bronchodilators?

It is well documented that SABAs administered by the inhaled route provide as great or greater bronchodilation with fewer systemic side effects than either the parenteral or oral routes.¹⁻⁶ In situations of acute bronchospasm, concerns over adequate penetration of aerosols into the bronchial tree led many clinicians to believe that the parenteral route of administration would be more effective than the inhaled route of administration. In clinical trials, however, SABAs were as effective as the standard treatment of subcutaneous epinephrine for ED treatment of acute asthma in adults and children.^{1-6,24} Therefore, short-acting aerosolized β_2 -agonists now are considered the agents of choice for ED or hospital management of asthma.¹ β_2 -Agonists should not be administered orally to treat acute episodes of severe asthma because of the slow onset of action, lower efficacy, and erratic absorption.¹

6. Q.C. received albuterol by nebulization. Would intermittent positive-pressure breathing (IPPB) or metered-dose aerosol administration of the SABA have been preferred? Is the dose given by nebulization the same as that given by a metered-dose inhaler (MDI)?

Aerosols are mixtures of particles (e.g., a drug-lipid mixture) suspended in a gas. An MDI consists of an aerosol canister and an actuation device (valve). The drug in the canister is a suspension or solution mixed with propellant. The valve controls the delivery of drug and allows the precise release of a premeasured amount of the product (Fig. 22-10). A second aerosol device, the air jet nebulizer, mechanically produces a mist of drug. The drug is placed in a small volume of solute (typically 3 mL of saline) and then placed in a small reservoir (nebulizer) connected to an air source such as a small compressor pump, oxygen tank, or wall air hose. Air travels from the relatively large-diameter tubing of the air source into a pinhole-sized opening in the nebulizer. This creates a negative pressure at the site of the air entry and causes the drug solution in the bottom of the nebulizer reservoir to be drawn up through a small capillary tube where it then encounters the rapid airflow. The drug solution is forced against a small baffle that causes mechanical formation of a mist (Fig. 22-11). IPPB devices aerosolize drugs in a similar manner as air jet nebulizers except that the airflow that exits the nebulizer in an IPPB device is enhanced to exceed atmospheric pressure. An ultrasonic nebulizer is a type of nebulizer that uses sound waves to generate the aerosol.

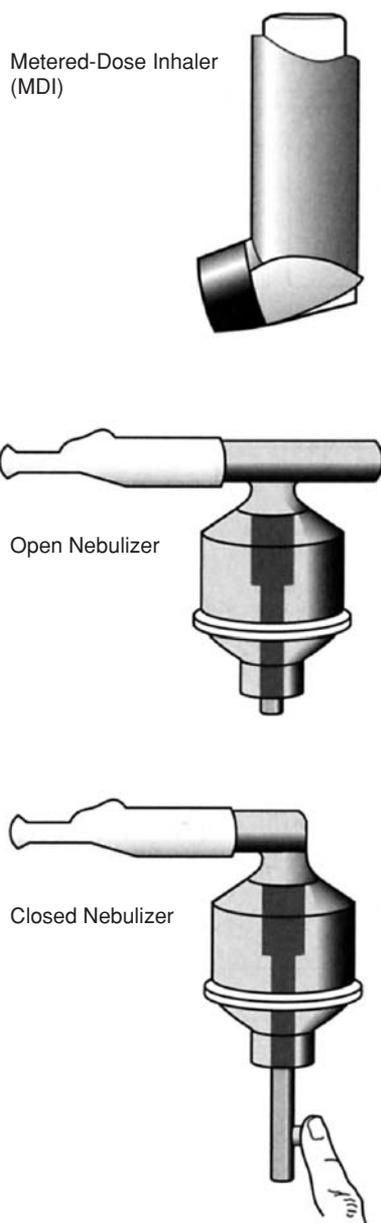

FIGURE 22-10 Metered-dose inhaler and nebulizer.

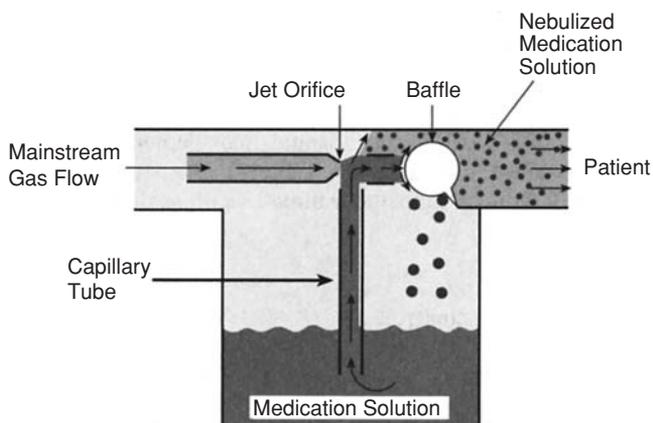

FIGURE 22-11 Air jet nebulizer.

Studies comparing responses to SABAs administered by nebulization versus IPPB have shown no significant advantages for the IPPB method of administration.⁵ Furthermore, dose-response studies that compared nebulization with IPPB and pressurized metered-dose aerosols in stable chronic asthma patients have shown no advantage among these methods of administration when equivalent doses are administered.^{5,25,26} Each method delivers approximately 10% of the beginning dose to the patient's airways.²⁷ Trials comparing metered-dose aerosols of short-acting inhaled β_2 -agonists with the nebulization of those same drugs in acute asthma also have shown no significant advantage for the nebulization method of administration when the metered-dose aerosolized administration was carefully supervised by experienced personnel and a spacer device was used.^{28,29} However, in some younger acutely ill children, it is difficult (even with supervision) to administer an effective SABA with a metered-dose canister. Because many patients and clinicians *perceive* that nebulizers provide more intensive therapy, it often is important psychologically to give at least the first dose of a SABA via a nebulizer. Thereafter, it is more cost-effective to use the therapeutically equivalent MDI plus spacer.³⁰

The dose ratio for SABAs delivered by MDI plus spacer versus nebulizer has varied in the literature. For children with mild acute asthma, 2 puffs of albuterol MDI attached to a spacer were not different from 6 to 10 puffs of albuterol or via nebulizer 0.15 mg/kg.³¹ In one double-blind trial in children with a severe exacerbation, investigators used a dose ratio of 1:5 (i.e., albuterol MDI-spacer 1 mg [10 puffs]: nebulized albuterol 5 mg).³² Nebulization of albuterol with compressed air or, preferably, oxygen was the preferred method of administration for Q.C. initially.

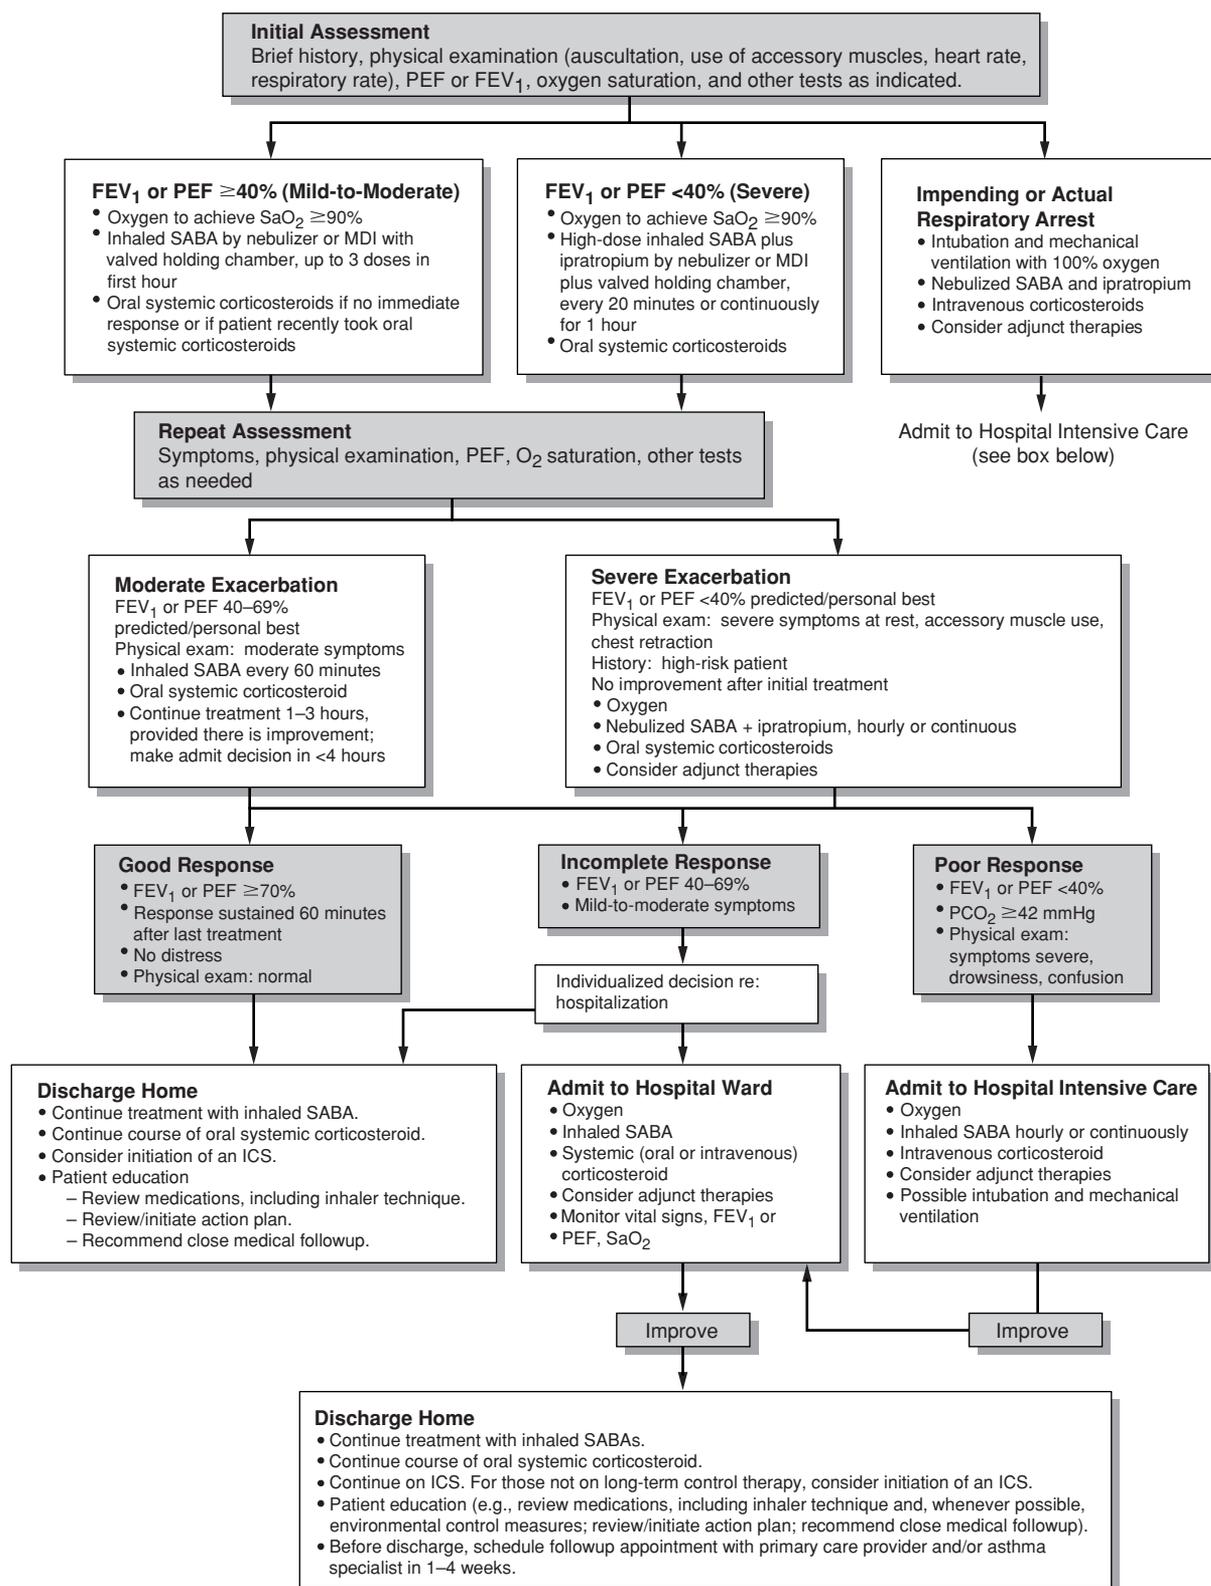

DOSING

7. Starting 20 minutes after the first albuterol dose, two more doses of 2.5 mg of albuterol were administered by nebulizer Q 20 minutes over the next 40 minutes. After three treatments, Q.C.'s breath sounds became increasingly clear. She was no longer in distress and could speak in complete sentences. Her PEF was now 70% of predicted, her SaO₂ was 97% on room air, and discharge to home was planned. Were the dose and dosing interval of albuterol appropriate for Q.C.?

Schuh et al.³³ demonstrated that a higher-dose albuterol regimen (0.15 mg/kg vs. 0.05 mg/kg every 20 minutes) produced significantly greater improvement with no greater incidence of adverse effects. Schuh et al.³⁴ subsequently reported greater efficacy of albuterol in a dose of 0.3 mg/kg (up to 10 mg) hourly over a dose of 0.15 mg/kg (up to 5 mg) hourly in children. The larger dose was tolerated as well as the 0.15 mg/kg dose. Therefore, Q.C.'s albuterol regimen of 2.5 mg (0.13 mg/kg) nebulized every 20 minutes for 40 minutes subsequent to her first dose of aerosolized albuterol could have been even more aggressive but was appropriate. Figure 22-12 and Table 22-5 list the doses for inhaled β -agonists for acute asthma as well as doses of other medications.¹

COMPARISON OF SHORT-ACTING INHALED β_2 -AGONISTS

8. Would another SABA have been more effective in the initial therapy of Q.C.?

Key: FEV₁, forced expiratory volume in 1 second; ICS, inhaled corticosteroid; MDI, metered dose inhaler; PCO₂, partial pressure carbon dioxide; PEF, peak expiratory flow; SABA, short-acting β₂-agonist; SaO₂, oxygen saturation

FIGURE 22-12 Management of asthma exacerbations: emergency department and hospital-based care. (Reprinted with permission from reference 1.)

Table 22-5 Dosages of Drugs for Asthma Exacerbations

| Medication | Dosages | | Comments |
|---|---|---|---|
| | Child Dose ^a | Adult Dose | |
| Inhaled Short-Acting β_2-Agonists | | | |
| Albuterol | | | |
| Nebulizer solution (0.63 mg/3 mL, 1.25 mg/3 mL, 2.5 mg/3 mL, 5.0 mg/mL) | 0.15 mg/kg (minimum dose 2.5 mg) every 20 min for 3 doses, then 0.15–0.3 mg/kg up to 10 mg every 1–4 hr as needed or 0.5 mg/kg/hr by continuous nebulization. | 2.5–5 mg every 20 min for 3 doses, then 2.5–10 mg every 1–4 hr as needed or 10–15 mg/hr continuously. | Only selective β_2 -agonists are recommended. For optimal delivery, dilute aerosols to minimum of 3 mL at gas flow of 6–8 L/min. Use large volume nebulizers for continuous administration. May mix with ipratropium nebulizer solution. |
| MDI (90 mcg/puff) | 4–8 puffs every 20 min for 3 doses, then every 1–4 hr inhalation maneuver as needed. Use VHC; add mask in children <4 yr. | 4–8 puffs every 20 min up to 4 hr, then every 1–4 hr as needed. | In mild to moderate exacerbations, MDI plus VHC is as effective as nebulized therapy with appropriate administration technique and coaching by trained personnel. |
| Levalbuterol (R-albuterol) | | | |
| Nebulizer solution (0.63 mg/3 mL, 1.25 mg/0.5 mL, 1.25 mg/3 mL) | 0.075 mg/kg (minimum dose 1.25 mg) every 20 min for 3 doses, then 0.075–0.15 mg/kg up to 5 mg every 1–4 hr as needed. | 1.25–2.5 mg every 20 min for 3 doses, then 1.25–5 mg every 1–4 hr as needed. | Levalbuterol administered in one half the mg dose of albuterol provides comparable efficacy and safety. Has not been evaluated by continuous nebulization. |
| MDI (45 mcg/puff) | See albuterol MDI dose. | See albuterol MDI dose. | |
| Pirbuterol | | | |
| MDI (200 mcg/puff) | See albuterol MDI dose; thought to be half as potent as albuterol on a milligram basis. | See albuterol MDI dose. | Has not been studied in severe asthma exacerbations. |
| Systemic (Injected) β_2-Agonists | | | |
| Epinephrine 1:1,000 (1 mg/mL) | 0.01 mg/kg up to 0.3–0.5 mg every 20 min for 3 doses subcutaneously | 0.3–0.5 mg every 20 min for 3 doses subcutaneously | No proven advantage of systemic therapy over aerosol. |
| Terbutaline (1 mg/mL) | 0.01 mg/kg every 20 min for 3 doses, then every 2–6 hr as needed subcutaneously | 0.25 mg every 20 min for 3 doses subcutaneously | No proven advantage of systemic therapy over aerosol. |
| Anticholinergics | | | |
| Ipratropium bromide | | | |
| Nebulizer solution (0.25 mg/mL) | 0.25–0.5 mg every 20 min for 3 doses, then as needed. | 0.5 mg every 20 min for 3 doses, then as needed. | May mix in same nebulizer with albuterol. Should not be used as first-line therapy; should be added to SABA therapy for severe exacerbations. The addition of ipratropium has not been shown to provide further benefit once the patient is hospitalized. |
| MDI (18 mcg/puff) | 4–8 puffs every 20 min as needed up to 3 hr. | 8 puffs every 20 min as needed up to 3 hr. | Should use with VHC and face mask for children <4 yr. Studies have examined ipratropium bromide MDI for up to 3 hr. |
| Ipratropium with albuterol | | | |
| Nebulizer solution (Each 3 mL vial contains 0.5 mg ipratropium bromide and 2.5 mg albuterol.) | 1.5 mL every 20 min for 3 doses, then as needed. | 3 mL every 20 min for 3 doses, then as needed. | May be used for up to 3 hr in the initial management of severe exacerbations. The addition of ipratropium to albuterol has not been shown to provide further benefit once the patient is hospitalized. |
| MDI (Each puff contains 18 mcg ipratropium bromide and 90 mcg albuterol.) | 4–8 puffs every 20 min as needed up to 3 hr. | 8 puffs every 20 min as needed up to 3 hr. | Should use with VHC and face mask for children <4 yr. |

(continued)

Table 22-5 Dosages of Drugs for Asthma Exacerbations (Continued)

| Medication | Child Dose ^a | Adult Dose | Comments |
|---|---------------------------------------|--|---|
| Systemic Corticosteroids | | | |
| (Applies to all three corticosteroids.) | | | |
| <i>Prednisone</i> | 1 mg/kg in 2 divided doses | 40–80 mg/day in 1 or 2 | For outpatient “burst,” use 40–60 mg in single or 2 divided doses for total of 5–10 days in adults (children: 1–2 mg/kg/day maximum 60 mg/day for 3–10 days). |
| <i>Methyl prednisolone</i> | (maximum = 60 mg/day) until PEF | divided doses until PEF | |
| <i>Prednisolone</i> | is 70% of predicted or personal best. | reaches 70% of predicted or personal best. | |

^aChildren, 12 yr of age.

MDI, metered-dose inhaler; PEF, peak expiratory flow; SABA, short-acting β_2 -agonist; VHC, valved holding chamber
Reprinted from reference 1.

Short-acting β_2 -specific agonists (e.g., albuterol) are preferred over nonspecific agonists (e.g., isoproterenol). Long-acting β_2 -agonists (e.g., salmeterol) are not indicated for treatment of asthma in the ED. Levalbuterol (R-albuterol) became available in the late 1990s, but further study is needed to determine whether this single isomer, higher-potency drug offers any clinically significant advantages (i.e., improved outcomes) over racemic albuterol to justify its higher cost.^{1,35}

Systemic Corticosteroids in the Emergency Department for Children

9. Should Q.C. receive corticosteroid therapy as part of her ED management?

Yes. Because asthma is primarily an inflammatory airway disease, the degree of inflammation associated with Q.C.'s current exacerbation should be considered. Per EPR-3¹ (Fig. 22-12), if there is not an immediate response to inhaled β_2 -agonist therapy, oral systemic corticosteroids should be administered (refer to further discussion of this subject in Questions 14 and 15). Furthermore, if Q.C. had a peak flow meter at home, earlier objective detection of the development of this exacerbation might have prevented an ED visit. When the PEF is in the red zone (<50% of personal best) and poorly responsive to SABAs, early intervention with oral corticosteroids is associated with a reduction in ED visits¹ (Fig. 22-13; refer to the Outcomes section at the end of the chapter). Q.C. and her parents should also understand that if respiratory distress is severe and nonresponsive to treatment, they should proceed to an ED or call 911. Finally, before going home from the ED, Q.C. and her parents should receive some basic education regarding asthma and its acute and long-term management. It is important to follow-up with more detailed education during future clinic visits. Based on EPR-3,¹ Q.C. should receive a short course of systemic corticosteroids as part of her discharge plan, thereby reducing her risk of re-exacerbation. Typically, oral prednisolone solution at a dose of 1 to 2 mg/kg in daily or divided doses twice daily is given for approximately 5 to 7 days. While this regimen is very effective, to improve compliance, several studies have examined shorter (1–2 day) courses of oral or intramuscular dexamethasone and have found similar results when compared with usual regimens of oral prednisone/prednisolone.^{36–38}

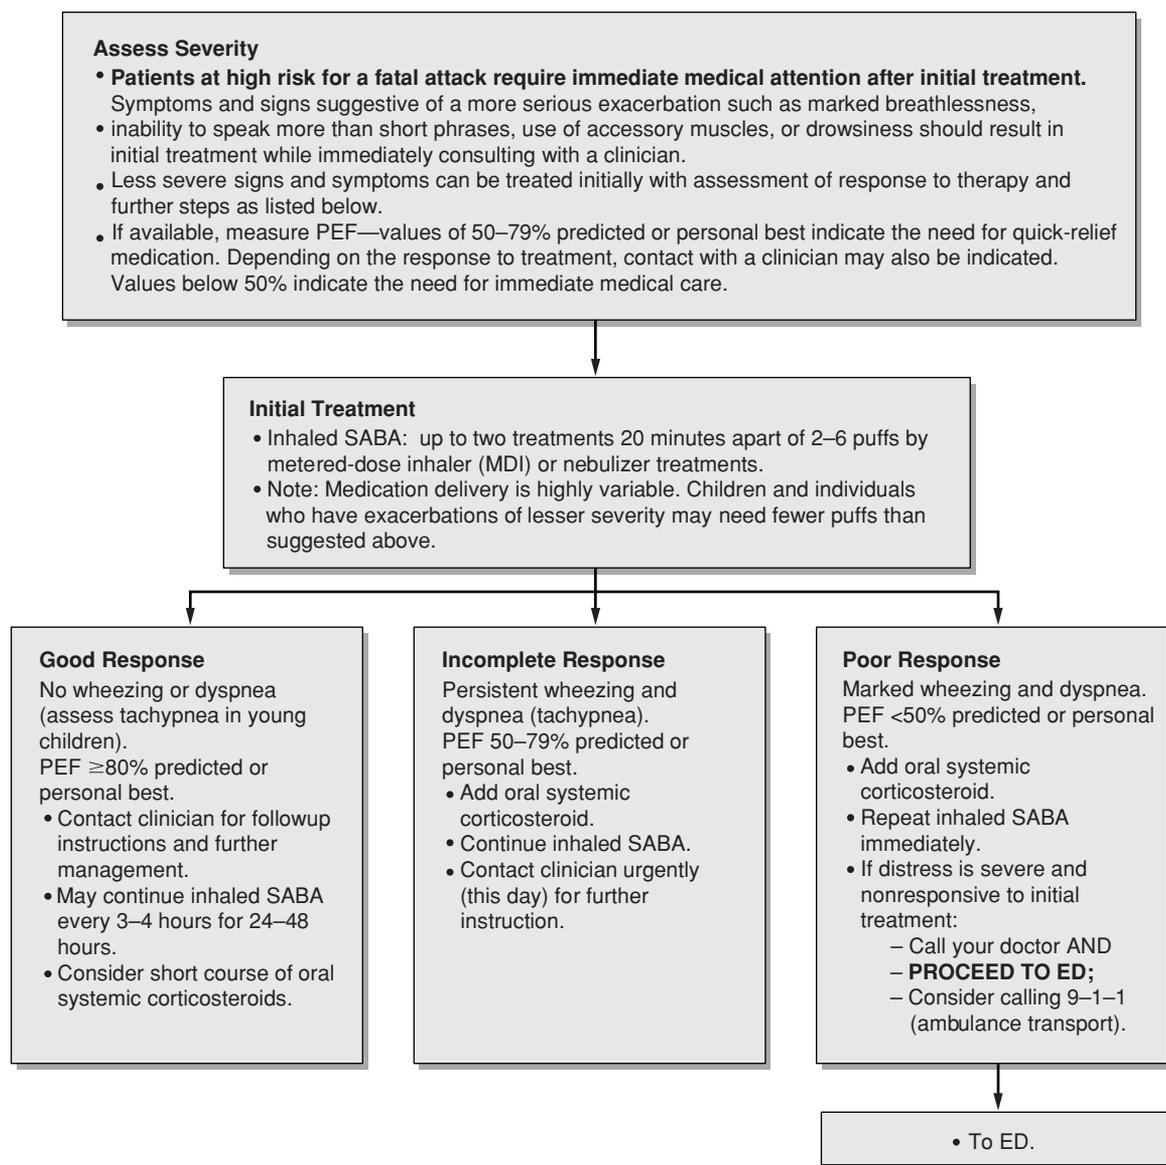

ADVERSE EFFECTS

10. H.T., a 45-year-old, 91-kg man with a long history of severe persistent asthma, presents to the ED with severe dyspnea and wheezing. He is able to say only two or three words without taking

a breath. He has been taking four inhalations of beclomethasone HFA (80 mcg/puff) BID and two inhalations of albuterol MDI QID PRN on a chronic basis. H.T. ran out of beclomethasone a week ago; since then, he has been using his albuterol MDI with increasing frequency up to Q 3 hr on the day before admission. He is a lifelong nonsmoker. His FEV₁ was 25% of the predicted value for his age and height, and his SaO₂ was 82%. Vital signs are as follows: heart rate, 130 beats/minute; RR, 30/minute; pulsus paradoxus, 18 mmHg; and BP, 130/90 mmHg. ABGs on room air were as follows: pH, 7.40; PaO₂, 55 mmHg; and PaCO₂, 40 mmHg. Serum electrolyte concentrations were sodium (Na), 140 mEq/L; potassium (K), 4.1 mEq/L; and chloride (Cl), 105 mEq/L. Because of the severity of the obstruction, H.T. was monitored with an electrocardiogram (ECG) that showed sinus tachycardia with occasional premature ventricular contractions (PVCs). Terbutaline 0.5 mg SC was administered with minimal improvement. H.T. then was started on O₂ at 4 L/minute by nasal cannula, followed by another injection of 0.5 mg terbutaline SC. Subsequently, H.T.'s heart rate increased to 145 beats/minute, more PVCs appeared on the ECG, and he complained of palpitations and shakiness. His PEF was now 25% of personal best. Laboratory values were pH, 7.39; PaO₂, 60 mmHg; PaCO₂, 42 mmHg; Na, 138 mEq/L; and K, 3.5 mEq/L. What adverse effects experienced by H.T. are consistent with systemic β_2 -agonist administration?

H.T. experienced palpitations, which may have been due to the widening of his pulse pressure from vasodilation or the PVCs.³ Albuterol, terbutaline, and all other β -agonists are cardiac stimulants that may cause tachycardia and, very rarely, arrhythmias. Because they are relatively β_2 -specific, the cardiac effects are more prominent with systemic administration (as opposed to inhalation) and at higher dosages. However, other causes of cardiac effects must also be considered, such as hypoxemia, which is also a potent stimulus for cardiac arrhythmias. Therefore, H.T.'s tachycardia and PVCs may have been caused by the β_2 -agonist, by the worsening of his airway obstruction (as reflected in the increase in PaCO₂), or by both of these variables.

The decrease in the serum potassium concentration from 4.1 mEq/L to 3.5 mEq/L could be attributed to β_2 -adrenergic activation of the Na⁺-K⁺ pump and subsequent transport of potassium intracellularly.^{39,40} However, at usual doses, aerosolized albuterol and terbutaline cause relatively little effect on serum potassium. The effects may be more noticeable with systemic (oral or injectable) administration. A β_2 -adrenergic-mediated increase in glucose and insulin secretion also can contribute to the intracellular shift of potassium.³⁹

Key: ED, emergency department; MDI, metered-dose inhaler; PEF, peak expiratory flow; SABA, short-acting β_2 -agonist (quick-relief inhaler)

FIGURE 22-13 Management of asthma exacerbations: home treatment. (Reproduced with permission from reference 1.)

H.T.'s potassium dropped from 4.1 to 3.5 mEq/L. Part of this drop may have been due to the terbutaline injections.

The shakiness (tremors) experienced by H.T. probably can be attributed to β_2 -receptor stimulation of skeletal muscle. Again, this effect is most prominent with oral or parenteral administration, but some patients are very sensitive to even small doses of SABAs. To minimize adverse effects, H.T. should have been given frequent high doses of inhaled albuterol rather than SC terbutaline on admission to the ED. He should have also initially been given nebulized ipratropium in addition to albuterol because his FEV₁ was <30% predicted.

β -Adrenergic Agonist Subsensitivity

11. Why did H.T. fail to respond to the initial therapy? Could tolerance to the β_2 -agonists have contributed?

Although tolerance to systemic effects of β_2 -agonists (e.g., tremor, sleep disturbances) is documented, tolerance to the airway response does not occur to a clinically significant extent.⁴¹ Even with long-term use, the intensity of response to β_2 -agonists is retained (i.e., the maximal percent increase in pulmonary function), but the duration of response with each dose may shorten. Such an effect is unlikely with intermittent use but may occur in patients who routinely use large, multiple doses daily. Possible explanations for this variability include downregulation of receptors, disease progression, or true drug tolerance. The exact contribution of each is not known. Therefore, H.T.'s failure to respond to the initial therapy most likely is due to the severity of his airway obstruction. H.T.'s history of severe chronic asthma, the slow progression of this attack, and the lack of response to his inhaled β_2 -agonist also are largely due to a significant inflammatory component to this attack.

Thus, bronchodilators would not be expected to immediately reverse the airway obstruction in H.T. It would be difficult to attribute his lack of initial response to therapy to β_2 -adrenergic subsensitivity. In addition, it is not likely that β_2 -adrenergic receptor polymorphisms could account for H.T.'s initial lack of response.⁴²

Although polymorphic variations are documented to be relevant in some stable patients,¹ further study is needed to establish clinical relevance.

Short-Acting Inhaled β -Agonists in Combination With Theophylline

12. When would the addition of theophylline to H.T.'s therapy be indicated?

Studies on the treatment of acute asthma in the ED have failed to demonstrate any benefit of adding theophylline to optimal, inhaled β -agonist therapy,^{1,43} and the NIH guidelines do not recommend this practice.¹⁻⁶ Further evidence of the lack of value of theophylline in the acute-care setting emerged in the 1990s. Several double-blind, randomized, placebo-controlled studies have demonstrated that theophylline does not add benefit to intensive therapy with inhaled β_2 -agonists and systemic corticosteroids in hospitalized adults⁴⁴ or children⁴⁵⁻⁴⁸ who fail to respond to aggressive ED therapy with SABAs. Note in Figure 22-12 from EPR-3¹ that theophylline is not recommended for routine management of hospitalized patients with asthma. Although one study⁴⁹ has shown a slight benefit of theophylline in hospitalized adult asthmatics, one of the authors of that study has since noted that if adequate doses of SABAs and systemic corticosteroids are used, theophylline is probably not routinely indicated.⁵⁰ While further research is needed to establish whether theophylline may add benefit to hospitalized patients who have impending respiratory failure, routine use of theophylline in hospitalized asthmatics no longer is justified.

13. Repeat measurements of PEF and ABGs indicate continued significant bronchial obstruction. What should be the next step in H.T.'s therapy?

H.T. should have had therapy initiated with inhaled SABAs and certainly now should be changed from systemic to an aerosolized β -agonist. Because of the concern for cardiac toxicity, a β_2 -selective agent such as albuterol should be selected. Three or four doses of albuterol, 5 mg by nebulizer administered every 20 minutes, should be started immediately with continuous monitoring of H.T.'s cardiac status. H.T.'s PEF (or preferably FEV₁) also should be monitored.

Short-Acting Inhaled β -Agonists in Combination With Corticosteroids

14. Are systemic corticosteroids appropriate for H.T.? When can a response be expected?

Corticosteroids have potent anti-inflammatory activity and are definitely indicated in H.T.¹⁻⁶ In patients like H.T. with acute asthma, corticosteroids decrease airway inflammation⁵¹⁻⁵⁴ and increase the response to β_2 -selective agonists.^{1,51}

Corticosteroids are not smooth muscle relaxants (i.e., not bronchodilators); however, they can relieve bronchial obstruction by improving the responsiveness of β_2 -receptors and by inhibiting numerous phases of the inflammatory response (e.g.,

cytokine production, neutrophil and eosinophil chemotaxis and migration, and release of inflammatory mediators).¹⁻⁶

The anti-inflammatory activity of corticosteroids is delayed for about 4 to 6 hours after the dose has been administered. Corticosteroid-induced restoration of responsiveness to endogenous catecholamines and exogenous β_2 -agonists, however, occurs within 1 hour of administration of the corticosteroid in severe, chronic, stable asthmatics.⁵¹ Significant improvement in objective measures (e.g., FEV₁) generally occurs 12 hours after administration.⁵³ Consequently, EPR-3¹ advocates early initiation of corticosteroids in cases of acute severe asthma. Corticosteroids also hasten the recovery of acute exacerbations of asthma⁵⁵⁻⁵⁹ and decrease the need for hospitalization if given early in the initial management of acute asthma in the ED.⁵⁴

Based on his initial presentation, H.T. should be started on systemic corticosteroid therapy immediately in the ED (Fig. 22-12). Preferably, oral corticosteroids would have been started at home before H.T.'s exacerbation escalated to this degree of severity (Fig. 22-13).

15. What would be an appropriate dosing regimen of corticosteroids for H.T. in the ED? Would the dose and route be the same if he were hospitalized?

Doses of corticosteroids used to treat acute asthma are largely empiric. Studies comparing very high dosages (e.g., intravenous [IV] methylprednisolone 125 mg every 6 hours in an adult) versus moderate dosages (40 mg every 6 hours) have shown no advantage with very high dosages.^{1,60,61} In addition, oral therapy is as efficacious as the IV route.^{1,60,61} Dosing recommendations for systemic corticosteroids in the management of asthma exacerbations in the ED or hospital are shown in Table 22-5. Higher corticosteroid dosages may be considered in patients with impending respiratory failure. When patients cannot take oral medication, IV methylprednisolone is preferred over hydrocortisone in patients with heart disease or fluid retention or when high dosages of corticosteroids are used; this is because it has less mineralocorticoid activity.

For patients who require IV corticosteroid therapy, the dosage can usually be reduced rapidly to 60 to 80 mg/day for adults (1-2 mg/kg/day for children) as the condition improves (usually after 48-72 hours). On discharge from the hospital, EPR-3 recommends, for example, prednisone 40 to 80 mg/day in one or two doses for 3 to 10 days. Although some clinicians may prescribe a tapering regimen, no taper is necessary in this situation. On the other hand, if the patient required long-term oral corticosteroid therapy before hospitalization, tapering the dose to the preadmission dosage is prudent. For patients who are discharged from the ED, ≤ 7 days of prednisone therapy usually is sufficient.

16. H.T. was given one dose of 60 mg methylprednisolone (Solu-Medrol) IV and three doses of albuterol 5 mg/ipratropium 0.5 mg by nebulizer Q 20 minutes in the ED (after the two initial doses of SC terbutaline). H.T. claimed slight subjective improvement after this therapy; yet, expiratory wheezes still were audible, and he still was using his accessory muscles for ventilatory efforts. His PEF improved only to 35% of predicted, and a repeat ABG measurement showed a PaCO₂ of 40 mmHg. What should be done at this time?

H.T. still is significantly obstructed despite intensive therapy in the ED. As a result, he should be admitted to the intensive care unit (ICU), where he can be monitored closely.

Respiratory Failure

Signs and Symptoms

17. What would be the best method of assessing the adequacy of therapy in H.T.? What are the signs of impending respiratory failure?

When patients continually must expand their chest wall with high lung volumes over a prolonged period, respiratory muscle fatigue may ensue, resulting in a decreased ventilatory effort. Clinical signs of impending respiratory failure include increased heart rate, decreased breath sounds, agitation from worsening hypoxia, or lethargy from increased CO₂ retention. These clinical signs and symptoms are relatively nonspecific and are affected by many variables. Thus, they should not be used to detect impending respiratory failure.

The best way to assess therapy is to monitor ABGs. The PaO₂ component of an ABG determination is not very helpful because of \dot{V}/\dot{Q} mismatching and the administration of oxygen. The PaCO₂ is the best indicator of hypoventilation in acute asthma¹; however, there is no single value for PaCO₂ that indicates impending respiratory failure, because different PaCO₂ values are acceptable under different clinical circumstances. A PaCO₂ of 55 mmHg 1 to 2 hours after intensive bronchodilator therapy or an increase in PaCO₂ of 5 to 10 mmHg/hour during aggressive therapy is an ominous sign. The fact that H.T.'s PaCO₂ is not rising with therapy is a good sign.

β_2 -Agonists and Other Potential Therapies

18. H.T. initially received two doses of terbutaline 0.5 mg SC and subsequently three doses of albuterol 5 mg/ipratropium 0.5 mg by nebulizer Q 20 minutes in the ED. He has also received IV methylprednisolone 60 mg. Would the IV administration of a β -agonist be indicated in H.T. at this time? What are other potential therapies in H.T.?

Although the use of IV β -agonists for asthmatics in the ICU formerly was advocated, current standards of care discourage the use of these agents.¹ H.T.'s history of PVCs and response to inhaled albuterol also suggest that IV β -agonists are inappropriate at this time. Since standard therapies already administered were not sufficient, IV magnesium sulfate may benefit severely ill patients like H.T.^{1,62} Recent research suggests that nebulized isotonic magnesium sulfate is a valuable adjunctive therapy to inhaled albuterol in the treatment of severe asthma exacerbations.⁶³ Further, heliox (a mixture of helium and oxygen) may also add benefit.^{1,64}

Theophylline

19. Intravenous theophylline is being considered for H.T. Is theophylline likely to be of benefit in impending respiratory failure?

It was stated previously that there is no role for theophylline in ED treatment, and its use is not justified for routine hospital admissions for asthma.¹ However, two studies suggest a potential benefit of theophylline for some patients in the ICU who have impending respiratory failure.^{65,66} The authors of these

studies point out that if theophylline is used, clinicians must be competent in dosing and monitoring serum concentrations. Based on a lack of evidence in several trials in hospitalized asthmatics,^{54–58} more trials are needed to evaluate if possible benefits outweigh risks of this drug for impending respiratory failure. Based on inconclusive evidence of improved patient response but documented increased risks, EPR-3 does not recommend the use of theophylline in the hospital.¹ H.T.'s clinicians decide not to use theophylline. If a clinician decides to use theophylline in this setting, a current pharmacokinetics text should be consulted to help ensure safe and effective dosing and monitoring.⁶⁷

RESPONSE TO THERAPY

20. H.T. has continued to improve slowly over the last 72 hours. The nebulizer treatments with albuterol are now administered Q 4 hr, and he is taking oral prednisone 80 mg/day in two divided doses. PEF measurements taken before and after the last albuterol treatment were 65% of predicted and 80% of predicted, respectively. Is H.T.'s long duration of recovery unusual?

No. In a patient such as H.T., whose condition progressively deteriorated over a long period, a slow reversal should be expected. The prolonged deterioration reflects an increasing inflammatory response in the lung. These patients require prolonged, intensive bronchodilator and anti-inflammatory therapy before maximal improvement is noted in pulmonary function tests. Thus, H.T. should continue to receive systemic corticosteroids for approximately 10 days after such a severe acute exacerbation of asthma.¹

Adverse Effects of Short-Term Corticosteroid Therapy

21. H.T. has been taking corticosteroids for a total of 6 days. Long-term corticosteroid use is associated with many adverse effects (e.g., adrenal suppression, osteoporosis, cataracts). What adverse effects are related to short-term corticosteroid use?

Short courses of daily corticosteroids are usually associated with minor side effects.^{55–59} Facial flushing, appetite stimulation, gastrointestinal irritation, headache, and mood changes ranging from a mere sense of well-being to overt toxic psychosis are the most commonly encountered adverse effects of short-term corticosteroid therapy. Acne can be exacerbated in patients susceptible to this skin problem, and weight gain also can occur because of sodium and fluid retention. In addition, hyperglycemia, leukocytosis, and hypokalemia are possible. All of these problems are transient and will disappear over time after the corticosteroids are discontinued. These short-term adverse effects are less common when small corticosteroid doses are used; however, corticosteroid doses must be adequate to prevent disease exacerbation. The minor risks of short-term use are far outweighed by the marked benefits.

Overuse of Short-Acting Inhaled β -Agonists

22. H.T.'s history of increased use of his SABA inhaler during the early stages of this asthma attack and the cardiac irregularities noted during admission suggest improper use of this medication. What are the risks from overuse of β_2 -agonists?

The overuse of SABAs as a possible risk factor for asthma death has been debated for decades, and this debate was revived in the early 1990s.⁶⁸ Because most deaths from asthma occur

outside the hospital setting before the patient can reach medical assistance, the primary cause of death in asthma most probably is due to underestimation of the severity of the asthma attack by the patient and delay in seeking medical help. Overuse of quick reliever medication suggests inadequate asthma control and can lead to fatal asthma.^{1,68}

The frequency of as-needed doses of albuterol is a good marker of the adequacy of inhaled anti-inflammatory therapy and environmental control measures. For example, if the patient needs the SABA more than two or three times a day, the clinician should reassess environmental control, increase the dose of inhaled anti-inflammatory therapy, or add other controller agents per the NIH guidelines.¹⁻⁶

Patients should be instructed verbally and in writing regarding the proper use of their inhalers during acute attacks and in recognizing when it is necessary to seek medical assistance (Fig. 22-13). Patients can continue using their short-acting β -agonist inhalers on an as-needed basis until they reach medical care. H.T. should be considered at high risk because of the severity of his latest attack and should be given oral corticosteroids to self-administer at the first sign of significant deterioration.¹ In addition, H.T. should have a home peak flow meter so that he can objectively determine the severity of his attacks. Finally, the β_2 -agonist controversy does not extend to use of high dosages in the acute-care setting. High dosages are essential in the ED and hospital and, as discussed previously, usually are tolerated very well.

CHRONIC ASTHMA

Classification of Severity

23. B.C. is a 3-year-old, 16-kg boy with a 1.5-year history of recurrent wheezing 3 days per week and nocturnal awakenings four times per month.

The following medications had been prescribed for B.C. by the primary care clinician: albuterol syrup (2 mg/5 mL) 1 teaspoonful TID and albuterol metered-dose aerosol inhalation QID PRN for wheezing. B.C. demonstrates the use of the inhaler with his mother's assistance. The mother holds the inhaler in B.C.'s mouth and actuates it at the end of a deep inhalation. B.C.'s mother tells the clinician that he appears "jittery" after taking albuterol syrup. What is the first step in deciding how to improve B.C.'s long-term drug therapy?

While keeping in mind the goals of therapy defined by the NIH guidelines (EPR-3),¹ the first step here is to classify B.C.'s asthma severity (refer to Table 22-1 for infants to age 4 years). Because B.C. has symptoms 3 days per week and 4 nights per month, he should be classified as "moderate persistent." Note that the presence of even one of the features of severity places the patient in that category.

Selection of Appropriate Initial Long-Term Therapy

24. What would be a reasonable initial regimen for B.C.?

Because B.C.'s asthma is classified as moderate persistent, the clinician is now in a position to select appropriate long-term therapy. Using EPR-3¹ for very young children (Fig. 22-7), low- or medium-dose inhaled corticosteroids (ICS) with an as-needed SABA would be the choice for B.C.¹ EPR-3 suggests an initial trial of low dose ICS in very young children who

have not previously been treated with ICS. B.C. could receive ICS treatments via nebulizer (budesonide) or MDI + spacer. Most children aged 3 years or younger cannot use dry powder inhalers because of inability to generate sufficient peak inspiratory flow (PIF). As B.C. matures, he may be able to use some dry powder inhalers (e.g. Diskus). Because oral β_2 -agonists are not recommended by EPR-3 and since the albuterol syrup was not well tolerated, they should not be used. If concurrent inhaled albuterol is administered correctly, PO albuterol is not needed and would only be expected to add adverse effects. B.C.'s mother must be educated about asthma, its treatment, and the appropriate use of medications (e.g., proper use of inhaler devices; refer to Questions 45 and 46).

25. It is anticipated that because of his young age, B.C. will find it difficult to use an MDI. What alternative inhalation devices are reasonable?

Children younger than 5 five years of age generally have a difficult time coordinating the use of standard MDIs; therefore, the ICS and short-acting β_2 -agonist should be administered by another mode of delivery. For example, the as-needed β_2 -agonist and scheduled ICS could be administered with an inhalational aid such as a spacer or valved holding chamber, which is connected to an MDI. A nebulized corticosteroid preparation (budesonide) is available for very young children.⁶⁹ Inhalation aids (also called *spacers*) significantly improve the efficacy of medications that are administered by MDI in very young children or other patients who are unable to coordinate the plain inhalers correctly.⁷⁰ The AeroChamber is a widely used valved holding chamber (the medication stays in the chamber for a few seconds until the patient inhales slowly and the inhalation valve opens). An example of a simple open tube device (i.e., without an inhalation valve) is the integrated spacer with the triamcinolone MDI (Azmacort). Studies have shown that many children as young as 2 and 3 years of age can use MDIs with spacer devices by modeling after a parent.^{71,72} Spacer devices with face masks are required for some young children. Extender device-assisted delivery of aerosolized medications is as effective as nebulization in the home management of chronic severe asthma⁷³ and even in the ED treatment of asthma in children.^{30-32,73} The InspirEase and AeroChamber are examples of devices that contain a flow indicator whistle that sounds if the patient inhales rapidly. This whistle is particularly effective in teaching the patient the appropriate slow inhalation technique. As a 3-year-old, B.C. may not need a spacer with a face mask, but the clinician should verify correct use of the device by observation of the patient and/or caregiver's administration technique.

Alternatively, the ICS could be administered to selected children by using a breath-activated dry powder inhaler (e.g., budesonide [Pulmicort Flexhaler] or fluticasone [combined with salmeterol in Advair Diskus]). In young children, Diskus has the advantage of requiring lower PIF than Flexhaler, and it has been used successfully in children as young as 4 years of age.⁷⁴ Another option is the Twisthaler used for delivery of mometasone (Asmanex), but it is only approved for children ≥ 12 years of age.

Many pediatricians may choose a nebulizer to administer short-acting β_2 -agonists to a 3-year-old child. This method is certainly acceptable and very common, but it takes longer to administer the medication (about 15 minutes), and the

device must be properly cleaned and maintained. Because B.C. recently turned 3 years old, therapy should be initiated with nebulized budesonide (Pulmicort Respules) in a low dose of 0.25 mg BID. As mentioned previously, EPR-3¹ suggests an initial trial of low-dose ICS in very young children who have not previously been treated with ICS. The plan is to switch B.C. to a dry powder inhaler or MDI-spacer in 12 months, as soon as he and his caregiver can demonstrate correct use. B.C.'s clinician should assess the response to low-dose budesonide in 4 weeks. Therapy can be stepped up if necessary and subsequently stepped down over the coming months, if possible, so that optimal asthma control is achieved at the lowest ICS dose possible.

26. B.C.'s parents are wary of their son taking corticosteroids on a continual basis after having read about serious side effects attributed to corticosteroids on the Internet. How should the parents be counseled?

Corticosteroids reach the systemic circulation minimally via inhalation in part because they are largely inactivated through first-pass hepatic metabolism. However, a dose-dependent response is evident, and clinically significant adverse events resulting from systemic exposure can occur, albeit more commonly with doses at the high end of the range. Long-term studies in pediatric patients have examined the effects of ICS on growth reduction, bone density, and adrenal suppression.

Although ICS can cause a mild and temporary reduction in growth velocity, final height attained in adulthood appears to be within normal limits.⁷⁵ Bone density and risk of fractures have not been found in the vast majority of investigations to be affected by ICS.⁷⁵ While a measurable reduction in serum and urinary cortisol levels is not an uncommon finding in studies of ICS, clinically significant adrenal insufficiency solely due to ICS is rare, although again it is more likely to occur with high doses.⁷⁵ In summary, these adverse effects are generally of minimal clinical significance, with the benefits of well-controlled asthma far outweighing the risks.

The most common local side effect with ICS therapy is oropharyngeal candidiasis (thrush), but this problem is rare with any delivery system. With MDIs, it can be further minimized by use of a spacer device. Rinsing the mouth with water after use of any ICS is also recommended. Another possible local side effect is hoarseness (dysphonia), and spacers may not effectively reduce this problem.⁷⁶ Dry powder devices (e.g., Flexhaler) may have less dysphonia associated with their use, but further study is required to verify this.⁷⁶

Seasonal Asthma

27. C.V., a 33-year-old woman, presents to the clinic with a history of asthma and seasonal allergic rhinitis ("hay fever") each spring but not the rest of the year. She describes her asthma as "mild" and intermittent. Except during springtime, her daytime symptoms occur less than once per week, and she does not have nocturnal symptoms. Each spring, however, these symptoms worsen, and she requires her albuterol inhaler (her only asthma medication) TID or QID every day. During springtime, she takes a nonprescription antihistamine, which offers some relief. How can C.V.'s management be improved?

C.V. appears to have intermittent asthma during most of the year but converts to moderate persistent asthma combined with worsening rhinitis symptoms in the springtime. This syndrome is consistent with a diagnosis of seasonal asthma and allergic rhinitis. Although as-needed albuterol is appropriate for most of the year for C.V., she needs anti-inflammatory therapy during the spring.¹ Therapy to reduce airway inflammation should begin before the onset of tree and grass pollen season and continue throughout the spring (e.g., 3 months). Per the NIH guidelines, an excellent treatment option for C.V. is low-dose ICS combined with a long-acting inhaled β_2 -agonist (LABA). Monotherapy with medium-dose ICS would also be an acceptable therapy. Not only are the causes and pathophysiology of allergic rhinitis and allergic asthma similar, poorly controlled rhinitis serves as a major asthma trigger. In addition, C.V. should also ideally receive an intranasal corticosteroid if antihistamines (preferably nonsedating) do not provide optimal relief of her allergic rhinitis. Intranasal corticosteroid therapy not only offers excellent relief of nasal symptoms but also improves asthma control.⁶ Good control of rhinitis is helpful in maintaining optimal asthma control^{1,2} (see Chapter 24, Acute and Chronic Rhinitis). Despite precautions listed in manufacturer literature that older (sedating) antihistamines should be avoided in asthma, these agents are safe in patients with asthma.^{1,2}

Corticosteroids

28. S.T., a 12-year-old girl with severe persistent asthma, has not been well controlled on mometasone (Asmanex) one inhalation daily (she admits to using it only when she feels as if she needs it) and uses as-needed inhaled albuterol MDI five or six times every day. When her symptoms worsen, she uses her "breathing machine" (nebulizer) at home. S.T. awakens most nights with wheezing. She has been hospitalized four times in the last 2 years and has required "bursts" of prednisone with increasing frequency. S.T. has missed many days of school in the past year and has withdrawn from physical education classes and her extracurricular sports activity after school. Her parents are concerned about her increased use of prednisone now that she is approaching puberty. S.T. is just finishing a 2-week course of prednisone 20 mg/day and has a round facies appearance typical of chronic oral corticosteroid use. On physical examination, S.T. has diffuse expiratory wheezes, and pulmonary function testing reveals significant reversibility. Her FEV₁ is only 60% predicted before use of albuterol in the physician's office and improves to 75% predicted 15 minutes after use of the SABA. What actions are needed to improve S.T.'s care?

Because S.T. is suffering needlessly and requiring frequent systemic corticosteroids, all efforts must be made to optimize other therapies and to minimize systemic corticosteroid toxicities. Although S.T. is receiving an ICS, she admits to poor adherence. Therefore, with her severe persistent asthma, she initially needs higher-dose ICS therapy. Per EPR-3,¹ she should also receive a LABA. Although short "bursts" of prednisone (e.g., 40 mg/day for 3 days) are very helpful occasionally, frequent short courses often indicate the need to optimize other therapies. Some patients require courses of 1 to 2 weeks. S.T. is requiring longer frequent bursts and is showing signs of adverse effects. Obviously, S.T. and her parents also need a concerted

Table 22-6 Estimated Comparative Daily Dosages for Inhaled Corticosteroids in Children

and persistent effort in patient education as a partnership (refer to Patient Education and Outcomes section).

ICS are chemically modified to maximize topical effectiveness while minimizing systemic toxicities. Tables 22-6 and 22-7 are taken from EPR-3^{1–5} and compare the dosages of ICS products. These differences in dosages (low, medium, and high) reflect differences among ICS in receptor-binding affinity and topical potency. There are also differences among these agents in oral bioavailability (i.e., absorption of drug that is swal-

lowed after inhalation) and systemic availability via absorption from the lungs. Of these two variables, absorption from the lungs is the most likely contributor to possible hypothalamic-pituitary-adrenal (HPA) suppression or other systemic effects. Fortunately, the total absorption has not been shown to be clinically important except at the higher recommended dosages. Although the various ICS are not equipotent on a microgram-per-microgram basis, major differences in efficacy or adverse effects are not firmly established.^{1,75,77} For patients with severe

persistent asthma, a logical choice would be a high-potency agent that would allow for a minimum number of inhalations per day, potentially improving treatment adherence. Furthermore, the delivery system used affects pulmonary deposition. For example, the Turbuhaler delivers about twice the dose of budesonide versus an MDI and is associated with excellent efficacy if used correctly.⁷⁸ Clinical trials evaluating fluticasone efficacy administered via the Diskus have likewise shown excellent efficacy.⁷⁹ The differences between the various dry powder inhalers is discussed later in this chapter. Addition of a spacer device to an MDI also enhances pulmonary deposition. In very high dosages (the equivalent of 1,600 mcg/day of beclomethasone dipropionate), all ICS produce some degree of HPA-axis suppression.⁷⁵ The clinical significance of this suppression has yet to be firmly established.

Although low to moderate dosages of ICS are accepted as being quite safe, very high dosages continue to be scrutinized regarding the potential adverse effects.⁸⁰ Clearly, for patients who require high dosages for optimal control of asthma, the benefits of therapy with these agents far outweigh the risks.^{1,75} A possible association between prolonged, very high dosages of ICS and cataracts⁸¹ and glaucoma⁸² has been reported. EPR-3 has summarized recent research that has allayed concerns regarding use of ICS therapy and growth suppression in children (i.e., the decrease in growth velocity is small, not progressive, and appears to be reversible).^{1,83,84}

29. How should S.T. be managed?

In the treatment of S.T., most clinicians would begin with a short course (e.g., 1 week) of systemic corticosteroids to maximally improve her pulmonary function. This approach is consistent with EPR-3¹, which recommends gaining quick control. Using short-course systemic therapy is logical because it is inexpensive, efficacious, and associated with low risk. While gaining quick control with a short course of oral corticosteroids, it is logical to start ICS in many patients at a low^{1,85} to moderate dosage (as defined in Tables 22-6 and 22-7). The evidence that ICS are highly effective in persistent asthma is unequivocal. Patients in this category who consistently take ICS are at a lower risk of hospitalization and death, and one study found an increased risk of death after discontinuation of ICS compared with patients who remained on these drugs.^{86,87} ICS therapy should be initiated concomitantly with a short course of systemic corticosteroid therapy. Patient education at this time may have greater effectiveness, because some patients are more attentive after having just experienced an exacerbation, and they know that change is needed to improve their health. Because S.T.'s asthma is classified as *severe* persistent, it is reasonable to start her on a moderate to high dosage of an ICS in combination with a LABA (Fig. 22-9 and Table 22-3). More aggressive therapy initially is especially important in S.T. because of her four hospitalizations in the last 2 years. In partnership with S.T. and her parents, her preference should be determined as to the delivery method (i.e., discuss options with her regarding breath-activated devices or MDI and spacer, including which spacer). Ideally, the clinician should recognize her emerging independence as a 12 year old and talk with her alone and then with her parents. After S.T. is stabilized for 3 months, attempts should be made to slowly decrease the ICS dosage every 3 months until the lowest-effective dosage is achieved. Administration of the total daily ICS dose is pre-

ferred twice daily or in many patients, with mild to moderate persistent asthma, once daily.¹ Since adherence is a major determinant of success or failure with ICS and other therapies, simplified regimens and continued patient education and contact are essential.¹

Combination of Inhaled Corticosteroids and Long-Acting Inhaled β_2 -Agonists

30. Because S.T. is 12 years old, what options are appropriate to minimize the ICS dosage, realizing that aggressive therapy is needed? What are the risks associated with LABAs? Clinicians should monitor for which local side effects in S.T. with ICS therapy?

LABAs have been very successful in prevention of “stepping up” the dose of ICS while markedly enhancing overall asthma control,^{78,79,88–90} and this fact is reflected in EPR-3¹. A reasonable therapeutic option for S.T. would be the combination of fluticasone 500 mcg and salmeterol 50 mcg via Diskus (Advair 500) 1 inhalation BID or the budesonide/formoterol (Symbicort) combination inhaler (160 mcg/4.5 mcg; 2 inhalations BID). S.T. should be reevaluated in 2 weeks. The plan is to “step down” the dose of fluticasone after excellent asthma control is achieved.

ADVERSE EFFECTS ASSOCIATED WITH LONG-ACTING INHALED β_2 -AGONISTS

31. S.T.'s parents recently discovered an article in a national newspaper that addressed concerns of using LABAs due to an increased risk of death. Since S.T.'s parents have called and left a message for the clinician, what would be important information to share with her family regarding this issue? What other side effects should S.T. and her family be aware of?

Several randomized trials for over a decade have demonstrated that LABAs have minimal adverse effects (e.g., tachycardia, tremor).^{1,78,79,88–90} Although there are limited data, based primarily on one study (SMART),⁹¹ there may be a very small increased risk of asthma-related death and asthma exacerbation in patients receiving LABAs. This small risk is likely due to patients receiving LABAs without concomitant ICS. In fact, EPR-3¹ recommends against the use of LABAs as monotherapy for long-term control of persistent asthma. SMART⁹¹ data suggested that blacks may be at greater risk, but much more study is needed to confirm these data. LABA therapy should *only* be used in combination with ICS in patients with asthma. Combination ICS/LABA therapy for asthma is safe and effective.^{1,92} EPR-3¹ suggests giving equal consideration to moderate dose of ICS alone or low-dose ICS combined with LABA for patients with moderate persistent asthma. For S.T., she has severe persistent asthma, and ICS/LABA combination therapy is preferred.¹

STEP-DOWN TREATMENT

32. After being adherent to her new therapy (fluticasone 500 mcg/salmeterol 50 mcg BID) for 1 month, S.T.'s asthma control has markedly improved. She required no ED visits or hospitalizations, was sleeping through the night, and began to exercise again. Her personal best PEF was 320 L/minute, and she was staying in her green zone (260–320 L/minute), requiring PRN albuterol no more than once per week. After 2 more months, S.T. continues to do well. Although S.T. clearly needs long-term ICS therapy, after 3 months of excellent response, her clinician is now

ready to step down from high-dose fluticasone. What is a prudent approach to dosage reduction?

EPR-3¹ suggests stepping down the dose at a rate of 25% to 50% every 3 months to the lowest dose that maintains control. A step down to fluticasone 250 mcg/salmeterol 50 mcg (Advair 250) BID would be a reasonable reduction in therapy for S.T. If a single ICS product had been started in S.T. initially (e.g., budesonide, beclomethasone, fluticasone), the dosage reduction would normally proceed at a slower pace. However, fluticasone 500 mcg daily, especially in combination with salmeterol, will likely be an adequate dose for S.T. After S.T.'s dose of fluticasone was stepped down to 500 mcg/day, she started requiring only slightly more PRN albuterol (but still was symptom free most days).

33. If symptoms recur during step-down, what management could possibly facilitate dosage reduction of the ICS in S.T.?

During follow-up evaluations, clinicians should carefully investigate factors that may contribute to poor asthma control, including exposure to inhalant allergens, indoor/outdoor irritants, medications, and tobacco smoke. Secondhand smoke exposure has been demonstrated to negate the benefit of ICS in children, and asthma patients who smoke have reduced response to ICS therapy.^{93,94}

Leukotriene Modifiers

34. P.W. is a 52-year-old man with mild persistent asthma. His asthma symptoms began when he was 2 years of age, and he has never smoked. P.W. has had numerous drug regimens for his asthma over the years, but he tells his physician that he wants the simplest regimen possible and that he prefers oral medication if at all possible. What is a good choice for controller therapy in P.W.?

In patients of any age with mild persistent asthma, and certainly in children or adolescents, an oral agent such as montelukast with once-daily dosing at bedtime (or zafirlukast with twice-daily dosing) has obvious advantages. An ICS is the preferred treatment for mild persistent asthma. Studies comparing ICS with LTRA have consistently demonstrated the superiority of ICS for most asthma outcome measures,¹ but in patients (adults or children) who much prefer oral therapy to inhaling medication every day, leukotriene modifiers are a reasonable option. The simplest and safest possible oral controller regimen for P.W. is montelukast 10 mg HS (with PRN inhaled albuterol). Bedtime dosing with montelukast is recommended because it will have peak activity late at night and in the early morning hours, when asthma symptoms tend to be more frequent. It is likely that this regimen will result in very good asthma control. If P.W. does not have good control of his asthma when he returns to the clinic in a few weeks, switching to a low-dose ICS in the evening only would keep the regimen simple while enhancing efficacy.

Cromolyn and Nedocromil

35. E.G. is a 7-year-old boy with mild persistent asthma. His family has just moved from the northeastern United States to the Midwest. E.G.'s new pediatrician notes that he has been previously managed only by "as-needed" inhaled albuterol. E.G.'s pediatrician is aware of the NIH guidelines¹ recommendation for ICS in mild persistent asthma, even in small children. However,

despite recent evidence in the literature regarding the safety of ICS, she is concerned about the risks of these agents in children and is considering a trial of cromolyn or nedocromil therapy combined with strict environmental control. If the trial fails, she plans to switch to the lowest possible dosage of ICS. Should cromolyn (Intal) or nedocromil (Tilade) be added to E.G.'s β_2 -agonist therapy? Is either agent preferred over theophylline or a leukotriene modifier in E.G.?

In studies of childhood asthma, cromolyn has been found to reduce symptoms and the need for acute-care visits, and this drug has an excellent safety profile.^{1–6,95} Although theophylline is a relatively weak bronchodilator, it also may have very modest anti-inflammatory effects.^{1,50} Note in Figure 22-8 from EPR-3¹ that theophylline, cromolyn, and nedocromil are *alternatives* as controller medications in mild persistent asthma (children 5–11 years of age). Nedocromil is an effective anti-inflammatory agent, especially for mild persistent asthma,¹ and is similar to cromolyn in efficacy and tolerability.¹ Cromolyn and nedocromil have similar mechanisms of action as anti-inflammatory agents, and their mechanisms are compared with other agents in Table 22-8.

Based on efficacy and safety concerns and the need to monitor serum theophylline concentrations, either cromolyn or nedocromil is a better option for E.G.'s controller therapy. E.G. can learn to use an MDI plus spacer device with proper teaching, but the concern is adherence to therapy with the required QID or TID dosing schedule. Cromolyn MDI two puffs QID would be an appropriate regimen here. Therapy should be continued for at least 4 weeks to determine response.

A simpler approach to managing mild persistent asthma in a young child whose physician does not choose the preferred low-dose ICS therapy is once-daily montelukast.¹ Taking a 5-mg cherry chewable montelukast tablet at bedtime is preferred as an option in E.G. over cromolyn, nedocromil, or theophylline.

Theophylline

Dosing

36. K.J., a 14-year-old, 40-kg girl, has a history of recurring cough and wheezing. These symptoms worsen on vigorous running or when she has an upper respiratory infection. She has not required hospitalization for these symptoms but has missed a few school days. She has symptoms daily and uses her pirbuterol inhaler more than two times daily. K.J. has a family history of asthma. A diagnosis of moderate persistent asthma is made. How should K.J. be managed?

Because K.J. has moderate persistent asthma, treatment with an anti-inflammatory agent is indicated. Low to moderate-dose ICS in combination with a LABA is the preferred treatment in a 14-year-old child with moderate persistent asthma.¹ However, K.J.'s clinician opts to prescribe theophylline in combination with a low dose of budesonide via the Flexhaler.

37. What dosage of theophylline is appropriate for K.J.?

Low doses of budesonide combined with twice-daily theophylline that resulted in a median serum theophylline concentration of 8.7 mcg/mL was superior in efficacy to high-dose budesonide as single controller therapy.⁹⁶ Thus, it is wise to give a therapeutic trial with low-dose theophylline initially, aiming for serum concentrations between 5 and 10 mcg/mL.

Table 22-8 Long-Term Control Medications

| <i>Name/Products (Listed Alphabetically)</i> | <i>Indications/Mechanisms</i> | <i>Potential Adverse Effects</i> | <i>Therapeutic Issues (Not All Inclusive)</i> |
|--|---|--|---|
| Corticosteroids (Glucocorticoids) Inhaled (ICS): Beclomethasone dipropionate Budesonide Flunisolide Fluticasone propionate Mometasone furoate Triamcinolone acetonide | <p><i>Indications</i></p> <ul style="list-style-type: none"> • Long-term prevention of symptoms: suppression, control, and reversal of inflammation. • Reduce need for oral corticosteroid. <p><i>Mechanisms</i></p> <ul style="list-style-type: none"> • Anti-inflammatory. Block late reaction to allergen and reduce airway hyperresponsiveness. Inhibit cytokine production, adhesion protein activation, and inflammatory cell migration and activation. • Reverse β_2-receptor downregulation. Inhibit microvascular leakage. | <ul style="list-style-type: none"> • Cough, dysphonia, oral thrush (candidiasis). • In high doses (Tables 22-6, 22-7), systemic effects may occur, although studies are not conclusive, and clinical significance of these effects has not been established (e.g., adrenal suppression, osteoporosis, skin thinning, and easy bruising). In low to medium doses, suppression of growth velocity has been observed in children, but this effect may be transient, and the clinical significance has not been established. | <ul style="list-style-type: none"> • Spacer/holding chamber devices with nonbreath-activated MDIs and mouth washing after inhalation decrease local side effects. • Preparations are not absolutely interchangeable on a mcg or per puff basis (Tables 22-6, 22-7 for estimated clinical comparability). New delivery devices may provide greater delivery to airways; this change may affect dose. • The risks of uncontrolled asthma should be weighed against the limited risks of ICS therapy. The potential but small risk of adverse events is well balanced by their efficacy. • “Adjustable dose” approach to treatment may enable reduction in cumulative dose of ICS treatment over time without sacrificing maintenance of asthma control. • Dexamethasone is not included as an ICS for long-term control, because it is highly absorbed and has long-term suppressive side effects. |
| Systemic: Methylprednisolone Prednisolone Prednisone | <p><i>Indications</i></p> <ul style="list-style-type: none"> • For short-term (3–10 days) “burst”: to gain prompt control of inadequately controlled persistent asthma. • For long-term prevention of symptoms in severe persistent asthma. suppression, control, and reversal of inflammation. <p><i>Mechanisms</i></p> <ul style="list-style-type: none"> • Same as inhaled. | <ul style="list-style-type: none"> • Short-term use: Reversible abnormalities in glucose metabolism, increased appetite, fluid retention, weight gain, mood alteration, hypertension, peptic ulcer, and rarely aseptic necrosis. • Long-term use: Adrenal axis suppression, growth suppression, dermal thinning, hypertension, diabetes, Cushing’s syndrome, cataracts, muscle weakness; in rare instances, impaired immune function. • Consideration should be given to coexisting conditions that could be worsened by systemic corticosteroids, such as herpes virus infections, varicella, tuberculosis, hypertension, peptic ulcer, diabetes mellitus, osteoporosis, and <i>Strongyloides</i>. | <ul style="list-style-type: none"> • Use at lowest effective dose. For long-term use, alternate-day am dosing produces the least toxicity. If daily doses are required, one study shows improved efficacy with no increase in adrenal suppression when administered at 3 PM rather than in the morning. |
| Cromolyn Sodium and Nedocromil | <p><i>Indications</i></p> <ul style="list-style-type: none"> • Long-term prevention of symptoms in mild persistent asthma may modify inflammation. • Preventive treatment prior to exposure to exercise or known allergen. <p><i>Mechanisms</i></p> <ul style="list-style-type: none"> • Anti-inflammatory. Blocks early and late reaction to allergen. Interferes with chloride channel function. Stabilizes mast cell membranes and inhibits activation and release of mediators from eosinophils and epithelial cells. • Inhibits acute response to exercise, cold dry air, and SO₂. | <ul style="list-style-type: none"> • Cough and irritation. • 15%–20% of patients complain of an unpleasant taste from nedocromil. | <ul style="list-style-type: none"> • Therapeutic response to cromolyn and nedocromil often occurs within 2 wk, but a 4- to 6-wk trial may be needed to determine maximum benefit. • Dose of cromolyn by MDI (1 mg/puff) may be inadequate to affect airway hyperresponsiveness. Nebulizer delivery (20 mg/ampule) may be preferred for some patients. • Safety is the primary advantage of these agents. |

Table 22-8 Long-Term Control Medications (Continued)

| Name/Products (Listed Alphabetically) | Indications/Mechanisms | Potential Adverse Effects | Therapeutic Issues (Not All Inclusive) |
|---|--|---|--|
| Immunomodulators | | | |
| Omalizumab (anti-IgE) For subcutaneous use | <p><i>Indications</i></p> <ul style="list-style-type: none"> • Long-term control and prevention of symptoms in adults (≥ 12 yr old) who have moderate or severe persistent allergic asthma inadequately controlled with ICS. <p><i>Mechanisms</i></p> <ul style="list-style-type: none"> • Binds to circulating IgE, preventing it from binding to the high-affinity ($F_{CE}RI$) receptors on basophils and mast cells. • Decreases mast cell mediator release from allergen exposure. • Decreases the number of $F_{CE}RIs$ in basophils and submucosal cells. | <ul style="list-style-type: none"> • Pain and bruising of injection sites has been reported in 5%–20% of patients. • Anaphylaxis has been reported in 0.2% percent of treated patients. • Malignant neoplasms were reported in 0.5% of patients compared with 0.2% receiving placebo; relationship to drug is unclear. | <ul style="list-style-type: none"> • Monitor patients following injection. Be prepared and equipped to identify and treat anaphylaxis that may occur. • The dose is administered either every 2 or 4 wk and is dependent on the patient's body weight and IgE level before therapy. • A maximum of 150 mg can be administered in one injection. • Needs to be stored under refrigeration at 2°–8°C. • Whether patients will develop significant antibody titers to the drug with long-term administration is unknown. |
| Leukotriene Receptor Antagonists | | | |
| Montelukast tablets and granules | <p><i>Mechanisms</i></p> <ul style="list-style-type: none"> • Leukotriene receptor antagonist; selective competitive inhibitor of $CysLT_1$ receptor. <p><i>Indications</i></p> <ul style="list-style-type: none"> • Long-term control and prevention of symptoms in mild persistent asthma for patients ≥ 1 yr of age. May also be used with ICS as combination therapy in moderate persistent asthma. | <ul style="list-style-type: none"> • No specific adverse effects have been identified. • Rare cases of Churg-Strauss have occurred, but the association is unclear. | <ul style="list-style-type: none"> • May attenuate EIB in some patients, but less effective than ICS therapy. • Do not use LTRA + LABA as a substitute for ICS + LABA. • A flat dose-response curve, without further benefit, if dose is increased above those recommended. |
| Zafirlukast tablets | <ul style="list-style-type: none"> • Long-term control and prevention of symptoms in mild persistent asthma for patients ≥ 7 yr of age. May also be used with ICS as combination therapy in moderate persistent asthma. | <ul style="list-style-type: none"> • Postmarketing surveillance has reported cases of reversible hepatitis and, rarely, irreversible hepatic failure resulting in death and liver transplantation. | <ul style="list-style-type: none"> • Administration with meals decreases bioavailability; take at least 1 hr before or 2 hr after meals. • Zafirlukast is a microsomal P450 enzyme inhibitor that can inhibit the metabolism of warfarin. INRs should be monitored during coadministration. • Patients should be warned to discontinue use if they experience signs and symptoms of liver dysfunction (right upper quadrant pain, pruritis, lethargy, jaundice, nausea), and serum ALTs should be monitored. |
| 5-Lipoxygenase Inhibitor | | | |
| Zileuton tablets | <p><i>Mechanisms</i></p> <ul style="list-style-type: none"> • Inhibits the production of leukotrienes from arachidonic acid, both LTB_4 and the cysteinyl leukotrienes. <p><i>Indications</i></p> <ul style="list-style-type: none"> • Long-term control and prevention of symptoms in mild persistent asthma for patients ≥ 12 yr of age. • May be used with ICS as combination therapy in moderate persistent asthma in patients ≥ 12 yr of age. | <ul style="list-style-type: none"> • Elevation of liver enzymes has been reported. Limited case reports of reversible hepatitis and hyperbilirubinemia. | <ul style="list-style-type: none"> • Zileuton is microsomal P450 enzyme inhibitor that can inhibit the metabolism of warfarin and theophylline. Doses of these drugs should be monitored accordingly. • Monitor hepatic enzymes (ALT). |

(continued)

Table 22-8 Long-Term Control Medications (Continued)

| Name/Products (Listed Alphabetically) | Indications/Mechanisms | Potential Adverse Effects | Therapeutic Issues (Not All Inclusive) |
|---|--|---|---|
| Long-Acting β_2-Agonists (LABA) <i>Inhaled LABA:</i> Formoterol Salmeterol <i>Oral:</i> Albuterol, sustained-release | <i>Indications</i> <ul style="list-style-type: none"> Long-term prevention of symptoms added to ICS. Prevention of EIB. <i>Not to be used to treat acute symptoms or exacerbations.</i> <i>Mechanisms</i> <ul style="list-style-type: none"> Bronchodilation. Smooth muscle relaxation following adenylate cyclase activation and increase in cyclic AMP, producing functional antagonism of bronchoconstriction. Compared with SABA, salmeterol (but not formoterol) has slower onset of action (15–30 min). Both salmeterol and formoterol have longer duration (> 12 hr) compared with SABA. | <ul style="list-style-type: none"> Tachycardia, skeletal muscle tremor, hypokalemia, prolongation of QTc interval in overdose. A diminished bronchoprotective effect may occur within 1 week of chronic therapy. Clinical significance has not been established. Potential risk of uncommon, severe, life-threatening or fatal exacerbation: see text for additional discussion regarding safety of LABAs. | <ul style="list-style-type: none"> Not to be used to treat acute symptoms or exacerbations. Should not be used as monotherapy for long-term control of asthma or as anti-inflammatory therapy. May provide more effective symptom control when added to standard doses of ICS compared with increasing the ICS dosage. Clinical significance of potentially developing tolerance is uncertain, because studies show that symptom control and bronchodilation are maintained. Decreased duration of protection against EIB may occur with regular use. Inhaled route is preferred because LABAs are longer acting and have fewer side effects than oral sustained-release agents. Oral agents have not been adequately studied as adjunctive therapy with ICS. |
| Methylxanthines Theophylline, sustained-release tablets and capsules | <i>Indications</i> <ul style="list-style-type: none"> Long-term control and prevention of symptoms in mild persistent asthma or as adjunctive with ICS in moderate or persistent asthma. <i>Mechanisms</i> <ul style="list-style-type: none"> Bronchodilation. Smooth muscle relaxation from phosphodiesterase inhibition and possibly adenosine antagonism. May affect eosinophilic infiltration into bronchial mucosa as well as decreases T-lymphocyte numbers in epithelium. Increases diaphragm contractility and mucociliary clearance. | <ul style="list-style-type: none"> Dose-related acute toxicities include tachycardia, nausea and vomiting, tachyarrhythmias (SVT), central nervous system stimulation, headache, seizures, hematemesis, hyperglycemia, and hypokalemia. Adverse effects at usual therapeutic doses include insomnia, gastric upset, aggravation of ulcer or reflux, increase in hyperactivity in some children, and difficulty in urination in elderly males who have prostatism. | <ul style="list-style-type: none"> Maintain steady-state serum concentrations between 5 and 15 mcg/mL. Routine serum concentration monitoring is essential due to significant toxicities, narrow therapeutic range, and individual differences in metabolic clearance. Absorption and metabolism may be affected by numerous factors that can produce significant changes in steady-state serum theophylline concentrations. Patients should be told to discontinue if they experience toxicity. Not generally recommended for exacerbations. There is minimal evidence for added benefit to optimal doses of SABA. Serum concentration monitoring is mandatory. |

ALT, alanine aminotransferase; Anti-IgE, anti-immunoglobulin E; EIB, exercise-induced bronchospasm; ICS, inhaled corticosteroids; IGS, inhaled glucocorticoids; INR, International Normalized Ratio; LABA, long-acting inhaled β_2 -agonist, LTRA, leukotriene receptor agonist; MDI, metered-dose inhaler; SABA, short-acting inhaled β_2 -agonist; SVT, supraventricular tachycardia.
 Reprinted from reference 1.

In the nonacute asthma patient in whom the theophylline dose requirement is unknown, dosages suggested for ages >1 year are listed in Table 22-9; infant dosing is listed in Table 22-10. Accordingly, the initial dosage in K.J. would be 300 mg/day in divided doses (i.e., 150 mg Q 12 hr). If tolerated, the dosage is increased at 3-day intervals by about 25% to the mean dose that usually is needed to produce a peak theophylline serum concentration between 5 and 10 mcg/mL. The final dosage can be adjusted by using the guidelines listed in Table 22-11. Serum

theophylline concentrations should be obtained at steady state (i.e., when there have been no missed doses and no extra doses have been taken for at least 48 hours).

Toxicity

38. M.M., a 14-year-old boy who has been treated with theophylline SR 300 mg BID, now complains of headache and difficulty in getting to sleep. Why should a theophylline serum concentration be evaluated?

Table 22-9 Theophylline Dosing Guide for Chronic Use^{a,b}

Starting dose for children 1–15 yr <45 kg: 12–14 mg/kg/day to maximum of 300 mg/day
 Starting dose for adults and children 1–15 yr >45 kg: 300 mg/day
 Titrate dose upward after 3 days if necessary and if tolerated to:

- 16 mg/kg/day to maximum of 400 mg/day in children 1–15 yr <45 kg
- 400 mg/day in adults and children >45 kg

Titrate dose upward after 3 more days if necessary and if tolerated to:

- 20 mg/kg/day to a maximum of 600 mg/day in children 1–15 yr <45 kg
- 600 mg/day in adults and in children >45 kg

^aDose using ideal body weight or actual body weight, whichever is less. These dosages do not apply if liver disease, heart failure, or other factors documented to affect theophylline clearance are present. Doses must be guided by monitoring serum concentrations to ensure optimal safety and efficacy.

^bDosing schedule dependent on product selected; sustained-release products are much preferred, if at all possible.
 Adapted from reference 98.

Theophylline side effects can be related to excessive serum concentrations, or adverse effects can be transient and unrelated to the amount in serum. Unfortunately, it is not always possible to determine which it might be. Side effects can include headache, nausea, vomiting, irritability or hyperactivity, insomnia, and diarrhea. With higher serum theophylline levels, cardiac arrhythmias, seizures, and death can occur.⁹⁷ Less severe symptoms may not be present before the onset of cardiac arrhythmias or seizures and cannot be relied on as a forewarning of these more serious adverse theophylline effects. It is important not to ignore any symptom consistent with theophylline toxicity. The insomnia and headaches experienced by M.M. may not be associated with excessive (i.e., out of the usual therapeutic range) serum theophylline concentrations, but a reduction in dosage should be contemplated because some patients experience toxicity when serum theophylline concentrations are within the therapeutic range. Guidelines for managing toxicity have been revised.⁹⁸

Table 22-10 Food and Drug Administration Guidelines for Theophylline Dosing in Infants^a

Premature Neonates

<24 days postnatal age: 1.0 mg/kg Q 12 hr
 ≥24 days postnatal age: 1.5 mg/kg Q 12 hr

Term Infants and Infants Up to 52 Wk of Age

Total daily dose (mg) = [(0.2 × age in weeks) + 5.0] × (kg body weight)

- Up to age 26 weeks; divide dose into 3 equal amounts administered at 8-hr intervals
- >26 weeks of age; divide dose into 4 equal amounts administered at 6-hr intervals

^aFinal doses adjusted to a peak steady-state serum theophylline concentration of 5–10 mcg/mL in neonates and 10–15 mcg/mL in older infants.
 Adapted from reference 98.

Drug Interactions

39. T.R., a 55-year-old woman with asthma, is well controlled on theophylline SR 300 mg BID, albuterol two puffs QID PRN, and mometasone (Asmanex) one inhalation at bedtime. A peak theophylline serum concentration obtained 3 months ago was 14 mcg/mL. Six months ago, on the same dose of theophylline, her serum concentration was 15 mcg/mL. M.M. presents with an upper respiratory tract infection, and clarithromycin 500 mg BID is prescribed. Is this antibiotic appropriate?

A large number of medications inhibit cytochrome P450 isoenzymes and are capable of inhibiting the metabolism of theophylline. Because theophylline is metabolized by CYP 1A2, 3A3, and 2E1, inhibitors of these isoenzymes can cause clinically significant interactions.^{50,98} Cimetidine, clarithromycin, and some (but not all) of the quinolone antibiotics (e.g., enoxacin, ciprofloxacin) are well documented to inhibit theophylline metabolism.^{1,50,98} Because numerous other drugs inhibit the metabolism of theophylline, all patients receiving this agent should be screened carefully for potential interactions. As with any drug interaction, mechanism, time course, management, and clinical significance should be assessed

Table 22-11 Adjusting Doses of Theophylline Based on Serum Concentrations

| Peak Theophylline Concentration (mcg/mL) ^a | Approximate Adjustment in Daily Dose | Comment |
|---|---|--|
| <5.0 | ↑ by 25% | Recheck serum theophylline concentration. |
| 5–10 | ↑ by 25% if clinically indicated | Recheck serum concentration; ↑ dose only if poor response to therapy. |
| 10–12 | Cautious 10% ↑ if clinically indicated | If asymptomatic, no ↑ needed. Recheck serum theophylline concentration before further dose changes. |
| 12–15 | Occasional intolerance requires a 10% ↓ | If asymptomatic, no dose change needed unless side effects present. |
| 16–20 | ↓ by 10%–25% | Even if asymptomatic and side effects absent, a dose ↓ is prudent. |
| 20–24.9 | ↓ by 50% | Omit 1 dose even if asymptomatic and side effects absent, a dose ↓ is indicated. |
| 25–29.9 | ↓ by >50% | Omit next doses even if asymptomatic and side effects absent; a dose ↓ indicated; repeat serum theophylline concentration after dose adjustment. |
| >30 | Omit next doses; ↓ by 60%–75% | Seek medical attention and consult regional poison center even if not symptomatic; if >60 years of age, anticipate need for treatment of seizures. |

^aIt is important that levels are obtained at steady state. If laboratory results appear questionable, suggest repeat measurements.

Table 22-12 Factors Affecting Serum Theophylline Concentrations^a

| <i>Factor</i> | <i>Decreases Theophylline Concentrations</i> | <i>Increases Theophylline Concentrations</i> | <i>Recommended Action</i> |
|---|---|--|--|
| Food | ↓ or delays absorption of some sustained-release theophylline (SR) products | ↑ rate of absorption (fatty foods) | Select theophylline preparation that is not affected by food. |
| Diet | ↑ metabolism (high protein) | ↓ metabolism (high carbohydrate) | Inform patients that major changes in diet are not recommended while taking theophylline. |
| Systemic, febrile viral illness (e.g., influenza) | | ↓ metabolism | Decrease theophylline dose according to serum concentration level. Decrease dose by 50% if serum concentration measurement is not available. |
| Hypoxia, cor pulmonale, and decompensated congestive heart failure, cirrhosis | | ↓ metabolism | Decrease dose according to serum concentration level. |
| Age | ↑ metabolism (1–9 yr) | ↓ metabolism (<6 mon, elderly) | Adjust dose according to serum concentration level. |
| Phenobarbital, phenytoin, carbamazepine | ↑ metabolism | | Increase dose according to serum concentration level. |
| Cimetidine | | ↓ metabolism | Use alternative H ₂ -antagonist (e.g., famotidine or ranitidine). |
| Macrolides: TAO, erythromycin, clarithromycin | | ↓ metabolism | Use alternative antibiotic or adjust theophylline dose. |
| Quinolones: ciprofloxacin, enoxacin, pefloxacin | | ↓ metabolism | Use alternative antibiotic or adjust theophylline dose. |
| Rifampin | ↑ metabolism | | Increase dose according to serum concentration level. |
| Ticlopidine | | ↓ metabolism | Decrease dose according to serum concentration level. |
| Smoking | ↑ metabolism | | Advise patient to stop smoking; increase dose according to serum concentration level. |

^aThis list is not all-inclusive; for discussion of other factors, see package inserts. Modified from reference 1.

before any interventions. For example, cimetidine decreases theophylline clearance within 24 hours, and this interaction should be circumvented by using another H₂-blocker or a proton pump inhibitor (Table 22-12). Classic inducers (e.g., rifampin) of cytochrome P450 also affect theophylline clearance, and patients should be monitored for decreased serum concentrations. In T.R., the interaction with clarithromycin can easily be circumvented by using azithromycin, which does not affect theophylline metabolism.

Anticholinergics

40. R.K. is a 24-year-old graduate student with moderate persistent asthma, which has been well controlled for 10 years with ICS therapy and albuterol PRN. Recently, he has noticed that his asthma symptoms tend to worsen when he has anxiety over major examinations. What drug therapy might be helpful in R.K.?

One of the myths related to asthma is that it is an emotional illness. It is true, however, that among many typical triggers (e.g., aeroallergens, exercise), emotional upset can be a precipitating factor in some asthmatics,¹ and it has been shown that inhaled anticholinergic bronchodilators can block this response.⁹⁹ Although it is not an established therapy in this

situation, a therapeutic trial of ipratropium given by an MDI is warranted in R.K. He probably only needs to use ipratropium a day or so before major examinations and on the day of the examination (i.e., he is well controlled all other times).

Anticholinergic bronchodilators also are useful in patients with asthma who are intolerant of the side effects of SABAs. For example, a patient who experiences nervousness or tremor with SABAs could use an ipratropium MDI as an alternative. Ipratropium is slower in onset (up to 30 minutes) but may be slightly longer acting than albuterol. As a general rule, anticholinergics are inferior to β_2 -agonists in patients with asthma and should not be used as a rescue drug. These agents also benefit some patients who have asthma and then, very unfortunately, smoke for several years and develop chronic obstructive pulmonary disease (COPD). Tiotropium (Spiriva) is an important agent in the treatment of COPD; further research is needed to determine if it has a role in the management of some patients with asthma.¹⁰⁰

ANTI-IMMUNOGLOBULIN E THERAPY

41. M.M. is a 30-year-old female with severe persistent asthma. Despite optimal assessment, drug therapy, environmental control,

and patient education per the principles of management detailed in EPR-3, she has had two recent hospitalizations due to asthma. Her allergist is considering anti-IgE therapy. Is M.M. a good candidate for such therapy? How would it be given? M.M. has a pretreatment IgE level of 90 IU/mL, and she weighs 55 kg.

Omalizumab (Xolair) is a humanized monoclonal anti-IgE antibody that binds to free IgE in serum. Thus, binding of IgE to high-affinity receptors on mast cells is subsequently inhibited, and the initiation of the allergic inflammatory cascade is blocked.^{1,101–105} Omalizumab is effective in reducing oral and ICS dose requirements in patients with severe asthma and in reducing exacerbations.^{101,102,105–107} This novel therapy is administered as a 150- to 375-mg subcutaneous injection every 2 or 4 weeks. The dose and frequency of administration are based on the serum total IgE level (IU/mL) and the patient's body weight. Therefore, M.M.'s omalizumab dose is 150 mg SC every 4 weeks.

Common side effects associated with omalizumab include injection site reactions, upper respiratory tract infections, sinusitis, and headache. Less common but potentially serious adverse effects include anaphylaxis (0.2% in postmarketing spontaneous reports), which can occur after any dose even if previous doses have been well tolerated and 24 or more hours after administration, and the development of malignant neoplasms (0.5% of omalizumab-treated patients compared with 0.2% in controls).

Because omalizumab is expensive and must be administered as a subcutaneous injection, it should be reserved for patients with severe asthma who are not adequately controlled with standard therapies. Despite the high cost, anti-IgE therapy might be cost-effective in selected patients with severe disease (e.g., those with frequent ED visits and hospitalizations), because an estimated <5% of asthma patients (severe disease) account for >50% of the dollars spent for asthma care.¹⁰⁸

42. As the nurse prepares the dose of omalizumab for M.M., what are some special considerations regarding administering and monitoring this drug?

Following reconstitution of omalizumab, the drug must be administered within 4 hours if stored at room temperature and within 8 hours when refrigerated. Due to its viscosity, the injection may take 5 to 10 seconds. No more than 150 mg is injected at each site. While the risk of anaphylaxis is rare, patients should stay in the physician's office for at least 30 minutes after injection of omalizumab and be educated regarding the signs and symptoms of anaphylaxis. After leaving the physician's office, patients should seek emergency medical treatment at the first sign of anaphylaxis. Despite the low risk of severe allergic reactions, the manufacturer recently added a black box warning regarding this risk.

EXERCISE-INDUCED ASTHMA

43. T.W., a 33-year-old woman, presents to the clinic with a history of severe coughing and chest tightness after exercise. She recently joined an exercise club to lose weight but is unable to keep up with others of her own age and relative condition when jogging outside. She recalls having mild respiratory problems as a young child but has never taken any asthma medications. She has a positive treadmill test for exercise-induced asthma (EIA). How should T.W. be treated?

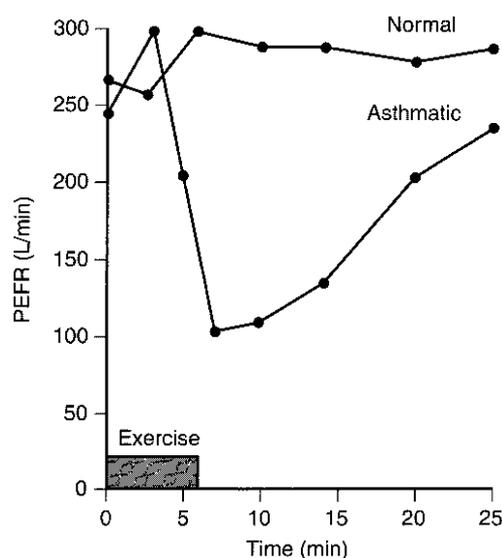

FIGURE 22-14 Changes in peak expiratory flow rate with exercise in an asthmatic and normal subject. PEFR, peak expiratory flow rate.

During sustained exercise, at least 90% of patients with asthma experience an initial improvement in pulmonary functions quickly followed by a significant decline (Fig. 22-14). This phenomenon may be the only symptom of subclinical asthma.^{1,109} Patients can be diagnosed by measuring the FEV₁ or PEF before and after exercise (6–8-minute treadmill or bicycle exercise test). A reduction of FEV₁ by >15% of the baseline value is a positive test.

Hyperventilation of cold, dry air increases the sensitivity to EIA and induces bronchospasm.¹⁰⁹ The main stimulus for EIA is respiratory heat loss, water loss, or both,¹⁰⁹ while breathing heated, humidified air completely blocks EIA in many patients.¹⁰⁹ Masks are indicated for patients with EIA in the wintertime, and patients with severe asthma accompanied by EIA also should be encouraged to swim or engage in other indoor exercise that does not promote EIA. A warm-up period before strenuous exercise is helpful in some patients. With appropriate premedication, most EIA can be prevented, so virtually all patients with stable asthma should be encouraged to exercise. The mechanism of bronchoconstriction after airway heat and water loss is still incompletely understood.¹⁰⁹

Although several drugs inhibit EIA, SABAs are generally the agents of choice for prophylaxis.^{1–6,109,110} Inhaled β_2 -agonists are superior to cromolyn.¹¹⁰ For typical periods of exercise (e.g., <3 hours), pretreatment with agents such as albuterol 5 to 15 minutes before exercise usually provides excellent protection from EIA.

For prolonged periods of exercise, LABAs (formoterol, salmeterol) provide several hours of protection.¹¹¹ Two differences in formoterol and salmeterol include the delivery systems for inhalation and the onset of action. If either of these agents is to be used to prevent EIA, it is important for the patient to inhale the medication at the proper time before exercise. Formoterol should be inhaled at least 15 minutes before exercise, and salmeterol administration should occur at least 30 minutes before vigorous activity. Patients who are receiving Q 12 hr therapy with either drug concomitantly with ICS for long-term control of asthma, should already be protected and therefore only use albuterol if symptoms occur after exercise.

With maintenance therapy, as opposed to single doses before exercise, bronchoprotection from exercise may be reduced to 5 hours with LABAs.¹ Formoterol is inhaled via the Aerolizer (a single dose is loaded each time), and salmeterol is inhaled through the Diskus (multiple-dose inhaler).

Leukotriene receptor antagonists (e.g., montelukast once-daily chronic therapy) have also been demonstrated to prevent EIA.¹¹² Finally, it is important to point out that in persistent asthma, long-term anti-inflammatory therapy is helpful in reducing the response to most asthma triggers, including exercise.¹ For most patients who have EIA only, use of a SABA 15 minutes before exercise is the only therapy needed.

Because of the hyperventilation of relatively cool, dry air, jogging is a potent stimulus for EIA. A number of possible therapeutic interventions exist for T.W. She could be encouraged to swim, because the inhalation of humidified warm air is less likely to produce EIA. However, if she wishes to continue jogging, two inhalations of a short-acting β_2 -agonist (e.g., albuterol) from a metered-dose aerosol 15 minutes before exercise should provide adequate protection for 2 to 3 hours. If outdoor temperatures are quite cool or cold, T.W. should jog indoors. T.W. also should be counseled to take two additional inhalations if she “breaks through” the initial protection and experiences tightness.

44. W.L., a 17-year-old boy, presents to the clinic with a complaint of dyspnea and coughing that has limited his ability to keep up with his basketball teammates. He states that it is worse when playing outdoors unless the gym is cold and that it seems to be worse (occurring sooner during exercise) than a month ago. W.L. experienced several bouts of bronchitis as a young child but has not had any problems for the past 6 years. His symptoms are consistent with EIA. How should his EIA be treated?

W.L. presents a special problem in that he is a teenager. Both for adolescents and children, peer pressure usually is extremely significant. Optimal prophylaxis is important to allow W.L. to compete at his best level. Embarrassment over not keeping up with teammates can be very hurtful now, and it has implications for setting habits of exercise into adulthood. Many adults with asthma do not exercise because they think they cannot do so based on childhood experiences. Lack of exercise can have a negative impact on physiologic and psychologic well-being. W.L. should receive preventive treatment with an inhaled β_2 -agonist. The question is whether he should receive a short-acting or a long-acting agent. The clinician should probe as to the duration of exercise. If W.L. exercises for >3 hours, formoterol or salmeterol administered 15 to 30 minutes before exercise would be a logical choice. Finally, the clinician should verify that exercise is the only factor that precipitates asthma symptoms. It could be that further questioning of W.L. will reveal persistent asthma or mild intermittent asthma beyond EIA only. If that is the case, long-term ICS or montelukast therapy should be started to reduce overall airway hyperresponsiveness.

PATIENT EDUCATION

45. A.B., a 26-year-old woman, calls her clinician and states that she has run out of her albuterol MDI. She has a prescription

for a budesonide dry powder inhaler but admits that she does not use this medication “because it doesn’t seem to work as well as her albuterol MDI.” A.B. has had asthma all of her life. She complains of symptoms most days but has not required visits to the ED or hospitalizations. The provider determines that A.B. is bothered most about daily shortness of breath and worries that her condition may get worse. What should the provider do in this situation?

If optimal long-term drug therapy of asthma is prescribed, treatment may still fail or be suboptimal if the patient does not receive adequate education. Patients with asthma require special educational efforts because of the use of inhalation devices and peak flow meters. In addition, it often is a major challenge to have patients and parents understand the critical importance of long-term daily controller therapy and environmental control. Of course, an important first step in educating asthmatics is to be caring and a good listener. Rather than sharing your knowledge initially, it is important to help establish a “partnership” with the patient by first asking the following question: “What is bothering you the most about your asthma?” Really listening to the patient and then addressing patient concerns is extremely important to successful education and long-term management. EPR-3 lists several patient education activities in Table 22-13.¹

Table 22-13 Key Educational Messages: Teach and Reinforce at every Opportunity

Basic Facts About Asthma

- The contrast between airways of a person who has and a person who does not have asthma; the role of inflammation
- What happens to the airways in an asthma attack

Roles of Medications—Understanding the Difference Between the Following:

- Long-term-control medications: prevent symptoms, often by reducing inflammation. Must be taken daily. Do not expect them to give quick relief.
- Quick-relief medications: short-acting β_2 -agonists relax muscles around the airway and provide prompt relief of symptoms. Do not expect them to provide long-term asthma control. Using quick-relief medication on a daily basis indicates the need for starting or increasing long-term control medications.

Patient Skills

- Taking medications correctly
 - Inhaler technique (demonstrate to patient and have the patient return the demonstration)
 - Use of devices, such as prescribed valved holding chamber, spacer, nebulizer
- Identifying and avoiding environmental exposures that worsen the patient’s asthma (e.g., allergens, irritants, tobacco smoke)
- Self-monitoring to:
 - Assess level of asthma control
 - Monitor symptoms and, if prescribed, peak flow
 - Recognize early signs and symptoms of worsening asthma
- Using written asthma action plan to know when and how to:
 - Take daily actions to control asthma
 - Adjust medication in response to signs of worsening asthma
 - Seek medical care as appropriate

Reprinted from reference 1.

Clinicians can be of invaluable assistance to the patient by repeatedly reinforcing education on the necessity to use anti-inflammatory (and LABA) therapies on a regular schedule. Many patients underuse long-term preventive therapy because no health professional took the time to adequately instruct them that most asthma symptoms are preventable. While underusing the most important medicines for long-term control, many patients overuse “quick relievers” (i.e., SABAs). Health care providers must be able to detect these problems and intervene to enhance patient care.

Because a large percentage of patients have difficulty using MDIs, teaching patients the correct use of MDIs (alone, or in combination with spacers) and dry powder inhalers is absolutely essential.^{1,113} In one study, 89% of patients could not perform all of the steps for MDI use correctly.^{1,114} Competent teaching requires *observation* of the patient using the devices initially and again on repeat visits to the clinic, hospital, or community pharmacy. Telling the patient about correct use is inadequate. Health professionals must demonstrate use of the devices (live or with videotapes) for patients who cannot use the devices correctly. Although there is more than one correct way to use an MDI, Table 22-14 summarizes two commonly accepted approaches.^{1,113} Many asthma experts prefer to use spacers to help ensure optimal efficacy. Spacers should be used in virtually all patients receiving ICS via an MDI, even those with perfect MDI technique, because spacers enhance efficacy and greatly reduce the risk of oropharyngeal candidiasis.^{115–117} On the other hand, spacers do not add efficacy to *correct* use of a β_2 -agonist MDI.¹¹⁸ Although any spacer can be helpful, marketed devices that have a flow indicator whistle when inhalation is fast may be preferred (e.g., AeroChamber, InspirEase).

Table 22-14 Steps to Correct Use of Metered-Dose Inhalers^a

1. Shake the inhaler well and remove the dust cap.
2. Exhale *slowly* through pursed lips.^b
3. If using the “closed-mouth” technique, hold the inhaler upright and place the mouthpiece between your lips. Be careful not to block the opening with your tongue or teeth.
4. If using the “open-mouth” technique, open your mouth wide and hold the inhaler upright 1–2 inches from your mouth, making sure the inhaler is properly aimed.
5. Press down on the inhaler *once* as you start a *slow*, deep inhalation.
6. Continue to inhale slowly and deeply through your mouth. Try to inhale for at least 5 seconds.
7. Hold your breath for 10 seconds (use your fingers to count to 10 slowly). If 10 seconds makes you feel uncomfortable, try to hold your breath for at least 4 seconds.
8. Exhale *slowly*.^c
9. Wait at least 30–60 seconds before inhaling the next puff of medicine.

^aIf using a spacer, see manufacturer’s instructions. Same basic principles of slow, deep inhalation with adequate breath hold apply. With spacers, put mouthpiece on top of your tongue to ensure that tongue does not block aerosol.

^bAs long as exhalation is slow, exhalation can take place over several seconds. Some experts insist on exhaling only a tidal volume, but the key is to exhale *slowly*.

^cIf patient has concomitant rhinitis, exhaling through the *nose* may be of benefit when using corticosteroids, cromolyn, or ipratropium (i.e., some medication may deposit in nose).

Studies have shown that health professionals, like some patients, generally are not competent in using MDIs.^{119–121} Obviously, the clinician should practice with a placebo inhaler and gain competence before teaching a patient. Among clinicians who educate asthmatics, pharmacists can be very helpful in teaching correct use of MDIs.¹²² Unfortunately, one study showed that community pharmacists commonly are not providing such teaching.¹²³

In addition to teaching the correct use of MDIs and spacers, clinicians should help patients via education regarding the correct use of breath-activated dry powder inhalers (e.g., Turbuhaler, Diskus, Aerolizer), breath-activated MDIs (e.g., Autohaler), and nebulizing machines.¹ When using the Flexhaler, for example, patients must clearly understand the need for a rapid (preferably 60 L/minute), deep inhalation (not slow as with an MDI).¹²⁴ Such rapid PIF is achievable by some young children, but many children <8 years of age have difficulty reaching PIF >60 L/minute.¹²⁴ With the Diskus, PIF does not have to be as rapid as with Flexhaler, but it should be >30 L/minute.¹²⁵ In addition, patients need to breath-hold 10 seconds if possible, as with an MDI.

Asthma Self-Management Plans

Objective monitoring of lung function at home with the use of peak flow meters can be very helpful to patients and health care professionals. EPR-3 discusses the debates about PEF versus symptom-based action plans.¹ Use of peak flow meters may be valuable in patients who have had severe exacerbations and those who are “poor perceivers” of deteriorating asthma control. Instructing patients on the correct use of the devices, including use of the green, yellow, and red zones is essential.¹ After establishing that optimal therapy has maintained the PEF in the “green zone” in the early morning, most patients can simply verify their values once daily in the early morning. Analogous to a traffic light, green, yellow, and red zones have been established to guide the patient and clinician. The *green zone* refers to a PEF that is 80% to 100% of “personal best” and generally indicates that therapy is providing good control. Before a course of optimal therapy to attain a personal best, the zones are set based on predicted values found in each peak flow meter package insert. The *yellow zone* indicates a PEF that is 50% to 79% of personal best. Patients should be instructed to call their physician or other health care provider for adjustment in preventive medication if the PEF stays in yellow zone after using two puffs of a β -agonist. The *red zone* indicates a PEF that is <50% of personal best. The patient should know to call his or her health care provider immediately if the use of an inhaled β -agonist does not bring the PEF to the yellow zone or green zone. Figure 22-15 gives an example of PEF monitoring, and Figure 22-16 gives an example of a written action plan.

Correct use of the peak flow meter includes standing, inhaling completely, forming a tight seal with the lips around the mouthpiece, exhaling as hard and fast as possible (blast!), and repeating this maneuver twice. The best of three attempts should be recorded. Beyond giving maximal effort when using peak flow meters, patients should be instructed to place the instrument well into the mouth on top of the tongue to avoid acceleration of air in the mouth with the tongue and buccal musculature. In essence, “spitting” into the peak flow meter causes a dramatic “false” elevation in PEF.¹²⁶ Some data

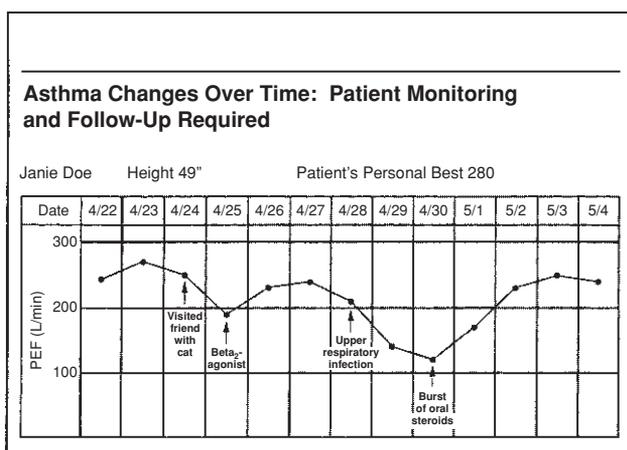

FIGURE 22-15 Asthma changes over time: patient monitoring and follow-up required. (Reproduced with permission from National Institutes of Health. Practical guide for the diagnosis and management of asthma 1997; NIH publication No. 97-4053.)

suggest that females need more initial coaching than men in giving maximum effort when using peak flow meters to ensure accurate assessments of PEF.¹²⁷

A.B. needs education regarding the benefits of long-term inhaled anti-inflammatory therapy. The clinician should explain with enthusiasm that A.B.'s budesonide is an extremely effective medicine and that it is the cornerstone of her asthma management. The delayed onset and safety of ICS must be stressed as well as the requirement of regular use every day. Teaching A.B. the differences between “preventers” and “quick relievers” is essential. Showing her colored pictures, models, or a video of inflamed airways can be very helpful—these teaching aids are available from several pharmaceutical manufacturers. Likewise, a peak flow meter should be given to A.B. and correct use ensured by observing her use of it along with establishment of green, yellow, and red zones, coupled with a written action plan developed by her asthma care provider.¹ A.B. needs to hear from the clinicians treating her that asthma is preventable, and in the words of a title to an NIH booklet for patients, “Your asthma can be controlled: Expect nothing less.” As part of comprehensive education, such a positive message from all of her caregivers, as well as carefully listening to A.B.'s concerns, can have a major impact on A.B., who has not been managing her asthma optimally.

46. A.B. tells the provider that she was previously instructed to place the albuterol MDI in front of her open mouth and spray rather than put the MDI in her mouth. She says she is confused because the package insert shows placement of the inhaler in the mouth. Finally, she is concerned that her albuterol was changed to “HFA.” What should the clinician tell A.B.?

A.B. is correct that this is a confusing issue to many patients and health professionals. A small number of studies show that the “open-mouth” technique is better, but several other studies with SABAs show that the “closed-mouth” technique is as good as or better than putting the MDI in front of the open mouth.^{1,113} In addition, the correctly performed closed-mouth technique is as efficacious with a β_2 -agonist as with a spacer¹¹⁸ or nebulizer.¹²⁸ Thus, the closed-mouth technique is perfectly

acceptable, as is the open-mouth technique with SABAs or LABAs. One caution with the open-mouth technique is that incorrect aiming of the MDI may result in the aerosol being sprayed onto the face or into the eyes. Finally, due to the phasing out of chlorofluorocarbon (CFC) propellants (prohibited after December 31, 2008), increasing numbers of patients are already using albuterol MDIs with non-CFC propellants (e.g., HFA [tetrafluoroethane]). A.B. should be reassured that albuterol-HFA MDIs have been tested extensively and work as well as her former MDI (but with a less forceful spray).¹²⁹

47. For patients who are using both a bronchodilator and an anti-inflammatory inhaler, is there a preferred sequencing of the inhalers?

For patients who have several inhalers, questions regarding sequencing of the inhalers are frequently asked. First, there is no well-documented evidence that outcomes are better using, for instance, a bronchodilator or an anti-inflammatory agent first. A commonsense approach is that using a rapid-onset bronchodilator such as a β_2 -agonist first and then an anti-inflammatory second has some appeal (i.e., quick relief and theoretically enhanced penetration of the anti-inflammatory). However, as discussed previously, short-acting β_2 -agonists are preferred for *as-needed use* (and before exercise) and are not generally used on a scheduled basis. Thus, if a patient is not symptomatic at the time the anti-inflammatory is scheduled, current literature suggests that the patient inhales only the anti-inflammatory agent. Therefore, it is usually *not* necessary to counsel patients regarding sequencing of inhaled medications. Because time is limited in counseling patients, teaching them correct inhalation technique, the purpose of each medication (controllers vs. quick relievers), and the need for strict adherence with controller therapies is far more important than spending precious time on the sequencing of inhalers.

NOCTURNAL ASTHMA

48. R.R., a 41-year-old man, presents to the clinic with a history of coughing and shortness of breath that awakens him at least two nights a week. Most mornings on awakening, he complains of chest tightness. He has a history of asthma since childhood and currently is managed with beclomethasone HFA 160 mcg BID via a spacer and albuterol (90 mcg/puff) two puffs Q 6 hr PRN, and before exercise. R.R.'s morning PEF is consistently in the yellow zone, usually at about 400 L/minute (personal best, 600 L/minute), whereas the evening PEF is consistently 550 to 600 L/minute. What treatment should be recommended?

Many patients with asthma complain of symptoms that awaken them in the night or occur on awakening in the morning. Morning cough with or without bronchospasm may be a clue to nocturnal asthma. Although nocturnal asthma may be appropriately viewed as simply another manifestation of airway inflammation, it is so common and troublesome among asthmatics that it deserves special note. Circadian rhythm in PEF is exaggerated in patients with asthma. The difference in PEF in nonasthmatics averages about 8% between 4 PM (maximal airflow) and 4 AM (minimal airflow), but in patients with asthma, the average variation can be as high as about 50%.^{130,131} Several mechanisms account for this diurnal variation in PEF. The following are examples of factors that contribute to nocturnal

Asthma Action Plan

For: _____ Doctor: _____ Date: _____
 _____ Hospital/Emergency Department Phone Number _____

GREEN ZONE

Doing Well

- No cough, wheeze, chest tightness, or shortness of breath during the day or night
- Can do usual activities

And, if a peak flow meter is used,

Peak flow: more than _____
 (80 percent or more of my best peak flow)

My best peak flow is: _____

Take these long-term control medicines each day (include an anti-inflammatory).

Medicine

How much to take _____ When to take it _____

Identify and avoid and control the things that make your asthma worse, like (list here): _____

Before exercise, if prescribed, take: 2 or 4 puffs _____ 5 to 60 minutes before exercise.

YELLOW ZONE

Asthma Is Getting Worse

- Cough, wheeze, chest tightness, or shortness of breath, or
- Waking at night due to asthma, or
- Can do some, but not all, usual activities

-Or-

Peak flow: _____ to _____
 (50 to 79 percent of my best peak flow)

First

Add: quick-relief medicine—and keep taking your GREEN ZONE medicine.

_____ 2 or 4 puffs, every 20 minutes for up to 1 hour
 (short-acting β_2 -agonist) Nebulizer, once

Second

If your symptoms (and peak flow, if used) return to GREEN ZONE after 1 hour of above treatment:

Continue monitoring to be sure you stay in the green zone.

-Or-

If your symptoms (and peak flow, if used) do not return to GREEN ZONE after 1 hour of above treatment:

Take: _____ 2 or 4 puffs or Nebulizer
 (short-acting β_2 -agonist)

Add: _____ mg per day For _____ (3–10) days
 (oral corticosteroid)

Call the doctor before/ within _____ hours after taking the oral steroid.

RED ZONE

Medical Alert!

- Very short of breath, or
- Quick-relief medicines have not helped, or
- Cannot do usual activities, or
- Symptoms are same or get worse after 24 hours in Yellow Zone

-Or-

Peak flow: less than _____
 (50 percent of my best peak flow)

Take this medicine:

_____ 4 or 6 puffs or Nebulizer
 (short-acting β_2 -agonist)

_____ mg
 (oral corticosteroid)

Then call your doctor NOW. Go to the hospital or call an ambulance if:

- You are still in the red zone after 15 minutes AND
- You have not reached your doctor.

DANGER SIGNS ■ Trouble walking and talking due to shortness of breath

■ Lips or fingernails are blue

■ Take 4 or 6 puffs of your quick-relief medicine AND

■ Go to the hospital or call for an ambulance _____ NOW!
 (phone)

FIGURE 22-16 Sample asthma action plan. (Reproduced from reference 1.)

asthma: increased release of inflammatory mediators,^{130,131} increased activity of the parasympathetic nervous system, lower circulating levels of epinephrine, and lower levels of serum cortisol (lowest at about midnight). In addition, for patients whose asthma is triggered by gastroesophageal reflux, this problem is worse at night and is another factor to consider.

The initial approach to managing nocturnal symptoms is the same as that for overall long-term therapy of persistent asthma, including adequate anti-inflammatory agents.^{1,131} ICS are often effective in eliminating or reducing nocturnal asthma, including symptoms and the drop in PEF.¹³¹ If low to moderate dosages (i.e., correctly inhaled every day) do not eliminate symptoms, a LABA (salmeterol, formoterol) is indicated. Also, the basic asthma treatment principle of good control of concomitant rhinitis and environmental control, especially in the bedroom (e.g., house dust mites, household pets), should be considered in the patient with nocturnal asthma symptoms.

Bedtime doses of SABAs do not have sufficient duration of action to prevent early morning symptoms. Salmeterol or formoterol, both of which have a 12-hour duration of action, are preferred. Before the advent of LABAs, long-acting oral agents such as SR theophylline often were indicated.¹³¹ Although SR theophylline is helpful, it has the potential to cause more adverse effects than inhaled agents, may interfere with sleep, and is less efficacious.¹³¹ Before a long-acting oral agent is prescribed, adequate inhaled anti-inflammatory therapy should be ensured and then LABAs should be used.

Because asthma is primarily an inflammatory disease and nocturnal symptoms are due largely to airway inflammation, the first drug therapy concern in R.R. is to ensure that he is strictly adhering to his beclomethasone therapy, and demonstrating excellent inhalation technique. If his use of the medication is optimal, a reasonable approach would be to add LABA therapy, because he is already at a moderate ICS dosage.

As part of optimal management of nocturnal asthma, R.R. also should be asked about avoiding or minimizing exposure to his asthma triggers (e.g., if he is allergic to cats, is there a cat in the bedroom?). Follow-up visits for R.R. should verify that the early morning and evening PEF are staying in the green zone and that symptoms, both during the night and on awakening in the morning, have been eliminated.

DRUG-INDUCED ASTHMA

49. M.B., 32-year-old woman with asthma, asks her clinician which over-the-counter medications would be preferred for minor aches and pains. M.B. says that she is very sensitive to aspirin (causes severe wheezing).

The clinician should counsel the patient regarding the fact that patients with asthma who are aspirin sensitive often react to other nonsteroidal anti-inflammatory drugs (NSAIDs) such as ibuprofen by developing asthma symptoms with the first dose. The health care professional should suggest acetaminophen. If M.B. says that acetaminophen does not give adequate relief of her pain, other options are salsalate² or consultation with a board-certified allergist with experience in aspirin and NSAID desensitization.¹³² The clinician should also suggest consultation with an allergist regarding a recent study that gives strong evidence that cyclo-oxygenase-2 (COX-2) inhibitors are safe

in aspirin-sensitive asthma.¹³³ This case also points out the need for health professionals to pay attention to patient use of nonprescription medications. Although drug-induced asthma may present as relatively mild symptoms in some patients, fatal asthma caused by medicinal agents has been reported numerous times. The most extensive literature on drug-induced asthma involves NSAIDs and β -blockers. Other drugs and drug preservatives also can induce symptoms of asthma, but because the topic is beyond the scope of this chapter, the reader is referred to other sources^{134,135} for further discussion.

The percentage of asthmatics reported to be aspirin sensitive ranges from 4% to 28%. Clinical manifestations of aspirin sensitivity include rhinorrhea; mild wheezing; or severe, life-threatening shortness of breath. Once the reaction has occurred, there is a refractory period of 2 to 5 days.¹³⁶ If an asthmatic is aspirin sensitive, it is likely that the patient also will react to most other NSAIDs. Aspirin and other NSAIDs share common mechanisms involving the arachidonic acid pathways, including inhibition of cyclo-oxygenase, which results in more rapid synthesis and overproduction of leukotrienes.¹³⁶ Not surprisingly, because leukotrienes are an important part of the mechanism of NSAID-induced asthma, inhibitors of 5-lipoxygenase such as zileuton are generally effective in blocking this response.¹³⁷ Similarly, leukotriene receptor antagonists such as zafirlukast and montelukast are generally effective in blocking aspirin-induced asthma.¹³⁸ Because most patients with asthma do not react to aspirin and other NSAIDs, the NIH guidelines recommend avoiding these agents only in patients with known sensitivity.¹ In addition, patients with severe persistent asthma or nasal polyps should be counseled regarding the risks associated with these drugs. In patients with known sensitivity, acetaminophen or salsalate are recommended for headaches and relatively minor pain.¹ For patients who are sensitive but who need to take aspirin (e.g., post myocardial infarction [MI] or an NSAID [(e.g., arthritis)]), it is possible to desensitize the patient, and daily use then prevents further reaction.¹³²

When discussing drug-induced asthma, the other major consideration is β -blockers. These agents should be used with great caution in patients with asthma. Because even β_1 -adrenergic blockers lose selectivity as dosages are increased, they, as well as nonselective β -blockers, should be avoided in most patients. Furthermore, ophthalmic timolol has been reported several times to cause fatal asthma and should absolutely be avoided in patients with a history of asthma.¹³⁹ Other β -blocker eye drops (e.g., betaxolol) have been reported to have less propensity to induce asthma, but all have some risk.^{134,140}

Two notable exceptions to using β -blockers in patients with asthma are patients who are post MI and patients with heart failure.¹⁴¹ Because β -blockers prolong life post MI and improve the care of patients with heart failure, benefits versus risks should be weighed. Risks outweigh benefits if a patient has severe persistent asthma.^{141,142} If a post-MI patient has mild intermittent asthma or well-controlled mild persistent (and possibly moderate persistent¹⁴¹) asthma with optimal management, a low dosage of atenolol 50 mg/day is a reasonable consideration where benefits may outweigh risks.¹⁴² Asthma patients have been shown to respond to inhaled β_2 -agonists when receiving this dosage of atenolol.¹⁴² While low

dosages of β -blockers are not proven to prolong life after an MI, some studies suggest efficacy of lower dosages. For patients with heart failure, metoprolol CR/XL is the cardioselective β -blocker approved in the United States, while carvedilol, which has nonselective β -blocker as well as α -blocking properties, can worsen asthma symptoms.¹⁴²

If a patient with asthma is given a β -blocker and initially reports no symptoms, subsequent exacerbations may not respond well to administration of usual doses of a β -agonist. The drug of choice for β -blocker-induced bronchospasm is ipratropium.¹⁴² A more subtle risk with β -blockers involves the adult with allergic rhinitis and a family history of asthma. If this individual is given a β -blocker for hypertension, symptoms of asthma could be induced, especially if another trigger is introduced such as running in cold, dry air.

OUTCOMES

50. C.C. is a 36-year-old woman admitted to the hospital for asthma. This is her second hospitalization in the past 2 years, and she has had three ED visits during the same period. She also complains of nocturnal awakenings at least 4 nights per week and is bothered that she is gaining weight, because she cannot exercise. Lack of exercise is also troubling her because her 5-year-old daughter wants her to go outside and play with her. C.C. has been taking flunisolide one puff BID without a spacer for years along with frequent PRN albuterol. C.C. carefully controls her home environment. What could her clinicians do to improve her outcomes, including quality of life?

C.C. needs a reassessment of her long-term management considering her very poor outcomes over the past 2 years. First, her clinicians need to establish a partnership with her in education regarding asthma and its management. Clearly, she needs dosage adjustment with her anti-inflammatory therapy. Her dosage is too low, plus she is receiving a low-potency corticosteroid. Based on her recent history, she should be treated initially with high-dose ICS and a LABA, preferably with a more potent ICS product that would require fewer inhalations per day (e.g., combination budesonide-formoterol or combination fluticasone-salmeterol). C.C. should have the importance of daily controller therapy stressed, including the need for strict adherence and proper inhalation technique. C.C. needs a written asthma action plan and an emergency supply of prednisone (i.e., to use when her PEF is in the red zone and unresponsive to albuterol). C.C. should be told to expect a reduced need for albuterol.

Numerous studies have documented that applying the principles of the NIH guidelines^{1–6} results in improved clinical outcomes, and many of these studies have been summarized in EPR-3.¹ Several studies have documented that pharmacists who are highly knowledgeable of the NIH guidelines and who work closely with patients and physicians improve outcomes, including reduced ED visits and hospitalizations.^{143–148} These successful studies involved highly motivated pharmacists, who were asthma experts based in university-affiliated clinics or in large private HMOs.

A recent randomized controlled trial based in community pharmacies with specially trained pharmacists has also shown very positive outcomes for patients with asthma.¹⁴⁸ Another

randomized controlled trial based in chain drug stores with staff pharmacists did not show a benefit related to attempts at asthma care.¹⁴⁹ Unfortunately, the level of training and incentives did not appear optimal, and the authors pointed out that the staff pharmacists were “not universally enthusiastic” about the program. The authors also described their intervention as “cumbersome” for the pharmacists. Further study is needed to assess asthma care in this setting when pharmacists are optimally trained, given appropriate incentives, and enthusiastic about the program.

When assessing the effect of comprehensive management on clinical outcomes, quality-of-life measures should be assessed as well as reduction in ED visits and hospitalizations.¹ To achieve optimal outcomes, attention to each of the four major components of management is required (objective assessment, environmental control, pharmacologic therapy, and patient education as a partnership). Examples of areas that pose special challenges for inner-city patients include psychosocial factors, underuse of controller medications, and passive cigarette smoke.^{150–153} As part of overall management to improve outcomes, recent studies have emphasized again the importance of good inhalation technique with ICS and education in use of peak flow meters.^{154,155}

51. C.C. returns to the clinic in 2 months and is elated because she is sleeping through the night and not waking up short of breath. In addition, she is beginning to exercise again, which makes her and her child very happy. C.C. has had no further ED visits. What should the clinician do at this point?

Optimal asthma management that improves outcomes is a continuous process of education and reassessment of the overall therapy. Observation of C.C. using her peak flow meter and inhalation devices on each clinic visit is important and should be routine. Having C.C. verbalize her understanding of the role of the ICS plus LABA versus albuterol and the action plan with “crisis” prednisone is important. Despite her current optimism, asking C.C. about her current asthma concerns is important. Over the next month or two, a trial of slowly stepping down the ICS dosage to a medium dose should be attempted. Finally, C.C. needs continued partnership with her clinician.

52. C.C. is in the clinic 2 years later, reflecting with her clinician over her total elimination of ED visits and hospitalizations as well as her improved quality of life. Her management initiated 24 months ago has continued, including environmental control, controller therapy tailored for her, PRN albuterol and early morning PEF monitoring, and partnership with her clinician. Unfortunately, C.C. forgot to get an influenza vaccine last October and became ill with influenza in early March. Although this episode only slightly worsened her asthma symptoms, when she was almost recovered from the flu, she went to the grocery store and breathed secondhand smoke unexpectedly. In addition, early spring tree and grass pollen was affecting her allergic rhinitis. By the time she got back to her house, she was wheezing and her PEF was in the yellow zone, but it responded to three puffs of albuterol. C.C. asks what she should have done if this series of events had resulted in her PEF decreasing to the red zone.

C.C. needs to be re-educated regarding the action plan based on symptoms and PEF values. Referring back to the written

plan for doses of albuterol and, if needed, oral corticosteroid therapy is important. Emphasizing the need for annual influenza vaccination in October is important. Reinforcement of the importance of continued preventive therapy that has given such remarkable success is appropriate for C.C. and reassuring her that despite this minor setback, she is in control of her asthma. The clinician should continue to work with her to further tailor the therapy, including control of rhinitis, to maintain optimal outcomes at the lowest dosages and the simplest possible regimen. Recent research has further emphasized the goal of simplified regimens and achieving the lowest effective doses of anti-inflammatory therapy.^{156,157}

COMPLEMENTARY ALTERNATIVE THERAPIES

53. C.C. is in the clinic a few months later. She is continuing to have excellent control of her asthma and allergic rhinitis. C.C. asks her health care professional for her opinion of herbal remedies for asthma as well as other nontraditional approaches to treatment.

Complementary and alternative approaches that have been used in the treatment of asthma include black tea, coffee, ephedra, marijuana, dried ivy leaf extract, acupuncture, meditation, and yoga.^{1,158,159} Despite the widespread use of alternative medications for chronic conditions, the clinician should discuss with C.C. that there is no established scientific basis for their use in the management of asthma.¹ Complementary alternative medicine cannot be recommended as a substitute for the drug therapy recommended by EPR-3 and other medical literature based on randomized controlled studies.

USE OF VALIDATED QUESTIONNAIRES FOR PATIENT SELF-ASSESSMENT OF ASTHMA CONTROL

54. A multidisciplinary group of health science center students have been invited to present a program on asthma at a local inner-city high school. The small group of nursing, pharmacy, and medical students are discussing the materials they want to use in the program. What would be some key points to cover, and are there validated instruments to assess asthma control that may be helpful?

Volunteer service to help educate patients with asthma is encouraged and has the potential to make a positive difference in the lives of patients and health science center students.¹⁶⁰ Examples of key points to cover at schools, churches, health fairs, or other venues include showing pictures and models of normal versus inflamed airways, avoidance of common asthma triggers, discussion of “preventer” versus “quick-reliever” medications, demonstrations of inhalers and peak flow meters, and written action plans. Discussion of prevention of EIA and showing pictures of famous athletes is of obvious importance. EPR-3 recommends that clinicians encourage patients to use self-assessment tools to determine whether asthma is well controlled.¹ Consequently, the health science center students also decide to use one of those validated questionnaires shown in EPR-3, the Asthma Control Test.¹⁶¹ The high school students will be told to take the brief test and give it to the clinicians caring for them. For patients whose asthma is not well controlled, the test scores can be a helpful tool in initiating or modifying long-term treatment.

Definitions

In 2001, the National Institutes of Health (NIH) and the World Health Organization (WHO) collaborated to develop the Global Initiative for Chronic Obstructive Lung Disease (GOLD) guidelines.¹ These guidelines address a wide variety of topics related to chronic obstructive pulmonary disease (COPD), including current concepts of pathophysiology, and recommendations regarding diagnosis and treatment. The guidelines are updated yearly, represent an international effort, and are based on the strength of the evidence supporting them. The most recent definition of COPD according to GOLD is as follows: “Chronic obstructive pulmonary disease (COPD) is characterized by chronic airflow limitation and a range of pathological changes in the lung, some significant extra-pulmonary effects, and important comorbidities which may contribute to the severity of the disease in individual patients. Thus, COPD should be regarded as a pulmonary disease, but these significant comorbidities must be taken into account in a comprehensive diagnostic assessment of severity and in determining appropriate treatment.”¹

Chronic obstructive pulmonary disease generally refers to emphysema or chronic bronchitis. Emphysema is pathologically defined and characterized by alveolar wall destruction and air-space enlargement. Chronic bronchitis is clinically defined as a chronic cough for at least 3 months for 2 consecutive years. Its pathologic hallmark involves inflammation and fibrosis of the small airways.²

Clearly, much overlap exists between these two conditions because both are primarily caused by cigarette smoking. It

should also be pointed out that small airway inflammation is an important characteristic of COPD, which appears to correlate with the more severe stages of the disease whether or not the patient has “chronic bronchitis.”³ Asthma, the other major disease entity characterized by airflow limitation, can clearly coexist in patients with COPD. Nevertheless, the pattern of airway inflammation in asthma differs significantly from that which occurs in COPD and asthma is not generally considered part of the spectrum of COPD.⁴

Epidemiology

Chronic obstructive pulmonary disease is an extremely important cause of morbidity and mortality. For example, the prevalence of COPD more than doubled between 1990 and 2002, making it the fourth leading cause of death in the United States.⁵ Furthermore, it is projected to be the third leading cause of death by the year 2020.¹ This increase in prevalence of COPD is felt to be related to the aging of the population and past smoking behavior, because COPD death rates and prevalence lag behind smoking rates by several decades. Because the smoking rates for women peaked later than rates for men, the increase in COPD prevalence in the United States is related primarily to an increase in COPD among women.⁶

The economic impact of COPD is also significant, with estimated annual treatment costs exceeding \$30 billion. This includes health care expenditures of \$18 billion and indirect costs of \$14 billion (e.g., lost earnings because of illness or early death).⁵

A major cause of disability, COPD currently is considered the 11th leading cause of disability worldwide. Current projections suggest that by the year 2020, COPD will be the 5th leading cause of disability worldwide, behind only ischemic heart disease, major depression, traffic accidents, and cerebrovascular disease.¹

Risk Factors

Clearly, cigarette smoking is the major risk factor for COPD. Most cases of COPD are attributed to a current or past history of cigarette smoking.¹ Importantly, with more severe disease, the relevance of cigarette smoking as a risk factor becomes even more pronounced. Evidence exists that among patients with severe emphysema ~99% have a history of regular cigarette smoking.⁷ It should be noted that only a few smokers develop clinically significant COPD, suggesting that other risk factors may be important cofactors with smoking in COPD development. Such factors include occupational dusts and chemicals,^{8–11} indoor and outdoor air pollution,^{12–14} and certain infections, including respiratory viruses¹⁵ as well as infection with human immunodeficiency virus (HIV).¹⁶ It is possible that such factors may upregulate the inflammatory response of the lungs to cigarette smoke.^{15,16} Genetic factors are also likely to be important, although precise genetic characteristics have not yet been elucidated.^{17–19} One exception is α_1 -antitrypsin deficiency, which affects <2% of patients with emphysema. Affected individuals have an inherited deficiency of this protective antiprotease and are at much greater risk of developing emphysema than the general population.²⁰

The risk of COPD from cigarette smoking is related to an accelerated loss of lung function. After age 35, nonsmokers experience a decline in forced expiratory volume in the first second of expiration (FEV₁) of about 20 to 30 mL/year. In smokers, the decline may be 50 to 120 mL/year.²¹ A model of the annual decline in lung function in nonsmokers, smokers, and susceptible smokers is illustrated in Figure 23-1.

Pathogenesis

The exact mechanisms responsible for the pathogenesis of COPD are not entirely clear, but likely involve activation of

the innate and adaptive immune system leading to chronic inflammation. In general, inhalation of noxious agents, such as cigarette smoke, leads to the activation of resident immune and parenchymal cells, which in turn, recruit additional inflammatory cells from the systemic compartment into the resident tissue and airway (Fig. 23-2). The activation and recruitment of immune cells is largely mediated through the production and release of cytokines and chemokines (Table 23-1). Recent evidence also supports a role for oxidant stress as a disease mediator.^{22,23} The consequences of an oxidant-rich environment include the activation of inflammatory genes, inactivation of antiproteases, stimulation of mucous secretion, and increases in plasma exudate.

The most well studied cause of COPD, and particularly emphysema, relates to protease–antiprotease imbalance. In this setting, inflammation promotes the production and release of proteases from inflammatory and parenchymal cells. When the local concentration of antiproteases becomes overwhelmed, proteases go unchecked and destroy the major connective tissue components in the lung, such as elastin, leading to the irreversible loss of alveoli (Table 23-2). The classic example of this occurs in patients with α_1 -antitrypsin deficiency.

Although the traditional idea of disease pathogenesis focuses on smoking-related lung *injury*, more recent hypotheses suggest that another important component of disease pathogenesis may involve inadequate lung *repair*. Indeed, recent studies demonstrate that normal lung homeostatic mechanisms are altered in COPD. This may involve inadequate production of growth factors as well as altered regulation of apoptosis, or programmed cell death.²⁴

Pathophysiology

The airflow obstruction caused by COPD is usually progressive and attributed to pathologic changes in the lung that affect the proximal airways, peripheral airways, lung parenchyma, and pulmonary vasculature.³ Alterations in tissue structure are caused by chronic inflammation that involves recruitment of inflammatory cells into the lung, as well as structural changes that result from repeated injury and tissue remodeling. The

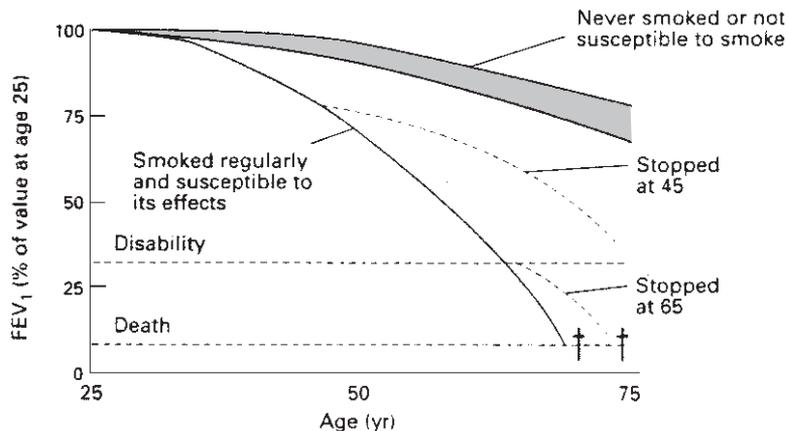

FIGURE 23-1 Model of annual decline in FEV₁ with accelerated decline in susceptible smokers. On stopping smoking subsequent loss is similar to that in healthy nonsmokers. (Modified from Fletcher C, Peto R. The natural history of chronic airflow obstruction. *BMJ* 1977;1:1645.)

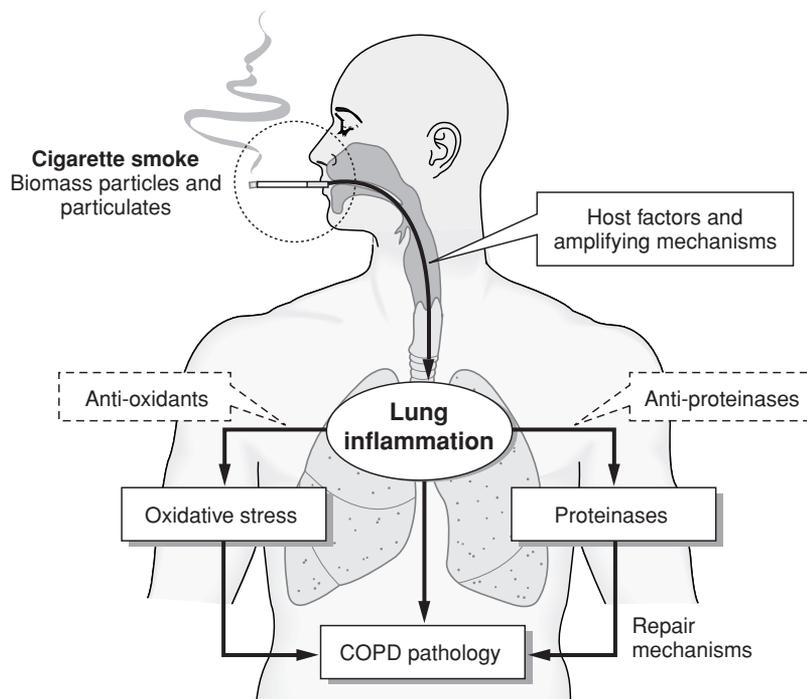

FIGURE 23-2 Pathogenesis of COPD. (Reprinted with permission from reference 1.)

magnitude of structural changes and tissue dysfunction varies among patients and is often distinguished by two major phenotypes that include chronic bronchitis and emphysema. Chronic airflow limitation can result from both of these processes. The GOLD or most recent American Thoracic Society (ATS) and European Thoracic Society guidelines²⁵ do not distinguish between these two entities; however, the classic definitions and pathophysiologic features are described here to aid in a better understanding of the disease process.

In the simplest view, *bronchitis* is inflammation of the bronchioles. The clinical definition from the ATS for *chronic bronchitis* is “the presence of chronic productive cough for 3 months in each of 2 consecutive years in a patient in whom other causes of chronic cough (e.g., asthma, congestive heart failure, gastroesophageal reflux) have been excluded.”²⁶ *Emphysema* is described as “abnormal permanent enlargement of the airspaces distal to the terminal bronchioles, accompanied by destruction of their walls and without obvious

Table 23-1 Inflammatory Cells and Mediators in Chronic Obstructive Pulmonary Disease (COPD)

| Cell | |
|---------------------------|--|
| Neutrophils | ↑ in sputum of normal smokers. Further ↑ in COPD and related to disease severity. Few neutrophils are seen in tissue. May be important in mucus hypersecretion and through release of proteases. |
| Macrophages | Greatly ↑ numbers in airway lumen, lung parenchyma, and bronchoalveolar lavage fluid. Derived from blood monocytes that differentiate within lung tissue. Produce increased inflammatory mediators and proteases in patients with COPD in response to cigarette smoke and may show defective phagocytosis. |
| T lymphocytes | Both CD4+ and CD8+ cells are increased in the airway wall and lung parenchyma, with ↑ CD8+:CD4+ ratio. ↑ CD8+ T cells (Tc1) and Th1 cells which secrete interferon- γ and express the chemokine receptor CXCR3. CD8+ cells may be cytotoxic to alveolar cells, contributing to their destruction. |
| B lymphocytes | ↑ in peripheral airways and within lymphoid follicles, possibly as a response to chronic colonization and infection of the airways. |
| Eosinophils | ↑ eosinophil proteins in sputum and ↑ eosinophils in airway wall during exacerbations. |
| Epithelial cells | May be activated by cigarette smoke to produce inflammatory mediators. |
| Mediators | |
| Chemotactic factors | <ul style="list-style-type: none"> • Lipid mediators: e.g., leukotriene B₄ (LTB₄) attracts neutrophils and T lymphocytes. • Chemokines: e.g., interleukin-8 (IL-8) attracts neutrophils and monocytes. |
| Proinflammatory cytokines | Cytokines, including tumor necrosis factor- α (TNF- α), IL-1 β , and IL-6 amplify the inflammatory process and may contribute to some of the systemic effects of COPD. |
| Growth factors | e.g., transforming growth factor- β (TGF- β) may induce fibrosis in small airways. |

fibrosis.” The degree of impairment of the small airways (bronchioles) or the lung parenchyma (alveoli and supporting structures) directly influences tissue dysfunction and the clinical symptoms of the patient (Fig. 23-3).

Large (Central) and Small (Peripheral) Airways

The large airways, which include the trachea and first generations of the bronchi, are a major site of inflammation and mucus hypersecretion. This results from an increase in numbers (hyperplasia) and enlargement (hypertrophy) of the submucosal glands and mucus-producing goblet cells within the surface epithelium.^{27,28} Overproduction of mucus in the large airways results in a chronic productive cough, as observed in chronic bronchitis, but this does not have a major impact on airflow limitation. Mucus hypersecretion coupled with impaired ciliary function, reduces mucociliary clearance, increases the accumulation of secretions, and enhances the risk of bacteria

colonization in an otherwise sterile environment.²⁹ As a result, recurrent infections often occur owing to the inability to clear pathogens.

The peripheral airway is composed of the smaller bronchi down to the terminal bronchioles, the smallest branches in the lung that are not involved in gas exchange. The extent of inflammation, fibrosis, and airway exudate in the peripheral airway correlates best with the reduction in airflow as measured by a decrease in FEV₁ or the FEV₁/FVC ratio.³ Chronic obstruction of the peripheral airway also results in air trapping on expiration, which contributes to hyperinflation. Hyperinflation places the respiratory muscles at a mechanical disadvantage and further reduces respiratory capacity. Hyperinflation can become more pronounced during exercise, leading to dyspnea and decreased exercise capacity. It is now known that hyperinflation can occur early in the course of COPD and is an important cause of exertional dyspnea.³⁰

Parenchymal Destruction

The terminal bronchioles lead directly to the alveolar ducts and sacs, the major site where gas exchange occurs. Emphysema is characterized by the destructive loss of alveolar walls and enlargement of the terminal airspaces resulting in a loss of gas-exchanging surface area.^{29,31} In advanced cases, large, balloon-shaped bullous lesions may develop. Rupture of these bullae can lead to collapse of lung segments (pneumothorax). *Panacinar emphysema* is a term used to describe when enlargement of the airspaces is relatively uniform throughout the entire acinus, and involves the respiratory bronchioles and alveoli. The lower lobes are most commonly involved. This is the pattern associated with α ₁-antitrypsin deficiency.²⁶ In centrilobular (centriacinar) emphysema, the primary lesions occur in the respiratory bronchioles, alveolar ducts, and central alveoli, with sparing of the peripheral acini. This is the most common pattern of emphysema and primarily involves

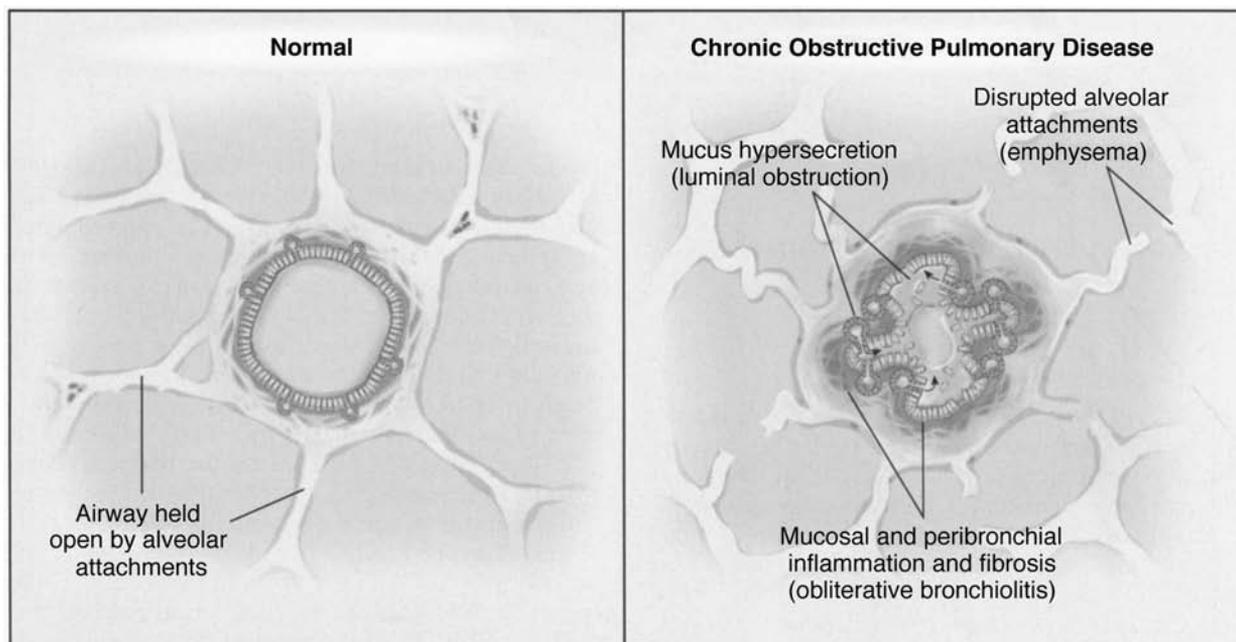

FIGURE 23-3 Inflammatory mechanisms in chronic obstructive pulmonary disease. (From Barnes PJ, Chronic obstructive pulmonary disease. *N Engl J Med* 200;343(4):269. Copyright © Massachusetts Medical Society, 2000.)

the upper lobes of the lung. The distinction between *panlobular* and *centrilobular* emphysema may be relevant with regard to disease pathogenesis and pathophysiology, but is generally not important clinically. Both phenotypes lead to gas exchange abnormalities and loss of lung elastic recoil and structural support. Abnormalities in gas exchange ultimately leads to hypoxemia, hypercarbia, or both. Loss of lung recoil and structural support promotes collapse of small airways during expiration and progressive airflow limitation.

Significant Comorbid Illness

In the later stages of disease, chronic hypoxemia causes persistent vasoconstriction in the lung vascular bed, particularly the small pulmonary arteries. This can result in permanent structural alteration of the blood vessels causing intimal hyperplasia and smooth muscle hypertrophy.³² The loss of pulmonary capillaries in emphysema can also contribute to increased pulmonary vasculature pressures. The cumulative impact of vascular changes can result in progressive pulmonary hypertension and eventually, right-sided cardiac failure (cor pulmonale).

As COPD progresses, additional systemic consequences can arise, including cachexia, skeletal muscle dysfunction, osteoporosis, depression, and anemia. The cause of these additional systemic disease processes is not entirely clear but likely involves the dynamic interplay of progressive respiratory dysfunction, lung and systemic inflammation, side effects from medication use, and physical debilitation.

In summary, although COPD is primarily a disease of the large and small airways and adjacent alveolar structures, it also includes important systemic consequences. The clinical consequences of the morphologic and pathophysiologic alterations include progressive dyspnea on exertion, chronic cough and sputum production, increased risk for respiratory infections, deconditioning, and an overall reduction in quality of life.

Comparison With Asthma

Because COPD and asthma are both common diseases, both illnesses can coexist in the same patient. Nevertheless, these conditions should be considered as separate and distinct entities (Fig. 23-4). For example, although inflammation is a key component of both conditions, the pattern of inflammation

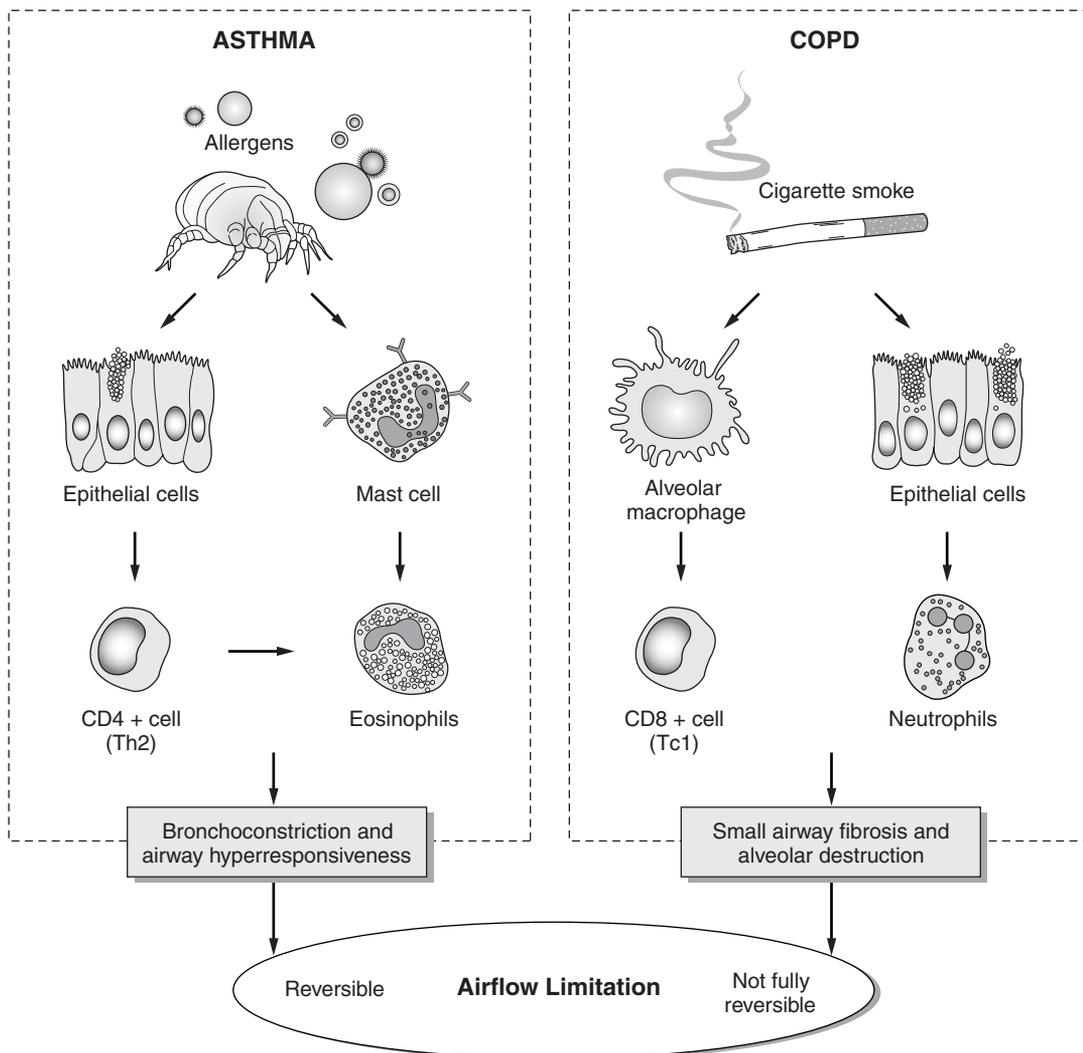

FIGURE 23-4 Inflammatory cascade in COPD and asthma. (Reprinted with permission from reference 1.)

differs significantly (Table 23-3). As a result, the pathophysiologic consequences, patient symptoms and response to medications typically differ. Asthma is generally not progressive and symptoms and airflow obstruction are often completely reversible. Patients with asthma respond well to anti-inflammatory medication, including inhaled glucocorticoids. Furthermore, in the absence of an acute exacerbation, significant gas exchange abnormalities are uncommon. COPD, on the other hand, is a progressive and often fatal disorder. Although bronchodilators are clearly helpful in COPD, the degree of bronchodilator reversibility is typically less than that seen in asthma. In addition, the beneficial effects of anti-inflammatory medication, including inhaled glucocorticoids, are much more modest. Patients with COPD, particularly those with emphysema, have substantial derangements in pulmonary gas exchange even at baseline.

α_1 -Antitrypsin Deficiency

The best characterized antiprotease in the lung is α_1 -antitrypsin. This serum glycoprotein is primarily produced in the liver and works by binding to and neutralizing proteases. As previously described, cigarette smoke can activate and attract inflammatory cells into the lung, thereby promoting the release of proteases such as elastase. Cigarette smoke can also inactivate endogenous protease inhibitors, including α_1 -antitrypsin, further supporting protease activity and increasing the risk of tissue damage. This risk of tissue damage is greatly accentuated in patients with α_1 -antitrypsin deficiency.

α_1 -Antitrypsin deficiency occurs in <2% of all COPD cases. Clinically significant disease is usually associated only with severe deficiency (i.e., serum α_1 levels <45 mg/dL; normal >150 mg/dL). The diagnosis of α_1 -antitrypsin deficiency is made by measuring circulating serum α_1 -antitrypsin levels, followed by phenotype analysis.³³ The PiM allele confers

production of the fully functional protein. Accordingly, a homozygous PiMM individual will produce a functional protein with normal plasma concentrations. Other gene types include PiS (normal serum levels of a poorly functioning enzyme), PiZ (an active form but poorly secreted leading to low circulating levels), and Pi null (gene polymorphism leads to production of a truncated protein and undetectable serum levels of functional protein). Different allele pairs can exist. PiMZ and PiSZ are heterozygous disorders, and PiSS is a homozygous phenotype, all with >35% of normal enzyme activity and a relatively low risk of developing emphysema. PiZZ is a rare homozygous disorder characterized by accelerated lung destruction and serum α_1 -antitrypsin levels approximately 15% of normal. In these rare patients, the disease develops as early as age 20, but more typically in the fourth to fifth decade of life.

Replacement therapy is available for patients with COPD with documented α_1 -antitrypsin deficiency and emphysema. Patients who do qualify typically receive weekly intravenous infusions of α_1 -antitrypsin to maintain acceptable antiprotease activity and minimize the progression of lung disease. This therapy is very expensive, not well tolerated by some (fever, chills, allergic reactions, flu-like symptoms), and has been hampered by supply problems. Currently, no placebo-controlled, randomized trials have documented the efficacy of replacement therapy. Case-controlled studies, however, suggest the replacement therapy may improve outcomes in patients with α_1 -antitrypsin deficiency, documented emphysema and an FEV₁ between 35% and 60% of predicted.²⁰ Three different formulations of α_1 -antitrypsin are available: Aralast, ProLastin, and Zemaira. No clinically significant differences exist among these preparations. Because the α_1 -antitrypsin products are derived from pooled human plasma, there are also associated risks for the transmission of infectious diseases (e.g., viral infections and Creutzfeldt-Jakob disease).

DIAGNOSIS AND PATIENT ASSESSMENT

The diagnosis of COPD is based on the presence of risk factors (generally smoking), clinical symptoms, and airflow obstruction on spirometric testing.¹ Generally, individuals with COPD present in the sixth decade of life (or later) with symptoms of cough, wheeze, or dyspnea on exertion.²⁵ Patients usually have at least a 20-pack/year history (e.g. averaging one pack of cigarettes a day for 20 years) history of cigarette smoking. Because the severity of COPD is related to the cumulative exposure to cigarette smoke, patients with more severe disease are likely to be older with a heavier smoking history. Cough and sputum production may be present for many years before airflow limitation develops, but not everyone with those symptoms will develop COPD. Dyspnea on exertion may not be present until the sixth or seventh decade.

On physical examination, patients with early COPD may not exhibit any changes.²⁵ Later, objective findings include the presence of a barrel chest (defined as an increase in the anteroposterior diameter of the chest), rales (defined as intermittent, nonmusical, brief crackle sounds), rhonchi (defined as continuous, musical high or low pitched sounds), prolonged expiratory phase, and cyanosis.¹ Symptomatic patients may present with decreased breath sounds, wheezes, or slight rales on auscultation. In advanced disease, cyanosis, edema, intercostal retractions, and pursed lip breathing may be present.¹

Spirometry Testing

Spirometry is the gold standard measurement in assessing and monitoring obstructive lung disease.^{1,25} In the evaluation of COPD, spirometry testing should be performed according to published guidelines, when the patient's condition is stable and after administration of two to four puffs of albuterol by metered dose inhaler. During spirometry, a full breath is taken, followed by a forceful exhalation of all the air that can be exhaled (forced vital capacity [FVC]). Flow rates and volumes of air that are expired at different time intervals can be recorded. The FEV₁ is the volume of air that can be expired within the first second of an FVC maneuver. A decrease in the FEV₁/FVC ratio indicates airflow obstruction. Although the range of normal for FEV₁/FVC depends on the age, sex, and height of the patient, a value of <0.70 indicates airflow obstruction that is compatible with COPD.^{1,25} Also, patients with COPD may have some improvement in spirometry testing with an acute bronchodilator challenge. The degree of reversibility is typically less than that seen with asthma, although up to 50% of patients with moderate to severe emphysema will have an increase in FVC with acute bronchodilator challenge that meets ATS criteria as significant. It is important to point out that, although a decrease in the FEV₁/FVC ratio categorizes the patient as having airflow obstruction, the disease severity is best assessed by examining the FEV₁ as a percent of predicted. Indeed, most major organizations that have provided recommendations regarding the clinical management of COPD use the percent of predicted FEV₁ to determine the disease severity.^{1,25} In addition to being critical for making the diagnosis of COPD, spirometry also affords the best objective way to monitor disease progression. Although optimal frequency of spirometric testing for patients with COPD is not known, spirometry should be considered if

there has been a persistent change in clinical symptoms (e.g., worsened dyspnea).

Other pulmonary function testing is sometimes used to assess patients with COPD. The determination of lung volumes, including the total lung capacity (TLC) and residual volume (RV) as well as measurements of the diffusing capacity for carbon monoxide may provide more detail regarding lung physiology. For example, a reduction in diffusing capacity of the lung for carbon monoxide (DL_{CO}) indicates disruption or destruction of the alveolar capillary interface and correlates with the degree of emphysema. Determination of lung volumes may be used to assess the presence of concomitant restrictive lung disease (e.g., idiopathic pulmonary fibrosis) in the case of diagnostic uncertainty. Patients with COPD typically have normal or increased lung volumes; a reduction in total lung capacity may indicate a superimposed restrictive process. Furthermore, lung volumes and diffusion capacity are used to assess patients for surgical procedures, such as lung volume reduction surgery.⁷ In general however, spirometric testing is adequate to make the diagnosis of COPD and follow the course of disease.^{1,25}

A chest x-ray (CXR) study is often performed during the initial assessment of patients with COPD. Because the CXR lacks sensitivity and demonstrates minimal changes until COPD is moderately severe, its main utility is in ruling out other disease processes that may be contributing to the patients symptoms. In severe disease, the chest radiograph may indicate hyperinflation manifested by a flattened diaphragm or evidence of pulmonary arterial hypertension characterized by enlarged pulmonary arteries.

Assessing the oxygen status of a patient with COPD can be done by pulse oximetry. This should be considered in patients with dyspnea and advanced disease, and patients with evidence of right ventricular pressure overload (e.g., peripheral edema, or jugular venous distension). Although a decrease in pulse oximetry (normal, ≥97%) is common in COPD, values of ≤88% are consistent with chronic respiratory failure and qualify the patient for supplemental oxygen. Arterial blood gas (ABG) determination is generally reserved for patients with severe disease (i.e., an FEV₁ <50% of predicted). ABG can more precisely define the oxygen status of a patient and can be used to assess whether the patient has carbon dioxide retention (normal PCO₂ = 40 mm Hg). Determining the α₁-antitrypsin concentration is indicated for patients developing COPD before age 45, and for patients who have emphysema without a significant history of cigarette smoking or who have a family history of emphysema.

Classification of Severity and Clinical Presentation

A number of staging systems have been proposed to categorize the severity of COPD. All are based primarily on the degree of airflow obstruction as assessed by the FEV₁.^{1,25,26} The staging system recommended by the most recent GOLD guideline is demonstrated in Table 23-4. The GOLD expert panel classifies disease severity into four stages based on spirometric measurements, symptoms, and complications.¹ This staging is intended to serve as an educational and research tool and to guide management strategies. It should be noted that, although FEV₁-based staging systems can provide important prognostic information, more comprehensive scoring systems may provide more discriminating information with regard to survival

Table 23-4 Spirometric Classification of Chronic Obstructive Pulmonary Disease (COPD) Severity Based on Post-Bronchodilator FEV₁

| Stage | Classification | Spirometry Results |
|-------|----------------|--|
| I | Mild | FEV ₁ /FVC <0.70 FEV ₁ ≥80% predicted |
| II | Moderate | FEV ₁ /FVC <0.70 50% ≤FEV ₁ <80% predicted |
| III | Severe | FEV ₁ /FVC <0.70 30% ≤FEV ₁ <50% predicted |
| IV | Very Severe | FEV ₁ /FVC <0.70 FEV ₁ <30% predicted or FEV ₁ <50% predicted plus chronic respiratory failure |

FEV₁: forced expiratory volume in one second; FVC: forced vital capacity; respiratory failure: arterial partial pressure of oxygen (Pao₂) <8.0 kPa (60 mm Hg) with or without arterial partial pressure of CO₂ (Paco₂) >6.7 kPa (50 mm Hg) while breathing air at sea level.

in COPD. For example, a scoring system based on body mass index, obstruction on spirometry, dyspnea level, and exercise capacity (BODE) can predict survival in COPD far better than the FEV₁ alone³⁴ (Table 23-5).

Natural Course

The natural course of COPD is highly variable, generally spanning 20 to 40 years and influenced by numerous factors, including genetic predisposition, exposure to inhaled irritants (tobacco smoke, workplace, or environmental pollutants), and repeated infections. The typical smoker who develops COPD remains asymptomatic for the first two decades of smoking, except for more frequent viral or bacterial upper respiratory tract infections. Clinical symptoms appear after significant irreversible lung damage occurs. After 25 to 30 years of smoking, mild dyspnea on exertion is commonly noted and can be accompanied by a morning cough; however, physical examination and chest radiograph are often unremarkable.²⁵ With

continued exposure to risks (e.g., cigarette smoking), the disease progresses and patients develop increased airflow limitation and worsened dyspnea on exertion, and increased cough and sputum production. Ultimately, structural changes result in alveolar hypoxia and the secondary problems of pulmonary hypertension and cor pulmonale.

Exacerbations, or flares, of COPD are common and can be infectious or noninfectious. Moderate to severe exacerbations may require hospitalization. Acute or chronic respiratory failure can develop secondary to an acute infection, or other factors, including oversedation, heart failure, or pulmonary embolism.^{35,36}

GENERAL MANAGEMENT CONSIDERATIONS

The overall goals for treatment of the patient with COPD are depicted in Figure 23-5.²⁵ The only interventions that have proved to reduce mortality in COPD are smoking cessation, oxygen therapy for patients with severe hypoxemia at rest, and lung volume reduction surgery for very select patients with advanced emphysema.^{7,37–39} As such, many of the interventions are aimed at alleviating symptoms and maximizing quality of life.

Because, continued cigarette smoking is associated with accelerated progression of disease in susceptible smokers, smoking cessation is critical to disease treatment. Strategies for smoking cessation are detailed in Chapter 85, Tobacco Use and Dependence. The benefits of smoking cessation in COPD include decreases in respiratory symptoms, exacerbation rate, and lung function decline.^{21,40} It should also be noted that cardiovascular complications, including coronary artery disease, are more common in patients with COPD and that smoking cessation may attenuate morbidity and mortality from this complication.

Immunizations provide protection against serious illness and death in patients with COPD.⁴¹ The efficacy, benefit, and cost-effectiveness of vaccination against influenza among this population are significant.⁴² Data concerning the value of vaccinating against pneumococcal pneumonia are lacking, but it is

Table 23-5 Variables and Point Values Used for the Computation of the Body-Mass Index, Degree of Airflow Obstruction and Dyspnea, and Exercise Capacity (BODE) Index

| Variable | Points | | | |
|---|--------------------------------------|--------------------------|----------------------|-----------------|
| | 0 | 1 | 2 | 3 |
| Body Mass Index (kg/m ²) | ≥21 | <21 | | |
| Obstruction of airflow (FEV ₁ % predicted) | ≥65 | 50–64 | 36–49 | ≤35 |
| Dyspnea? | None or only with strenuous exertion | Walking up a slight hill | Walking on the level | Getting dressed |
| Exercise capacity (6 min walk distance, feet) | >1,148 | 820–1,149 | 492–819 | <492 |

Approximate 4-year survival based on total BODE score:

0–2 points: 80%

3–4 points: 70%

5–6 points: 60%

7–10 points: 20%

recommended in the GOLD guidelines because of a favorable risk:benefit ratio.¹

Pulmonary rehabilitation is an exercise-based program aimed at maximizing the patient's functional status and quality of life. Multiple studies have now documented the beneficial effects of pulmonary rehabilitation, particularly with respect to improved exercise tolerance and alleviation of dyspnea.⁴³ In addition, cost-effective analysis suggests that pulmonary rehabilitation programs are very cost-effective.⁴⁴ Pulmonary rehabilitation programs are multidisciplinary programs typically running for 6 to 12 weeks, two to three sessions per week. A number of interventions are used, including breathing retraining, psychosocial counseling, education, dietary counseling, and airway clearance techniques for patients with chronic sputum production. Arm strengthening and arm endurance exercises are important because patients with COPD commonly have excessive dyspnea when utilizing their upper extremities.⁴³ The most important component of a pulmonary rehabilitation program is lower extremity endurance training, often utilizing a treadmill or bicycle ergometer. Because the large muscle groups have diminished oxidative capacity,^{45–47} likely related to deconditioning and chronic inflammation,^{48,49} patients with COPD convert to anaerobic metabolism, leading to increased lactate production for a given level of activity⁵⁰ and, subsequently, increased CO₂ production. Lower extremity endurance training can significantly improve mitochondrial oxidative capacity in patients with COPD.^{45,51} This physiologic benefit is felt to be an important mechanism whereby pulmonary rehabilitation exerts its effect. Other important effects, such as alleviation of depression and anxiety, may be important as well.⁴³

As mentioned, patients with severe resting hypoxemia have improved mortality with supplemental oxygen treatment. Based on studies published in the 1980s, it has been found that patients with a PO₂ ≤55 mm Hg (corresponding to an oxygen saturation of ~88%), have decreased mortality and

evidence of better end-organ function when treated with supplemental oxygen.^{38,39} Whether supplemental oxygen benefits subjects with moderate hypoxemia, corresponding to an oxygen saturation of 89% to 93%, is the objective of an ongoing, randomized, multicenter study, the Long-Term Oxygen Treatment Trial (LOTT).

PHARMACOTHERAPY

The fundamental goals of medication use are to prevent or control symptoms, reduce the frequency and severity of exacerbations, and improve both health status and exercise tolerance. The currently available medications used to treat COPD, however, do not alter the natural course of this condition; therefore, pharmacotherapy should be individualized for each patient and focused on the management of symptoms to improve quality of life.^{21,52–54} Because of the potential for limited benefit with therapy, a specific set of desired goals must be defined for each patient before therapy is initiated. The initial outcomes should be realistic and developed jointly by the caregiver and the patient. In general, COPD is a progressive disease and general guidelines will apply to most patients with COPD as they begin to require pharmacologic management.

- The number of medications will cumulatively increase as disease worsens.
- Patients will eventually require daily maintenance therapy for sustained periods unless adverse effects of the medication(s) preclude further use.
- Interindividual variability in medication response is expected and requires careful monitoring over a continuum of time to ensure an acceptable benefit:risk ratio is achieved.

When medications are initiated or modified, a minimal trial period of several weeks to a few months is usually recommended before determining their full benefit. Single-dose challenges and frequent alterations in therapy do not allow adequate assessment and can compromise patient compliance. No consensus currently exists on the most appropriate outcome measure or degree of improvement needed to be determined clinically significant.

Although the standard for assessing benefit from treatment has been to measure spirometric improvement in FEV₁, many patients will not demonstrate noticeable changes following either an acute or extended therapeutic trial of any therapy. Increasingly, clinicians are considering other measures to determine the benefit of therapy. These include measuring improvements in quality of life, dyspnea, and exercise tolerance.⁵⁵ Other appropriate measures may include COPD exacerbation rates, utilization of health care resources, and mortality. In most patients, it is important to consider the use of multiple outcome measures, both objective and subjective, to guide the therapeutic decision-making process.

Bronchodilators

Bronchodilators are central to the symptomatic management of COPD and include short-acting and long-acting β_2 -agonists, short-acting and long-acting anticholinergic agents, and theophylline. These medications, although pharmacologically distinct, improve airflow primarily by reducing bronchial airway smooth muscle tone. In COPD, the spirometric response, as

measured by FEV₁, can be variable and, in many cases, will demonstrate no change, although the patient subjectively feels better. This can be attributed to treatment facilitating emptying of the lungs and a reduction in thoracic hyperinflation at rest and during exercise. No clear evidence exists for benefit of one bronchodilator over another in the chronic management of COPD, although inhaled therapy is generally preferred over oral therapy to achieve a more rapid onset of action and to minimize the risk of systemic exposure and adverse events. A short-acting, selective β_2 -agonist or short-acting anticholinergic (ipratropium) are rational first-line treatments for patients with mild disease. Initially, medication should be given for symptomatic relief on an as-needed (PRN) basis. As disease progresses and the frequency of symptoms increases along with medication requirement, the patient should be transitioned onto daily maintenance bronchodilator therapy.³¹ At this point, substitution of a short-acting agent with a long-acting agent of the same class is recommended because the bronchodilatory effect will be sustained over a longer duration and reduce the number of daily inhalations. This strategy will also enhance patient compliance. The use of short-acting agents should still be recommended for acute symptomatic relief, especially because the long-acting inhaled agents take a significantly longer period of time for onset of effect following inhalation. The side effects of bronchodilators, particularly β_2 -agonists, are predictable and dose dependent, even with excessive use of inhaled agents. The most common adverse effects are an extension of stimulation of β_2 -adrenergic receptors that can produce resting sinus tachycardia or provoke cardiac dysrhythmias in predisposed individuals, especially the elderly. Precipitation of somatic tremors and hypokalemia can also occur with excessive use.

The relationship between β_2 -agonist use and cardiovascular complications remains somewhat controversial. It is recognized that albuterol and long-acting inhaled β_2 -sympathetic agents can induce systemic sympathetic states, hypokalemia, and other metabolic derangements that can contribute to cardiac rhythm disturbances. This has led to speculation that these abnormalities could contribute to an increase in cardiovascular death among patients with COPD using β_2 -agonist inhalers.⁵⁶ Nevertheless, this speculation has been largely refuted by the recently published TORCH (Towards a Revolution in COPD Health) study, in which >6,000 patients with COPD were randomized to salmeterol, fluticasone, combination salmeterol–fluticasone, or placebo.⁵⁷ Overall mortality, cardiovascular mortality, and cardiovascular-related adverse events were no greater in the salmeterol group compared with any of the other groups.

Inhaled anticholinergic agents have less potential to cause adverse events by virtue of their positive charge at physiologic pH leading to negligible systemic absorption. Excessive dry mouth is the most common complaint from patients who use inhaled anticholinergic agents, both short- and long-acting. Cardiovascular complications have been reported with regularly scheduled use of ipratropium bromide, but this association requires further investigation.⁵⁸

It is not unusual to find reports in the literature that suggest superiority of one bronchodilator class over another for COPD treatment. It is difficult, however, to predict individual responses to treatment. For some patients, β_2 -agonist bronchodilators will increase airflow, improve pulmonary function

test results, and reduce symptoms of dyspnea.⁵⁹ Others may achieve greater improvement with an anticholinergic in comparison with a β_2 -agonist.^{60,61} Still, others may not have a reversible component with either drug, but still may perceive symptomatic benefit.^{62,63} Because single-dose trials of inhaled bronchodilators are usually inadequate in predicting long-term response to bronchodilator therapy, a minimum of a 1- to 2-week course of therapy should be administered before evaluating the response.^{59,64}

The risks and potential benefits of theophylline have been long debated.^{65,66} Although objective evidence demonstrating a patient benefit is often absent, patients with advanced stage COPD may report a worsening of symptoms when theophylline is withdrawn.⁶⁶ Currently, theophylline is reserved for patients who do not tolerate, or fail to adequately respond, to a combination of first-line inhaled bronchodilators. The major limitation of theophylline is its relatively narrow therapeutic window and potential to cause significant adverse events. Despite these limitations, it is known that theophylline may positively contribute to a favorable patient response, in the absence of improved pulmonary function, through other mechanisms that include stimulation of diaphragmatic contractility and anti-inflammatory effects. Based on these positive attributes, a more specific class of phosphodiesterase-4 (PDE-4) inhibitors has recently been developed. Cilomast is an orally active, potent, selective PDE-4 inhibitor that has shown benefit in phase III clinical trials involving patients with COPD by maintaining pulmonary function, reducing exacerbations, and improving health status.⁶⁷ In comparison with theophylline, cilomast has much less potential for drug–drug interactions and should not require drug level monitoring, thereby making it an attractive alternative pending further clinical study.

Glucocorticoids

Historically, initiation of a short (2-week) course of oral glucocorticoids was often advocated to identify patients with COPD who might benefit from long-term treatment. Recent evidence however, indicates that a short course challenge is a poor method to predict patients who will benefit from long-term inhaled corticosteroid use.^{54,68} Based on the lack of evidence and risk for significant side effects that include steroid myopathy and loss of bone density, chronic systemic corticosteroid therapy is not generally recommended. For patients with COPD experiencing an acute exacerbation of their disease, the short-term use of systemic corticosteroids has proven efficacy.

In contrast, inhalation of glucocorticoids leads to substantially less systemic absorption, thereby minimizing many of the risks associated with systemic corticosteroid therapy. Based on this, several national and international studies have been conducted to evaluate the potential benefit of inhaled corticosteroid maintenance therapy.^{52–54,69} Well-conducted clinical trials have revealed that daily treatment with inhaled glucocorticosteroids does not delay the long-term decline in FEV₁ in patients with COPD. Daily use can result, however, in a reduction in the frequency of exacerbations and an improvement in overall health status, particularly in patients with more advanced disease.^{70–73} Recently, it has been shown that inhaled glucocorticoid use in combination with a long-acting β_2 -agonist is more

effective than either agent alone or placebo in patients with advanced COPD.⁵⁹ Specifically, patients using combination therapy (one inhalation twice daily) experienced decreased exacerbations, improved spirometric values, and increased health status. Although no difference was seen in mortality or disease progression among treatment groups, some advocate maintenance therapy with inhaled glucocorticoids in symptomatic patients with COPD with an FEV₁ <60% predicted.⁷⁴ The safety of chronic inhaled glucocorticoids beyond 3 years use is unknown. Safety concerns include decreased bone density, ocular changes, and increased risk of pneumonia. Until definitive trials are completed, long-term patient safety must be taken into consideration and weighed with the beneficial effects of the medication.

PHARMACOLOGIC THERAPY BY DISEASE SEVERITY

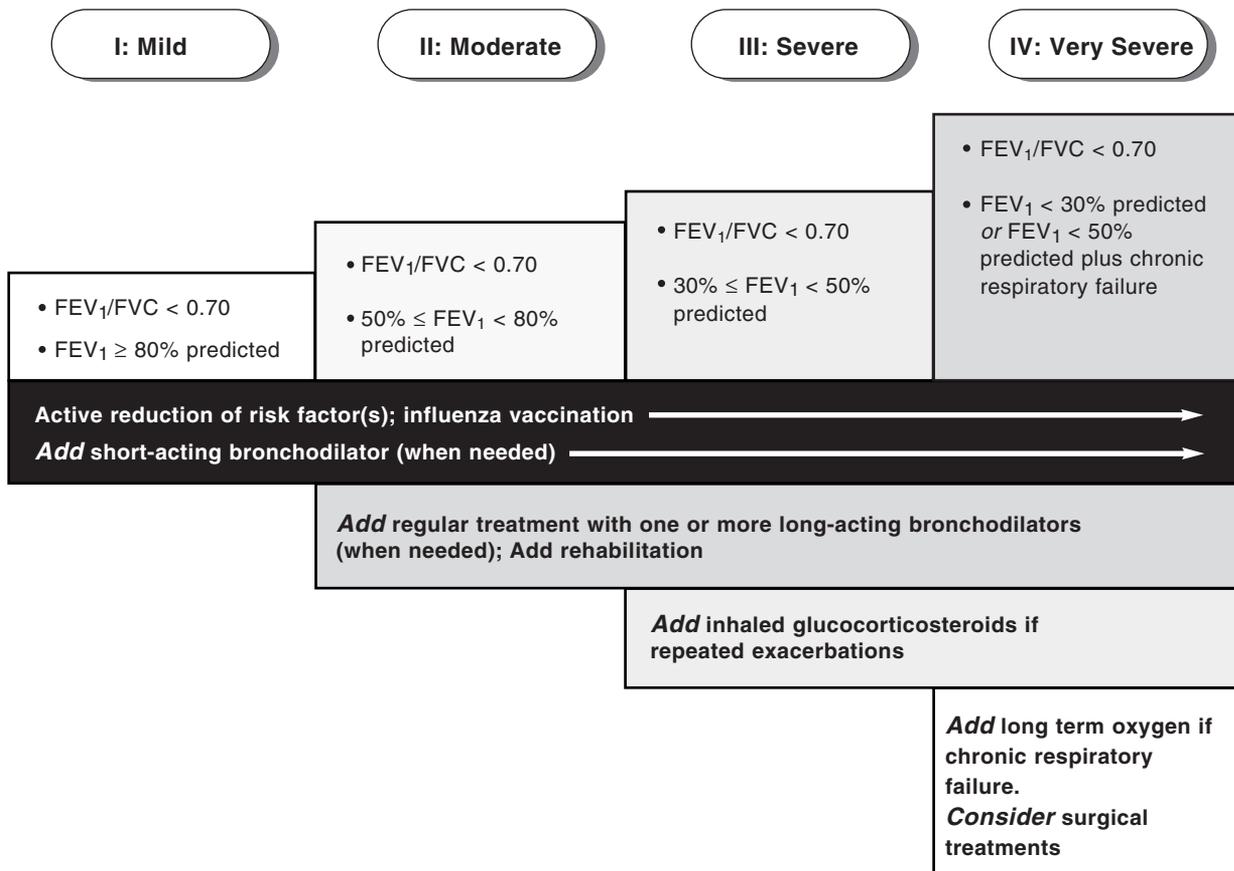

As described, it is expected that patients with COPD will require an increase in the dose and number of medications to effectively manage their disease over time. Figure 23-6 provides a summary of the recommended strategy for pharmacologic therapy. Patients with infrequent or intermittent symptoms (stage I: mild COPD) will initially require use of one short-acting bronchodilator on an as-needed basis. As disease progresses beyond this stage (stage II: moderate to stage IV: very severe COPD), PRN use of bronchodilators alone will not

maintain adequate relief from these symptoms. Patients will begin to manifest daily symptoms that require maintenance therapy. At this point, regular treatment with one or more long-acting bronchodilator agents is recommended. Patients should also continue to use a short-acting bronchodilator PRN for additional symptomatic relief. In patients with a postbronchodilator FEV₁ of <50% predicted (stage III to stage IV COPD) and a history of repeated exacerbations, maintenance therapy with an inhaled glucocorticosteroid should be added to the long-acting bronchodilators.

In general, nebulization of bronchodilators is primarily reserved for the acute care setting for quick symptomatic relief and is not advocated routinely for home use. In select patients who are not achieving maximal benefit with standard inhalation delivery devices, a 2-week trial with nebulized therapy can be considered and then continued if a clear benefit is observed.⁷⁵

COPD EXACERBATION

An acute exacerbation of COPD is defined as an acute worsening of a patient's chronic symptoms (dyspnea, cough, sputum production) necessitating treatment. Acute exacerbations of COPD are important events in the natural history of this disease.^{76,77} They are associated with considerable morbidity; severe exacerbations are associated with an increased mortality.⁷⁷ Furthermore, acute exacerbations are responsible

**Postbronchodilator FEV₁ is recommended for the diagnosis and assessment of severity of COPD.*

FIGURE 23-6 Therapy at each stage of COPD. (Reprinted with permission from reference 1.)

for a high percentage of health care costs associated with COPD.⁷⁸

The cause of acute exacerbations is believed to be a result of respiratory tract infections, either viral or bacterial, air-pollution, or other environmental exposures.^{79,80} These triggers can initiate increased bronchospasm and airway resistance in an individual with already compromised lung function. Although mild exacerbations may be readily managed with outpatient therapy, severe exacerbations can result in respiratory failure and death, particularly if they occur in a patient with severe COPD.

Key therapeutic interventions for acute COPD exacerbations include regular bronchodilator therapy, a short course of systemic corticosteroid therapy, and antibiotics. Bronchodilator therapy is given PRN by metered dose inhaler (MDI) or nebulizer every 3 to 4 hours. Systemic corticosteroids are commonly given for a 7- to 10-day course. Although 30 to 40 mg/day for 7 to 10 days is commonly used, the optimal dose is not known.⁸¹ High-dose intravenous corticosteroids (methylprednisolone 125 mg every 6 hours) have been shown to be effective in hospitalized patients.⁸² Such large doses, however, are associated with an increased risk of hyperglycemia and it is not known whether this regimen is superior to lower dose oral regimens.

Antibiotic use in the setting of an acute exacerbation should be made based on the presence of the following respiratory symptoms: increased dyspnea, sputum volume, and sputum purulence. Data suggest that if two of the three are increased, antibiotics are beneficial.⁸³ The optimal antibiotic regimen for acute COPD exacerbations has not been rigorously studied. For many outpatients, however, generic, low-cost antibiotics, including amoxicillin, trimethoprim-sulfamethoxazole or doxycycline may be very effective. Indeed, these agents can effectively cover the most common bacterial causes of acute exacerbations, including *S. pneumoniae*, *Haemophilus influenzae*, and *Moraxella catarrhalis*. Hospitalized patients, particularly those in respiratory failure, have a higher risk for more resistant organisms and should receive broad-spectrum antimicrobials that include activity against *Pseudomonas aeruginosa*.²⁵

STAGE I (MILD) COPD

1. T.A., a 51-year-old white male smoker, presents with daily cough and mild dyspnea on exertion with strenuous activity. He has noticed that walking up two flights of steps bothers him, when previously it did not. He has had a slight amount of wheezing, but no chest pain. He has no known chronic medical problems. He has smoked 1.5 packs/day for 34 years and he continues to smoke that amount. His physical examination is unremarkable. Chronic obstructive pulmonary disease is suspected. What diagnostic test should be ordered?

Diagnosis

Spirometry is the gold standard diagnostic test for making the diagnosis of COPD. The main values gleaned from spirometry will include the FVC, FEV₁, and the FEV₁/FVC ratio. An FEV₁/FVC <0.70 indicates obstruction to expiratory flow consistent with COPD. The severity of disease is best assessed

by the FEV₁ as a percent of predicted. The diagnosis of COPD can be made based on the presence of symptoms (dyspnea, cough, wheeze), risk factors (most often associated with a history of regular cigarette smoking), and airflow obstruction on spirometry.¹

2. Office spirometry demonstrates an FEV₁/FVC of 0.69 and an absolute FEV₁ of 81% of predicted. At what GOLD stage of COPD is this patient? What other diagnostic tests would be necessary before initiating therapy?

Based on GOLD guidelines, this patient would be considered to have mild COPD (GOLD stage I). A CXR study is often performed to exclude other respiratory diagnoses contributing to the patient's symptoms; however, the abnormal spirometry is sufficient to make the diagnosis of COPD and to initiate therapy.

In certain cases of diagnostic uncertainty or in patients with severe disease being considered for surgical intervention, such as lung volume reduction surgery, a complete set of pulmonary function tests, including the determination of lung volumes and DL_{CO} may be performed. Complete pulmonary function testing, however, is not necessary to make the diagnosis of COPD.

In patients with more severe symptoms or airflow obstruction, assessment of oxygen status by means of pulse oximetry or ABG may be necessary. For example, ABGs are recommended if the FEV₁ is <50% of predicted.¹ An α_1 -antitrypsin level to rule out α_1 -antitrypsin deficiency is generally reserved for patients with disease onset at a young age (<50 years of age), or in patients with a strong family history of COPD.¹

Therapeutic Management

3. What therapeutic interventions should be recommended for T.A. at this point?

Smoking Cessation

Clearly, the most important intervention at this point is smoking cessation.⁸⁴ Although pharmacologic interventions for smoking cessation are covered elsewhere in the text (see Chapter 85, Tobacco Use and Dependence), it should be pointed out that a personalized message may be beneficial for this patient. Indeed, discussion of spirometry results with the patient can provide an important opportunity to deliver a personalized message. It can be explained to T.A. that he is beginning to develop definite irreversible abnormalities in his pulmonary function and, therefore, is a "susceptible" smoker. It is critical for him to stop smoking and thereby prevent continued deterioration in lung function.

Immunizations

In addition to smoking cessation, this patient's immunization status should be evaluated.⁸⁴ According to the GOLD guidelines and in the absence of contraindications, T.A. is a candidate for vaccination against influenza and pneumococcal pneumonia, even though he is in the early stages of COPD.¹ Patients with COPD are at risk for increased morbidity and mortality if they develop either of these infectious complications.

Individuals at greatest risk for significant morbidity and mortality from influenza pneumonia are those with chronic

disease, including lung disease. Optimally, the influenza vaccine should be administered between October and January. This allows an adequate antibody response before the peak influenza season, which typically occurs within the first quarter of the year. Annual immunization is required to ensure adequate antibody protection against influenza virus and is effective in reducing morbidity and mortality from influenza.⁸⁵ The influenza vaccine is administered intramuscularly; the live attenuated intranasal preparation is not recommended for patients with COPD.

Pneumococcal polysaccharide vaccine (Pneumovax 23) is also recommended for patients with COPD.¹ This vaccine consists of antigen that provides protection against 23 common strains of *Streptococcus pneumoniae*. Candidates for this vaccine include individuals at risk for significant morbidity and mortality if they develop a pneumococcal infection, including patients with chronic lung disease and even those potentially immunocompromised following prolonged use of systemic corticosteroids. Data concerning efficacy of the vaccine in this population are limited, but the GOLD guidelines recommend its use based on expert opinion and a favorable risk:benefit ratio.^{1,86} Pneumococcal polysaccharide vaccine is recommended to be administered subcutaneously or intramuscularly as a one-time dose. In some cases, patients require a second dose after 5 years, commonly when the initial dose was administered before age 65.⁸⁷ Pneumococcal polysaccharide vaccine used for this purpose should be differentiated from the conjugated, 7-valent pneumococcal vaccine (Prevnar) that is used as a primary immunizing series for infants to provide protection against invasive pneumococcal disease.

To manage T.A.'s symptoms, treatment with a PRN bronchodilator may be reasonable to start. Bronchodilators are the primary pharmacologic therapy used in the management of COPD.^{1,25}

Available bronchodilator therapies include β_2 -agonists, anticholinergics, and methylxanthines (theophylline). For initial treatment, the most common choice for T.A. would be a short-acting, inhaled β_2 -agonist, (e.g., albuterol), an inhaled anticholinergic (e.g., ipratropium), or the combination of these two agents. Any of these therapies has a relatively short onset of action and is effective in relieving symptoms.

β_2 -Agonists

β_2 -Agonists produce bronchodilation by relaxing bronchial smooth muscle through activation of cyclic adenosine monophosphate (cAMP).⁸⁸ The inhalation route of delivery for bronchodilators is recommended over oral therapy based on safety and efficacy. The dose response curve among all available bronchodilators is relatively flat and similar. No evidence suggests that one agent is superior to another.

Albuterol is the most frequently used agent in this class. It is available as a MDI 90 mcg/inhalation and a solution for nebulization (2.5 mg/0.5 mL). The onset of action of short-acting β_2 -agonists (e.g., albuterol, pirbuterol) is rapid (within 5 minutes) and generally reaches maximal effect in 15 to 30 minutes. The duration of action is approximately 4 hours. Although inhaled β_2 -agonists are usually well tolerated, some patients experience adverse effects (tremors, tachycardia, or nervousness) with even low dosages. Although concern has been expressed about the safety of short-acting, inhaled β_2 -agonists in patients with cardiac disease, a cohort study using the Saskatchewan

Health Services database concluded that there was no increased risk for fatal or nonfatal myocardial infarction in patients using these agents.⁸⁹

Anticholinergics

The parasympathetic (cholinergic) nervous system plays a primary role in the control of bronchomotor tone in COPD. By inhibiting cyclic guanosine monophosphate (cGMP) in the lung, aerosolized anticholinergic drugs are effective bronchodilators. The bronchodilation produced by anticholinergics in patients with stable COPD is equal or superior to that achieved by inhaled β_2 -agonists.

Ipratropium bromide is the primary short-acting anticholinergic agent used in COPD. It is marketed as both an MDI (18 mcg ipratropium per puff) and as a solution for nebulization (0.5 mg ipratropium/2.5 mL). Anticholinergics have an average onset of effect within 15 minutes, with a maximal bronchodilator effect in 60 to 90 minutes, although some patients may experience more rapid symptom relief. The duration of action is 6 hours. Although some reports suggest a quicker onset of action, patients should be advised that the relief of acute symptoms will be slower compared with an inhaled β_2 -agonist. A typical dose of ipratropium is two to four inhalations three (TID) to four times (QID) daily. Although well tolerated, some patients experience dry mouth, nausea, and blurred vision with use of ipratropium.

Ipratropium's anticholinergic actions are localized predominantly in the lungs, with an apparent specificity of action in the larger airways. Because it has minimal effects on sputum viscosity, there is little problem with drying of airway secretions. In addition, ipratropium's structure as a quaternary amine increases its polarity, thereby minimizing absorption from the lung and systemic side effects. These structural properties also reduce penetration across the blood-brain barrier, reducing the incidence of confusion and other central nervous system (CNS) side effects.

Combination β_2 -Agonists–Anticholinergics

Combination therapy with two different classes of bronchodilators is appealing, because it may decrease the cumulative dose of individual agents, thereby decreasing the risk of side effects while maintaining the benefits of each medication. In addition, anticholinergics and β -agonists have different mechanisms of action, and combining the two classes may provide additional benefit. Indeed, it has been demonstrated that combination therapy results in significantly greater increases in FEV₁ compared with use of either albuterol or ipratropium alone.⁹⁰

STAGE II (MODERATE) COPD

4. J.O., a 46-year-old woman with a 32-pack/year history of cigarette smoking, presents with increasing shortness of breath. She gets winded walking on level ground after about 100 yards. She quit smoking 2 years ago. The chronic cough that she previously had lessened after smoking cessation but the dyspnea is now somewhat worse, despite use of an albuterol inhaler on a PRN basis. On examination, mild wheezing is noted. A CXR is unremarkable. Office spirometry demonstrates an FEV₁/FVC of 0.54 and an absolute FEV₁ of 2.0 L or 60% of predicted.

Postbronchodilator treatment demonstrated an FEV₁ increase by 100 mL, a 5% increase. How should J.O. be treated?

Therapeutic Management

This patient would be considered to have moderate COPD or GOLD stage II. She has had progression of dyspnea despite smoking cessation and the addition of a short-acting β_2 -agonist. Because pharmacologic management of COPD involves a step-wise approach, regular use of a long-acting bronchodilator would be the next step in treatment.

The main classes of long-acting bronchodilators currently available include β_2 -agonists and anticholinergics. Both classes have been shown to improve quality of life and reduce dyspnea in patients with COPD.

Long-Acting β_2 -Agonist

The role of inhaled, long-acting β_2 -agonists in the chronic management of COPD has become well established in recent years. Available evidence with both salmeterol and formoterol shows improved pulmonary function, reduced dyspnea, and enhanced quality of life in patients with COPD.^{1,25} Additionally, these agents offer the convenience of a long duration of action allowing twice daily dosing. A plateau in bronchodilation is achieved for most patients at the recommended dose for each agent, so no benefits exist in exceeding the recommended dose. In addition, higher doses will increase the risk of adverse events associated with β_2 -agonist excess. Therefore, salmeterol should be prescribed as 42 mcg (50 mcg in a dry powder device) twice daily and formoterol at 12 mcg twice daily.

Inhaled, long-acting β_2 -agonists relieve symptoms, and improve exercise tolerance and health status for patients with COPD. Several recent studies reported the value of these agents in improving spirometry and overall quality of life.^{91–93} Clinical evidence suggests that long-acting β_2 -agonists are equally or more effective than short-acting β_2 -agonists or ipratropium. Based on these results and the convenience of twice daily dosing, these agents are reasonable options for bronchodilator therapy in patients experiencing chronic persistent symptoms.^{1,25}

Tiotropium

Vagal cholinergic tone is a reversible component of the airway limitation in COPD. Stimulation of the vagal parasympathetic nerves causes the release of acetylcholine, which then binds to muscarinic receptors to produce bronchoconstriction and secretion of mucus. Three muscarinic subtypes have been identified in human airways: the M1, M2, and M3 receptors. Tiotropium is a long-acting anticholinergic that binds to the M1, M2, and M3 muscarinic receptors of bronchial smooth muscle.⁹⁴ Although tiotropium dissociates rapidly from the M2 receptor, it dissociates much more slowly from the M1 and M3 receptors. In fact, its dissociation from the M1 and M3 receptors is 100 times slower than that of ipratropium. M1 receptors are located on parasympathetic ganglia, where they facilitate postganglionic transmission, thus enhancing cholinergic tone. M3 receptors are found on airway smooth muscle and mucous glands, where activation leads to bronchoconstriction and mucus secretion. Conversely, M2 receptors are located on postganglionic nerve endings, where they serve as autoreceptors regulating acetylcholine release and, thereby, cholinergic

tone. Thus, anticholinergics, by virtue of antagonizing M1 and M3, relax airway smooth muscle and can reduce mucus secretion. M2 blockade, however, augments acetylcholine release and thus enhances cholinergic tone. Therefore, the slower dissociation rate from both the M1 and M3 receptors enhances bronchodilation and allows the convenience of once-daily dosing.

This agent has a very long duration of action and can provide effective bronchodilation with once daily dosing. Numerous studies have documented its beneficial effect on pulmonary function and quality of life. An ongoing clinical trial is being performed to see whether tiotropium improves the natural history of disease (i.e., alters the slope of FEV₁ decline over time). Tiotropium is also a quaternary amine with limited systemic absorption; therefore, the agent is well tolerated with dry mouth being the major side effect.

J.O. should be started on a long-acting bronchodilator, such as salmeterol, formoterol, or tiotropium. It should be noted that the tolerability and efficacy of the available long-acting bronchodilators are comparable. The choice of agent is largely based on considerations, such as the frequency of drug administration, the patient's ability to use the inhalation device correctly, and any out-of-pocket costs incurred by the patient. J.O. should also be instructed to continue her albuterol two puffs every 4 hours PRN. A 3-month follow-up visit should be scheduled to assess her response.

5. J.O. is started on tiotropium one puff (18 mcg) daily and returns to the office for a check-up in 3 months as recommended. She has had significant benefit from the medication and has had decreased wheezing and a noticeable improvement in her exercise tolerance. She asks to have spirometry repeated to see if her lung function has improved on the new medication. Spirometry is repeated and no significant improvement noted in her FEV₁. She wonders how she can feel better, with improved exercise tolerance without an improvement in her lung function.

Increasing evidence suggests that bronchodilators, including long-acting β_2 -agonists and anticholinergics, may reduce exercise-related dyspnea in patients with COPD by decreasing dynamic hyperinflation.⁹⁵ This improvement may be independent of marked changes in spirometry performed at rest. Indeed, because of flow limitation, these patients who exercise can have significant worsening of air-trapping, which can worsen lung compliance and adversely affect respiratory muscle mechanics. A number of studies have shown that alleviation of such “dynamic hyperinflation” may be an important mechanism whereby bronchodilators improve exercise tolerance in patients with obstructive lung disease.⁹⁵

6. J.O. seemed to do reasonably well for a number of years, but now, 5 years later, she has noticed progressive dyspnea on exertion. She is now having difficulty carrying laundry up from her basement and she has noticed that her overall activity level has been curtailed. Repeat office spirometry now shows an FEV₁/FVC of 0.49 and an absolute FEV₁ of 49% of predicted. J.O. has been compliant with her tiotropium regimen and has had no other significant changes to her medical history. She remains smoke free and is not exposed to second-hand smoke in her home and work environments. What therapeutic intervention(s) should be considered at this point?

At this point, J.O. would be considered to have severe COPD, or GOLD stage III. She is symptomatic now, despite the regular use of a long-acting bronchodilator. To continue with the step-wise approach, addition of another long-acting bronchodilator with a different mechanism of action would be reasonable. Evidence suggests that the combination of a long-acting anticholinergic and a long-acting β_2 -agonist can increase lung function compared with either agent used alone.^{96,97} Salmeterol and formoterol have a similar side-effect profile and have similar effectiveness. Either salmeterol one inhalation (50 mcg) every 12 hours or formoterol, one inhalation (12 mcg) twice daily would be reasonable options for J.O.

Safety of Long-Acting Bronchodilators

7. J.O. calls the next day, having read something on the internet regarding possible increased risk of death in people with obstructive lung disease who take long-acting bronchodilators. She is reluctant to take it. What should you tell her?

Although some evidence in asthma indicates that use of long-acting bronchodilators may be associated with an increased risk of death; such evidence does not exist in patients with COPD. In fact, the TORCH study demonstrated no increased risk of death or adverse events among patients prescribed salmeterol compared with placebo.⁵⁹ The patient should be reassured that long-acting bronchodilators are safe in COPD.

8. J.O. also wonders if anything else other than her medication can be done for her. What advice might be given?

Pulmonary Rehabilitation

At this point, pulmonary rehabilitation should be strongly considered. In fact, a comprehensive multidisciplinary pulmonary rehabilitation program should be considered in any patient with COPD experiencing persistent shortness of breath despite pharmacologic management.⁴³

Increasing evidence points to COPD as a systemic process,⁹⁸ and pulmonary rehabilitation addresses the systemic nature of the disease. Figure 23-7 illustrates the cycle that occurs in COPD. Although the proximate cause of disability involves the respiratory system, leading to dyspnea on exertion, this in turn has systemic consequences. Although the changes may be fairly subtle to start, most patients will gradually manifest increasing limitations in their activity. This results

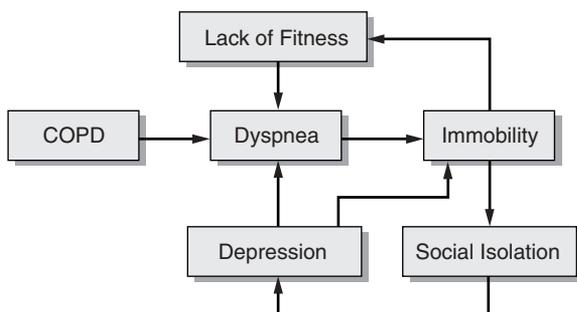

FIGURE 23-7 The Cycle of Physical, Social and Psychosocial Consequences of COPD. (Reprinted with permission from reference 1.)

in substantial deconditioning. It is likely that this deconditioning, in addition to other factors such as systemic inflammation, adversely affect skeletal muscle function. Indeed, evidence is clear that oxidative capacity is diminished in patients with COPD,⁴⁵⁻⁴⁷ which results in overall decreased aerobic capacity and results in increased lactic acid production for a given level of activity.⁵⁰ The increased acid load will lead to a greater requirement for ventilation, which makes dyspnea more severe. The more dyspneic the patient is, the less activity he or she will do, leading to more deconditioning and recapitulation of the downward spiral.

Pulmonary rehabilitation is an exercise-based, multidisciplinary program that seeks to address this cycle.⁴³ Most programs generally last 8 to 12 weeks and involve two to three sessions per week. Education, particularly about medication use, as well as psychosocial counseling and breathing retraining are important components of the program. An important component of breathing retraining involves coaching patients how to use pursed lip breathing effectively. Pursed lip breathing involves pursing the lips together (as in whistling) during exhalation. This helps to slow down respirations and also provides a back pressure in the small airways, preventing dynamic airway collapse and exercise-induced hyperinflation. The major intervention, however, is exercise training, especially endurance training of the lower extremities (e.g., using a treadmill or bicycle ergometer). Numerous studies have demonstrated that a rehabilitation program can significantly improve exercise capacity and quality of life, as well as decrease health care utilization.⁴³ This may partly be related to the beneficial effects of exercise on the oxidative capacity of the skeletal muscles.

J.O. should be referred to a local outpatient pulmonary rehabilitation program. A typical program involves 2-hour sessions, three times per week for 10 weeks. The sessions will involve education, breathing retraining, and strength and endurance exercise training.

STAGE III (SEVERE) COPD

9. R.L., a 66-year-old man with diabetes mellitus and severe (stage III) COPD, presents with increased cough with productive discolored sputum following a “cold.” He had been hospitalized 6 weeks earlier with community-acquired pneumonia. He is a former smoker (quit 10 years ago); current medications includes formoterol inhalation powder (12 mcg twice daily [BID]), albuterol MDI two puffs every 4 hours PRN and theophylline 200 mg BID. He also has increased dyspnea and chest tightness. On examination, he is in no acute distress and vital signs are stable. There is increased wheezing on chest examination and the rest of the examination is unchanged. Room air pulse oximetry is 90% and a CXR in the office shows no infiltrates. How should this patient be treated?

Acute Exacerbation of COPD

Antimicrobial Therapy

This patient has increased sputum purulence and increased dyspnea consistent with an exacerbation of COPD. It is not uncommon for such an exacerbation to be triggered by an upper

respiratory viral infection. Given that the patient has increased dyspnea and purulent sputum production, a course of systemic corticosteroids (e.g., 30 to 40 mg of prednisone daily for 7 to 10 days) and a course of antibiotics is warranted. In outpatients with low risk factors, a low-cost antibiotic regimen is a reasonable option. Amoxicillin, trimethoprim–sulfamethoxazole or doxycycline could be used. Although other antibiotics are commonly given, no data support that they are superior in this setting when compared with these conventional, less-expensive agents. An acute exacerbation of COPD is one of the few instances where antibiotic therapy is warranted to treat a respiratory infection in the absence of evidence of lower respiratory tract involvement (i.e., pneumonia).

Patients with COPD and risk factors for poor outcome (severe COPD, comorbid conditions, history of frequent exacerbations) may be more susceptible to resistant pathogens. As such, guidelines recommend that a broader spectrum antibiotic regimen be considered, including β -lactam/ β -lactamase inhibitor combinations, quinolone antibiotics, or second- or third-generation cephalosporins.^{1,25}

Because of his recent hospitalization, R.L. is at increased risk for resistant pathogens, including *P. aeruginosa*. A broad-spectrum antimicrobial regimen, such as oral ciprofloxacin, 750 mg BID or oral levofloxacin 750 mg every day for 7 to 14 days would be appropriate. A course of oral prednisone, 30 mg daily for 7 to 10 days is also indicated to improve R.L.'s lung function, reduce his hypoxemia, and hasten his recovery time.

10. R.L. was treated with oral ciprofloxacin 750 mg BID and demonstrated a decrease in sputum volume and purulence with less dyspnea after 3 days of therapy. However, 5 days later he is feeling palpitations and has become nauseous. What laboratory value should be checked?

This patient has clinical evidence of theophylline toxicity. Both gastrointestinal complaints (e.g., nausea) and CNS symptoms, including sleep difficulty and nervousness, are consistent with theophylline toxicity. Other adverse reactions associated with methylxanthines are cardiac irritability (tachycardia or arrhythmias) and seizures. All these side effects are dose related. Gastrointestinal intolerance, nervousness, and insomnia can occur at any serum concentration, but increase in frequency when serum concentrations are >15 mcg/mL.

In R.L., the addition of the antibiotic ciprofloxacin to his regimen most likely resulted in a drug interaction causing a rise in his theophylline concentration. The potential for an interaction with theophylline varies among the available fluoroquinolone antibiotics. Drug interactions are dependent on several factors, including the dose of each agent and the baseline serum theophylline concentration. Elevations in the theophylline concentration of 25% are typical with ciprofloxacin interactions, although elevations of 50% have been observed. In R.L., a theophylline concentration should be obtained and further doses withheld until results are known.

In general, theophylline metabolism is associated with significant interpatient and inpatient variability. Patients should be monitored closely for early signs of toxicity as well as for the initiation of drugs that potentially may interact. Understanding and recognizing the potential for drug interactions can allow safe and effective therapy with theophylline.

11. A theophylline serum concentration is measured for R.L. It is reported as 21 mcg/mL. What action should be taken?

The serum concentration is consistent with the interaction between theophylline and ciprofloxacin reported in the literature. His symptoms do not appear life-threatening at this point, so a conservative approach to treatment is appropriate. Theophylline should be withheld for one dose and then restarted at a lower dose (100 mg BID) until the ciprofloxacin therapy is completed. Alternatively, theophylline could be withheld until the antibiotic treatment is finished or discontinued. As mentioned, theophylline has a narrow therapeutic window and has the potential for serious toxicity as is evidenced by the current case. If the patient is unclear how beneficial the theophylline has been, a trial off of the medication is reasonable. After approximately 2 to 4 weeks, R.L. should be reassessed. If he feels that his chronic symptoms are no different without the drug, it should be withheld. On the other hand, his symptoms may become more pronounced without the theophylline and it could then be restarted. Alternatively, it would be reasonable to replace theophylline with an additional long-acting bronchodilator from a different class, in this case, tiotropium.

Chronic obstructive pulmonary disease has a progressive course, highlighted by a worsening of symptoms over time. Because step-wise therapy is recommended, it is not uncommon to find patients on multiple medications “added-on” in an attempt to alleviate symptoms. Nevertheless, it is important periodically to assess the patient to determine if all the medications are continuing to provide symptomatic benefit and are still needed. This may result in a “step-down” approach.

STAGE IV (VERY SEVERE) COPD

12. K.K., a 57-year-old woman with a long history of COPD presents to establish care. She is concerned about her recurring hospitalizations because of lung problems. She has been to the emergency department five times in the last year and admitted twice because of episodes of worsening cough, sputum production and dyspnea. Her most recent FEV₁/FVC was 0.46 and her absolute FEV₁ was 45% of predicted. She is currently taking tiotropium one puff (18 mcg) as well as albuterol inhaler PRN for shortness of breath (SOB). She uses oxygen at 2 L/minute when sleeping (~8 hours/night). She is a former smoker, 50 pack years, but quit 2 years ago. What change in treatment would you recommend?

Inhaled Corticosteroid Therapy

This is a patient with advanced COPD, who has had significant deterioration in status and repeated COPD exacerbations and who is an ideal candidate for regular use of an inhaled corticosteroid. A number of multicenter, randomized, controlled clinical trials have demonstrated the efficacy of inhaled corticosteroids in COPD.^{70–73} The data have supported the use of inhaled corticosteroids in advanced COPD and in patients with frequent exacerbations. Regular use of inhaled corticosteroids can decrease the frequency of acute exacerbations and improve health-related quality of life.

The recently published TORCH study has defined the benefits and potential side effects of inhaled corticosteroids in a broader patient population of COPD.⁵⁷ In this multicenter, randomized, placebo-controlled study, mean FEV₁ was 50% predicted, but entry criteria did not require a history of repeated exacerbations. More than 6,000 patients were randomized to either an inhaled corticosteroid (fluticasone 500 mcg BID), inhaled salmeterol (50 mcg BID), combination fluticasone 500 mcg/salmeterol 50 mcg BID, or placebo. Subjects were followed for approximately 3 years. A significant benefit was seen as measured by decreased exacerbation rates in subjects taking either inhaled fluticasone or a combination of fluticasone–salmeterol therapy. Also, an improvement was found in mortality with combination therapy that approached, but did not reach statistical significance. Overall adverse side effects with inhaled corticosteroids were similar to placebo. An increased risk, however, was seen of lower respiratory tract infections with inhaled fluticasone or fluticasone–salmeterol. Of note, patients did not experience an increased risk of ocular manifestations or decreased bone density with inhaled corticosteroid treatment.

K.K. is already taking tiotropium so a decision must be made regarding step-up therapy. A number of potential interventions exist at this point. The first would be to discontinue the tiotropium and initiate a combination inhaled corticosteroid–long-acting β_2 -agonist. Secondly, an inhaled corticosteroid could be added to the tiotropium. Finally, recent data suggest that inhaled tiotropium and combination inhaled corticosteroid–long-acting β_2 -agonist therapy may have significant benefits.⁹⁹ Currently, any of these three choices is reasonable provided no other major contraindications in doing so exist. It should be noted that currently two corticosteroid–long-acting β_2 -agonist inhalers are available: Advair (fluticasone–salmeterol) and Symbicort (budesonide–formoterol). No data suggest that one preparation is superior to the other in the treatment of COPD.

The exact duration of treatment that inhaled glucocorticoids should be given before making an assessment of their benefit is not clear. Generally, an adequate trial is at least 4 to 6 weeks. One rationale for the use of inhaled glucocorticoids in COPD is, however, the prevention of acute exacerbations. As such, it can be very difficult to measure objectively the clinical benefit of the medication in individual patients.

Oxygen Therapy

13. P.J., a 62-year-old man with long-standing COPD, presents with worsening dyspnea on exertion. He is currently prescribed combination fluticasone–salmeterol (Advair 250/50 one puff BID), tiotropium (Spiriva 18 mcg one puff every day), and PRN albuterol (two to four puffs every 4 to 6 hours PRN). P.J. reports excellent compliance with his medications and an evaluation of his inhaler technique reveals he is able to use all three devices correctly. He has undergone pulmonary rehabilitation in the past with some benefit. He is no longer exercising, however. He has smoked 1.5 packs of cigarettes a day for 40 years (60 pack years), but quit 1 year previously. His most recent FEV₁/FVC is 0.41 and his FEV₁ is 1.25 L, or 38% of predicted. His room air oxygen saturation at rest is 85%. On examination, reduced breath sounds are noted in

his chest and he has lower extremity edema. His physician recommended supplemental oxygen; however, he is resistant and wonders what kind of benefit he might receive.

The Nocturnal Oxygen Treatment Trial, a randomized controlled study, studied patients with COPD and severe hypoxemia PaO₂ \leq 55 mm Hg, or PaO₂ \leq 59 mm Hg associated with polycythemia, or peripheral edema.³⁸ Patients were randomized to continuous oxygen or nocturnal oxygen. The primary outcome variable was mortality. Subjects using continuous oxygen had a significantly greater survival and improved end-organ function, including improved cognitive function. The Medical Research Council Study published in 1981, using similar entry criteria, demonstrated a significant survival benefit with continuous supplemental oxygen compared with no oxygen.³⁹

Based on these studies, supplemental oxygen is currently recommended for severe hypoxemia currently defined as an oxygen saturation $<$ 88% or PaO₂ \leq 55 mm Hg (oxygen saturation $<$ 90% or PaO₂ \leq 59 mm Hg in the presence of polycythemia or clinical evidence of pulmonary hypertension; e.g., peripheral edema). These guidelines (Table 23-6) are used by Medicare and most insurance companies as criteria to determine coverage for supplemental oxygen. This patient should be encouraged to use supplemental oxygen because it is one of the few available interventions that has been associated with improved survival in COPD.

In addition to supplemental oxygen, the patient should be re-enrolled in pulmonary rehabilitation. As mentioned, existing data suggest that this intervention can improve quality of life and exercise tolerance and decrease health care utilization.

Surgical Treatments for COPD

14. The patient is prescribed supplemental oxygen and enrolls in a pulmonary rehabilitation program. These interventions are successful in improving exercise tolerance; however, he presents 12 months later complaining of worsening dyspnea. In addition, although he is compliant with the oxygen, he is wondering if any other interventions available might improve his lung function and allow him to “get off” of oxygen.

He is re-evaluated with pulmonary function studies, which demonstrate a reduced FEV₁/FVC ratio of 0.38 and an absolute FEV₁ of 29% of predicted. In addition, lung volume

^a Proven to improve survival.

^b Efficacy not proven.

determinations show severe hyperinflation (TLC = 135% of predicted and air-trapping RV = 292% of predicted). His CXR shows marked decrease in lung markings in the upper lung zones with vascular crowding in the lower lung fields. What therapeutic options are available for P.J.?

Lung volume reduction surgery, which involves the surgical removal of approximately 30% of the volume of each lung, can significantly improve quality of life, exercise tolerance, and mortality in selected patients with COPD. The National Emphysema Treatment Trial (NETT) demonstrated that patients with severe, upper lobe predominant emphysema who have lung volume reduction surgery have significant benefits in health-related quality of life as well as exercise tolerance.⁷ Subjects who also had persistently poor exercise tolerance before surgery appeared to have the most benefit compared with control subjects with similar impairment. These patients also had a mortality benefit.⁷ The rationale for the surgery is that removing the areas of the lung most involved with emphysema can improve the physiology of the remaining lung. This includes improvement in expiratory airflow and improved lung elastic recoil as well as improved ventilation perfusion matching. The major patient selection criteria for lung volume reduction surgery are depicted in Table 23-7. Following a successful surgery, patients can have improved gas exchange and may no longer require supplemental oxygen.

The CXR for this patient suggests upper lobe predominant emphysema. This would need to be confirmed with a high

| Moderate to severe airflow obstruction |
| Hyperinflation |
| Upper lobe predominant emphysema |
| Nonsmoker |
| Rehabilitation potential |

resolution computed tomography (CT) scan of the chest. Furthermore, the patient would need to complete a comprehensive pulmonary rehabilitation program before surgery. Only few centers within the United States are certified by Medicare to perform lung volume surgery and this could be an important issue for P.J., depending on where he lives. It should be stressed that lung reduction surgery is only appropriate for a select group of patients with advanced emphysema.

Recent studies utilizing bronchoscopic lung volume reduction are currently being evaluated and may prove to be a less invasive option to perform lung reduction in patients with severe emphysema.¹⁰⁰

In patients with severe emphysema, another option is lung transplantation. This intervention has not been shown to decrease mortality, but can improve quality of life and exercise tolerance in carefully selected candidates.¹⁰¹ Patients considered are those with severe disease, whose life expectancy is <5 years and individuals with an FEV₁ <25% of predicted.

CONCLUSIONS 24-24**Definitions**

Rhinitis is an inflammatory condition affecting the mucous membranes of the nose and upper respiratory system. The term is used broadly to encompass a syndrome of nasal symptoms characterized by periods of rhinorrhea (nasal discharge), pruritus (itching), sneezing, congestion, and postnasal drainage (postnasal drip). These nasal symptoms can be accompanied by ocular redness, itching, and discharge. Rhinitis can be exacerbated by the development or presence of sinusitis. The most common form of rhinitis occurs in response to an allergen, although a variety of other causes have been demonstrated.^{1,2}

Practice parameters for the diagnosis and management of allergic and nonallergic rhinitis were published in 1998 by a Joint Task Force representing the American Academy of Allergy, Asthma and Immunology (AAAAI), the American College of Allergy, Asthma and Immunology (ACAAI), and the Joint Council on Allergy, Asthma and Immunology.¹ Following this, the European Academy of Allergology and Clinical Immunology published a consensus statement on the treatment of allergic rhinitis in 2000.² More recently, evidence linking asthma and allergic rhinitis epidemiologically, pathologically,

and physiologically was published.³ These data support the tenet that upper respiratory allergic disorders and asthma represent components of a single inflammatory airway syndrome.⁴ The resulting guidance, known as *Allergic Rhinitis and Its Impact on Asthma* (ARIA), was adapted for use specifically by pharmacists.⁵ An updated version of ARIA has now been published, with the goal of extending the knowledge of allergic rhinitis and filling gaps in areas such as the use of complementary and alternative therapies, rhinitis in developing countries, and rhinitis in athletes.⁶

Prevalence and Impact

Prevalence rates for rhinitis are difficult to quantify because the condition is often undiagnosed, different definitions have been used, and the data collection methods vary.^{7,8} In addition, because rhinitis in its mildest form is largely self-managed, it is likely that health statistics under represent the actual scope of the problem⁹ and that the prevalence of rhinitis is increasing.¹⁰ Despite these confounders, a conservative estimate suggests that up to 30% of adults (and even more children) are affected by allergic rhinitis (representing the greatest proportion of this

family of diagnoses), making it the sixth most common chronic illness in the United States.^{11,12}

Rhinitis can lead to sleep disorders, loss of appetite, general weakness, fatigue, mood disorders, decreased concentration, and difficulty learning.^{1,9,13} Despite the impact of symptoms and the burden of disease, less than half (47%) of nasal allergy sufferers reported seeing a health care practitioner about their symptoms in the last 12 months.⁸ Although symptom severity is associated positively with seeking treatment, 41% of patients who reported several nasal allergy symptoms in the past week had not seen a doctor about this within the last year.⁸ Most nasal allergy sufferers report taking medication for their condition; with more than half (53%) reporting that they have used a non-prescription medication and more than a third (36%) reporting that they have used a prescription nasal spray in the past 4 weeks.⁸ Most patients taking medications for their symptoms, however, report that they are less than very satisfied with the products they use.⁸

Although rhinitis does not lead to the mortality associated with some illnesses, its prevalence and negative health impact make it an important health problem in the United States. Allergic diseases are the most frequent contributor to the total cost of health-related absenteeism and presenteeism (i.e., being physically present at the workplace, but not being fully functional because of disruptive medical symptoms), with allergic rhinitis being the most prevalent of the allergic diseases. Most employees report annual allergic symptoms on average of 52.5 days, absence 3.6 days, and lack of productivity 2.5 hrs/day when experiencing symptoms.¹² The most recent estimates of the annual cost of allergic rhinitis range from \$2 to \$5 billion.¹⁴ The total cost of allergic rhinitis in 2002 was estimated to be \$4.86 billion, including \$4.2 billion in direct costs (e.g., emergency department visits, clinic visits, prescription medications) and \$666 million in indirect costs.¹⁵ Clearly, acute and chronic rhinitis has a great impact on the physical and economic health of Americans.

Applied Anatomy and Physiology of the Nose

An understanding of the anatomy and physiology of the nose is helpful in understanding the pathophysiology and presentation

of rhinitis, as well as the rationale for various pharmacotherapeutic approaches. The primary functions of the nose are smell, speech, and conditioning of inspired air. Related to the latter, the nose and upper airway warm, humidify, and filter air for delivery to the lungs.¹⁶

The external nose is pyramidal and consists of paired nasal bones and associated cartilage. Its base has two elliptical-shaped openings called nares, or nostrils. Internally, a septum separates the nasal cavity into two halves and consists of bone and cartilage covered by a mucosal membrane.¹⁷ The lateral walls of the internal cavity contain the conchae, or turbinates. These bony projections increase surface area substantially and contribute to turbulence of airflow, which is useful in filtering and conditioning inspired air. Sinuses and eustachian tubes open into the nasal cavity near the turbinates, as do the lacrimal drainage ducts.¹⁷ Figure 24-1 shows a lateral view of the head with the nasal anatomy labeled.

The membranes of the nasal cavity consist primarily of ciliated columnar epithelial cells with mucus-producing goblet cells interspersed among them. The tiny cilia beat rhythmically to transport mucus across the upper airway membrane to the nasopharynx. The cilia-lined mucous membranes of the nose provide a physical barrier of defense to microorganisms and other particles in the inspired air.¹⁶ In addition, respiratory secretions residing on these mucous membranes contain immunoglobulin A (IgA), which serves as an immunologic defense.¹⁷

The autonomic nervous system controls the vascular supply and the secretion of mucus to the nasal membrane. Sympathetic activation results in vasoconstriction, which decreases nasal airway resistance. Parasympathetic stimulation results in glandular secretion and nasal congestion.¹⁸ The mucosa is also innervated by the nonadrenergic–noncholinergic system (NANC). Neuropeptides from these nerves (e.g., substance P and neurokinins) play a role in vasodilation, mucus production and inflammation, although their significance is unclear. The trigeminal nerve also provides sensory innervation; the stimulation of which can result in sneezing and itching.¹⁸

During normal breathing, inspired air flows through the external nose before turning posteriorly almost 90 degrees into the nasopharynx. The airstream then makes another right angle

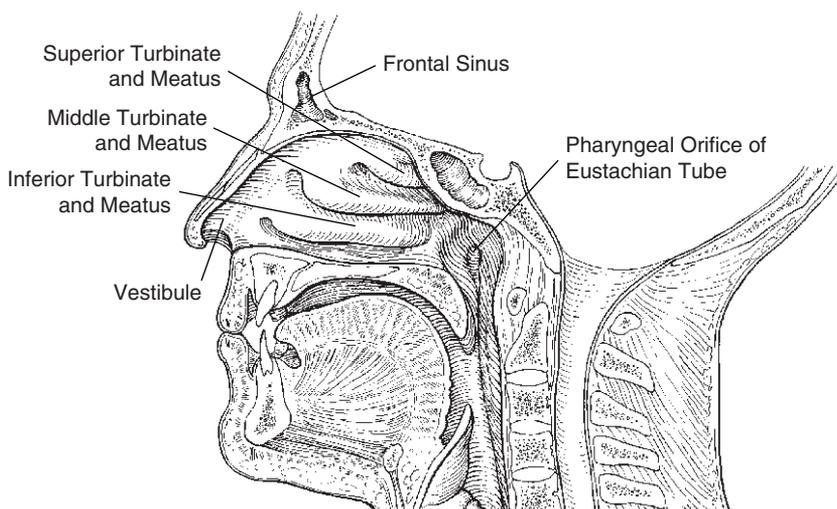

FIGURE 24-1 Lateral view of the head with nasal anatomy. (Reprinted with permission from the LifeArt Human Anatomy II collection.)

turn through the pharynx and larynx toward the lower airway. The upper airway diameter is extremely narrow in places, allowing for close contact between inhaled air and mucosal surfaces. Under normal conditions, turbinates in either side of the nasal cavity swell or contract alternately, resulting in preferential airflow through the right or left nasal cavity. This process is disrupted in the presence of inflammation and congestion. Normal nasal physiology is also affected by the presence of anatomic deformities including septal deviation, nasal polyps, or both.¹⁷

CLASSIFICATION OF RHINITIS

Rhinitis is not a single disease but rather has multiple causes and underlying pathophysiologic mechanisms.^{1,19} Figure 24-2 depicts the common causes of acute and chronic rhinitis symptoms. Strictly speaking, some of these are not causes of rhinitis, but rather disorders (e.g., nasal septal deviation, foreign body) with symptoms that mimic inflammatory conditions of the nose. These conditions are considered in the differential diagnosis of allergic rhinitis.

Acute

The most common cause of acute rhinitis is a viral upper respiratory infection or the common cold. In most patients, these viral infections are self-limited and require only symptomatic treatment.¹⁹ Nasal foreign bodies, especially in young children, are a common cause of acute rhinitis and should be suspected when a pediatric patient presents with acute unilateral symptoms.¹⁶ Hormonal causes of acute rhinitis, usually associated with a clear, watery discharge without other symptoms, include hypothyroidism and pregnancy.^{18,20} Finally, the development of acute rhinitis-like symptoms has been attributed to

some medications. Angiotensin-converting enzyme inhibitors (ACEI), β -blockers, reserpine, nonsteroidal anti-inflammatory drugs (NSAID), oral contraceptives, phosphodiesterase type 5 inhibitors, and over use of topical decongestants all have been associated with nasal effects.^{21,22}

Chronic

Chronic rhinitis can be classified as allergic or nonallergic. Allergic causes are typically associated with atopy, an inherited tendency to develop a clinical hypersensitivity condition.² The current guidelines classify allergic rhinitis as either intermittent or persistent based on frequency of symptoms.⁶ This has replaced the earlier classification system (seasonal or perennial), which was based on both frequency of symptoms and the allergen responsible.¹ Patients with any form of allergic rhinitis can experience symptoms ranging from mild to severe. This classification system is summarized in Figure 24-3.

Nonallergic causes of chronic rhinitis symptoms include idiopathic rhinitis, nonallergic rhinitis with eosinophilia syndrome (NARES) and anatomic abnormalities.¹⁹ Idiopathic rhinitis, also called *vasomotor rhinitis*, refers to symptoms associated with environmental stimuli, including temperature changes, strong odors, tobacco smoke, stress, or emotional factors.²³ NARES occurs frequently in middle-aged patients who have no evidence of allergic disease excepting the presence of eosinophils in the nasal smear. In these cases, increased permeability of the nasal mucosa is likely caused by non-IgE-mediated inflammation, and neurogenic mechanisms may play a role in membrane hyperreactivity.¹⁹

Common anatomic causes of chronic rhinitis include nasal septum deviation, nasal polyps, tumors, choanal atresia (a congenital condition where the mouth and nose are not connected), and enlarged adenoids and tonsils. Often these anatomic abnormalities require surgical intervention.¹⁸

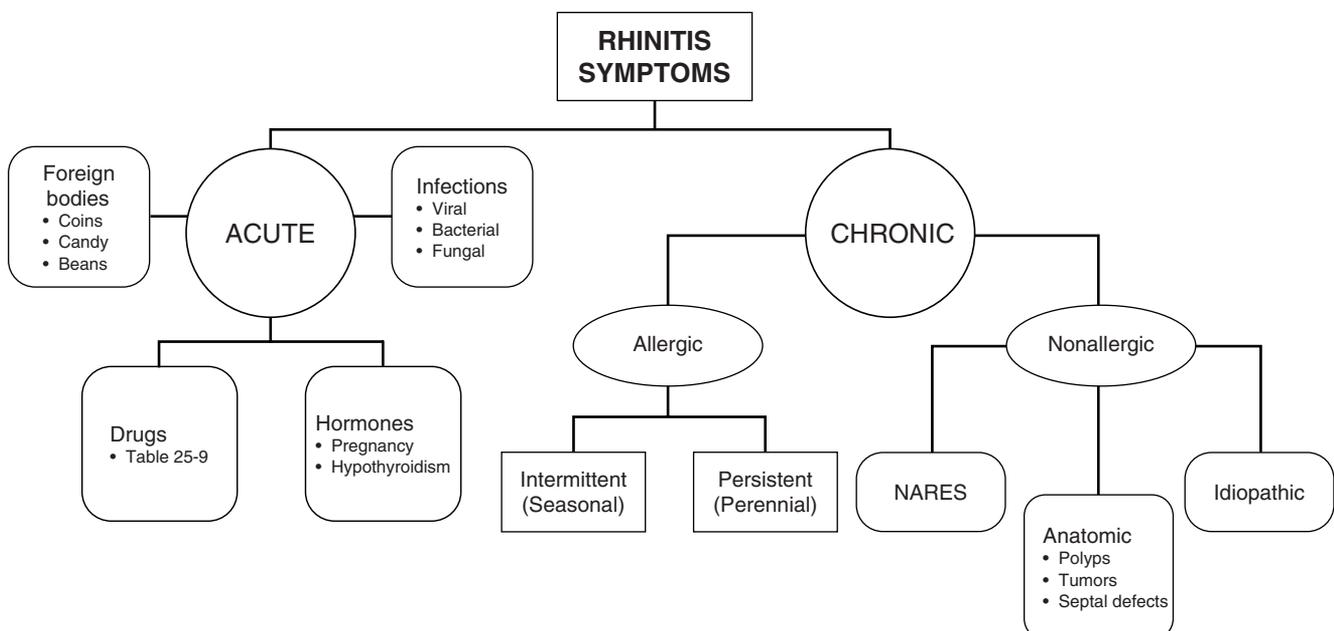

FIGURE 24-2 Possible causes of acute and chronic rhinitis symptoms NARES, nonallergic rhinitis with eosinophilia syndrome.

| Intermittent ^a Disease | Persistent ^b Disease |
|--|---|
| Symptoms occur: Fewer than 4 days/week <i>or</i> for fewer than 4 weeks | Symptoms occur: At least 4 days/week <i>and</i> for at least 4 weeks |
|  | |
| Mild | Moderate-Severe |
| All of the following: | At least <i>one</i> of the following: |

ARIA, Allergic Rhinitis and its Impact on Asthma

FIGURE 24-3 ARIA classification of allergic rhinitis. (Adapted from references 4,6.)

ETIOLOGY OF ALLERGIC RHINITIS

Genetic, environmental, and lifestyle influences are associated with the development of allergic rhinitis.⁶ Problems with methodology and sample size in genome-wide screening studies preclude any definitive conclusions about candidate genes for allergic rhinitis⁶; however, atopy is a significant inheritable factor, and the risk of a child developing allergic symptoms is 50% with one atopic parent and 66% with two atopic parents.²⁴ Environmental exposures, particularly early in life are also important in the development of symptoms.²⁵ In addition, lower socioeconomic status may be a risk factor for development of allergic rhinitis.²⁶

One theory, referred to as the *hygiene hypothesis*, is that the initial differentiation of lymphocytes early in life has either positive or negative influences on the development of subsequent allergies. In the normal development of the immune system, the lymphocytes differentiate into either Th1 or Th2 cells based on environmental stimuli. Factors associated with a Th1 (allergy protective) response include exposures to various bacteria and viruses, the presence of older siblings, and early attendance in day care. Factors associated with a Th2 (predisposition to allergies) response include environmental exposures to house dust mites, cockroaches, or early, frequent antimicrobial use.^{24,27}

In patients with intermittent allergic rhinitis, pollens and airborne mold spores are the most common allergens. Although the pollen season varies with geographic location, grasses, trees, and weeds can be problematic for many people during active pollination. In the United States, ragweed is a primary cause of intermittent symptoms and sensitivity to this pollen is historically referred to as “hay fever.”¹⁹

In patients with persistent allergic rhinitis, the major allergens are house dust mites, indoor molds, animal dander, and cockroach antigen. Another common cause is occupational exposure, in which symptoms can be precipitated by agents such as flour, wood, and detergents.¹⁹

PATHOPHYSIOLOGY

The primary pathophysiologic feature in allergic rhinitis is inflammation of mucous membranes of the nose. Common symptoms include sneezing, watery discharge, itching of the

nose and eyes, nasal obstruction, and postnasal dripping of secretions.^{1,6}

The pathogenesis of allergic rhinitis and asthma includes numerous areas of commonality. Inflammation is a central mechanism and the role of cytokines in this process is similar. This has led many scientists and clinicians to adopt the concept of “one airway, one disease.”⁶ Further evidence for this association includes that rhinitis is a known risk factor for asthma, some patients with rhinitis exhibit bronchial hyperresponsiveness, viral upper respiratory tract infections are a common cause of asthma exacerbations, and sinusitis can worsen asthma.⁶ Some treatment strategies, including pharmacotherapy, have a role in both rhinitis and asthma.

Allergic rhinitis is characterized by an immunoglobulin E (IgE)-mediated response that involves three primary steps: sensitization, early-phase events, and late-phase events. This process is depicted in Figure 24-4. Sensitization occurs after initial allergen exposure in a susceptible patient and involves the production of IgE antibodies. These antibodies bind to receptors on other cells, including mast cells. On subsequent exposure, an interaction occurs between the complex of the allergen, IgE antibody, and the mast cell, such that a cross-linking occurs that results in activation and initiation of the inflammatory response. The events can occur early after exposure if the mediators are preformed or late if mediators are synthesized after the process begins or are attracted to the area through chemotaxis.²⁸

Sensitization

In an atopic patient, the result of initial exposure to allergens is production of IgE. Following initial exposure, antigen-presenting cells of the immune system react to allergens deposited on the nasal mucosa. This results in helper T-lymphocyte differentiation into Th2 cells, which are associated with production of cytokines and other mediators of inflammation. As a result, memory cells programmed for IgE production are produced.^{6,24,28}

Early Response

When a susceptible patient is exposed to an allergen to which previous sensitization has occurred, an early-phase allergic

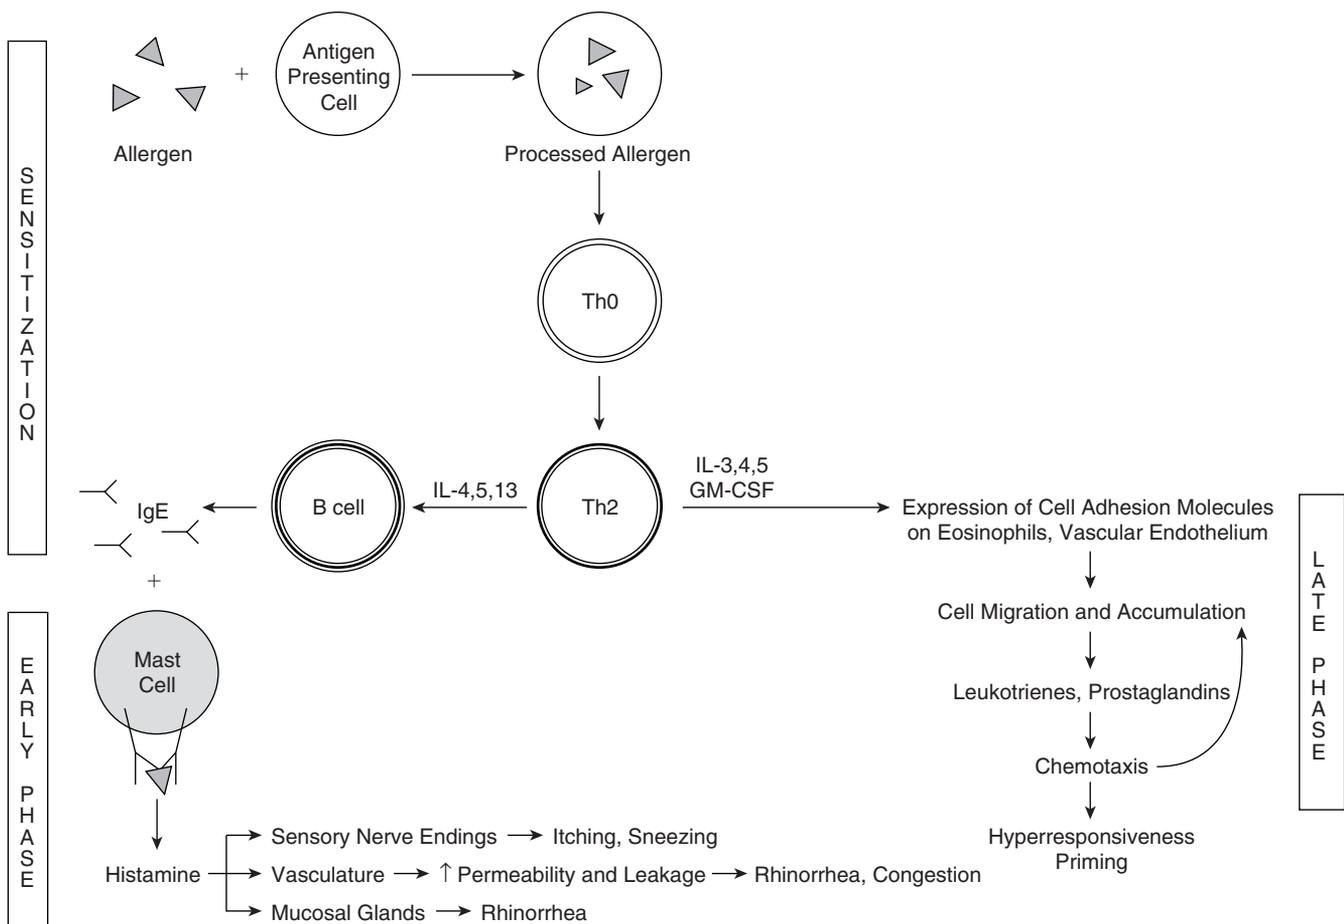

FIGURE 24-4 Pathophysiology of allergic rhinitis.

response generally occurs. This reaction is attributed largely to the interaction between the allergen, IgE, and the sensitized mast cell, resulting in mast cell degranulation. Other cells, including basophils, play an important role as well. As a result, mediators of the allergic response, including histamine, are released along with various chemotactic factors, which amplify and perpetuate the allergic response. Because these mediators are already present in the mast cell, they act within minutes to cause the common symptoms of allergic rhinitis, including itching, sneezing, and congestion.^{28,29,30}

Histamine receptors (H_1) are present throughout the nasal mucosa and their activation results in vascular engorgement, leading to nasal congestion, direct stimulation of mucus secretion, and increased glandular secretion.³⁰ In addition, parasympathetic nervous system stimulation results in cholinergically mediated nasal secretions. Finally, stimulation of peripheral nerve receptors results in itching and sneezing reflexes.¹⁹

Late Response

Up to one-third of patients with allergic rhinitis also experience a late response that develops approximately 8 hours after initial exposure and may persist for up to 4 hours. In this phase, the nature of inflammation is even more complex, and nasal congestion is a prominent feature. Numerous cells and

mediators, including T lymphocytes, cytokines, eosinophils, neutrophils, macrophages, mast cells, and leukotrienes, play important roles. These additional mediators, attracted to the area through chemotaxis, sustain the inflammatory response. This response is also perpetuated through continued exposure to the offending allergen.³¹

DIAGNOSIS AND ASSESSMENT OF RHINITIS

The diagnosis of rhinitis is not defined by one specific laboratory test; rather, it is related to the coordinated results of a thorough patient interview, including medication history, pertinent physical examination, and a limited number of relevant laboratory assessments.³² Because both allergic and nonallergic stimuli are common; health care practitioners must be able to distinguish these to develop effective management strategies.¹⁹

History, Signs, and Symptoms

The patient history for rhinitis should include a discussion of the onset, character, frequency, duration, and severity of the patient's symptoms and any identifiable factors that provoke or relieve these symptoms.^{1,19,32} Common nasal symptoms suggestive of allergic rhinitis include watery rhinorrhea, nasal pruritus, sneezing, and nasal congestion. Sneezing can occur paroxysmally or be preceded by itching of the nose, ears, eyes,

and throat. Some patients experience concomitant allergic conjunctivitis, with symptoms such as bilateral pruritic; watery, red eyes; and even photophobia.^{5,19} The presence of other nasal symptoms (e.g., nasal obstruction as a sole symptom, mucopurulent rhinorrhea, chronic sinus pain, recurrent epistaxis, and anosmia) may be important in differentiating allergic rhinitis from other causes.¹⁸

Information about the patient's medical history, current illnesses or conditions, and all current and past medications should be collected. Because genetic factors are predictors of allergic rhinitis,²⁴ information about parental atopy should be obtained, if possible. In addition to family history, other common predisposing factors of allergic rhinitis (e.g., serum IgE >100 IU/mL before 6 years of age, exposure to indoor allergens, and personal history of eczema) should be queried.

The negative impact of rhinitis on a patient's quality of life can be substantial, and it is important to assess this during the patient interview. Symptoms (e.g., congestion, rhinorrhea, and sneezing) and symptom-induced interference with necessary (i.e., work, school) and enjoyable (e.g., hobbies, family events) activities can lead to patient irritability, anxiety, and exhaustion.¹⁵ The questions listed in Figure 24-5 provide a guide to collecting the information needed to initiate and modify therapy based on the underlying causes of the rhinitis symptoms.

Physical Examination

During a physical examination for rhinitis, the patient's nose should be inspected for nasal patency, position of the septum, appearance of the nasal mucosa (especially over the turbinates), quantity and appearance of secretions, and abnormal growths.^{1,19,32} If the nasal passage is extremely occluded, application of a topical vasoconstrictor (e.g., oxymetazoline 0.025%) allows better visualization. Common physical characteristics of patients with allergic rhinitis are clear nasal discharge and pale, boggy, swollen nasal mucosa.^{18,19,32}

The patient's eyes, ears, pharynx, sinuses, and chest should also be examined.^{1,19,31} Chronic mouth breathing because of nasal obstruction can cause recognizable facial characteristics or dental abnormalities, such as allergic shiners and nasal crease.³²

Laboratory Tests

Several diagnostic tests are available for confirming a diagnosis of allergic rhinitis in patients who present with a suggestive history and symptoms. Microscopic examination of nasal secretions can be performed, but current recommendations suggest that this is more commonly used by subspecialists or in research.¹⁹ In allergic conditions, the clinician would expect numerous eosinophils to be present in the sample; however, this could also be true of NARES or nasal polyps.¹

Immediate hypersensitivity skin tests are used to demonstrate an IgE-mediated response of the skin. This provides confirmatory evidence for a specific allergy.³³ A variety of skin test methods are available; however, the prick and puncture test (in which the wheal and flare reaction is evaluated 15 minutes after allergen administration) is the preferred technique.^{6,33} Another method of assessing specific allergens is serum-specific IgE sensitivity via *in vitro* testing (e.g., radioallergosorbent testing

[RAST]). In selected cases, other diagnostic tests, such as sinus x-ray study, computed tomography (CT), rhinomanometry, and spirometry may be useful.^{18,33,34}

GENERAL MANAGEMENT OF ALLERGIC RHINITIS

The treatment goals for allergic rhinitis are to prevent or relieve symptoms, and improve quality of life without prohibitory concerns about adverse effects or expense. These goals should be achievable through the establishment of a therapeutic partnership with a competent and caring clinician. With appropriate treatment, the patient should be able to maintain a normal lifestyle and perform desired activities.³⁵ Common management strategies include patient education, allergen and irritant avoidance, and pharmacotherapy.⁶ Figure 24-6 depicts an algorithm for the general management of allergic rhinitis.

Patient Education

An increasing trend is seen in health care to limit clinical recommendations to those based on sound evidence.³⁶ Despite the paucity of data about the benefits of patient education in patients with allergic rhinitis, it is likely to play a significant role in treatment adherence.¹ Considerations for patient education include instruction about the disease and specific triggers, the range of symptoms, and the role of various treatments. An appropriate understanding of prevention versus treatment strategies is critical to achieving optimal outcomes.

Allergen and Irritant Avoidance

Although the benefit of allergen avoidance has proved difficult to document, most national and international guidelines recommend using this strategy in a comprehensive management plan for allergic rhinitis.³⁷ Various strategies for minimizing exposure to known allergens (e.g., pollens, house dust mites, molds, animal dander, and cockroaches) are commonly employed for prevention. Because little evidence supports a single physical or chemical intervention to reduce allergen exposure, a multifaceted approach should be used.⁶ Efforts to reduce exposure to irritants (e.g., tobacco smoke, indoor or outdoor pollutants) should also be recommended.³⁸

Pharmacotherapy

Several classes of medications are used in the management of allergic rhinitis.^{38,39} Choices should be based on goals of treatment, safety, efficacy, cost-effectiveness, adherence, severity, comorbidity, and patient preferences.³⁵ Therapy can be administered orally, topically, or systemically and medications may be used on a regular schedule or an as needed basis.¹ Few cost-effectiveness data exist comparing the classes of therapy, excepting the second generation antihistamines and nasal corticosteroids, which have both been shown to be cost-effective.⁴⁰ Table 24-1 summarizes the effectiveness of agents for specific symptoms used in the treatment of allergic rhinitis.

Antihistamines

Antihistamines are most effective for reducing sneezing, itching, and rhinorrhea. They also diminish eye symptoms, but have minimal effects on nasal congestion.^{1,4} Although first generation antihistamines (FGA) are efficacious, their use is limited by anticholinergic and sedative effects which challenge

1. Which of the common symptoms of rhinitis is the patient experiencing?
 - Sneezing, nasal itching, runny nose, nasal congestion, postnasal drip, altered sense of smell, watery eyes, itching eyes, ear “popping”
2. What color are the nasal secretions?
 - Clear, white, yellow, green, blood-streaked, rusty brown
3. When did the symptoms first appear?
 - Infancy, childhood, adulthood
4. Where the symptoms associated with a change in state/environment?
 - After a viral upper respiratory infection, after a traumatic blow to the head or face, upon moving into/visiting a new dwelling, after obtaining a new pet
5. How often do the symptoms occur?
 - Daily, episodically, seasonally, constantly
6. For how long has this symptom pattern persisted?
 - Days, weeks, months, years
7. Which factors or conditions precipitate symptoms?
 - Specific allergens, inhaled irritants, climatic conditions, food, drinks
8. Which specific activities precipitate symptoms?
 - Dusting, vacuuming, mowing grass, raking leaves
9. Are other members of the family experiencing similar symptoms?
10. Which of the following are prevalent in the household?
 - Carpeting heavy drapes, foam or feather pillows, stuffed toys, areas of high moisture (basements, bathrooms), tobacco use (by patient or others)
11. Does the patient have other medical conditions that can cause similar symptoms?
12. Is the patient taking any medications that might cause or aggravate these symptoms?
13. What prescription and nonprescription medications have been used for these symptoms in the past? Were they effective? Did they cause any unwanted effects?
14. What is the patient's occupation?
15. What are the patient's typical leisure activities?
16. To what extent have the symptoms interfered with the patient's lifestyle (i.e., are they disabling or merely annoying)?
 - Greatly, somewhat, not much

FIGURE 24-5 Patient history interview.

their cost-effectiveness.⁴¹ The magnitude of these effects is a subject of debate; nonetheless, newer antihistamines (second generation antihistamines, SGA) are recommended as first-line therapy for mild allergic rhinitis.^{1,2,34} Antihistamines are available in oral, ophthalmic, and nasal formulations and can also be found in combinations with oral decongestants. They are most effective when administered before allergen exposure.

Nasal Corticosteroid Agents

Nasal corticosteroids, which are recognized as the most effective medication class for the treatment of allergic rhinitis, are particularly useful for more severe or persistent symptoms.^{18,34} Although achieving optimal outcomes depends on the patient's ability to use the device correctly, if administered as intended, these agents are appropriate for all symptoms, are generally

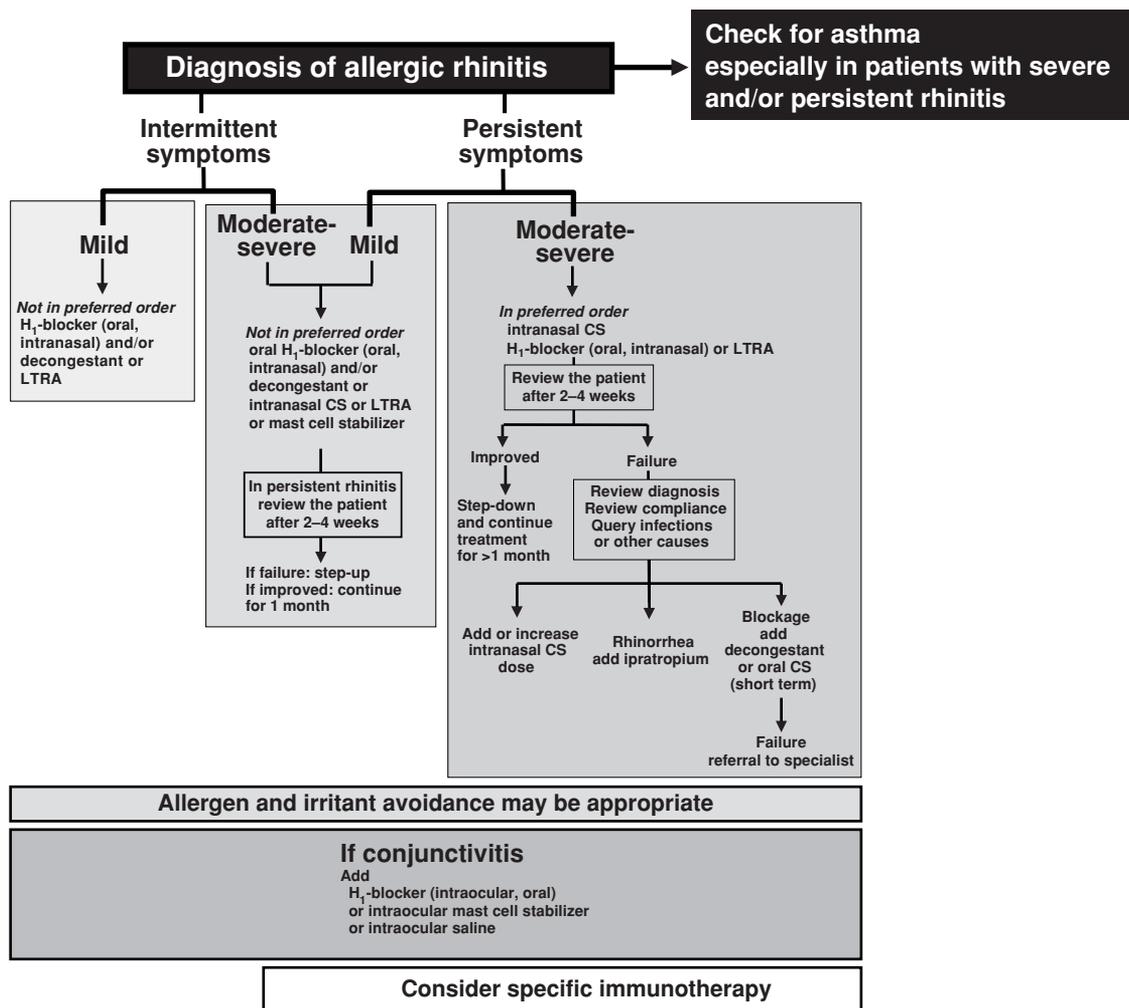

FIGURE 24-6 Treatment algorithm for allergic rhinitis. Treatment should be directed at predominant symptoms (i.e., for eye symptoms in absence of other symptoms use ophthalmic preparation). Prevention strategies are more effective than treatment strategies. For intermittent symptoms, begin treatment several weeks before antigen exposure and discontinue when no longer needed. CS, corticosteroid; LTRA, leukotriene receptor antagonist (leukotriene modifier). (Adapted from reference 6.)

well tolerated, and have few adverse effects.³⁴ They are most beneficial when dosed on a regular schedule; some evidence indicates, however, that they are effective when used on an as needed basis.⁴² Nasal corticosteroids are also useful for some forms of nonallergic rhinitis.

Leukotriene Modifiers

Leukotriene modifiers are effective in relieving many of the nasal symptoms of allergic rhinitis.^{43,44} In some studies, the efficacy of leukotriene modifiers is comparable to antihistamines⁴⁴; however, they are generally recommended as adjunct treatment as opposed to monotherapy. These agents may have a role in concomitant asthma and allergic rhinitis, particularly, if both diseases are relatively mild.⁴⁵

Cromolyn

Intranasal cromolyn, a nonsteroidal agent, acts as a mast cell stabilizer and, although safe, it is generally less efficacious than other therapies. Because it is administered four to six times daily and requires several weeks to be effective, it is best

reserved for acute prophylaxis before exposure to a known allergen and for use by children or in pregnancy.⁴⁶

Decongestants

Oral and nasal decongestants can effectively reduce nasal congestion produced by allergic and nonallergic forms of rhinitis.¹ Oral agents are often combined with antihistamines, but they can lead to profound side effects (e.g., insomnia, nervousness, urinary retention) and should be used with caution in elderly patients and in those with arrhythmias, hypertension, and hyperthyroidism. Nasal agents are not typically associated with these effects, but should be limited to short-term use to avoid rebound nasal congestion.² Recent restrictions on the sale of nonprescription formulations containing pseudoephedrine and questions regarding the efficacy of phenylephrine have resulted in challenges to the optimal use of oral decongestants.

Anticholinergic Agents

Intranasal ipratropium bromide is an anticholinergic agent effective in reducing watery, nasal secretions in allergic rhinitis,

Table 24-1 Effectiveness of Agents^a Used in Management of Allergic Rhinitis

| | <i>Rhinorrhea</i> | <i>Nasal Pruritus</i> | <i>Sneezing</i> | <i>Nasal Congestion</i> | <i>Eye Symptoms</i> | <i>Onset</i> |

Adapted from references 2, 43.

nonallergic rhinitis, and viral upper respiratory infections.^{1,4} Anticholinergic agents have no significant effects on other symptoms.

Ophthalmic Therapies

Ophthalmic products used to treat symptoms of allergic conjunctivitis include antihistamines, mast cell stabilizers, decongestants and nonsteroidal anti-inflammatory agents. These agents are effective in reducing ocular symptoms and may be used in combination with oral and intranasal agents.

Immunotherapy

Allergen immunotherapy should be considered for patients who have severe symptoms despite optimal pharmacotherapy, require systemic corticosteroids, or have coexisting conditions such as sinusitis and asthma.¹ The clinical efficacy of immunotherapy by subcutaneous injection (SIT), sometimes called “allergy shots,” is well established.⁴⁷ A recent meta-analysis of sublingual immunotherapy (SLIT) showed a reduction in symptoms and medication requirements.⁴⁸ Studies involving nasal immunotherapy (NIT) are ongoing.

Anti-IgE Therapy

Omalizumab is a recombinant humanized monoclonal anti-IgE antibody that complexes free circulating IgE in the body. The complex cannot interact with mast cells and basophils and, thus, reduces IgE-mediated allergic reactions. When administered as a subcutaneous injection once or twice monthly, oma-

lizumab has been shown to decrease all nasal symptoms and improve quality of life in patients with allergic rhinitis.⁴⁹ Currently, this therapy is approved only for people 12 years of age and older with moderate to severe allergy-related asthma inadequately controlled with inhaled corticosteroids. Recently, the U.S. Food and Drug Administration (FDA) called for a black box label warning to alert users that omalizumab can cause potentially life-threatening allergic reactions after any dose, up to 24 hours after the dose is given and even if there was no reaction to the first dose.⁵⁰

Nondrug Therapies

Supportive care is the foundation of treatment for patients with symptoms of allergic rhinitis.¹ These strategies can be helpful during an acute worsening of symptoms as well as for the patient who suffers chronically. Supportive care can ameliorate discomfort, relieve mild symptoms, and assist with side effects from pharmacotherapies. Examples include the application of compresses to the sinuses or external nasal passages and humidification of mucous membranes with artificial tears or nasal saline solutions.

Recently, the effectiveness of irradiation as a nondrug treatment option for allergic rhinitis has been explored.⁵¹ To date, these studies have shown modest improvement in nasal symptom scores, with mild side effects in small numbers of participants; although larger, controlled trials are needed before safety, efficacy, and cost-effectiveness can be established.

SPECIFIC THERAPEUTIC OPTIONS

Antihistamine Therapy

1. L.B. is a 57-year-old man with a history of controlled hypertension for 10 years and intermittent allergic rhinitis since childhood (confirmed sensitivity to birch tree pollen via skin testing). L.B. presents with complaints of nasal itching, sneezing, clear rhinorrhea, and stuffiness. He usually experiences similar symptoms with added ocular itching every spring, but has noticed that the problem has become persistent since he moved into an older home in the historic district of town. In the past, L.B. has successfully self-medicated his seasonal symptoms with an over-the-counter (OTC) antihistamine and decongestant (diphenhydramine 50 mg and pseudoephedrine 60 mg TID to QID as needed for symptoms), although “nothing seems to help much with the itchy eyes.” L.B.’s chronic medications are hydrochlorothiazide 25 mg every morning and amlodipine 10 mg every day. He denies any other medical problems, is afebrile, and his blood pressure is 128/82 mm Hg. He has no history of adverse drug reactions or drug allergies. He does not smoke, but drinks alcohol socially.

Diagnosis of Allergic Rhinitis

2. What elements of L.B.’s presentation indicate a probable diagnosis of allergic rhinitis?

L.B. is exhibiting the classic symptoms of persistent (perennial) allergic rhinitis with intermittent (seasonal) exacerbations: nasal itching, sneezing, watery (often profuse) rhinorrhea, and congestion.¹⁹ His history of positive skin tests and that his symptoms previously responded to antihistamine or decongestant also support the diagnosis. In the past, L.B. has experienced symptoms predictably at the onset of the tree pollination season, with only minimal symptoms during the remainder of the year. Moving into an older home, however, has likely triggered latent sensitivities to dust mite allergens and mold spores.

Allergen Avoidance Measures

3. What allergen avoidance strategies could L.B. use to minimize his exposure to triggers?

Allergen avoidance is commonly used to reduce symptoms in sensitized patients. General agreement is that allergen avoidance should lead to an improvement of symptoms; however, little evidence supports the use of a single physical or chemical method.^{37,52} A need exists for well-controlled studies to assess the effects of multiple approaches to allergen avoidance.⁵³ Although total allergen avoidance is often impractical to implement, simple changes that can reduce exposure to many perennial triggers, such as house dust mites, animal dander, and mold, can assist with symptom control.¹

Dust mite avoidance (e.g., the use of impermeable covers on box springs, mattresses, and pillows) has traditionally been used as a method of reducing allergen exposure. Although this practice continues to be recommended frequently, a recent study demonstrated despite reduced exposure to antigen, this strategy alone did not reduce symptoms in patients with allergic rhinitis.⁵⁴ Other methods of reducing antigen exposure include washing bedding at least weekly in hot water (>130°F) and reducing humidity in the home to below 50%. In addition,

replacing carpets with linoleum, tile, or wood floors and replacing curtains and heavy draperies with blinds that can be wiped clean has been recommended.¹

Mold avoidance is difficult when outdoor humidity levels are high, but removing carpeting may be effective in reducing buildup. Live plants should be removed from the home to reduce mold contamination from the soil. Air conditioners should be used, and filters should be changed frequently to reduce humidity and assist with air filtration.¹

Because L.B. has recently moved into an older home, he may not have used these avoidance strategies. These should be recommended and explained during the initial clinical consultation.

Therapeutic Objectives for Allergic Rhinitis

4. What are the therapeutic objectives in treating L.B.?

The therapeutic objectives for the treatment of allergic rhinitis are to control symptoms and permit all usual daily activities with no adverse effects of therapy. In patients with seasonal exacerbations, another objective is to prevent the onset of symptoms by anticipating the patient’s season of sensitivity. In L.B.’s case, he should use environmental measures to reduce exposure and then begin chronic treatment with possible add-on therapy instituted 2 weeks before the start of pollen season.

5. L.B. has used diphenhydramine for many years with good symptom relief and, as he recalls, only minimal daytime sedation. He asks your opinion regarding whether this is the best treatment for his allergic symptoms. He specifically requests the most cost-effective treatment available because he must pay cash out-of-pocket for any medications.

Choice of Therapeutic Agent

6. What therapy do you recommend and how should it be initiated?

Because of their convenience, oral antihistamines are recommended as initial therapy in patients with allergic rhinitis, particularly those with mild symptoms.⁵⁵ They reduce symptoms of nasal itching, sneezing, and rhinorrhea, with variable effectiveness on ocular symptoms but no efficacy for nasal congestion. FGA (e.g., diphenhydramine, brompheniramine, chlorpheniramine, and clemastine) can cause significant side effects because of their sedative and anticholinergic properties. Their use has been supplanted by the SGA (e.g., loratadine, desloratadine, fexofenadine, cetirizine, and levocetirizine), which are equally effective with fewer side effects.^{6,56}

In general, SGA include agents marketed after 1980 with one or more of the following properties: (a) improved H₁-receptor selectivity, (b) absent or reduced sedative effects, and (c) antiallergic properties separate from antihistamine effects.⁵⁵ The first SGA, astemizole and terfenadine, were withdrawn from the market because of potential cardiovascular toxicity, usually related to higher doses and interactions with agents metabolized via the cytochrome P450 system.⁵⁵ This is not a significant concern with currently available SGA; however, many of the current agents undergo substantial hepatic metabolism and some evidence exists of potential drug interactions or variability in metabolic capacity associated with this.⁵⁶ Some references have begun referring to the most recently

approved agents (i.e., fexofenadine, desloratadine, and levocetirizine) as third generation agents (TGA) to highlight that they are active metabolites of other products. The Consensus Group on New Generation Antihistamines concluded, however, that on the basis of evidence, these agents do not merit a new class title because they do not demonstrate distinct clinical advantages over the SGA.^{57,58} For this reason, they will be discussed as SGA in this chapter.

Antihistamines block the effects of histamine by one of two mechanisms: (a) as an H₁-receptor antagonist and (b) as an inverse agonist of the H₁-receptor.⁵⁹ Whereas all marketed antihistamines have sufficient effects on the histamine receptor to provide clinical benefits, the SGA are more specific for the peripheral histamine receptor than are the FGA⁶⁰ and, for this reason, they present a lower risk for adverse effects, such as sedation.

L.B. has experienced a good response to an FGA without complaints of excessive drowsiness. However, sedation includes both drowsiness (i.e., the subjective state of sleepiness or lethargy) and impairment (i.e., an objective decrease of absence of specific physical or mental abilities)⁶¹ and evidence indicates that cognitive impairment can occur, even in the absence of overt drowsiness.^{61,62}

In light of these findings, the Joint Task Force on Practice Parameters in Allergy, Asthma and Immunology has stated “many patients may not perceive performance impairment that is associated with FGAs. Consequently, SGAs that are associated with less risk or no risk for these side effects should usually be considered.”⁶¹ In another expert consensus statement on the use of antihistamines in the treatment of allergic rhinitis, experts agreed that many of the FGA produce sedation, impairment, and reduced quality of life. They acknowledge that allergic rhinitis is more appropriately treated with SGA in all patients.⁶² One exception to this is pregnant women in whom there is more long-term data on the use of FGA and, thus, they are preferred by the American College of Obstetrics and Gynecology.⁶³ If these drugs are not tolerated, cetirizine or loratadine may be considered, ideally after the first trimester.

Second generation agents prevent the onset of symptoms better than they reverse symptoms that are already present. Also, the maximal antihistamine effects occur several hours after the drug’s serum concentration peaks.⁵⁸ For maximal effect, therefore, the SGA should be administered before allergen exposure, whenever possible. For the same reason, chronic dosing is preferred to intermittent dosing.

Essentially, all the antihistamines listed in Table 24-2 are equally effective.^{58,60} Therefore, the choice of agent is based on duration of action, side-effect profile (especially drowsiness and anticholinergic effects), risk of drug interactions, and cost.⁶⁴ Some patients claim that one product is more helpful in relieving their symptoms than another; however, for many years there have been reports that tolerance to specific agents can occur after consistent use. Although no pharmacologic explanation exists for these observations,⁶⁴ patients may experience benefit from switching therapies if the perception of tolerance occurs.

The major advantages of SGA are their selectivity to the H₁-receptor and their reduced central nervous system (CNS) sedative effects.⁵⁸ Desloratadine, fexofenadine, loratadine, and levocetirizine—at prescribed doses—are reported to have an

incidence of sedation that does not differ from placebo for both somnolence and performance impairment.⁶⁵ Cetirizine and intranasal azelastine are not considered to be entirely non-sedating, although the incidence of sedation is less than with FGA.^{58,66} Another advantage of SGA is that most products can be dosed once daily to improve patient adherence to therapy. Specific antihistamines are compared in Table 24-2. In the case of L.B., it would be reasonable to begin therapy with loratadine 10 mg daily, because as an SGA, it has demonstrated efficacy with minimal side effects and is also available without a prescription.

Nasal Antihistamines

7. L.B. has a friend who had side effects from antihistamines and had been given a nasal spray instead. Is it possible to give antihistamines by this route, or is L.B. confusing this with other topical therapies, such as decongestants or corticosteroids?

An aqueous intranasal solution (125 mcg/spray) of azelastine is approved for the treatment of allergic rhinitis. This drug has an objectionable taste, making it unsuitable for oral administration, but the nasal and ophthalmic formulations have been shown beneficial in allergic rhinitis and conjunctivitis.^{67–69} In studies comparing intranasal azelastine with oral antihistamines and placebo, azelastine has been found to be equal to the oral antihistamines,⁶⁶ although a meta-analysis comparing azelastine with nasal corticosteroids suggests that nasal corticosteroids were superior in efficacy in all but ophthalmic symptoms.⁶⁷ As with the oral agents, the intranasal formulation is less effective for nasal congestion than it is for nasal itching, sneezing, and rhinorrhea.⁶⁷ Dosing recommendations for azelastine (for adults and children > 12 years of age) are two sprays in each nostril twice a day. Before the first use and anytime when the product has not been used for 3 days or more, the dosage form must be primed. This is accomplished by pumping the spray mechanism two to four times until a consistent mist is expelled.

The side effects of azelastine are comparable to the FGA in terms of somnolence (10%–15%) and headache (15% to 30%).⁷⁰ Intranasal azelastine can also cause local side effects, including nasal irritation, dry mouth, sore throat, and mild epistaxis. Bad aftertaste remains a significant problem, occurring in up to 20% of patients, even those using the ophthalmic formulations. A potential role for intranasal antihistamines is for patients who do not respond adequately to oral antihistamines.⁶⁷ In addition, some patients may prefer the intranasal route of administration or benefit from concomitant therapy with nasal antihistamines and nasal corticosteroids. As a prescription-only product, a nasal antihistamine would be more expensive than many oral alternatives.

Decongestant Therapy

8. What role do decongestants have in L.B.’s treatment?

Nasal congestion is often much less severe in patients who experience only intermittent symptoms, but as L.B.’s symptoms have become persistent since his move, the exact frequency and severity of his nasal congestion should be assessed before recommending drug therapy. In patients with only mild, intermittent symptoms, saline irrigation (administered as

Table 24-2 Oral Antihistamines^{a,b} Commonly Used in Allergic Rhinitis

| Generic Name (Example Brand Product) | Adult Dose | Pediatric Dose ^c | Other Effects | | |

^a Many oral antihistamines are sold as combination products with the oral decongestants pseudoephedrine and phenylephrine. The addition of the decongestant may alter the dosing scheme for the product. As of 2005, pseudoephedrine products have been placed behind the pharmacy counter in the United States. Federal law limits the quantity available for purchase to 9 g/mo, 3.6 g/day with signature and photo identification. Individual states may have additional restrictions regarding the sale of pseudoephedrine, consult local boards of pharmacy for details.

^b Some oral antihistamines are available in both short-acting and extended or sustained release formulations. Refer to package insert for specific dosing instructions for long-acting products.

^c The Centers for Disease Control and Prevention has released a report concerning the use of antihistamines and decongestants in infants less than 2 years of age. In October 2007, The Consumer Healthcare Products Association on behalf of the makers of over-the-counter (OTC) cough and cold medicines announced voluntary market withdrawals of oral cough and cold medicines that refer to “infants”. Although these medicines are safe and effective when used as directed, rare patterns of misuse leading to overdose have been identified, particularly in infants. The voluntary withdrawal does not affect medicines intended for children age 2 and older; however, clinicians are reminded always to ask caregivers about the use of OTC products in order to avoid exposure to multiple medications containing the same or similar ingredients.

^d Currently available by prescription only.

Adapted from references 57, 64, 98.

frequently as needed) is helpful in soothing and moisturizing irritated nasal mucosa. Antihistamines do little to relieve nasal congestion; therefore, patients with moderate to severe congestion may require a combination of an antihistamine with a decongestant. The combination of an antihistamine and an oral decongestant is more effective than either component alone in the treatment of allergic rhinitis.⁵⁶

Both the topical (nasal) and the oral decongestants are sympathomimetics that directly stimulate α_1 -adrenergic receptors, resulting in vasoconstriction. Local effects on the nasal mucosa include decreased tissue hyperemia, decreased tissue swelling,

decreased nasal congestion, and improved nasal airway patency.⁵⁶ The primary oral decongestants are phenylephrine and pseudoephedrine. Until 2005, pseudoephedrine was the more popular agent; however, because of the potential to use it in the manufacture of illicit substances (e.g., methamphetamine), restrictions on the allowable quantity and methods for purchasing pseudoephedrine-containing products have been implemented at both the state and federal levels. These restrictions have resulted in the reformulation of many oral decongestant products to include phenylephrine as an alternative decongestant. A recent meta-analysis has questioned the

^dLimit duration of treatment to <10 days (preferably, <5 days) to minimize risk of rebound congestion. Adapted from reference 98.

efficacy of phenylephrine as a decongestant in doses approved for nonprescription use and further study is needed before it should be routinely recommended.⁷¹ The available oral and topical decongestants, all of which are available without prescription, are compared in Table 24-3.

Oral decongestants can cause systemic side effects, particularly those associated with CNS stimulation (e.g., nervousness, restlessness, insomnia, tremor, dizziness, and headache).¹⁸ Cardiovascular stimulation (e.g., tachycardia, palpitations, increased blood pressure) also can occur, so patients with hypertension should be monitored carefully while taking oral decongestants.⁷² Because oral decongestants are not associated with the development of rebound congestion, in most patients, they are appropriate for chronic use. They are not recommended, however, for use during pregnancy.⁶³ Topical administration of decongestants generally does not lead to systemic side effects; however, these agents are not appropriate for chronic use in rhinitis because of their potential for causing rebound congestion (see Question 33).

Because L.B. is complaining of nasal congestion, he will require a decongestant in addition to the loratadine. He may choose to use a fixed-dose combination product (e.g., loratadine + pseudoephedrine) or to supplement the daily loratadine with pseudoephedrine as needed. Although L.B. has used pseudoephedrine in the past without a problem, he may require education regarding the new procedures for purchasing this product while assuring him that the new restrictions are not related to the drug's safety as a decongestant. In addition, al-

though his hypertension is controlled, his blood pressure should be monitored regularly to detect any deterioration.

Ocular Therapies

9. L.B.'s new therapies are effective for his persistent nasal symptoms; however, in the spring he complains that his eyes are itchy and watery and that the loratadine and pseudoephedrine do not seem to be helping. How are L.B.'s ocular symptoms related to his allergic rhinitis?

Relationship between Ocular and Nasal Symptoms

Allergic ocular disease is part of the full range of allergic diseases, including rhinitis, eczema, and asthma, which share a common pathophysiology and inflammatory presentation.⁷³ The most common of the allergic ocular diagnoses is seasonal (intermittent) allergic conjunctivitis, which accounts for up to 50% of all ocular allergy cases. The symptoms of both intermittent and persistent allergic conjunctivitis are identical in that they are caused by allergic response in the conjunctiva to airborne allergens. Seasonal symptoms commonly occur in response to pollens, whereas perennial symptoms are more often associated with house dust mites. The symptoms of allergic conjunctivitis are itchy eyes, with or without a burning sensation, and a watery discharge or tearing. Physical examination reveals conjunctival surfaces that are mildly injected (reddened) with varying degrees of conjunctival edema.

Swelling of the eyelids can also occur. The symptoms are usually bilateral, but not always symmetric.⁷³

Because of the potential for long-term damage to vision, persistent ocular conditions should always be assessed by an eye care professional. Other ocular problems that can be confused with allergic conjunctivitis include atopic keratoconjunctivitis, keratopathy, and giant papillary conjunctivitis (see Chapter 51, Eye Disorders).

Choice of Therapeutic Agent

10. What are the treatment options for L.B.'s allergic conjunctivitis, and how does the clinician choose between the available options?

Seasonal and perennial allergic conjunctivitis are treated similarly with only the duration of the treatment course differing (i.e., intermittent versus persistent treatment). Nonpharmacologic treatment includes avoidance of aeroallergens to the extent possible, cold compresses or the use of refrigerated eye drops, and lubrication with frequent application of saline or tear substitutes. Part of the effectiveness of all of the ocular preparations, including lubricating eye drops, is attributable to physical dilution and irrigation of aeroallergens from the eye.⁷³

The available therapeutic options for management of allergic conjunctivitis include topical ocular administration of antihistamines, vasoconstrictors, mast cell stabilizers, and NSAID (Table 24-4). Randomized, controlled trials have demonstrated that these agents significantly reduce ocular symptoms, including itching, and improve sleep.^{73–77} These ocular medications act by the same mechanisms as their nasal counterparts. In addition, topical ophthalmic corticosteroids have a limited role in the acute management of allergic conjunctivitis; however, they are not indicated for prolonged use because of the risk of serious infectious complications in the eye.

In the case of L.B., a trial of antihistamine + vasoconstrictor combination eye drops (e.g., pheniramine maleate + naphazoline hydrochloride) for management of acute symptoms is an appropriate recommendation for short-term use. Note that the overuse of ocular vasoconstrictors can lead to rebound conjunctivitis, similar to that occurring with nasal decongestants (see section, Drug-Induced Nasal Congestion). If the patient exhibits chronic symptoms, consider a switch to a nasal corticosteroid (which may have better efficacy for combination symptoms⁷⁸) or refer to specialist care.

Cromolyn Therapy

11. J.C. is a 10-year-old girl who recently began experiencing rhinorrhea and sneezing when visiting her father in another state a couple of times each year. On questioning, J.C.'s mother reveals that, although J.C. has not complained of symptoms previously, her father adopted a puppy from the local animal shelter about a year ago and the symptoms correspond to the times that the child spends with the dog. J.C. will be visiting her father again next month, and she is hoping to purchase something without a prescription to prevent her from "getting sick and missing out on her summer vacation." What options are available to treat J.C.'s intermittent symptoms of allergic rhinitis?

J.C. appears to have mild allergic rhinitis triggered by exposure to animal dander. When it is possible to anticipate symptoms, as in J.C.'s case, initiating prophylactic therapy can help lessen the impact of allergen exposure.¹ J.C. appears to be a good candidate for treatment with intranasal corticosteroids or cromolyn sodium, administered regularly beginning several weeks before each trip. Because the mother indicates that she wants to select an OTC product, allergen avoidance strategies plus cromolyn nasal spray would be a reasonable choice for initial therapy. The drawbacks to this are its out-of-pocket cost, its technique-dependent administration, its multiple daily dosing requirements (up to six times daily), and its reduced effectiveness compared with other treatments.⁴⁰

12. What strategies should J.C.'s father use to minimize exposure to the allergic triggers?

To minimize J.C.'s exposure to allergens, the dog should be kept out of the child's bedroom at all times and, when possible, kept outside or confined to an uncarpeted area of the home. J.C.'s father should use a high-quality air filter and should vacuum the home with a double-filter system while J.C. is out of the house. Although evidence is unclear on this topic, it may be helpful to wash the dog weekly while the child visits. The additional expense of regular, commercial cleaning of air ducts is not cost justified.¹

Instructions for Use

13. How should J.C. be advised to use cromolyn nasal spray to prevent her symptoms?

To be effective, cromolyn nasal spray must be dosed several times each day, which can have a detrimental effect on adherence.⁴⁶ The initial dose for the 4% cromolyn sodium nasal spray is one spray in each nostril four to six times daily. In some patients, symptom control can be maintained with dosing two to three times per day. J.C. should be instructed to begin therapy at least two weeks before her planned visit because of the delay in the onset of action for this agent.

The clinician should ensure that both parent and child can demonstrate appropriate administration technique before therapy is initiated. On first use, the device should be primed until a consistent spray is achieved. J.C. should be instructed to gently blow her nose and then spray the cromolyn sodium solution into each nostril in a slightly upward direction, parallel to the nasal septum.

Topical nasal cromolyn has an excellent safety profile, including minimal incidence of adverse effects. Local irritation occurs in <10% of patients, with burning, stinging, and sneezing being the most common manifestations. The safety of cromolyn has made it a popular choice as initial therapy for children with allergic rhinitis and for treating rhinitis during pregnancy.⁶³ Table 24-5 includes information about intranasal cromolyn dosing and availability.

Intranasal Corticosteroid Therapy

14. A.C. is an 8-year-old boy with allergic rhinitis and asthma. He has been treated with a budesonide Flexhaler for asthma and loratadine for rhinitis. His mother reports that he frequently sneezes, complains of an itchy nose and eyes, and does not sleep well at night because of nasal congestion. She also reports that

Table 24-4 Topical Ophthalmic Medications Commonly Used for Allergic Conjunctivitis

| Generic Name (Example Brand Product) | Available Dosage Forms/Strength | Dose |
|---|--|--|
| Antihistamines | | |
| Azelastine (<i>Optivar</i>) | Ophthalmic solution: 0.05% | Adults and children ≥ 3 yrs: 1 drop into each affected eye(s) every 12 hrs |
| Emedastine (<i>Emadine</i>) | Ophthalmic solution: 0.05% | Adults and children ≥ 3 yrs: 1 drop in the affected eye(s) up to 4 times daily |
| Antihistamine/Decongestant Combinations | | |
| Antazoline + Naphazoline (<i>Vasocon-A</i>) ^a | Ophthalmic solution: antazoline phosphate 0.5% naphazoline HCl 0.05% | Adults and children ≥ 6 yrs: 1–2 drops in the affected eye(s) every 6 hrs for up to 3 days |
| Pheniramine + Naphazoline (<i>Naphcon-A</i>) ^a | Ophthalmic solution: naphazoline HCl 0.025% pheniramine maleate 0.3% | Adults and children ≥ 6 yrs: 1–2 drops in the affected eye(s) every 6 hrs for up to 3 days |
| Antihistamine/Mast Cell Stabilizers | | |
| Ketotifen (<i>Zaditor</i>) ^a | Ophthalmic solution: 0.025% | Adults and children ≥ 3 yrs: 1 drop in the affected eye(s) every 8–12 hrs |
| Olopatadine (<i>Patanol</i>) | Ophthalmic solution: 0.1% | Adults and children ≥ 3 yrs: 1–2 drops in the affected eye(s) 2 times daily at an interval of 6–8 hrs |
| Mast Cell Stabilizers | | |
| Cromolyn Sodium (<i>Crolom</i>) | Ophthalmic solution: 4% | Adults and children ≥ 4 yrs: 1–2 drops in the affected eye(s) 4–6 times daily |
| Lodoxamide (<i>Alomide</i>) | Ophthalmic solution: 0.1% | Adults and children ≥ 2 yrs: 1–2 drops in affected eye(s) 4 times daily for up to 3 mos |
| Nedocromil (<i>Alocril</i>) | Ophthalmic solution: 2% | Adults and children ≥ 3 yrs: 1–2 drops in the affected eye(s) every 12 hrs |
| Pemirolast (<i>Alamast</i>) | Ophthalmic solution: 0.1% | Adults and children ≥ 3 yrs: 1–2 drops in each affected eye(s) every 6 hrs |
| Nonsteroidal Anti-Inflammatory Drugs (NSAID)^b | | |
| Ketorolac (<i>Acular</i>) | Ophthalmic solution: 0.5% | Adults and children ≥ 3 yrs: 1 drop into the affected eye(s) 4 times daily. |
| Corticosteroids | | |
| Loteprednol (<i>Alrex</i>) | Ophthalmic suspension 0.2% | Adults: 1 drop into the affected eye(s) 4 times daily |

^a Available without a prescription.

^b Other ophthalmic NSAID (diclofenac, flurbiprofen, suprofen) indicated for intraoperative miosis and for postcataract surgery, but not approved for allergic conjunctivitis.

Adapted from reference 98.

she usually cannot give him loratadine on a daily basis because it makes him drowsy at school. His asthma has been well controlled in the past; however, she is concerned that he is experiencing some shortness of breath and that this might be related to his allergies. While you are talking to him, you note that A.C. breathes exclusively through his mouth, sniffs frequently, and rubs his nose. You also notice dark circles under his eyes. What signs and symptoms of allergic rhinitis is A.C. displaying?

A.C. is displaying the classic signs of allergic airways disease in children. He is sniffing and snorting in response to nasal itching and discharge. The frequent upward rubbing of the nose (generally with the palm of the hand) is known as the “allergic salute” and is caused by nasal itching. Long-standing symptoms can lead to facial abnormalities, including the formation of a transverse crease across the bridge of the nose. Infraorbital

discoloration can develop with frequent rubbing of the eyes in patients with severe ocular itching and the resultant dark circles under the eyes are commonly known as “allergic shiners.”³²

Role in Therapy

15. What would be the role of intranasal corticosteroids for this patient?

Intranasal corticosteroids are the most effective therapy available for the treatment of allergic rhinitis. They are safe, well tolerated, and are highly effective in reducing itching, sneezing, rhinorrhea, and congestion.⁷⁹ Nasal corticosteroids may also be beneficial in relieving cough associated with postnasal drip in patients with allergic rhinitis.⁸⁰ In addition to improving all nasal symptoms, evidence also suggests that intranasal administration of corticosteroids effectively relieves

Table 24-5 Additional Oral and Topical Agents for Rhinitis

| Antihistamine Azelastine (<i>Astelin</i>) | Nasal spray: 137 mcg/spray | 2 sprays/nostril every 12 hrs | Children 5–11 yrs: 1 spray/nostril every 12 hrs |
| Mast cell stabilizer Cromolyn Sodium (<i>Nasalcrom</i>) ^a | Nasal spray: 5.2 mg/spray | 1 spray/nostril every 4–6 hrs | Children ≥ 2 yrs: 1 spray/nostril every 4–6 hrs |
| Anticholinergic Ipratropium (<i>Atrovent</i>) ^b | Nasal spray: 21 mcg/spray (for perennial symptoms), 42 mcg/spray (for seasonal symptoms) | 2 sprays/nostril up to 4 times daily (MAX = 672 mcg/day) | Children ≥ 5 yrs: 2 sprays/nostril up to 4 times daily (MAX = 672 mcg/day) |

^a Available without a prescription

^b Optimum dosage varies with the response of the individual patient, however; it is always desirable to titrate an individual to the minimum effective dose to reduce the risk of side effects. In addition, the safety and efficacy of the use of ipratropium 42 mcg nasal spray beyond 3 weeks in patients with seasonal allergic rhinitis has not been established. Adapted from reference 98.

ocular symptoms.⁸¹ These agents also have demonstrated efficacy for nonallergic rhinitis, rhinitis medicamentosa, and nasal polyposis.^{22,23} The currently available nasal corticosteroids are listed in Table 24-6.

Intranasal corticosteroids perform well in clinical trials when compared with other therapeutic options. They are frequently rated as more effective than antihistamines, although their effects are technique-dependent.^{82,83} In a systematic review of the medical literature performed by the Agency for Healthcare Research and Quality, nasal corticosteroids provided significantly greater relief of symptoms compared with

antihistamines for various nasal symptoms and total nasal symptom scores.⁸⁴

Mechanism of Action

16. How do intranasal corticosteroids work to reduce symptoms?

Corticosteroids interact with a specific steroid receptor in the cytoplasm of a cell, and the steroid receptor complex then moves into the cell nucleus where it influences protein synthesis.⁸⁵ Among the proteins synthesized is lipocortin,

Table 24-6 Intranasal Corticosteroids^a Commonly Used for Rhinitis

| Generic Name (Example Branded Product) | Available Dosage Forms/Strengths | Adult Dose ^a | Pediatric Dose ^a |
|--|-------------------------------------|---|--|
| Beclomethasone (<i>Beconase AQ</i>) | 42 mcg/spray | 1–2 sprays/nostril twice daily | Children 6–12 yrs: 1–2 sprays/nostril twice daily |
| Budesonide (<i>Rhinocort Aqua</i>) | 32 mcg/spray | 1 spray/nostril once daily (MAX 4 sprays/nostril daily) | Children 6–12 years: 1 spray/nostril once daily (MAX 2 sprays/nostril daily) |
| Fluticasone propionate (<i>Flonase</i>) | 50 mcg/spray | 2 sprays/nostril once daily or 1 spray/nostril twice daily | Children 4–17 yrs: 1–2 sprays/nostril once daily |
| Fluticasone furoate (<i>Veramyst</i>) | 27.5 mcg/spray | 2 sprays/nostril once daily | Children 2–11 years: 1–2 sprays/nostril daily |
| Flunisolide (<i>Nasarel</i>) | 29 mcg/spray | 2 sprays/nostril twice daily (MAX 8 sprays/nostril daily) | Children 6–14 years: 1 spray/nostril three times daily or 2 sprays/nostril twice daily (MAX 4 sprays/nostril daily) |
| Mometasone (<i>Nasonex</i>) | 50 mcg/spray | 2 sprays/nostril once daily | Children 2–11 yrs: 1 spray/nostril once daily |
| Triamcinolone (<i>Nasacort AQ</i>) | 55 mcg/spray | 2 sprays/nostril once daily | Children 6–11 yrs: 1–2 sprays/nostril once daily |

^a It is always desirable to titrate an individual patient to the minimum effective steroid dose to reduce the risk of side effects. When the maximum benefit has been achieved and symptoms have been controlled, reducing the steroid dose might be effective in maintaining control of rhinitis symptoms. Adapted from reference 98.

which inhibits the breakdown of phospholipids to arachidonic acid; this, in turn, inhibits the formation of prostaglandins and leukotrienes. Topical corticosteroids reduce the number of eosinophils, basophils, and mast cells in the nasal mucosa and epithelium; directly inhibit the release of mediators from mast cells and basophils; reduce mucosal edema and vasodilation; stabilize the endothelium and epithelium, resulting in decreased exudation; and reduce the sensitivity of irritant receptors, resulting in decreased itching and sneezing.³³ Topical corticosteroids inhibit both the early- and late-phase reactions to antigen challenge, in contrast to systemic corticosteroids, which inhibit only the late-phase reaction in allergic rhinitis.⁸⁶

17. Are there any specific considerations related to the use of intranasal corticosteroids in treating allergic rhinitis in a patient with concomitant asthma?

Based on the relationship between inflammation in the upper and lower airways, and the similar immunologic mechanisms involved in allergic rhinitis and asthma, it is a reasonable assumption that poor control of upper airway allergies can have a negative impact on asthma control.^{87–89} In fact, rhinitis is a risk factor for asthma development,⁹⁰ and poorly controlled rhinitis can aggravate asthma control.⁹¹ In a patient with asthma, treatment of allergic rhinitis with nasal corticosteroids can reduce airway hyperresponsiveness and symptoms of asthma.⁹²

Historically, the use of antihistamines was considered problematic for patients with asthma because of a theoretic concern about excessive drying of airway secretions caused by the anticholinergic properties of these agents. It is now clear that most patients with asthma can take any of the antihistamines without adverse pulmonary effects.

Choice of Therapeutic Agent

18. What are considerations in selecting among the various nasal corticosteroid products?

Currently marketed intranasal corticosteroid products vary in the pharmacologic characteristics that can influence patient acceptance and adherence; however, there do not appear to be significant advantages with regard to efficacy among them.⁹³ Topical application is very effective in controlling nasal symptoms with minimal risks of systemic effects.⁹⁴ Primary differences among products include potency, dosing regimens, delivery systems, spray volume, and patient preference.⁹⁵

The method to determine potency among topical corticosteroids is to measure topical vasoconstrictive activity on the skin. Cutaneous vasoconstriction may not consistently correlate with anti-inflammatory potency in the nasal mucosa, however.⁹⁶ Potency can also be described as a measure of lipophilicity because agents that are highly lipophilic may have faster absorption and longer residence at the receptor in the mucosa. The lipophilicity from highest to lowest among current products is flunisolide, triamcinolone, budesonide, beclomethasone, fluticasone, and mometasone.⁹⁶

The topical-to-systemic potency relationship should also be considered as the ideal agent should exhibit high topical potency and low systemic activity. After topical administration, the corticosteroid may reach the systemic circulation by absorption across the nasal mucosa or through gastrointestinal

absorption of the swallowed portion of the dose.⁹⁶ Among the available agents, mometasone and fluticasone have the lowest systemic bioavailability, ranging from 0.1% to <2%. Beclomethasone may exert greater systemic effects owing to its metabolism to an active metabolite (beclomethasone 17-monopropionate). For this reason, newer agents are often favored over beclomethasone.⁹⁷

Studies have shown that varying sensory attributes (e.g., taste, smell, aftertaste, throat rundown, nose runout, and feel of spray in nose and throat) affect acceptability of, and preference for, particular nasal corticosteroid products.^{93,95} Although more patients rated aftertaste as the most important feature determining their preference,⁹³ no head-to-head trials have directly compared the available products and, thus, some degree of experimentation may be required in individual patients.

Safety

19. How safe are intranasal corticosteroids in this situation?

The corticosteroids currently available for intranasal administration are listed in Table 24-6. Among available products, intranasal corticosteroids have similar efficacy in clinical trials.⁸¹ Budesonide, flunisolide, triamcinolone, and beclomethasone are indicated for ages 6 years or older. Fluticasone and mometasone are labeled for ages 4 years and older and 2 years and older, respectively.⁹⁸

A common concern regarding the use of corticosteroids in children is the risk of growth suppression. In 1998, the FDA required new labeling on inhaled and intranasal corticosteroid preparations to alert health care providers that use of these products in children may reduce their rate of growth. Although beclomethasone may be associated with reduced growth velocity,⁹⁹ numerous studies have shown no growth delay in children treated long term with newer intranasal steroids.^{100–102}

In 2003, the FDA approved revised labeling for fluticasone nasal spray, indicating no adverse effect on growth even with use for up to 1 year. Data are lacking, however, about the potential risk of reduced growth velocity associated with a combination of intranasal and orally inhaled corticosteroids. With this in mind, it is appropriate to recommend agents with low systemic bioavailability and to utilize the lowest effective dose.

Other potential adverse effects of chronic nasal corticosteroids have been investigated. Prolonged topical use of intranasal corticosteroids does not impose a significant risk for mucosal atrophy, histologic changes in nasal mucosa have not been demonstrated, and intranasal candidiasis has never been documented.¹⁰³ Although the effects of systemic steroids on the eyes are well-established, nasal steroids have not been shown to increase intraocular pressure.¹⁰⁴ A report from the National Registry of Drug-Induced Ocular Side Effects linked 21 cases of bilateral posterior subcapsular cataracts to the use of intranasal or inhaled corticosteroids¹⁰⁵; however, several of these patients were also on systemic corticosteroids or had used high-dose beclomethasone for more than 5 years. The risk of cataracts with the newer agents has not been established.¹⁰⁵

It may be important for the clinician to consider the total corticosteroid load in atopic patients who may be treated with an inhaled or systemic preparation for asthma, intranasal

preparation for rhinitis, and dermatologic preparation for eczema, although no guidelines to follow exist in this area. Although nasal steroids are considered safe and are sometimes available without a prescription from pharmacies outside the United States, recently a Joint Taskforce for the American Academy of Allergy, Asthma and Immunology issued a position statement recommending that these agents remain prescription-only and prescribed under the direct supervision of a physician.¹⁰⁶

Instructions for Use

20. A.C. is given a prescription for budesonide, two actuations in each nostril twice daily. How should he be counseled to use this drug?

Although nasal corticosteroids have an excellent safety profile, some local adverse effects can occur. The currently available products are all aqueous solutions delivered via a manual spray pump; these are much less drying than the original propellant-based aerosol formulations of the same products. The most commonly reported side effect is epistaxis, with excessive nasal dryness and crusting also reported.³² A more serious concern is the risk for nasal septal perforation. Proper technique in using the nasal corticosteroid products can reduce the risks for these side effects.¹

Patient education is important to ensure proper use of, and response to, the intranasal corticosteroids. A.C. should be instructed to blow his nose gently before using the nasal inhaler as severe blockage of the nasal passage may prevent deposition of the drug at the intended site of action. If the patient is severely congested, a short course (up to 3 days) of topical decongestant used just before the intranasal corticosteroid may be indicated. The patient should be instructed to direct the spray away from the nasal septum. This is accomplished by pointing the applicator nozzle straight and back using the contralateral hand to ensure application is parallel to the septum.³²

Therapeutic benefit to nasal steroids is generally appreciated in as few as 2 days, although some newer agents (e.g., budesonide, mometasone, and fluticasone) may begin to relieve symptoms within hours.⁸¹ Fluticasone has been effective when used on an as-needed basis.⁴² Nonetheless, it is reasonable to advise patients that full benefit may not be realized for up to 3 weeks.

Systemic Corticosteroids

21. What is the role of systemic corticosteroid therapy for allergic rhinitis?

In contrast to the minimal side effects of the topical corticosteroids, systemic administration of these drugs can cause numerous, and at times serious, side effects. Systemic administration, therefore, must be reserved for only short-term, adjunctive therapy in cases of severe, debilitating rhinitis. In such cases, a short course of relatively high-dose corticosteroid, so-called “burst” therapy, can be administered. Prednisone 40 mg/day for adults or 1 to 2 mg/kg/day for children (or an equivalent dose of a comparable compound) every morning for up to 7 days effectively relieves acute, severe rhinitis symptoms. If A.C. were to have a particularly severe exacerbation of his allergic rhinitis such that it interfered with sleep or ability to attend school, an oral corticosteroid burst would be indicated. More likely, A.C. would require a short course of systemic corticosteroids for an acute asthma exacerbation, but

despite the stimulus, short course oral steroids should result in improved nasal symptoms.

Combination Therapy

22. Would there be an advantage in combining various therapies for allergic rhinitis in this patient?

The rationale for combining agents to treat allergic rhinitis is based on the theoretic benefit of additive or synergistic reactions. Various combinations have been studied. Concomitant use of antihistamines and decongestants has been shown to relieve individual nasal symptoms as well as the total symptom score as compared with either agent alone. When combinations of antihistamines and nasal corticosteroids were compared with either agent alone, the combination was superior to antihistamine monotherapy but not to treatment with nasal corticosteroids alone.¹⁰⁷ In one study using an algorithm for treatment, this combination, however, was the standard for severe rhinitis.¹⁰⁸ Studies evaluating the combination of antihistamines and leukotriene modifier therapies have yielded inconsistent results.^{109,110} Therefore, it is unclear that the combination is superior to monotherapy with either agent alone and it is likely less effective than treatment with nasal steroids alone.⁸³ When combination therapy of any kind is used, once symptoms are controlled, one agent should undergo a trial for discontinuation.

Leukotriene-Modifying Agent Therapy

23. K.H. is a 58-year-old man with allergic rhinitis. He has experienced symptoms during ragweed pollen season for several years. He has used various antihistamines for his symptoms during this time with moderate success. At times, K.H. has self-medicated with nonprescription medications, including clemastine and diphenhydramine. This year, he initiated therapy with diphenhydramine 1 week before the pollen season, but began experiencing symptoms of urinary retention after 10 days. His physician advised him that this might be related to the antihistamine aggravating his enlarged prostate and he was given a prescription for fexofenadine. After 1 week, K.H. complains that the medication is not working. After seeing an advertisement on television, he inquires about the use of a leukotriene modifier for his allergic rhinitis. What is the mechanism for the K.H.’s urinary discomfort attributed to the diphenhydramine?

K.H. is exhibiting symptoms of urinary outflow obstruction or prostatism. Common features of this are frequency, hesitancy, slow urine stream, dribbling, and bladder fullness after voiding. The most common cause of obstruction is benign prostatic hyperplasia (BPH). Because the prostate is located anatomically around the urethra, enlargement of the gland can obstruct urine flow.¹¹¹

The bladder and urethra are made up of smooth muscle tissue that is innervated by the sympathetic and parasympathetic divisions of the autonomic nervous system. The detrusor musculature is predominantly innervated by β -adrenergic and cholinergic receptors, whereas the bladder neck (or outlet) is innervated predominately by α -adrenergic receptors. Sympathetic stimulation causes relaxation of the detrusor muscle to allow bladder filling, closure of the urethra, and decreased bladder emptying. Cholinergic stimulation of the detrusor causes contraction of the detrusor to cause bladder emptying. Initially, the detrusor musculature can compensate for the urethral

obstruction in BPH. Eventually, however, the detrusor muscle fibers hypertrophy and decompensate, resulting in urinary retention and detrusor hyperreflexia manifesting as urinary frequency, urgency, urge incontinence, and nocturia.¹¹¹

When K.H. took diphenhydramine, the anticholinergic properties of the drug blocked detrusor contraction and precipitated acute urinary retention.¹¹² In this case, therapy with a SGA (i.e., fexofenadine) is more appropriate because these agents have little to no anticholinergic side effects.

Efficacy

24. What is the rationale and evidence that a leukotriene modifier might be beneficial in this case of allergic rhinitis?

Leukotrienes are important inflammatory mediators in the upper and lower airways and are present in nasal secretions of patients with allergic rhinitis. They serve as inflammatory mediators that result in increased vascular permeability, tissue edema, mucus secretion, and increased eosinophils. These actions lead to the symptoms of allergic rhinitis, as well as those of asthma.⁴³ In clinical trials, leukotriene modifiers relieve nasal symptoms in patients with allergic rhinitis⁴⁴ with similar efficacy to SGA⁴⁵ and less efficacy than nasal corticosteroids.¹¹³

In actual use, the benefit of leukotriene modifiers has been modest; therefore, their role is typically adjunctive to the use of first-line agents for allergic rhinitis.¹¹⁴ Clinical decisions about the value of combining treatments should be based on the specific clinical situation. Because K.H. has experienced intolerance to first-generation antihistamines and a lack of efficacy with second-generation antihistamines, a trial with a leukotriene-modifying agent is appropriate. Note that a patient with mild asthma and allergic rhinitis may benefit from therapy with a leukotriene modifier with or without an antihistamine. If used, however, a risk exists of a rare complication known as *Churg-Strauss syndrome*, which is characterized by eosinophilia, vasculitic rash, worsening pulmonary symptoms, cardiac complications, and neuropathy.⁹⁸ Table 24-5 includes information about the use and availability of montelukast, which is currently the only leukotriene modifier approved for allergic rhinitis.

Complementary and Alternative Therapies

25. C.L., a 25-year-old woman presents in mid-August complaining that her allergies are worsening daily. Symptoms are nasal discharge and obstruction, repetitive sneezing, and itching of the nose, eyes, and throat. She is fatigued and has difficulty concentrating. Her symptoms have been occurring in late spring and summer since high school, and she has used a variety of medications intermittently over the years. C.L. is a competitive runner but has been unable to run as far or as often as usual owing to symptoms. She is also reluctant to use medications as they may be prohibited by her race sponsors. A running partner mentioned that she could control her allergy symptoms with diet, exercise, and herbal remedies purchased at a local nutritional supplement shop. She asks your advice about this. What, if any, alternative treatments have been shown to be efficacious in allergic rhinitis?

Alternative treatments are common among adults with rhinitis and should be taken into account by health care providers. A survey of 300 adults indicated that herbal agents,

caffeine-containing products, homeopathy, acupuncture, aromatherapy, reflexology, and massage were common alternative treatments for respiratory conditions.¹¹⁵ Still, because allergic rhinitis is largely a self-managed disease, it is likely that reported use of these agents is underestimated. For these reasons, patients should always be questioned specifically about the use of alternative therapies during the patient interview. Although some alternative approaches have been deemed to be safe, efficacy for many modalities has not been clearly established.³⁹ In addition, some complementary therapies have been associated with side effects and potential drug interactions.^{116,117}

Some reports have indicated that patients with allergic rhinitis may benefit from hydration and a diet low in sodium, omega-6 fatty acids, and transfatty acids, but high in omega-3 fatty acids (e.g., fish, almonds, walnuts, pumpkin, and flax seeds), and at least five servings of fruits and vegetables per day.¹¹⁸ These recommendations are not without merit, because they may be beneficial for the population at large, but insufficient evidence exists to support specific value for allergic rhinitis symptoms.

No good clinical data are available on the efficacy of supplements containing vitamin C, grapeseed extract, bee pollen and honey, burdock, ginger, freeze-dried stinging nettle leaves, or quercetin (a bioflavonoid found in apples, buckwheat, grapes, red onions, red wine, and white grapefruit).^{39,119} Further studies are needed to assess the efficacy of these supplements and herbs.

Menthol delivered in lozenges and rubs has been shown to have an ameliorating effect on nasal congestion; however, the effects are short-lived.¹²⁰ Other forms of aromatherapy suggested to relieve nasal congestion include massaging the essential oils of lavender and niaouli around the sinuses, or inhaling eucalyptus and peppermint oils.¹²¹

For the motivated patient, mind-body interventions, such as yoga, hypnosis, and biofeedback-assisted relaxation and breathing exercises, are beneficial for stress reduction, in general, which may improve the quality of life associated with rhinitis symptoms and treatment.¹¹⁶ Acupuncture has been shown to have an attributive effect in inflammatory diseases such as rhinitis; however, not sufficient data are found to recommend this therapy at this time.¹²² Although some studies have shown that patients with allergic rhinitis who received homeopathic dilutions of allergens had significantly better nasal air flow than those in the placebo group, overall no difference was seen in subjective measurement on a visual analog scale.¹²³

A recent study reported that butterbur extract was as effective as cetirizine for symptoms of hay fever¹²⁴; however, these results have been challenged on methodological concerns.¹²⁵ Further investigation is required to determine the role of butterbur extract in the management of rhinitis.¹²⁶

Reports regarding the use of intranasal zinc for upper respiratory symptoms, particularly those associated with the common cold, have been conflicting. Although zinc gels and sprays are popular OTC products, they have been shown to be ineffective in a double-blind, placebo-controlled clinical trial¹²⁷ and have been associated in zinc-induced anosmia syndrome, particularly when the products are sniffed deeply.¹²⁸

It has been suggested that herbs that support improved immune function could theoretically also help to ease symptoms of allergy.¹²⁹ With this in mind, echinacea has become one of the top-selling herbal products in the United States. Echinacea, however, is closely related to sunflowers, daisies,

and ragweed—all members of the Compositae (Asteraceae) family.¹³⁰ The possibility that cross-sensitivity between echinacea and other environmental allergens may trigger allergic reactions is supported by an Australian review of all adverse drug reports, including cases of anaphylaxis, associated with echinacea.¹³¹ Patients with known allergy to these plants should be cautioned regarding the use of echinacea products.

Although a variety of alternative remedies are widely available and used frequently in self-treatment, based on evaluation of these data, there is no firm recommendation for C.L. regarding the use of alternative therapies in allergic rhinitis.³⁹

Immunotherapy

26. R.C. is a 25-year-old schoolteacher who has experienced allergic symptoms since childhood, but noticed a worsening after she graduated from college and moved to a new area of the country. Although she has mild symptoms year-round, she has severe exacerbations during April through–June and August through October each year. During these periods, she feels that exposure to cut grass and weeds provoke profound nasal symptoms. She also notes that when she spends more time outdoors in spring and early fall, her regular therapy, fluticasone nasal spray, is less effective. She has added loratadine during this time, but is frustrated by having to take so many medications while continuing to experience symptoms. R.C. asks your opinion about allergy shots, remarking that she started them as a child with some relief, but moved after a year and never resumed treatment. Is allergen immunotherapy effective for reducing symptoms of allergic rhinitis?

Efficacy

Allergen-specific immunotherapy has long-term efficacy, induces clinical and immunologic tolerance, and may prevent progression of allergic disease.^{132,133} This process usually involves subcutaneous injection (sometimes called “allergy shots”) of dilute solutions of allergen extracts to increase tolerance to allergens so that the threshold for symptoms is increased (i.e., subsequent exposure elicits no or mild symptoms).

Immunotherapy administered via SIT has been used empirically since the early 1900s, and its efficacy has been documented in many controlled trials.¹³⁴ A meta-analysis of 51 published studies involving 2,871 patients concluded that SIT is effective in the treatment of allergic rhinitis.⁴⁷ In addition, studies of immunotherapy for allergic rhinitis in children suggest that immunotherapy may prevent the onset of asthma.^{135,136} Taken together, these studies show that SIT should be considered a supplement to drug therapy in specific patients and possibly be used earlier in the course of allergic disease to achieve maximal benefit.²

Allergen Testing

27. How can the clinician determine R.C.’s specific sensitivities?

Skin testing using the modified prick test method or a prick-puncture method is used to confirm the diagnosis of allergic rhinitis and to determine specific allergen sensitivities. Skin testing is a highly sensitive and relatively inexpensive objective measurement of allergen sensitivity. Small quantities of allergen are introduced into the skin by pricking or puncturing the skin in the immediate presence of the diluted allergen ex-

tract. Fifteen to 35 tests are placed on the upper portion of the back or the palmar surface of the forearms. A positive skin test produces a wheal and flare at the site within 15 to 30 minutes of application. An experienced clinician, usually an allergist, should conduct skin testing using high-quality allergen extracts and should interpret the results.¹³⁷

The allergens tested vary with geographic location, emphasizing the most common offending plant species that generate airborne particles. Pollen, the primary particle, is produced by trees, grasses, and weeds. Each of these plant groups generally pollinate at about the same time each year: trees in the spring, grasses from early to midsummer, and weeds from late summer into fall before the first killing frost. The onset and potency of the pollen season varies with geographic location and weather, particularly with respect to temperature and moisture. Seasonality can be misleading, however, because settled pollen particles from a previous season may be resuspended in the air following the spring snow melt or periods of heavy winds.

Mold spores also are common airborne allergens. The outdoor molds release their spores from early spring through late fall. Within this long season, spore counts increase and decrease, depending on the presence of local flora on which these molds grow (e.g., grain and other crops, forests, and orchards). Some perennial allergens (e.g., house dust mites, insect and animal dander, and some indoor molds) occur consistently across all geographic distributions. In each case, skin test results must be correlated with the patient’s clinical history.¹³²

R.C.’s perennial symptoms with seasonal exacerbations indicate sensitivity to the common perennial allergens with a particular sensitivity to seasonal allergens such as tree, grass, and weed pollen, but these subjective relationships should be confirmed with skin testing.

An alternative to skin testing is the radioallergosorbent test, in which the patient’s serum is tested for allergen-specific IgE antibodies. However, this test is less sensitive and more expensive than skin testing.¹³⁸ It is indicated only in selected clinical situations: when a patient consistently reacts positively to the negative control skin test (dermatographism), when antihistamine therapy cannot be discontinued, or when the patient has extensive atopic dermatitis or other skin lesions. Blood eosinophil counts and total serum IgE antibody measurements are neither sensitive nor sufficiently specific to be useful in the diagnosis of allergic rhinitis.¹

28. Because R.C. is currently using medications (fluticasone nasal spray and loratadine) for her symptoms, should these be discontinued before skin testing?

Antihistamines blunt the wheal-and-flare reaction by blocking the effects of histamine on capillaries. Different antihistamines vary in the extent to which they can inhibit wheal formation and in the duration of the inhibitory effect (Table 24-7). Depending on the agent selected, antihistamines must be discontinued from 24 hours to 10 days before skin testing and even then, considerable interpatient variability exists in blocking effects.¹³⁹ For best results, R.C.’s loratadine should be discontinued 10 days before her skin testing.

Other allergy medications, including cromolyn and nasal corticosteroids, have no effect on skin tests. Likewise, most asthma medications, including leukotriene modifiers, inhaled β_2 -agonists, cromolyn, theophylline, and inhaled and

Table 24-7 Effects of Antihistamines on Allergen Skin Tests

| Drug | Extent of Suppression ^a | Half-life (hr) ^b | Duration of Suppression (day) |
|------------------|------------------------------------|-----------------------------|-------------------------------|
| Brompheniramine | + | 24.9 | 1–4 |
| Cetirizine | +++ | 7.4–11 (7) | 3–10 |
| Chlorpheniramine | + | 24.4 (11) | 1–4 |
| Clemastine | ++ | 21.3 | 1–10 |
| Cyproheptadine | +/- | 16 | 1–4 |
| Desloratadine | + /+++ | 27 (27) | 3–10 |
| Diphenhydramine | +/- | 4–9 | 1–4 |
| Fexofenadine | ++ | 14 (18) | 3–10 |
| Hydroxyzine | ++ | 20 (7.1) | 1–10 |
| Loratadine | + /+++ | 11–24 (3.1) | 3–10 |
| Promethazine | + | 12 | 1–4 |

^a+++ , extensive; ++ moderate; +, mild; +/- minimal to none, - unknown.

^bParentetical numbers indicate half-life in children.

Adapted from references 1, 98, 140.

short-course systemic (burst) corticosteroids have no effect on skin tests.^{137,140,141} R.C. can continue the use of fluticasone nasal spray while she waits to be skin tested.

Oral β_2 -agonists, long-term systemic corticosteroids, and high-potency topical corticosteroids (applied to the skin testing sites) may block cutaneous wheal-and-flare reactions. Tricyclic antidepressants are potent inhibitors of the wheal-and-flare reaction, and their effects can last up to 10 days. Phenothiazine-type antipsychotics and antiemetics (e.g., chlorpromazine, prochlorperazine) also can block cutaneous reactions to allergens. β_2 -blockers can increase skin reactivity.¹³⁷ Depending on the indication for drug therapy, however, discontinuation of these drugs before skin testing is not always advisable. Recommendations for discontinuing antihistamines before allergen skin testing are listed in Table 24-8.

29. Is R.C. a candidate for immunotherapy injections?

Immunotherapy via SIT is indicated for patients with evidence of sustained, clinically relevant IgE-mediated disease and a limited spectrum of allergies (i.e., one or two clinically relevant allergens) and in whom pharmacotherapy and avoidance measures are insufficient.¹⁴² Further considerations are the patient's attitude to available treatment modalities, costs of treatment, and the quality of allergen vaccines available for treatment.¹³² In the case of R.C., she has year-round symptoms with seasonal exacerbations, she has not experienced symptom relief when using appropriate therapies, and she is motivated to try immunotherapy. In addition, a previous trial in childhood was beneficial. For these reasons, skin testing and a trial of immunotherapy with specific allergens are reasonable.

Other Forms

30. Are there alternatives to injectable delivery of immunotherapy?

Traditional subcutaneous immunotherapy presents some disadvantages, such as costs, adherence, and rare systemic reactions. Because regular injections can be unacceptable to some patients, alternative methods of delivering antigens, such as SLIT and NIT, have been investigated.^{143–145} A recent review of sublingual therapy for allergic rhinitis determined that SLIT is a safe treatment that significantly reduces symptoms

and medication requirements in allergic rhinitis.⁴⁸ Less evidence is found about the efficacy of NIT, but a recent multicenter trial in children suggests improvement in nasal symptom scores as compared with placebo.¹⁴⁵ Neither SLIT nor NIT is currently available in the United States and, although both have shown potential, SIT is still optimal in severe allergic rhinitis with signs of bronchial hyperreactivity.⁴⁷

Length of Therapy

31. If R.C. decides to proceed with immunotherapy, how long should her therapy continue and how long will the effects last?

After identifying the offending allergens via skin testing, subcutaneous immunotherapy is generally administered in two phases. During the build-up phase, increasing doses of allergen are given once or twice a week until a predetermined target or maintenance dose is achieved. This usually takes 3 to 4 months (e.g., 16–18 injections). Once this maintenance dose is reached, shots are usually administered every 2 to

Table 24-8 General Recommendations for Discontinuation of Antihistamines before Allergen Skin Testing

1. Remind patient that allergic symptoms may return during the antihistamine-free period, but that reliable skin tests cannot be performed in a patient taking antihistamines.
2. Discontinue any short-acting antihistamine (i.e., those in Table 24-7 with a duration of suppression ≤ 4 days) 4 days before skin testing.
3. Discontinue longer-acting antihistamines (i.e., those in Table 24-7 with a duration of suppression > 4 days) at an interval appropriate to their duration of effect (e.g., hydroxyzine should be discontinued 10 days before skin testing)
4. Before applying the full battery of skin tests, apply histamine (positive) control and glycerinated diluent (negative) control tests. Application of a 1 mg/mL histamine base equivalent should yield wheal-and-flare diameters of 2–7 mm and 4.5–32.5 mm, respectively, to be considered a normal histamine reaction. A normal cutaneous reaction to histamine control suggests that accurate skin testing can be performed.

Adapted from reference 140.

3 weeks over the ensuing several years of treatment. Clinical improvement with immunotherapy usually occurs in the first year. In a small percentage of patients, there is no improvement and immunotherapy is discontinued. If symptoms are reduced, however, injections are usually continued for 4 to 5 years of maintenance therapy.¹³²

Although immunotherapy can lead to long-term remission of symptoms, one drawback is the lengthy treatment period. Preliminary data involving a 2-year study of 19 patients allergic to ragweed who underwent one allergy shot per week for 6 weeks before the ragweed season suggest that significant relief can be obtained from a shorter term of treatment.¹⁴⁴ SIT alters the natural course of disease and evidence suggests that efficacy persists long after therapy ends.¹⁴⁶

Risks

32. What are the risks associated with immunotherapy?

Local adverse reactions (i.e., redness, swelling) to immunotherapy can be common, but the risk of severe reaction (i.e., anaphylaxis) is low. A new classification system for grading systemic reactions has been proposed, which categorizes these into immediate (occurring within 30 minutes) and late (developing after 30 minutes).¹³² In addition, pretreatment with antihistamines during immunotherapy induction has been shown to reduce the incidence of such adverse events. In view of the occasional occurrence of systemic side effects following injections, it is important that SIT be performed by personnel who are fully trained and experienced in the early recognition and treatment of such reactions.⁴⁷

DRUG-INDUCED NASAL CONGESTION

33. L.K. is a 27-year-old man who has suffered intermittent symptoms of allergic rhinitis. He reports that his symptoms are most bothersome in the spring and associated with blooming of various grasses. During these periods, he typically uses chlorpheniramine, which relieves his symptoms adequately. This season, he reports that his symptoms have been more severe, with sneezing, runny nose, and extreme itching in his nose. He has tried chlorpheniramine and recently switched to loratadine, with partial relief of symptoms. He also states that nasal congestion has been more of an issue with this episode and to address this he has used xylometazoline nasal spray for the past 3 weeks. Despite increasing the use of nasal spray from two to four times a day, however, he reports that the congestion is getting worse. What might be an explanation for L.K.'s increasing need for nasal decongestant?

L.K. may be experiencing rhinitis medicamentosa (RM) or rebound congestion, a condition characterized by nasal congestion without rhinorrhea, postnasal drip, or sneezing and is associated with overuse of topical nasal decongestants.²² For this reason, topical decongestant therapy should be limited to no more than 10 days, but because the time course can vary among patients, preferably fewer than 5 days.¹⁴⁷

Etiology

34. Why does rhinitis medicamentosa occur?

Sympathomimetic, or adrenergic, agents stimulate α -adrenergic receptors on blood vessels, resulting in vasoconstriction. In the nasal mucosa, the therapeutic effect is relief of nasal congestion associated with edematous, congested blood vessels as a result of the allergic response. Rhinitis medicamentosa occurs as a result of a rebound phenomenon where the vessels in the nasal mucosa become more engorged and edematous as a result of overstimulation of α -adrenergic receptors.¹⁴⁸ As a result, patients use the decongestant more frequently and may increase the dose for relief, creating a vicious cycle. This problem is commonly reported with topical decongestants, but is uncommon with oral agents. Note that topical decongestants should never be used in infants younger than 6 months of age because they are obligate nose breathers and the resulting rebound congestion could cause obstructive apnea.

The precise mechanism of rhinitis medicamentosa is unknown, but theories suggest it may be secondary to the decreased production of endogenous sympathetic norepinephrine through a negative feedback mechanism. With prolonged use or following discontinuation of topical decongestants, the sympathetic nerves may be unable to maintain vasoconstriction because norepinephrine release is suppressed.¹⁴⁷ It has also been suggested that benzalkonium chloride (BKC), used in topical decongestant products as a preservative, worsens rhinitis medicamentosa; therefore, some authors recommend using BKC-free products, even though no evidence exists of worsening congestion in subjects who use nasal glucocorticoids containing BKC.²² In addition to rhinitis medicamentosa, systemic medications and some drugs of abuse can cause nasal congestion or other nasal symptoms.²² Table 24-9 lists drugs capable of causing rhinitis symptoms.

Strategies for Resolution

35. What are possible strategies to recommend to L.K. to address this problem?

The best strategy for managing rhinitis medicamentosa is prevention, but when that fails, several options for treatment exist.¹⁴⁷ Patients must be educated about the effects and potential complications of topical decongestants whenever they are prescribed or purchased without a prescription. Ideally, topical decongestant use should be limited to fewer than 5 days. If longer treatment is required, the patient should take a 1- to 2-day holiday during which the topical agent is not used before resuming treatment.

In any case of drug-induced nasal congestion, the most important intervention is to discontinue the offending agent and, if necessary, substitute another therapy that will not cause nasal symptoms.²² In the case of topical decongestants, discontinuation of the nasal spray can be difficult for the patient and presents the clinician with a therapeutic challenge. It also is important to appropriately treat the underlying cause of the nasal congestion that led to the overuse of the topical decongestant.

A simple strategy is to discontinue the topical decongestant spray. This can be done abruptly, but is likely to cause the patient considerable discomfort for the first 4 to 7 days after discontinuation.¹⁴⁷ There are also strategies to ameliorate the uncomfortable symptoms for the patient. The use of saline

gestant spray in the right nostril every other dose. Later, use saline twice for each decongestant dose. Eventually, the decongestant is discontinued totally in the right nostril and saline is substituted. Repeat the process for the left nostril. Saline can be used as often as needed throughout this process and after the topical decongestant is completely withdrawn. This method has been suggested in several reviews, although no prospective trial results are available to support it.²² Thus, this method should be combined with careful patient education, support, and frequent follow-up.

IDIOPATHIC RHINITIS

36. M.S., a 29-year-old man, complains of profuse watery rhinorrhea that has been a chronic and progressively worsening problem for the past 5 years. He also experiences some nasal congestion with the rhinorrhea, but denies nasal itching or sneezing. Although the symptoms tend to remit and exacerbate, they do not occur in any definable seasonal pattern. His symptoms are worsened by exposure to tobacco smoke, strong fumes such as paint or ammonia, and hot coffee, and they often are associated with headaches. Also, the rhinorrhea is substantially worse on exposure to cold air. M.S. has no other medical problems and no family history for allergies. He does not smoke and drinks only occasionally. His only medication, beclomethasone dipropionate (42 mcg/spray), two sprays in each nostril twice daily as needed, only partially relieves the symptoms. M.S. sniffs and blows his nose several times during the medical history taking. Physical examination reveals a mildly erythematous nasal mucosa and a minimally edematous inferior turbinate. Copious nasal discharge is clear and watery and air movement through the nose is relatively good. There is no sinus tenderness. The remainder of his physical examination is normal. Microscopic examination of a nasal smear demonstrates only a few neutrophils and no eosinophils. What information about M.S. supports the diagnosis of idiopathic rhinitis?

Diagnosis

Idiopathic rhinitis is a diagnosis of exclusion encompassing those patients with nasal mucous membrane inflammation with no proved immunologic, microbiologic, pharmacologic, hormonal, or occupational cause.²³ The syndrome is sometimes called “vasomotor rhinitis,” but using this terminology can be confusing because the cause of the symptoms has still not been clearly identified.^{1,19} The prevailing theory holds that an imbalance in the autonomic nervous system exists in which the cholinergic parasympathetic activity exceeds the α -adrenergic activity in the nasal mucosa.²³ Theoretically, this is the reason that stimuli that normally increase parasympathetic activity in the nose, such as cold air and inhaled irritants, aggravate symptoms.¹⁴⁹ Still, substantial debate exists over whether idiopathic rhinitis represents a *localized* allergic response in the absence of systemic atopic markers¹⁵⁰ as well as the evidence for inflammatory pathophysiology in the disease.¹⁵¹

The symptoms of idiopathic rhinitis are variable. Most patients experience perennial nasal obstruction accompanied by profuse, watery nasal and postnasal discharge. Many patients complain of nasal obstruction as the primary symptom, whereas for others it is rhinorrhea. Sneezing is usually not

nose drops or spray can moisturize and alleviate nasal irritation. Intranasal corticosteroids often help decrease the tissue inflammation associated with rhinitis medicamentosa and can help patients in the immediate period after discontinuing the topical decongestant. Oral decongestants can also be used for the recovery period. In refractory cases, a short course of systemic corticosteroids may be necessary.²² Note that if the patient has used the topical decongestant continuously for many months or even years, the nasal mucosa can be damaged irreversibly.

An alternative to abrupt cessation of the topical decongestant is to recommend that the patient discontinue use of the topical decongestant one nostril at a time. In this case, the patient can continue using the topical agent in one nostril while waiting for resolution of the condition in the other nostril. When the drug is withdrawn completely from one nostril, begin decreasing the amount of drug used in the other nostril. For example, have the patient substitute normal saline nasal spray for decon-

a prominent symptom and nasal itching is uncommon.^{1,19,23} Headache may occur and usually is frontal or localized over the bridge of the nose. In patients with chronic nasal obstruction, chronic sinusitis and significant morbidity can result. In contrast to allergic rhinitis, the onset of symptoms in patients with idiopathic rhinitis usually occurs in adulthood, but before 40 years of age.¹⁹

Patients report worsening of their symptoms when exposed to nonspecific irritants, including tobacco smoke, industrial pollutants, strong odors and perfumes, newsprint, chemical fumes; cold, dry air; changes in humidity; and ingestion of very cold or very hot beverages or spicy foods. Most patients have no history or evidence of atopy.¹⁹

The appearance of the nasal mucosa also is variable. The turbinates are usually erythematous and, during an exacerbation, considerable quantities of nasal secretions usually are present. Mast cells may be present in the nasal smear; however, by definition, nasal eosinophilia is not present. Skin tests are usually negative.²³

37. M.S.'s symptoms of bothersome watery rhinorrhea, nasal congestion, and headache without itching or sneezing are typical. His complaint of worsening symptoms with exposure to noxious inhalants, cold air, and hot beverages supports the diagnosis of idiopathic rhinitis. The nasal smear, which notably lacks large numbers of eosinophils, initially differentiates this disease from NARES. M.S. asks what causes idiopathic rhinitis and what can be done to alleviate his symptoms. What are the available nonpharmacologic and pharmacologic treatments for idiopathic rhinitis?

Choice of Therapeutic Agent

Nasal symptoms in patients with idiopathic rhinitis have been shown to be influenced by psychological factors. Some therapeutic benefit may be realized by establishing an ongoing, trusting relationship between the health care provider and the patient. This should include a thorough explanation of the disease state and the realistic outcomes of therapy for most patients. Psychotherapy is helpful in some cases. In addition, patients should be instructed to avoid as many aggravating factors as possible, such as smoking, exposure to smoke or other irritants, and very cold or very hot beverages. Saline irrigation is valuable as a general soothing and moisturizing treatment. Exercise may be particularly helpful for patients with idiopathic rhinitis because it increases sympathetic tone.²³

Pharmacotherapy for idiopathic rhinitis should be directed toward the predominant symptoms of the individual patient.²³ For patients with predominant nasal congestion and minimal rhinorrhea, the intranasal corticosteroids may be helpful. The addition of oral decongestants may improve nasal obstruction in some patients with idiopathic rhinitis, but objective measures of improvement are affected variably and side effects can be problematic.

M.S.'s case is typical of the often frustrating course in treating idiopathic rhinitis.²³ Commonly, multiple therapeutic plans fail, and M.S. has responded incompletely and unsatisfactorily to intranasal corticosteroids. Surgical treatments have been attempted for patients in whom medical management fails, although recent clinical evidence is limited primarily to case reports.¹⁵²

In patients such as M.S., who have rhinorrhea as their predominant symptom, nasal ipratropium bromide, a topically active congener of atropine, may decrease nasal secretions.²³ Also, FGA may be helpful because of their anticholinergic drying effects. In general, however, FGA are less effective in the treatment of idiopathic rhinitis than for allergic rhinitis, and patients may have difficulty complying with therapy because of side effects. Of note, the nonsedating SGA have little value in idiopathic rhinitis because they lack anticholinergic properties.

38. How does ipratropium bromide work for idiopathic rhinitis and how effective is it?

Ipratropium bromide's quaternary ammonium structure makes it lipophobic; therefore, it is absorbed poorly from the nasal mucosa and gastrointestinal tract and does not cross the blood–brain barrier. It significantly reduces rhinorrhea (as measured by the number of nose-blowing episodes or daily number of tissues used), but has no effect on sneezing or nasal obstruction.¹⁵³

The recommended dose of ipratropium bromide is two sprays of the 0.03% nasal solution (42 mcg) in each nostril two to three times per day, but dosage individualization (from 168 to 1,600 mcg/ day) is often required to achieve symptomatic relief.⁹⁸ A 0.06% nasal formulation is also available, but its use is typically reserved for short-term treatment of common cold symptoms. Table 24-5 includes information about intranasal ipratropium dosing and availability.

In general, intranasal ipratropium bromide is well tolerated, although its use is associated with dose-related side effects.¹ The most common side effects are nasal dryness, nasal burning, bloody nasal discharge (epistaxis), dry or sore throat, and dry mouth.¹ Theoretically, elderly men with BPH may experience difficulty in urinating, but the risk is low because of negligible systemic absorption. No significant adverse cardiovascular or blood pressure effects have been observed.

CONCLUSIONS

The initial management of acute and chronic rhinitis should be directed at preventing symptoms, which can be achieved through a variety of pharmacologic and nonpharmacologic methods. Plans for allergic rhinitis, the most common form, should include patient education, allergen or irritant avoidance and the appropriate medications, including immunotherapy, if indicated. Control of the disease process is the expected outcome—in which patients are able to live their lives comfortably without symptoms or impairment. Customizing therapy for each patient based on symptom history and response to treatments is important. Rhinitis can be controlled and effective management can greatly improve the quality of patients' lives.

Drug-Induced Pulmonary Disorders

Deborah Sako Kubota and James Chan

PULMONARY FIBROSIS 25-1

**TYROSINE KINASE INHIBITOR-INDUCED
INTERSTITIAL LUNG DISEASE 25-9**

**AMIODARONE-INDUCED PULMONARY
TOXICITY 25-10**

**GEMCITABINE-INDUCED PULMONARY
TOXICITY 25-11**

ACKNOWLEDGMENTS 25-12

Because the lungs are exposed directly to the atmospheric environment and whole circulating blood across an enormous surface area, they are uniquely susceptible to the effects of air- and blood-borne toxins. More than 350 drugs and diagnostic agents are known to cause pulmonary injuries of varying pathophysiological patterns, degrees of severity, and pathogenic mechanisms that involve the airways, lung parenchyma, pulmonary vasculature, pleura, and neuromuscular system.^{1,2}

The resolution of acute drug-induced pulmonary disorders is dependent on early recognition and identification of the offending agent, its prompt withdrawal, and the initiation of management strategies. The diagnosis of drug-induced pulmonary toxicity generally rests on the exclusion of other causes or disorders with similar presentation. Therefore, it is incumbent on health care providers to have an awareness of the clinical findings consistent with drug-induced pulmonary disorders. An understanding of the mechanism of reaction and possible risk factors for adverse reactions is invaluable in the selection of alternative therapies to avoid or minimize toxicities.³

Drug-induced pulmonary disorders can be subdivided into categories based on the pathophysiological patterns of involvement. Some drugs can produce more than one pattern. Tables 25-1 and 25-2 include some commonly encountered pathology and implicated drugs with clinical details of the pulmonary reactions. This is not a complete listing of pathophysiological patterns or drugs reported to cause pulmonary disorders. For more comprehensive drug lists and greater detail, the reader is referred to several general reviews on this topic, including an online database.²⁻⁹

Generally, the initial step in the management of drug-induced pulmonary disorders is the discontinuation of the offending agent, where possible. Some management strategies include the use of corticosteroids. However, the potential benefit of corticosteroid therapy for the treatment of the serious acute respiratory distress syndrome (ARDS) remains controversial and appears to vary with the drug involved, the extent and type of toxicity elicited, the dosage of corticosteroid, and the time of the administration of corticosteroid therapy during the course of the reaction.¹⁰⁻¹²

PULMONARY FIBROSIS

1. A.E., a 35-year-old man with recently diagnosed Stage IIIB non-seminoma testicular cancer, has completed four cycles of bleomycin, etoposide, and cisplatin (BEP) therapy. A residual retroperitoneal mass is identified, and surgical resection under general anesthesia is scheduled. What is A.E.'s total lifetime dose of bleomycin, and how is this information relevant to his scheduled surgical procedure?

BEP administered every 3 weeks for four cycles is the recommended treatment of Stage IIIB non-seminoma testicular cancer. Bleomycin 30 units is administered weekly for three doses per cycle, for a cumulative dose of 360 units.¹³

Pulmonary toxicity is present in 10% of patients receiving bleomycin, and although it rarely progresses to pulmonary fibrosis, it can lead to death in 1% of all patients who receive this drug. Pulmonary fibrosis is the dose-limiting toxicity of bleomycin. It is recommended that the cumulative lifetime dose of bleomycin be restricted to <400 units, because pulmonary toxicity is rarely fatal at total cumulative doses of <400 units. The incidence increases appreciably if >450 units are given, and approaches a 10% fatality rate when patients receive cumulative doses >550 units. Additional risk factors include older age (increases with every decade over 30 years), renal insufficiency (creatinine clearance <35 mL/minute), and concomitant use of cisplatin.¹⁴⁻¹⁸

There have been reports of postoperative deaths attributed to the use of supplemental oxygen in patients given bleomycin. This combination may be synergistic for pulmonary toxicity. Although there have been data indicating that restricting inspired oxygen concentration (fraction of inspired oxygen [FiO₂]) to 22% to 25% mitigates the toxicity of combination use, there have also been data showing that the use of higher concentrations (37%–45% FiO₂) may not lead to respiratory failure. As data to support all practices of oxygen administration to patients receiving bleomycin are currently available, it has been recommended that inspired oxygen concentrations be kept at the lowest level that provides adequate tissue oxygenation (oxyhemoglobin saturation by pulse oximetry, SpO₂ >90%), particularly in patients with other risk factors.^{15,19}

Table 25-1 Drugs Associated with Pulmonary Disorders^a

| Drugs | Pulmonary Reactions ^b | Drugs | Pulmonary Reactions ^b |
|--|----------------------------------|---|----------------------------------|
| Acebutolol | IVc | Inhaled pentamidine | I |
| Adenosine | I | Interferon- α | IVb, IVc, VIII |
| Allopurinol | IX | Interferon- β | IIb, VI |

Table 25-2 Drug-Induced Pulmonary Disorders

| Reaction/Drugs | Clinical Remarks |
|--|---|
| I. Bronchospasm, wheezing, and cough | <ul style="list-style-type: none"> Bronchospasm is the most common drug-induced pulmonary adverse event. Many drugs cause bronchospasm via different pathophysiological mechanisms, including extension of pharmacologic effect, direct airway irritation, sensitization with subsequent anaphylactic reactions (IgE-mediated), and anaphylactoid (non-IgE-mediated) reactions.^{8,9,43} Clinical presentation is the same as with nondrug-induced bronchospasms (asthma, COPD; i.e., cough, shortness of breath, wheezing, chest tightness). Risk factors include pre-existing hyperreactive lung disease, smoking, advanced age, and respiratory infections.^{8,9} General management consists of withdrawal and avoidance of the causative agent and potential cross-reactive agents. Treat acute anaphylaxis with small doses of injectable epinephrine: in adults, administer 0.3 to 0.5 mL of a 1:1,000 dilution intramuscularly in the lateral thigh and supplementary treatment, including oxygen, corticosteroids, and parenteral antihistamines.⁴⁴ Inhaled β_2-agonists are useful for persistent bronchospasm.^{8,9,44} |
| Adenosine | <ul style="list-style-type: none"> IV adenosine is associated with a 12% to 28% incidence of dyspnea, which is generally transient.⁴⁵ Although there have been reports of bronchospasm when administered to patients with asthma or COPD, recent data indicate that adenosine does not cause bronchospasm as measured by spirometry, but can cause dyspnea, with an increased intensity in asthmatics.^{43,46} |
| Amphotericin B | <ul style="list-style-type: none"> Pulmonary reactions (bronchospasm and dyspnea) to amphotericin B infusions may be chemical, not allergic. Risk is related to rate of infusion, rather than to dose. This has been reported for both conventional and liposomal formulations.⁴⁷ Although generally rapid in onset, there have been delayed reactions for up to several weeks. May involve direct injury of endothelial cells, enhanced pulmonary leukostasis, and release of cyclo-oxygenase (COX) products from the metabolism of arachidonic acid. Characteristic infusion-related chills and fever are related to amphotericin-induced tumor necrosis factor-α (TNF-α) and interleukin (IL)-1 production. Pulmonary infiltrates consistent with acute pulmonary edema are common. The drug should be withdrawn, and corticosteroids, nonsteroidal anti-inflammatory drugs (NSAIDs), epinephrine, or aminophylline may be administered. Cautious re-exposure with a slowed rate of infusion and premedication could allow for treatment continuation with the same drug. True allergic reactions to amphotericin are extremely rare. Desensitization in an intensive care unit can be considered in a patient with previous anaphylactic reaction who requires amphotericin therapy.⁴⁷⁻⁴⁹ |
| Angiotensin-converting enzyme inhibitors (ACEIs) | <ul style="list-style-type: none"> Incidence of ACEI-induced cough is 5% to 35% and is twice as likely in women. Likely mediated by bradykinin and substance P normally degraded by angiotensin-converting enzyme, prostaglandins stimulated by bradykinin, or activation of bradykinin receptors. Can occur in the absence of pre-existing hyperreactivity. Characterized by dry, persistent cough, and tickling sensation in the throat, without changes in pulmonary function. Onset from 24 hours to 1 year after start of drug (average 14.5 weeks). Not dose dependent. Cough resolves in 1 to 4 weeks after drug discontinuation (up to 3 months in some patients). In a minority of patients, cough will not recur on rechallenge. Switching therapy to an angiotensin-receptor blocker or agent of another drug class is an option.^{8,9,43,50} |
| Antibiotics cephalosporins penicillins sulfonamides | <ul style="list-style-type: none"> Cephalosporins, penicillins, and sulfonamides are commonly involved in IgE-mediated bronchospasm. For some compounds, desensitization protocols have been developed.^{9,51} |
| Antineoplastic agents asparaginase taxanes paclitaxel docetaxel | <ul style="list-style-type: none"> Asparaginase is the most common cause of antineoplastic-induced hypersensitivity reactions (increases from 3%–32% after fourth weekly IV dose). Reactions can be immediate type I IgE-mediated or delayed type II IgM- and IgG-mediated, with symptoms ranging from transient rash to moderate bronchospasm and severe hypotension with or without anaphylaxis. Risk factors include the number of previously administered doses, previous reaction to asparaginase, IV route of administration and higher doses ($\geq 25,000$ U/m²). PEG-asparaginase is tolerated in the majority of patients with hypersensitivity to asparaginase.⁵² Hypersensitivity reactions occur in up to 42% of patients receiving paclitaxel (2% serious)⁹ and in 25% to 50% of patients receiving docetaxel.⁵³ Symptoms include dyspnea and bronchospasm, as well as urticaria, angioedema, and hypotension. Most reactions occur with the first exposure. To prevent severe hypersensitivity reactions, patients should be premedicated. Regimens typically include a steroid and histamine H₁- and H₂-blocker. In cases of severe reactions, rechallenge should not be attempted.^{9,53,54} |
| β -adrenergic receptor blockers (β -blockers) acebutolol metipranolol atenolol metoprolol betaxolol nadolol bisoprolol penbutolol carteolol pindolol carvedilol propranolol labetalol sotalol levobunolol timolol | <ul style="list-style-type: none"> Noncardioselective β-blockers cause bronchoconstriction in almost all asthmatics by antagonizing the maintenance of normal airway tone by the sympathetic nervous system. They also compromise the bronchodilator effect of inhaled β-adrenergic treatment. Oral, intravenous (IV), and ophthalmic formulations have been implicated. Inhaled anticholinergic agents (e.g., ipratropium bromide) are indicated for β-blocker-induced bronchoconstriction. β_2-agonists will not be effective. Use of cardioselective β-blockers in the lowest dose possible can be considered for chronic obstructive pulmonary disease (COPD) patients who would benefit from β-blocker therapy. However, cardioselectivity is compromised with increasing doses, potentially resulting in β_2 antagonism and bronchoconstriction.^{8,9,55,56} |

(continued)

Table 25-2 Drug-Induced Pulmonary Disorders (Continued)

| Reaction/Drugs | Clinical Remarks |
|--|--|
| Contrast media | <ul style="list-style-type: none"> Acute life-threatening reactions to iodinated contrast media are rare (1.4%) and have decreased with the introduction of nonionic, low-osmolality contrast agents. Iodinated agents can illicit the release of histamines and other mediators via direct degranulation of mast cells. Pretesting for reactions is not useful. Premedication in at-risk patients with corticosteroids, antihistamines, or combinations thereof is not universally supported.^{57,58} |
| Fentanyl | <ul style="list-style-type: none"> IV fentanyl-induced cough can be explosive and ranges in frequency from 28% to 65%. It appears to increase with rapid injection. Fentanyl cough is attenuated by pretreatment with inhaled cromolyn sodium and corticosteroids. IV ketamine and lidocaine have decreased the frequency, but not the severity of cough.^{9,59,60} |
| Inhalants/nebulized agents and preservatives benzalkonium chloride (BAC) corticosteroids cromolyn desflurane ethylenediamine tetra-acetic acid (EDTA) inhaled human insulin inhaled pentamidine sulfites | <ul style="list-style-type: none"> Carrier agents (particles, propellants, and dispersants), pH, osmolality, or temperature of inhalational and nebulized agents used in the treatment of asthma may cause bronchial irritation. Propellants comprise 58% to 99% of metered-dose inhaler products. If there is no response or a history of increased wheezing after inhaled treatment, a change in specific product should be considered.^{9,20} Inhaled corticosteroids, N-acetylcysteine, pentamidine, and desflurane are known airway irritants. Preservatives (e.g., sulfites, metabisulfites, benzalkonium chloride, EDTA) found in some nebulized solutions can provoke reactions. Inhaled sulfites may stimulate afferent parasympathetic receptors on the lung surface. BAC directly stimulates airway irritant C fibers and causes mast cell degranulation. EDTA potentiates histamine-induced bronchoconstriction.^{8,9,61} Human insulin inhalation powder (Exubera) has been associated with a nearly 30% incidence of mild, rarely productive cough, which occurred within seconds to minutes after administration and decreased with continued use. The manufacturer discontinued marketing this product in January 2007.^{95–97} Inhaled pentamidine has been associated with cough (38% incidence) and bronchospasm (15% incidence). Prior treatment with an inhaled bronchodilator may help prevent these effects.^{9,98} |
| Nonsteroidal Anti-Inflammatory Drugs (NSAIDs) aspirin | <ul style="list-style-type: none"> NSAIDs and Aspirin have the highest incidence of drug-induced bronchospasm (6%–34%). May be due to inhibition of COX with resultant ↑ synthesis of proinflammatory leukotrienes and ↓ synthesis of anti-inflammatory prostaglandin, PGE₂. Rapid and often life-threatening reaction. Primary therapy is avoidance of NSAIDs that inhibit COX, including selective COX-2 inhibitors. The degree of cross-reactivity is dependent on the potency of inhibition. Sodium salicylate, salicylamide, and choline magnesium trisalicylate can be taken safely. Acetaminophen is a very weak COX inhibitor; on average, <5% of this population will react to acetaminophen, but the incidence increases (34%) with high doses (>1,000 mg). Pretreatment with leukotriene receptor antagonists (LTAs) does not provide consistent prophylaxis. Desensitization to aspirin under medical supervision is an option and will confer protection to cross-reacting NSAIDs.^{8,9,43} |
| Sulfites | <ul style="list-style-type: none"> Ingestion of sulfites used as preservatives in food and wine can elicit bronchoconstriction (5% incidence), particularly in patients with corticosteroid-dependent asthma.⁸ |
| II. Acute pulmonary edema | <ul style="list-style-type: none"> Typical symptoms include dyspnea, chest discomfort, tachypnea, and hypoxemia with crackles on auscultation. Foamy tracheal exudates may develop with alveolar flooding. May be associated with fever and lead to acute respiratory distress syndrome (ARDS).^{2,62} Management focuses on adequate life support, then specific therapy that targets the causes of the accumulation of extravascular water in the lungs. Useful strategies would limit further accumulation of fluid and favor its removal from the lungs.⁶³ |
| II. a. Cardiogenic | <ul style="list-style-type: none"> Cardiogenic (increased pressure) pulmonary edema can have an insidious onset, as the barriers to fluid and protein that flow into the lungs remain intact. Symptoms may be only vague fatigue, mild pedal edema, and exertional dyspnea. Iatrogenic causes include IV fluids with resultant cardiovascular fluid overload.⁶³ |
| IV fluids contrast media magnesium sulfate | <ul style="list-style-type: none"> The amount of Contrast media infused, irrespective of the osmolality, may be a major cause of contrast media-induced pulmonary edema. Risks may be reduced by decreasing the volume injected and ensuring a normal state of hydration prior to infusion. Can also cause anaphylactoid reactions. However, pathogenesis may not be related to anaphylaxis or fluid overload, but may involve the chemical irritation of the pulmonary endothelium via formation of endothelium-derived prostacyclin.^{3,57,58} IV Magnesium sulfate tocolysis-induced pulmonary edema appears to be due to the delivery vehicle, rather than to the drug itself because higher risk is associated with higher infusion rates and lower drug concentrations. Incidence of pulmonary edema is significantly increased when given with β₂-agonists.⁶⁴ |
| II. b. Noncardiogenic pulmonary edema (NCPE) | <ul style="list-style-type: none"> NCPE comprises most cases of drug-induced pulmonary edema via drug-related increases in capillary pulmonary permeability. Can develop within a few days after exposure or immediately after drug administration with rapid alveolar flooding. Fluid in alveolar spaces will contain high concentrations of protein. In addition to drug discontinuation, treatment may require mechanical ventilatory support with positive pressure. Corticosteroid treatment (methylprednisolone 1 mg/kg) started early in the course of ARDS has been shown to be beneficial, but remains controversial.⁶⁵ Condition will recur with drug rechallenge.^{2,3,10} |

Table 25-2 Drug-Induced Pulmonary Disorders (Continued)

| Reaction/Drugs | Clinical Remarks |
|---|---|
| Antineoplastic agents cytarabine gemcitabine interleukin-2 (IL-2) mitomycin muromonab CD3 vinca alkaloids | <ul style="list-style-type: none"> Rare reaction with antineoplastic agents. Likely due to a cytokine-mediated inflammatory response. High incidence of cytarabine-induced NCPE noted with moderate or high doses in patients with leukemia. Although rarely seen with gemcitabine (0.1% incidence), NCPE may occur after a single dose, but is generally seen after repeated administration. IL-2-induced NCPE is dose related, with an estimated incidence of 3% to 20%. Although severe, it is reversible on discontinuation of IL-2. The combination mitomycin/vinblastine is associated with an estimated 2% incidence of NCPE. A cytokine release syndrome (CRS) commonly occurs with initial doses of muromonab CD3 and may result in serious, potentially fatal cardiorespiratory effects, including pulmonary edema (cardiogenic and noncardiogenic). Overhydration increases the risk of pulmonary edema. Pretreatment with methylprednisolone may reduce cytokine levels and incidence of CRS.^{3,62} |
| IV β_2 -agonists ritodrine terbutaline isoxsuprine | <ul style="list-style-type: none"> IV tocolytic β_2-agonists may cause peripheral vasodilation (with rapid reversal on discontinuation) and resultant large shift of intravascular volume into tissues, including the lungs. Incidence is 0.5% to 5%. It is not clear whether the pathogenic mechanism is cardiogenic or noncardiogenic based on conflicting reports of left ventricular function. Risk factors include excessive administration, infusions >24 hours, anemia, twin or multiple gestations, corticosteroid use, low serum K^+, sustained tachycardia (>140 beats/min). In addition to drug withdrawal, treatment should include oxygen supplementation, fluid restriction with diuretic therapy, and acid-base management.^{3,66} |
| Cocaine | <ul style="list-style-type: none"> Cocaine abuse is associated with numerous patterns of pulmonary reactions, including pulmonary edema. Whether the mechanism is cardiogenic or noncardiogenic remains speculative.²⁰ |
| Hydrochlorothiazide (HCTZ) | <ul style="list-style-type: none"> HCTZ-induced NCPE is rare, but has occurred within one hour of the first oral dose of HCTZ. Can also develop unexpectedly later in treatment. Usually a history of previous thiazide exposure with mild reaction. More commonly reported in women. May be an idiosyncratic reaction or direct toxic effect. Clinical recovery is rapid, usually within 1 to 2 days. Avoid thiazide diuretics. Other sulfonamide nonantibiotics (e.g., furosemide or glyburide) and antibiotics are not expected to cross-react.^{2,3,67} |
| Naloxone | <ul style="list-style-type: none"> High-dose or rapidly infused naloxone may cause pulmonary edema.⁶⁸ |
| Opiates heroin methadone morphine propoxyphene | <ul style="list-style-type: none"> Common complication of intoxication with opiates, including morphine, heroin, methadone, and propoxyphene.⁶⁴ Heroin-induced pulmonary edema is common after IV use. Heroin via injection or inhalation can cause other acute reactions, including bronchospasm. Secondary bacterial and aspiration pneumonias are frequent complications. Treatment consists of naloxone, in addition to respiratory support.⁶⁹ |
| Salicylates | <ul style="list-style-type: none"> Risk factors for salicylate reaction include serum levels >40 mg/dL, neurologic abnormalities, and proteinuria.³ |
| III. Pulmonary hypertension | <ul style="list-style-type: none"> Drug-induced primary (idiopathic) pulmonary hypertension (PPH) is rare, but life threatening. Early stages may be asymptomatic. The most frequent presenting symptom is exertional dyspnea, which may be present at rest as the disease progresses. Fatigue, weakness, chest pain, or syncope may also be reported. In addition to supplemental oxygen, management may include diuretics, inotropic agents, anticoagulants, prostacyclin analogues (e.g., epoprostenol), an endothelin receptor antagonist (e.g., bosentan), and calcium channel blockers (nifedipine, amlodipine, and diltiazem have been used most frequently) in patients with proven acute vasoreactivity.^{70,102} |
| Appetite suppressants fenfluramine derivatives amphetamine derivatives | <ul style="list-style-type: none"> The widely implicated anorectic agents are no longer marketed, but stimulants, in particular methamphetamine, have also been strongly associated with the development of PPH. Patients with idiopathic PPH were approximately ten times more likely to have had stimulant use than those with PPH and known risk factors.⁷¹ |
| Serotonin-specific reuptake inhibitors (SSRIs) | <ul style="list-style-type: none"> The risk of persistent pulmonary hypertension of the newborn (PPHN) in mothers taking SSRI antidepressants in the second half of their pregnancy is increased from 0.1% in the general population to 0.6%.⁷² |
| IV. Interstitial lung disease (ILD) | <ul style="list-style-type: none"> ILD is the most common drug-induced lung disease and can lead to respiratory failure. Presentation may be acute, subacute, or chronic. Symptoms include nonproductive cough, dyspnea, low-grade fever, and diffuse reticular infiltrate on chest x-ray. Diagnosis is based on temporal association between exposure and development of pulmonary infiltrate with meticulous exclusion of other potential causative factors. Types of ILD include interstitial pneumonia, pulmonary eosinophilia, bronchiolitis obliterans organizing pneumonia (BOOP), pulmonary fibrosis, and diffuse alveolar damage (DAD). Oxidant injury, either through the increased production of oxidants (e.g., bleomycin, cyclophosphamide, nitrofurantoin) or the inhibition of the antioxidant system (e.g., carmustine, cyclophosphamide, nitrofurantoin) accounts for the majority of drug-induced ILD.^{2,7,73} Management tends to be empirical. Following drug withdrawal, respiratory failure is commonly treated with high-dose methylprednisolone, with dose reduction and gradual taper after response. Respiratory distress is commonly treated with low-dose methylprednisolone (1 mg/kg or 60 mg/day) with gradual dose reduction. Immunosuppressants have been used for patients who cannot tolerate corticosteroids or who are unable to taper corticosteroids.²¹ |

(continued)

Table 25-2 Drug-Induced Pulmonary Disorders (Continued)

| Reaction/Drugs | Clinical Remarks |
|---|---|
| IV. a. Interstitial infiltrates/pneumonia Epidermal growth factor receptor (EGFR) antagonists/ tyrosine kinase inhibitors (TKIs) cetuximab erlotinib gefitinib imatinib Gemcitabine | <ul style="list-style-type: none"> • Interstitial infiltrates represent changes on the chest x-ray that occur from diseases involving the space between the alveolus and capillary. The infiltrates consist of fluid and/or cells that gather in this area of the lung. • EGFR antagonist/TKIs have been rarely associated with ILD. Gefitinib has been available longer, and there is more information available regarding gefitinib-induced ILD. The worldwide incidence of gefitinib-induced ILD is 1%, with a higher percentage noted in Japan (2%). It may be fatal in one-third to 40% of cases. There are also reports of ILD associated with erlotinib, and, rarely, cetuximab and imatinib. Because epidermal growth factor signaling may play an important role in the coordination of recovery from lung injury, EGFR inhibition may reduce the ability of pneumocytes to respond to lung injury.^{23,31} • Relatively uncommon reaction to gemcitabine. Risk factors include concomitant administration of bleomycin, vinorelbine, paclitaxel, docetaxel, or chest radiotherapy. The rate could be as high as 48% in patients with Hodgkin's disease who received a combination of gemcitabine and bleomycin. Median time to diagnosis was 48 days after initiation of gemcitabine. May be related to release of proinflammatory cytokines such as TNF-α.^{42,74} |
| Methotrexate | <ul style="list-style-type: none"> • Pulmonary infiltrate is the most common form of lung toxicity with methotrexate (1%–10%). Serum surfactant protein (SP-D) and protein KL-6 levels are related to the severity of the pneumonitis.^{75,76} |
| Nitrofurantoin | <ul style="list-style-type: none"> • Nitrofurantoin-induced acute pneumonitis may be one of the most common of the drug-induced diseases. In a series of patients reporting adverse effects from this drug, 43% reported acute pulmonary reactions. It does not appear to be dose related. Onset of symptoms, fever, dyspnea, and cough occurs within 1 month. Characterized by alveolar interstitial infiltrates, often without pleural involvement. In one series of cases, 52% of patients had infiltrates alone, 15% had infiltrates and effusions, and only 3% had only effusions.^{6,66} |
| Sirolimus | <ul style="list-style-type: none"> • Sirolimus has about an 8% incidence of pulmonary reaction. The major risk factors appear to be high dose (>5 mg/day) and high trough level (>15 ng/mL). Other potential risk factors include use of a loading dose, late exposure compared with de novo treatment, allograft dysfunction, hypervolemia, older age, and male gender.⁷⁷ |
| IV. b. Pulmonary fibrosis Cytotoxic drugs bleomycin busulfan carmustine cyclophosphamide interferon- α , - β mitomycin | <ul style="list-style-type: none"> • Pulmonary fibrosis is characterized by accumulation of excessive connective tissue in the lung caused by prolonged exposure to certain drugs. It may or may not be preceded by inflammation (pneumonitis). Evidence suggests that activation of the coagulation cascade and generation of coagulation proteases play a key role. The mean survival time for patients with pulmonary fibrosis has been estimated at five months, but earlier diagnosis and cessation of causative agent may have decreased mortality rates.^{7,78} • Bleomycin is the cytotoxic agent with the highest incidence of pulmonary toxicity (3%–40%). Risk factors include cumulative dose (threshold 400–450 U), older age (increases with each decade over 30 years), and radiation therapy. Pneumonitis rarely progresses to fibrosis, but can be fatal (1%). High concentrations of oxygen (FiO₂ \geq25%) should be avoided when possible due to the possible enhancement of pulmonary toxicity. Bleomycin should be immediately stopped at finding a decrease \geq15% in pulmonary function tests (diffusing capacity for carbon monoxide [DLCO] and vital capacity). Although response to corticosteroids is highly variable, prednisone 60–100 mg/day is recommended.^{7,14,17,79} • Busulfan pulmonary fibrosis (“busulfan lung”) is rare (1%–4%), but usually progressive and fatal. It can occur 1 to 10 years after drug discontinuation. Risk factors include cumulative dose (threshold 500 mg), radiation therapy, and length of therapy.^{7,14,20,66,79} • Carmustine risk factors include cumulative dose, young age (<7 years), oxygen therapy, and prior lung disease. In one study, 10% of patients receiving 1,000 mg/m² of carmustine and 100% of those receiving 1,400 mg/m² experienced pulmonary toxicity; overall incidence is approximately 30%–40%. The onset may be very delayed, with a reported occurrence 17 years after treatment. Nitrosourea-induced pulmonary fibrosis may not respond to corticosteroids.^{7,14,20,79} • The incidence of cyclophosphamide-induced pneumonitis is unknown, but may be largely underestimated. An early onset pneumonitis, occurring within 1 to 6 months of the start of therapy, generally responds to drug withdrawal. However, a delayed pneumonitis, developing after months or years of therapy, can result in progressive fibrosis and pleural thickening, with minimal response to drug withdrawal or corticosteroid therapy.⁶⁶ • Interferon-α, -β may include or exacerbate sarcoidosis. Sarcoidosis most often (90%) manifests in the lungs and can lead to pulmonary fibrosis.¹⁰³ • Mitomycin is associated with many types of pulmonary toxicities, including pneumonitis, NCPE, and pleural effusions. Incidence ranges from 10% (monotherapy) to 35% (combined with vinca alkaloids). Risk factors include radiation or oxygen therapy. In patients receiving mitomycin with other anticancer drugs, the FiO₂ concentration perioperatively should be maintained at <50%. Toxicity is not clearly dose dependent. A favorable response to corticosteroid therapy, possibly greater than for other chemotherapy-induced pulmonary injuries, has been reported.^{7,66,79} |

Table 25-2 Drug-Induced Pulmonary Disorders (Continued)

| Reaction/Drugs | Clinical Remarks |
|---|--|
| Non-cytotoxic agents amiodarone bromocriptine cabergoline ergot derivatives heroin (IV) methysergide nitrofurantoin pergolide IV abuse of oral drugs | <ul style="list-style-type: none"> The incidence of amiodarone-induced pulmonary toxicity is dose related: 0.1%–0.5%, up to 200 mg/day; 5%–15%, up to 500 mg/day; and as high as 50%, in doses of 1,200 mg/day. Can occur within 2 weeks or up to more than a decade into treatment. Amiodarone therapy may enhance drug-induced pulmonary toxicity with cyclophosphamide. Length of recovery time or recurrence may be correlated with high body mass index.^{2,32,80–82} Pulmonary fibrosis appears to be a class effect of ergot-derived dopamine agonists (pergolide, bromocriptine, cabergoline, methysergide). Condition is often irreversible. Pergolide was recently withdrawn from the U.S. market due to the potential for valvulopathy.^{99–101} Nitrofurantoin is involved in several forms of pulmonary injury. Most common are an acute hypersensitivity pneumonitis and a chronic alveolitis/fibrosis (nitrofurantoin lung), which do not overlap clinically (see interstitial infiltrates, BOOP, pulmonary eosinophilia, and pleural effusions). Overall estimated incidence of pulmonary injury is <0.01%, with chronic reactions occurring far less commonly than acute. The chronic form is related to dose and duration of therapy, and is commonly found in patients on long-term therapy for persistent bacteriuria. It is characterized by insidious, progressive dyspnea, nonproductive cough, interstitial pneumonitis, and fibrosis, which may impair pulmonary function permanently and may continue to deteriorate. Onset may occur 6 months to many years after either continuous or intermittent use. The utility of corticosteroids in the management of nitrofurantoin pulmonary fibrosis is unclear.^{6,7,66,83} The use of IV heroin and of drugs intended for oral use (e.g., crushed methylphenidate pills) can lead to the development of interstitial or vascular foreign body granulomas (talcosis) from the injection of filler materials used as tablet binders or used to cut heroin. Symptoms range from dyspnea and cough to pulmonary hypertension, right-sided heart failure, and sudden death. Radiographs may be normal or show diffuse micronodular densities. Bronchoalveolar lavage (BAL) contains increased lymphocytes and intracellular and free talc. Corticosteroids do not provide consistent improvement.^{66,69} |
| IV. c. Bronchiolitis obliterans organizing pneumonia (BOOP)/cryptogenic organizing pneumonia | <ul style="list-style-type: none"> BOOP is an inflammation of the lungs characterized by alveolar fibrosis. The clinician needs to distinguish between underlying connective tissue disease (e.g., polymyalgia) and drug-induced disease. Clinical signs and symptoms include dyspnea, low-grade fever, and, occasionally, acute pleuritic chest pain. Typically, chest films show migratory opacities if taken over a period of weeks or months. There may be occasional “normal” chest x-rays even with continued exposure. The pattern of the opacities may be suggestive of the causative agent. Although resolution of symptoms and radiographic abnormalities generally respond to the discontinuation of medication or corticosteroid therapy, in rare cases, the outcome is fatal.^{2,5} More than 20 medications are associated with BOOP.⁵ Radiographic patterns: Patchy, stellate shadows or diffuse infiltrates may suggest nitrofurantoin. Multiple shaggy nodules may suggest bleomycin, carbamazepine, minocycline, or statins. Biapical masses have been associated with mesalamine or sulfasalazine.² |
| Antimicrobials amphotericin B cephalosporins minocycline nitrofurantoin | |
| Cytotoxic drugs bleomycin doxorubicin | |
| Cardiovascular drugs acebutolol amiodarone | |
| HMG CoA reductase inhibitors (statins) | |
| Anti-inflammatory drugs gold mesalamine sulfasalazine | |
| Miscellaneous carbamazepine cocaine interferon- α , - β penicillamine ticlopidine | |
| V. Pulmonary eosinophilia | <ul style="list-style-type: none"> Pulmonary eosinophilia is characterized by pulmonary infiltration of eosinophils in alveolar spaces, the interstitium, or both. When found with peripheral eosinophilia, it is often called PIE (pulmonary infiltrates with eosinophilia) syndrome. Diagnosis is confirmed by demonstration of an excess of eosinophilia either in lung biopsy or in BAL. Loeffler syndrome is an acute eosinophilic pneumonia with transient pulmonary infiltrates and peripheral blood eosinophilia, characterized by mild or absent respiratory symptoms. Churg-Strauss syndrome (CSS) is a systemic, multiorgan necrotizing vasculitis that includes pulmonary eosinophilia. Drug-induced cases of pulmonary eosinophilia typically show ground-glass opacities in a peripheral and upper lobe distribution.^{84–86} |

(continued)

Table 25-2 Drug-Induced Pulmonary Disorders (Continued)

| Reaction/Drugs | Clinical Remarks |
|--|---|
| V. Pulmonary eosinophilia (Cont'd) | <ul style="list-style-type: none"> Corticosteroids are indicated in severe cases; however, because eosinophils are very sensitive to corticosteroids, their complete disappearance from the bloodstream within hours of administration may obscure the diagnosis.^{84,86} Many drugs have been implicated in causing pulmonary eosinophilia, but the number with established causality with multiple case reports is much less. The drugs most commonly causing pulmonary eosinophilia are antimicrobial agents (penicillins, clarithromycin, and levofloxacin) and NSAIDs.⁸⁶ |
| Isotretinoin | <ul style="list-style-type: none"> Isotretinoin-induced PIE is rare, but in one case showed >20% pleural fluid eosinophilia (>10% of nucleated cells).⁶ |
| Leukotriene antagonists (LTAs) zafirlukast zileuton | <ul style="list-style-type: none"> Cases of LTA-induced CSS are suggested by case reports and postmarketing surveillance. It is not clear if this rare disorder is a direct drug effect or an unmasking of a pre-existing condition on withdrawal of corticosteroids for asthma on initiation of LTA therapy.^{43,85} |
| Minocycline | <ul style="list-style-type: none"> Minocycline has been associated with pulmonary lupus, hypersensitivity pneumonitis, pleural effusions, and eosinophilic pneumonia. Several cases of respiratory distress have also been reported, including one of a relapsing form of hypersensitivity eosinophilic pneumonia that required mechanical ventilation.^{86,87} |
| Nitrofurantoin | <ul style="list-style-type: none"> Most cases of nitrofurantoin-induced acute pneumonitis have peripheral eosinophilia (in 83% of patients) and lymphopenia. Pleural eosinophilia has been described (see pulmonary fibrosis, interstitial pneumonia, BOOP, and pleural effusions). The acute effects may be observed within 1 month.^{6,66,83} |
| NSAIDs | <ul style="list-style-type: none"> There have been case reports of NSAIDs (ibuprofen, naproxen, diclofenac, indomethacin, sulindac, and meloxicam) causing PIE. Prevalence of NSAID-induced PIE is likely underestimated.^{88–90} |
| VI. Pleural inflammation | <ul style="list-style-type: none"> Drug-induced pleural reactions are rare compared with those affecting the parenchyma. Pleural reactions range in presentation from asymptomatic effusion to acute pleuritis to symptomatic pleural thickening. Common symptoms of pleural effusion are pleuritic chest pain, dyspnea, and cough. Suggested mechanisms for the development of drug-induced pleural disease include hypersensitivity or allergic reaction, direct toxicity, increased production of oxygen-free radicals, suppression of antioxidant defenses, and chemically-induced inflammation.⁶ |
| Dantrolene | <ul style="list-style-type: none"> The incidence of dantrolene-induced pleural effusion is rare, but likely underestimated. Onset has occurred from 2 months to 12 years of initial administration. Effusion is usually unilateral, with peripheral and pleural fluid eosinophilia. Fever may be present. Structural similarity to nitrofurantoin suggests an immunologic basis for this reaction. Drug withdrawal results in rapid symptomatic recovery; however, it may take several months for complete resolution of the effusion.^{6,91,92} |
| Ergot alkaloids bromocriptine cabergoline methysergide pergolide | <ul style="list-style-type: none"> Pleural effusions or thickening can result from the chronic administration of ergot alkaloids, including bromocriptine, cabergoline, and pergolide. Approximately 6% of patients receiving bromocriptine develop pleuropulmonary complications. Fibrosis typically occurs 12 to 48 months after initiation of therapy and appears to be dose related. Pleural lymphocytosis or eosinophilia may occur. Pleural effusion responds to drug withdrawal; however, fibrosis may not completely resolve.^{6,91} Less than 1% of patients taking methysergide experience pleuropulmonary reactions (pleural effusions and fibrosis). Symptoms occur 1 month to 3 years after initiation of therapy. Increased stimulation of fibroblast activity via increased levels of serotonin is a proposed pathogenic mechanism. Symptoms improve on discontinuation; however, pleural thickening may persist.^{6,91} |
| IL-2 | <ul style="list-style-type: none"> IL-2-induced pleuropulmonary complications occur in approximately 75% of patients, with pleural effusions in approximately 50% of patients receiving IL-2. Capillary leak results in effusions and noncardiogenic pulmonary edema. Pleural effusions may persist in 17% of patients at 4 weeks after drug discontinuation.⁶ |
| Nitrofurantoin | <ul style="list-style-type: none"> Up to one-third of acute nitrofurantoin-induced pleuropulmonary reactions may include pulmonary effusions, rarely without concomitant parenchymal involvement. In contrast, pleural effusions are rare with the chronic nitrofurantoin syndrome. Effusions are usually bilateral and responsive to prompt drug withdrawal. Severe symptoms can be treated with corticosteroids.⁶ |
| VII. Diffuse alveolar hemorrhage (DAH) and vasculitis | <ul style="list-style-type: none"> DAH is characterized by bleeding from pulmonary capillaries, leading to the accumulation of red blood cells in the alveolar spaces. Symptoms include varying degrees of hemoptysis (may be absent in up to 33% of cases), cough, and progressive dyspnea. Hematocrit is reduced with hemorrhagic BAL. Presentation is usually acute, often resulting in respiratory failure by intra-alveolar clotting. DAH can develop in many systemic conditions, and it is difficult to prove drug causality. Drug-related pathogenic mechanisms include hypersensitivity reaction, direct toxicity diffuse alveolar damage (DAD), and coagulation defects. Pulmonary capillaritis, the most frequent underlying histology, and pulmonary veno-occlusive disease (PVOD), a fibrous obliteration of pulmonary venules and small veins, are considered autoimmune reactions.^{2,93} |

Table 25-2 Drug-Induced Pulmonary Disorders (Continued)

| Reaction/Drugs | Clinical Remarks |
|---|---|
| Anticoagulants Dextran 70 Platelet aggregation inhibitors Platelet glycoprotein IIb/IIIa inhibitors Thrombolytic agents | <ul style="list-style-type: none"> • Anticoagulant and thrombolytic agents cause pulmonary hemorrhage without damage to the interstitial compartment. Anticoagulant-related bleeding is generally managed by withdrawal of the drug. In addition to drug withdrawal, the addition of corticosteroids may be indicated in other forms or significant cases of DAH.^{2,93} |
| Chemotherapeutic agents bleomycin carmustine gemcitabine mitomycin vinca alkaloids | <ul style="list-style-type: none"> • Chemotherapeutic agents cause direct epithelial injury and damage to the alveolar capillary basement membrane, which can result in DAH. Outcomes are poor (50%–100% mortality), and although high-dose corticosteroid therapy is the only recommended treatment, effectiveness is questionable.⁹³ • Bleomycin, carmustine, gemcitabine, mitomycin, and vinca alkaloids have been associated with the development of PVOD.⁹³ |
| Cocaine Hydralazine Mitomycin Nitrofurantoin Penicillin Phenytoin Propylthiouracil | <ul style="list-style-type: none"> • Pulmonary capillaritis has occurred with phenytoin and propylthiouracil.⁹³ • Other drugs associated with hypersensitivity reactions with concomitant DAH include penicillin, sulfasalazine, and hydralazine.⁹³ • Smoking crack cocaine, either due to cocaine or the residual solvents, may cause hemoptysis and pulmonary infiltrates due to DAH. Onset is usually within hours and is reversible on discontinuation. There is also a possible relationship between IV cocaine and alveolar hemorrhage.^{69,93} |
| VIII. Diffuse alveolar damage (DAD) | <ul style="list-style-type: none"> • In DAD, the alveolar epithelial cells are sloughed, and the lung interstitium becomes edematous. Chronic inflammation and fibroproliferation of the alveolar walls can present early in the process. The histopathological basis for ARDS is DAD. In severe cases, DAH can develop with resultant hemoptysis. DAD presents with dyspnea, diffuse pulmonary infiltrates, and ARDS unresponsive to conventional therapy. DAD of recent onset may respond to corticosteroid therapy; however, chemotherapeutic agent-induced DAD carries a poor prognosis.^{2,93} • Chemotherapeutic agents associated with the development of DAD, which may be accompanied by DAH, include antibiotics, alkylating agents, antimetabolites, nitrosoureas, podophyllotoxins, tretinoin, gefitinib, imatinib, irinotecan, interferon-α, IL-2, and sirolimus. The reaction is more severe and frequent with multiple drug treatments or with concurrent radiation therapy or oxygen.² • Noncytotoxic drug-induced DAD is unusual, but has been associated with aspirin, narcotics, crack cocaine, nitrofurantoin, carbamazepine, penicillamine, hydrochlorothiazide, and simvastatin.² |
| Alkylating agents Antibiotics Antimetabolites Aspirin Carbamazepine Chemotherapeutic agents Cocaine Epidermal growth factor receptor (EGFR) antagonists Hydrochlorothiazide Interferon- α IL-2 Irinotecan Narcotics Nitrofurantoin Nitrosoureas Penicillamine Podophyllotoxins Simvastatin Sirolimus | |
| IX. Drug hypersensitivity syndrome (DHS) | <ul style="list-style-type: none"> • DHS is a systemic idiosyncratic reaction defined by the presence of fever, rash, and organ involvement, including pneumonitis or pulmonary infiltrates. It is associated with aromatic anticonvulsants (phenytoin, carbamazepine, phenobarbital, felbamate, lamotrigine, oxcarbazepine, and zonisamide), and is most commonly reported with phenytoin, carbamazepine, and phenobarbital. DHS develops within 8 weeks of treatment, with a 1 in 1,000 to 10,000 incidence.^{2,94} Clinical presentations may involve dermatologic, hematologic, lymphatic, or internal organ systems. Pulmonary reactions include lymphoid interstitial pneumonia, interstitial lung disease, eosinophilic pneumonia, and pleural effusion. Management involves drug withdrawal, supportive care and corticosteroid therapy. Although improvement occurs in a few days after drug discontinuation for most patients, a few experience acceleration of the disease. Continued corticosteroid therapy may be necessary to avoid relapse. There is a mortality rate of up to 10% for DHS. Rechallenge with the drug or related drugs results in relapse of increased severity.² • Drugs known to cause DHS include allopurinol, anticonvulsants (particularly carbamazepine, phenytoin, and phenobarbital), and sulfonamides. Other drugs less commonly associated with DHS include abacavir, atenolol, azathioprine, bupropion, captopril, diltiazem, gold, leflunomide, minocycline, nevirapine, NSAIDs, sulfasalazine, and trimethoprim.^{2,94} |
| Allopurinol Anticonvulsants carbamazepine phenytoin Sulfonamides | |

2. What is the postulated mechanism for bleomycin toxicity?

Bleomycin toxicity is attributed to direct cytotoxic injury to the lung epithelium, likely caused by free radical generation following binding of the drug to DNA. It is postulated that the relative lack of hydrolase (an enzyme necessary for degradation of bleomycin) in the lung may contribute to increased pulmonary levels of the drug with resultant toxicity. Studies in animals have confirmed that bleomycin is concentrated in the lungs and skin.¹⁶

3. How can A.E. be monitored for pulmonary toxicity?

There are no pathognomonic signs or symptoms of bleomycin-related pulmonary damage. Patients usually present with dyspnea, tachypnea, and a nonproductive cough, which can develop from days to weeks. Rales, initially at the bases and then throughout the lungs, may be present on physical examination. Signs and symptoms usually precede changes on the chest radiograph. The utility of pulmonary function tests as an indicator for the extent of the pulmonary damage produced by bleomycin is controversial. Spirometry usually shows a restrictive pattern in the presence of cytotoxic drug-induced pulmonary damage; however, such changes may not always be present in patients with subclinical bleomycin-induced pulmonary fibrosis. For this reason, pulmonary function tests are of questionable predictive value.^{16,20}

4. How should A.E. be managed?

Because A.E.'s total cumulative dose of bleomycin is 360 U, he should not receive further treatments of bleomycin to avoid exceeding the recommended total cumulative dose of 400 U. His treatment team should be apprised of A.E.'s treatment with bleomycin to ensure management of the oxygen concentration as recommended in bleomycin-exposed patients.^{13,15}

TYROSINE KINASE INHIBITOR-INDUCED INTERSTITIAL LUNG DISEASE

5. J.T., a 55-year-old male with Stage IV, performance status 1, non-small cell lung cancer (NSCLC), adenocarcinoma, completed four cycles of cisplatin/etoposide with disease stabilization. Prior to chemotherapy, he had undergone radiotherapy with 20 treatments of 200 centigray (cGy) per treatment, for a total of 4,000 radiation doses (rads). On return from visiting his family in Japan, 5 months after completing therapy, treatment with erlotinib 150 mg orally was initiated due to disease progression. After 1 month of erlotinib therapy, J.T. was admitted to the hospital due to complaints of increasing cough and dyspnea at rest. He denied resumption of smoking, which he had quit on diagnosis of lung cancer. He was afebrile. Crackles were audible bilaterally. His pulmonary function test results were indicative of a restrictive condition: forced vital capacity (FVC) 61.5% of predicted, forced expiratory volume in 1 second (FEV₁) 69.5% of predicted, FEV₁/FVC ratio 87.7%, 110% predicted, and diffusion capacity for carbon monoxide (DLCO) 48.6% of predicted. Parenchymal shadows were present on his initial chest radiograph. The subsequent high-resolution computed tomography (HRCT) revealed bilateral diffuse ground-glass infiltrates and interlobular septal thickening of the lower lung fields. Lab results included white blood cell count 6,600/mm³, erythrocyte sedimentation rate

(ESR) 30 mm/hour (normal, ≤10 mm/hour in males), and normal electrolyte panel. Electrocardiogram and echocardiogram were normal. Blood and sputum were negative for culture and various infectious pathogen antibody titers. What causes of dyspnea should be investigated in this patient?

The potential causes of dyspnea in a patient with NSCLC include infection, cancer progression, pulmonary embolism (may develop in up to 20% of lung cancer patients), fluid overload, and drug-induced pulmonary disorder. His laboratory and blood culture results argue against the presence of infection. Findings are not suggestive of heart failure or pulmonary embolism. The chest radiograph is not suggestive of disease progression; however, bronchoscopy and bronchoalveolar lavage (BAL) may be useful in some cases of dyspnea in patients with NSCLC to assess for cancer progression versus opportunistic infections.²¹

6. What findings would be suggestive of a tyrosine kinase (TNK) inhibitor-induced interstitial lung disease (ILD)?

A definitive diagnosis depends on the rigorous elimination of other potential etiologies. Other possible causes can be ruled out based on clinical criteria. The short interval between the initiation of erlotinib therapy and the onset of symptoms should raise suspicion that these events are related. The onset of symptoms with erlotinib-induced lung injury has been reported as early as 5 days after start of therapy, but has also been reported after 9 months (median 39 days). Symptoms have typically appeared in the first 1 to 2 months of gefitinib treatment. The presence of bilateral diffuse ground-glass opacities on HRCT is a characteristic finding of drug-induced ILD, although it may not be definitive.^{21–23}

7. Why might J.T. have been at greater risk for TNK-inhibitor ILD?

TNK-inhibitors gefitinib and erlotinib are rarely associated with the development of ILD. In the data reviewed by the U.S. Food and Drug Administration (FDA), ILD occurred in ≤1% of patients receiving either agent. The global incidence of gefitinib-induced ILD is about 1%, with a higher incidence in Japan (2%). Several smaller studies in Japan have reported incidences ranging from 4% to 6%. Reasons for higher incidences in Japan may be due to genetic differences involving polymorphisms of transporter genes and drug-metabolizing enzyme genes.²⁴ Risk factors identified for gefitinib-induced ILD are male gender, history of smoking, pre-existing pulmonary fibrosis, or other pulmonary comorbidities and radiotherapy.^{24,25}

8. J.T.'s physician decides to treat J.T. for TNK-inhibitor ILD. How should he proceed, and what recovery might be expected for J.T.?

There is no treatment specific to TNK-inhibitor-induced ILD. Although the discontinuation alone of the TNK-inhibitor may result in symptom resolution, corticosteroids can be used to treat respiratory symptoms.²⁶ The treatment of drug-induced ILD tends to be empirical, and the optimal dose and duration of corticosteroids for the treatment of most ILDs is not known.^{21,27} For patients with severe symptoms of drug-induced ILD, high-dose intravenous (IV) methylprednisolone (e.g., 250 mg four times daily for 3 days) is commonly used. The dose is reduced to a maintenance

oral dose (e.g., 0.5–1 mg/kg/day) for several weeks before a gradual dose reduction.^{21,29} One of many suggested regimens for the tapering of oral corticosteroids (not specific to ILD treatment) recommends decreasing by ≤ 2.5 mg prednisone equivalents (e.g., 2 mg methylprednisolone) every 1 to 2 weeks.²⁸ For less severe symptoms, initiation with oral methylprednisolone (1 mg/kg/day or 60 mg/day) is commonly used to treat drug-induced ILD.²¹

In a retrospective review of four patients diagnosed with gefitinib-induced ILD, all patients discontinued gefitinib and responded favorably to IV methylprednisolone up to 1 g/day. Therapy was reduced to oral maintenance doses of 20 mg to 30 mg/day of oral prednisone.²⁴ Two case reports of erlotinib-induced ILD reported response to oral steroids (doses not specified). A third case report described the successful resolution of symptoms following a course of 250 mg of IV methylprednisolone given every 6 hours for 3 days, followed by oral prednisone 60 mg daily, with tapering of dose after 2 weeks. Several of these patients also required supplemental oxygen.^{23,29,30} Not all reported cases of TNK-inhibitor-induced ILD have noted successful resolution with corticosteroid therapy.²⁴ Although immunosuppressive agents (azathioprine and cyclophosphamide 1–2 mg/kg/day) with or without corticosteroids have been tried in the treatment of ILDs with variable success, their role remains to be determined.²⁷ Prognosis can vary significantly from complete resolution to death. Cessation of therapy can result in spontaneous resolution after 2 weeks, or the patient may respond to corticosteroid therapy. If diagnosed early, prognosis with treatment is good. However, permanent and irreversible loss of lung function may result once fibrosis has occurred. Some patients may require supplemental oxygen.²⁹ Gefitinib-induced ILD has been associated with high mortality rates (i.e., one-third in one report and 40% in another small study).^{23,26,31}

Based on available evidence from case reports, J.T.'s physician decided to discontinue erlotinib and administer IV methylprednisolone 250 mg every 6 hours for 3 days. Thereafter, oral prednisone 60 mg daily was given for 2 weeks, with rapid reduction of lung opacities. Dosage was then tapered.

AMIODARONE-INDUCED PULMONARY TOXICITY

9. R.W., a 55-year-old man admitted with a 5-day history of fatigue, exertional dyspnea, and tachypnea, reports that his symptoms have progressively worsened to the point at which he can no longer walk his dog around the neighborhood without feeling “out of breath.” He denies experiencing coughing or chest pain. He has a medical history of recurrent ventricular tachycardia and a 10-year history of hypertension controlled with benazepril. Physical examination reveals a tachypneic, tired-looking man with no signs of congestive heart failure evident on physical examination. Diffuse inspiratory crackles are audible on lung auscultation. His blood pressure and temperature are unremarkable. A chest radiograph shows patchy interstitial infiltrates, and HRCT reveals diffuse ground-glass opacities. BAL reveals the appearance of foamy alveolar macrophages and lamellated inclusion bodies. All laboratory tests are within normal limits, except for an elevated ESR. His medications on admission include amiodarone 400 mg every day (QD; initiated 12 months previously) and benazepril 40 mg

QD. What signs and symptoms are consistent with a diagnosis of amiodarone-induced pulmonary toxicity in R.W.?

Amiodarone-induced pulmonary toxicity (APT) is one of the leading causes of amiodarone discontinuation. The estimated risks of APT from clinical trials range from 1% to 5%; however, risk appears to be linked to indexes of exposure (a composite of daily dosage and duration of treatment).^{2,26} APT can appear within a few days following an initial loading dose or after more than a decade of treatment, with an average onset of 18 to 24 months into treatment. APT is not a single clinical entity and can present as various patterns of pulmonary toxicity, including interstitial pneumonitis, organizing pneumonia, ARDS, pulmonary nodules, and pulmonary fibrosis. Patients commonly present with an insidious progression of symptoms. Fatigue and progressive dyspnea often present for several weeks to months prior to diagnosis. Nonproductive cough, pleuritic chest pain, crackles, weight loss, and hypoalbuminemia can also be present. APT is characterized by alveolar, interstitial, or mixed alveolar interstitial shadows on imaging, and commonly presents with an asymmetric pattern of involvement (in contrast to other drug-induced pulmonary disorders). Differential diagnosis includes left ventricular dysfunction, pulmonary infarction, bronchoalveolar carcinoma or lymphoma, and pulmonary toxicity caused by other commonly prescribed cardiovascular drugs. A thorough physical examination is vital to exclude a diagnosis of congestive heart failure because this population is at high risk for this disorder.^{2,32,33}

The earliest sign of APT is typically a precipitous decrease in DLCO. However, this finding alone does not establish a diagnosis. Conversely, a lack of clinically meaningful APT is indicated by the presence of a stable diffusing capacity. Leukocytosis, increased circulating lactate dehydrogenase levels, and an elevated ESR are often noted in patients with APT. Histologic appearances of the lung include septal thickening; interstitial edema; nonspecific inflammation; fibrosis; and lipids within the interstitial, endothelial cells, and alveolar spaces. A large number of free foamy intra-alveolar macrophages support a diagnosis of APT. The role of BAL in the diagnosis of APT is controversial, as a wide range of abnormalities can be found in the BAL of patients with APT. Foam cells with lamellar inclusions in BAL of patients chronically exposed to amiodarone is a routine finding, not necessarily indicative of drug toxicity. However, the diagnosis of classic APT is unlikely in the absence of foam cells. R.W.'s pulmonary complaints, radiographic findings, elevated ESR, and BAL results are all consistent with a diagnosis of APT.^{2,32,33}

10. What are risk factors that predispose patients to developing amiodarone-induced pulmonary toxicity?

Risk factors include a higher drug dosage and longer duration of therapy. Prevalence increases from 0.1% to 0.5% with doses up to 200 mg/day to 5% to 15% with doses up to 500 mg/day, and up to 50% with doses of 1,200 mg/day. A review of pulmonary toxicity associated with low-dose amiodarone reported the average age of affected patients was 77 years; the elderly may be at higher risk for APT. Other risk factors include pre-existing lung disease, male gender, and exposure to high concentrations of oxygen, as during surgical procedures.^{2,32} R.W.'s overall exposure to amiodarone (dose and duration)

may have increased his risk of developing pulmonary toxicity.^{2,32,33}

11. What is the likely mechanism of APT in R.W.?

During chronic therapy, amiodarone and its metabolite desethyl-amiodarone (DEAm) accumulate extensively in the tissue of the lung, as well as liver, skin, thyroid, and eye. At therapeutic serum concentrations, both agents are toxic to lung cells, and this toxicity is likely increased by the 100-fold and 500-fold concentration ratio of amiodarone and DEAm in lung tissue. The localization of amiodarone and DEAm, respectively, in cell lysosomes leads to blockage of the turnover of endogenous phospholipids, which then also accumulate in the lung and lead to the characteristic finding of foamy lipid-laden macrophages in BAL or lung tissue of patients receiving chronic amiodarone therapy. Efflux from tissues is slow, and significant amounts of both compounds have been found in the lungs of patients on autopsy 1 year after treatment cessation.^{2,32,33}

12. How should R.W. be managed?

Due to the persistence of significant levels of amiodarone and DEAm in lung tissues, the sole withdrawal of amiodarone may not result in improvements in symptoms or imaging. Patients showing substantial involvement on imaging or hypoxemia should be given corticosteroids to try to hasten recovery and possibly minimize the likelihood of lung fibrosis. Continued exposure to amiodarone after discontinuation of the drug necessitates the administration of corticosteroid therapy for extended periods of time to prevent recurrences of symptoms during tapering, which have been reported up to 8 months after the discontinuation of amiodarone. Recurrences may be more severe than the initial episode of APT and may lead to respiratory failure or death. Six months, and more often 1 year, is a reasonable estimate for duration of corticosteroid therapy. Although no data from controlled studies are available, accumulated clinical evidence supports the use of corticosteroids when there are potentially life-threatening signs due to APT. Good data on the dosing and duration of corticosteroid therapy are lacking. However, one suggested regimen is to initiate with a sufficient dosage (e.g., 0.75–1 mg/kg of oral prednisolone or equivalent, or 40–60 mg daily) and maintain pending clinical and radiographic response.^{32,34,35} The long-term use of corticosteroids requires monitoring for adverse effects, including opportunistic infections. Following tapering over at least 2 to 6 months and discontinuation of corticosteroid therapy, patients should be monitored for recurrence of APT.^{2,32,33,35}

Clinical symptoms may resolve within 2 to 4 weeks; however, chest radiographic findings usually clear over 3 months or more. In some cases, pulmonary toxicity may actually progress before it begins to resolve. However, there is a 10% mortality rate from APT, which increases to 21% to 33% for patients admitted to the hospital for amiodarone pneumonitis. The mortality rate is 50% for those who develop ARDS, even if the drug is discontinued and IV corticosteroid therapy is given.^{2,32,33} The routine use of corticosteroids in patients with persistent ARDS (>14 days) is currently not recommended, although the place of corticosteroid therapy in the treatment of acute ARDS remains controversial.^{36,37} Other pharmacotherapies (e.g., beta-adrenergic agonists, prostaglandin E1, indomethacin) have not shown any survival benefit.³⁷

It was decided that R.W. would likely respond to the discontinuation of amiodarone, followed by treatment with oral corticosteroids. He was started on 40 mg of prednisone with radiologic improvement noted after 2 weeks. The prednisone was then tapered gradually over 6 months. Sotalol treatment was initiated to address R.W.'s ventricular tachycardia.

13. What steps could possibly lead to the prevention or earlier detection of APT?

Given the potential for severe consequences of APT, the early detection of the APT is desirable. However, it has not been proved that earlier diagnosis necessarily improves prognosis. There are currently no evidence-based standards for screening for APT in patients receiving amiodarone. Candidates for amiodarone therapy should be carefully selected, and amiodarone should be titrated to the lowest possible effective dose. The 2007 Heart Rhythm Society guide for clinicians treating patients with amiodarone recommends that chest x-ray and pulmonary function tests, including DLCO, be obtained at baseline and on clinical suspicion of pulmonary toxicity. A pulmonologist should be consulted for patients with abnormal chest x-ray, abnormal pulmonary function test, or unexplained new cough or dyspnea.³⁴ The optimal frequency of monitoring has not been determined; however, more frequent monitoring of pulmonary function and/or imaging every 3 to 6 months should be undertaken in patients with the greatest risk of developing APT (e.g., those with poor lung function or previous pneumonectomy). Although yearly serial pulmonary function testing in patients receiving conventional doses of amiodarone is likely unrewarding because APT is uncommon in this subset of patients, such patients should be instructed to contact their physicians if they experience symptoms indicative of pulmonary toxicity (e.g., cough, shortness of breath).^{32,38}

GEMCITABINE-INDUCED PULMONARY TOXICITY

14. C.B. is a 66-year-old man with NSCLC. One year previously, he had a right upper lobe (RUL) wedge resection and radiation therapy. He now presents with a large local recurrence and enlarged bilateral mediastinal lymph nodes. Weekly IV gemcitabine treatment is initiated. He receives gemcitabine 1 g/m² on days 1, 8, and 15, followed by a 2-week rest period. After the second cycle, he presents to the emergency department with complaints of dyspnea on exertion. Physical examination reveals that he has significant peripheral edema, and his vital signs are notable for an O₂ saturation of 82% on room air. C.B. has maintained good room air saturations at all times, despite a 100 pack-year history of smoking and a history of RUL wedge resection. A chest radiograph shows increased interstitial markings. C.B. is admitted to the hospital for further workup of his dyspnea.

How do patients with gemcitabine-induced pulmonary toxicity usually present?

Different terms have been used to describe gemcitabine-associated lung injuries with similar presentations (i.e., capillary leak syndrome, noncardiogenic pulmonary edema, interstitial pneumonitis, acute pneumonitis, ARDS, acute pulmonary toxicity, or acute lung injury). Mild dyspnea occurs in 25% of patients receiving gemcitabine, but there have been only occasional reports of severe lung injury from initial clinical trials or reports to the FDA or manufacturer. Although most

cases of gemcitabine-induced pulmonary toxicity are mild and self-limiting, severe lung injury (22%–42%) was recently reported as the dose-limiting toxicity when combination gemcitabine regimens were administered to patients with Hodgkin disease.⁴¹ The most common clinical findings in a review of severe gemcitabine-associated lung injury reports were dyspnea (70%), fever (35%), pulmonary infiltrates (22%), cough (19%), respiratory distress (18%), and hypoxia (14%). The median time to diagnosis was 48 days (range, 1–529 days). Pulmonary toxicity may develop with the first dose of gemcitabine, but more commonly develops after multiple cycles; however, it is not clear whether this is dose related.^{39–42}

15. How is gemcitabine-induced pulmonary toxicity diagnosed?

As with other drug-induced pulmonary toxicities, this is a diagnosis of exclusion. Temporal association is important, as is ruling out other causes such as infection, metabolic causes, cardiac compromise, lymphangitic spread, and disease progression. Typical radiologic features include diffuse interstitial and alveolar changes on chest radiograph. Computed tomography shows a ground-glass appearance in conjunction with increased interstitial markings.⁴²

16. What is the mechanism of gemcitabine-induced pulmonary toxicity?

The mechanism of gemcitabine-induced lung toxicity is unknown. Cytarabine, another pyrimidine analog, has been known to cause a syndrome of noncardiogenic pulmonary edema in 13% to 28% of patients and develops after treatment with conventional and high-dose regimens. Histopathological studies of these patients show interstitial and intra-alveolar proteinaceous edema consistent with ARDS. It is postulated

that damage to the capillary endothelial cells causes the leakage of the fluid resulting in pulmonary edema. In view of the structural and metabolic similarities between the two drugs, it is likely that they share the same mechanism of pulmonary injury.⁴²

17. What risk factors that predispose C.B. to the development of gemcitabine-associated pulmonary toxicity?

There is a subset of patients that appears to be more prone to developing pulmonary symptoms, including men, age older than 65 years, significant smoking history, concomitant administration of bleomycin, chemotherapeutic agents known to release cytokine mediators of inflammation (e.g., paclitaxel, docetaxel, or vinorelbine), concomitant or prior radiotherapy, and primary lung neoplasm. C.B. has four such risk factors, including age, a 100 pack-year smoking history, and NSCLC treated with radiation therapy.^{39,41,42}

18. How should C.B. be managed?

It has been reported that gemcitabine-associated pulmonary toxicity is generally self-limiting on discontinuation and is often responsive to glucocorticoid therapy alone or plus a diuretic. However, fatal outcomes have resulted from high-risk combinations of chemotherapeutic agents. Gemcitabine should be discontinued, and C.B. should be started on oral corticosteroid therapy (prednisone 40–100 mg has been used) and low-dose furosemide (20–40 mg has been used).^{39,41,42}

ACKNOWLEDGMENTS

We want to thank Randolph H. Noble, MD, FCCP, and Mary E. White, MLS, for their invaluable assistance in the preparation of this chapter.

Upper gastrointestinal (GI) disorders include a wide spectrum of maladies that range in importance from simple discomfort to life-threatening illness and include dyspepsia, peptic ulcer disease (PUD), gastroesophageal reflux disease (GERD), and upper GI bleeding. The majority of upper GI disorders are acid-related diseases in which gastric acid plays an important role in their development, progression, and treatment. In the United States, over 40 billion dollars is spent yearly treating GI disorders, with over 10 billion dollars of this amount spent on proton pump inhibitors (PPIs), a primary pharmacotherapeutic option used to reduce gastric acid secretion.^{1,2} These diseases place a substantial burden on both patients and the health care system. It has been estimated that in 2002, over 5.5 million outpatient clinic visits were for patients evaluated for a diagnosis of GERD, and an additional 2.3 million were seen for dyspepsia or gastritis complaints.¹ Between 250,000 and 300,000 patients are hospitalized each year for upper GI bleeding, and despite numerous advances in diagnostic techniques and management strategies, mortality rates of approximately 9% are reported with more than 2.5 billion dollars spent each year to manage these patients.^{3–6}

The introductory section of this chapter includes a brief discussion of the physiology of the upper GI tract and the pharmacotherapy of drugs used to treat upper GI disorders. This section highlights the most important aspects associated with these topics. A more in-depth and comprehensive review can be found in GI textbooks or journal articles that discuss upper GI physiology and the pharmacology, pharmacokinetics, interactions, and side effects of the drugs.

PHYSIOLOGY OF THE UPPER GASTROINTESTINAL TRACT

The upper GI tract consists of the mouth, esophagus, stomach, and the duodenum (Fig. 26-1). Ingested food or liquids pass from the mouth through the esophagus and into the stomach. As these substances enter into the esophagus, the lower esophageal sphincter (LES), an area of smooth muscle near the distal end of the esophagus, relaxes to allow their entry into the stomach. The LES usually remains contracted to prevent the reflux of gastric contents into the esophagus. However, peristaltic con-

tractions of the esophageal muscles allows the LES to remain open until all food has entered the stomach.⁷ Although the LES is the primary barrier for the prevention of gastric refluxate entering the esophagus, healthy individuals reflux throughout the day and night without clinical consequences.⁸

The stomach consists of three distinct anatomical regions, each of which possesses specialized functional processes (Fig. 26-1). The cardia, which is the uppermost portion of the stomach at the junction between the esophagus and stomach, is responsible for the mucus secretion that protects against the acid milieu of the stomach. The body, which makes up the majority of the surface area (80%–90%) of the stomach, contains the parietal cells, which are responsible for gastric acid and intrinsic factor (required for vitamin B₁₂ absorption) secretion. The body also contains the peptic (chief) cells, which secrete pepsinogen (a precursor to pepsin). Pepsinogen, under acidic conditions in the stomach, is converted to pepsin (a proteolytic enzyme), which is responsible for breaking down protein. The antrum makes up the final 10% to 20% of the stomach. It contains the G cells, which secrete the hormone gastrin, which through a feedback mechanism stimulates acid secretion by the parietal cell. The final portion of the upper GI tract is the duodenum, which begins just after the pylorus and extends to ligament of Trietz. At this point, the jejunum begins the first portion of the lower GI tract.

The parietal cell is responsible for secreting gastric acid (Fig. 26-2). Three stimuli (neurologic, physical, and hormonal) trigger the parietal cell to secrete acid. Neurologic impulses, from the central nervous system (CNS) and initiated by the sight, smell, and taste of food, travel along cholinergic pathways to stimulate the release of acetylcholine, which arrives via nerve endings and activates the muscarinic receptor on the parietal cell.⁹ Ingested food causes gastric distention, which triggers the release of acetylcholine and also stimulates G cells within the antrum to produce gastrin. Elevated intragastric pH also stimulates the production of gastrin. Gastrin works via a feedback mechanism which, although produced in response to elevated pH, can be inhibited by low gastric pH. The stomach is protected from overproduction of gastric acid by the release of somatostatin from antral D cells, which signal the G cell to

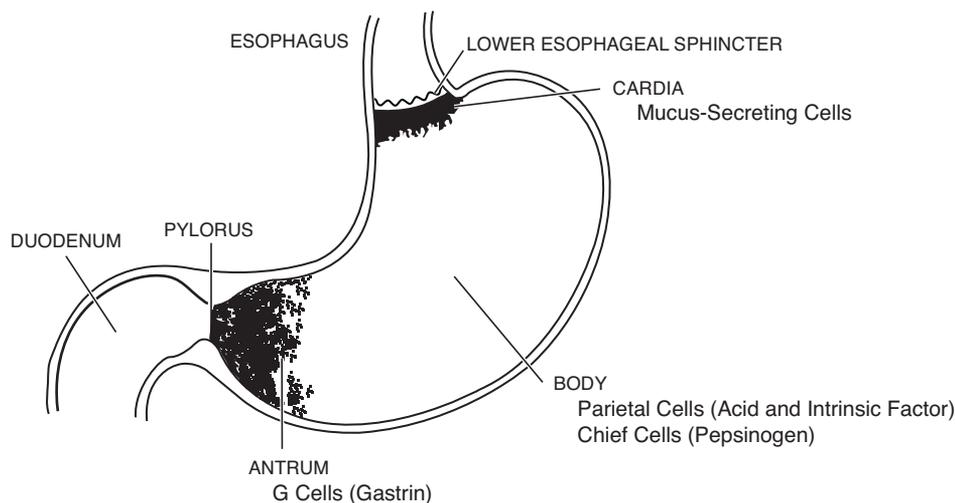

FIGURE 26-1 Gastrointestinal anatomic regions.

stop producing gastrin.¹⁰ Gastrin enters the blood and arrives at the parietal cell, where it binds to the gastrin receptor. Acetylcholine and gastrin promote the release of histamine from the mast cell or enterochromaffinlike (ECL) cells, which then bind to the histamine H_2 -receptor on the parietal cell. Histamine release is associated with both postprandial and nocturnal acid secretion. The gastrin, histamine H_2 , and muscarinic receptors are located on the basolateral membrane of the parietal cell (Fig. 26-2). Binding of any of these receptors leads to a cascade of events that stimulates gastric acid secretion. Calcium influxes into the parietal cell, leading to increased intracellular levels of calcium. Levels of cyclic adenosine monophosphate (cAMP) also increase and activate intracellular protein phosphokinases. This activates the hydrogen-potassium adenosine triphosphatase (H^+/K^+ -ATPase) or proton pump to move into position in the secretory canaliculus located in the apical membrane of the parietal cell. The proton pump is an ion transport pathway that transports hydrogen ions out of the cytoplasm and into the secretory canaliculus, where they are exchanged for potassium ions that enter the parietal cell via the opposite ion channel. In the secretory canaliculus, the hydrogen ion combines with chloride from the blood to form hydrochloric acid (HCl), which is then released from the secretory canaliculus into the gastric acid lumen.¹¹ The proton pump is the final common pathway for gastric acid secretion.^{9,11}

PHARMACOTHERAPY OF DRUGS USED TO TREAT ACID-RELATED DISORDERS

The following section briefly reviews the pharmacotherapy of drugs used to treat acid-related disorders (Table 26-1). Their therapeutic use is discussed under each specific GI disorder.

Antacids and Alginic Acid

Antacids are widely used to relieve mild and infrequent symptoms associated with acid-related diseases. They act by neutralizing gastric acid and thus increasing intragastric pH.¹² The elevation of intragastric pH is dose dependent and usually requires a substantial dose to raise the intragastric pH above 4 or 5.^{12,13} Antacids are very quick acting and modestly elevate intragastric pH within minutes, but their duration of action is short (about 30 minutes on an empty stomach). The duration of action can be extended to 3 hours when given with or within 1 hour after a meal.¹² Antacids are available as individual salts or as combination of salts of magnesium, aluminum, calcium, or sodium. Aluminum- and magnesium-containing salts are also able to bind bile salts.¹² Aluminum salts may enhance mucosal protection by increasing mucosal prostaglandins, stimulating mucus and bicarbonate secretion and enhancing microvascular blood flow. Antacids also inhibit the action of pepsin. These findings suggest that in addition to their neutralizing capacity, antacids have other mechanisms by which they act. This helps to explain their many pharmacotherapeutic benefits.^{9,12} A review of specific antacid products and their acid-neutralizing capacity is discussed elsewhere.¹² Antacids can also be combined with alginic acid. Alginic acid, however, is not an acid-neutralizing agent. It acts by forming a viscous solution that floats on top of the gastric contents and theoretically protects the esophageal mucosa from the potent acid refluxate.¹⁴

Antacids are generally well tolerated. The magnesium-containing antacids may cause a dose-related osmotic diarrhea, but combining it with aluminum salts (which can cause constipation when used alone) can offset this side effect. When higher doses of combination magnesium/aluminum antacids are used, the predominating side effect is diarrhea.^{12,15} Small amounts of aluminum and magnesium are absorbed systemically and have the potential to accumulate in patients with renal insufficiency and lead to toxicity. Thus, magnesium-containing antacids should be avoided in patients with a creatinine clearance <30 mL/minute, and chronic use of aluminum-containing antacids in patients with renal failure should be avoided.^{12,15} Hypercalcemia has been described in patients taking prolonged courses of large doses of calcium carbonate (>20 g/day in patients with normal renal function and >4 g/day in patients with renal failure).^{9,12} High-dose regimens of calcium (4–8 g/day) in combination with alkalinizing agents (sodium bicarbonate) can produce the milk-alkali syndrome (i.e., hypercalcemic nephropathy with alkalosis).^{9,12,15} Aluminum-containing antacids (with the exception of aluminum phosphate) binds to dietary phosphate within the GI tract to form insoluble salts that are excreted in feces. High-dose or frequent administration may lead to hypophosphatemia.^{9,12,15} Sodium bicarbonate should not be used for long periods of time (especially in the renally impaired patient) because systemic alkalosis can result from the accumulation of bicarbonate. Additionally, the high sodium content (274 mg sodium/g sodium bicarbonate) has been associated with sodium retention and may pose a problem in patients with hypertension, ascites, severe renal dysfunction, or congestive heart failure.^{9,12,15}

Antacids may interfere with the absorption of many orally administered drugs (e.g., digoxin, phenytoin, isoniazid, ketoconazole, itraconazole, iron preparations) that require an acidic

^a Although FDA-labeled for this indication, H₂RAs are not recommended even in higher dosages because they are not as effective as the PPIs.

^b Initial starting dose; daily dosage must be titrated to gastric acid secretory response.

^c Duration of treatment should not exceed 14 consecutive days; if needed, repeat 14-day treatment every 4 months.

BID twice a day; GERD, gastroesophageal reflux disease; HS, at bedtime; NSAID, nonsteroidal anti-inflammatory drug; OTC, over-the-counter; PRN, as needed; QD, every day; QID, four times a day; Rx, prescription; TID, three times a day.

environment for dissolution and absorption.^{12,14,16} This may lead to potential therapeutic failures with these medications. Calcium-, aluminum-, or magnesium-containing antacids can bind to concomitantly administered drugs and interfere with the absorption of drugs that are susceptible to complexation with these salts. Tetracyclines and the fluoroquinolones are susceptible to this interaction, as they bind to divalent and trivalent cations.¹⁵ The bioavailability of ciprofloxacin for example is reduced by >50% when concomitantly administered with an antacid, because aluminum and magnesium ions chelate with the antibiotic to form an insoluble and inactive complex. The administration of ciprofloxacin 2 hours before an antacid increases ciprofloxacin bioavailability more than when administered 2 hours after the antacid.¹⁷ An increase in gastric pH may also result in the premature dissolution and altered absorption of enteric-coated dosage forms as the enteric coating is usually designed to dissolve at a pH >6.0.¹⁶ Urinary alkalization may result in increased urinary excretion (salicylates) or decreased excretion (amphetamines and quinidine) leading to decreased or increased blood concentrations, respectively.^{12,15} The majority of these drug interactions can be avoided by separating the antacid from the interacting drug by a minimum of 2 hours.¹⁵

H₂-Receptor Antagonists

There are currently four H₂-receptor antagonists (H₂RAs) approved for use in the United States. These include cimetidine, ranitidine, famotidine, and nizatidine. All four agents are available in prescription and over-the-counter (OTC) dosage forms as well as oral and parenteral formulations (nizatidine is not available parenterally in the United States). H₂RAs competitively and selectively inhibit the action of histamine on the H₂ receptors of the parietal cells, thus reducing both basal and stimulated gastric acid secretion (Fig. 26-2). Although the relative antisecretory potency on a milligram-per-milligram basis differs (famotidine has the greatest potency followed by nizatidine, ranitidine, and cimetidine), this is not an important factor, as standard oral dosages of the four H₂RAs have been adjusted accordingly to have an equipotent antisecretory effect (Table 26-1).¹⁸ Oral absorption from the small intestine is rapid, and peak drug concentrations usually are achieved within 1 to 3 hours after administration.¹⁸ The bioavailability is lower for cimetidine, famotidine, and ranitidine because they are absorbed incompletely and undergo first-pass metabolism resulting in 40% to 65% bioavailability. The bioavailability of nizatidine is considered near 100% since this agent does not undergo first-pass metabolism.^{9,18,19} Parenteral H₂RAs given by the intravenous (IV) route have 90% to 100% bioavailability. All four drugs are eliminated by a combination of hepatic metabolism, glomerular filtration, and tubular secretion.¹⁸ Hepatic metabolism is the principal pathway for the elimination of cimetidine, famotidine, and ranitidine, whereas renal excretion is the major route for elimination of nizatidine.^{9,18–22} For each of these agents, the elimination half-life is increased, the total body clearance is decreased, and dosage reduction is recommended for patients with moderate to severe renal insufficiency. The pharmacokinetics appear to be unaffected by hepatic dysfunction; however, in patients with combined hepatic failure and renal insufficiency, dosage reduction is likely necessary.²⁰

The H₂RAs are remarkably safe, and the frequency of severe adverse effects is low for all four drugs.^{9,23} A meta-analysis of randomized placebo-controlled trials reported no difference in the incidence of adverse events of cimetidine versus placebo.²⁴ The most common adverse effects include GI discomfort (e.g., diarrhea, constipation), CNS effects (e.g., headache, dizziness, drowsiness, lethargy, confusion, psychosis, and hallucinations), and dermatologic effects (e.g., rashes).^{9,23} The most frequent hematologic adverse effect is thrombocytopenia, which occurs in about 1% of patients but is reversible on discontinuation of the H₂RA.²⁵ Although thrombocytopenia is more commonly reported with IV administration, it is likely that the overall incidence of H₂RA-associated thrombocytopenia is overestimated.²⁶ Hepatotoxicity, although uncommon, has been described primarily in patients receiving IV H₂RAs.²⁷ Cimetidine has demonstrated weak antiandrogenic effects, and its use in high doses (hypersecretory conditions) has been associated with gynecomastia and impotence in men. This effect is reversible with discontinuation of the medication or by switching to another H₂RA.^{23,28} Patients at highest risk of developing any of these adverse effects include the elderly, those requiring higher doses (usually parenteral), and those with altered renal function.⁹

All four H₂RAs can potentially alter the absorption and reduce the bioavailability of drugs that require an acidic environment for absorption. The most important of these interactions is with ketoconazole, which requires an acidic pH for dissolution and absorption. Concomitant administration of a H₂RA and ketoconazole may lead to therapeutic failure of the antifungal.^{9,16} Cimetidine has the greatest potential to cause drug interactions because of its ability to inhibit several hepatic CYP450 isoenzymes. The greatest concern is with those agents that have a relatively narrow therapeutic window (e.g., theophylline, lidocaine, phenytoin, quinidine, and warfarin).¹⁶ Although ranitidine is more potent on a molar basis, it binds less intensely to the CYP450 isoenzyme system than cimetidine. Thus, when used in equipotent doses, there is less potential for interactions. Famotidine and nizatidine do not bind appreciably to the CYP450 system and do not interact with drugs that are metabolized through this hepatic system.¹⁶ Since the H₂RAs undergo renal tubular excretion, there is a potential for competition with other medications.²⁹ Cimetidine and ranitidine inhibit the tubular secretion of procainamide by as much as 44%, but famotidine does not have this effect.³⁰ Tachyphylaxis or tolerance has been described with all H₂RAs because of up-regulation of the H₂-receptor site. It appears to occur more frequently with high-dose parenteral formulations but has also been described with oral therapy.^{31,32} Tolerance to the antisecretory effect may develop after several days of regularly scheduled (continuous) use but can be avoided by taking the H₂RA only when needed.

Proton Pump Inhibitors

PPIs are highly specific inhibitors of gastric acid secretion and include omeprazole, lansoprazole, rabeprazole, pantoprazole, and esomeprazole. These agents are substituted benzimidazoles and act by irreversibly binding to the H⁺/K⁺-ATPase (proton pump). The PPIs are the most potent inhibitors of gastric acid secretion in that they inhibit the terminal step in the acid production cycle.^{9,33–35} They inhibit both basal and

stimulated gastric acid secretion in a dose-dependent and sustained fashion.³⁴ The PPIs are prodrugs and require an acidic environment for conversion to the active sulfonamide. They are absorbed in the small intestine (protected from the acidic milieu of the stomach by enteric coating) and taken via the bloodstream to the acidic secretory canaliculus of the parietal cell for protonation to the active form (Fig. 26-2).^{9,33,35} This conversion requires an actively secreting proton pump, and hence, these agents are most efficacious when taken 30 to 60 minutes prior to a meal on an empty stomach.³⁵ Despite the short plasma elimination half-lives of these agents (~ 1–2 hours), the duration of the antisecretory effect is considerably longer (48–72 hours depending on the agent used) because of covalent (irreversible) binding to the proton pump.^{9,35,36} The PPIs have similar acid-inhibitory effects and healing rates when used in equivalent doses (Table 26-1).^{37–42} The PPIs are superior to the H₂RAs in terms of acid reduction and mucosal healing.^{37,43} A dosage reduction is not required in patients with renal insufficiency; however a dosage reduction is recommended for patients with severe hepatic impairment.^{9,44}

The oral PPIs are formulated as delayed-release enteric-coated granules within capsules (omeprazole, lansoprazole, esomeprazole), delayed-release enteric-coated tablets (pantoprazole, rabeprazole, OTC omeprazole), a rapidly disintegrating tablet (lansoprazole), delayed-release oral suspension (lansoprazole), and an immediate release formulation (omeprazole and sodium bicarbonate capsules and powder for oral suspension). IV formulations in the United States include pantoprazole and esomeprazole. Various methods of administration, specific dosage forms, and compounding options for patients with special needs (e.g., dysphagia, gastric tubes) will be discussed later in this chapter (see Upper Gastrointestinal Bleeding section).

The short-term adverse effects of PPIs are relatively infrequent and comparable to the H₂RAs or placebo. The most common side effects include GI discomfort (e.g., nausea, diarrhea, abdominal pain), CNS effects (e.g., headache, dizziness), and rare isolated reactions (e.g., skin rash, increased liver enzymes).^{9,45} The immediate-release formulation of omeprazole contains sodium bicarbonate, and care should be taken in sodium-restricted patient populations, as discussed in the Antacids section. All PPIs are metabolized by the hepatic cytochrome P450 microenzyme system. Omeprazole and esomeprazole have been described as inhibiting CYP2C19 and decreasing the clearance of diazepam, phenytoin, and R-warfarin, while lansoprazole increases the metabolism of theophylline by inducing CYP1A.^{35,46} Although the clinical importance of these interactions is thought to be negligible, care should be taken when combining these agents to prevent possible toxicity or therapeutic failure. An increase in intragastric pH may increase the bioavailability of orally administered medications (e.g., digoxin, nifedipine) or decrease the absorption of ketoconazole and cefpodoxime.^{35,47}

The PPIs have been associated with a number of adverse effects when used long term and in high dosages. However, in most cases, there is insufficient evidence to support a causal relationship between the PPI and the effect. There is evidence to suggest a relationship between elevated serum gastrin concentrations and ECL hyperplasia as a result of the PPI's profound ability to inhibit gastric acid secretion. It has been hypothesized that this can progress to gastric carcinoid tumors (a pre-

cursor of gastric cancer). Although ECL hyperplasia has been described with the use of PPIs, there is no clinical evidence to suggest that long-term (>10 years) therapy progresses to a higher grade of hyperplasia or gastric ECL carcinoid.^{9,48,49} Atrophic gastritis has been observed in gastric corpus biopsies from patients treated long term with omeprazole and positive for *Helicobacter pylori*. However, review of the data by the Food and Drug Administration (FDA) has been inconclusive and not able to show causality between long-term use of PPIs, *H. pylori*, and atrophic gastritis.^{9,49,50}

PPIs have been associated with an increased risk of infections (e.g., pneumonias, enteric infections) possibly due to the ability of the microorganisms ability to survive in a less acidic environment.^{49,51–53} Acute nosocomial infections (pneumonia) associated with critically ill patients will be described later when discussing high-dose oral and parenteral PPI therapy (see Upper Gastrointestinal Bleeding section). Enteric infections and cancer have also been described due to potential bacterial overgrowth. The most common pathogens are *Clostridium difficile*, *Salmonella typhimurium*, and *Campylobacter jejuni*; however, data suggest that they rarely lead to illness.^{51,52} A retrospective database study of PPI use describes a near threefold increase in the risk of *C. difficile*-associated diarrhea in patients receiving PPIs versus patients not on a PPI, but the overall risk remains low and should not be considered a contraindication to therapy.⁵² Bacterial overgrowth (secondary to PPI treatment) has been hypothesized to increase the risk of gastric cancer, because bacteria in the stomach responsible for conversion of dietary nitrates to nitrites can flourish at a higher pH and increase the development of N-nitrosamines (a carcinogenic by-product). Presently, there are no convincing studies to support the increased production of N-nitrosamines in humans with prolonged PPI therapy.^{49,51} Long-term PPI use in older patients on high dosages has also been associated with an increased risk of hip fractures through the presumed inhibition of calcium absorption by PPI-induced hypochlorhydria.⁵⁴ Although the overall risk was low and was statistically significant, data from previous studies reported normal calcium absorption in patients on PPIs for at least 4 years.⁵⁵ Additional studies are required to confirm a causal relationship.

A decrease in vitamin B₁₂ (cyanocobalamin) has been described in patients with long-term PPI use and may occur because gastric acid is required to liberate the vitamin from dietary sources.^{49,55} This may only be problematic in the elderly, vegetarians, and patients with chronic alcohol ingestion. PPIs have been associated with interstitial nephritis, but this is an extremely rare finding.⁵⁶ Although the long-term effects associated with PPIs appear to be rare, the benefit of long-term use must always be weighed against potential risks for the patient.

Sucralfate

Sucralfate (an aluminum salt of a sulfated disaccharide) promotes gastric mucosal protection by shielding ulcerated tissue from aggressive factors such as acid, pepsin, and bile salts.⁵⁷ At a pH of 2.0 to 2.5, sucralfate binds to damaged and ulcerated mucosa, forming a physical barrier against injury from these aggressive factors. The drug has minimal systemic absorption and does not possess antisecretory activity. Sucralfate may also have other protective actions related to the stimulation of

mucosal prostaglandins.⁹ The most common side effect associated with sucralfate is constipation, which occurs in about 3% of patients. This is most likely due to the aluminum content of the compound. Because aluminum toxicity has occurred secondary to accumulation in patients with renal insufficiency, long-term use should be avoided.⁹ Since aluminum salts can bind with dietary phosphate in the GI tract, the potential for hypophosphatemia exists (see Antacids section). Sucralfate tablets are large, and some patients, particularly the elderly, may have difficulty swallowing them. Gastric bezoar formation has also been described.⁵⁸ A liquid formulation is available for patients with swallowing difficulties. The bioavailability of oral fluoroquinolones, warfarin, phenytoin, levothyroxine, quinine, ketoconazole, amitriptyline, and theophylline may be reduced when concomitantly administered with sucralfate.^{9,16} The mechanism of these interactions is thought to be caused by binding of the medication with sucralfate in the GI tract, thus limiting their absorption. Because of these interactions, sucralfate should be given at least 2 hours after these medications.

Misoprostol

Misoprostol, a synthetic prostaglandin E₁ analog, is the only prostaglandin analog approved for use in the United States. Misoprostol acts primarily by enhancing mucosal defense mechanisms.⁹ It produces cytoprotective effects by stimulating the production of mucus and bicarbonate, improving mucosal blood flow, and reducing mucosal cell turnover similar to the effects of endogenous prostaglandin.⁹ Misoprostol also produces a dose-dependent inhibition of gastric acid, but even at high doses, it is less than that of the H₂RAs. The use of misoprostol is limited because of its potential to cause a dose-dependent diarrhea (in up to 30% of patients) and abdominal cramping.⁹ Taking the drug with meals may help to reduce the diarrhea. Decreasing the daily dose may reduce the diarrhea, but efficacy may be compromised⁵⁹ (see Peptic Ulcer Disease section). Other troublesome side effects include nausea, flatulence, and headaches.⁹ Misoprostol is excreted primarily as metabolites in the urine, but a dose reduction is not required in patients with renal insufficiency. Misoprostol is an abortifacient because of its uterotrophic effects. Thus, it is contraindicated in women who are pregnant who take it for a GI indication.^{9,60} Use in women in their childbearing years requires a negative serum pregnancy test and adequate contraception.

Bismuth Salts

Bismuth subsalicylate has been used for years as an OTC option for many GI ailments. Although its mechanism of action is not completely understood, bismuth is thought to work by binding to and protecting mucosal lesions and enhancing cellular protective mechanisms. Bismuth also has an antimicrobial effect, primarily against *H. pylori*.⁹ Bismuth salts have no acid-inhibitory effects. Bismuth-containing products have few side effects, but patients with renal impairment may have a decreased elimination of the bismuth. Bismuth subsalicylate should be used with caution in patients on concomitant salicylates, as the potential exists for salicylate toxicity or increased risk of bleeding. Patients with salicylate allergies or sensitivities should also be warned of the salicylate component. Long-

term use is also not advised. Bismuth salts are associated with a harmless black coloring of the stools due to colonic conversion of bismuth to bismuth sulfide and a potential black discoloration of the tongue with liquid dosage forms.⁹ Bismuth subcitrate potassium (biscalcitate) is only available as a combination product with metronidazole and tetracycline for the treatment of *H. pylori*⁶¹ (see Peptic Ulcer Disease section). Although side effects are similar to bismuth subsalicylate, it has the advantage of not containing salicylate.

DYSPEPSIA

The term *dyspepsia* is derived from the Greek words that mean “hard or difficult digestion” and refers to a subjective feeling of pain or discomfort located primarily in the upper abdomen.^{62–63} Although the symptom complex and duration may vary, most patients complain of acute dyspeptic symptoms (indigestion) that are often but not necessarily restricted to food or alcohol consumption; medications such as nonsteroidal anti-inflammatory drugs (NSAIDs), antibiotics such as erythromycin, digoxin, theophylline, and bisphosphonates; and smoking or a stressful lifestyle (Fig. 26-3). Chronic dyspepsia is defined as recurrent symptoms that may include epigastric pain, abdominal bloating, belching, nausea, vomiting, and early satiety (early sense of fullness with meals). Clinicians consider heartburn an accompanying symptom, but regulatory agencies in the United States and Rome II diagnostic criteria have adopted a definition of chronic dyspepsia for clinical research purposes that excludes heartburn.^{63,64} For some individuals, dyspepsia occurs regularly and may indicate a serious underlying medical problem.

Patients who have not undergone diagnostic testing are referred to as having “uninvestigated” dyspepsia, while those who have undergone testing (usually upper endoscopy) are said to have “investigated” dyspepsia (Fig. 26-3). The four major causes of investigated dyspepsia include chronic PUD, GERD with or without esophagitis, malignancy, and functional or idiopathic dyspepsia. Functional dyspepsia is a clinical syndrome in which there is no evidence of mucosal damage related to PUD, GERD, or malignancy found at endoscopy. Specific types of functional dyspepsia include nonulcer dyspepsia (NUD), which describes “ulcer-like” symptoms, and nonerosive reflux disease (NERD), which describes “GERD-like” symptoms in an endoscopy-negative patient.

Epidemiology

Dyspepsia is a common problem that occurs in about 25% of the U.S. population when patients with typical GERD symptoms are excluded.⁶² When all patients with heartburn or regurgitation are excluded, the prevalence is lower. The prevalence remains stable, as the number who develop dyspepsia is similar to the number who no longer complain of symptoms.

Pathophysiology

Acute, infrequent dyspepsia is most often related to food, alcohol, smoking, or stress. Chronic dyspepsia may be related to an underlying cause such as PUD, GERD, or malignancy or may not have any known cause (endoscopy-negative, functional, idiopathic dyspepsia). About 40% of patients with functional

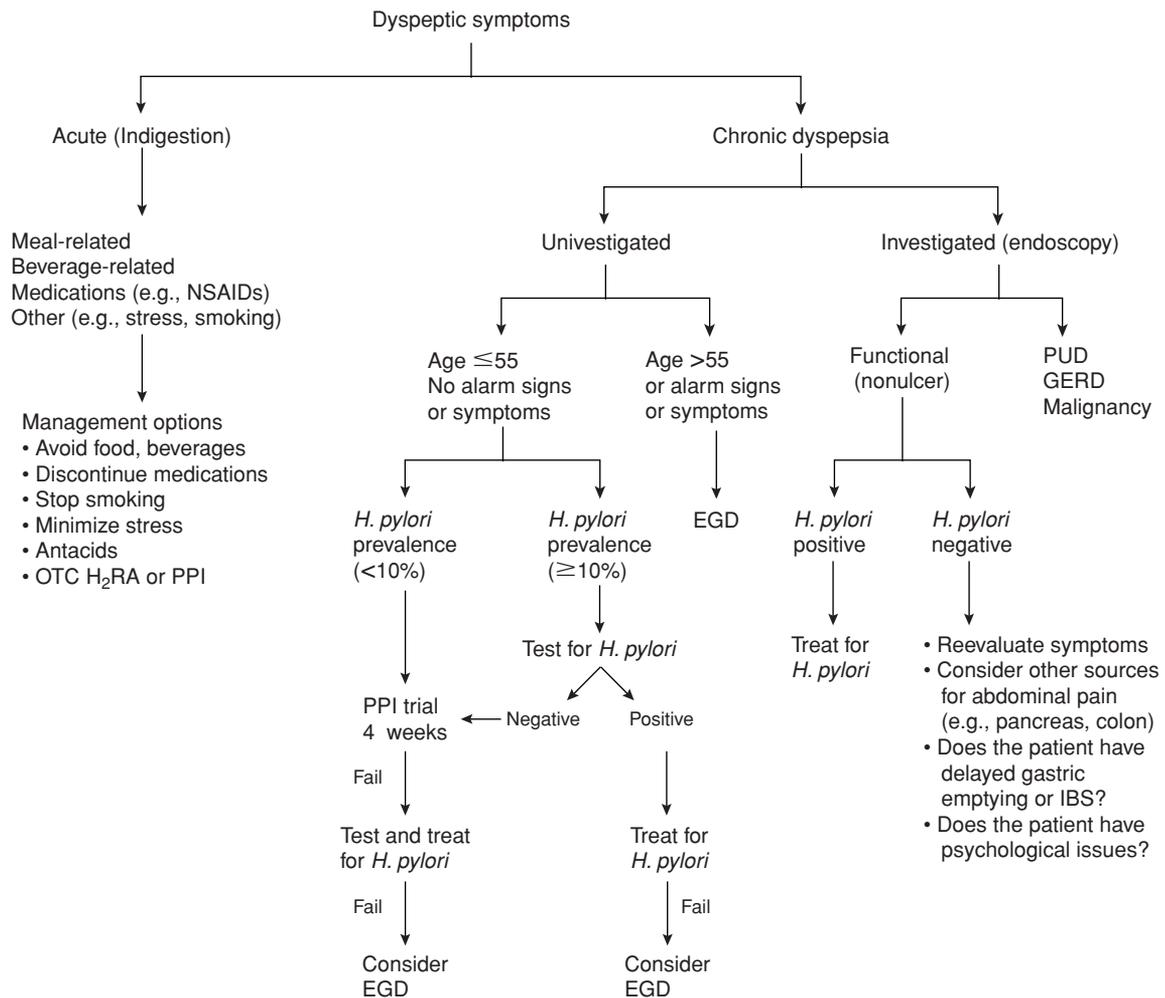

FIGURE 26-3 Management of dyspeptic symptoms. GERD, gastroesophageal reflux disease; *H. pylori*, *Helicobacter pylori*; H₂RA, H₂-receptor antagonist; OTC, over-the-counter; PPI, proton pump inhibitor; PUD, peptic ulcer disease.

dyspepsia have pathophysiological disturbances that involve delayed gastric emptying.⁶³ There is also evidence that the esophagus, stomach, duodenum, and other regions of the GI tract are hypersensitive and may be associated with irritable bowel syndrome, especially in women.⁶³ Others have failed to find a pathological association between functional dyspepsia and gastroduodenal motility, hypersensitivity, or any other GI abnormality and suggest that psychologic disturbances are an important contributing factor. Although *H. pylori* infection has been identified in 20% to 60% of patients with functional dyspepsia, its pathophysiological relevance remains uncertain.⁶²

Clinical Assessment and Diagnosis

Acute, infrequent dyspepsia is usually self-limiting and generally requires no further investigation. Chronic dyspeptic symptoms cannot be used to predict endoscopic findings of PUD, GERD, or malignancy in patients with uninvestigated dyspepsia.^{63,65,66} In addition, individual symptoms or symptom subgroups such as PUD-like, GERD-like, or dysmotility-like dyspepsia are not useful in distinguishing organic dis-

ease from functional dyspepsia, nor does it appear to aid in management. This is because there is considerable overlap of symptoms among patients with PUD, GERD, malignancy, and functional dyspepsia.

The clinical assessment of uninvestigated dyspeptic in patients ≤ 55 years of age with no alarm signs or symptoms includes a test-and-treat *H. pylori* option, which is preferable in geographic areas of moderate to high prevalence of *H. pylori* infection $\geq 10\%$ ⁶³ (Fig. 26-3). *H. pylori* testing should be conducted by using a nonendoscopic validated test (see Tests for Detecting *Helicobacter pylori* section). New-onset dyspepsia in an older individual is considered an independent risk factor for an underlying malignancy such as gastric cancer.⁶³ Dyspeptic patients > 55 years of age or those with alarm signs or symptoms should undergo upper endoscopy (Fig. 26-3). Other alarm features that assist in identifying serious underlying diseases, especially malignancy, include early satiety, anorexia, worsening dysphagia or odynophagia, unexplained weight loss ($> 10\%$ body weight), vomiting, anemia, GI bleeding, lymphadenopathy, jaundice, a history of PUD, a family history of upper GI tract cancer, previous gastric surgery, or malignancy.⁶³ Although a symptom duration threshold has not

been established, a long history of symptoms or antisecretory drug use may suggest a serious underlying condition.

Treatment

The recommended strategies for managing dyspepsia are presented in Figure 26-3. Individuals with acute dyspepsia (indigestion) can be effectively treated with self-directed therapy using antacids or OTC antisecretory drugs if they are unable or unwilling to avoid offending foods and beverages, stop smoking, or discontinue troublesome medications. The initial management of patients ≤ 55 years of age with uninvestigated dyspepsia and no alarm features depends on the prevalence of *H. pylori* and whether the patient is *H. pylori* positive or negative (Table 26-2). Empiric therapy with a PPI for 4 weeks is considered first line and cost effective in areas with a low prevalence of *H. pylori* and in patients who are *H. pylori* negative.⁶³ One meta-analysis reports better symptomatic outcomes with a short course of a PPI when compared with H₂RAs, alginate, or placebo.⁶⁷ The PPI should be stopped after 1 month if the patient's symptoms respond to treatment. If symptoms recur, then longer-term PPI treatment may be considered, but the need for a PPI should be evaluated every 6 to 12 months.⁶² If standard doses of a PPI fail, a short course of doubling the PPI dose may be considered.⁶² Prokinetics are not recommended as first-line therapy for uninvestigated dyspepsia in the United States.^{62,63} Patients who are *H. pylori* positive should receive a PPI-based eradication regimen^{62,65} (see *Helicobacter pylori*-Related Ulcers section).

Early endoscopy with biopsy for *H. pylori* is recommended for patients > 55 years of age and those with alarm features. In the event that an abnormality is found, such as PUD, GERD, or malignancy, it should be treated accordingly. The management of NUD is challenging and should take into consideration the cost-effectiveness of treatment.² Analyses of trials evaluating H₂RAs and PPIs show that less than one-third of patients become asymptomatic and that PPIs may be marginally superior

to H₂RAs.⁶³ An economic review, however, suggests that PPIs are cost-effective for NUD in the United States.⁶⁸ There is no evidence to support the use of antacids or sucralfate,⁶⁹ but simethicone may be of benefit.⁷⁰ The effectiveness of *H. pylori* eradication in NUD remains controversial, as some meta-analyses show a beneficial effect⁷¹ while others fail to confirm such benefits⁷² (Table 26-2). An update of these meta-analyses, however, reports a small therapeutic gain with eradication.⁷³ The beneficial effects of eradication may last for up to 5 years.⁷⁴ Although the benefit of prokinetics have been reported, most studies were conducted with cisapride, which was withdrawn from the U.S. market.⁶⁹ The use of available prokinetics (metoclopramide, erythromycin) should be reserved for difficult-to-treat patients because of their limited efficacy and side effects.⁶³ Antidepressants are often prescribed in NUD but are of uncertain efficacy.⁶³ Alternative therapies, including herbal products, remain unproven.⁶³ Patients with persistent dyspepsia despite a negative endoscopy in whom PPI therapy and *H. pylori* eradication fails should have their diagnosis reevaluated.

PEPTIC ULCER DISEASE

PUD is one of the most common gastroenterologic diseases affecting the upper GI tract.⁹ Chronic peptic ulcers are defects in the gastric (gastric ulcer) or duodenal (duodenal ulcer) mucosa that require gastric acid for their formation. Chronic peptic ulcers differ from erosions and gastritis in that the ulcer extends deeper into the muscularis mucosa. Stress ulcer is an acute form of peptic ulcer, but it occurs primarily in critically ill patients and differs in its underlying pathogenesis (see Stress-Related Mucosal Bleeding section).

Epidemiology

Peptic ulcers develop in 10% of Americans during their lifetime and result in impaired quality of life, work loss, and high-cost medical care.⁹ A declining ulcer rate for younger men and an increasing rate for older women has shifted the prevalence of PUD in the United States from predominantly men to a comparable rate in men and women.⁹ Hospitalizations, operations, physician visits, and deaths in the United States have declined by $> 50\%$ during the last four decades.⁹ While hospital admissions for uncomplicated duodenal ulcer have decreased, admissions for ulcer-related complications (bleeding and perforation) have increased.⁹ Although the overall mortality from PUD has decreased, death rates have increased among older patients (> 75 years) and are most likely related to the use of NSAIDs.

Etiology and Risk Factors

H. pylori and NSAIDs are the two most common causes of chronic PUD and influence the chronicity of the disease.⁹ Less common causes include hypersecretory states such as Zollinger-Ellison syndrome (ZES) (see Zollinger-Ellison Syndrome section), viral infections (e.g., cytomegalovirus), radiation, and chemotherapy (e.g., hepatic artery infusion).⁹ Factors that may increase the risk of a peptic ulcer include alcohol ingestion, cigarette smoking, diet, and psychologic stress; corticosteroids; and chronic diseases such as chronic renal failure,

Table 26-2 Indications for Testing and Treating *Helicobacter pylori* Infection

Recommended (evidence established)

- Uninvestigated dyspepsia (depending on *H. pylori* prevalence)
- PUD (active gastric or duodenal ulcer)
- History of PUD (confirmed ulcer not previously treated for *H. pylori*)
- Gastric MALT lymphoma
- Following resection of early gastric cancer
- Reduce the risk of recurrent bleeding from gastroduodenal ulcer

Controversial (evidence not well established)

- NUD
- Individuals using NSAIDs (no signs/symptoms of peptic ulcer)
- GERD
- Individuals at risk for gastric cancer
- Individuals with unexplained iron deficiency anemia

GERD, gastroesophageal reflux disease; MALT, mucosa-associated lymphoid tissue; NUD, nonulcer dyspepsia; NSAID, nonsteroidal anti-inflammatory drug; PUD, peptic ulcer disease.

hepatic cirrhosis, chronic pancreatitis, chronic pulmonary disease, and Crohn's disease.⁹

Helicobacter pylori–Related Ulcers

H. pylori infection is causally linked to chronic gastritis, PUD, mucosa-associated lymphoid tissue (MALT) lymphoma, and gastric cancer (Table 26-2), but only 20% of infected individuals develop symptomatic ulcers and <1% develop gastric cancer.^{9,75,76} Differences in strains account for the variable pathogenesis of the organism.^{75,76} Evidence is lacking to support a causal role for *H. pylori* and GERD,^{77,78} extragastric manifestations (e.g., cardiovascular disease),⁷⁹ or iron deficiency anemia.⁸⁰

The prevalence of *H. pylori* varies by geographic location, socioeconomic environment, ethnicity, and age.⁷⁵ The infection is more common in developing countries than in industrialized countries. Prevalence in the United States is estimated to be 30% to 40%⁸⁰ but is higher in older individuals and in African and Latin Americans.⁸¹ The higher prevalence among older individuals reflects acquisition during infancy and early childhood.⁹ However, infection rates in the United States have been declining in children because of improved socioeconomic conditions.^{80,81} Prevalence is not affected by gender or smoking. Transmission occurs by the fecal–oral route from an infected person or from fecal-contaminated water or food.⁹ Individuals living in the same household are at risk for infection.^{9,81} *H. pylori* can also be transmitted through vomitus or the use of inadequately sterilized endoscopes.⁹ Transmission by the oral–oral route has been postulated, but it is unlikely.

Nonsteroidal Anti-inflammatory Drug-Induced Ulcers

There is considerable evidence linking the chronic use of NSAIDs with injury to the GI tract.^{9,82–84} Gastric and duodenal ulcers develop in 15% to 30% of chronic NSAID users,⁹ whereas 1% to 2% experience serious ulcer-related complications.^{82,83} Gastric ulcer is most common and develops primarily in the antrum.⁷⁵ NSAIDs may cause ulcers in the esophagus and the colon, but these ulcers occur less frequently.^{9,84} It has been estimated that about 16,500 NSAID-related deaths and 107,000 hospitalizations occur annually in the United States,^{82,83} but the death rates may be overstated because of the recent decline in hospitalizations.⁸⁴ Over 111 million NSAID prescriptions are filled each year in the United States at a cost of about 5 billion dollars.⁸² Additionally, about 2 million dollars is spent annually on OTC NSAIDs.⁸² The risk factors for NSAID-induced ulcers and upper GI complications are listed in Table 26-3. Combinations of factors confer an additive risk.

Pathophysiology

A physiological balance exists in healthy individuals between gastric acid secretion and gastroduodenal mucosal defense. Peptic ulcers occur when the balance between aggressive factors (gastric acid, pepsin, bile salts, *H. pylori*, and NSAIDs) and mucosal defensive mechanisms (mucosal blood flow, mucus, mucosal bicarbonate secretion, mucosal cell restitution, and epithelial cell renewal) are disrupted.⁹ Increased acid secretion may occur in patients with duodenal ulcer, but most patients with gastric ulcer have normal or reduced rates of

Table 26-3 Risk Factors for Nonsteroidal Anti-inflammatory Drug-Induced Ulcer and Ulcer-Related Upper Gastrointestinal Complications

Established

- Confirmed prior ulcer or ulcer-related complication
- Age >65 years
- Multiple or high-dose NSAID use
- Concomitant use of aspirin (including cardioprotective dosages)
- Concomitant use of an anticoagulant, corticosteroid, bisphosphonate, clopidogrel, or SSRI
- Selection of NSAID (selectivity of COX-1 vs. COX-2)

Controversial

- *H. pylori*
- Alcohol consumption
- Cigarette smoking

COX-1, cyclo-oxygenase-1; COX-2, cyclo-oxygenase-2; NSAID, nonsteroidal anti-inflammatory drug; SSRI, selective serotonin reuptake inhibitor.

acid secretion.¹¹ Pepsin is an important cofactor that plays a role in the proteolytic activity involved in ulcer formation. Mucosal defense and repair mechanisms protect the gastroduodenal mucosa from noxious endogenous and exogenous substances.⁹ The viscous nature and near-neutral pH of the mucus-bicarbonate barrier protect the stomach from the acidic contents in the gastric lumen. The maintenance of mucosal integrity and repair is mediated by the production of endogenous prostaglandins. When aggressive factors alter mucosal defense mechanisms, back diffusion of hydrogen ions occurs with subsequent mucosal injury. *H. pylori* and NSAIDs cause alterations in mucosal defense by different mechanisms and are important factors in the formation of peptic ulcers.

Helicobacter pylori–Related Ulcers

H. pylori is a gram-negative, spiral-shaped bacillus that thrives in a microaerophilic environment. The bacterium resides between the mucus layer and surface epithelial cells in the stomach or any location where gastric-type epithelium is found.^{9,75} Flagella enable it to move from the lumen of the stomach, where the pH is low, to the mucus layer, where the pH is neutral. The acute infection is accompanied by transient hypochlorhydria, which enables the organism to survive the acidic gastric juice.⁸⁵ Although the exact method by which *H. pylori* induces hypochlorhydria is uncertain, it is hypothesized that its urease-producing ability hydrolyzes urea in the gastric juice and converts it to ammonia and carbon dioxide, which creates a neutral microenvironment that surrounds the bacterium.⁷⁵ Adherence pedestals permit the bacterium to attach to gastric-type epithelium and prevent it from being shed during cell turnover and mucus secretion. Colonization of the body of the stomach is associated with gastric ulcer. Duodenal ulcers are thought to arise from colonization by antral organisms of gastric-type epithelium that develops in the duodenum in response to changes in duodenal pH.^{9,75}

The exact mechanism by which *H. pylori* infection leads to ulceration is not yet known. Direct mucosal damage is produced by virulence factors (e.g., vacuolating cytotoxin,

elaborating bacterial enzymes) and adherence.^{86,87} Approximately 50% of *H. pylori* strains produce vacuolating cytotoxin (VacA), which leads to cell death and possibly gastric cancer.⁸⁷ Strains with cytotoxin-associated gene (CagA) protein are associated with duodenal ulcer, atrophic gastritis, and gastric cancer.^{75,76,86} *H. pylori* infection also causes alterations in the host immune response,^{9,75} hypergastrinemia leading to increased acid secretion,^{9,75} and carcinogenic conversion of susceptible gastric epithelial cells.^{76,86,87}

Nonsteroidal Anti-inflammatory Drug-Induced Ulcers

Nonselective NSAIDs (Table 26-4), including aspirin, cause peptic ulcers and upper GI complications by systemically inhibiting protective prostaglandins in the gastric mucosa.⁹ NSAIDs inhibit cyclo-oxygenase (COX), the rate-limiting enzyme in the conversion of arachidonic acid to prostaglandins. There are two COX isoforms: cyclo-oxygenase-1 (COX-1), which is found in the stomach, kidney, intestine, and platelets, and cyclo-oxygenase-2 (COX-2), which is induced with acute inflammation.⁹ The inhibition of COX-1 is associated with upper GI and renal toxicity, while the inhibition of COX-2 is related to anti-inflammatory effects.^{9,88} Nonselective NSAIDs, including aspirin, inhibit both COX-1 and COX-2 to varying degrees and decrease platelet aggregation, which may increase the risk for upper GI bleeding.⁹ The partially selective NSAIDs may be associated with less GI toxicity.^{9,88–90} Selective COX-2 inhibitors have a similar efficacy to the nonselective NSAIDs but with fewer harmful GI effects.^{9,90} In contrast to the nonselective NSAIDs, the COX-2 inhibitors do not possess antiplatelet effects. Two selective COX-2 inhibitors, rofecoxib and valdecoxib (Table 26-4), were withdrawn from the U.S. market in 2004 because of concerns about cardiovascular safety. Celecoxib, a NSAID initially marketed as a COX-2 inhibitor, is now considered a partially selective agent.

Aspirin and nonselective NSAIDs also have a topical (direct) irritating effect on the gastric mucosa, but the resulting inflammation and erosion usually heals within a few days.⁶³ Formulations such as enteric-coated aspirin, buffered aspirin, NSAID prodrugs, and parenteral or rectal preparations may

spare topical effects on the gastric mucosa, but all have the potential to cause a gastric ulcer because of their systemic inhibition of endogenous prostaglandins.^{9,91}

Clinical Presentation

Signs and Symptoms

The signs and symptoms associated with a peptic ulcer range from mild epigastric pain to life-threatening upper GI complications.⁹ A change in the character of the pain may indicate an ulcer-related complication. The absence of epigastric pain, especially in the elderly who are taking NSAIDs, does not exclude the presence of an ulcer or related complications. Although the reasons for this are unclear, they may be related to the analgesic effect of the NSAID. There is no one sign or symptom that differentiates a *H. pylori*-related ulcer from a NSAID-induced ulcer. Ulcer-like symptoms may occur in the absence of peptic ulceration in association with *H. pylori*-related gastritis or duodenitis.

Complications

The most serious life-threatening complications associated with chronic PUD are upper GI bleeding (10%–15%), perforation into the abdominal cavity (7%), and gastric obstruction (2%).⁹ The incidence of ulcer-related upper GI bleeding and perforation is increased in older patients taking NSAIDs. The bleeding may be occult (hidden), present as melena (black-colored stools), or hematemesis (vomiting of blood). Mortality is high in patients who continue to bleed or who rebleed after the initial bleeding has stopped (see Upper Gastrointestinal Bleeding section) and in patients with a perforated ulcer. The pain associated with perforation is typically sudden, sharp, and severe, beginning initially in the epigastric area but quickly spreading throughout the upper abdominal area. Gastric outlet obstruction is caused by previous ulcer healing and then scarring or edema of the pylorus or duodenal bulb and can lead to symptoms of gastric retention, including early satiety, bloating, anorexia, nausea, vomiting, and weight loss.

Clinical Assessment and Diagnosis

Tests for Detecting *Helicobacter pylori*

The detection of *H. pylori* infection can be made by using gastric mucosal biopsies in patients undergoing upper endoscopy or by nonendoscopic tests^{9,80,92} (Table 26-5). The selection of a specific method is influenced by the clinical circumstance and the availability and cost of the individual test. The endoscopic tests require a mucosal biopsy for the rapid urease test, histology, or culture. Medications that reduce urease activity or the density of *H. pylori* may decrease the sensitivity of the rapid urease test by up to 25%.⁸⁰ When possible, antibiotics and bismuth salts should be withheld for 4 weeks and H₂RAs and PPIs for 1 to 2 weeks prior to endoscopic testing. Patients who are taking these medications at endoscopy will require histology in addition to the rapid urease test. Two biopsies are taken from different areas of the stomach because patchy distribution of *H. pylori* can result in false-negative results. Acute ulcer bleeding at the time of testing is likely to decrease the sensitivity of the rapid urease test and histology and increase the likelihood of false-negative results.^{80,93}

Table 26-4 Selected Nonsteroidal Anti-inflammatory Drugs

Salicylates

Acetylated: aspirin
Nonacetylated: trisalicylate, salsalate

Nonsalicylates^a

Nonselective (traditional) NSAIDs: ibuprofen, naproxen, tolmetin, fenoprofen, sulindac, indomethacin, ketoprofen, ketorolac, flurbiprofen, piroxicam
Partially selective NSAIDs: etodolac, diclofenac, meloxicam, nabumetone
Selective COX-2 inhibitors: celecoxib, rofecoxib^b, valdecoxib^b

^aBased on COX-1/COX-2 selectivity ratio *in vitro*.

^bWithdrawn from U.S. market.

COX-2, cyclo-oxygenase-2; NSAIDs, nonsteroidal anti-inflammatory drugs.

Table 26-5 Diagnostic Tests for *Helicobacter pylori* Infection**Tests Utilizing Gastric Mucosal Biopsy in Patients Undergoing Endoscopy****Rapid Urease Test**

- Tests for active *H. pylori* infection; >90% sensitivity and >95% specificity.
- Withhold H₂RAs and PPIs 1 to 2 weeks prior to testing and antibiotics and bismuth salts 4 weeks prior to testing to reduce the risk of false negatives.
- In the presence of *H. pylori* urease, urea is metabolized to ammonia and bicarbonate resulting in an increase in pH, which changes the color of a pH-sensitive indicator.
- Results are rapid (usually within a few hours), and test is less expensive than histology or culture.

Histology

- Considered “gold standard” for detection of *H. pylori* infection; >95% sensitivity and >95% specificity.
- Permits further histologic analysis and evaluation of infected tissue (e.g., gastritis, ulceration, adenocarcinoma); tests for active *H. pylori* infection.
- Results are not immediate; not recommended for initial diagnosis; more expensive than rapid urease test.

Culture

- Permits sensitivity testing to determine antibiotic choice or resistance; 100% specific.
- Use usually limited to patients who fail several courses of eradication therapy; tests for active *H. pylori* infection.
- Results are not immediate; not recommended for initial diagnosis; more expensive than rapid urease test.

Tests That do not Utilize Gastric Mucosal Biopsy**Urea Breath Test**

- Tests for active *H. pylori* infection; >95% sensitivity and >95% specificity.
- Radiolabeled urea with either C¹³ or C¹⁴ is given orally; urease secreted by *H. pylori* in the stomach (if present) hydrolyzes radiolabeled urea to produce radiolabeled CO₂, which is exhaled and then quantified from the expired breath; radiation exposure is minimal.
- Withhold H₂RAs and PPIs 1 to 2 weeks prior to testing and antibiotics and bismuth salts 4 weeks prior to testing to reduce the risk of false negatives.
- Used to detect *H. pylori* prior to treatment and to document posttreatment eradication.
- Results usually take about 2 days; less expensive than tests that utilize gastric mucosal biopsy but more expensive than serologic tests.
- Availability and reimbursement is inconsistent.

Serologic Antibody Tests

- Detects IgG antibodies to *H. pylori* in serum, whole blood or urine; quantitative serologic tests have a sensitivity of about 85% and specificity of about 79%.
- Qualitative in office tests; provide results quickly (usually within 15 minutes) but yield more variable results.
- Tests are widely available and inexpensive.
- Not of benefit in documenting eradication, because antibodies to *H. pylori* remain positive for years following successful eradication of the infection.
- Results not affected by H₂RAs, PPIs, antibiotics, or bismuth.

Fecal Antigen Test

- Identifies *H. pylori* antigen in stool; sensitivity and specificity comparable to the UBT for initial diagnosis.
- H₂RAs, PPIs, antibiotics, and bismuth may cause false-negative results but to a lesser extent than the UBT.
- Considered an alternative to detecting *H. pylori* prior to treatment and documenting posttreatment eradication.

H₂RA, H₂-receptor antagonist; IgG, immunoglobulin G; PPI, proton pump inhibitor; UBT, urea breath test.
Adapted from references 9, 80, and 92, with permission.

Three nonendoscopic tests are available to detect *H. pylori* infection and include the urea breath test (UBT), serologic antibody detection tests, and the fecal antigen test^{9,80,92} (Table 26-5). If endoscopy is not planned, these tests are a reasonable choice to determine *H. pylori* status, as they are noninvasive, more convenient, and less expensive than the endoscopic tests. However, testing should only be undertaken if eradication therapy is planned for positive results. The UBT tests for active *H. pylori* infection and is the most accurate noninvasive test.^{80,92} The ¹³carbon (nonradioactive isotope) and ¹⁴carbon (radioactive isotope) tests require that the patient ingest radiolabeled urea, which is then hydrolyzed by *H. pylori* (if present in the stomach) to ammonia and radiolabeled bicarbonate. The radiolabeled bicarbonate is absorbed in the blood and excreted in the

breath. A mass spectrometer is used to quantitative ¹³carbon, whereas ¹⁴carbon is measured by using a scintillation counter. The serologic antibody tests are a cost-effective alternative for the initial diagnosis of *H. pylori* infection. Antibodies to *H. pylori* can be assessed quantitatively by using the laboratory-based enzyme-linked immunosorbent assay (ELISA) or qualitatively by using the office-based kits. Because the antibody tests do not differentiate between active infection and previously eradicated *H. pylori*, they should not be used to confirm eradication.^{9,80,92} The fecal antigen test identifies *H. pylori* antigens in the stool by enzyme immunoassay.^{80,92} It is less expensive and easier to perform than the UBT and may be useful in children. Although comparable to the UBT in the initial detection of *H. pylori*, the fecal antigen test may be less

accurate when used to document eradication post treatment. Salivary and urine antibody tests are under investigation.⁹²

Laboratory Tests, Radiography, and Endoscopy

Generally, laboratory tests are not helpful in the diagnosis of PUD. Fasting serum gastrin concentrations are only recommended for patients unresponsive to therapy or those suspected of having a hypersecretory disease. Serum hematocrit (Hct) and hemoglobin (Hgb) and stool hemoccult tests assist in the evaluation of ulcer-related bleeding.

Gastric acid secretory studies are not routinely performed for patients suspected of having an uncomplicated peptic ulcer. However, measurements of acid secretion are instrumental in the evaluation of patients with severe, recurrent PUD that is unresponsive to standard drug therapy. Acid secretion is expressed as basal acid output (BAO), in response to a meal (meal-stimulated acid secretion), or as maximal acid output (MAO).¹¹ The BAO, meal-stimulated acid secretion, and MAO varies according to age, gender, health, and time of day. The BAO follows a circadian rhythm, with the highest acid secretion occurring at night and the lowest in the morning. An increase in the BAO:MAO ratio suggests a basal hypersecretory state such as ZES.

Confirmation of a peptic ulcer requires visualizing the ulcer either by GI radiography or upper endoscopy.⁹ Radiography is often the initial diagnostic procedure because is less expensive than endoscopy and more widely available. Double-contrast radiography is preferred because it detects 60% to 80% of ulcers, while tests using single-barium contrast detect 30% of peptic ulcers.⁹ Fiberoptic upper endoscopy (esophagogastroduodenoscopy [EGD]) is the gold standard, as it detects >90% of peptic ulcers and permits direct inspection, biopsy, visualization of superficial erosions, and sites of active bleeding. Upper endoscopy is preferred if complications are suspected or if an accurate diagnosis is required. If a gastric ulcer is found on radiography, malignancy should be excluded by direct endoscopic visualization and histology.

Clinical Course and Prognosis

The clinical course of PUD is characterized by periods of exacerbations and remissions unless the underlying cause is removed.⁹ Eradication of *H. pylori* decreases ulcer recurrence and complications. Prophylactic cotherapy or the use of a selective COX-2 inhibitor decreases the risk for ulcers and related complications in high-risk patients taking NSAIDs. It is estimated that about 20% of patients with chronic PUD experience ulcer-related complications. Mortality is highest in patients with gastric ulcer. Adenocarcinoma in *H. pylori*-infected patients occurs over 20 to 40 years and is associated with a lifetime risk <1%.^{9,76}

Treatment

Therapeutic Goals

The therapeutic goals for treating PUD depend on whether the ulcer is related to *H. pylori* or associated with a NSAID. Treatment goals may differ depending on whether the ulcer is initial or recurrent and whether complications have occurred. Treatment is aimed at relieving ulcer symptoms, healing the ulcer, preventing ulcer recurrence, and reducing ulcer-related

complications. When possible, the most cost-effective drug regimen should be utilized.

Nonpharmacologic Therapy

Patients with PUD should discontinue NSAIDs (including aspirin) if possible. Patients unable to tolerate certain foods and beverages (e.g., spicy foods, caffeine, and alcohol) may benefit from dietary modifications. Lifestyle modifications including reducing stress and decreasing or stopping cigarette smoking is encouraged.

Probiotics containing strains of *Lactobacillus* and *Bifidobacterium* and foodstuffs (e.g., cranberry juice and some milk proteins) with bioactive components have been studied in at-risk individuals to proactively control colonization of *H. pylori*. When combined with eradication regimens, the same probiotic strains have been reported to augment *H. pylori* eradication by possibly decreasing mucosal inflammation.⁹⁴ The regular intake of probiotics may eventually become a low-cost alternative for individuals at risk for *H. pylori* infection and may enhance eradication in conjunction with drug treatment regimens.

Patients with ulcer-related complications may require surgery for bleeding, perforation, or obstruction. Surgery for medical treatment failures (e.g., vagotomy with pyloroplasty or vagotomy with antrectomy) are rarely performed because of effective medical management. However, patients may present with postoperative consequences (e.g., postvagotomy diarrhea, dumping syndrome, anemia) associated with these procedures.

Pharmacotherapy

Drug regimens used to eradicate *H. pylori* are identified in Table 26-6. First-line therapy should be initiated with a PPI-based three-drug regimen (Fig. 26-4). If a second course of treatment is required, the PPI-based three-drug regimen should contain different antibiotics or a four-drug regimen with a bismuth salt, metronidazole, tetracycline, and a PPI should be used. Successful treatment will heal the ulcer and eradicate the infection (cure the disease). Treatment of *H. pylori*-positive patients with a conventional antiulcer drug is not recommended because of the high rate of ulcer recurrence and complications. Combining a PPI and H₂RA or sucralfate and either a H₂RA or PPI is not recommended, because it adds to drug costs without improving efficacy. Maintenance therapy with a PPI or H₂RA (Table 26-1) should only be necessary in high-risk patients with a history of ulcer complications, those with *H. pylori*-negative ulcers, and patients with other concomitant acid-related diseases (e.g., GERD).

Drug regimens used to treat and prevent NSAID-induced ulcers are identified in Table 26-1. Patients with NSAID-induced ulcers should be tested to determine their *H. pylori* status. *H. pylori*-positive patients should be initially treated with a PPI-based three-drug eradication regimen (Fig. 26-4). If the patient is *H. pylori*-negative, the NSAID should be discontinued and treatment should be initiated with antiulcer medications. The duration of treatment should be extended if the NSAID is continued. Prophylactic cotherapy with a PPI or misoprostol or switching to an NSAID with greater COX-2 selectivity is recommended for patients at risk of developing ulcer-related upper GI complications.

Table 26-6 Oral Drug Regimens Used to Eradicate *Helicobacter pylori* Infection

| Drug Regimen | Dose | Frequency | Duration |
|--|----------------------------|------------------------|-------------------------|
| Proton Pump Inhibitor–Based Three-Drug Regimens | | | |
| PPI | Standard dose ^a | BID ^a | 10–14 days ^b |
| Clarithromycin | 500 mg | BID | 10–14 days ^b |
| Amoxicillin ^c | 1 g | BID | 10–14 days ^b |
| or | | | |
| PPI | Standard dose ^a | BID ^a | 10–14 days ^b |
| Clarithromycin | 500 mg | BID | 10–14 days ^b |
| Metronidazole ^c | 500 mg | BID | 10–14 days ^b |
| Bismuth-Based Four-Drug Regimens | | | |
| Bismuth subsalicylate ^d | 525 mg | QID | 10–14 days |
| Metronidazole | 250–500 mg | QID | 10–14 days |
| Tetracycline | 500 mg | QID | 10–14 days |
| plus | | | |
| PPI | Standard dose ^a | QD or BID ^a | 10–14 days |
| or | | | |
| H ₂ RA ^e | Standard dose ^e | BID ^e | 4–6 wks |
| Sequential Therapy^f | | | |
| PPI | Standard dose ^a | BID ^a | Days 1–10 |
| Amoxicillin | 1 g | BID | Days 1–5 |
| Clarithromycin | 250–500 mg | BID | Days 6–10 |
| Metronidazole | 250–500 mg | BID | Days 6–10 |
| Salvage or Rescue Therapy | | | |
| Bismuth subsalicylate ^d | 525 mg | QID | 10–14 days |
| Metronidazole | 250–500 mg | QID | 10–14 days |
| Tetracycline | 500 mg | QID | 10–14 days |
| PPI | Standard dose ^a | QD or BID ^a | 10–14 days |
| or | | | |
| PPI | Standard dose ^a | BID ^a | 10–14 days |
| Amoxicillin | 1 g | BID | 10–14 days |
| Levofloxacin | 500 mg | QD | 10–14 days |

^aOmeprazole 20 mg BID; lansoprazole 30 mg BID; pantoprazole 40 mg BID; rabeprazole 20 mg BID or QD; esomeprazole 20 mg BID or 40 mg QD.

^bAlthough 7-day regimens provide acceptable eradication rates, the preferred treatment duration in the United States is 10 to 14 days.

^cUse amoxicillin in nonpenicillin-allergic individuals; substitute metronidazole for amoxicillin in penicillin-allergic patients.

^dPylera, a prepackaged *H. pylori* regimen, contains bismuth subcitrate potassium (bismuth subcitrate) 140 mg as the bismuth salt in place of bismuth subsalicylate, metronidazole 125 mg and tetracycline 125 mg per capsule. The patient is directed to take three capsules/dose with each meal and at bedtime. A standard dose of a PPI is added to the regimen and taken twice daily. All medications are taken for a 10-day period.

^eSee Table 26-1 for standard peptic ulcer healing dosage regimens.

^fRequires validation in the United States.

BID, twice a day; H₂RA, H₂-receptor antagonist; PPI, proton pump inhibitor; QID, four times a day; QD, every day.

HELICOBACTER PYLORI–RELATED PEPTIC ULCER

1. R.L. is an otherwise healthy 45-year-old man who works in a high-stress job as an air traffic controller at a major airport. He complains of a 2-week history of “burning stomach pain” sometimes accompanied by “indigestion and bloating.” The pain initially occurred several times a day, usually between meals, and sometimes awakened him at night, but it has increased in frequency over the last week. Initially, the pain was temporarily reduced by food or antacids. Last week, R.L. tried an OTC H₂-receptor antagonist that “lasted longer” but did not provide adequate symptom relief. R.L. indicates that he experienced a similar type of pain about 10 years ago when he was treated

with omeprazole for a suspected peptic ulcer. He has smoked one pack of cigarettes daily for the past 20 years, has an occasional glass of red wine with dinner, and usually drinks 4 to 6 cups of caffeinated coffee throughout the day. R.L. takes acetaminophen for occasional headaches and a multivitamin but denies the use of any other OTC or prescription medications, including NSAIDs. He denies nausea, vomiting, anorexia, weight loss, and any changes in stool consistency or color. A review of other body systems is noncontributory. There are no known food or drug allergies.

Physical examination is normal except for epigastric tenderness on palpation of the upper abdomen. Vital signs include a temperature of 98.8°F, blood pressure of 132/80, and a heart rate

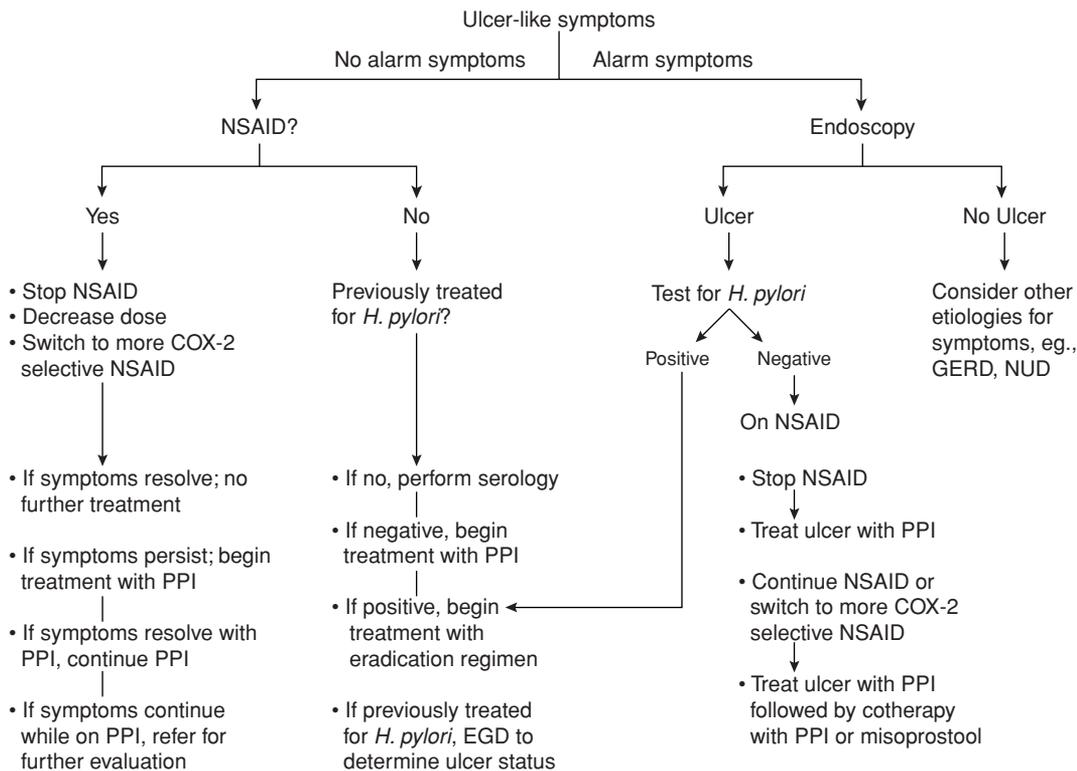

FIGURE 26-4 Management of peptic ulcer disease. *H. pylori*, *Helicobacter pylori*; H₂RA, H₂-receptor antagonist; NSAID, nonsteroidal anti-inflammatory drug; NUD, nonulcer dyspepsia; PPI, proton pump inhibitor.

of 78 beats/minute. Pertinent laboratory values include Hgb of 14.0 g/dL, Hct of 44%, and a negative stool guaiac test. All other laboratory values are within normal limits. What signs and symptoms are suggestive of a recurrent peptic ulcer?

Most patients with PUD present with abdominal pain that is epigastric and often described as burning or gnawing, while others complain of abdominal discomfort, fullness, or cramping. Epigastric pain, however, does not necessarily correlate with an ulcer, as patients with ulcer-like symptoms may have NUD and asymptomatic patients may have an NSAID-induced ulcer. Heartburn, bloating, and belching may accompany the pain. Ulcer pain typically occurs during the day but can also awaken the patient from sleep (nocturnal pain). In patients with a duodenal ulcer, epigastric pain frequently occurs between meals and is often relieved by food, but this varies from patient to patient. Alternatively, food may precipitate or accentuate pain in patients with a gastric ulcer.

The severity of ulcer pain varies from patient to patient. The pain may be seasonal, occurring more frequently in the spring or fall and occurring in clusters lasting up to a few weeks followed by a pain-free period or remission lasting from weeks to years. Antacids and antisecretory medications usually provide relief of ulcer pain in most patients. Pain usually diminishes or disappears during treatment, but epigastric pain after healing often suggests an unhealed or recurrent ulcer. Changes in the character of the pain may suggest the presence of complications. Nausea, vomiting, anorexia, and weight loss are more common with gastric ulcer but may also be suggestive of ulcer-related complication. The diagnosis of PUD cannot be

made on symptoms alone and requires visualization of the ulcer crater.

2. R.L. underwent upper endoscopy (EGD), which revealed a single 0.5-cm ulcer in the duodenal bulb. The ulcer base was clear without evidence of active bleeding. Antral gastritis was biopsy positive for *H. pylori*. What risk factors may have contributed to ulcer recurrence in this patient?

R.L. indicates that he had a similar type of abdominal pain about 10 years ago, when he was treated with omeprazole for a suspected peptic ulcer. When conventional antiulcer therapy (e.g., PPI) is discontinued after ulcer healing, 60% to 100% of patients develop a recurrent ulcer within 1 year.^{9,75} The most important factors that influence ulcer recurrence are *H. pylori* infection and NSAID use. It is not known whether R.L. underwent testing for *H. pylori* 10 years ago. The patient denies the use of OTC and prescription NSAIDs. The long-term use of maintenance therapy with conventional antiulcer medications (Table 26-1) may have been an option for this patient at the time he was treated for a suspected peptic ulcer, because it reduces ulcer recurrence to 20% to 40% at 1 year.⁹ However, the eradication of *H. pylori* (in a *H. pylori*-positive patient) decreases ulcer recurrence to <10% at 1 year, cures the disease, and eliminates the need for long-term maintenance therapy in most patients.^{9,75}

Other factors such as cigarette smoking, psychologic stress, and diet may have contributed to ulcer recurrence in this patient. There is epidemiologic evidence linking cigarette smoking to PUD. The risk appears proportional to the number of cigarettes smoked per day and is greatest when >10 cigarettes

are smoked per day.⁹ Although a number of mechanisms have been postulated, including delayed gastric emptying, inhibition of pancreatic bicarbonate secretion, promotion of duodenogastric reflux, reduction in mucosal prostaglandin production, and increases gastric acid secretion. There is insufficient evidence to conclude that cigarette smoking actually causes a peptic ulcer.⁹ However, cigarette smoking, nicotine, or other components of smoke may provide a favorable milieu for *H. pylori* infection.

R.L. works as an air traffic controller, which is a high-stress job. However, the importance of psychological stress and how it affects PUD is complex and probably multifactorial. Results from controlled trials are conflicting and have failed to demonstrate a cause-and-effect relationship.⁹ However, the clinical observation of ulcer patients with high-stress jobs and a stressful lifestyle suggest that they are adversely affected. Emotional stress may induce behavioral risks such as cigarette smoking and the use of NSAIDs or alter the inflammatory response or resistance to *H. pylori* infection.

Caffeine-containing coffee, tea, and cola beverages, constituents in decaffeinated coffee or tea, caffeine-free carbonated beverages, and alcoholic beverages such as beer and wine all increase gastric acid secretion, but there is no evidence that they increase the risk for PUD. Certain foods (e.g., spicy) may cause dyspepsia but do not cause peptic ulcers. In high concentrations, alcohol is associated with acute gastric mucosal damage and upper GI bleeding, but there is insufficient evidence to confirm that alcohol causes ulcers.⁹ Dietary restrictions and bland diets do not alter the frequency of ulcer recurrence. Because certain foods and beverages may exacerbate or worsen ulcer symptoms, the patient may decide to avoid them. R.L. is otherwise healthy and does not have any other medical conditions (e.g., chronic renal failure) that are associated with an increased risk of PUD (see Etiology and Risk Factors section).

3. What are the goals of therapy when treating this patient?

The goals of therapy in a *H. pylori*-positive patient with an active ulcer, a previously documented ulcer, or a history of an ulcer-related complication is to render the patient asymptomatic, heal the ulcer, eradicate the infection, and cure the disease. Treatment should be effective, well-tolerated, easy to comply with, and cost-effective. Drug regimens should have an eradication rate of at least 70% (intention-to-treat) and should minimize the potential for antimicrobial resistance.^{75,80,95,96} The use of a single antibiotic, bismuth salt, or antiulcer drug does not achieve this goal.⁷⁵ Two drug regimens (PPI and amoxicillin or clarithromycin) are not recommended in the United States because of marginal eradication rates and because the use of only one antibiotic increases the risk for antibiotic resistance.^{9,75}

Primary Treatment of *Helicobacter pylori* Infection

4. What is the preferred *H. pylori* eradication regimen for this patient? Which factors should be taken into consideration when selecting an eradication regimen?

The selection of a first-line eradication regimen should include an antibiotic combination that permits second-line treat-

ment (if necessary) with different antibiotics. The antibiotics that have been most extensively studied and found to be effective in various combinations include clarithromycin, amoxicillin, metronidazole, and tetracycline.^{9,75} The recommended first-line eradication therapies in the United States are the PPI-based three-drug regimens^{75,80,95,96} (Table 26-6). When given in recommended dosages, most recent studies report intention-to-treat eradication rates of 70% to 80%.⁸⁰ Increasing the antibiotic daily dose usually does not improve eradication rates. When combined with a PPI and clarithromycin, the inclusion of amoxicillin or metronidazole provides similar eradication rates.⁹⁷ However, amoxicillin is usually preferred initially because it is associated with little or no bacterial resistance, has fewer adverse effects, and leaves metronidazole as an option for second-line therapies.⁹ Thus, the PPI-amoxicillin-clarithromycin regimen is an acceptable first-line regimen for R.L., as he has no known allergies to drugs (including penicillin) and has not received previous eradication therapy.

The recommended duration of treatment in the United States is 14 days, even though 10 to 14 days is typically used and international guidelines recommend a treatment duration of 7 to 10 days.⁸⁰ A meta-analysis of seven trials indicates that a 14-day course of a PPI-based triple therapy containing clarithromycin yielded better eradication rates than a 7-day course and showed a trend toward improved efficacy with a 10-day course when compared with 7 days.⁹⁸ A large randomized trial also reports the superiority of a 14-day eradication regimen over a 7-day regimen.⁹⁹ A longer treatment duration favors a higher eradication rate and is less likely to be associated with antimicrobial resistance.^{75,80} A treatment duration <7 days is not recommended and is associated with unsatisfactory eradication rates. A meta-analysis of 13 studies indicates that twice-daily dosing of the PPI in the PPI-based regimens containing clarithromycin may be superior to a single daily dose.¹⁰⁰ Pretreatment with a PPI dose prior to initiating *H. pylori* eradication does not appear to decrease eradication rates.¹⁰¹ Prolonged treatment with the PPI beyond 14 days is not necessary for ulcer healing in most patients.

A 14-day bismuth-based four-drug regimen that contains a H₂RA (Table 26-6) yields eradication rates similar to those achieved with a PPI-based three-drug regimen containing clarithromycin.^{75,80} A meta-analysis of five randomized trials reports eradication rates of 79% for PPI-based clarithromycin triple therapy and 80% for bismuth-based quadruple therapy when using intention to-treat analysis.¹⁰² Quadruple therapy (bismuth, metronidazole, and tetracycline) using a PPI instead of a H₂RA permits a shorter duration of treatment (10 days vs. 14 days) and may provide increased efficacy in patients with metronidazole-resistant strains of *H. pylori*.^{102,103} Comparable eradication rates have been achieved by using a novel bismuth-based quadruple therapy containing bismuth subcitrate potassium (biscalcitate) in place of bismuth subsalicylate and a twice-daily PPI¹⁰⁴ (Table 26-6). Increasing the duration of quadruple therapy to 1 month does not substantially increase eradication. The bismuth-based four-drug regimens are as effective as the PPI-based three-drug regimens containing clarithromycin and are indicated as first-line therapy. However, the complexity of these regimens often relegates them to second-line status in clinical practice.

Alternative first-line therapies are needed because of the declining eradication rates reported with the PPI-based three-drug regimens containing clarithromycin and the bismuth-based four-drug regimens.⁸⁰ These lower eradication rates have been attributed to an increase in clarithromycin and metronidazole resistance. Sequential therapy with a PPI and amoxicillin for 5 days followed by a PPI, clarithromycin, and an imidazole for an additional 5 days (Table 26-6) has achieved eradication rates that are superior to the PPI-based three-drug regimens containing clarithromycin.^{80,105} An increased efficacy has also been reported with sequential therapy in patients with clarithromycin-resistant *H. pylori* strains.¹⁰⁶ The rationale for sequential eradication therapy is to initially treat the patient with antibiotics that rarely promote resistance (e.g., amoxicillin) in order to reduce the bacterial load and preexisting resistant organisms and then to follow with different antibiotics to kill the remaining organisms. Although the precise mechanism for the success of sequential therapy is uncertain, the higher efficacy may be related to the increased number of antibiotics (amoxicillin, metronidazole, and clarithromycin) to which the organism is exposed. Although sequential therapy looks promising, it must be validated in the United States before it can be recommended as first-line eradication therapy.

Patient Education

5. R.L. is prescribed a 14-day PPI-based three-drug eradication containing amoxicillin and clarithromycin. What instructions would you provide R.L. regarding his medications?

R.L. should be informed of the importance of taking his medications as prescribed in order to minimize treatment failure and the development of antibiotic resistance. He should be advised that the PPI is an integral part of the three-drug regimen and should be taken twice daily 30 to 60 minutes before breakfast and dinner (see Pharmacotherapy Proton Pump Inhibitor section) along with the amoxicillin and clarithromycin (Table 26-6). If he were taking a bismuth-based four-drug regimen containing a PPI, all medications except the PPI should be taken four times a day with meals and at bedtime. If the PPI is to be taken once daily, it should be taken 30 to 60 minutes prior to breakfast; if twice daily, the second dose should be taken 30 to 60 minutes prior to dinner.

R.L. should also be informed of the most common side effects associated with his treatment regimen. All antibiotics included in the *H. pylori* eradication regimens are usually associated with mild side effects, including nausea, abdominal pain, and diarrhea. *C. difficile*-associated diarrhea, a serious antibiotic-related complication, occurs occasionally. Oral thrush and vaginal candidiasis (in women) may also occur. Clarithromycin and metronidazole may cause taste disturbances. If R.L.'s medications included metronidazole, tetracycline, or a bismuth salt, he should be provided additional information on these medications. Metronidazole-containing regimens increase the frequency of side effects (especially when the dose is > 1 g/day) and may be associated with a disulfiramlike reaction in patients who consume alcohol. Tetracycline may cause photosensitivity and should not be used in children

because it may cause tooth discoloration. Bismuth salts may cause darkening of the tongue and stool.

Regimens for the Management of *Helicobacter pylori* Infection in Patients With Penicillin Allergies

6. What would have been the preferred initial *H. pylori* eradication regimen if R.L. had a documented allergy to penicillin?

There are two first-line treatment options if R.L. had a documented allergy to penicillin. Metronidazole can be substituted for amoxicillin in the PPI-based three-drug regimen, as similar eradication rates are achieved^{97,107} (Table 26-6). Alternatively, the bismuth-based four-drug regimens may also be used, as they provide similar eradication rates to the PPI-based three-drug regimens.

7. What drug substitutions are acceptable in the PPI-based three-drug and bismuth-based four-drug eradication regimens?

Substitution of one PPI for another is acceptable and does not enhance or diminish eradication rates in either the three- or four-drug regimens.^{80,108} A PPI may be substituted for a H₂RA in the bismuth-based four-drug regimen (Table 26-6). However, a H₂RA should not be substituted for a PPI in the three-drug regimens¹⁰⁹ unless the patient is unable to tolerate the PPI.¹¹⁰ There are insufficient data to support the substitution of ampicillin for amoxicillin, doxycycline for tetracycline, and azithromycin or erythromycin for clarithromycin.

Substitution of clarithromycin 250 to 500 mg four times a day for tetracycline in the bismuth-based four-drug regimen yields similar results, but substitution of amoxicillin for tetracycline lowers the eradication rate and is not recommended.^{9,102}

8. What are the most important predictors of *H. pylori* treatment outcomes, and how may they alter R.L.'s response to treatment?

The two most important factors in predicting a favorable response to *H. pylori* eradication are medication adherence and antibiotic resistance.^{75,80,96,111,112} Medication adherence decreases with multiple medications, increased frequency of administration, increased duration of treatment, intolerable adverse effects, and costly drug regimens. Although a longer treatment duration may contribute to nonadherence, missed doses in a 7-day regimen may also lead to failed eradication.¹¹¹ The bismuth-based four-drug regimen requires the patient to take medications four times a day and as many as 18 tablet/capsules per day. The complexity of this regimen explains why many consider it second-line even though it is similar in efficacy to the PPI-based three-drug regimens that are taken twice daily. While mild side effects are common with all of the eradication regimens, some patients will experience clinically important effects that lead to discontinuation of a specific drug or of the entire regimen. There are limited data to suggest that smoking, alcohol consumption, and diet may negatively impact eradication.¹¹¹

Antibiotic resistance is an important determinant of successful *H. pylori* eradication.^{80,87,96,111} Antibiotic resistance rates among *H. pylori* strains in the United States from 1993 to 1999 were reported to be 37.0% for metronidazole, 10.0%

for clarithromycin, and 1.4% for amoxicillin.¹¹³ More recent data collected from 1998 to 2002 reveal resistance rates of 25.0% for metronidazole, 13.0% for clarithromycin, and 0.9% for amoxicillin.¹¹⁴ Although difficult to compare, it appears that clarithromycin rates have increased, while metronidazole and amoxicillin have remained relatively stable. It is likely that the increase in clarithromycin resistance may explain, in part, the decreasing efficacy of clarithromycin-containing eradication regimens.⁸⁰ The clinical importance of metronidazole resistance is uncertain, as higher metronidazole doses and the synergistic effect of combining metronidazole with other antibiotics appears to render resistance to metronidazole more relative. Alternatively, even though resistance to clarithromycin is lower, it is more likely to affect the clinical outcome.^{80,111} Resistance to amoxicillin and tetracycline is uncommon. Resistance to bismuth has not been reported. Other factors that may contribute to treatment failure include the specific *H. pylori* strain and CYP2C19 polymorphism when PPIs are used as part of the eradication regimen.⁸⁰

9. What parameters should be monitored to determine R.L.'s response to treatment?

Posttreatment testing to confirm eradication is recommended for patients with a *H. pylori*-related ulcer, persistent dyspeptic symptoms, MALT lymphoma, or early gastric cancer.⁸⁰

However, posttreatment testing is neither practical nor cost-effective for all patients with a *H. pylori*-positive peptic ulcer.⁸⁰ When endoscopy follow-up is not necessary, the UBT (Table 26-5) is the preferred test to confirm eradication of *H. pylori*. To avoid confusing bacterial suppression with eradication, the UBT must be delayed at least 4 weeks after the completion of treatment. The term *eradication* or *cure* is used when post-treatment tests conducted 4 weeks after the end of treatment do not detect the organism. Antibody tests should be avoided post treatment, because antibody titers remain elevated for a long period of time (up to 1 year) before they return to the uninfected range following successful eradication.^{9,80,92} If performed post treatment, only a negative test is considered to be reliable.

Upper endoscopy should only be used to confirm eradication and ulcer healing if indicated (e.g., severe or frequent recurrent symptoms, current or previous ulcer complication), as the procedure is costly and invasive. When endoscopic follow-up is necessary, testing to prove eradication includes a biopsy for the rapid urease test and histology (Table 26-5). Ulcer healing can also be confirmed at that time.

In clinical practice, the need for confirmation of ulcer healing and eradication must be weighed against the need, feasibility, availability and cost of tests and procedures. Although posttreatment testing to confirm *H. pylori* eradication is recommended, patients like R.L., who present with an uncomplicated *H. pylori*-positive ulcer, are usually monitored for symptomatic recurrence 1 to 2 weeks post completion of drug therapy.⁸⁰ The absence of symptoms is considered a surrogate marker for successful ulcer healing and eradication. The persistence, or recurrence, of symptoms within 2 weeks after the end of treatment suggests failure of ulcer healing or eradication or an alternative diagnosis such as GERD.

Therapy for Refractory *Helicobacter pylori* Infection

10. What other drug regimens can be used if R.L. fails initial eradication therapy with a PPI-amoxicillin-clarithromycin regimen?

Eradicating *H. pylori* is more difficult after initial treatment fails, as attempts to eradicate the organism are extremely variable.^{75,96} Second-line regimens should (a) avoid using antibiotics that were used during initial therapy, (b) use antibiotics that have less problems with resistance, (c) use drugs that have a topical effect (e.g., bismuth), and (d) employ a 10- to 14-day treatment regimen.¹¹¹ If R.L. was not successfully eradicated initially with omeprazole-amoxicillin-clarithromycin, he should receive second-line therapy with bismuth subsalicylate, metronidazole, tetracycline, and a PPI for 10 to 14 days^{75,80,111,115} (Table 26-6). An eradication rate of 76% has been reported in the pooled analysis of 16 studies and 24 abstracts when bismuth quadruple therapy is used as second-line therapy after initial treatment failure.¹¹⁶

A PPI-based triple therapy containing levofloxacin and amoxicillin (Table 26-6) has been evaluated as second-line therapy in patients with persistent infection. The results of a meta-analysis containing four randomized trials indicates that a 10-day PPI-based three-drug regimen containing levofloxacin was superior to a 7-day bismuth-based four-drug regimen and was associated with fewer side effects.¹¹⁷ Although the results from the levofloxacin-based regimens look promising, they require validation. A PPI-based three-drug regimen containing rifabutin and amoxicillin reported a 91% eradication rate, but side effects were common.¹¹⁸ Regimens using furazolidone (100 mg four times a day) in place of metronidazole in either the PPI-based three-drug regimens or the bismuth-based four-drug regimen have been studied and yield variable eradication rates.¹¹¹ However, furazolidone is not available in the United States.

NONSTEROIDAL ANTI-INFLAMMATORY DRUG-INDUCED PEPTIC ULCER

11. A.D. is a 70-year-old woman who retired from teaching about 5 years ago. Several days ago, she noticed black “tarry” stools and was hospitalized for an upper GI bleed most likely secondary to NSAID use. She complains of “feeling tired” and occasionally dizzy for about 1 week. A.D. presents with a 5-year history of rheumatoid arthritis for which she takes naproxen 250 mg in the morning and 500 mg in the evening. She states that prior to admission, she was also taking prednisone 10 mg daily about a week for her arthritic pain that was not controlled with naproxen. She denies any history of previous ulcer or ulcer-related complication. Other prescription medications include hydrochlorothiazide 25 mg daily for hypertension. OTC self-directed medications include enteric-coated aspirin 81 mg daily, calcium carbonate, and a multivitamin. A.D. does not use tobacco or drink caffeinated beverages but does have an occasional beer with friends. She denies epigastric pain, nausea, vomiting, anorexia, and weight loss but notes a recent change in stool color. A review of other body systems are noncontributory other than previously indicated. There are no known food or drug allergies.

Physical examination reveals a well-developed weak woman in no acute distress. The abdomen was normal with no pain on

palpation. Bowel sounds were normal with no guarding, masses, hepatomegaly, or splenomegaly. The rectum was normal but with guaiac-positive stool. Vital signs include a temperature of 98.9°F, blood pressure of 100/65, and a heart rate of 90 beats/minute. Pertinent laboratory values include Hgb of 11.0 g/dL, Hct of 35%, blood urea nitrogen (BUN) 40, and serum creatinine (SrCr) 1.5 mg/dL. All other laboratory values are within normal limits. What factors place A.D. at increased risk for developing an NSAID-induced ulcer and related upper GI bleeding?

The use of a nonselective NSAIDs (e.g., naproxen) is linked to a three- to fourfold increase in upper GI complications while there is a two- to threefold increase with COX-2 inhibitors when partially and highly selective agents are evaluated as a group⁹⁰ (Table 26-4). The risk for NSAID-induced ulcer and related complications is dose related, but ulcers can occur at any dosage, including low doses of OTC NSAIDs.¹¹⁹ Upper GI events can occur at any time during treatment with an NSAID, as the risk for complications is similar throughout treatment. The use of cardioprotective dosages (81–325 mg/day) of aspirin in combination with another NSAID increases the risk of upper GI complications to a greater extent than the use of either drug alone.^{82,84,89} The use of buffered or enteric-coated aspirin confers no added protection from ulcer or GI complications.^{89,91} Corticosteroids do not increase the ulcer risk when used alone, but the risk is increased twofold in corticosteroid users such as A.D. who are also taking concurrent NSAIDs.¹²⁰ A.D.'s age (70 years) is an independent risk factor for NSAID-induced ulcers, as risk increases linearly with the age of the patient¹²⁰ (Table 26-3). The increased incidence in older patients may be explained by age-related changes in gastric mucosal defense. The combined risk factors greatly increase A.D.'s risk for an NSAID-related upper GI event, as ulcer risk is additive.

A.D. did not have a history of an ulcer or ulcer-related complication. However, the risk of a NSAID ulcer or complication increases 14-fold in a patient with a previous ulcer or complication.⁹ The risk of upper GI bleeding is also markedly increased when NSAIDs are taken with anticoagulants or medications such as clopidogrel.⁹⁰ Selective serotonin reuptake inhibitors (SSRIs) have been reported to independently increase the risk of upper GI bleeding,¹²¹ although more recent data suggest the increased bleeding risk may be less than that initially reported.¹²² Whether *H. pylori* is a risk factor for NSAID-induced ulcers is uncertain.^{89,123} Because the incidence of PUD is higher in a *H. pylori*-positive patient taking NSAIDs, it is possible that they have additive effects.¹²⁴

12. A.D. was admitted for further evaluation and treatment. An upper endoscopy (EGD) revealed two bleeding antral ulcers (0.2 and 0.4 cm). An antral biopsy was reported to be *H. pylori* negative. All medications were discontinued. Oral oxycodone was instituted at 5 mg every 6 hours when needed to control A.D.'s arthritic pain while she was hospitalized. Consideration was given to decreasing the naproxen dose and switching to acetaminophen, a nonacetylated salicylate, or a partially selective NSAID (Table 26-4), but none of these options were satisfactory for this patient. Treatment was initiated with a continuous infusion of IV pantoprazole for 3 days and then she was switched to oral pantoprazole 40 mg BID. A.D. was discharged on pantoprazole 40 mg QD and naproxen 250 mg in the morning and 500 mg in the evening.

All other oral medications were reinstated except for the prednisone. Will A.D.'s gastric ulcer heal if she continues to take the naproxen?

The naproxen should be discontinued, if possible, in the presence of an active ulcer.^{82,120} If A.D. were able to discontinue the naproxen permanently, a PPI would be preferred, as it provides a more rapid rate of ulcer healing (4 weeks) and symptom relief than H₂RAs or sucralfate (6–8 weeks).⁹ Because the naproxen was reinstated at discharge in the presence of an active ulcer, a PPI is the drug of choice, as potent acid suppression is required to heal the ulcer and relieve the symptoms.^{82,120} However, the duration of PPI therapy should be extended from 4 weeks to 8 to 12 weeks.

13. Which ulcer-healing regimen would you have recommended if A.D. was reported to be *H. pylori* positive?

All patients with PUD should be tested for *H. pylori*. If positive, patients should be treated with an eradication regimen. A PPI-based eradication regimen is recommended in a *H. pylori*-positive patient with an active ulcer who is also taking an NSAID. One reason for this is that it is not possible to determine whether the *H. pylori*, the NSAID, or both actually caused the ulcer. In addition, if an individual is tested and found to be *H. pylori* positive, he or she should be offered eradication therapy whether or not there is a documented ulcer. The selection of a specific regimen (Table 26-6) depends on a number of factors, including whether the individual is penicillin allergic.

Strategies to Reduce the Risk of NSAID-Induced Peptic Ulcers

14. Three months later, A.D. returned to her gastroenterologist for a follow-up EGD, which confirmed that the gastric ulcers were healed. On return to her primary care physician, the pantoprazole was changed to ranitidine 150 mg BID. Other medications at this time include naproxen 250 mg in the morning and 500 mg in the evening, enteric-coated aspirin 81 mg QD, calcium carbonate, and multivitamins. What pharmacological options are available to reduce the risk of a NSAID ulcer now that A.D.'s initial ulcer is healed and she continues to take the naproxen and aspirin?

Strategies to reduce the risk of NSAID ulcers and upper GI complications in a patient taking a nonselective NSAID include cotherapy with a PPI or misoprostol or the use of a selective COX-2 inhibitor in place of the nonselective NSAID.^{82,88,89,120,125,126} All PPIs, when used in standard dosages (Table 26-1), are effective for this indication. A reduction in upper GI complications in high-risk patients receiving PPI cotherapy has been reported in two small studies.^{127,128}

The H₂RAs should not be recommended as prophylactic cotherapy to reduce the risk of NSAID ulcers. Although standard H₂RA dosages (Table 26-1) are effective in reducing the risk of a duodenal ulcer, they are not effective in reducing the risk of gastric ulcer, which is the most common ulcer associated with NSAIDs.^{82,88,89,120} Higher H₂RA dosages (e.g., famotidine 40 mg twice daily) reduce the risk of gastric and duodenal ulcer but are less effective than a PPI.^{88,89} There are no studies that have evaluated the use of H₂RAs in reducing the risk of ulcer-related upper GI complications. The H₂RAs may be used when necessary to relieve NSAID-related dyspepsia.

Misoprostol reduces the risk of NSAID-induced gastric and duodenal ulcers.^{82,88,89,120} An important trial in rheumatoid arthritis patients indicates that misoprostol also reduces the risk of upper GI complications in high-risk patients.¹²⁹ Initially, the recommended dosage was 200 mcg four times a day, but diarrhea and abdominal cramping limited its use. A dosage of 200 mcg three times a day is comparable in efficacy to 800 mcg/day and should be used in patients unable to tolerate the higher dose.^{82,88,89} When misoprostol 800 mcg/day was compared with lansoprazole (15 mg/day or 30 mg/day) or placebo, misoprostol and both dosages of lansoprazole reduced the risk of ulcer recurrence, although the PPI was better tolerated.¹³⁰ A misoprostol dosage of ≤ 400 mcg/day reduces the incidence of diarrhea but is less efficacious. A fixed dosage form containing misoprostol 200 mcg and diclofenac (50 mg or 75 mg) is available, but flexibility to individualize dosage is lost.

Two large multicenter clinical trials evaluated the GI safety of COX-2 inhibitors, one using celecoxib (CLASS)¹³¹ and the other rofecoxib (VIGOR).¹³² Their trials reported a reduction of 50% to 60% in upper GI events with the COX-2 inhibitors when compared with non- and partially selective NSAIDs. The initial 6-month analysis of celecoxib in the CLASS trial revealed a lower rate of ulcer complications, but evaluation of the data at 13 months indicated that celecoxib did not have a GI safety advantage over ibuprofen or diclofenac.^{88,133} The most likely explanation for these results is that celecoxib is not as highly a selective COX-2 inhibitor as was originally anticipated.¹³⁴ Thus, its improved GI safety when compared with nonselective NSAIDs has not been established. Further analysis of the results indicated that patients taking cardioprotective doses of aspirin had a similar rate of upper GI events as those taking either diclofenac or ibuprofen.¹³¹ Thus, the gastroprotective benefits of celecoxib may be negated in patients taking low-dose aspirin. Aspirin appears to have similar effects on other COX-2 inhibitors. Unlike the CLASS study, the VIGOR trial excluded aspirin users. Results from this trial indicated that ulcers and related complications were lower with rofecoxib than with naproxen.¹³²

Cyclo-oxygenase-2 Inhibitors and Cardiovascular Toxicity

15. What is the concern regarding the use of COX-2 inhibitors and the risk for cardiovascular toxicity?

The risk for cardiovascular events in patients taking COX-2 inhibitors increases with a number of factors, including increased COX-2 selectivity, higher dosages, a longer duration of treatment, and preexisting cardiovascular risk.^{133–136} Although ulcers and ulcer-related complications were less likely with rofecoxib than with naproxen in the VIGOR trial, there was an increased number of myocardial infarctions and thrombotic strokes observed with rofecoxib.¹³² Similar cardiothrombotic events were observed in other rofecoxib studies of longer duration.¹³⁷ In 2004, rofecoxib was withdrawn from the U.S. market. Soon thereafter, valdecoxib was also taken off the market amid concerns about cardiovascular risk.

The cardiovascular safety of celecoxib has also been evaluated, but the risk of myocardial infarction and thrombotic stroke is less certain. Although there appeared to be no difference in cardiovascular risk when celecoxib was compared with diclofenac and ibuprofen in the CLASS trial,¹³¹ a dose-

related increase was reported in one large trial.¹³⁸ Celecoxib remains available in the United States, but cardiovascular risk must be evaluated in each patient when considering the use of this drug. Patients with cardiovascular disease or risk factors for cardiovascular disease are at greatest risk for cardiovascular events with celecoxib. The lowest effective dose should always be used for the shortest duration of time.

There is increasing evidence that certain non- and partially selective NSAIDs (e.g., ibuprofen, diclofenac, and meloxicam) may also increase the risk of myocardial infarction and thrombotic stroke.¹³⁹ The American Heart Association has published recommendations for NSAID use in persons with confirmed cardiovascular disease or risk factors.¹⁴⁰ Recommendations include initiating short-term treatment with less risky options such as acetaminophen or aspirin, tramadol, or narcotics. A NSAID should be considered if these medications are either inappropriate or not effective. The preferred nonselective NSAID is naproxen, because it does not appear to increase cardiovascular risk. NSAIDs with increasing COX-2 selectivity (Table 26-4) may be tried if symptoms are not relieved. However, selective COX-2 inhibitors should be reserved for those patients in whom there are no other alternatives and should be used in the lowest effective dose for the shortest period of time. Thus, GI safety of NSAIDs and selective COX-2 inhibitors must be weighed against the potential increase in cardiovascular risk.

16. How does a COX-2 inhibitor compare with a PPI and a non- or partially selective NSAID when used to decrease ulcer risk and related complications? Have any studies evaluated GI safety in patients taking a COX-2 inhibitor plus a PPI?

Two small nonplacebo controlled trials in *H. pylori*-negative patients at high risk for NSAID-related complications compared celecoxib versus a PPI plus a nonselective or partially selective NSAID.^{141,142} These trials were undertaken before the GI and cardiovascular safety of celecoxib was questioned. In the first trial, celecoxib was compared with lansoprazole plus naproxen,¹⁴¹ while in the second, celecoxib was compared with omeprazole plus diclofenac.¹⁴² The results of these two studies indicate that when celecoxib was compared with a PPI plus a NSAID in high-risk patients, ulcer complications rates were similar but fairly high in both groups.^{141,142} Cotherapy using a COX-2 inhibitor plus a PPI in high-risk patients should be considered, but this regimen is reported to have a very modest benefit when compared with a nonselective NSAID plus a PPI.¹⁴³

17. What factors should be considered when evaluating management strategies for patients at risk of a developing a NSAID-induced ulcer? What risk reduction strategies are considered acceptable for A.D.?

Strategies to reduce the risk of NSAID-induced ulcers and related complications depend on the assessment of risk for each patient (Table 26-3). Although some have attempted to define levels of risk, there are no universally accepted definition.^{82,88,125,126,144} In general, individuals with no risk factors, most individuals <65 years of age, and those taking NSAIDs in the short term are considered to be at low risk and

usually do not require risk-reduction cotherapy. Some patients may benefit from a partially selective NSAID (Table 26-4). Patients at moderate risk include those >65 years of age with one or two risk factors, excluding a history of a prior ulcer or ulcer-related complication. The preferred risk reduction strategy in this group is cotherapy with a PPI. Although cotherapy with misoprostol is also effective, it is used as a second-line therapy because of frequent daily dosing and a dose-dependent diarrhea. When indicated, the patient may be switched to a selective COX-2 inhibitor. The use of a nonselective or partially selective NSAID and a PPI is most likely as effective as a selective COX-2 inhibitor.¹²⁵

Patients like A.D., who have a history of a prior ulcer and ulcer-related upper GI bleed, are at high-risk for future NSAID-related ulcers and complications and require an effective risk-reduction strategy. Additionally, A.D. has other factors that contribute to her high-risk status, including her age (70 years), concurrent use of a nonselective NSAID (naproxen) and enteric-coated aspirin, and the use of corticosteroids. Ranitidine should be discontinued, and A.D. should be switched to an evidence-based risk-reduction regimen. Although the optimal strategy for a high-risk patient like A.D. is unknown, the preferred strategy should take into consideration the risks, benefits, and cost of treatment. High-risk patients may benefit from several strategies, including PPI or misoprostol cotherapy with a nonselective or partially selective NSAID or a selective COX-2 inhibitor. If celecoxib is used, the risk of cardiovascular effects must be weighed against the gastroprotective benefits, especially since A.D. has a history of hypertension. Patients at very high risk, including those with a prior ulcer or complication, renal dysfunction (creatinine clearance <30 mL/minute) and cardiovascular disease should avoid NSAIDs and selective COX-2 inhibitors and should be treated with other analgesics (e.g., tramadol, narcotics), keeping in mind that NSAIDs and selective COX-2 inhibitors are also associated with fluid retention, hypertension, and renal failure.^{133,134} The recommended risk-reduction strategy for A.D. is cotherapy with a PPI or misoprostol.

18. What information should be conveyed to A.D. regarding the combined use of OTC aspirin and NSAIDs?

Counsel A.D. to discuss the use of enteric-coated aspirin with her physician to be certain that the benefit of taking cardioprotective aspirin outweighs the risk for an ulcer-related complication. A.D. should be advised that enteric-coated aspirin may protect against the topical mucosal damage in the stomach and minimize dyspepsia, but the enteric coating does not prevent an ulcer from forming. Even low-dose aspirin (e.g., 81 mg/day) remains capable of causing an ulcer, especially when used in conjunction with a NSAID (naproxen). Buffered aspirin may cause less dyspepsia, but buffering does not prevent ulcers. Taking food, milk, or an antacid with aspirin or NSAIDs may minimize dyspepsia but does not prevent an ulcer.

Inform A.D. that she should not take OTC NSAIDs in conjunction with her naproxen unless advised to do so by her physician, as combining NSAIDs use will the risk for ulcers and upper GI bleeding. Advise A.D. that even though NSAIDs available for self-treatment may have different generic names (e.g., ibuprofen, naproxen) or brand names (e.g., Advil, Aleve),

they all belong to the same drug class and have similar side effects.

19. A.D.'s physician decides to maintain her on naproxen and enteric-coated aspirin but changes the ranitidine to lansoprazole 30 mg QD. What instructions should you provide A.D. regarding her medications?

A.D. should be advised of the major signs and symptoms of upper GI bleeding and cardiovascular disease and what action should be taken if these signs or symptoms develop. She should be instructed to take the lansoprazole every day 30 to 60 minutes prior to breakfast and continue taking naproxen twice daily. The importance of adhering to PPI cotherapy must be stressed, especially since A.D. may not have accompanying dyspeptic or ulcerlike symptoms. There is a strong relationship between the level of adherence to gastroprotective medication and the risk for ulcers and serious GI complications in patients like A.D. who are high-risk NSAID users.¹⁴⁵ Older patients, like A.D., who are at risk for osteoporosis and hip fractures and who require long-term PPI therapy should be counseled to take recommended dosages of a calcium salt and vitamin D and have periodic bone density examinations.⁵⁴

20. What parameters should be monitored to determine A.D.'s response to treatment?

High-risk patients like A.D. who continue to take a NSAID should be closely monitored for upper abdominal pain and signs or symptoms associated with bleeding, obstruction, or perforation. The presence of upper abdominal pain or a change in the severity of the pain may suggest an upper GI complication. Every effort should be made to monitor A.D.'s compliance to her PPI regimen because of the strong relationship between nonadherence and the risk of upper GI complications in high-risk NSAID users.

ZOLLINGER-ELLISON SYNDROME

ZES is an uncommon gastric acid hypersecretory disease characterized by severe recurrent peptic ulcers that result from a gastrin-producing tumor (gastrinoma).¹⁴⁶⁻¹⁴⁸ The primary tumor is usually located in the duodenum or pancreas, but other locations (e.g., mesenteric lymph nodes, spleen, stomach, liver) have been described.¹⁴⁷ Although most gastrinomas occur sporadically, about 20% occur in association with multiple endocrine neoplasia type 1 (MEN 1), which is an autosomal dominant inherited syndrome.^{146,147} Most gastrinomas are malignant and tend to be slow growing, but a small number grow and metastasize rapidly to the regional lymph nodes, liver, and bone. Abdominal pain is the most predominant symptom and is usually related to persistent peptic ulcers, which are less responsive to antisecretory therapy. Duodenal ulcers occur most often, but ulcers may also occur in the stomach or jejunum. Diarrhea, which is present in more than half of patients, may precede ulcer symptoms and results from massive gastric acid hypersecretion, which activates pepsinogen and contributes to mucosal damage.^{146,147} Steatorrhea may also occur and results from inactivation of pancreatic lipase by intraluminal acid. This leads to the precipitation of bile acids, which in turn reduces micelle formation necessary for fatty acid absorption. Vitamin B₁₂ deficiency may develop secondary to malabsorption related to reduced intrinsic factor activity. GERD often occurs

and is complicated by esophageal ulcers and strictures. Other symptoms include nausea, vomiting, upper GI bleeding, and weight loss. Bleeding is related to duodenal ulceration and is the presenting symptom in about 25% of patients.

Epidemiology

The incidence of ZES in the United States is 0.1% to 1.0% among patients with duodenal ulcer.^{146,148} The average age at presentation is between 45 and 50 years, with men being slightly more affected than women. The morbidity and mortality of ZES is low because of improved medical and surgical management.

Pathophysiology

The pathophysiology of ZES is related to a nonbeta islet cell gastrin-secreting tumor that stimulates the parietal cells of the stomach to hypersecrete gastric acid.^{146,147} Large amounts of gastrin are produced by the gastrinoma cells, usually resulting in a profound hypergastrinemia. The gastric parietal cell mass is expanded in response to the trophic effects of hypergastrinemia and causes an increase in basal and stimulated acid output. Hypersecretion of gastric acid results in severe mucosal ulceration, diarrhea, and malabsorption and is responsible for the signs and symptoms associated with ZES.

Clinical Assessment and Diagnosis

The diagnosis of ZES is established when the fasting serum gastrin is >1,000 pg/mL and the BAO is >15 mEq/hour in patients with an intact stomach (or >5 mEq/hour in the post-gastric surgery patient) or when hypergastrinemia is associated with a gastric pH value <2.^{146,147} When serum gastrin is between 100 and 1,000 pg/mL and gastric pH is <2, a provocative test (secretin or calcium) is recommended to assist in the diagnosis.¹⁴⁷ Imaging techniques are performed to localize the tumor and are useful in evaluating metastatic disease. Upper endoscopy is performed to confirm mucosal ulcerations. The use of PPIs may mask the clinical presentation and complicate the diagnosis.¹⁴⁹

Treatment

The goal of treatment for ZES is to pharmacologically control gastric acid secretion and to surgically resect the tumor, if possible. The oral PPIs are the drugs of choice for controlling acid secretion. Treatment should be initiated with omeprazole 60 mg/day or an equivalent oral dose of lansoprazole, pantoprazole, esomeprazole or rabeprazole (Table 26-1) and should be titrated to maintain a BAO <10 mEq/hour (1 hour prior to next dose) in uncomplicated patients or <5 mEq/hour in patients with complicated disease.^{146–148} Once adequate control of acid secretion has been achieved, the daily PPI dose should be gradually reduced and administered every 8 to 12 hours. In most patients, an omeprazole dose of 60 to 80 mg/day reduces the BAO to target levels, but doses as high as 360 mg/day have been required.^{147,148} IV PPIs should be reserved for those patients who are not able to take oral medications.¹⁴⁷ The H₂RAs are no longer used to treat ZES, even though they were initially proven to be effective (Table 26-1). Results of long-term studies

indicate that the use of H₂RAs in treating ZES is limited by poor control of gastric acid hypersecretion and the need for high and frequent doses.¹⁴⁷

Octreotide, a synthetic somatostatin analogue, also inhibits gastric acid secretion and decreases serum gastrin concentrations, but its subcutaneous route of administration, frequent dosing (100–250 mcg three times a day), and side effects (abdominal pain, diarrhea, gallstones, and pain at the injection site) make it less desirable for use in treating ZES.¹⁴⁷ Slow-release formulations of octreotide (Sandostatin LAR) can be administered less frequently (at 4-week intervals) and may be useful in controlling temporal growth.¹⁴⁷ Patients with metastatic gastrinomas can be treated with chemotherapeutic agents to inhibit tumor growth or may require resection of the tumor. Localization and surgical removal of the gastrinoma should be considered in all patients unless widespread metastases exist.

GASTROESOPHAGEAL REFLUX DISEASE

GERD is a common acid-related GI disorder associated with a wide array of symptoms, the most frequent of which is heartburn, and acid regurgitation. Gastroesophageal reflux (GER) is defined as the retrograde passage of gastric contents from the stomach into the esophagus. It is primarily the result of transient relaxation of the LES. When the LES is relaxed, the esophagus is exposed to small amounts of acidic stomach contents. This normal physiological event occurs many times throughout the day in healthy individuals.^{8,150} Protective mechanisms such as esophageal peristalsis and bicarbonate-rich saliva quickly return the acidic pH to normal. GERD develops when alterations in reflux result in symptoms, mucosal injury, or both.¹⁵¹ Esophageal injury occurs with continued exposure of the mucosa to gastric acid and results in inflammation that can progress to ulceration (erosive esophagitis).^{8,152} Complications associated with long-standing GERD include esophageal strictures, Barrett's metaplasia (replacement of normal esophageal squamous epithelium by specialized intestinal-like columnar epithelium), and adenocarcinoma of the esophagus.⁸

Epidemiology

GERD is a chronic disease that affects patients across all age groups with equal distribution between men and women.⁸ The prevalence of GERD appears to be greater in the Western population with patients presenting with more clinically important disease and complications than in Eastern countries (especially Asian populations) where GERD is uncommon. However, recent studies suggest that GERD may be emerging in the Eastern populations and that its increasing prevalence may someday match Western populations.¹⁵³ When considering the symptoms of GERD, such as heartburn and acid regurgitation, the overall prevalence in the United States is approximately 45%.⁸ In Western populations, 25% of patients report heartburn monthly, 12% weekly, and 5% describe daily symptoms.¹⁵⁴ It has also been estimated that 7% of the U.S. population have complicated GERD associated with erosive esophagitis; however, this finding is difficult to validate, as most patients do not undergo diagnostic esophageal endoscopy.⁸ Many patients with erosive esophagitis are asymptomatic on diagnosis, which

suggests that symptoms do not correlate with the degree of esophageal injury. Up to 75% of patients who undergo endoscopic procedures due to symptoms associated with GERD have normal esophageal findings.¹⁵⁵ These patients are identified as having functional heartburn, NERD, or endoscopy-negative reflux disease (ENRD). Other patients with GERD have symptoms that occur outside of the esophagus which are considered atypical or extraesophageal manifestations of GERD. Extraesophageal manifestations may be present with or without accompanying typical symptoms (e.g., heartburn). Extraesophageal manifestations have been estimated to occur in about 80% of patients with at least weekly symptoms of GERD (see Extraesophageal GERD section).¹⁵⁶

Childhood GERD appears to continue into adolescence and adulthood. Although most infants develop physiological regurgitation, or spitting up, the majority (95%) will have abatement of symptoms by 1.0 to 1.5 years of age.^{157,158} However, infants with persisting symptoms beyond 2 years of age are at risk of developing complicated GERD.^{159,160} One prospective study evaluated children with a prior diagnosis of complicated GERD (erosive esophagitis) made at about 5 years of age and then reevaluated the subjects 15 years later. This study revealed that 80% of the children reported monthly symptoms of heartburn and regurgitation, while 23% described weekly symptoms. In addition, 30% still required antisecretory therapy, and 24% underwent antireflux surgery¹⁶¹ (see Chapter 93, Pediatric Considerations). Pregnancy has also been associated with an increased incidence of GERD with 30% to 50% of pregnant women complaining of heartburn; however, in patients without a previous diagnosis of GERD, the symptoms resolve when the child is born.⁸ The mechanisms for GERD in pregnancy are related to (a) the hormonal effects of progesterone and estrogen, which lower LES pressure, and (b) increasing intra-abdominal pressure^{8,162} (see Chapter 46, Obstetric Drug Therapy).

Complications associated with GERD include esophageal erosions (5%), strictures (4%–20%), and Barrett's metaplasia (8%–20%).⁸ Male gender and advancing age (men and women) are associated with an increase in the prevalence of esophageal complications, presumably due to refluxed acidic contents damaging the mucosa over time.⁸ Patients with GERD may have a decrease in quality of life. When comparing quality of life in patients with GERD to those with other chronic medical diseases, the quality of life in GERD patients was between patients with psychiatric disorders and patients with mild heart failure.¹⁶³

Etiology and Risk Factors

The causes of GERD are associated with factors that increase the frequency or duration of GER leading to increased contact of the acidic refluxate with the esophageal mucosa. Risk factors associated with GERD include dietary and lifestyle factors, drugs, and certain medical and surgical conditions^{8,15,150–152,164–166} (Table 26-7). These factors may precipitate or worsen GERD symptoms by lowering the LES pressure (e.g., nitrates, progesterone, foods high in fat, mint, chocolate) or having a direct irritating effect on the esophageal mucosa (e.g., citrus, tomatoes, bisphosphonates). Stress reflux from increased intra-abdominal pressure has been associated with overeating, coughing, and bending or straining to lift heavy objects as well as tight-fitting clothing.^{8,15} Certain

Table 26-7 Risk Factors Associated With Gastroesophageal Reflux Disease

| Drugs | Dietary |
|--------------------------------|--------------------------------------|
| α -adrenergic agonists | Foods high in fat |
| Anticholinergics | Spicy foods |
| Aspirin | Carminatives (peppermint, spearmint) |
| Barbiturates | Chocolate |
| Benzodiazepines | Caffeine (coffee, tea, colas) |
| β_2 -adrenergic agonists | Garlic or onions |
| Bisphosphonates | Citrus fruits and juices |
| Calcium channel blockers | Tomatoes and juice |
| Dopamine | Carbonated beverages |
| Estrogen | |
| Isoproterenol | Lifestyle |
| Iron | Cigarette/Cigar smoke |
| Narcotics | Obesity |
| Nitrates | Supine body position |
| NSAIDs | Tight-fitting clothing |
| Progesterone | Heavy exercise |
| Potassium | |
| Prostaglandins | Medical/Surgical Conditions |
| Quinidine | Pregnancy |
| Tetracycline | Scleroderma |
| Theophylline | ZES |
| Tricyclic antidepressants | Gastroparesis |
| Zidovudine | Nasogastric tube intubation |

NSAID, nonsteroidal anti-inflammatory drug; ZES, Zollinger-Ellison syndrome. Adapted from references 8, 15, 150–152, and 164–166, with permission.

medical and surgical conditions such as gastroparesis, scleroderma, ZES, and long-term placement of nasogastric tubes may also be associated with GERD.⁸ Although it has been suggested that the eradication of *H. pylori* infection may increase the risk of GERD symptoms and esophagitis, additional information is needed to confirm this association.^{80,167,168}

Pathophysiology

The pathophysiology of GERD is associated with defects in transient relaxations of the LES, esophageal acid clearance and buffering capabilities, anatomy, gastric emptying, mucosal resistance and with exposure of the esophageal mucosa to aggressive factors (gastric acid, pepsin, and bile salts) leading to esophageal damage.

Transient Relaxations of the Lower Esophageal Sphincter

The LES, when in a resting state, remains at a high pressure (10–30 mmHg) to prevent the gastric contents from entering into the esophagus.⁸ Pressures are lowest during the day and with meals and highest at night.⁸ Transient relaxations of the LES are short periods of sphincter relaxation that are different from those that occur with swallowing or peristalsis.^{8,169,170} They occur due to vagal stimulation in response to gastric distension from meals (most common), gas, stress, vomiting, or coughing and can persist >10 seconds.⁸ These transient relaxations of the LES are associated with virtually all GER events in healthy individuals but account for 50% to 80% of occurrences in patients with pathogenic GERD.⁸ Thus, not all transient relaxations of the LES are associated with GERD.

A small percentage of patients may also have a continuously weak and hypotensive LES (decreased LES resting tone). Stress reflux increases intra-abdominal pressure and may blow open the hypotensive LES.⁸ When LES pressures remain constantly low, the risk for serious complications (e.g., erosive esophagitis) increase dramatically. Scleroderma, which is related to fibrosis of smooth muscle, may reduce LES tone and increase the potential for GERD.¹⁷¹

Esophageal Acid Clearance and Buffering Capabilities

Although the number of reflux events and quantity of refluxate are notable, it is the duration of time the mucosa is in contact with these noxious substances that determines esophageal damage and complications. More than 50% of patients diagnosed with severe esophagitis have decreased acid clearance from the esophagus.⁸ Peristalsis is the primary mechanism by which acid refluxate is removed from the esophagus. Other mechanisms include swallowing, esophageal distension in response to refluxate, and gravity (which is only effective when the patient is in an upright position).

Saliva plays an important role in the neutralization of gastric acid within the esophagus. Its bicarbonate-rich content buffers the residual acid that remains in the esophagus after peristalsis.⁸ However, saliva is only effective on small amounts of gastric acid, as patients with larger volumes of acid refluxate may not have the neutralizing capacity in saliva necessary to protect the esophagus.⁸ Swallowing increases the rate of saliva production and esophageal acid clearance. The reduction of swallowing that occurs during sleep is associated with nocturnal GERD. Patients with decreased saliva production (e.g., elderly, patients taking medication with anticholinergic effects, and those with certain medication conditions such as xerostomia or Sjogren's syndrome) may also be at increased risk of developing GERD.¹⁷²

Anatomic Abnormalities

Hiatal hernia (protrusion of the upper portion of the stomach into the thoracic cavity due to weakening in the diaphragmatic muscles) is frequently described as a cause of GERD, but its causal relationship remains uncertain.⁸ Although hiatal hernia is associated with a greater degree of esophagitis, strictures, and Barrett's metaplasia, not all patients with hiatal hernia develop symptoms or complications. This may be related to the size of the hiatal hernia and its effect on LES pressure.⁸ An increase in the size of the hernia may decrease its ability to remain below the diaphragm during swallowing and thus reduces LES pressure. Hypotensive LES in combination with hiatal hernia increases the likelihood of reflux and complicated disease.⁸

Gastric Emptying

Delayed gastric emptying increases the volume of gastric fluid remaining within the stomach that is available for reflux and is associated with gastric distension.⁸ Although delayed gastric emptying is present in up to 15% of patients with GERD, a causal relationship has not been established.^{8,173} Because some patients such as those with diabetic gastroparesis also have GERD, the association between delayed gastric emptying and GERD cannot be overlooked.⁸

Mucosal Resistance

The capability of the esophageal mucosa to endure contact with and withstand injury from gastric refluxate (acid and pepsin) is a substantial determinate for the development of GERD. When considering the mucosal resistance within the esophagus compared with that of the stomach and duodenum, the esophagus is less resistant to damage from gastric acid.⁸ However, mucosal resistance in the esophagus is composed of many defensive factors working in tandem to prevent esophageal injury. An increase in mucosal cell thickness and intracellular junctional complexes prevents the diffusion of hydrogen ions from penetrating into the esophageal epithelium and leading to cell death.⁸ The esophagus also secretes a protective mucous layer and bicarbonate.¹⁷⁴ Enhanced blood flow in response to an acidic environment within the esophagus improves tissue oxygenation, provides nutrients, and helps to maintain a normal acid-base balance.⁸ Esophageal injury also occurs when the concentration of acid and pepsin exceed the protection afforded by mucosal resistance mechanisms.

Aggressive Factors Associated With Esophageal Damage

The gastric refluxate, which is composed primarily of gastric acid and pepsin, is the primary aggressive factor associated with GERD. The development and degree of mucosal damage is dependent on the pH and contents of the refluxate as well as the total exposure time of refluxate with the esophageal mucosa. A pH <4 is usually required to produce injury to the esophageal mucosa, but as the refluxate becomes more acidic, the mucosal damage is accelerated.⁸ The addition of pepsin (which is converted from secreted pepsinogen in an acidic pH) to the acidic refluxate will markedly increase the propensity of the refluxate to compromise mucosal resistance and increases the potential for esophageal bleeding.^{8,173,175} Duodenogastric reflux or alkaline reflux containing bile acids and pancreatic juices may also contribute to esophagitis. Because gastric and duodenogastric reflux are often concomitantly present, their actions may be additive in causing esophageal damage. The duration of total exposure time of the esophagus to the refluxate is the primary mechanism involved in the development of GERD and its complications. The longer the duration of exposure time, the greater the possibility of severe disease, including progression to Barrett's metaplasia.

Eradication of *Helicobacter pylori*

The relationship between *H. pylori* infection and GERD remains controversial.¹⁶⁷ Early studies suggest that *H. pylori* eradication is associated with increased gastric acidity and subsequent development of erosive esophagitis.^{80,167} In contrast, it appears that *H. pylori* may be protective against GERD symptoms and related complications.^{80,166,167} This is presumably due to the microorganisms ability to decrease the acidity of the refluxate, as it does not appear to affect the functional defense mechanisms of the esophagus.^{167,168} Although *H. pylori* testing in patients with GERD is not standard practice, if the patient is tested and found to be *H. pylori* positive, eradication is recommended⁸⁰ (see Primary Treatment of *Helicobacter pylori* section).

Clinical Presentation

Signs and Symptoms

21. W.J. is a 39-year-old, 130-kg, 67-inch-tall man who presents with complaints of indigestion. He describes a burning sensation behind his breastbone and some belching that is often associated with an acid taste in the back of his mouth. He indicates that his symptoms began a few months ago, and they only occur a few times a month, especially after eating large or spicy meals. Also, if he eats too close to his bedtime, the burning keeps him up at night. He has used liquid antacids in the past for these symptoms and states they work fairly well, but he has to take frequent doses, as the symptoms return quickly. He asks if there is something that he could take to prevent his symptoms. He does not take any other medications. Which of W.J.'s symptoms are consistent with GERD?

Symptoms that are typically associated with GERD include heartburn, or pyrosis (a retrosternal burning that occurs in the upper esophagus and travels up through the throat), regurgitation of gastric contents into the throat, or in many patients, the presence of both.^{8,176} These symptoms may be episodic or meal related and are often alleviated by antacids.^{8,176} Heartburn, the most frequent typical symptom, is caused by the contact of acidic refluxate with nerve endings within esophageal mucosa.⁸ Other symptoms include water brash (salty or sour fluid occurring abruptly within the mouth), early satiety, belching, hiccups, nausea, and vomiting.⁸ Worrisome symptoms (alarm signs or symptoms) include dysphagia (trouble swallowing), odynophagia (painful swallowing), vomiting of blood, bloody or tarry stools, unexplained weight loss, and anemia.^{8,176} These symptoms suggest complicated disease such as erosive esophagitis, esophageal stricture, malignancy, or GI bleeding and require immediate evaluation by a health care professional. Some patients, such as the elderly, may not have typical GERD symptoms, but present initially with alarm symptoms.^{8,177} This is due in part to older patients having a reduced pain perception and a possible reduction in the acidity of the refluxate.⁸ Other patients may present with only extraesophageal or atypical symptoms (see Treatment of the Extraesophageal Manifestations of GERD section). Despite the lack of esophageal symptoms, the potential for serious esophageal damage exists, as there is no correlation between symptoms and the degree of esophageal injury.⁸ W.J.'s symptoms of a burning sensation (heartburn), regurgitation soon after eating spicy or large meals, and the association of symptoms with eating a meal near his bedtime are all consistent with GERD. The fact that his symptoms are relieved by his use of antacids is also suggestive of GERD.

Treatment

Therapeutic Goals

22. What are the therapeutic goals for the treatment of W.J.'s GERD?

The therapeutic goals for the management of GERD are to alleviate symptoms, promote esophageal healing, prevent recurrence, provide cost-effective pharmacotherapy, and avoid long-term complications.⁸ One long-term consequence is Bar-

rett's esophagus, or Barrett's metaplasia, which is identified in 10% to 15% of GERD patients on endoscopic evaluation.⁸ This premalignant condition may predispose the patient to esophageal adenocarcinoma. Patients with Barrett's esophagus have a 30- to 125-fold greater risk of developing esophageal cancer than an age-matched population.¹⁷⁸ GERD is a chronic disease that carries the potential for serious complications.

Nonpharmacologic Measures and Self-Directed Treatment

23. What lifestyle and dietary changes may potentially reduce W.J.'s GERD symptoms?

Lifestyle and dietary modifications comprise the initial step in managing patients with GERD^{15,166,176,179} (Table 26-8). Strategies should be discussed with the patient and tailored to his or her specific needs. The paucity of evidence to date suggests that although many patients may benefit from these modifications, they are unlikely to completely alleviate symptoms in most patients.^{176,179} Lifestyle modifications are aimed at reducing acid exposure within the esophagus by increasing LES pressure, decreasing intragastric pressure, improving esophageal acid clearance, and avoiding specific agents that irritate the esophageal mucosa. There is evidence to support several modifications that reduce esophageal gastric acid exposure and symptoms.¹⁷⁹ These include raising the head of the bed 6 to 8 inches by using blocks underneath the legs of the bed or using a foam wedge instead of traditional pillows; sleeping in a left lateral decubitus position; and weight loss, which also decreases intra-gastric pressure.¹⁷⁹ Avoiding large meals within 3 hours of bedtime or lying down in the supine position may also decrease symptoms.

Patients with GERD symptoms should avoid troublesome foods and beverages (Table 26-7). However, the evidence suggesting benefit is absent or unclear.^{176,179} When possible, appropriate alternative OTC or prescription medications that do not exacerbate GERD symptoms should be recommended. It is likely that most GERD patients have tried many of the dietary and lifestyle modifications without obtaining satisfactory relief of their symptoms and that others will not be amenable to making these changes in their life. However, appropriate lifestyle and dietary modifications should be recommended to all patients with GERD symptoms.

W.J. should be counseled to lose weight, wear loose-fitting clothing, and avoid eating spicy meals that he knows will exacerbate his symptoms. Recommend that he avoids eating at least 3 hours before bedtime and that he considers raising the head of his bed 6 to 8 inches with wooden blocks. W.J. should be asked to keep a journal in order to track symptoms in relationship to diet and lifestyle and to record the effect of any lifestyle and dietary modifications. The health care practitioner should review the journal and discuss with W.J. which dietary and lifestyle factors trigger symptoms and which measures are most effective in relieving his symptoms.

24. Which OTC treatment options (if any) would you recommend for W.J.?

Many patients with mild, infrequent symptoms can be managed with OTC medications^{8,15,176,180-182} (Fig. 26-5). First, a determination must be made as to the suitability of the patient for self-treatment. If the patient does not meet the criteria for

Table 26-8 Dietary and Lifestyle Modifications Used to Manage Gastroesophageal Reflux Symptoms

| Dietary | Medication | Lifestyle |
|--|---|--|
| Avoid foods listed in Table 26-7 | Avoid medications with a potential to relax the lower esophageal sphincter or have a direct irritant effect on the esophageal mucosa (Table 26-7) | Stop or decrease smoking/tobacco |
| Avoid eating large meals | Medications with the potential to irritate the esophagus should be taken with a full glass of water | Avoid alcohol |
| Avoid eating within 3 hours of bedtime | | Weight loss ^a Elevate the head of bed 6–8 inches or use a foam wedge ^a Sleep in the left lateral decubitus position ^a |

^aSufficient evidence exists to support lifestyle modification.

Adapted from references 8, 15, 166, 176, and 179, with permission.

self-treatment as described below, he or she should be referred for further medical evaluation.^{15,176} It is important to ensure that the following are not present: alarm signs or symptoms, severe or frequent (2 or more days a week) heartburn lasting >3 months, presence of extraesophageal manifestations (see Question 28), or symptoms that persist despite appropriate drug therapy. OTC antacids and H₂RAs are the drugs of choice for patients with mild, infrequent heartburn. The non-prescription PPI (omeprazole) should be reserved for patients who experience frequent heartburn.¹⁵

Antacids remain an effective option for treating mild, infrequent heartburn, as they rapidly (within minutes) relieve symptoms, but the duration of symptom relief only lasts about 30 minutes when taken on an empty stomach.^{8,15,176} The duration can be extended for several hours if taken within 1 hour after a meal.¹⁵ Antacids are available in tablet and liquid form

and are usually interchangeable when used in recommended dosages.¹⁵ The dose can be repeated every 1 to 2 hours as needed, but the maximum recommended daily dose should not be exceeded. The addition of alginic acid to the antacid may improve symptom relief for some patients.^{8,180} Patients requiring frequent or regular antacid use for more than 2 weeks should be reevaluated, as an OTC H₂RA or PPI may be needed.¹⁵ About 20% of patients will achieve symptom relief with the use of antacids.^{8,176} Antacids are not effective in healing erosive esophagitis.⁸

The OTC H₂RAs are indicated for mild to moderate infrequent GERD symptoms.^{15,176} When compared with antacids, their onset of symptom relief occurs within 30 to 45 minutes, and they have a longer duration of action (up to 10 hours).^{8,15} One benefit of the H₂RAs is that they can be taken prior to eating a heavy or spicy meal as prophylaxis for postprandial

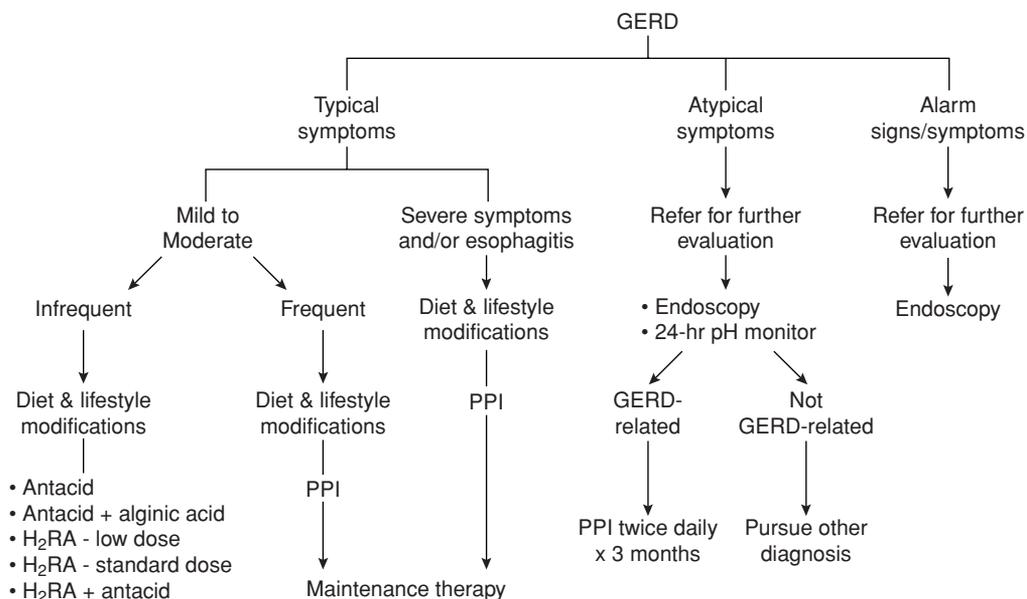

FIGURE 26-5 Management of gastroesophageal reflux disease. H₂RA, H₂-receptor antagonist; PPI, proton pump inhibitor.

GERD symptoms.^{8,15,175} They also have a beneficial effect on reducing nocturnal acid secretion.¹⁵ Tachyphylaxis (tolerance) has been reported with continued use of H₂RAs, but this effect can be overcome with intermittent or as-needed use.¹⁵ OTC H₂RAs are available in one-half the original prescription low dose and as the full prescription doses. Patients should use the lower OTC dose twice daily for mild, intermittent symptoms and the higher dose twice daily for moderate symptoms¹⁵ (Table 26-1). The four OTC H₂RAs (cimetidine, famotidine, ranitidine, nizatidine) are interchangeable when used in recommended dosages.^{15,175} Patients should avoid cimetidine if the potential for a clinically important drug interaction exists with drugs metabolized by the hepatic CYP P450 enzyme system. When used for self-treatment, the H₂RA dose should not exceed two doses per day, and the treatment duration should not exceed 2 weeks. Use beyond 2 weeks should be under the care of a health care provider.^{8,15}

Omeprazole is available OTC in the original prescription strength of 20 mg. A potent inhibitor of gastric acid, it is indicated for use in patients with frequent heartburn (2 or more days a week).¹⁵ The onset of symptom relief is slower (2 to 3 hours) than with the H₂RAs, and complete relief may require up to 4 days after initiating therapy. The PPIs are superior to the H₂RAs with regard to symptom relief and duration of acid suppression.¹⁵ Patients should take omeprazole 30 to 60 minutes prior to a meal (breakfast is preferable) and not take more than 20 mg daily for up to 2 weeks. Another course of therapy should not be taken more than every 4 months unless directed by a health care provider, as this may indicate more serious disease.^{15,176}

W.J. is an appropriate candidate for self-treatment because his symptoms are mild and occur infrequently, and he has no alarm symptoms. Although antacids are an acceptable option for W.J., he has tried these and is unhappy with the frequency of dosing needed to relieve his heartburn. Because W.J. has requested a medication to specifically “prevent” meal-related symptoms, he should take a H₂RA 30 to 60 minutes prior to eating or drinking. If symptoms remain infrequent but are unrelated to meals, the use of an OTC H₂RA as needed for symptoms may be required. He can increase the dose to twice daily if symptom relief is not optimal and may consider OTC omeprazole if symptoms occur more than 2 days a week. If he continues to have symptoms beyond 2 weeks, the symptoms become more severe, or they are accompanied by alarm symptoms, he should be referred for further evaluation.

Severe Disease With Complications

25. L.F. is a 48-year-old woman who presents to her primary care provider complaining of recurrent heartburn occurring daily for the past 6 weeks. She states that the heartburn occurs frequently after meals and often wakens her at night. Lately, she has been experiencing difficulty swallowing solid foods. L.F. currently smokes two packs of cigarettes per day and likes to have a glass of wine each night before bedtime. She states that she occasionally uses OTC ranitidine 150 mg orally up to twice daily, which temporarily relieves her symptoms. What diagnostic modalities are available for the evaluation of her GERD?

Clinical Assessment and Diagnosis

Numerous diagnostic options exist for the evaluation of the patient with presumed GERD. The medical history should include the identification of specific symptoms and an assessment of symptom frequency, severity, and duration as well as risk factors or triggers. An empiric diagnosis can be made in the majority of patients based on the symptoms of heartburn and regurgitation. However, patients who present with severe symptoms, alarm symptoms, or long-standing GERD or who do not respond to empiric therapy warrant further diagnostic evaluation.

Acid Suppression Empiric Test

A trial of a PPI is commonly used to empirically diagnose typical GERD-like symptoms in patients without alarm symptoms or symptoms of complicated disease. Doses used in clinical trials range from 20 mg to 60 mg omeprazole (or equivalent) once daily for up to 4 weeks.^{1,183} If symptoms are relieved after a short trial of a PPI, an empiric diagnosis of GERD may be made and other invasive and costly diagnostic methods may be avoided.^{8,150,176,180,184} However, this methodology is not without its limitations. The test cannot differentiate between other acid-related disorders such as PUD, and studies evaluating its ability to detect GERD versus other diagnostic options have been equivocal.^{8,183,184} Despite these shortcomings, guidelines suggest that an empiric trial of a PPI is appropriate in selected patients given its ease of use and reduced cost.¹⁷⁶ The empiric use of a PPI may also be beneficial in identifying patients with extraesophageal manifestations of GERD⁸ (see Treatment of Extraesophageal Manifestations of GERD section). Further diagnostic evaluation is warranted in patients who do not respond to acid suppressive therapy, who present with alarm symptoms or symptoms suggestive of complicated disease, or who have long-standing GERD where the possibility of Barrett’s esophagus exists.

Upper Endoscopy and Biopsy

Upper endoscopy is the primary diagnostic method for evaluating the esophageal mucosa for injury or cellular changes. This test is highly specific yet only moderately sensitive for the diagnosis of GERD, since many patients present with nonerosive disease. There are four primary reasons why endoscopy is performed in patients suspected of having GERD.^{8,185} The first is to rule out significant disease (e.g., adenocarcinoma of the esophagus) or complications (e.g., stricture); the second is to screen for Barrett’s metaplasia; the third is the ability to evaluate and grade the severity of esophagitis; and the fourth is to allow the provider to optimize treatment and predict the long-term course of the disease. The endoscope can be fitted with surgical instruments to allow the operator to perform procedures or obtain tissue specimens for biopsy. Endoscopic grading of the esophagus is based on the level of inflammation and mucosal damage. Two endoscopic classification systems are used for the grading of esophagitis^{186,187} (Table 26-9). The Savary-Miller classification categorizes patients from grade 0 to grade 4 based on the severity of mucosal erosions of the esophagus.¹⁸⁶ The addition of a grade 5 was added to include the diagnosis of Barrett’s esophagus.¹⁸⁸ Although this classification system is no longer recommended in the United States,

Table 26-9 Classification Systems for Endoscopically Determined Esophagitis**The Savary-Miller Classification System of Esophagitis**

| | |
|---------|---|
| Grade 0 | Normal esophageal mucosa |
| Grade 1 | Erythema or diffusely red mucosa, edema causing accentuated folds |
| Grade 2 | Isolated round or linear erosions extending from the gastroesophageal junction upward, not involving entire circumference |
| Grade 3 | Confluent erosions extending around entire circumference or superficial ulceration without erosions |
| Grade 4 | Complicated cases; erosions as in grade 3 plus deep ulcerations, strictures, or columnar epithelium-lined esophagus |
| Grade 5 | Presence of Barrett's metaplasia |

The Los Angeles Classification System of Esophagitis

| | |
|---------|--|
| Grade A | One (or more) mucosal break no longer than 5 mm that does not extend between the tops of two mucosal folds |
| Grade B | One (or more) mucosal break more than 5 mm long that does not extend between the tops of two mucosal folds |
| Grade C | One (or more) mucosal break that is continuous between the tops of two or more mucosal folds but that involves <75% of the circumference |
| Grade D | One (or more) mucosal break which involves at least 75% of the esophageal circumference |

Adapted from references 186–188, with permission.

it is still used in many practices. The Los Angeles classification is preferred because it is more specific and categorizes patients from A to D based on the number of mucosal breaks, their size, and the amount of surface area with esophagitis involvement.¹⁸⁷ There is no classification for normal esophagus with this system and symptomatic patients are often classified with NERD.

Biopsy of the esophageal mucosa is performed during endoscopy, and tissue samples are evaluated by microscopy for evidence of Barrett's metaplasia or neoplastic disease.⁸ In patients with suspected Barrett's metaplasia, the biopsy is obtained after the esophagus has healed to prevent misinterpretation of the inflammatory markers for dysplastic syndrome. Mucosal biopsy for inflammatory markers in nonerosive disease remains debatable.

24-Hour Continuous Ambulatory pH Monitoring

Ambulatory pH monitoring is a valuable diagnostic test for evaluating GERD. It is especially helpful in patients who have not responded adequately to reasonable pharmacotherapy, in patients with nonerosive disease, and when there is the need to correlate reflux events with symptoms. A small (2–3 mm diameter) pH electrode is threaded through the patient's nostril (similar to placing a nasogastric tube), past the patient's larynx, to approximately 5 cm above the LES in the distal esophagus.^{1,8} Once it is connected to a logging device, which documents pH measurements every few seconds, it allows for the determination of reflux events (defined as esophageal pH <4), duration of reflux events, and percentage of time within a 24-hour period that the patient's pH is <4. The patient is asked to keep a diary to record symptomatic events that can be correlated with a decrease in esophageal pH. This is especially important when correlating extraesophageal manifestations with reflux events.

Radiologic Testing

The barium esophagram (barium swallow) is used primarily to identify suspected esophageal abnormalities such as strictures, narrowing, and hiatal hernia and to determine peristalsis disorders.⁸ The procedure is relatively noninvasive and inexpensive when compared with endoscopy.

Esophageal Manometry

Esophageal manometry is used to evaluate the patient's LES pressure and esophageal peristalsis.⁸ This procedure does not have a specific role in the diagnosis of GERD, as it does not detect the presence of acid within the esophagus. It is used primarily to evaluate patients prior to 24-hour continuous ambulatory pH monitoring and antireflux surgical procedures (e.g., Nissen fundoplication) to determine the location of the LES.^{8,189}

26. L.F.'s frequent severe symptoms continue despite full-dose OTC H₂RA therapy and the presence of warning signs warranted that she undergo endoscopy, which revealed moderate esophagitis (Los Angeles grade C), the presence of an esophageal stricture, and no evidence of Barrett's metaplasia. Esophageal dilation was performed during the procedure to widen the lumen of the esophagus. What treatment options exist for L.F.?

Pharmacotherapy**Antacids**

Antacids are useful only in the relief of mild symptoms associated with GERD (see Nonpharmacologic Measures and Self-Directed Treatment section). Because of their short duration of action and inability to heal erosive esophagitis, they are not an option for treating moderate to severe GERD.⁸

H₂-Receptor Antagonists

The H₂RAs are effective in treating patients with mild to moderate GERD, but response rates vary with the severity of disease, the dose of the drug, and the duration of therapy. The H₂RAs are considered equally effective when used in equipotent doses for symptomatic relief and esophageal healing (Table 26-1). They are effective in reducing nocturnal symptoms but only modestly effective in relieving meal-related symptoms, as they only block one mechanism of parietal cell activation (the H₂ receptor).⁸ The H₂RAs relieve symptoms in about 50% to 60% of patients treated after 12 weeks of continuous therapy and are superior to placebo.^{176,190} Increasing the H₂RA dose may not improve symptoms in some patients.¹⁹¹ Esophageal healing requires higher doses (e.g., famotidine 40 mg BID) compared with those used for

symptom relief (Table 26-1). Esophageal healing rates with the H₂RAs are reported to be about 50% after 8 to 12 weeks of treatment, but rates will vary depending on the degree of esophagitis.^{176,190} For example, endoscopic healing rates in trials with high-dose H₂RAs were approximately 60% to 90% in patients with grades I and II esophagitis but were only 30% to 50% in patients with more severe disease (grades III and IV esophagitis).^{8,190} When a H₂RA is used to heal the esophagus, higher daily dosages and prolonged treatment (8–12 weeks) are required.¹⁷⁶ Some investigators have attributed inadequate esophageal healing to the development of tachyphylaxis.¹⁸⁰

Proton Pump Inhibitors

The PPIs are the drugs of choice for patients with frequent moderate to severe GERD symptoms and esophagitis because they provide more rapid relief of symptoms and esophageal healing than do the H₂RAs. When used in recommended dosages, all of the PPIs provide similar rates of symptom relief and esophageal healing (Table 26-1). Their superior efficacy, when compared with the H₂RAs, is related to their ability to maintain an intragastric pH >4 for a long duration time (up to 24 hours/day vs. up to 10 hours with a H₂RA).^{15,192} Typically, PPIs are taken once daily 30 to 60 minutes before breakfast, but if a second dose is required, it should be taken prior to the evening meal.

A large meta-analysis of 16 trials confirms that PPIs are superior to the H₂RAs for achieving rapid and complete relief of GERD symptoms. Complete symptom relief (within 4–12 weeks) was achieved in 77.4% of patients taking a PPI versus 47.6% of those taking and H₂RA ($p < 0.0001$).¹⁹⁰ PPIs have also been shown to heal esophagitis more quickly and effectively than the H₂RAs. In the same meta-analysis, which evaluated 43 double or single blinded, randomized studies (including patients with severe esophagitis), the PPIs (83.6%) were more effective than H₂RAs (51.9%) at healing erosive esophagitis at 12 weeks.¹⁹⁰ Healing also occurred more quickly with PPI therapy in that by week two, 63.4% of patients had healed with the PPI, while it took 12 weeks with the H₂RAs for 60.2% of patients to heal.¹⁹⁰ Another large meta-analysis, which evaluated over 33 randomized trials, demonstrated similar results with 81.7% of patients healed at 8 weeks with a PPI versus 52.0% with a H₂RA.¹⁹³

Esophageal healing among the five PPIs appears to be equivalent, as about 85% to 90% of patients achieve complete healing at 8 weeks in numerous head-to-head trials with equivalent doses.^{38–41} One meta-analysis, which compared esophageal healing rates among omeprazole 20 mg, lansoprazole 30 mg, pantoprazole 40 mg, and rabeprazole 20 mg (each given once daily), reported no statistical difference.³⁷ However, all of the PPIs were superior to ranitidine 300 to 600 mg/day. Esomeprazole 40 mg once daily has been reported to be superior to omeprazole 20 mg once daily, both at 4 and 8 weeks, when used to heal erosive esophagitis.¹⁹⁴ However, the esomeprazole 40 mg and omeprazole 20 mg dosages are not equipotent, and this study has been heavily criticized based on this fact. Another study, which compared equipotent doses of esomeprazole (40 mg) and lansoprazole (30 mg), also suggests that esomeprazole has superior healing rates (92.6% vs. 88.8%, respectively).⁴⁰ In contrast, a similar study comparing lansoprazole 30 mg with esomeprazole 40 mg showed no statistical difference in esophageal healing, albeit with a smaller population.⁴¹ Given

the disparity in the results of these comparative trials, some clinicians prefer esomeprazole 40 mg/day as a better option, especially for those patients with severe erosive esophagitis. However, clinical evidence to support this practice is minimal.

The ability of a high-dose PPI to reverse Barrett's metaplasia remains controversial.⁸ Although studies have demonstrated islands of normal squamous epithelium returning, no data have determined that this is associated with a risk reduction in adenocarcinoma.⁸ In fact, others have suggested that this return of normal mucosa may actually mask carcinogenic changes occurring deeper in the gastric mucosa.¹⁹⁵

Improvement of quality of life has also been evaluated in patients receiving PPI therapy in the management of GERD. A recent study comparing esomeprazole with ranitidine over a period of 6 months showed a significant improvement in both physical functioning and sleep with the PPI therapy.¹⁹⁶

Prokinetic Agents

Two prokinetic agents, metoclopramide and bethanechol, may be effective in the management of GERD. Both drugs stimulate the motility of the upper GI tract without altering gastric acid secretion and increase LES pressure.⁸ Although these drugs may provide relief of symptoms, they are ineffective in healing erosive esophagitis unless they are combined with a H₂RA or PPI. Prokinetics are not widely used to treat GERD, because they are not as effective as other treatments and are associated with numerous side effects. Prokinetics are reserved for patients who are refractory to other available treatment options or who have delayed gastric emptying.

Sucralfate

Sucralfate appears to be effective in treating mild cases of GERD and possibly mild esophagitis but is not effective in the management of severe disease.¹⁹⁷ Given better options at this time, sucralfate is rarely used in the management of GERD.

The PPIs are considered the drugs of choice for patients with frequent or severe GERD symptoms, or who have complicated disease, because of their potent inhibition of gastric acid secretion^{176,180–182} (Fig. 26-5). In this case, L.F., who presents with severe esophagitis (Los Angeles grade C), will require a PPI taken once daily in order to relieve her symptoms and heal the esophagus (Table 26-1). A reasonable option for L.F. would be lansoprazole 30 mg daily to be taken 30 to 60 minutes prior to breakfast each morning for the next 8 weeks; however, if the cost of pharmaceuticals is a issue for L.F., generic omeprazole 40 mg daily would also be appropriate. L.F. should also be counseled regarding lifestyle and dietary modifications, including smoking cessation and abstinence from alcohol. She should avoid eating large meals prior to bedtime and may wish to elevate the head of her bed by 6 to 8 inches with wooden blocks.

Maintenance Therapy

27. L.F.'s symptoms resolved in about 2 weeks after starting PPI therapy, and she remained asymptomatic after 8 weeks. She then underwent endoscopy again, which revealed that the esophagus had healed completely. Her primary care physician then stopped

the PPI. Now, 2 weeks later, she is experiencing mild heartburn. Is L.F. a candidate for long-term maintenance therapy?

GERD is chronic disease. Up to 80% of patients with severe esophagitis and 15% to 30% with less severe disease have a symptomatic relapse within 6 months after discontinuing treatment.⁸ The goal of maintenance therapy is to keep the patient symptom-free and prevent potentially life-threatening complications. Continuous maintenance therapy with a daily PPI is more effective than a H₂RA, with reported relapse rates of 25% and 50%, respectively.⁸ Thus, PPIs are the drugs of choice for maintaining remission in patients with healed esophagitis. A H₂RA may be considered for patients with mild nonerosive disease. Although one-half of the PPI dose used for esophageal healing has been suggested, guidelines indicate that the recommended maintenance dose should be the dose that is required to render the patient asymptomatic.^{176,180} Maintenance therapy with lansoprazole 15 mg to 30 mg once daily should be initiated in L.F., given the level of her esophagitis and recurrence of symptoms after the PPI was discontinued, to reduce the risk of morbidity associated with this chronic, relapsing disease.

On-Demand Pharmacotherapy

The use of intermittent (on-demand) courses of PPI therapy (2–4 weeks) have been suggested as being potentially beneficial in patients with GERD.^{198–203} One trial, which compared continuous maintenance therapy with esomeprazole 20 mg daily versus on-demand therapy with the same drug and dose in patients with healed erosive esophagitis, reported that continuous therapy was superior to on-demand therapy (81% vs. 58%, respectively) in maintaining endoscopic remission at 6 months.²⁰³ The ability to maintain remission with on-demand therapy was reduced as the severity in esophagitis increased. Although numerous studies with a variety of PPIs have demonstrated patient satisfaction with on-demand therapy,^{199–202} a systemic review of 17 trials evaluating the use of on-demand therapy indicates that intermittent therapy should only be considered in patients with mild, nonerosive disease.¹⁹⁸

Combination of a Proton Pump Inhibitor and H₂-Receptor Antagonists

The addition of a H₂RA at bedtime to a once or twice daily PPI regimen is sometimes used for patients who continue to have nocturnal symptoms, although the evidence to support this combination remains inconclusive. The rationale for this practice is based on evidence that suggests a period of nocturnal acid breakthrough (defined as intragastric pH <4 for longer than 1 hour during the night) in a significant number of patients despite twice-daily PPI therapy, suggesting that histamine release may have an important function in nocturnal acid secretion.²⁰⁴ One study suggests that the addition of a H₂RA to a twice-daily PPI regimen resulted in a statistically significant reduction in nocturnal acid breakthrough during the sleeping hours.²⁰⁴ This trial, however, evaluated only a single bedtime dose of a H₂RA and did not consider the tachyphylaxis that can occur with continuous use. A more recent trial using a twice-daily PPI regimen with continuous use of a H₂RA for 4 weeks demonstrated no difference in nocturnal acid sup-

pression, suggesting that tolerance does play an important role in the use of H₂RAs for this indication.³² It has been theorized that one way to possibly avoid this occurrence is to use the H₂RA on only an as-needed basis when lifestyle and dietary modifications are not effective for preventing nocturnal symptoms.⁸

Nonerosive Reflux Disease

Up to 75% of patients with typical GERD symptoms who undergo endoscopy will not have evidence of esophagitis or complicated disease.²⁰⁵ These patients are described as having functional heartburn, NERD or ENRD and usually undergo 24-hour ambulatory pH monitoring to determine whether abnormal reflux is present despite a negative endoscopy. A trial of a PPI is usually indicated despite no esophageal findings, as many patients will respond to this therapy.²⁰⁵ Further medical evaluation is usually required if a patient does not respond to PPI therapy despite a doubling of the daily dose.

Extracardiac Manifestations

28. S.P. is a 71-year-old retired gentleman who was eating dinner with his wife when he experienced a sudden onset of chest pain described as crushing, burning, and squeezing. His wife notified emergency personnel, who transported S.P. to the emergency department. His past medical history reveals some cardiovascular risk factors, including age, hypertension, hyperlipidemia, and a sedentary lifestyle. His medications prior to admission include aspirin 81 mg daily, hydrochlorothiazide 25 mg daily, and atorvastatin 40 mg at bedtime. He also takes OTC famotidine 20 mg daily as needed for dyspepsia. On examination, he complains of substernal crushing chest pain that has lasted over 1 hour. He is diaphoretic and extremely anxious. He denies any shortness of breath, pain radiating to upper extremities or jaw, or cough. His vital signs include a temperature of 99.1°F, blood pressure 155/95 mmHg and heart rate of 115 beats/minute. Pertinent laboratory results at this time are white blood cell (WBC) count 7,700/mm³, Hgb 14.2 g/dL, Hct 45%, platelets 270,000/mm³, SrCr 1.1 mg/dL, BUN 11 mg/dL, total cholesterol 161 mg/dL, low-density lipoprotein 96 mg/dL, high-density lipoprotein 30 mg/dL, triglycerides 190 mg/dL, sodium (Na) 141 mEq/L, potassium (K) 4.1 mEq/L, and troponin I 0.3 ng/mL. Electrocardiogram reveals sinus tachycardia with no evidence of ST-segment elevation, depression, or T-wave inversion or new left bundle branch block. Because of S.P.'s cardiovascular risk factors and indeterminate troponin, he underwent immediate diagnostic cardiac catheterization, which showed normal coronary angiography and an ejection fraction of 65%. S.P. was diagnosed with noncardiac chest pain (NCCP). Could S.P.'s chest pain be associated with an extracardiac manifestation of GERD?

Extracardiac (atypical) manifestations of GERD are those signs and symptoms that occur outside of the esophagus yet are presumed to be associated with GERD. The extracardiac manifestations of GERD include NCCP; pulmonary symptoms; and complaints related to the ear, nose, and throat; as well as hypersalivation and dental erosions (Table 26-10). Interestingly, these symptoms are often the only complaint that a patient has when he or she presents to the health care provider.^{206,207}

Table 26-10 Atypical Manifestations of Gastroesophageal Reflux Disease

| Noncardiac Chest Pain | Pulmonary |
|------------------------------|---------------------------------|
| Ear, nose, and throat | Chronic cough |
| Laryngitis/Pharyngitis | Nonallergic, nonseasonal asthma |
| Hoarseness | Aspiration |
| Globus sensation | Bronchiectasis/Bronchitis |
| Laryngeal cancer | Sleep apnea |
| Sinusitis | Idiopathic pulmonary fibrosis |
| Otitis | Pneumonia |
| Other | |
| Hypersalivation | |
| Dental erosions | |

Noncardiac Chest Pain

About 30% of patients with anginalike chest pain have normal coronary arteries or minimal microvascular disease as demonstrated by cardiac angiography.²⁰⁸ About 40% to 50% of these patients will have concomitant GERD as demonstrated by an abnormal esophageal endoscopy or ambulatory pH monitoring.^{209,210} The symptoms associated with NCCP are very similar to those associated with cardiac angina. The chest pain is usually described as crushing, squeezing, or burning; retrosternal in location; and with or without lateral radiation to the upper extremities, back, neck, or jaw. The pain is often temporally related to a meal or occurs nocturnally, usually awakening the patient and continuing for hours. The onset of pain may coincide with a reflux episode, and symptoms are often relieved by oral antacid therapy.²¹¹ Numerous trials have evaluated the use of acid suppression as a means to treat NCCP once cardiac etiology has been ruled out through appropriate evaluation.^{212–216} The PPI test, in which a short course (1–8 weeks) of high-dose (twice-daily) PPI is used, is an effective diagnostic tool and is associated with a reduction in costs compared with other diagnostic methods of GERD. An appropriate workup for coronary artery disease must be performed in all patients presenting with chest pain *prior* to considering a GI cause or trial of antireflux therapy. This is especially important in women, the elderly, and diabetic patients, as their initial presentation may be similar to GI complaints when in fact an acute coronary syndrome is present.

Asthma and Gastroesophageal Reflux Disease

GERD may play a role in the pathophysiology of asthma. Reports suggest that concomitant GERD occurs in 34% to 89% of the asthmatic population.²¹⁷ Two theoretical mechanisms exist as to how GERD can potentially exacerbate asthma symptoms. The reflex theory proposes that symptoms result from the direct irritation of the vagus nerve when refluxate comes into contact with the esophageal mucosa, resulting in reflex bronchospasm.²¹⁸ In contrast, the reflux theory proposes that aspiration of refluxed acid into the lungs causes caustic injury of tissue within the bronchial tree, resulting in asthmatic symptoms.²¹⁹ An important meta-analysis of trials that evaluated the effects of antireflux therapy on patients with asthma indicates that asthma symptoms improved in 69% of patients,

that the use of asthma medications was reduced by 62%, and that only 26% of the subjects showed improvement in evening peak expiratory flow rate. All other pulmonary function tests (PFTs) showed little or no change with antireflux therapy.²²⁰ However, this meta-analysis only evaluated studies of up to 8 weeks in duration. A recent trial with esomeprazole 40 mg daily for 3 months demonstrated improvements in PFTs and a decreased use of short-acting rescue bronchodilators in asthmatics with GERD compared with asthmatics without GERD.²²¹ One-third of the patients in the GERD group were also able to reduce their dose of inhaled corticosteroid and remained stable.

Otolaryngology Symptoms and Gastroesophageal Reflux Disease

GERD is the most common etiologic factor in 80% of patients with chronic hoarseness²²² and in 25% to 50% of patients with a globus sensation (the feeling that something is caught in the throat).^{223–226} Symptoms relating to GERD are responsible for up to 10% of the patients seen by otolaryngologists.²²⁷ The most likely mechanism for the pathophysiology of GERD-related laryngitis is that damage and inflammation occurs at night while the patient is sleeping. It is during this time when upper esophageal sphincter pressures are especially low and the protective or neutralizing mechanisms of cough and salivation are suppressed.²²⁸ This damage may be in addition to injury or laryngeal inflammation sustained from other causes such as excessive voice usage, chronic throat clearing or cough, vomiting, or injury from endotracheal tubes.²²⁹ The extent of injury in GERD-related hoarseness is directly related to the exposure time of the pharyngeal mucosa to the refluxate as well as the pH. Patients with GERD-related hoarseness usually do not have any other GERD-related symptoms. The diagnostic procedure of choice is laryngoscopy and should be considered in all patients presenting with GERD-related hoarseness. Once the diagnosis of GERD-related hoarseness or laryngitis is established, the patient will likely require extended high-dose PPI therapy with the realization that the majority of patients will relapse within 6 weeks once therapy is discontinued.²³⁰

S.P.'s chest pain is not of cardiac origin based on angiographic findings. Therefore, it is reasonable to presume that he has an extraesophageal manifestation of GERD. S.P.'s symptoms were meal related, and he has a history of dyspepsia for which he takes an OTC H₂RA. The H₂RA should be discontinued, and S.P. should be given a trial of empiric twice-daily PPI therapy for a 2 to 4 week period. If symptoms are severe, the use of endoscopy (to determine if esophageal damage is present) or 24-hour esophageal pH monitoring (to correlate reflux events with symptomatic chest pain) is appropriate.

Treatment of the Extraesophageal Manifestations of Gastroesophageal Reflux Disease

Treatment should be initiated with a high-dose (twice-daily) PPI for at least 3 months before considering drug therapy to be ineffective.²⁰⁸ Alternatively, it is possible that GERD may not be the cause of the patient's symptoms.

29. S.P. responded well to the trial of omeprazole 40 mg orally twice daily and has not had chest pain in 2 months. He has heard that surgical options exist that may eliminate his need for

medications, as they are very expensive for him. Is S.P. a candidate for antireflux surgery?

Antireflux Surgery

Numerous surgical and endoscopic procedures exist for patients with GERD. These include, but are not limited to, Nissen fundoplication, Toupet partial fundoplication, Belsey Mark IV repair, and the Hill posterior gastropexy repair, as well as newer endoscopic techniques.⁸ The primary goal of these procedures is to restore LES pressure by repairing a hiatal hernia or diaphragmatic hiatus. Appropriate candidates include patients who are in a good health and request another treatment option due to poor medication adherence, patients who are unable to afford their medication, patients who suffer from side effects or worry about risks with long-term therapy, patients with extraesophageal symptoms who have responded well to antireflux therapy, or patients experiencing volume regurgitation and aspiration of gastric contents who have not responded to PPI therapy.^{8,209} Despite the availability of these surgical options, the consideration of antireflux surgery is one in which the benefits should be heavily weighed against the risks of such an invasive approach, as these procedures are not without potential complications. The effectiveness of these procedures has been questioned, as many patients will still require drug therapy.²⁰⁹ S.P. has responded well to high-dose PPI therapy for his NCCP, but he describes some financial difficulties with affording his medications. Alternatively, he is 64 years of age, which may increase the risk associated with surgery. S.P. should be referred for further medical evaluation to determine whether he is a candidate for antireflux surgery.

UPPER GASTROINTESTINAL BLEEDING

Upper GI bleeding is a common medical emergency that occurs in about 170 cases per 100,000 adults annually and is associated with increased morbidity and mortality as well as substantial costs to the health care system.^{231,232} Despite advances in endoscopic hemostatic therapy and pharmacotherapy, the mortality rate associated with upper GI bleeding remains at 7% to 10%, which is the same as it has been for the last 30 to 40 years. However, mortality is higher in hospitalized patients.^{3,231,233–235} Upper GI bleeding can be categorized as either variceal or nonvariceal bleeding (see Chapter 28, Complications of End-Stage Liver Disease). Nonvariceal bleeding describes bleeding associated with PUD or stress-related mucosal bleeding (SRMB). Other causes include erosive esophagitis, Mallory-Weiss tear (a tear near the gastroesophageal junction associated with retching or coughing), and malignancy.²³⁵ Although PUD and SRMB are both acid-related disorders, their presentation and pathophysiology differ.

PEPTIC ULCER BLEEDING

Epidemiology

About 50% of all upper, nonvariceal GI bleeding is due to PUD.^{4,233,234} Bleeding ulcers account for approximately 150,000 hospitalizations in the United States each year.^{233,234} The mortality rate for peptic ulcer bleeding can be as high as 10%. It has been suggested that an older presenting pa-

tient population (>60 years of age) with a greater number of comorbidities may account for this continued high mortality rate.^{3,231,233,234} Fortunately, the vast majority (80%) of upper GI bleeding events are self-limited and require only minimal intervention.^{3,234–236} Length of stay has been dramatically reduced due to a majority of patients who receive early endoscopy (within 24 hours of admission) and up to 35% who undergo endoscopic hemostatic procedures.⁴ However, in the 20% of patients who continue to bleed or rebleed after appropriate intervention, mortality increases to nearly 40%.^{4,232}

Pathophysiology

The most common causes of upper GI bleeding in patients with PUD are NSAID use and *H. pylori* infection. Bleeding occurs when an ulcer extends deeper into the mucosa and erodes the wall of a blood vessel.^{234,235} The incidence of *H. pylori* infection in bleeding ulcers is 15% to 20% lower than in patients with nonbleeding ulcers.^{9,234} Bleeding associated with PUD is generally not caused by the hypersecretion of gastric acid, with the exception of patients with ZES.²³⁴ The pathophysiology and risk factors associated with PUD are described earlier in this chapter (see Peptic Ulcer Disease section).

Clinical Assessment and Diagnosis

The clinical presentation of a patient with a bleeding peptic ulcer usually includes the presence of melena (dark, tarry stools), which occurs in 20% of patients, hematemesis (vomiting of blood) in 30%, and both in about 50% of patients. Up to 5% of patients present with hematochezia (bloody diarrhea) indicative of rapid and substantial blood loss.²³⁴ The primary step in evaluating the patient is to assess the degree of urgency for rapid medical management.²³⁵ Hypovolemia due to substantial blood loss can rapidly lead to shock. The initial management of these patients should focus on volume resuscitation and improving the patient's hemodynamic status. Clinical features suggestive of high-risk for rebleeding or mortality include patients >60 years of age, serious comorbidities (e.g., hepatic or renal dysfunction, cardiac or pulmonary disease), hemodynamic instability (e.g., hypotension, tachycardia), shock, poor health, continued bleeding, mental status changes, and prolonged prothrombin/activated partial thromboplastin time (aPTT) (or elevated international normalized ratio [INR]).^{3,231,234–237} These patients should immediately be transferred to an intensive care setting.

Most patients should receive early diagnostic endoscopic evaluation within 24 hours of presentation to determine the source of the bleeding, to predict the risk for rebleeding, and, when required, to perform endoscopic interventions directed at stopping the bleeding ulcer and restoring hemostasis.^{231,235} Risk of rebleeding may be predicted based on the presenting lesion(s) identified on endoscopy.²³⁴ The most common ulcer identified on endoscopy is a clean-base ulcer found in about 42% of patients. This ulcer has a very low risk of rebleeding (5%), and the patient can usually be discharged immediately after recovery from the endoscopy and managed with appropriate antisecretory therapy. Intermediate stigmata of bleeding include lesions identified as flat-spot ulcers and/or adherent clots, which have a risk of rebleeding of 10% and 22%, respectively. Although endoscopic procedures are not

usually necessary with flat-spot ulcers, adherent clots remain an area of controversy and usually require the endoscopist to attempt to remove the clot and manage the underlying lesion as appropriate.²³⁵ Patients identified with high-risk ulceration (nonbleeding visible vessel or active bleeding) will require endoscopic intervention and have a high risk of rebleeding (43% and 55%, respectively) despite intervention. Nonbleeding visible vessel and active bleeding are associated with an 11% mortality on initial presentation.²³⁴ Ulcer size is also predictive of mortality and rebleeding, as ulcers >1 or 2 cm in diameter confer greater risk.^{233,234} Despite appropriate endoscopic hemostasis, 10% to 30% will rebleed within 48 to 72 hours following treatment.^{231,233,235} Mortality associated with rebleeding is about 25% to 37%.^{232,235} Patients undergoing endoscopy should be tested for *H. pylori* infection with biopsy (rapid urease test), as infection with this organism is associated with an increased risk of rebleeding.^{4,231} Because false negatives can occur in the presence of active bleeding, all *H. pylori*-negative patients should have a confirmatory follow-up test with serologic antibody testing on discharge to ensure that the patient is not infected.²³¹

Treatment

Patients with upper GI bleeding require rapid risk stratification based on the presenting signs and symptoms. Patients with hemodynamic instability require immediate institution of resuscitative measures.^{235,238} IV access should be obtained with a large-bore catheter to facilitate the administration of fluids and blood products.⁴ Intravascular volume should initially be repleted with normal saline to prevent the patient from going into hypovolemic shock. During this time, blood can be typed and crossed in the event a transfusion is required.³²⁵ A nasogastric tube should be placed to allow for lavage and determination of the upper GI tract as the source of the bleed and evaluation of continued bleeding.^{4,231,238}

Endoscopic evaluation with hemostatic techniques (when required) should be performed as soon as safely possible.^{231,235} Endoscopic hemostasis is the cornerstone of management for patients with serious bleeding ulcers, as it reduces the incidence of rebleeding, the need for surgery, and mortality when compared with placebo or drug therapy.²³¹ Endoscopic procedures include thermocoagulation, laser therapy, injection therapy (epinephrine, ethanol, or saline), injection with sclerosing agent, or placement of endoscopic clips. Combining thermocoagulation with injection therapy is superior to either therapy alone and hemoclippping alone in patients with serious ulcer bleeding.^{231,233} Despite initial hemostasis, however, the potential for rebleeding remains high, especially in patients with high-risk lesions.^{234,235}

Improvements in hemostatic parameters (e.g., platelet aggregation, inactivation of pepsin, and correction of coagulation) leading to clot stabilization correlate directly with an intragastric pH >6).^{232,233,236} Therefore, treatment with an antisecretory drug is beneficial in patients after endoscopy to promote healing of the lesion. After the acute phase, the patient should be placed on appropriate drug therapy to continue healing and prevent ulcer recurrence (see Peptic Ulcer Disease section). Patients who are *H. pylori* positive should receive appropriate eradication therapy.^{4,231}

H₂-Receptor Antagonists

Once widely used to manage upper GI bleeding, the H₂RAs are now considered inferior to the PPIs for reducing the incidence of rebleeding and the need for surgery.^{231,233} This is likely due to the inability of the H₂RAs to achieve an intragastric pH ≥6 (even with continuous IV administration) and the rapid development of tachyphylaxis (especially with high IV doses).^{231–233,236,239} Thus, the H₂RAs are no longer recommended for the prevention of rebleeding associated with a peptic ulcer.²³¹

Proton Pump Inhibitors

The PPIs are the drugs of choice to reduce the incidence of PUD-related rebleeding and the need for surgical intervention.^{240–244} However, no clinical trials were able to show a mortality benefit when entire treatment cohorts were evaluated. A Cochrane Collaboration meta-analysis of 24 studies evaluating randomized, controlled trials that compared IV or orally administered PPIs with H₂RAs or placebo showed similar results with a reduction in rebleeding, surgery, and repeat endoscopic treatment.²⁴⁰ Although no reduction in the number of deaths were identified when all patients were considered, PPI treatment of patients at the highest risk of mortality, as evidenced by endoscopically determined active bleeding or nonbleeding visible vessel, did impart a mortality benefit. All-cause mortality was also reduced in Asian trials, with a concomitant greater reduction in the incidence of rebleeding and need for surgery than in trials performed elsewhere in the world. This may be explained by the inclusion of a younger patient population, more potent acid suppression because of genetic polymorphism in P450 metabolism leading to a slower clearance of PPIs, a lower parietal cell mass, and a greater incidence of *H. pylori* infection.²⁴⁰

Despite the data, important questions remain as to the most appropriate dose and route of administration for PPIs in patients with peptic ulcer bleeding. Evidence suggests that patients with low-risk lesions (clear-base or flat-spot ulcers) may be treated with oral PPIs and immediately discharged after endoscopy, as rebleeding is infrequent in this population.^{231,240,245} However, in patients with higher-risk endoscopic stigmata, a parenteral PPI should be administered and titrated to an intragastric pH >6 after the endoscopic procedure.^{231,240} Current guidelines suggest an initial IV bolus equivalent to 80 mg of omeprazole followed by a continuous IV infusion of 8 mg/hour of the omeprazole equivalent for 72 hours (although no head-to-head trials of omeprazole equivalence have been performed with pantoprazole or esomeprazole, most clinicians consider them equivalent on a milligram-per-milligram basis).^{231,232,233,236,240} Rebleeding is highest during this first 72 hours and is the reason for such high-dose therapy.^{233,235} This strategy has been compared with standard-dose therapy with IV omeprazole 40 mg/day in a retrospective analysis that found the high-dose therapy to be superior with respect to rebleeding, surgical requirement, and mortality.²⁴⁶ One meta-analysis has also suggested that PPI therapy is associated with reduced blood transfusion requirements.²⁴⁷ Some patients may be switched to an oral PPI if rapid stabilization occurs, but careful clinical assessment should be performed to ensure the patient is stable.²⁴⁵ Early initiation of a PPI bolus infusion prior to endoscopy has been shown to reduce the proportion of patients with active bleeding once endoscopy is

performed, reduce the requirements for endoscopy, and reduce hospital stay.²⁴⁸ However, this strategy should not replace early endoscopic management in high-risk patients, as combination PPI therapy with endoscopic maneuvers have been proven to be better than monotherapy with an IV PPI.^{231,249} High-dose oral PPI therapy after endoscopic treatment may also be efficacious in patients with peptic ulcer bleeding.^{236,240} However, one trial evaluating the use of high-dose esomeprazole (40 mg orally twice daily for 3 days) versus placebo after endoscopic hemostasis failed to show a reduction in rebleeding, transfusions, surgery, or mortality.²⁵⁰

Other Agents

The use of somatostatin or octreotide is not recommended for the treatment of patients with nonvariceal upper GI bleeding, as there is no evidence of benefit to support their use.²³¹ However, these agents are commonly used in the management of variceal bleeding (see Chapter 28, Complications of End-Stage Liver Disease).

STRESS-RELATED MUCOSAL BLEEDING

Acute stress-related mucosal damage (SRMD) is a type of erosive gastritis that occurs in critically ill patients with severe physiological stress (e.g., surgery, trauma, organ failure, sepsis, severe burns, neurologic injuries).^{236,251–253} The term *stress ulcer* is a misnomer in that SRMD may range from numerous diffuse superficial erosive mucosal lesions (those that do not penetrate the muscularis mucosa) to major deep ulceration (penetration of the muscularis mucosa and potentially submucosa).^{254,255} Initial lesions occur early (<24 hours) and appear as subepithelial petechiae that can develop into superficial erosions and ulcerations.^{253,254} Early stress-related mucosal lesions are multiple, usually asymptomatic, without perforation, and commonly bleed from superficial mucosal capillaries.^{252,254} The gastric fundus is the most likely anatomical region of the stomach to be involved. Distal lesions involving the gastric antrum and duodenum have also been described, but tend to appear later in the hospital course and are often deeper and associated with a greater probability for bleeding.²⁵⁴ SRMB from these lesions may be categorized into three distinct types based on clinical presentation.^{252–255} Occult bleeding is defined as aspirated gastric fluid or stool that is guaiac-positive for the presence of occult blood and without other signs or symptoms. Overt bleeding, defined as frank hemorrhage identified by hematemesis (bloody vomitus or the appearance of coffee grounds in gastric aspirates or vomitus), hematochezia (bloody diarrhea), or melanic stools. Clinically important bleeding or life-threatening bleeding is the presence of overt bleeding that is associated with hemodynamic changes (tachycardia, hypotension, orthostatic changes, or hemoglobin concentration decline of >2 g/dL) and the requirement of transfusion of blood products. Endoscopic therapy is generally not a viable option because of the extensive distribution of lesions associated with SRMB.²³⁵

Epidemiology

The majority (>75%) of critically ill patients admitted to intensive care units (ICUs) will develop mucosal lesions consistent with SRMD within 24 hours of admission.^{252–255} Only a

small percentage (up to 6%) of these patients will progress to clinically important GI bleeding.^{252–255} Clinically important SRMB has been associated with an increased length of stay in the ICU by up to 11 days and results in substantial increases in the cost of health care.^{252–254,256} The mortality of clinically important SRMB approaches 50%, but mortality may also be associated with underlying comorbidities related to the critical illness.^{236,253}

Pathophysiology

Numerous factors have been identified in the pathogenesis of SRMD and resultant bleeding. These include gastric acid and pepsin secretion, disruptions to the normal homeostatic mechanisms that protect the gastric mucosa against the highly acidic environment (decreases in prostaglandin, bicarbonate, and GI mucus formation as well as impaired turnover of gastric epithelium), GI motility disturbances, and mucosal ischemia resulting from decreased blood flow.^{252,253,255} Gastric acid is likely the central factor associated with development of SRMD.²⁵⁴ Because of the absence of protective defenses, substantial amounts of acid are not required for the formation of lesions, but some acid is required for damage to occur.²⁵⁵ Although some patients may have increased acid secretion (e.g., sepsis, CNS injuries, small bowel resections), the majority of critically ill patients have normal or decreased acid secretion.^{251,254,255} Pepsin secretion is associated with the lysis of clots due to its proteolytic action on fibrin.²⁵⁰ Gastric prostaglandins play a key role in the cellular defense against gastric acid.²⁵⁵ These prostaglandins are responsible for maintaining the integrity of the mucosal barrier by stimulating mucus and bicarbonate production; regulating blood flow; and to some degree, inhibition of acid production. Mucosal ischemia secondary to splanchnic hypoperfusion also plays a large role in the pathogenesis of SRMD.^{252,255} Mucosal ischemia is associated with reduced ability to neutralize hydrogen ions leading to intracellular acidosis within the mucosa and subsequent cell death. These factors all contribute to an imbalance by increasing injurious factors and reducing the protective mechanisms within the gastric fundus.

Risk Factors

30. J.S., a 58-year-old, 110-kg male was admitted to the medical ICU for severe necrotizing pancreatitis identified on abdominal computed tomography. The patient was immediately made “nothing by mouth” (NPO) and started on imipenem/cilastatin 1,000 mg IV Q 8 hr. He was given meperidine 50 mg intramuscularly Q 6 hr for pain. He subsequently developed shortness of breath on his third day after admission. He required intubation and was placed on a ventilator. A chest x-ray showed a left lower lobe infiltrate suggestive of hospital-acquired pneumonia. Antibiotic coverage was increased with the addition of ciprofloxacin 400 mg IV q12h and linezolid 600 mg IV Q 12 hr. He has a temperature of 103.5°F, heart rate of 115 beats/minute, and blood pressure of 70/40 mmHg. Pertinent laboratory results at this time are WBC count 38,000/mm³, Hgb 13.6 g/dL, Hct 40%, platelets 150,000/mm³, SrCr 1.3 mg/dL, BUN 24 mg/dL, INR 1.0, aPTT 39 seconds, aspartate aminotransferase (AST) 292 Units/L, alanine aminotransferase (ALT) 305 Units/L, amylase 508 Units/L, and lipase 624 Units/L. In addition to the antimicrobials and initiation

of fluid resuscitation, the critical care team is considering stress ulcer prophylaxis. What risk factors does J.S. have (if any) for SRMB, and is he a candidate for stress ulcer prophylaxis?

Numerous risk factors have been associated with SRMB^{251–254} (Table 26-11). However, a large landmark, multicenter, prospective study involving more than 2,200 critically ill patients admitted to a medical ICU identified only the requirement of mechanical ventilation (respiratory failure) or coagulopathy as independent risk factors for development of clinically important bleeding.²⁵⁷ Considering the cost associated with the reduction of risk related to SRMB, the authors concluded that only these two risk factors warrant the use of prophylactic therapy. Because not all risk factors impose the same level of risk, clinical guidelines and most practitioners recommend prophylaxis only when the patient is mechanically ventilated, has a coagulopathy, or when two or more of the remaining risk factors are present.^{251,253} (Table 26-11). J.S.'s risk factors include septic shock as evidenced by hemodynamic instability and mechanical ventilation. Therefore, a prophylactic regimen to reduce the risk of SRMB is appropriate.

Treatment

31. What options exist to prevent SRMB in J.S.?

Not all patients admitted to the critical care unit will require prophylaxis for SRMB. However, since mortality can be high in patients when bleeding occurs, evaluation of risk is of absolute importance to ensure that protective pharmacotherapy is initiated in appropriate patients.^{251–253} Because acid is required for mucosal injury, the inhibition of gastric acid is the primary target when pharmacotherapy is used to reduce the risk of SRMB. An intragastric pH >4 is the recommended goal of therapy.^{233,236,251–255} Therapeutic options include the use of antacids, sucralfate, H₂RAs, and PPIs (Table 26-12).

Antacids

The use of aggressive antacid therapy is superior to placebo in reducing clinically important SRMB when an intragastric pH >3.5 is maintained.^{252,253} Although antacids are effective

in preventing SRMB, their use has fallen out of favor due to difficult administration regimens (every 1–2 hours) with the continuous requirement of intragastric pH monitoring for dose titration, electrolyte abnormalities (especially in patients with renal dysfunction), diarrhea, constipation, and the potential risk of aspiration pneumonia.^{252–254} In addition, an elevated intragastric pH can lead to the proliferation of bacteria within the stomach, and aspiration of these microbes may be associated with nosocomial pneumonia.²⁵²

Sucralfate

Sucralfate is effective in preventing SRMB but does not have an important effect on intragastric pH.^{258,259} Despite the fact that antisecretory therapy is preferred, sucralfate remains an available therapeutic option. Early studies suggested a reduction in nosocomial pneumonia with sucralfate when compared with ranitidine or antacids. However, a more recent randomized trial involving 1,200 mechanically ventilated patients revealed no increase in pneumonia with the H₂RAs when compared with sucralfate or antacids.²⁶⁰ The usual dose of 1 g four times daily can present problems within the critical care setting because of multiple daily dosing, binding of other drugs, and occlusion of nasogastric tubes (may be reduced with available suspension). Other potential issues include the potential for aluminum toxicity in patients with renal failure, constipation, and electrolyte imbalances. The concomitant use of sucralfate with antisecretory therapy may reduce the effectiveness of sucralfate as an intragastric pH <4 is needed for conversion to its active form, which binds to the gastric mucosa.²⁵³

H₂-Receptor Antagonists

The H₂RAs are effective in preventing SRMB and are the most widely used for this indication.^{261,262} Although only cimetidine

Table 26-12 Stress-Related Mucosal Bleeding Prevention: Regimens and Doses

| Agent | Dose and Frequency of Administration | FDA Approval ^a |
|--|--|---------------------------|
| Antacid | 30 mL PO/NG Q 1–2 hr | No |
| Cimetidine | 300 mg IV Q 6–8 hr or 300 mg IV loading dose, then 50 mg/hr continuous IV infusion | No Yes |
| Famotidine | 20 mg IV Q 12 hr or 1.7 mg/hr continuous infusion | No No |
| Ranitidine | 50 mg IV Q 6–8 hr or 6.25 mg/hr continuous infusion | No No |
| Sucralfate | 1 g PO/NG Q 6 hr | No |
| Omeprazole | 20–40 mg PO/NG ^b Q 12–24 hr | No |
| Omeprazole/ Sodium bicarbonate powder for oral suspension | 40 mg PO/NG initially, followed by 40 mg in 6–8 hr as a loading dose, then 40 mg PO/NG Q 24 hr | Yes |
| Lansoprazole | 30 mg PO/NG ^{b,c} Q 12–24 hr | No |
| Pantoprazole | 40 mg IV/PO/NG ^b Q 12–24 hr | No |
| Esomeprazole | 40 mg IV Q 12–24 hr | No |

^aFor prevention of stress-related mucosal bleeding.

IV, intravenous; NG, by nasogastric tube; PO, by mouth; Q, every.

continuous infusion has been FDA-labeled for the prevention of SRMB, continuous or intermittent infusions of ranitidine and famotidine are most often used for this indication.^{236,252} Continuous infusions have been suggested as being more effective in maintaining a pH >4, but there are no data comparing these two treatment options with respect to clinical outcomes.²⁵⁴ Despite this, intermittent dosing is used more commonly than continuous infusions for the prophylaxis of SRMB.^{236,252,261,262}

Numerous meta-analyses have evaluated the effectiveness of H₂RAs for prophylaxis of SRMB.^{263,264} Cook et al. reviewed 63 randomized trials and determined that prophylaxis with the H₂RAs was associated with a statistically significant reduction in overt and clinically important upper GI bleeding when compared with no therapy and a significant reduction in overt bleeding when compared with antacids.²⁶³ A trend toward reduced clinically important bleeding was identified when H₂RAs were compared with sucralfate, but this was not statistically significant. In another meta-analysis, ranitidine was shown to be of no benefit in preventing SRMB and increased the risk of pneumonia.²⁶⁴ However, neither of these meta-analyses included the large study involving 1,200 mechanically ventilated patients that compared sucralfate, ranitidine, and placebo.²⁶⁰ Despite these conflicting results, the H₂RAs remain a recommended option for the prophylaxis of SRMB.^{261,262} One shortcoming of H₂RAs is that tolerance may develop (within 72 hours) and thus theoretically lead to potential prophylaxis failure.²³⁹ The H₂RAs are eliminated renally, and dosage reductions may be required in patients with renal failure.

Proton Pump Inhibitors

The PPIs, because of their profound ability to inhibit gastric acid secretion and lack of tolerance to their antisecretory effect, would appear to be the preferred option for preventing SRMB. However, there is very little evidence to confirm their clinical superiority to the H₂RAs for this indication. Observational studies have compared the PPIs with H₂RAs or placebo in critically ill patients in small populations using varied pre-

determined end points.²⁵³ These studies suggest that the PPIs provide greater acid suppression compared with the H₂RAs and are likely to be as effective in preventing SRMB.^{265–267} One study in 359 critically ill patients evaluated the use of immediate-release omeprazole suspension in bicarbonate given via nasogastric tube at a dose of 40 mg for two doses, then 40 mg/day versus IV cimetidine given as a 300 mg bolus and then infused at 50 mg/hour (dosing was adjusted for patients with renal dysfunction).²⁶⁸ The results indicate that the PPI-bicarbonate suspension was associated with a greater mean time of intragastric pH >4 than the cimetidine infusion but that the rate of clinically important bleeding did not differ between cimetidine (6.8%) and omeprazole (4.5%). The FDA considered the immediate-release omeprazole-bicarbonate suspension to be noninferior to cimetidine for the prevention of SRMB.²⁶⁹

The incidence of nosocomial pneumonia in patients receiving PPI therapy in the critical care setting has been evaluated. A 22-month observational study in 80 patients receiving either omeprazole or ranitidine did not find a difference in the rates of nosocomial pneumonia between the two groups, thus suggesting rates may be equivalent.²⁷⁰ Numerous alternative administration options exist for patients in the critical care setting who cannot take medications by mouth, have nasogastric tubes in place, or have difficulty swallowing^{253,269,271} (Table 26-13). The PPIs are becoming first-line therapy for the prevention of SRMB, but additional studies are needed to confirm the most effective dose and route of administration in order to obtain optimal clinical outcomes in patients at risk of SRMB.^{252,261}

Monitoring

32. J.S. has been started on famotidine 20 mg IV every 12 hours. How should this pharmacotherapy be monitored for safety and efficacy?

The famotidine dose should be adjusted to maintain an intragastric pH >4 and should be based on severity of the patient's illness, renal function, and intragastric pH measurements. The intragastric pH can be determined with an indwelling probe or by measuring the pH of nasogastric aspirates. The patient

should be monitored for signs of bleeding (e.g., presence of blood or coffee ground material in nasogastric aspirates, hematemesis, hematochezia, or melena), hypotension, reductions in hemoglobin or hematocrit, and thrombocytopenia.

33. Over the next 6 days, J.S. improves and is subsequently removed from mechanical ventilation and transferred to the medical ward. He is now able to eat normally. Should J.S. be continued on SRMD prophylaxis?

Patients receiving prophylaxis for SRMB should be evaluated for the continued presence of risk factors. As the patient improves, the risk factors should in turn be reversed, and the

need for SMRB prophylaxis should diminish. Factors such as extubation, correction of coagulopathies, discharge from the intensive care setting, and the ability to take oral feeding advocate the discontinuation of prophylaxis. Erstad et al. surveyed 153 institutions with the United States and found that in 65% of the hospitals, >25% of patients remained on SRMB prophylaxis after discharge from the ICU.²⁷² This can lead to increased costs, the potential of the patient being discharged on medication for which there is no indication, and future potential adverse effects from the medication. Since J.S. does not possess any risk factors for SRMB, the famotidine should be discontinued at this time.

OVERVIEW OF INFLAMMATORY BOWEL DISEASE

Definition and Epidemiology

Inflammatory bowel disease (IBD) is a generic classification for a group of chronic, idiopathic, relapsing inflammatory disorders of the gastrointestinal (GI) tract. IBD is common in developed countries.¹ It is estimated that more than 600,000 persons in the United States have IBD, and the prevalence of these disorders ranges from 20 to 200 per 100,000 people; however, the prevalence of IBD may actually be greater because many affected patients may be asymptomatic or have mild symptoms for which they do not seek medical attention.^{2,3} By convention, IBD is divided into two major disorders: ulcerative colitis (UC) and Crohn's disease (CD).^{2,4} However, approximately 10% to 15% of patients with IBD have symptoms that defy this schema.⁵ Both UC and CD frequently affect a similar group of patients (Table 27-1). Whites appear to have the higher incidence of IBD compared with Asians or blacks.⁶ In particular, Jews of European descent may have up to a fourfold increase in the incidence of IBD. Studies have found trends toward an increased incidence of IBD in

urban compared with rural communities. Hypotheses for this trend include overcrowding, exposure to infectious agents, and lifestyle differences. Although both UC and CD are generally considered diseases of the young, with peak incidences from ages 20 to 40 years, about 15% of IBD cases are diagnosed in patients older than 60 years.⁷ There seems to be no significant gender preference for IBD.

Etiology

The true cause of IBD is unclear; however, hypotheses for these disorders include a combination of genetic abnormalities, chronic infection, environmental factors (bacterial, viral, and dietary antigens), autoimmunity, and other abnormalities of immunoregulatory mechanisms.¹ Whatever the mechanism, it is now generally agreed that the symptoms of IBD result from dysregulation of the mucosal immune system. The role of genetics has been strongly supported by epidemiologic studies, showing familial aggregation, consistent ethnic differences, and an increased concordance rate in monozygotic twins. Patients with a first-degree relative with IBD are at an

Table 27-1 Population Characteristics of Patients at High Risk for Inflammatory Bowel Disease Development

increased risk of developing the disorder, with a frequency of up to 40%.⁸ Detailed mapping of chromosome 16 in the Human Genome Project found a strong association with the *NOD2* (also termed *CARD15*) gene and increased susceptibility to CD, particularly ileal and ileocolonic disease.⁹ Evidence exists that patients with an *NOD2* polymorphism have a weakened mucosal immune response to bowel flora, which may cause chronic inflammation.⁹ Smoking has been the most consistent and most studied environmental factor associated with IBD. Interestingly, the effects of smoking are different between UC and CD, with smokers having a decreased risk of developing UC but an increased risk for CD.³ Use of nonsteroidal anti-inflammatory drugs (NSAIDs) has been associated with exacerbation of IBD.¹⁰

Although emotional stress has long been believed to play a role in IBD flares, objective evidence to support this notion remains scant. Debated for decades, the theory of an infectious etiology for IBD remains appealing.⁸ Murine models of colitis have shown a decreased development of IBD in a microbe-free environment. Repeated exposure of the GI tract to a particular micro-organism may trigger the immune dysregulation evident in this disease. However, some investigators believe that normal intestinal flora may be a catalyst for IBD. As mentioned previously, patients may be genetically predisposed to mucosal immune dysregulation, and either normal flora or bacterial pathogens may trigger the inflammatory response that leads to IBD. At various times, common intestinal organisms such as *Escherichia coli* and unusual bacteria such as *Mycobacterium paratuberculosis* have been investigated as causes of IBD, although no definitive conclusions regarding their etiologic role have been reached.¹¹

Pathogenesis

Under normal conditions, the mucosal immune system interacts with luminal antigens and mucosal bacteria on a continuous basis to maintain a state of controlled inflammation. As might be expected, the GI tract is exposed to an extremely high number of antigenic substances daily, and a delicate balance must exist for the system to operate properly. Several immune-specific genes partially determine the type of antigens that will trigger the immune response. In IBD, this immune response is perpetuated and an autoimmune cascade occurs. Thus, proinflammatory cytokines in the gut trigger an “attack” on the colonic mucosa by leukocytes and other factors leading to edema, ulceration, and destruction of the tissue. Normal immune regulators fail to halt this process and

the disease progresses. This can be due to a lack of regulatory or suppressor cells, an enhanced numbers of T cells, or both. The T-cell immune response is Th1 dominated, which is manifested by an increased production of interferon and tumor necrosis factor which promotes macrophage activation and development of delayed-type hypersensitivity response. In UC, Th2 response dominates with an increased production of interleukin (supports humoral-mediated immunity).¹² Studies have demonstrated that this increase of proinflammatory cytokines, chemokines, prostaglandin, and reactive oxygen species leads to increased inflammation and tissue destruction.⁵

Clinical Presentation

UC usually presents as shallow, continuous inflammation of the colon ranging from limited forms of proctitis (rectal involvement only) to disease involving the entire colon. Crypt abscesses consisting of accumulations of polymorphonuclear neutrophil (PMN) cells, necrosis of the epithelium, edema, hemorrhage, and surrounding accumulations of chronic inflammatory cells are typical in UC.¹³ Fistulas, fissures, abscesses, and small bowel involvement are not present. The inflammation is limited to the mucosa, which presents as friable, granular, and erythematous, with or without ulceration. Most patients with UC experience a chronic, intermittent course of disease. Chronic, loose, bloody stools are the most common symptom of UC.^{2,4} Other common complaints include tenesmus (urge to defecate) and abdominal pain. Patients with pancolitis usually have more severe symptoms than those with disease limited to the rectum. Mild UC is defined as fewer than four stools a day, no systemic signs of toxicity, and a normal erythrocyte sedimentation rate (ESR). Moderate disease is characterized by more than four stools a day but minimal evidence of systemic toxicity. Severe disease is defined as more than six bloody stools a day, fever, tachycardia, anemia, and/or an ESR >30.^{14,15} Proctitis is usually considered a separate type of UC for treatment purposes. Relapses and remissions are common in UC, with up to 70% of patients with active disease relapsing within 1 year after induction treatment.^{16,17}

CD is a chronic, transmural, patchy, granulomatous, inflammatory disease that can involve the entire GI tract, from mouth to anus, with discontinuous ulceration (so-called “skip lesions”), fistula formation, and perianal involvement. The degree of colonic involvement is variable; however, the terminal ileum is most commonly affected. Intestinal involvement is characteristically segmented and can be interrupted by areas of normal tissue. Unlike UC, the severity of the disease does not correlate directly with the extent of bowel involvement. Patients usually present with one of three patterns of disease: predominantly inflammatory, stricturing, or fistulizing. These patterns are the primary determinants of the disease course and the nature of complications.³ The inflammatory infiltrate is made up of T and B lymphocytes, macrophages, and plasma cells.

The disease course of CD is variable. Years of frequent relapses may be followed by complete remission. Patients with IBD often require surgery to control symptoms. For patients with UC, surgery is often curative. In contrast, in patients with CD, the frequency of recurrent disease after surgery is high and anatomically correlates with the original pattern of the disease.¹⁸

Table 27-2 Pathophysiological Differences Between Ulcerative Colitis and Crohn's Disease

| Characteristic | Ulcerative Colitis | Crohn's Disease |
|--------------------------------|---|---|
| Incidence (per year) | 6–12/100,000 | 5–7/100,000 |
| Anatomical location | Colon and rectum | Mouth to anus |
| Distribution | Continuous, diffuse, mucosal | Segmental, focal, transmural, rigid, thick, edematous, and fibrotic |
| Bowel wall | Shortened, loss of haustral markings, generally not thickened | |
| Gross rectal bleeding | Common | Infrequent |
| Crypt abscesses | Common | Infrequent |
| Fissuring with sinus formation | Absent | Common |
| Noncaseating granulomas | Absent | Common |
| Strictures | Absent | Common |
| Abdominal mass | Absent | Common |
| Abdominal pain | Infrequent | Common |
| Toxic megacolon | Occasional | Rare |
| Bowel carcinoma | Greatly increased | Slightly increased |

Adapted from references 1–4, 17, and 18.

Patients usually present with abdominal pain and chronic, often nocturnal, diarrhea.^{2,4,18} Weight loss, low-grade fever, and fatigue are also common. Features such as abdominal masses or abscesses and fistula (an abnormal communication between two organs) can make management of CD difficult and often require surgical intervention. Fistulizing disease is particularly difficult to treat and is the source of significant morbidity in CD patients. Enterocutaneous and enterorectal fistula are common, but other types, such as enterovaginal, can occur. Fistula can be excruciatingly painful, can be a source of infection, and can also exert significant psychosocial distress. Other similarities and differences in the pathophysiology of these disease states are outlined in Table 27-2.^{2,3,17,18} Extraintestinal manifestations of IBD that can cause significant morbidity include reactive arthritis, uveitis, ankylosing spondylitis, pyoderma gangrenosum, and primary biliary cirrhosis. Although their incidence varies, many of the manifestations of UC and CD are similar, as summarized in Table 27-3.^{5,17,18}

A careful patient history, physical examination, and endoscopic and radiologic studies are necessary to determine the severity of IBD. Laboratory studies such as an increased ESR can also aid in the diagnosis, but no single marker is pathognomic. Defining the severity of CD is a difficult, yet important step in successful treatment.¹⁹ Current guidelines from the American College of Gastroenterology define mild-to-moderate CD as ambulatory patients who are able to tolerate oral feeding without signs of systemic toxicity. Moderate-to-severe disease is defined as patients with symptoms of fever, weight loss, abdominal pain, nausea and vomiting, and/or significant anemia. Severe fulminant disease refers to patients with persistent symptoms despite standard induction regimens or those with signs of severe systemic toxicity.¹⁹

Table 27-3 Extraintestinal Complications of Ulcerative Colitis and Crohn's Disease

| Manifestation | Ulcerative Colitis (%) | Crohn's Disease (%) |
|--------------------------------|------------------------|---------------------|
| Acute arthropathy | 10–15 | 15–20 |
| Erythema nodosum | 10–15 | 15 |
| Pyoderma gangrenosum | 1–2 | 1–2 |
| Iritis/uveitis | 5–15 | 5–15 |
| Ankylosing spondylitis | 1–3 | 3–5 |
| Sacroiliitis | 9–11 | 9–11 |
| Primary sclerosing cholangitis | 2–7 | 1 |
| Cholelithiasis | <1 | 15–30 |
| Nephrolithiasis | <1 | 5–10 |
| Amyloidosis | <1 | Rare |

Treatment

When considering IBD therapy, one must appreciate that the cause of the disease is unknown and, therefore, precludes definitive therapy. In addition, specific therapy depends on the anatomical location of the disease. Other factors to take into consideration are coexisting medical conditions, patient perception of quality of life, medication adherence behavior, lifestyle (e.g., smoking), dietary factors, and patient's knowledge of the disease.⁴

With the advent of newer treatments for IBD, aggressive goals of therapy should be considered. These would include (a) complete relief from symptoms (induction and maintenance of remission); (b) improving quality of life; (c) maintaining adequate nutritional status; (d) relieving intestinal inflammation, dysfunction, and the development of cancer; and (e) reducing the need for surgery or chronic corticosteroid use.²⁰ The ideal medications should be effective, easy to administer with few side effects, and cost effective.^{14,15,19}

Most drug therapies for IBD have been tested for both UC and CD (Table 27-4). It is important to differentiate therapy used for acute exacerbations from those used to maintain remission.¹⁴

Aminosalicylates

Aminosalicylates were the first class of drugs to show benefits in IBD. The prototypical agent is sulfasalazine, which is composed of sulfapyridine (a sulfonamide antibiotic) linked by an azo bond to 5-aminosalicylic acid (5-ASA). The former moiety acts as a carrier to transport 5-ASA past its primary absorption site in the upper intestine. Later, cleavage of the azo bond by lower intestinal bacteria releases 5-ASA (the active moiety) for localized action in the colon. Systemic absorption of the sulfapyridine is responsible for most of the drug's adverse effects, but contributes nothing to the therapeutic benefit.

A significant number of patients discontinue this medication because of dose-dependent adverse effects, including nausea, vomiting, headache, alopecia, and anorexia. Other idiosyncratic adverse effects include hypersensitivity rash, hemolytic anemia, hepatitis, agranulocytosis, pancreatitis, and male infertility. This poor adverse effect profile has led to the development of safer sulfa free compounds that contain only 5-ASA.

Table 27-4 Pharmacotherapy for Inflammatory Bowel Disease

| Drug | Indication | Dose | Adverse Reactions | Comment |
|-------------------|--|--|--|---|
| Sulfasalazine | UC: mild-to-moderate maintenance CD: limited role | See Table 27-5 | N/V, diarrhea, HA, rash, myelosuppression | High ADR rate has caused use to decline |
| Mesalamine | UC: mild-to-moderate induction/maintenance CD: limited role | See Table 27-5 | N/V, diarrhea, HA, abdominal pain | Topical forms effective for proctitis and distal UC |
| Olsalazine | As above | See Table 27-5 | As above, diarrhea common | |
| Balsalazide | As above | See Table 27-5 | As above | |
| Corticosteroids | UC: mild-to-severe induction CD: mild-to-severe induction | Various | Hyperglycemia, CNS excitation, immunosuppression, osteoporosis, cataracts | Goal should be avoiding chronic use in UC and CD |
| Budesonide | UC: limited role CD: mild-to-moderate induction/maintenance | 9 mg daily | As above for corticosteroids, probably less short-term effects | Long-term use may still cause chronic corticosteroid ADRs |
| 6-MP/azathioprine | UC: mild-to-severe maintenance CD: mild-to-severe maintenance | 6-MP: 0.75–1.5 mg/kg/day Azathioprine: 1.5–2.5 mg/kg/day | N/V, diarrhea, HA, rash, myelosuppression (esp. neutropenia), pancreatitis | |
| Methotrexate | UC: limited role CD: mild-to-moderate induction/maintenance | 25 mg IM/SQ weekly induction dose, then 15 mg weekly for maintenance | N/V, stomatitis, hepatotoxicity, pulmonary fibrosis | Usually reserved for patients who have failed 6-MP/azathioprine |
| Infliximab | UC: moderate-to-severe induction/maintenance CD: moderate-to-severe induction/maintenance (fistulizing disease) | 5 mg/kg IV at weeks 0, 2, and 6, then Q 8 weeks thereafter | Infusion reactions (acute and delayed), immunosuppression, reactivation of latent infection (TB, hepatitis B, histoplasmosis), may worsen neuromuscular disease and congestive heart failure | Probable small increase in lymphoma Scheduled treatment preferred to episodic treatment to maintain response and decrease delayed infusion reactions |

UC, ulcerative colitis; CD, Crohn's disease; N/V, nausea/vomiting; HA, headache; ADR, adverse drug reaction; CNS, central nervous system; 6-MP, 6-mercaptopurine; IM, intramuscularly; SQ, subcutaneously; IV, intravenously; TB, tuberculosis.
Adapted from references 15 and 35.

Techniques to decrease systemic absorption and maximize local delivery of 5-ASA to the lower bowel include creating pH-dependent materials to delay drug dissolution and developing hybrid or dimer molecules of 5-ASA that are activated by gut bacteria (Fig. 27-1). Various synonyms and generic

names have been assigned to these 5-ASA derivatives, including aminosalicylate, mesalamine, and mesalazine (in Europe). Up to 90% of sulfasalazine-intolerant patients are able to tolerate these newer agents, and use of sulfasalazine has largely fallen out of favor for the treatment of IBD.²¹ Various

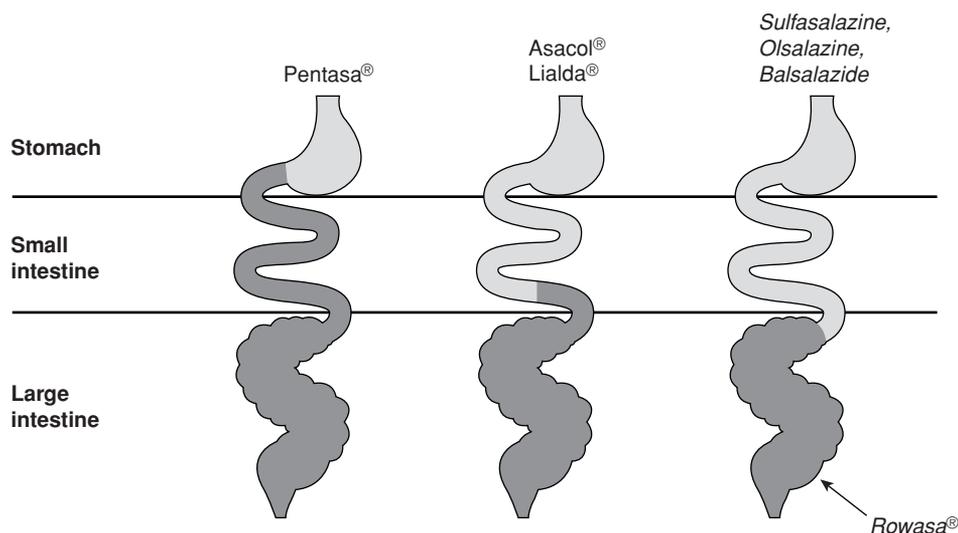

FIGURE 27-1 Sites of action of the 5-ASA compounds. Adapted from Gary Lichtenstein, MD, Professor of Medicine, University of Pennsylvania, Philadelphia.

mesalamine products have been developed for oral or rectal administration. Administration of mesalamine by retention enemas or suppositories is significantly more effective in the treatment of active distal colitis than placebo and at least as effective as sulfasalazine given rectally or orally.²² Olsalazine consists of two 5-ASA molecules connected by a diazo bond that is cleaved in the gut to release both active moieties. The newest 5-ASA agent to be approved for UC is balsalazide.²³ Similar to olsalazine, balsalazide is a 5-ASA dimer that is cleaved by gut bacteria to its active form. Significant efficacy advantages of any 5-ASA drug over another have not been demonstrated.^{23,24} Combination oral and rectal therapy for ulcerative proctitis may be superior to either modality alone.²⁵ 5-ASA suppositories are indicated for proctitis, whereas enema formulations can be useful in IBD confined to the distal colon. With the exception of abdominal pain, cramps, and discomfort (8.1%), rectally administered mesalamine is well tolerated.^{22,26} Enemas or suppositories should be administered in the evening. Mesalamine enemas are significantly more expensive than oral forms of 5-ASA. The oral 5-ASA agents are effective in inducing remission in mild-to-moderate UC and for maintaining remission in UC and perhaps for mild CD confined to the colon. Recent studies, some using newer formulations of 5-ASA, have evaluated the use of higher doses of these drugs for UC. Two trials examined a 6-week course of high-dose (4.8 g daily) Asacol[®] tablets versus standard-dose therapy (2.4 g daily).²⁷ A pooled analysis of these trials demonstrated that patients receiving higher doses of 5-ASA were more likely to achieve treatment success than those in the standard-dose group (72% vs. 58%, $p < 0.05$). Adverse effects of the oral 5-ASA compounds include diarrhea (especially with olsalazine), headache, arthralgias, abdominal pain, and nausea. Interstitial nephritis has rarely been reported with chronic use of mesalamine, but the association remains controversial. Cross-reactive allergic reactions to mesalamine in patients with a previous reaction to sulfasalazine have also been documented. An important drug interaction is the possibility of increasing 6-mercaptopurine levels in patients receiving balsalazide.²⁸

Corticosteroids

Corticosteroids are the most commonly used agents in the treatment of acute flares in patients with moderate-to-severe IBD.^{5,15,19} The anti-inflammatory actions of corticosteroids are well known, but how these translate into their full mechanism of controlling IBD is not completely understood. First-line treatment for moderate-to-severe active UC includes doses of corticosteroid equivalent to 40 to 60 mg of prednisone. Data are insufficient to demonstrate any difference between single versus divided oral doses or continuous versus intermittent bolus intravenous (IV) administration. IV doses should be equivalent to hydrocortisone 300 mg/day or methylprednisolone 40 to 60 mg/day.¹⁵ Although corticosteroids are effective for inducing remission in most cases of IBD, up to 30% of patients may not respond. Corticosteroids are not effective and should be avoided for maintenance therapy of CD and UC.^{2,19}

Topical steroids (enemas, foams, and suppositories) are beneficial for distal colitis and can serve as an adjunct in patients with rectal disease that also have more proximal disease and have failed topical 5-ASA therapy.^{15,29} Steroids are absorbed to a significant extent from the rectum and, with long-term use, can cause adrenal suppression.³⁰ Oral enteric-coated budesonide is approved for the treatment of CD. Budesonide pos-

sesses a high degree of topical anti-inflammatory activity with low systemic bioavailability.³¹ The Entocort EC formulation of budesonide delivers drug primarily to the ileum and ascending colon.³² It was believed that these factors would make budesonide more effective than traditional corticosteroids, while decreasing systemic side effects. Current data suggest that budesonide may be as effective or slightly less effective than traditional corticosteroids in active CD. Short-term corticosteroid-associated adverse effects may be less than with traditional agents, but adrenal suppression has been detected in study patients receiving budesonide, and its long-term safety profile remains to be determined.³³ The use of budesonide to maintain remission in patients with CD remains uncertain.³⁴ European guidelines for CD consider budesonide the preferred treatment for mild ileocolonic disease.³⁵

Immunomodulators

Azathioprine and 6-mercaptopurine (6-MP) are commonly used for the management of steroid-dependent and quiescent IBD. Azathioprine is converted to 6-MP, which is then metabolized to thioinosinic acid, the active agent that inhibits purine ribonucleotide synthesis and cell proliferation. It also alters the immune response by inhibiting natural killer cell activity and suppressing cytotoxic T-cell function.³⁰ Azathioprine (2–2.5 mg/kg/day) and 6-MP (1–1.5 mg/kg/day) are used in the treatment of active UC and CD in patients whose conditions have not responded to systemic steroids.^{5,15,36} These agents are also used as maintenance therapy for both UC and CD and may be used as “steroid-sparing” agents in patients unable to be weaned from corticosteroids.³⁷ Because of the long onset of action of 6-MP and azathioprine, many clinicians prefer to induce remission with either corticosteroids or infliximab and use these agents for maintaining remission. Adverse effects of 6-MP/azathioprine include rash, nausea, pancreatitis, and diarrhea. Myelosuppression, especially neutropenia, may have a delayed onset, and clinicians should monitor the complete blood count monthly for the first 3 months of treatment, then every 3 months thereafter.¹⁹ Neutropenia necessitating discontinuation of therapy occurs in approximately 10% of patients. Despite previous concerns, it appears these agents do not increase the risk of developing lymphoma.

Methotrexate (MTX), a folate antagonist, impairs DNA synthesis. It may also reduce interleukin-1 (IL-1) production or induce apoptosis of selected T-cell populations.^{26,30} MTX appears to be ineffective for induction or maintenance of UC.³⁸ However, data suggest that MTX (15–25 mg IM weekly) may have a role for both initial and chronic treatment of CD.^{39,40} The onset of effect often takes weeks to months with MTX. Most experts and recent guidelines suggest reserving MTX use for patients with CD intolerant of, or refractory to, 6-MP/azathioprine treatment.³⁵ Adverse effects with MTX include stomatitis, neutropenia, nausea, hypersensitivity pneumonitis, alopecia, and hepatotoxicity. MTX-induced nausea and stomatitis may be prevented by the addition of folic acid 1 mg PO daily. Some data suggest that even the risk of hepatotoxicity may be ameliorated by folate use.⁴¹

Cyclosporine (CSA), which selectively inhibits T-cell-mediated responses, has advantages over azathioprine, 6-MP, and MTX because of its more rapid onset of action.³⁷ Both oral and IV forms have been used to manage severe UC.⁴² Due to serious adverse effects, CSA is usually reserved for patients with severe UC refractory to corticosteroids. CSA 4 mg/kg IV

daily has been used in severe steroid-refractory UC.¹⁵ A recent randomized controlled trial found equal efficacy (about 85% response) with a 2-mg/kg dose compared to the standard 4-mg/kg dose.⁴³ The role of CSA therapeutic drug monitoring for this indication has not been firmly established but may be beneficial for toxicity monitoring.⁴³ The use of CSA for maintenance therapy or nonfistulizing disease is uncertain.

Infliximab

Early research indicating an increase in the amount of tumor necrosis factor- α (TNF- α) in the stool of patients with active CD, as well as an increase in the amount of lamina propria cells in the gut, led investigators to target this cytokine for treatment of CD.⁴⁴ Infliximab is a recombinant chimeric monoclonal antibody that binds to human TNF- α and neutralizes its biological activity by binding with high affinity to both soluble cell receptors and free TNF- α in the blood. Infliximab is indicated for a broad spectrum of IBD patients. This includes inducing and maintaining remission in patients with moderate-to-severe active CD who have had an inadequate response to conventional treatment.^{45,46} It is also effective for healing CD fistula, with data showing that chronic treatment can maintain fistula closure and decrease the need for surgery.^{47,48} Most recently, infliximab received an indication for the induction and maintenance of moderate-to-severe UC refractory to other treatment.⁴⁹ For all indications, infliximab is given as a 5 mg/kg IV infusion over 2 hours. An induction regimen, administered at 0, 2, and 6 weeks is followed by a maintenance infusion every 8 weeks. Some clinicians will increase the dose to 10 mg/kg in patients experiencing a loss of response. The response to infliximab is usually rapid, often occurring within several days, and can be dramatic in up to 60% of patients. Recent European guidelines for CD outline the importance of this therapy, especially in patients with corticosteroid intolerance or dependence.³⁵ Because infliximab is a monoclonal antibody, a number of immunologic-mediated adverse effects are associated with therapy. Antibodies to infliximab have been detected in up to 60% of CD patients using the drug,⁵⁰ and although a causative relationship remains unclear, patients who develop these antibodies may be at more risk not only for infusion reactions but also for reduced efficacy over time. Immediate infusion-related reactions such as fever, chills, pruritus, urticaria, and (rarely) severe cardiopulmonary symptoms can occur in about 1% of patients. Delayed hypersensitivity reactions resembling serum sickness and severe pulmonary symptoms are rarely reported and are more common in patients receiving episodic (rather than scheduled maintenance) treatment.⁵¹ Use of infliximab with concomitant immunosuppressives, such as azathioprine, decreases the development of these antibodies. Infectious complications, including pneumonia, cellulitis, sepsis, cholecystitis, endophthalmitis, furunculosis, and reactivation of tuberculosis and histoplasmosis, have also been reported in 2% to 6% of patients.^{52,53} Tubercular infections, including reactivation of latent disease are a particular concern with infliximab, and patients should be appropriately screened for latent disease before starting infliximab treatment.⁵⁴ Patients who have latent tuberculosis (usually identified by a positive tuberculin test) must start antitubercular treatment before use of infliximab can be considered. Patients with active tuberculosis should not receive the drug. Numerous case reports of reactivation of hepatitis B have also been published, and

some experts recommend a serum hepatitis screen before therapy with infliximab begins.⁵⁵ Lupuslike symptoms, such as arthralgias, have been seen rarely and usually resolve after discontinuation of the drug. Patients with serious active infections, a history of chronic infections, a history of a neural demyelinating disorder, or severe heart failure should avoid infliximab treatment.⁵² The latter two cautions are due to previous reports of exacerbations of multiple sclerosis and heart failure when patients with those diseases received anti-TNF- α therapy.

Other Biological Therapies

Success with infliximab in IBD has led scientists to develop and test other biological therapies designed to either block proinflammatory mediators or enhance anti-inflammatory mediators in the gut. Therapies, such as oncept and interleukins-10 and -11, have been examined or are undergoing investigation for CD.⁵⁶ To date, three other biologic agents are approved in the United States for the treatment of moderate-to-severe CD: the humanized α 4-integrin antibody natalizumab, the fully humanized anti-TNF- α antibody adalimumab, and, most recently, pegylated humanized Fab' fragments against TNF- α (certolizumab pegol). Two randomized controlled trials have found that natalizumab may be beneficial for induction and maintenance of remission in a small subset of patients, but at the increased risk of developing progressive multifocal leukoencephalopathy, a potentially fatal adverse effect.⁵⁷ Natalizumab is approved for inducing and maintaining remission in adults with moderate-to-severe CD who have had an inadequate response to or are unable to tolerate conventional therapies. Adalimumab is approved for the treatment of moderate-to-severe CD and may be particularly useful in patients with an attenuated response to infliximab.⁵⁸ Clinical studies have suggested a roughly equivalent symptom response between adalimumab and infliximab, and because the former drug is also a potent TNF- α blocker, similar safety concerns and adverse effects have been shown between the two agents.^{59–60} Certolizumab contains only the antibody receptor for TNF- α bound to polyethylene glycol to increase its duration in the body. Like the other biologic agents discussed it is effective in both inducing and maintaining remission in CD.⁶¹ Infectious and other adverse effects have been reported in clinical trials that are similar to other TNF- α blockers. The precise place in therapy of the newer biologic agents for CD is controversial. Most experts consider infliximab the biologic agent of first choice with the other agents reserved for a loss/lack of efficacy or adverse effects. Some experts are also advocating the earlier use of these agents in an attempt to forestall or prevent CD complications such as fistula development, but this topic is also controversial.⁶²

Antibiotics

Because an infectious etiology has been proposed for IBD, it stands to reason that antibiotics may have some utility.^{5,11,14} All studies showing benefit of antibiotics have been in patients with CD; no consistent benefit has been demonstrated for patients with UC.^{15,19,63} Metronidazole, which also has immunosuppressive properties, is the best studied antibiotic. It is especially effective in patients with perianal and postoperative CD, with benefits improving as the dosage is increased up to a maximum of 2 g/day.⁶⁴ Adverse effects with chronic, high-dose metronidazole include metallic taste and peripheral neuropathy, which is common. The European guidelines for

CD relegate the use of metronidazole to active gut infection, bacterial overgrowth, or perianal CD for a maximum duration of 6 months.³⁵

Nutritional Therapies

Nutritional therapies for IBD have been used because dietary intraluminal antigens may stimulate a mucosal immune response.⁸ Patients with active CD respond to bowel rest, total parenteral nutrition (TPN), or total enteral nutrition. Bowel rest and TPN are as effective as corticosteroids for inducing remission in patients with active CD in the short term.⁶⁵ Enteral nutrition, with elemental or peptide-based preparation, appears to be as efficacious as TPN, without its associated complications. Unfortunately, poor compliance often limits this modality. Neither enteral nor parenteral nutrition is effective treatment for the maintenance of remission.¹⁸ UC is not effectively treated with either TPN or enteral nutrition.

Supportive Therapy

Symptomatic management of IBD is important to the patient's quality of life. This includes pain relief and diarrhea control. Loperamide or diphenoxylate-atropine may be used to treat mild symptoms provided obstruction or toxicity is not evident.²⁶ Severe worsening of symptoms and abdominal distention may indicate toxic megacolon caused by the inability to empty rapidly produced secretory products of the bowel. Patients should be monitored for iron and vitamin B₁₂ deficiencies, especially if ileal involvement is extensive or resection has been performed.

Surgery

Surgery is indicated in the treatment of UC when the patient (a) fails to respond to medical management acutely or chronically, (b) develops uncontrollable drug-related complications, (c) experiences impaired quality of life from the disease or its drug therapy, (d) develops complications of a severe attack (perforation, acute dilation), (e) fails to grow and develop at a normal rate, or (f) develops carcinoma of the rectum or colon.¹⁷ In addition, patients who have had UC for longer than 10 years or who demonstrate premalignant changes on rectal biopsy may be managed surgically as a prophylactic measure against colonic carcinoma.⁶⁶

Generally accepted indications for surgical intervention in patients with CD include failure of medical management, incapacitation because of the disease or its drug therapy, retarded growth and development in children, intestinal obstruction, fistula formation, abscess formation, toxic megacolon, perforation and hemorrhage, and carcinoma.¹⁹ Despite advances in medical treatment of CD, surgical intervention is common in these patients.

ULCERATIVE COLITIS

Pathophysiology and Clinical Presentation

1. C.M., a 25-year-old female college student, has had episodic, watery diarrhea and colicky abdominal pain relieved by defecation for the past 9 months. Eight weeks before admission, the diarrhea increased to 3 to 5 semiformal stools daily. The frequency of the stools gradually increased to 5 to 10 times a day 1 week ago. At that time, C.M. noted bright red blood in the stools. Stool frequency has now increased to 10 to 15 per day, although the volume of each stool is estimated to be only "one-half cupful." She feels

a great urgency to defecate, even though the volume is small. She has not traveled outside the United States, has not been camping, and has not taken any antibiotics within the past 6 months.

C.M. complains of anorexia and a 10-lb weight loss over the past 2 months. For the past 4 months, she has had intermittent swelling, warmth, and tenderness of the left knee, which is unassociated with trauma. She denies any skin rashes or any difficulties with her vision. A review of other body systems and social and family history are noncontributory.

C.M. appears to be a slightly anxious and tired young woman of normal body habitus. Her temperature is 100°F; her pulse rate is 100 beats/minute and regular. Physical examination is normal, except for evidence of acute arthritis of the left knee and tenderness of the left lower abdomen to palpation.

Stool examination shows a watery effluent that contains numerous red and white cells with no trophozoites. Stool cultures and an amebiasis indirect hemagglutination test are negative. Other laboratory values include hematocrit (Hct), 32% (normal, 33%–43%); hemoglobin (Hgb), 8.5 g/dL (normal, 12.3–15.3 g/dL); white blood cell (WBC) count, 15,000/mm³ (normal, 4.4–11.3/mm³) with 82% PMNs (normal, 50%–70%); ESR, 70 mm/hour (normal, <20 mm/hour); serum albumin, 2.4 g/dL (normal, 3.5–5.0 g/dL); and alanine aminotransferase (ALT), 35 U/mL (normal, 8–20 U/mL).

Sigmoidoscopy showed evidence of granular, edematous, and friable mucosa with continuous ulcerations extending from the anus throughout the colon.

What is the most likely cause of C.M.'s diarrheal illness, and what is the evidence for this? How should the signs and symptoms be managed and monitored?

C.M.'s presentation is typical of a patient with new onset UC. Drug-induced (pseudomembranous colitis) and infectious (parasitic) causes of diarrhea have been ruled out by history (no travel outside the United States, no recent camping, no antibiotic use) and stool examination. As discussed previously, UC is an inflammation of the mucosal layer of the colon and rectum.¹⁷ Characteristically, the inflammation does not extend beyond the submucosa, and transmural ulcers are rare. On examination, the mucosa appears erythematous and is friable. Differentiation from CD is made by sigmoidoscopic and radiologic evidence of continuous distribution of pathology (as opposed to segmental), as well as the anatomical location (confined to colon and rectum).

C.M. presents with the classic triad of UC clinical symptoms: chronic diarrhea, rectal bleeding, and abdominal pain. The diarrhea is secondary to the decreased colonic absorption of water and electrolytes and diminished colonic segmental contractions that normally serve to decrease the flow of bowel content. A good indication of the severity of the patient's disease is the volume of stool passed per day.^{15,17} C.M.'s disease would be classified as severe. As the severity of the disease increases, incontinence and nocturnal diarrhea commonly occur. Diarrhea can vary in severity from three to four bowel movements daily to one to two bowel movements per hour. The stools are usually soft, mushy, formed, and often contain small amounts of mucus mixed with blood, although in patients with mild, early involvement, blood and mucus may be totally absent. In addition to the diarrhea, the malabsorption of water and electrolytes causes dehydration, weight loss (as observed in C.M.), and electrolyte disturbances.

C.M.'s rectal bleeding is secondary to colonic mucosal erosions and occurs in most patients with UC.¹⁷ Generally, bright red blood mixed in the stools indicates a colonic origin, whereas blood-streaked stools indicate an anal or rectal origin. The anemia associated with UC is generally secondary to this rectal bleeding. It presents as a hemorrhagic or iron-deficiency anemia, depending on the acuteness of the bleeding. Hemoglobin and hematocrit laboratory values often are decreased as in C.M.'s case. Chronic inflammatory disease–induced hypoalbuminemia is often exacerbated by malnutrition.

C.M.'s abdominal pain and cramping are caused by spasm of the irritated and inflamed colon. This abdominal pain is commonly associated with urgency to defecate. As illustrated by C.M., the pain is usually relieved with defecation, even though the stool volume may be small.

C.M.'s arthritis and elevated liver enzymes (alkaline phosphatase and ALT) are indicative of the extraintestinal manifestations that occur in IBD (Table 27-3). Her nonspecific symptoms (i.e., anorexia, fatigue, weight loss, anxiety, tachycardia) could become profound during an exacerbation of UC.²³ Fever, leukocytosis, and increased ESR are also systemic manifestations of an inflammatory disease. Rehydration is important to assure fluid balance and maintain good renal function.

2. Would it be safe to administer loperamide to C.M.?

Treatment of the diarrhea associated with UC is often difficult. In patients with mild-to-moderate disease, antidiarrheals, such as loperamide or diphenoxylate with atropine, may help minimize chronic diarrhea. Extreme caution must be used, however, especially in patients with severe disease because of the chance of inducing toxic megacolon (see question 13). For this reason, antidiarrheals are best avoided in patients with severe active disease and, if used, should be titrated according to the volume of stool produced. Bulk-forming agents, such as psyllium, may be helpful for patients suffering from constipation caused by ulcerative proctitis.⁶⁷

Remission Induction

Corticosteroids

3. What agents can be used to induce disease remission in C.M.?

Corticosteroids are the most effective agents to induce remission of acute, severe exacerbations of UC.¹⁵ Clinical improvement or remission occurs in 45% to 90% of patients taking 15 to 60 mg/day of prednisone, with an increased response at 40 to 60 mg/day. However, corticosteroids are not beneficial for maintaining remission. One strategy to minimize adverse effects of therapy with corticosteroids includes well-defined tapering regimens. Once improvement has occurred, prednisone is tapered by 5 to 10 mg/week until the dose is 15 to 20 mg/day. The dosage is then tapered by 2.5 to 5 mg/week until the drug is discontinued. Unfortunately, a subset of patients will experience a disease flare if the steroid dosage is decreased or tapered too quickly. IV corticosteroids are an important option, especially in patients who have poor oral intake. Patients with active distal disease can be treated with hydrocortisone enemas; however, 5-ASA topical therapy is as or more effective. Other medications that could be considered for induction of remission would include cyclosporine and infliximab. Due

to cost and safety issues with these agents, they should probably be considered only in fulminant disease or in those who have failed corticosteroids.⁶⁸

4. Methylprednisolone at a dosage of 40 mg IV Q 6 hr is ordered. What are the treatment goals for C.M.?

The goal of parenteral corticosteroid therapy for C.M. should be to achieve a rapid therapeutic response as measured by decreased frequency of stools, decreased pain, and decreased fever and heart rate. This goal may be attained with a high initial dose followed by a gradual dosage reduction to minimize the development of corticosteroid adverse reactions. The initial dose, as well as the rate of a subsequent dosage reduction, should be individualized based on the severity of the patient's signs, symptoms, and disease course.

Poorly nourished patients in whom oral intake is expected to be absent for more than 7 days should receive parenteral nutrition, and treatment should be continued until oral feeding is tolerated.⁶⁹ An adequate response is defined as resolution of fever, improved patient well-being, no tachycardia, and less abdominal tenderness on palpation. Diarrhea is usually considered to be resolved with four or fewer bowel movements daily. Stools are rarely formed at this stage, but macroscopic bleeding has stopped. Patients can then receive oral prednisone, a 5-ASA drug, and a light diet. If the patient does not respond within 72 hours of starting high-dose corticosteroids, cyclosporine, infliximab, or surgery may be indicated (see question 16). Once C.M.'s symptoms are controlled, the goal should be to switch to oral corticosteroids and discharge her from the hospital.

ORAL ADMINISTRATION

5. C.M. is responding well to methylprednisolone. She is afebrile, her abdominal pain is reduced (to a score of 5 on a 1–10 scale), and her diarrhea is decreasing. When is the oral route of corticosteroid administration indicated in UC? What are the most appropriate dosages?

Oral corticosteroids are effective for the initial treatment of mild-to-moderate acute UC.²⁶ In addition, they should be substituted for parenteral corticosteroids once a satisfactory initial response of more severe exacerbations has been achieved. In one controlled trial, 40 mg/day of prednisone was significantly more efficacious than 20 mg/day in controlling ambulatory patients with moderately severe acute UC.³⁰ Prednisone doses of 60 mg/day had no additional therapeutic value, but caused more adverse effects. In addition, a single 40-mg morning dose of prednisone was as effective as and more convenient than an equivalent divided dose (10 mg QID). Therefore, the initial dose of corticosteroid for a patient with moderately severe acute UC is 40 mg of prednisone or its equivalent administered once daily in the morning.

TOPICAL ADMINISTRATION

6. What if C.M.'s UC was limited to the distal colon or rectum? Would topical corticosteroids be indicated? When should other topical agents be used (e.g., 5-ASA)?

Topically administered 5-ASA and corticosteroids, in the form of suppositories, foams, and retention enemas, are effective in the management of acute, mild-to-moderate UC that is limited to the distal colon and rectum.^{22,70,71} To justify the use of such a difficult route of administration, a clear-cut advantage

of either increased efficacy or decreased side effects over other administration routes for these agents must be demonstrated.

Theoretically, 5-ASA and corticosteroids administered via this topical route provide a higher concentration of drug to the diseased mucosal area, exerting a local anti-inflammatory effect while minimizing systemic side effects. Unfortunately, variable but significant systemic absorption (up to 90%) and adrenal suppression occur from the topical administration of corticosteroid to the rectum and distal colon.³¹ Therefore, the beneficial effects produced by topical use of these agents may accrue from both systemic and local effects. The apparent and relatively low incidence of corticosteroid side effects associated with topical administration may be related to the low doses used and to the infrequent administration (daily to twice daily) needed to control mild acute UC. When prednisolone is given in equivalent doses orally and rectally, the incidence of side effects and therapeutic effects are similar.⁷²

5-ASA suppositories and enemas are preferred over topical corticosteroids for the treatment of distal UC and proctitis because they produce higher remission rates in proctitis and effectively maintain remission of distal UC.^{71,73,74} For distal UC, therapy is initiated with a nightly enema (4 g mesalamine), and the response should be evaluated in 3 to 4 weeks. If remission is attained, therapy can be tapered to one enema every third night. Simultaneous therapy with oral plus topical mesalamine showed greater efficacy than either alone in achieving remission of distal UC.^{15,23} Administering one suppository twice daily for 3 to 6 weeks of 5-ASA is generally sufficient to induce disease remission in patients with mild acute proctitis. Improvement should be seen in 2 to 3 weeks, and therapy should be maintained until complete remission is achieved. Therapy can then be tapered to one suppository or enema, two to three times weekly. If topical corticosteroids are to be used to manage mild, acute UC, the corticosteroid of choice would be the one with the lowest absorptive characteristics. Unfortunately, no trials have compared the absorption characteristics of all corticosteroids available for administration by this route. The available evidence indicates that, of the hydrocortisone salts, the acetate is the least absorbed.⁷⁵

ADVERSE EFFECTS

7. What particular corticosteroid adverse effects are of importance in patients with IBD?

Corticosteroid side effects and precautions for use often limit the therapeutic effectiveness of these agents and should never be overlooked⁷⁶ (see Chapter 44, Connective Tissue Disorders: The Clinical Use of Corticosteroids, for a detailed discussion of these effects). Certain glucocorticoid adverse effects are of particular importance in patients with IBD in that they may mimic, mask, or intensify symptoms and complications of this disease. For example, the symptoms of one of the major complications of intestinal perforation, peritonitis, may be masked by corticosteroids. Other deleterious effects of corticosteroids include hyperglycemia, avascular necrosis, cataract formation, and central nervous system effects, including mood disorders, insomnia, psychoses, and euphoria.

Corticosteroids have been noted to mask the clinical signs of abdominal and pelvic abscess in IBD patients, resulting in septic complications. Other corticosteroid adverse effects that may be secondary to either the drug and/or IBD include retardation of growth and development in prepubescent patients, osteoporosis with secondary pathological fractures and spinal column decompression, and hypokalemic alkalosis.⁷⁶ Patients with IBD may have decreased bone mineral density, especially with prolonged use of corticosteroids. This is an often overlooked side effect of these drugs. One study suggested that even budesonide, with its low overall bioavailability causes this adverse effect.⁷⁷ Thus, calcium, vitamin D supplements, and possibly bisphosphonates (e.g., alendronate 5 mg daily) are recommended to minimize metabolic demineralization in all IBD patients taking corticosteroids for longer than 3 months.⁷⁸

8. C.M. is still responding well to oral prednisone; however, her blood glucose concentrations have ranged from 250 to 450 mg/dL (normal, 70–110 mg/dL). Her physician would like to try another modality for active treatment. What other drugs could be used for remission induction?

Sulfasalazine and 5-ASA

Previously, sulfasalazine was considered the drug of choice in UC exacerbation because of its demonstrated efficacy and reduced toxicity when compared to corticosteroids.³⁰ However, controlled trials have shown that corticosteroids may act more promptly than sulfasalazine alone for severe acute UC.^{5,30} Sulfasalazine use has declined significantly since the availability of better tolerated 5-ASA formulations (Table 27-5). Clinical

Table 27-5 Comparison of Aminosalicylate Compounds

| Generic (Trade) | Delivery System | Intestinal Site of Release | Usual Dose and Frequency |
|----------------------------|--|--|---|
| Balsalazide (Colazal) | Bacterial cleavage of azo bond | Colon | 750 mg PO TID |
| Mesalamine (Asacol) | pH-dependent coating (Eudragit S) dissolves at pH \geq 7 | Ileum (distal), colon | 800 mg PO TID |
| Mesalamine (Lialda) | Multi-matrix (pH-sensitive coating and delayed-release) | Ileum (distal), colon | 2.4–4.8 g PO QD |
| Mesalamine (Pentasa) | Controlled-release microspheres | Duodenum, jejunum, ileum, colon | 1 g PO QID |
| Mesalamine (Rowasa) | Direct topical therapy | Rectum (supp) Descending colon/rectum (enema) | 500 mg PR QD-BID 4 g/60mL enema PR QHS |
| Olsalazine (Dipentum) | Bacterial cleavage of azo bond | Colon | 500 mg PO BID |
| Sulfasalazine (Azulfidine) | Bacterial cleavage of azo bond | Colon | Initially 500 mg PO BID; increase to 1g PO TID-QID |

BID, twice daily; PO, orally; PR, per rectum; QHS, at bedtime; QID, four times daily; TID, three times daily; supp, suppository

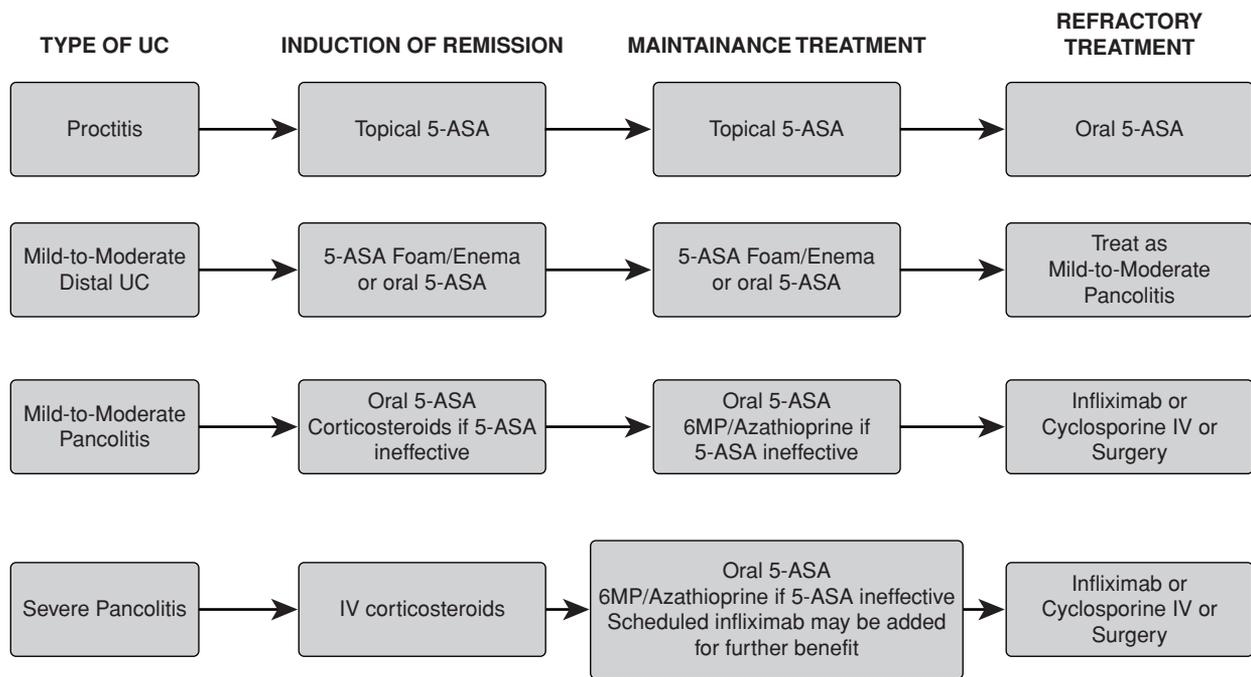

FIGURE 27-2 Treatment algorithm for ulcerative colitis. 5-ASA, mesalamine products, including mesalamine (e.g., Asacol, Pentasa, Rowasa), olsalazine, and balsalazide (see text for selection guidelines); UC, ulcerative colitis; pancolitis, extensive ulcerative colitis; 6MP, 6-mercaptopurine; IV, intravenous. Source: Adapted from references 15 and 76.

improvement or remission of mild-to-moderate UC can be attained in 40% to 74% of patients treated with oral 5-ASA in doses ranging from 1.5 to 4.8 g/day with further improved response at dosages >2 g/day.^{23,79} For mild-to-moderate proctitis or proctosigmoiditis, topical 5-ASA has been effective in 60% to 89% of patients. Both suppositories (0.5–2 g/day) and enemas (1–4 g/day) have been used.⁷³ In summary, oral 5-ASA compounds are usually considered first-line therapy for mild-to-moderate exacerbations of UC, with systemic corticosteroids reserved for more severe active UC or milder disease that has failed 5-ASA treatment. Even though sulfasalazine is less expensive than mesalamine compounds, the latter drugs are usually chosen because of their superior tolerability. Figure 27-2 describes a treatment approach to UC.

Remission Maintenance

Mesalamine

9. C.M. feels much better and claims to be “back to normal.” Her abdominal pain is gone, and she currently has two formed, nonbloody stools daily. Most of her laboratory parameters have returned to normal (ESR, 25 mm/hour; blood glucose, 80 mg/dL; WBC, 8,000/mm³). She is currently taking mesalamine (Asacol®) 400 mg PO TID. What drug regimen should be used to maintain disease remission in C.M.?

5-ASA agents significantly reduce the incidence of relapse in UC patients who are in remission.^{15,23} At 12 months, about 65% to 70% of patients remain relatively symptom free compared to placebo.⁸⁰ As discussed previously, the anatomical site of disease is an important consideration in the selection

of a 5-ASA preparation. Data also suggest that, if tolerated, a higher dosing strategy has a higher treatment success rate and should be the goal for most patients. In contrast, oral and topical corticosteroids do not prevent relapse of UC once remission has occurred.

On the basis of this information, C.M.’s mesalamine should be titrated to a total dose of 4.8 g in divided doses. If she experiences a relapse, a course of oral corticosteroids may be needed to re achieve remission. Prophylactic therapy should be continued indefinitely unless intolerable adverse effects develop.²⁶

ADVERSE EFFECTS

10. C.M.’s mesalamine has been increased to 1,200 mg QID for UC maintenance therapy. Several days after starting this higher dose of mesalamine, C.M. developed anorexia, nausea, and epigastric pain. What is the possible cause of C.M.’s symptoms? How can they be minimized?

C.M. appears to be experiencing adverse effects of mesalamine. Although usually better tolerated than sulfasalazine, unwanted adverse effects occur in 10% to 45% of patients.³⁰ Most 5-ASA adverse reactions are dose related and tend to occur early in the course of therapy.

Dose-related 5-ASA adverse effects can be minimized by initiating the patient on a low dosage (1–2 g/day) and gradually increasing the amount to tolerated therapeutic levels of 2.4 to 4.8 g/day.⁸¹ If dose-related reactions do occur, the drug should be discontinued until the symptoms subside, then it may be reinstated at a lower dosage. C.M.’s symptoms are probably dose-related adverse reactions to the mesalamine. The dosage should be decreased, or the drug temporarily withheld. If tolerated, the dosage can be increased slowly as necessary, or she

can be switched to another agent to maintain disease remission such as an immunomodulator.

TERATOGENICITY

11. C.M. would like to have a baby. What are the fertility and pregnancy concerns in a patient with IBD? Should she receive 5-ASA maintenance therapy if she becomes pregnant and plans to breast-feed her baby?

Fertility concerns are common in patients with IBD because many of these patients are of child-bearing age. Fertility is generally normal in patients with IBD, with the exception of active CD.⁸² In males, fertility may be reduced due to azoospermia if they are using sulfasalazine. Pregnant women with UC tend to have normal outcomes, but some evidence suggests that patients with CD have an increased risk for preterm delivery and babies with lower birth weights. Pregnancy itself does not seem to activate quiescent disease. Because active disease increases the chances of a complicated pregnancy, efforts to control IBD are critical. Increases in congenital defects or newborn toxicity have not been attributed to sulfasalazine or standard-dose mesalamine use during pregnancy.⁸³ Thus, UC patients being maintained on these agents can be continued on the drug during pregnancy.⁸⁴ The supplemental dose of folate recommended for most pregnant women may need to be increased whenever sulfasalazine therapy is prescribed.⁸¹ Little data on olsalazine or balsalazide use in pregnancy exist.

Although sulfasalazine and sulfapyridine do appear in breast milk, the actual concentrations are estimated to be low.⁸⁵ In addition, the ability of sulfapyridine and sulfasalazine to displace bilirubin is minimal, which probably explains why the literature has no reports of jaundice in breastfed babies whose mothers take sulfasalazine. Conservatively, it is appropriate to monitor bilirubin concentrations in infants nursing from mothers taking this drug. The American Academy of Pediatrics classifies mesalamine and sulfasalazine as agents that have produced adverse effects in a nursing infant and advises cautious use during breast-feeding because of possible allergic reactions. Thus, C.M. may continue her mesalamine therapy during conception and pregnancy, but she and her providers will have to weigh the risks of potential toxicity versus the benefits of breast-feeding. If C.M. decides to breast-feed, she should carefully monitor the infant for signs of diarrhea.

Other agents may be used in pregnant patients with IBD. Human studies suggest that prednisone and prednisolone are well tolerated and appear to pose a small risk to the fetus in utero. In fact, IBD is more detrimental to the fetus than corticosteroids, thus warranting continued use when necessary during pregnancy.⁸² The American Academy of Pediatrics considers prednisone to be compatible with breast-feeding. The studies of metronidazole have arrived at conflicting conclusions. Several studies, case reports, and reviews have described the use of metronidazole as safe for use during pregnancy,⁸⁶ whereas others have shown possible associations with malformations.⁸⁷ These malformations include, but are not limited to, hydrocele (two cases), congenital dislocated hip (one case), metatarsus varus (one case), mental retardation (one case), and midline facial defects (two cases). The long-term risks from metronidazole exposure have not been fully elucidated. The Centers for Disease Control and Prevention recommends that metronida-

zole be considered contraindicated during the first trimester. Using the drug for trichomoniasis in the second and third trimesters may be acceptable if other therapies have failed. For other indications, the risk–benefit ratio must be considered.

Immunosuppressants are alternatives for patients with refractory IBD. These agents can cause low fetal birth weight and congenital abnormalities, but they have been used safely in pregnant transplant patients.⁸² Due to a paucity of objective information concerning 6-MP/azathioprine use in pregnancy, these agents should only be used if absolutely necessary to maintain quiescent disease activity. Due to possible maternal toxicity, the role of CSA is limited. Methotrexate is contraindicated during pregnancy⁸⁶ (see Chapter 46, *Obstetric Drug Therapy*).

12. C.M.'s dose of mesalamine was decreased to 800 mg BID. After 2 weeks, C.M. continued to have nausea, diarrhea, and headache severe enough to cause her to miss classes and call in sick from her part-time job. What types of therapy should be considered at this point?

Immunosuppressive and Biological Agents

The results of several trials suggest azathioprine and 6-MP are appropriate alternatives for patients with active UC that has not responded to systemic steroids.^{15,37} These drugs are also used to maintain remission, although they are probably used more in CD than UC for this purpose (see Question 20).

Infliximab is now approved in the United States for moderate-to-severe UC (both for induction therapy and to maintain remission) that is refractory to other modalities. Due to the cost and adverse effects of the drug, it should probably be reserved for patients with severe symptoms or patients who cannot tolerate other treatments.

CSA has also been used to treat active UC. In one clinical trial, an 82% response rate was achieved using IV CSA 4 mg/kg/day for severe steroid-refractory UC.⁸⁸ CSA blood levels should be obtained, although correlation of clinical response and toxicity to blood levels has not been consistent. Many drug interactions and adverse effects are associated with CSA. Hypertension, gingival hyperplasia, hypertrichosis, paresthesias, tremors, headaches, electrolyte disturbances, and nephrotoxicity are common.²⁶ Studies using oral CSA for maintenance of remission in UC have been disappointing.⁴² In C.M., a reasonable choice would be azathioprine 2.5 mg/kg/day. Monthly monitoring of WBC counts and periodic assessment for any signs and symptoms of pancreatitis would be appropriate.

Toxic Megacolon

Signs and Symptoms

13. One year has passed since C.M. last had an acute attack of UC. She has been taking azathioprine 2.5 mg/kg/day. Now she presents with a fever of 104°F, a heart rate of 110 beats/minute, abdominal pain, weakness, and a sudden decrease in frequency of bowel movements. Physical examination discloses abdominal distention with nonlocalized rebound tenderness, tympany, and no bowel sounds. Abnormal laboratory values include a leukocytosis of 15,000 WBC/mm³ and serum potassium of 3.0 mEq/L (normal, 3.5–5.0 mEq/L). Other laboratory parameters, including serum

amylase and lipase, are within normal limits. Radiographic examination of the abdomen shows the transverse colon dilated to 9 cm. What is the most probable cause of C.M.'s symptoms? What are potential sequelae of this complication of IBD?

C.M.'s signs and symptoms are consistent with an acute dilation of the colon associated with systemic toxemia. This complication of UC, commonly referred to as toxic megacolon, occurs in about 5% of patients at some time during their disease course.¹⁷ Toxic megacolon is also a complication of Crohn's colitis and ileocolitis.

Toxic megacolon represents the most life-threatening complication of IBD and has an overall mortality rate of up to 16% with perforation. It is defined as a severe attack of colitis with total or segmental colonic dilation.¹⁷ A patient is considered toxic if colonic dilation is present with two or more of the following symptoms: temperature >101.5°F, tachycardia with a pulse rate >100 beats/minute, leukocytosis with a WBC count >10,000 cells/mm³, or hypoalbuminemia with an albumin <3.0 g/dL. Other symptoms include abdominal distention and tenderness, anemia, hypotension, and electrolyte imbalance. Signs and symptoms present in C.M. that are consistent with toxic megacolon include prostration, fever, tachycardia, electrolyte imbalance, abdominal pain and tenderness, leukocytosis, dilation of the colon to a diameter >6 cm, signs of diminished colonic peristalsis as evidenced by decreased stool frequency, and absence of bowel sounds. Other signs consistent with this diagnosis include dehydration, anemia, and hypoalbuminemia.¹⁵ Colonic perforation followed by peritonitis and hemorrhage is the major complication of toxic megacolon. C.M.'s condition should be considered a medical emergency.

PREDISPOSING FACTORS

14. What factors does C.M. have that predispose her to toxic megacolon? What drugs should be avoided in C.M.?

A contributing factor that predisposes C.M. to the development of toxic megacolon is hypokalemia, which decreases bowel wall muscular tone.^{17,89} Other predisposing factors include the use of antispasmodics, such as the opiates or anticholinergic agents, and irritant cathartics, such as castor oil, barium enemas, and hypoproteinemia, which produces bowel wall edema.^{17,89} Although corticosteroids may be necessary for the treatment of IBD, they may mask signs of peritonitis, a precursor to toxic megacolon.

MEDICAL MANAGEMENT

15. What medical therapeutic modalities should be considered for the treatment of C.M.'s toxic megacolon?

General supportive measures are used to arrest the necrotic process taking place in the colon. C.M.'s bowel should be allowed to rest. Nothing should be taken by mouth, and nasogastric suction should be initiated to prevent passage of swallowed air and fluid into the colon. Fluid and electrolyte imbalances must be addressed, and C.M.'s hypokalemia should be corrected as quickly as safely possible. She should also be given adequate nutritional support, including TPN, if a prolonged recovery is anticipated. High doses of IV corticosteroids should be initiated. C.M. is not currently taking steroids, but if she were, the dose would need to be increased to prevent adrenal insufficiency. A blood sample should be sent for culture and

sensitivity, and C.M. should begin empiric antibiotic therapy because she exhibits signs and symptoms of systemic bacteremia and sepsis (e.g., leukocytosis, fever, tachycardia). The antibiotic regimen chosen should include an agent effective against anaerobes and *Enterobacteriaceae* because both types of organisms occur in large numbers in the colon.

Other measures that may be appropriate in patients with toxic megacolon would include discontinuance of any drugs (e.g., opiates, anticholinergic agents) that decrease intestinal peristalsis and might predispose the patient to this condition. C.M. must be monitored carefully for signs of improvement or persistent dilation, perforation, peritonitis, and hemorrhage.

SURGICAL INTERVENTION

16. C.M. has been treated as previously described for 3 days. Nevertheless, her abdominal radiologic examination indicates no diminution in the caliber of the distended bowel, her temperature continues to spike to 103°F with negative blood cultures, and the abdomen remains distended and silent. Fluid and electrolyte imbalances have been restored. How should C.M. be managed at this point?

Within the first 72 hours of therapy and observation, the need for corrective surgery will be determined.^{15,89} The three general patterns of response are improvement, no change, and deterioration. Those who improve with medical therapy demonstrate decreased colonic distention, a return of bowel sounds, and a decreased pulse and temperature. Medical management should be continued in these patients as long as they continue to show progress. Unfortunately, only 50% of toxic megacolon patients respond satisfactorily to medical therapy.¹⁷

C.M.'s course is illustrative of most patients with toxic megacolon who show fluctuating degrees of response to medical management. These patients may appear to respond initially with decreased tachycardia and fever but become toxic again in 2 to 3 days. Despite signs of improvement, change in bowel sounds or a decrease in colonic size may be variable. If these objective parameters do not improve, perforation of the colon may occur unless they are managed surgically (subtotal colectomy and ileostomy). Early surgery reduces the overall mortality rate in patients such as C.M.

17. J.K. is a 49-year-old man who has had UC for 22 years. His disease is fairly well controlled with mesalamine tablets 800 mg PO TID. He has not had any UC flares for more than 5 years. He underwent a colonoscopy 1 week ago for routine cancer screening. Pathology results from this procedure indicate premetaplastic lesions in several areas of his colon. What are C.K.'s medical and surgical options for treatment of these lesions?

Of the various therapeutic modalities available for the management of UC, surgery is the most definitive form of therapy in that it is curative in most instances.⁹⁰ Because the lesions in UC are generally localized and continuous, colectomy will remove the primary focus of the disease. It will also eliminate both extraintestinal and local complications of UC in most patients. In addition, patients may require further surgery for anastomotic leaks, intraperitoneal abscesses, adhesions, obstruction, stomal ileitis, and mechanical problems associated with the ileostomy. Patient acceptability of ileostomies is poor, and major psychological adjustments are required of patients and their families.⁸¹ Patients must be given support and educated with regard to the care of their ileostomies; this includes

the prevention and management of common skin problems as well as control of odor and leakage of the effluent. Therefore, even though UC can be cured by surgery, it is indicated only after all reasonable nonsurgical forms of therapy have been exhausted. Considering the degree of inflammatory damage that occurs in colonic tissue, it is probably not surprising that the risk for colon cancer is elevated in patients with UC. Interestingly, at least one study has suggested that chronic 5-ASA therapy may be protective against colon cancer.⁹² Surveillance colonoscopies are recommended on a regular basis (usually every 1–2 years after the patient has had the disease 10 years) to screen for precancerous lesions.⁶⁶ If dysplastic lesions are detected, as they have been in J.K., surgical resection is usually considered the treatment of choice. Thus, even in patients with well-controlled UC, surgery may be required for cancer prevention.

CROHN'S DISEASE

Pathophysiology and Clinical Presentation

18. J.P., a 30-year-old man, was well until 18 days ago when he developed crampy right lower quadrant abdominal pain associated with an increased frequency of semiformal stools (four to five per day). The pain was episodic at first, exacerbated by meals, and somewhat relieved by defecation. During this time, J.P. experienced anorexia and a 15-lb weight loss. He denied any change in vision, joint pain, or the appearance of skin rashes. He has not traveled outside the United States or taken antibiotics recently.

Physical examination is essentially normal, except for soft, loose, watery stools that are streaked with fat and positive for occult blood. The abdomen is tender on palpation of the right lower quadrant. Pertinent laboratory values include Hct, 28% (normal, 39%–49%); Hgb, 9 g/dL (normal, 14.0–17.5 g/dL); WBC count, $14.0 \times 10^9/L$ (normal, $4.4\text{--}11.3 \times 10^9/L$); and ESR, 60 mm/hour (normal, <20 mm/hour).

Results of sigmoidoscopy and rectal biopsy are negative. Stool cultures and toxin studies for *Clostridium difficile* are negative, as is the examination for signs of trophozoites. A barium enema shows an edematous ileocecal valve and a terminal ileum that has a nodular irregularity of the mucosa. Follow-up endoscopy reveals a cobblestone-appearing terminal ileum with areas of normal tissue separated by diseased mucosa.

Which of J.P.'s signs, symptoms, and laboratory data are consistent with CD? Describe the pathophysiological basis for J.P.'s clinical presentation.

J.P., like most patients with CD, presents with the classic symptom triad of abdominal pain, diarrhea, and weight loss.¹⁸ His most frequent symptom is right lower quadrant abdominal pain, which is secondary to an indolent inflammatory process in the ileocecal area. Diarrhea is also a characteristic symptom; however, in contrast to UC, the stools are usually partly formed, and gross blood is generally not visible. If the disease is limited to the colon, the diarrhea may be of the same quality and quantity as that associated with UC. If the disease is limited to the ileum, as it appears to be with J.P., the diarrhea is generally moderate, with four to six stools daily. If ileal involvement is significant, bile salt malabsorption may occur, resulting in steatorrhea. Weight loss may be pronounced in patients with long-standing CD^{2,18} because of anorexia and malabsorption.

Rectal bleeding often occurs in patients with CD, particularly those with colonic involvement, although it is not as

common as that associated with UC. Slow blood loss may occur in patients with disease limited to the small intestine, which may cause occult blood-positive feces and, eventually, anemia, as illustrated by J.P. Massive hemorrhage is usually a late complication of CD and is generally due to transmural ulceration and subsequent erosion into a major blood vessel.

J.P.'s leukocytosis and increased ESR demonstrate that, like UC, CD is a systemic disease. Extraintestinal manifestations such as arthritis, liver disease, and skin rash occur in CD with the same frequency as UC (Table 27-3).³ However, some types of extraintestinal disease appear to be more common in UC (e.g., primary biliary cirrhosis) than CD (e.g., pyoderma gangrenosum).⁹⁴

Most patients with CD have recurrent, symptomatic episodes of pain and diarrhea with gradual progression of their disease to shorter and shorter asymptomatic periods. Although the clinical course is generally progressive, 10% of patients will remain essentially asymptomatic after a few acute episodes.⁵ Other patients may only manifest a slight fever for years until a late complication of the disease, such as fistula formation, develops. Alternatively, CD may be rapidly progressive.

Remission Induction

19. What agents can be used to induce a remission of J.P.'s CD?

Because the clinical course of CD varies among patients, the management of this disease must be individualized. The anatomical location of the disease is also an important determinant of therapy. Most investigations evaluating the treatment of acute symptomatic CD have ignored this factor and are therefore difficult to assess or compare.²⁶

Corticosteroids

Corticosteroids are the most widely used therapeutic agents for the treatment of active, symptomatic CD.^{19,95} A systematic review of the literature confirms that steroids have a valuable role in remission induction.³¹ Landmark studies have demonstrated that approximately 60% to 80% of patients with active CD will respond to a course of steroids. These agents seem to be particularly effective in ileal and ileal-colonic disease and can induce remission in even moderate-to-severe CD. Budesonide is recommended in the European CD guidelines for active mild-to-moderate ileocolonic CD.³⁵

5-ASA

Although previously used extensively for mild to moderate CD, current trial data and expert opinion have limited the role of 5-ASA drugs to mild active colonic CD. A large meta-analysis comparing 5-ASA (Pentasa) versus placebo found a small and probably clinically insignificant treatment benefit.⁹⁶ Some experts still argue in favor of chronic 5-ASA treatment, especially in light of the possible role of these agents in colon cancer protection, as mentioned previously. Recent European guidelines suggest that sulfasalazine is an option only in mild active colonic CD.³⁵

Other Induction Agents

The immunomodulators azathioprine, 6-MP, and MTX have onset action of weeks to months and are not usually appropriate therapy alone for treatment of a CD flare. Infliximab is effective as a treatment for both active and quiescent disease. It can be

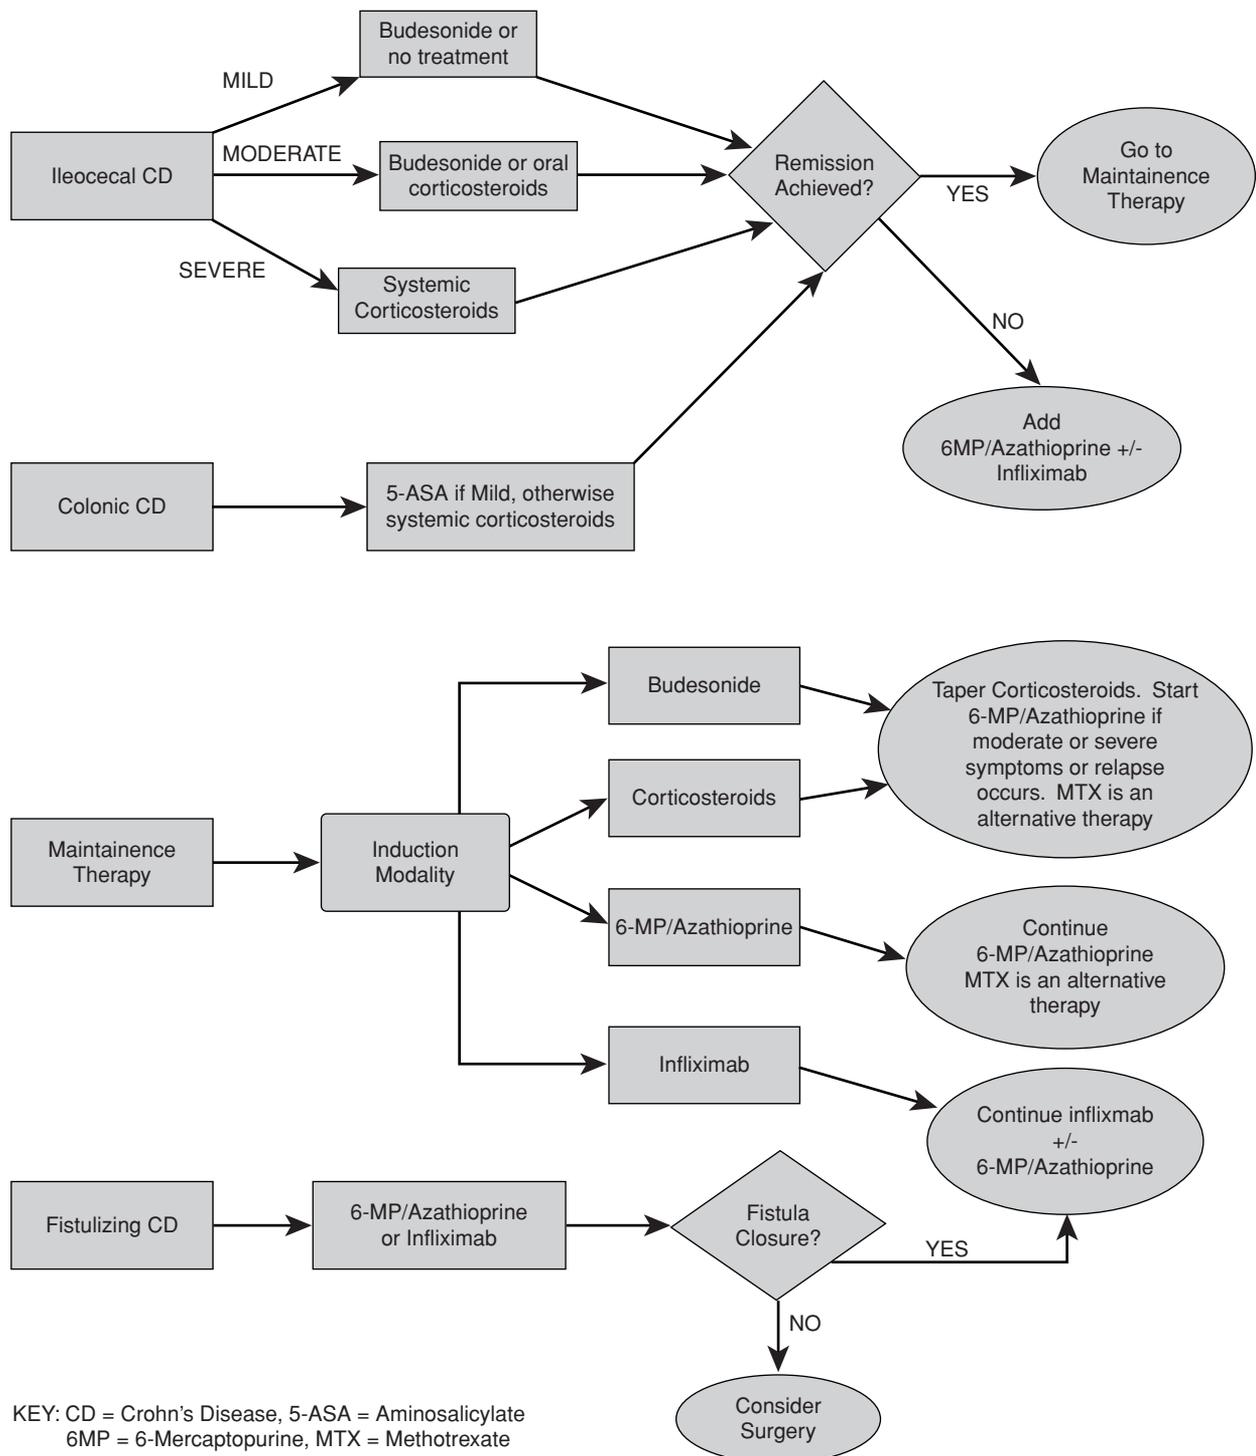

FIGURE 27-3 Treatment algorithm for Crohn's disease.

used alone due to its rapid onset; however, many experts elect to have patients on concomitant immunomodulator therapy, based on the theory that this decreases the development of anti-infliximab antibodies. Due to its expense and concerns of safety, use of infliximab is often reserved for severe disease, as a steroid-sparing strategy, or in patients who do not tolerate other modalities. A treatment algorithm based on guidelines^{19,35} for the treatment of CD is depicted in Figure 27-3.

Remission Maintenance

20. After 4 weeks of prednisone 40 mg daily, J.P. experienced fewer symptoms of CD; he has one to two well-formed stools a day, increased appetite and weight, decreased abdominal pain and tenderness, and normal body temperatures. Should prednisone be discontinued? What agents are effective in maintaining remission of symptoms in patients with CD?

Corticosteroids

Once prednisone has induced remission of active symptomatic CD, attempts should be made to taper the drug.¹⁹ The tapering schedule is usually fairly slow (typically, a dose reduction of 5%–10% per week), taking several weeks to months to complete. Several studies have demonstrated that corticosteroids are ineffective in maintaining remission in CD, and many patients continue to have active disease while receiving therapy. However, a significant subset of patients (25%) with CD requires chronic administration of corticosteroids to prevent recurrence of symptoms (termed steroid-dependent CD).⁹⁷ Given the poor long-term adverse effect profile of steroids, many clinicians attempt treatment with other modalities to maintain remission.

Sulfasalazine

Large long-term studies have shown that the continued use of sulfasalazine or mesalamine in patients with symptomatic CD is not significantly more effective in preventing recurrence of symptoms than placebo, irrespective of original disease location.⁹⁸ An exception to this may be the maintenance of postsurgical CD.⁹⁹

6-Mercaptopurine/Azathioprine

Evidence suggests that both 6-MP and azathioprine have a major role in maintenance treatment of CD.¹⁰⁰ In addition, these agents are often used as a “steroid-sparing” strategy. Recent guidelines recommend the use of 6-MP and azathioprine in most relapsing cases of CD, regardless of anatomical site, and for both severe and steroid-dependant disease.³⁵ Provided patients are appropriately monitored, these agents are safe with a favorable risk–benefit ratio. Both 6-MP and azathioprine are the first-line immunomodulators used in CD. Should these agents be ineffective or not tolerated, either MTX or infliximab can be used to maintain remission.²² Some experts believe that infliximab should be used earlier in the course of relapsing disease, especially in patients with fistula.¹⁰¹

In summary, J.P.’s prednisone should be tapered as suggested previously and then discontinued if possible. As the tapering regimen is begun, J.P. should start 6-MP 1.5 mg/kg/day or azathioprine 2.5 mg/kg/day. This is due to the long onset of effect for the latter drugs (usually 3–6 months). J.P.’s WBC counts should be monitored regularly and he should be counseled regarding the signs and symptoms of severe infection (e.g., fever, sore throat, or chills) and pancreatitis (e.g., severe epigastric pain and nausea).

ADVERSE EFFECTS

21. Six weeks after starting to taper J.P.’s prednisone dosage (currently, 10 mg/day) and the initiation of azathioprine, he returns to the clinic for routine laboratory monitoring. His WBC count is 1,800/mm³ with an absolute neutrophil count of 1,100/mm³. He is afebrile and without complaint. His physical examination is negative for any sign of infection. Why is J.P. experiencing leukopenia? What is the treatment for this side effect?

6-MERCAPTOPYRINE/AZATHIOPRINE MONITORING

Azathioprine is a prodrug that is converted to the active moiety, 6-MP, in the liver. 6-MP is then metabolized by xanthine oxidase, hypoxanthine-guanine-phosphoribosyltransferase, or thiopurine-S-methyltransferase (TPMT). Genetic polymor-

phism determines the extent of TPMT activity. In approximately 90% of whites, TPMT activity is considered high, but the remainder of the population have either intermediate or low TPMT activity.¹⁰⁰ These patients are predisposed to 6-MP/azathioprine myelosuppression because diminished TPMT activity leads to the metabolism of these compounds being shunted to the other enzymatic pathways. Accumulation of the 6-thioguanine byproducts is correlated with leukopenia. Recently, a laboratory test to assess TPMT activity has been developed and found to be effective in guiding therapy with azathioprine or 6-MP, while minimizing the incidence of bone marrow suppression.¹⁰² Some data even suggest that patients with a high TPMT level may be less likely to respond to these drugs.¹⁰³ Still, the optimal role for this test remains to be fully determined, and although some experts are screening patients before initiating therapy with azathioprine or 6-MP, routine use cannot be recommended at this time.

In patients who have developed neutropenia from azathioprine therapy, as J.P. has, the primary treatment is to discontinue azathioprine. In most cases, the WBC count will normalize over several days to weeks. In extreme cases, the use of granulocyte colony-stimulating factor may be considered.¹⁰⁴ J.P. should be monitored for signs and symptoms of infection, and the azathioprine should be held. Frequent, probably daily, WBC determinations should be made until the count is above 3,000/mm³.

Other Agents

22. J.P.’s leukocyte count returns to normal after 2 weeks. Unfortunately, he experiences a flare of his CD symptoms; specifically, an increase in diarrhea and abdominal pain that J.P. has noted over the past 5 days. What other agents should be considered to maintain remission in J.P.?

A number of other immunosuppressive drugs have been examined in CD. Methotrexate produces and maintains remission in patients with refractory disease. Clinical improvement or reduction in corticosteroid dosages have been observed with 15 mg/week oral methotrexate or 25 mg/week of intramuscular or subcutaneous methotrexate in 39% to 54% of patients who had active bowel disease or fistulas.¹⁰⁵ In clinical studies, GI toxicity was the most common reason for discontinuing treatment, but neutropenia and liver enzyme elevations were also reported.¹⁰⁶ European guidelines recommend reserving methotrexate for patients who have failed or are intolerant of 6-MP/azathioprine. Some experts consider MTX to be inferior to 6-MP/azathioprine in CD, but no comparison studies have been published to date.

CSA has a limited role for remission induction treatment in patients with severe, refractory CD. It has no role in maintaining remission.

METRONIDAZOLE

Metronidazole has been advocated for the treatment of active CD, especially that involving fistulas or the perineal area. Earlier controlled trials demonstrated that 800 mg/day of metronidazole is at least as effective as sulfasalazine (3,000 mg/day) in treating active CD and that it was more effective than placebo in patients with disease relapse.^{18,107} In contrast to these positive reports, Ambrose and others demonstrated in a prospective, randomized trial that although metronidazole

was more effective than placebo in improving symptoms after 2 weeks of therapy (67% vs. 35%) for patients with relapse of their disease, no difference was noted at the end of 4 weeks of therapy.¹⁰⁸ Recent guidelines recommend that antibiotics have little role in the maintenance of remission in CD, but may be helpful in fistulizing disease or in patients with abscesses. Taste disturbances and peripheral neuropathy are the most commonly reported adverse effects associated with metronidazole treatment. The long-held dogma that ethanol causes a disulfiramlike reaction with metronidazole has been questioned.¹⁰⁹

INFLIXIMAB

23. J.P. has developed an enterocutaneous fistula with his latest disease exacerbation, and nothing is helping him achieve remission. What alternatives exist?

Infliximab is now firmly established as an important therapy in the treatment of CD, especially fistulizing disease. However, a number of concerns regarding this agent must be discussed with the patient before initiation of therapy. It is an expensive therapy (about \$15,000/year), and a full pharmacoeconomic analysis of this agent in CD has not yet been published.¹¹⁰ Infliximab should be considered for moderate-to-severe disease that does not respond to other therapies. Fistulizing disease seems to respond particularly well to infliximab, and its use may avert the need for surgery.¹¹¹ Acute and delayed hypersensitivity reactions can occur and are occasionally life threatening. Some clinicians premedicate patients with a combination of diphenhydramine, acetaminophen, or corticosteroids before an infusion; however, the most effective strategy to avoid a serious reaction is to regularly monitor vital signs during infliximab infusion and slow the rate or stop the infusion if any symptoms develop. The majority of reactions consist of headache, flushing, itching, and dizziness, with anaphylactic reactions rarely occurring. It is hypothesized that patients who receive regular infliximab therapy or are taking concomitant immunosuppressive drugs are at a decreased risk for these reactions.¹¹² Also of concern is the development of human antichimeric antibodies in some patients receiving infliximab.

Infliximab should be avoided in patients who have a serious active infection. Due to reports that infliximab treatment may reactivate tuberculosis, all patients considered for treatment must receive a tuberculin skin test to rule out the disease (see Chapter 61, Tuberculosis). If this test is negative and, because J.P. does not appear to have any other contraindications, he would seem to be an appropriate candidate for infliximab. If latent tuberculosis is found, antitubercular treatment must be initiated before infliximab can be considered.⁵² In addition, screening for hepatitis B (and probably C) is reasonable due to the number of cases describing reactivation of these viral infections. Concern that use of infliximab may increase the risk of malignancies is currently under investigation. Studies examining this issue may be difficult to interpret because CD itself may cause an increase in lymphoproliferative cancers.⁴⁴ Also, other immunosuppressant agents commonly used for CD (e.g., MTX, CSA) may increase the risk of developing cancer.³⁷ Current data concerning a link between infliximab use and malignancy are conflicting.¹⁰⁹ To date, the balance of data suggests a small but real risk of developing lymphoma in CD patients using

infliximab, but despite this, its use is associated with an increase in quality adjusted years of life.^{114–116}

24. J.P. consents to the use of infliximab, and it is successful at keeping him symptom free. However, after 2 years of remission, J.P. is hospitalized for an acute exacerbation of right lower quadrant pain associated with abdominal distention, lack of bowel movements, and vomiting over the past 24 hours. Radiographic studies indicate partial small bowel obstruction at the terminal ileum. Is surgery indicated at this time?

SURGERY IN CROHN'S DISEASE

Because medical therapy of CD is often inadequate, 78% of patients with this disease will require surgery within 20 years of symptom onset.⁶ In contrast to UC, surgical removal of the involved bowel in CD is not a definitive form of therapy. CD can recur even after extensive resections.¹⁸ Various investigations have determined that cumulative recurrence rates after surgery for this disease are as high as 80%, depending on the surgical procedure and disease location. Therefore, multiple operations and their attendant risks are often necessary over the life span of the CD patient. Depending on the amount and site of the bowel removed during surgery, specific malabsorption syndromes can occur (e.g., vitamin B₁₂ malabsorption with removal of the terminal ileum). If an ileostomy is part of the surgical procedure, the patient will have to undergo significant psychological adjustments. Therefore, surgery is indicated only for specific complications that are unresponsive to medical therapy and should be avoided if possible.⁸⁶

OVERVIEW OF IRRITABLE BOWEL SYNDROME

Irritable bowel syndrome (IBS) is one of the most common chronic disorders causing patients to seek medical treatment. It exerts a significant economic burden and is responsible for considerable morbidity in Western countries. Until recently, little was understood about the pathophysiology or etiology of this disorder. Indeed, some controversy exists today as to whether IBS is a distinct syndrome or a grouping of several chronic GI disorders. Still, investigators have made strides in understanding IBS, particularly the role of the enteric nervous system in the etiology of this disorder. As a result, new pharmacotherapeutic options are emerging for patients suffering from this often bewildering condition.

IBS can be defined as “a functional bowel disorder in which abdominal pain is associated with defecation or a change in bowel habit with features of disordered defecation and distension.”^{117,118} The incidence of IBS has been reported to be 15% to 20% in Western countries.¹¹⁹ It is the most common disorder seen by gastroenterologists and is commonly seen by primary care clinicians as well.^{120,121} Prevalence rates are dependent on IBS diagnostic criteria, which have varied over the years. A female gender predominance of about 3:1 is evident in most epidemiologic studies of IBS.¹²² Some studies have demonstrated a white predominance in IBS, whereas other studies have found no such association.¹²³ Many patients with IBS never seek medical attention, and those who do tend to see their physician frequently.¹²⁴ Many of these patients also suffer from other functional disorders, such as fibromyalgia and interstitial cystitis, and psychiatric disorders,

such as major depression and generalized anxiety disorder.¹²⁵ As mentioned previously, the economic costs associated with IBS are considerable; it is estimated that IBS accounts for \$33 billion in direct and indirect costs in the United States annually.¹²⁶

Pathophysiology

Although knowledge of the cause of IBS remains incomplete, several theories have emerged to explain the underlying pathophysiology of this disorder. Previously, the primary cause of IBS was believed to be psychiatric or psychosomatic. This picture was at least partially validated by the finding that many IBS patients had psychiatric comorbidities. More recently, it is believed that factors such as psychological stress may exacerbate the disease, but they are not the sole cause of IBS.¹²⁷ It has long been known that IBS patients tend to exhibit visceral hypersensitivity to colonic stimulation or manipulation. Although concomitant anxiety and hypervigilance undoubtedly played a role in such observations, it is now believed that the reaction to visceral stimuli in these patients results in the perception of abdominal pain, whereas patients without IBS would have no symptoms. The etiology of this hypersensitivity is the focus of intense research efforts. Theories have emerged suggesting that the activation of silent gut nociceptors due to ischemia or infection may lead to increased abdominal pain in IBS.¹²⁷ Other experts propose that an increase in the excitability of neurons in the dorsal horn of the spinal cord lead to gut hyperalgesia. An abnormality in the processing of ascending signals from the dorsal horn may be responsible for a lower pain threshold in IBS patients. Similarly, findings suggest that neurotransmitter abnormalities may cause the symptoms of IBS. Of particular interest is the role of serotonin (5-HT) in the etiology of this disorder. Greater than 95% of the body's 5-HT is located in the GI tract and is stored in many cells, such as enterochromaffin cells, neurons, and smooth muscle cells. When released, this 5-HT can trigger both GI smooth muscle contraction and relaxation, as well as mediate GI sensory function.¹²⁸ Different 5-HT receptor subtypes may be responsible for these differing actions. A study examining rectal biopsy specimens in patients with IBS found defects in 5-HT signaling, supporting the theory of neurotransmitter abnormalities.¹²⁹ The primary 5-HT subtypes in the GI tract are 5-HT₃ and 5-HT₄. Some data suggest that IBS patients may have higher levels of 5-HT in the colon compared with control subjects.¹³⁰ Thus, these receptors have become the target of pharmacotherapeutic manipulation for IBS.

Another proposed pathological mechanism of IBS is altered colonic motility. Diarrhea, constipation, and abdominal bloating are common features of IBS. Patients with IBS are often categorized as having either diarrhea-predominant or constipation-predominant disease.¹³¹ About one-half of patients with IBS report increased symptoms postprandially, and patients with diarrhea-predominant IBS (DP-IBS) have been shown to have an exaggerated response to cholecystokinin after eating, leading to increased colonic propulsions.¹³² However, constipation-predominant IBS (CP-IBS) patients tend to have fewer colonic propulsions postprandially. Patients in whom bloating is the primary symptom of IBS may have gas production from poor fermentation of carbohydrates.¹³³ This has

led investigators to search for a link between food intolerance and IBS.

Etiology

The pathogenesis of IBS is poorly understood, although consensus theories are emerging. Some investigators believe that inflammation of the GI mucosa associated with infection may be the triggering factor that results in IBS, although this notion is controversial.^{134,135} The fact that symptoms associated with IBS can appear in up to 30% of patients who had an episode of bacterial gastroenteritis in the recent past lend credence to an infectious etiology.¹³⁶ Also controversial is the possible association of a history of physical or sexual abuse and the development of IBS.¹²⁷ Most IBS patients under emotional or psychological stress will report an exacerbation of their symptoms, but this is not surprising considering that such stressors affect non-IBS patients' GI function as well.¹³⁵ Familial clustering of IBS patients suggests that both genetics and formative environments may play a role in the pathogenesis of this disorder.¹³⁷ Finally, food intolerances (e.g., lactose intolerance) may be involved in the etiology of IBS or may be misdiagnosed as IBS.

Diagnosis

One of the more challenging and frustrating aspects of IBS is its lack of biochemical or physical markers that are pathognomic for the disorder. Thus, the diagnosis of IBS is usually symptom based.¹³⁸ Unfortunately, this lack of "objective" criteria for diagnosis can propagate the notion that IBS is a psychological or psychosomatic disorder. Many patients express frustration with the traditional medical establishment and individual providers.¹³⁹ In addition, the lack of a definitive marker for diagnosis may lead clinicians to order excessive testing and procedures in patients with suspected IBS. To address these issues, guidelines for the diagnosis and management of IBS have been published in the United States and Canada.^{138,140} Both guidelines suggest that extensive testing in IBS patients is usually unnecessary provided that patients are younger than 50 years and do not present with any so-called "alarm symptoms" (Table 27-6). Several symptom-driven criteria have been published, including the recently proposed Rome III criteria (Table 27-7). Both consensus panels agree that once IBS is diagnosed, it should be further differentiated by symptom pattern into DP-IBS, CP-IBS, or pain-predominant IBS (PP-IBS). Because there is no known cure for IBS, it is logical to use these subgroups to help direct symptomatic therapy. In most cases, the primary clinician can successfully manage the IBS patient

Table 27-6 Alarm Symptoms Requiring Gastroenterology Consultation

using the treatment algorithm depicted in Figure 27-4. However, the presence of alarm symptoms or an unusual finding on routine examination (e.g., thyroid abnormality) may prompt further referrals and testing.

There are limited data concerning the natural history of IBS.¹²⁷ IBS is generally considered a benign disease with a good prognosis.¹³⁷ Patients' symptoms often wax and wane, and, in some cases, the syndrome resolves spontaneously.¹³⁸

Management

25. V.H. is a 33-year-old woman who presents with complaints of severe abdominal pain (rated 6 on a scale of 1–10), bloating, and the passage of hard pelletlike stools about every 3 days. This has gone on for about 6 months, and V.H. notices that an “attack” occurs usually after a large meal. Her past medical history is significant for a generalized anxiety disorder. Her current medications include buspirone and YAZ[®] (drospirenone and ethinyl estradiol). Her immediate family is alive and well, except for a brother with depression. She drinks socially and does not smoke or use illicit drugs. V.H. is concerned that her symptoms are indicative of cancer. How should the clinician respond to V.H.'s concerns?

Patient Education

Clinicians must reassure patients with IBS that their symptoms are real. Furthermore, patients should be thoroughly counseled concerning the prognosis of IBS. Many patients are fearful that their symptoms are indicative of severe pathology such as cancer. Reassurance and education are vital to assuage fears and to reinforce the generally benign nature of this disorder. Involving patients at the earliest stages in their treatment plan is vital for patient acceptance and to avoid “doctor shopping.”¹²⁴ Helping patients discover triggers that may exacerbate IBS symptoms is an effective strategy for treating the disorder and empowering the patient. This may include having the patient keep a food diary and attending IBS educational classes.^{124,133} As noted previously, psychological disorders are present in a large segment of IBS patients. The clinician should again reinforce the notion that IBS is not “all in the patient's head.” However, treatment of comorbid disorders, including the discovery of a history of physical or sexual abuse (and possible posttraumatic stress disorder), is an important component in successfully treating IBS.^{125,144}

26. After a discussion concerning IBS, V.H. seems less worried. She relates her concern that her dietary habits are responsible for the symptoms she is experiencing. She wonders if changing her diet will “cure” her of IBS. What is the role of diet in the treatment of IBS? Will V.H. be relieved of her IBS symptoms if she changes her diet?

Diet

As mentioned previously, food intolerance may cause symptoms similar to those associated with IBS. Patients with lactose intolerance can experience pain, bloating, and diarrhea after ingesting milk-based products. A dietary and symptom diary may reveal such an intolerance, and avoidance of the implicated foods would constitute effective treatment.¹²⁴ Unfortunately, most patients with IBS have difficulty complying with exclusion diets or will not achieve significant relief with them. Patients with CP-IBS may benefit from increased dietary consumption of fiber.¹⁴⁵ Both U.S. and Canadian IBS guidelines state that an increase in dietary fiber (e.g., wheat bran up to 20 g daily) is a reasonable first-line treatment for CP-IBS.^{137,140} However, large doses of fiber can lead to abdominal gas and bloating, and overall objective long-term evidence of benefit in IBS is lacking.^{146,148}

27. V.H. has gradually increased her dietary fiber over the past 6 weeks. The frequency of her stools has improved slightly, but she often still feels constipated. In addition, new symptoms of abdominal bloating have occurred in the past week. What is a reasonable strategy to treat V.H.'s CP-IBS?

Pharmacotherapy for Constipation-Predominant IBS

In patients with CP-IBS in whom fiber therapy fails, other standard laxatives may be tried for symptomatic relief.¹⁴⁰ Few well-designed trials looking at any laxative for IBS have been published. The Canadian IBS guidelines recommend occasional use of osmotic laxatives such as citrate of magnesia or lactulose. These agents are usually well tolerated, although they can occasionally cause abdominal bloating. Other adverse effects of the osmotic laxatives include diarrhea, taste disturbances, and hypermagnesemia (especially in patients with renal impairment). Some experts believe that newer laxatives containing propylene glycol may be better tolerated, but no data in IBS patients exist to support this.¹²⁷ Although laxatives may provide relief of constipation, they will not effectively treat abdominal pain. Thus, other treatments will be required in many patients.

28. Several months have passed since V.H. was first diagnosed with CP-IBS. She has had therapeutic trials of several agents that were either poorly tolerated (poor palatability of propylene glycol) or lacked effectiveness. What other options are available for treating V.H.'s CP-IBS?

Tegaserod

Stimulation of the 5-HT₄ receptor accelerates colonic transit and has been exploited as a target for pharmacotherapy of CP-IBS. The first of these agents, tegaserod, was approved in the United States for women with CP-IBS. Tegaserod is a specific 5-HT₄ partial agonist that has been evaluated in several 12-week trials. These studies evaluated tegaserod 6 mg PO BID versus placebo in women with at least a 3-month history of CP-IBS symptoms.^{148,149} The primary outcome measures were patient-assessed global improvement of IBS symptoms and specific improvement in abdominal pain and bloating. The studies demonstrated a modest but significant benefit with tegaserod. Unfortunately post-marketing analysis by the FDA found an increase incidence of heart attack, stroke, and unstable angina in patients receiving the drug and in April 2008, the

manufacturer of tegaserod halted all sales and marketing of this agent.¹⁵⁰

29. L.K. is a 38-year-old woman who has a long history of abdominal pain and episodic diarrhea. L.K. works as a sales representative for a major software vendor and is called on periodically to make formal presentations. She finds that just before these presentations she develops “attacks” of abdominal pain and

diarrhea. Her past medical history is significant for fibromyalgia, which manifests as chronic tiredness and fatigue. She has no other medical problems and takes no medications. She does not drink, smoke, or use illicit drugs. She has undergone an extensive workup, including colonoscopy, upper GI endoscopy with small bowel follow-through, CT abdominal scans, serum electrolytes, thyroid function tests, and stool studies. These procedures and tests were negative, and L.K.’s gastroenterologist has diagnosed

her with IBS. L.K. currently has one to two loose stools daily. They are not greasy appearing or foul smelling. She has bouts of abdominal pain (severity of 7 on a 1–10 scale) with or without diarrhea several times daily. She describes the pain as “stabbing” and “cramping.” She has not noted any temporal relationship to meals or that certain foods exacerbate her condition. What pharmacologic options are available for L.K.’s abdominal pain? What adverse effects are associated with these medications?

Pain-Predominant IBS

Antispasmodics

Drugs that possess smooth muscle relaxation properties, usually by anticholinergic pathways, have long been used to treat IBS. In the United States, the two most commonly prescribed antispasmodics are hyoscyamine and dicyclomine, both of which possess significant anticholinergic properties.¹²⁴ Clinical trials that have examined the use of these agents in IBS have been plagued by small numbers and methodologic problems, and recently several meta-analyses have been conducted to provide insight in this area. The most recently published of these analyses had results in agreement with older studies, namely, that smooth muscle relaxants were superior to placebo in improving abdominal pain, although they were less effective at treating other IBS symptoms.¹⁵¹ Most of the trials reviewed did not use antispasmodic agents available in the United States. Both U.S. and Canadian guidelines list antispasmodics as options for PP-IBS. If prescribed, an “as needed” strategy of use is preferred to continuous dosing due to anticholinergic adverse effects.¹³⁵

Antidepressants

The previous meta-analysis and the guidelines recommend the use of tricyclic antidepressants for patients with severe or continuous abdominal pain. The analgesic effects of these agents are well known, and it is believed that these agents may work by a similar mechanism in PP-IBS.¹⁵² One separate study examined the use of amitriptyline (in doses up to 75 mg daily) for patients with IBS.¹⁵³ It found that active treatment did improve feelings of well-being and abdominal pain, but had a large dropout rate due to adverse effects. Low doses of tricyclic antidepressants (e.g., amitriptyline 10–25 mg at bedtime) are often effective in relieving abdominal pain and diarrhea. A 3-month trial at a target dose of drug (e.g., amitriptyline 50 mg) should be attempted before therapeutic failure is confirmed.¹⁵⁵ Secondary amine tricyclic antidepressants (nortriptyline, desipramine) are better tolerated by many patients than tertiary amines (amitriptyline, imipramine) due to decreased anticholinergic adverse effects such as sedation, dry mouth and eyes, urinary retention, and weight gain. The evidence supporting the use of other antidepressants is limited; however, a small controlled study with fluoxetine in CP-IBS (with pain) did show some benefit.¹⁵⁴

30. Two weeks after L.K. starts nortriptyline 25 mg Q HS, she reports significant relief from both her abdominal pain and fatigue. She reports that she is sleeping better, and she now rates her pain as a 2 on a 1-to-10 scale. Her diarrhea has improved somewhat; however, she still suffers from a “diarrhea attack” before each presentation. What other treatments are available for DP-IBS? What are the risks and benefits of these treatments?

Diarrhea-Predominant IBS

Standard Antidiarrheals

Small bowel and colonic transit is accelerated in patients with DP-IBS; thus, drugs that slow this process should be effective in relieving diarrhea.¹³⁵ Loperamide, an opioid agonist that penetrates poorly into the central nervous system, is the preferred agent for DP-IBS.¹²⁴ Meta-analyses have found loperamide to be an effective agent for improving diarrhea and, in some cases, improving patients’ global well-being.^{147,155} As with the antispasmodics, “as-needed” treatment is preferred to scheduled dosing (e.g., 2–4 mg PO up to four times daily as needed). Prophylactic dosing before a stressful situation or an event during which bathroom access is limited is particularly effective. Diphenoxylate with atropine is generally considered a second-line agent due to its increased risk of anticholinergic adverse effects. Finally, cholestyramine is occasionally used in refractory cases of DP-IBS, especially when bile acid malabsorption is suspected.¹⁵⁶ This agent is often poorly tolerated due to palatability problems. Cholestyramine also has a significant number of drug interactions of which the clinician must be aware.

Alosetron

Alosetron is a highly potent 5-HT₃ receptor antagonist that slows colonic transit time, increases intraluminal sodium absorption, and decreases small intestinal secretions.¹⁵⁷ Constipation is the most frequently reported adverse effect in clinical studies (approximately 30% of alosetron patients), with approximately 10% of patients withdrawing from studies for this reason.¹⁵⁷ Postmarketing reports of severe constipation with cases of bowel obstructions and ischemic colitis were reported.¹⁵⁸ Bowel perforation and, rarely, death were also reported with alosetron use, and the drug was voluntarily withdrawn from the market in November 2000. Following extensive lobbying by several patient groups, alosetron was reintroduced to the U.S. market in June 2002, with restricted conditions for use. Prescribers must be registered with the drug manufacturer, and patients must sign a patient–physician agreement and be provided with a written medication guide. The new starting dose and regimen for alosetron is 1 mg PO daily for 1 month. If, after 4 weeks, this is well tolerated but does not adequately control IBS symptoms, then the dosage can be increased to 1 mg BID.¹⁵⁹ It is imperative that patients not start alosetron if they have a history of problems with constipation, bowel obstruction or ischemic colitis, IBD, or a thromboembolic disorder. Patients must immediately discontinue alosetron if they become constipated or have symptoms of ischemic colitis, such as new or worsening abdominal pain, bloody diarrhea, or blood in the stool. A recent review of the mandatory postmarketing surveillance system designed to monitor the safety of the drug found an overall low rate of ischemic colitis.¹⁶⁰

Emerging Therapies

Currently, numerous agents are being investigated for all types of IBS.¹⁶¹ Several serotonergic agonists and antagonists, including cilansetron and renzapride, have shown some efficacy in small trials and are undergoing further examination. Alvimopan, a peripheral μ -opioid antagonist designed for opioid-induced constipation may have utility in CP-IBS;

however, formal studies are needed to delineate its role. The possible association of bacterial GI infection and IBS have prompted some investigators to postulate that small bowel flora overgrowth may be responsible for the symptoms of IBS.¹⁶² The nonabsorbable antibiotic rifaximin (indicated for treatment of traveler's diarrhea) was shown in a small study to improve global symptoms in IBS for up to 10 weeks, so further study of this modality is warranted.¹⁶³ Probiotic agents such as *Lactobacillus plantarum* and *Bifidobacterium infantis*, which

may alter colonic inflammation, have shown some efficacy in a small study.¹⁶⁴ Most recently lubiprostone, a gastrointestinal chloride channel activator that enhances intestinal fluid secretion and acts as a laxative, was approved in the United States for CP-IBS in women over age 18. Published data to date suggest that 8 mcg orally twice daily is effective in improving constipation and abdominal pain in CP-IBS, but nausea and diarrhea are limiting adverse effects.¹⁶² Lubiprostone's role in CP-IBS is yet to be fully defined.

OVERVIEW

According to the National Vital Statistics Report published by the Center for Disease Control and Prevention, chronic liver disease and cirrhosis is the 12th leading cause of death in the United States accounting for approximately 26,000 deaths each year.¹ Cirrhosis, or end-stage liver disease, can be defined as fibrosis of the hepatic parenchyma resulting in nodule formation and altered hepatic function, which results from a sustained wound healing response to chronic or acute liver injury from a variety of causes. Although there are other common causes of cirrhosis, most cases of cirrhosis worldwide result from chronic viral hepatitis, or liver injury associated with chronic alcohol consumption.² This chapter describes the pathogenesis of cirrhosis and the associated complications of portal hypertension (esophageal varices, gastric varices, ascites, spontaneous bacterial peritonitis, hepatic encephalopathy, and hepatorenal syndrome), the clinical symptoms of these complications, and the pharmacologic approach to their treatment.

PATHOGENESIS OF CIRRHOSIS

The liver consists of the hepatic parenchyma (hepatocytes) and a large proportion of nonparenchymal cells, including sinusoidal endothelial cells, Ito cells, and macrophages also known as Kupffer cells. Most of the liver's role in detoxification (phase I and II metabolism) takes place within the hepatocytes, whereas the nonparenchymal cell population provides physical and biochemical structure to the liver as well as active transport of substances into the bile.³ Although the liver has a strong capacity to regenerate, this ability can be impaired by toxic or viral agents, such as ethanol and hepatitis viruses.⁴

Stress on the liver, such as chronic ethanol abuse in humans, leads to liver injury and over time cirrhosis and a disruption of hepatic function. Fatty liver or steatosis from ethanol, the first stage of liver injury, is characterized by lipid deposition in the hepatocytes. Steatosis is followed by liver inflammation (steatohepatitis), hepatocyte death, and collagen deposition leading to fibrosis. The specific mechanisms by which chronic ethanol-induced liver injury is initiated and progresses

are not completely understood.⁵ Research into the causes of alcohol-related liver injury has primarily focused on the role of ethanol-induced oxidative stress on the liver. Multiple pathways leading to oxidative stress have been described, and many systems likely contribute to the ability of ethanol to induce a state of oxidative stress. It is important to note that not all heavy drinkers develop liver cirrhosis.⁶ Factors such as gender, genetic predisposition, and chronic viral infection play a role in the development and progression of ethanol-induced liver disease.⁷

Hepatitis C virus (HCV) affects millions of people worldwide, with approximately 20% of infections progressing to cirrhosis.⁸ The progression of liver disease in patients with HCV is dependent on both patient and viral factors. Although the mechanisms by which HCV causes liver damage are not well known, a few proposed mechanisms for liver injury associated with HCV infection include diminished immune clearance of HCV, oxidative stress, hepatic steatosis, increased iron stores, and increased rate of hepatocyte apoptosis.⁹ Because only a small percentage of patients infected with HCV develop cirrhosis, factors other than viral clearance, such as the individual's immune response to the virus, age at the time of infection, gender, hepatic iron content, and HCV genotype are all implicated as cofactors in the development of cirrhosis.¹⁰

Among other causes, autoimmune hepatitis, primary biliary cirrhosis, primary sclerosing cholangitis, biliary atresia, metabolic disorders (e.g., Wilson's disease and hemochromatosis), chronic inflammatory conditions (e.g., sarcoidosis), and vascular derangements can lead to hepatic fibrosis and cirrhosis.² Although not common, end-stage liver disease can also stem from problems related to obesity. An estimated 20% of Americans have nonalcoholic fatty liver disease (NAFLD), a condition that in most cases has no symptoms, but is occasionally characterized by symptoms of upper abdominal discomfort and right upper quadrant fullness. The most common physical examination findings are obesity and occasionally hepatomegaly, with biopsy results showing macrovesicular steatosis or fatty liver. Risk factors commonly associated with the development of NAFLD include obesity, hyperlipidemia, and diabetes. Although corticosteroids cause fatty liver, NAFLD diagnosis excludes corticosteroids and other causes of fatty liver such as hepatitis B, hepatitis C, autoimmune hepatitis, and Wilson's disease. Nonalcoholic steatohepatitis (NASH) is a more serious form of NAFLD. Most patients generally tolerate NAFLD well, whereas NASH can lead to cirrhosis. Current evidence suggests that insulin resistance and lipid peroxidation play a role in the pathogenesis of this condition.^{11,12} Regardless of the cause of end-stage liver disease, the most frequent complications of portal hypertension are esophageal or gastric varices, ascites with or without spontaneous bacterial peritonitis, hepatic encephalopathy, and hepatorenal syndrome.¹³

COMPLICATIONS OF CIRRHOSIS

Portal Hypertension

The portal vein begins as a confluence of the splenic, superior mesenteric, inferior mesenteric, and gastric veins, and ends in the sinusoids of the liver (Fig. 28-1). Blood in the portal vein contains substances absorbed from the intestine, and delivers these substances to the liver to be metabolized before entering

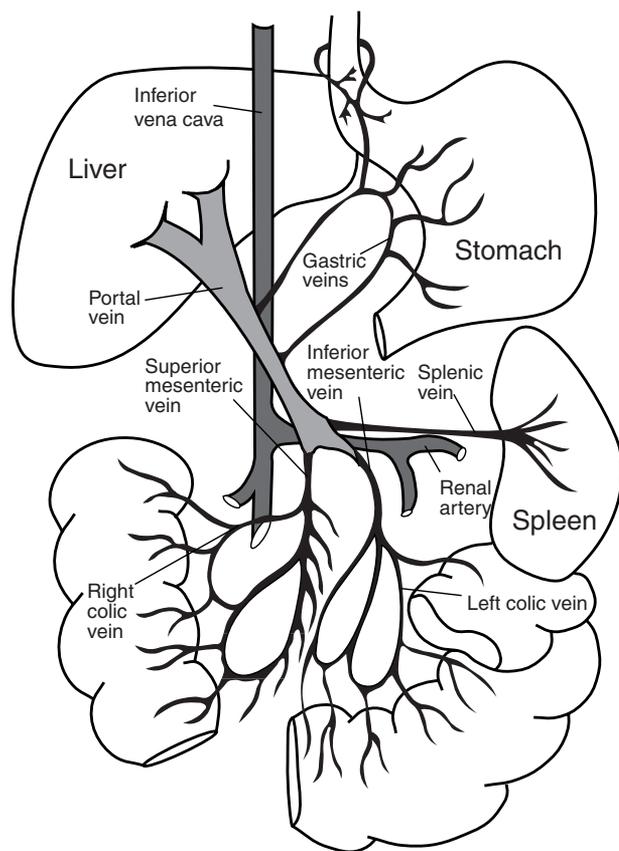

FIGURE 28-1 Schematic diagram of portal venous system.

the systemic circulation.^{14,15} Once the portal blood reaches the liver, it crosses through a high-resistance capillary system within the hepatic sinusoids.

Portal pressure is a function of flow and resistance to that flow across the hepatic vasculature, and described mathematically by Ohm's law (Pressure = Flow × Resistance).¹⁶ In cirrhosis, increased intrahepatic resistance results from intrahepatic vasoconstriction that is hypothesized to be caused by a deficiency in intrahepatic nitric oxide (NO). Increased intrahepatic resistance also results from an enhanced activity of vasoconstrictors, and by structural changes within the liver owing to liver regeneration, sinusoidal compression, and fibrosis. Portal hypertension results from both an increase in resistance to portal flow and also an increase in portal venous inflow, which is hypothesized to be caused by splanchnic vasodilation that, in turn, is secondary to increase NO production in the extrahepatic circulation leading to vasodilation and increased in-flow.¹⁷

Portal pressure can be assessed by the use of surgical procedures which are invasive and not routinely performed. The hepatic venous pressure gradient (HVPG), which reflects the gradient between the portal vein and vena cava pressure, is another accurate, safe, and less invasive procedure that has been widely accepted as a measurement of the portal venous pressure gradient.^{18–20} Normal portal pressure is generally below 6 mmHg, and in cirrhotic patients may increase to 7 to 9 mmHg. Clinically significant portal hypertension develops, however, when the portal pressure increases above 10 to 12 mmHg, the threshold for complications of portal hypertension, such as

Table 28-1 Classification and Etiologies of Portal Hypertension

| Classification | Prehepatic | Intrahepatic | Posthepatic |
|----------------|-------------------------|---|---|
| Etiologies | Splenic vein thrombosis | Hepatic cirrhosis | Hepatic vein obstruction (Budd-Chiari syndrome) |
| | Portal vein thrombosis | Hepatic fibrosis Nodular regeneration (with distortion of hepatic veins) | Inferior vena cava obstruction Right-sided heart failure |

esophageal varices and ascites.^{19,21} Portal hypertension can be further classified as prehepatic, intrahepatic, or posthepatic portal hypertension (Table 28-1).^{22–24} Persistent portal hypertension may (a) change both blood flow as well as the lymphatic circulation and lead to ascites formation; (b) increase pressure in the vessels that branch off the portal vein, such as the coronary veins, leading to the formation of esophageal varices; and (c) lead to the development of increased abdominal collateral circulation. Hepatic encephalopathy and hepatorenal syndrome are other complications associated with advanced cirrhosis and portal hypertension.^{22–24}

Laboratory Findings

Laboratory evaluations may not reflect the extent of the parenchymal necrosis, cellular regeneration, and fibrotic nodular scarring in cirrhotic liver disease. Conventional liver “function” tests, such as the serum aminotransferases (aspartate aminotransferases [AST, formerly known as SGOT], alanine aminotransferases [ALT, formerly known as SGPT]), and alkaline phosphatase, are actually better characterized as liver “injury” tests and are modestly helpful to the clinician for screening hepatobiliary disease and following liver injury progression. These tests, however, do not quantitatively measure the functional capacity of the liver. The aminotransferases are released during the normal turnover of liver cells (see Chapter 2, Interpretation of Clinical Laboratory Tests). High serum concentrations of aminotransferases suggest release of these enzymes from injured hepatocytes. The serum concentrations of AST and ALT may initially rise very high with acute liver injury and then fall when the cause for liver injury is removed or when necrosis is so severe, that few hepatocytes remain.

Because alkaline phosphatase is present in high concentrations in biliary canaliculi (as well as bone, intestines, kidneys, and white blood cells [WBC]), an increase in the serum concentration of alkaline phosphatase is greater with biliary injury rather than during a parenchymal injury. High serum concen-

trations of gamma glutamyl transpeptidase and bilirubin are also suggestive of biliary injury. Increases in alkaline phosphatase, and AST, ALT, or both serum concentrations may suggest hepatic injury, but because they are also found intracellularly in other places in the body, their elevation is not diagnostic for liver disease.^{25,26}

Serum concentrations of proteins such as albumin, or factor V and VIII, as well as coagulation tests such as the prothrombin time (PT) and international normalized ratio (INR), can provide insight into the functional capacity of the liver. The hepatic parenchymal cells exclusively synthesize albumin, therefore albumin concentrations can provide some indication of hepatocellular function. Changes in albumin concentration are nonspecific, however, and can be influenced by other factors, including poor nutrition, renal wasting (proteinuria), and gastrointestinal (GI) losses. Prolongation of PT owing to vitamin K deficiency often caused by cholestasis, usually improves within 24 hours after a 10-mg subcutaneous or oral dose of vitamin K. A prolonged PT owing to poor hepatic synthetic function is not responsive, however, to the administration of vitamin K. If the INR requires rapid correction because of bleeding or a planned invasive procedure, fresh frozen plasma should be transfused.²⁷

A number of the factors described above have been incorporated into the Child-Turcotte-Pugh classification of liver disease severity (Table 28-2).^{22–24,28,29} This classification yields a scoring system to help clinicians grade disease severity, and predict the long-term risk of mortality and quality of life. A person with Child-Turcotte-Pugh class A cirrhosis may survive as long as 15 to 20 years, whereas those with class C cirrhosis may survive only 1 to 3 years.³⁰ The main limitation of the Child-Turcotte-Pugh classification is the use of subjective measures, such as ascites and hepatic encephalopathy, which are subject to clinical interpretation and may be altered by therapy.^{31,32}

An alternative method for assessing short-term survival in patients with liver disease is the Model for End-Stage Liver

Table 28-2 Child-Turcotte-Pugh Classification of Severity of Liver Disease^a

| Score | 1 Point | 2 Points | 3 Points |
|-------------------------------------|---------|--------------------------|------------------------------|
| Bilirubin (mg/dL) | <2 | 2–3 | >3 |
| Albumin (mg/dL) | >3.5 | 3–3.5 | <3 |
| Prothrombin time (sec) ^b | <4 | 4–6 | >6 |
| Ascites | None | Easily controlled (mild) | Poorly controlled (moderate) |
| Encephalopathy (grade) | None | Mild (1 and 2) | Advanced (3 and 4) |

^aClass A, <7 points; class B, 7–9 points; class C, 10–15 points.

^bSeconds prolonged.

Disease (MELD) score that utilizes laboratory values, and is used to predict short-term (3 month) mortality associated with liver disease. The MELD score is calculated by the formula³²:

$$\text{MELD score} = (0.957 \times \ln[\text{creatinine mg/dL}] + 0.378 \times \ln[\text{total bilirubin mg/dL}] + 1.120 \times \ln[\text{INR}] + 0.643) \times 10$$

Because of the good correlation between the MELD score and short-term mortality as well as the objective nature of the MELD scoring system, it has replaced the Child-Turcotte-Pugh score in the United Network for Organ Sharing (UNOS) prioritization of organ allocation of cadaveric livers for transplantation.^{33–35} MELD scores range from 6 (less ill) to 40 (gravely ill).³⁶ A high MELD score is strongly associated with early pretransplantation wait-list mortality. Therefore a patient with a higher MELD score is given priority by UNOS in terms of organ allocation.

1. R.W. is a 54-year-old man with a 2-week history of nausea, vomiting, and lower abdominal cramps without diarrhea. Despite chronic anorexia, he has managed to drink a fifth of vodka (750 mL) and eat about two meals a day for the past 2 years. During this time, he experienced a 30-lb weight loss. He began drinking 9 years ago when his wife became disabled following diagnosis of a brain tumor. Two years ago, his alcohol consumption increased from one pint to a fifth daily. Recently, he has noted bilateral edema of his legs, an increased tenseness and girth of his abdomen, jaundice and scleral icterus. His medical history is noncontributory, other than a history of spontaneous bacterial peritonitis (SBP).

Physical examination reveals an afebrile, jaundiced, and cachectic male in moderate distress. Spider angiomas were found on his face and upper chest. In addition, palmar erythema was noted. Abdominal examination reveals prominent veins on a very tense abdomen. The liver edge is percussed below the right costal margin and ascites is noted by shifting dullness and a fluid wave. The spleen is not palpable. On neurologic examination, R.W. is awake and oriented to person, place, and time. Cranial nerves II to XII are grossly intact, but a decrease in vibratory sensation of the lower extremities is noted bilaterally. Admission laboratory data are as follows: sodium 135 mEq/L; chloride 95 mEq/L; potassium 3.8 mEq/L; bicarbonate 25 mEq/L; blood urea nitrogen (BUN) 15 mg/dL; serum creatinine (SrCr) 1.4 mg/dL; glucose 136 mg/dL; hemoglobin 11.2 g/dL; hematocrits (Hct) 33.4%; AST 212 IU (normal, 0–35 IU); alkaline phosphatase 954 IU (normal, 30–120 IU); PT 13.5 seconds with a control of 12 seconds (INR 1.1); total/direct bilirubin 18.8/10.7 mg/dL (normal, 1.0/<0.5 mg/dL); albumin 2.3 g/dL (normal, 3.5–4.0); and guaiac positive stools. On admission to the hospital, the impression is alcoholic cirrhosis, ascites, and heme-positive stools.

What subjective and objective evidence are compatible with alcoholic cirrhosis in R.W.?

Clinical Presentation

R.W.'s liver function tests (elevated AST, alkaline phosphatase, and bilirubin) and physical findings (an enlarged, palpable liver edge; jaundice; spider angiomas on his face and upper chest; palmar erythema; and cachexia) are all consistent with advanced alcoholic cirrhosis in a patient with a history of chronic alcohol abuse. The prolonged PT and hypoalbuminemia suggest impaired hepatic synthesis of both albumin and vitamin

K-dependent clotting factors. The low albumin contributes to both the ascites and edema. The bilirubin of 18.8 mg/dL suggests that vitamin K absorption may be a factor in the prolonged PT. The presence of ascites (an enlarged fluid-filled abdomen) and prominent abdominal veins are suggestive of portal hypertension. A biopsy of the liver may confirm or establish the presence and severity of cirrhosis. R.W.'s prolonged PT, however, will increase the risk of bleeding from a liver biopsy. R.W.'s positive guaiac finding could be indicative of bleeding esophageal varices but could also be explained by bleeding from another GI source. This needs to be confirmed by endoscopy. He is oriented to person, place and time, but needs to be fully tested for hepatic encephalopathy. R.W.'s MELD score is 22 which predicts a 90-day mortality of approximately 20%.³³ A patient's MELD score may increase or decrease over a period of time depending on the patient's clinical status and treatment. A number of MELD scores will be calculated over the course of R.W.'s treatment if the patient is listed as a transplantation candidate to determine his status for organ allocation.³⁶ Muscle wasting and poor nutrition are the most common causes of weight loss in patients with alcoholic cirrhosis (see Chapter 84, Alcohol Use Disorders).

ASCITES

Pathogenesis of Ascites

2. What physiologic mechanism predisposes R.W. to fluid accumulation in the peritoneal cavity?

Ascites, or accumulation of fluid in the peritoneal cavity, is the most commonly encountered clinical symptom of cirrhosis.³⁷ This complication can be detected during the physical examination when >3 L of fluid has accumulated. In addition to an obviously enlarged abdomen, R.W. was found to have a positive fluid wave and shifting dullness, indicating that the abdominal enlargement is not simply obesity. The fluid wave can be observed by having the patient lie on his or her back. While supporting one side of the abdomen with one hand, use the second hand to tap the opposite side of the abdomen. A wave of fluid moving across the abdomen can be felt by the hand on the opposite side. If the diagnosis is in doubt, ascites is confirmed with ultrasound. Once ascites develops, the 1-year survival rate decreases to about 50%.³⁷

In cirrhosis, hepatic venous outflow is restricted, resulting in an increase in the portal vein back-pressure. High hepatic venous pressure leads to high intrasinusoidal pressure and development of ascites across the hepatic capsule. Portal hypertension from cirrhosis is associated with splanchnic dilatation and increased splanchnic blood flow. This increase in splanchnic blood flow is associated with an upregulation of endothelial nitric oxide synthase (eNOS) and increased production of a potent vasodilator, NO. This increase in NO has been proposed as a major mediator of the arterial dilatation and hyperdynamic circulation in cirrhosis.³⁸ NO leads to an overall vasodilated state. The systemic compensation to this vasodilation is an increase in cardiac output and sodium and water retention in the kidneys as a result of activation of the renin-angiotensin aldosterone system (RAAS).³⁹ The activation of RAAS, in addition to R.W.'s hypoalbuminemia (2.3 g/dL) leads to worsening of

the ascites. Exudation of fluid from the splanchnic capillary bed and the liver surface when the drainage capacity of the lymphatic system is exceeded, and decreased ability of fluid to be contained within the vascular space owing to impaired hepatic albumin synthesis, contributes to the development of ascites.

Goals of Therapy

3. What are the therapeutic goals in the treatment of R.W.'s ascites?

The goals of treatment for R.W.'s ascites are to mobilize ascitic fluid; to diminish abdominal discomfort, back pain, and difficulty in ambulation; as well as to prevent complications (e.g., bacterial peritonitis, hernias, pleural effusions, hepatorenal syndrome, and respiratory distress). The goal is a weight loss of 0.5 to 1 kg/day, which corresponds to a net fluid volume loss of about 0.5 to 1 L/day. Treatment of ascites in R.W. should be undertaken cautiously and gradually because acid-base imbalances, hypokalemia, or intravascular volume depletion caused by overly aggressive therapy can lead to compromised renal function, hepatic encephalopathy, and death.^{40–42} The initial medical management of ascites involves restriction of sodium intake and the use of diuretics to promote salt and water excretion.^{40,42}

Fluid and Electrolyte Balance

4. The 24-hour urinary electrolytes for R.W. were Na, 10 mEq/L and K, 28 mEq/L. Why would sodium or water restriction be appropriate (or inappropriate) for R.W.?

Urinary Na:K Ratio

Normally, the urine concentration of electrolytes mirrors the serum concentration of electrolytes (i.e., sodium concentration is greater than that of potassium). A reversal of this pattern (i.e., potassium excretion exceeding sodium excretion) may indicate a relative hyperaldosteronism secondary to diminished renal blood flow and low oncotic pressure. A study by Trevisani et al.⁴³ evaluated renal sodium and potassium handling, and plasma aldosterone in a 24-hour period in cirrhotic patients without ascites ($n = 7$), with ascites ($n = 8$), and healthy controls ($n = 7$). Plasma aldosterone was significantly higher in patients with ascites, resulting in reduced renal sodium excretion, and more than doubling of renal potassium excretion in comparison to healthy controls.⁴³ For urine electrolyte monitoring to be meaningful, the first sample must be obtained before initiating diuretic therapy.^{44,45}

Sodium Restriction

Although serum sodium in patients with ascites is often low, they are total body sodium overloaded. Sodium restriction has been shown to enhance mobilization of ascites, because fluid loss and weight change are directly related to sodium balance in patients with portal-hypertension-related ascites.⁴⁶ This finding has been incorporated into the American Association for the Study of Liver Diseases (AASLD) guidelines for the treatment of ascites. The AASLD recommends that dietary sodium should be restricted to $\leq 2,000$ mg/day [88 mmol/day].⁴² Although bedrest has been advocated in the past, no controlled

trials support this practice. R.W. should benefit from sodium restriction of ≤ 2 g/day.

Water Restriction

A large prospective, observational study ($n = 997$) by Angeli et al.⁴⁷ evaluated the prevalence of low serum sodium concentration and the association between serum sodium levels with severity of ascites and complications of cirrhosis. The results indicated that low serum sodium levels are a common feature in patients with cirrhosis, and that serum sodium concentrations < 135 mEq/L are associated with a poor control of ascites as well as a greater frequency of hepatic encephalopathy, hepatorenal syndrome, and spontaneous bacterial peritonitis compared with patients with serum sodium concentrations within the normal range (135–145 mEq/L).⁴⁷ In addition, very low serum sodium concentrations (< 120 mEq/L) are independent predictors of 3- to 6-month mortality from the MELD score in patients with end-stage liver disease. The AASLD recommends that water restriction should be implemented in cirrhotic patients who have severe dilutional hyponatremia (serum Na < 120 –125 mEq/L).⁴² For R.W., water restriction is not indicated at this time because his serum sodium concentration is within normal limits (135 mEq/L).

Diuretic Therapy

Choice of Agent

5. R.W. was prescribed sodium restriction after initial evaluation. Spironolactone 100 mg/day and furosemide 40 mg/day were ordered to induce diuresis. Why is spironolactone preferred over other diuretics in the treatment of ascites?

Most patients with advanced liver disease have high circulating levels of aldosterone.⁴⁸ High serum concentrations of aldosterone may be attributed to both increased production and decreased excretion of the hormone. Increased portal pressure, ascites, depletion of intravascular volume, and decreased renal perfusion can lead to activation of the RAAS.⁴⁹ In addition, hepatic shunting also increases aldosterone production by decreasing renal blood flow.⁵⁰ The liver metabolizes aldosterone, and hepatic impairment prolongs the physiologic half-life of aldosterone.⁵¹ The AASLD consensus guidelines recommend the use of spironolactone as the initial diuretic of choice in the treatment of ascites.⁴² Although no large comparative studies have evaluated different diuretics as first-line treatment of ascites, spironolactone is a rational diuretic choice for R.W. based on its aldosterone antagonist activity. Perez-Ayuso et al.⁵² conducted a small randomized trial to study the efficacy of furosemide versus spironolactone in nonazotemic cirrhotic patients ($n = 40$) with ascites. They found that spironolactone was more effective than furosemide, and that the activity of the renin-aldosterone system influences the diuretic response to furosemide and spironolactone in patients with cirrhosis. In the study, patients were treated with furosemide (initial doses of 80 mg/day, maximal dose of 160 mg/day) or spironolactone (initial dose 150 mg/day, maximal dose of 300 mg/day). Patients not responding to furosemide or spironolactone were later converted to the alternate therapy. The results showed a higher response to spironolactone than furosemide (18/19 vs. 11/21; $p < 0.01$). Of the 10 non-responders to furosemide, 9 responded to spironolactone when therapy was

switched. The authors also found that patients with higher renin and aldosterone levels did not respond to furosemide and required higher doses of spironolactone to achieve a diuretic response.⁵²

Some clinicians may initiate spironolactone at a dose of 25 mg once or BID; however, much larger doses (100–400 mg/day) are generally necessary to antagonize the high circulating levels of aldosterone present in patients with ascites.⁴² The diuretic effect is enhanced when spironolactone is combined with sodium restriction (0.5–2 g/day).⁴¹ In addition, furosemide can be started to minimize the risk of hyperkalemia and enhance diuresis. The AASLD guidelines recommend starting spironolactone 100 mg and furosemide 40 mg simultaneously and maintaining a 100:40 mg ratio. The doses of both oral diuretics can be increased simultaneously every 3 to 5 days (maintaining the ratio) to achieve adequate response. Usual maximal doses are 400 mg/day of spironolactone and 160 mg/day of furosemide.⁴² In controlled clinical trials, sodium restriction and diuretic therapy are effective in 90% of patients without renal failure.^{53–55}

Triamterene and amiloride can be used as alternatives to spironolactone if intolerable side effects (e.g., gynecomastia) occur with spironolactone.^{42,57} In a small trial conducted by Angeli et al.,⁵⁸ cirrhotic patients were randomized to receive amiloride (n = 20) or potassium canrenoate (an active metabolite of spironolactone not available in the United States; n = 20), to study the efficacy of each drug in nonazotemic cirrhotic patients with ascites. The initial doses of amiloride and potassium canrenoate were 20 and 150 mg, respectively, and were increased (up to 60 and 500 mg/day) if no response occurred. Nonresponders to the highest doses of each drug were later converted to the alternate agent. A higher response rate was seen in the canrenoate group versus the amiloride group (14/20 vs. 7/20; $p < 0.025$). The authors also assessed plasma aldosterone activity and found that all responders to amiloride had normal plasma aldosterone concentrations, and all nonresponders to amiloride who later responded to potassium canrenoate had increased levels of plasma aldosterone.⁵⁸

Eplerenone (a selective aldosterone blocker, more specific for the aldosterone receptor with a lower affinity for progesterone and androgen receptors than spironolactone) has been studied in patients with heart failure, hypertension, and renal disease.^{59,60} The usual dose for eplerenone is 25 to 50 mg/day.⁶¹ No dosage adjustment is needed with mild to moderate liver disease, but severe liver disease has not been studied.⁶² Approximately 10% of patients treated with spironolactone develop gynecomastia or breast pain, with 2% requiring drug discontinuation.⁶³ In contrast, gynecomastia occurs at a similar rate with eplerenone as with placebo (0.5%).^{64,65} Eplerenone is also much more expensive than spironolactone.⁶⁵ The lower risk of gynecomastia with eplerenone may make it a useful alternative to spironolactone. However, given its higher cost and the lack of data in the treatment of ascites and patients with severe liver disease, its eventual role in ascites treatment remains unclear.

R.W. should receive spironolactone 100 mg and furosemide 40 mg simultaneously (and maintaining a 100:40 mg ratio) as recommended by the AASLD.⁴² This approach to therapy may be taken, as long as the patient is carefully monitored for diuretic complications and a clinical response to diuresis (see Questions 6, 7, and 8).

Monitoring CLINICAL RESPONSES

6. What clinical responses should be monitored to ensure the therapeutic effectiveness of spironolactone therapy for R.W.?

Because ascitic fluid is slow to re-equilibrate with vascular fluid, diuresis >0.5 to 1 kg/day (0.5–1 L) may be associated with volume depletion, hypotension, and compromised renal function.⁴² Patients may tolerate a faster diuresis if peripheral edema is present. Once edema has resolved, a scaled back weight loss, not to exceed 0.5 kg/day, can be used as a rule of thumb to minimize the risk of renal insufficiency induced by plasma volume contraction and other diuretic-induced complications.^{42,66} Monitoring body weight and abdominal girth are routinely performed in both the inpatient and outpatient settings. Monitoring fluid intake and urine output are performed primarily for inpatients, owing to practical constraints in the outpatient setting. Ideally, urine output should exceed fluid intake by about 300 to 1,000 mL/day. These measurements do not account for nonrenal fluid losses; therefore, total fluid loss will be somewhat higher. Abdominal girth measurement (circumference around the abdomen) is subject to error, because of its dependence on patient position and measurement location on the abdomen.⁵⁶ Attempts should be made to standardize patient position (e.g., sitting at a 45-degree angle) and location of measurement (level of umbilicus) to minimize variability in abdominal girth measurements.

LABORATORY PARAMETERS

7. What laboratory parameters could be monitored to assess the therapeutic efficacy of R.W.'s spironolactone treatment?

Serum concentrations of creatinine and urine chemistries (sodium and potassium) can be monitored to define and guide the need for increasing dosage of spironolactone. A low baseline urine Na:K ratio (<1.0) suggests high intrinsic aldosterone activity and that larger dosages of spironolactone may be needed, as is the case for R.W. If necessary, the dosage of adjunctive diuretic therapy may be doubled after a few days.⁴⁹ AASLD recommends increasing both spironolactone and furosemide simultaneously every 3 to 5 days (maintaining a 100:40 mg ratio) to achieve adequate diuresis and maintain a normal serum potassium.⁴²

Diuretic Complications and Management

8. The spironolactone dosage was increased to 200 mg/day and 80 mg/day (maintaining a 100:40 mg ratio). What potential complications from the diuretic therapy might arise in R.W. and how can they be minimized?

ELECTROLYTE AND ACID-BASE DISTURBANCES

Hyponatremia, hyperkalemia, metabolic alkalosis, and uncommonly hypokalemia occur as side effects of diuretic therapy in patients with ascites. Hyponatremia results from a reduction in filtered sodium, an increase in sodium reabsorption and a reduction in free water clearance (dilutional hyponatremia). Diuresis exacerbates hyponatremia by causing volume depletion and antidiuretic hormone (ADH) release. Hyponatremia, if present, usually can be corrected by temporary withdrawal of diuretics and free water restriction.^{53,67–69} Although serum sodium may be low, these patients are total body sodium

overloaded. Hyperkalemia is common in patients with refractory ascites and impaired renal function requiring high doses of diuretics such as spironolactone. Hyperkalemia can be approached in multiple ways, depending on the clinical situation (see Chapter 12, Fluid and Electrolyte Disorders). Furosemide is added to the therapeutic regimen to maintain normal serum potassium. Decreasing or holding spironolactone may be appropriate depending on the patient's renal function and serum potassium.⁴² Metabolic alkalosis, another acid-base disorder found in cirrhotic patients as a result of loop diuretics, occurs because of increased urinary hydrogen loss from enhanced distal hydrogen secretion. Hypokalemia often accompanies metabolic alkalosis owing to loop diuretics.^{42,68} Furosemide can be temporarily withheld in patients presenting with hypokalemia.⁴² R.W. has some degree of renal impairment (SrCr 1.4 mg/dL) and is receiving spironolactone and furosemide. Therefore, his electrolytes and renal function tests should be monitored daily while hospitalized. After hospital discharge, monitoring will be dictated by the stability of the patient and need for diuretic dosage adjustments. For example, outpatients may need electrolytes and renal function monitoring once or twice weekly early after hospital discharge to as infrequently as every 3 months for the very stable patient.

PRERENAL AZOTEMIA

Prerenal azotemia usually results from over diuresis with subsequent compromise of intravascular volume and decreased renal perfusion. In addition to looking for clinical signs of hypovolemia, such as dizziness, orthostatic hypotension, and increased heart rate, frequent measurements of BUN and serum creatinine concentrations provide a relatively simple means of assessing the intravascular volume. A gradual rise in serum creatinine, BUN as well as the BUN:serum creatinine ratio can serve as a warning to slow the rate of diuresis.⁷⁰ In a small study conducted by Pockros et al.,⁶⁶ serial measurements of plasma volume and ascites volume were made during treatment with diuretics in patients with cirrhosis (n = 14). Patients with ascites and no edema were able to mobilize >1 L/day during rapid diuresis, but at the expense of plasma volume contraction and renal insufficiency. Patients with peripheral edema appear to be somewhat protected from these effects and may safely undergo diuresis at a more rapid rate (>2 kg/day) until edema resolves.⁶⁶ Others suggest, however, that the maximal daily fluid loss should not exceed >0.5 L/day (>0.5 kg/day) for patients with ascites alone or >1 L/day (>1 kg/day) for those with both ascites and edema to prevent plasma volume depletion and decreased renal perfusion. If faster removal of ascites is required because of respiratory distress, large-volume paracentesis may be more effective than rapid diuresis (see Question 9).^{42,45,71,72}

Because R.W. presented with both edema and ascites, an initial fluid loss of up to 1 L/day would be reasonable. The rate of weight loss should be slowed not to exceed >0.5 L/day when the edema resolves. Gradual diuresis avoids diuretic-induced depletion of intravascular fluid volume by permitting ascitic fluid to equilibrate with intravascular fluid. Long-term management of ascites is done in the outpatient setting. Severe cases with respiratory distress or impaired ambulation as well as patients with spontaneous bacterial peritonitis require hospitalization. If outpatient therapy is an option, a weekly

evaluation initially would be prudent to prevent over diuresis and electrolyte disturbances.⁵³

Refractory Ascites

9. Over the next several days, R.W.'s spironolactone dosage was increased to 400 mg/day. Furosemide was simultaneously increased to 80 mg twice daily (BID) without major improvement in his diuresis. Laboratory data revealed that R.W.'s SrCr had increased to 3.2 mg/dL (calculated creatinine clearance: 26 mL/minute) and his BUN had increased to 45 mg/dL. Serum electrolytes were as follows: K, 3.1 mEq/L; Na, 130 mEq/L; Cl, 88 mEq/L; and bicarbonate, 32 mEq/L. R.W. became progressively short of breath because of restricted diaphragmatic movement secondary to his significantly enlarged abdomen. What therapeutic measures are appropriate for refractory (diuretic-resistant) ascites?

Because of the increase in SrCr and respiratory distress, R.W.'s ascites treatment needs modification. Patients with cirrhosis experiencing respiratory distress despite diuretic and sodium restriction warrant more aggressive second-line treatment, including large volume paracentesis, shunting procedures, or both.⁴² Paracentesis involves the removal of ascitic fluid from the abdominal cavity with a needle or a catheter. Although paracentesis can remove large amounts of ascitic fluid (e.g., 10 L), removal of as little as 1 L of fluid may provide considerable relief from the painful stretching of skin and the respiratory distress that occurs with massive ascites. The ascitic fluid often reaccumulates rapidly after paracentesis owing to transudation of fluid from the interstitial and plasma compartments into the peritoneal cavity. The major complications of overly aggressive, large-volume paracentesis include hypotension, shock, oliguria, encephalopathy, and renal insufficiency. Other potential complications of paracentesis are hemorrhage, perforation of the abdominal viscera, infection, and protein depletion.⁴²

Albumin

10. R.W. continues to reaccumulate ascitic fluid and is exhibiting signs of declining renal function. A 6-L paracentesis coupled with a 50-g albumin infusion is ordered. Why are albumin infusions used in conjunction with paracentesis?

Large volume (>4 L) paracentesis should be performed for patients with tense ascites resulting in respiratory distress or impaired ambulation. Large volume paracentesis alone is associated, however, with paracentesis-induced circulatory dysfunction (PICD). PICD is characterized by a reduction in systemic vascular resistance and significant increase in plasma renin activity and plasma norepinephrine.⁷³ Following paracentesis, a period of impaired circulatory function occurs, which manifests as worsening renal function 24 to 48 hours after the procedure.⁷⁴ Intravenous (IV) albumin infusions are commonly administered to prevent PICD following large volume paracentesis.⁴²

Although albumin is costly and sometimes in short supply, for some patients, it is an appropriate treatment in conjunction with paracentesis.⁷⁵ Patients treated with large volume paracentesis (≥6 L/day) and IV albumin (40 g after each tap) were compared with patients treated with paracentesis and saline solution. The incidence of PICD was significantly higher in the

saline-treated group versus the albumin-treated group (33.3% vs. 11.4%, respectively). The prevalence of PICD following paracentesis depends on the volume of ascites removed.⁷⁵ For large volume paracentesis ≥ 6 L, 8 to 10 g of albumin is typically administered for each liter of ascites removed.⁴² Post-paracentesis albumin infusion may not be necessary for a single paracentesis of <4 to 5 L.⁴² Use of albumin in combination with large volume paracentesis produces an expansion of circulating blood volume, increases cardiac output, and suppresses release of renin and norepinephrine.⁷⁴

The effects of albumin administration for a variety of indications on patient mortality have also been evaluated. Wilkes et al.⁷⁶ conducted a meta-analysis of 55 randomized, controlled trials comparing albumin therapy with crystalloid therapy, no albumin, or lower doses of albumin on patient mortality (27 involved surgery or trauma; 4 involved burns; 5 involved hypoalbuminemia; 6 involved high-risk neonates; 5 involved ascites; and 8 involved other indications). For all trials, the relative risk for death was 1.11 (95% confidence interval [CI], 0.95–1.28). For ascites, in particular, the relative risk for death was 0.93 (95% CI, 0.67–1.28). Overall, albumin did not affect mortality.⁷⁶ In a study by Sort et al.,⁷⁷ patients with SBP ($n = 126$) were randomized to receive IV antibiotics alone ($n = 63$) or IV antibiotics and albumin ($n = 63$). Albumin (1.5 g/kg) was administered at the time of SBP diagnosis, and again on day 3 (1 g/kg). The albumin group had a lower incidence of renal impairment (10% vs. 33%; $p = 0.002$), overall mortality at 3 months (22% vs. 41%; $p = 0.03$) and hospital mortality (10% vs. 29%; $p = 0.01$) than the group that did not receive albumin.⁷⁷

Dextran 70 and Other Plasma Expanders

The use of synthetic plasma expanders in combination with large volume paracentesis has been explored as a therapeutic option for patients with ascites refractory to diuretics and fluid restriction.^{78,79} Gines et al.⁷⁹ studied patients with as-

cites refractory to diuretic therapy. Patients were randomized to paracentesis plus albumin ($n = 97$), dextran 70 ($n = 93$), or polygeline ($n = 99$). More patients treated with dextran 70 (34.4%) or polygeline (37.8%) versus those receiving albumin (18.5%) experienced PICD. In addition, during follow-up, patients who experienced PICD versus those who did not, had a shorter time to first readmission (1.3 vs. 3.5 months; $p = 0.03$) and a shorter survival (9.3 vs. 16.9 months; $p = 0.01$).⁷⁹ Hydroxyethyl starch, an effective colloid agent for intravascular volume expansion, should not be used in patients with chronic liver disease, because repeated administration of this agent to patients with cirrhosis has been reported to accumulate in the hepatocytes, causing severe portal hypertension and acute liver failure.⁸⁰ R.W. should be given 50 g of 25% albumin administered at a rate of 3 mL/minute, for the 6 L of ascitic fluid removed. More rapid administration than 3 mL/minute in hypoproteinemic patients can cause circulatory overload and pulmonary edema. R.W. should be monitored for anaphylactic reactions (rare), hypo- and hypertension, and signs of pulmonary edema.^{81–83}

Alternative Therapy

11. What alternative treatments are available for management of refractory ascites? How would these alternatives be applied in R.W.'s case?

Transjugular Intrahepatic Portosystemic Shunt

Transjugular intrahepatic portosystemic shunt (TIPS) is another option for patients who are refractory to the pharmacologic interventions described above. It is an interventional (nonsurgical) technique for establishing a shunt in patients with portal hypertension (Fig. 28-2).⁸⁴ The TIPS procedure involves opening a conduit between the hepatic vein and intrahepatic segment of the portal vein with an expandable metal stent placed during an angiographic procedure. This

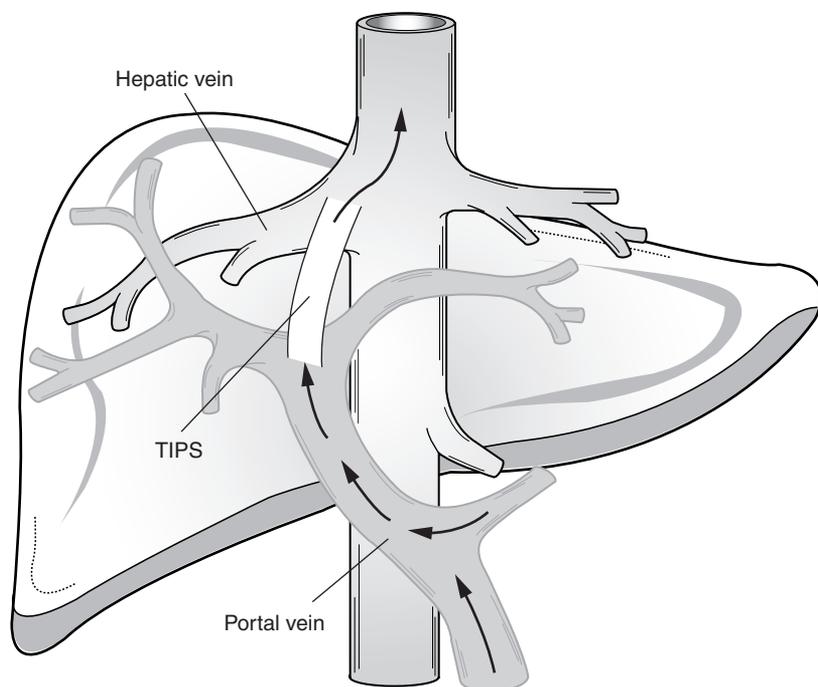

FIGURE 28-2 Transjugular intrahepatic portosystemic shunt (TIPS) decompressing the portal circulation into the systemic circulation. (Reproduced with permission from reference 84.)

low-resistance channel allows blood to return to the systemic circulation and reduces portal pressure. In addition, TIPS may improve urinary sodium excretion. The major complications of TIPS include severe encephalopathy, and shunt occlusion. Hepatic encephalopathy (see Question 19) occurs in approximately 20% of patients following TIPS.⁸⁴ Because of poor prognosis, liver transplantation should be considered for appropriate candidates refractory to pharmacologic treatment and or shunt placement.⁴² Selection of surgical shunt procedures may include evaluation of liver transplantation candidacy as some procedures may complicate the feasibility of a future liver transplantation procedure.

A study by Gines et al.⁸⁵ evaluated TIPS versus large volume paracentesis plus albumin in the control of refractory ascites. Patients with cirrhosis and refractory ascites were randomly assigned to TIPS ($n = 35$) or repeated paracentesis plus IV albumin ($n = 35$). The probability of survival without liver transplantation was 41% at 1 year and 26% at 2 years in the TIPS group, as compared with 35% and 30%, respectively in the paracentesis group not significant (NS). Recurrence of ascites and development of hepatorenal syndrome (49% and 9%, respectively) were lower in the TIPS group compared with the paracentesis group (83% and 31%, respectively; $p = 0.003$ and $p = 0.03$) whereas the frequency of severe hepatic encephalopathy was greater in the TIPS group ($p = 0.03$). The calculated costs of procedures performed per patient in the TIPS group were 103% greater than those in the paracentesis and albumin group.⁸⁵

Treatment guidelines recommend TIPS for the treatment of refractory ascites in patients for whom paracentesis is contraindicated, ineffective as determined by the frequency of repeated paracentesis (more than three times per month), or intolerant of repeated large volume paracentesis.^{42,86}

Peritoneovenous Shunt

A peritoneovenous shunt consists of a surgically implanted valve in the abdominal wall, an intra-abdominal cannula, and an outflow tube tunneled subcutaneously from the valve to a vein that empties directly into the superior vena cava. In this manner, ascitic fluid can be withdrawn from the abdominal cavity and be returned to the vascular space. Multiple contraindications exist to surgical shunts and significant surgical risks that increase with worsening hepatic function.⁸⁷ Gines et al.⁸⁸ compared peritoneovenous shunting (LaVeen Shunt) with paracentesis plus albumin infusions, and found shunting to be more effective in the long-term management of ascites as reflected by a longer period before readmission, a lower number of readmissions for ascites, and lower diuretic requirements. Peritoneovenous shunting did not improve survival over paracentesis, and the probability of shunt occlusion was 52% after 2 years.⁸⁸ In summary, the lack of survival benefit, surgical complications, including fibrous adhesions complicating future liver transplantation, and high risk of shunt occlusion have led to the reserving of peritoneovenous shunt procedures for patients with ascites and fairly well-preserved renal and hepatic function and are not candidates for liver transplantation, in whom more standard therapies fail.⁴²

Clonidine

It has been shown that the activation of the sympathetic nervous system leads to renal hypoperfusion and sodium retention.

The activated sympathetic nervous system stimulates renal α_1 -adrenoreceptors and causes decreases in renal blood flow and glomerular filtration rate. Additionally, norepinephrine increases proximal tubular reabsorption of sodium and enhances renin, aldosterone, and vasopressin secretions.^{89–91} Preliminary evidence has suggested that clonidine may be of benefit in refractory ascites and those with an activated sympathetic nervous system. Lenaerts et al.⁹² conducted a very small study comparing repeated large volume paracentesis with the combination of clonidine–spironolactone in the treatment of patient with refractory ascites. Study patients ($n = 20$) were randomly assigned to receive repeated large volume paracentesis (4–5 L every 48 hours) plus IV albumin (7 g/L of ascites) until ascites disappeared, or a combination of clonidine 0.075 mg BID for 8 days and then clonidine 0.075 mg BID with spironolactone 200 to 400 mg daily for 10 days. Both groups were discharged with spironolactone adjusted according to individual response (maximal dose of 400 mg/day). During the first hospitalization, the mean weight loss in the paracentesis group was higher than in the clonidine group, but the mean hospital stay was shorter in the clonidine group ($p \leq 0.01$). Clonidine decreased sympathetic activity and increased glomerular filtration rate. During the follow-up, the number of rehospitalizations for ascites was higher and the mean time to the first readmission was shorter in the paracentesis group than in the clonidine group ($p \leq 0.01$).⁹²

Lenaerts et al.⁹¹ also studied the effects of clonidine on ascites treatment in patients with cirrhosis and an activated sympathetic nervous system (plasma norepinephrine concentration > 300 picogram/mL). Patients were randomized to receive placebo ($n = 32$) or clonidine 0.075 mg BID ($n = 32$) for 3 months, as well as spironolactone 200 mg/day (furosemide 40 mg/day was added for insufficient response). Diuretics were individually titrated to response. The time needed for diuretic response was shorter and diuretic dosage lower in the clonidine group than placebo. In addition, the diuretic complications (hyperkalemia and renal impairment) were significantly lower in the clonidine group ($p < 0.01$). The time to the first readmission for tense ascites was shorter in the placebo group than in the clonidine group.⁹¹ The addition of clonidine to diuretic therapy may be an effective therapeutic modality; however, a large randomized trial is needed to establish the role of clonidine in the treatment of ascites.

In consideration of R.W.'s increasing serum creatinine concentration, rising BUN, and the grave prognosis of hepatorenal syndrome, TIPS is a reasonable therapeutic alternative if R.W. cannot tolerate or requires frequent large volume paracentesis.

Spontaneous Bacterial Peritonitis

Pathogenesis

12. Should R.W. receive spontaneous bacterial peritonitis prophylaxis?

Spontaneous bacterial peritonitis is an infection that occurs in cirrhotic patients and accounts for about 25% of the infections in this population. SBP is defined as the spontaneous infection of the ascitic fluid in the absence of an identified intra-abdominal source of infection or inflammation. This condition has a mortality rate of about 30% to 50%.^{93,94} The diagnosis of SBP is defined by a polymorphonuclear cell count (PMN) of ≥ 250 cells/mm³ or a positive bacterial culture of the ascitic

fluid. Patients with ascites caused by cirrhosis, with overlapping complications such as prior episodes of SBP and upper GI bleeding, and patients with low-protein (≤ 1 g/dL) ascites are at an increased risk for the development of SBP. Gram-negative enteric bacilli account for most SBP episodes (most commonly by *Escherichia coli* and *Klebsiella* species).^{95,96} The primary mechanism for SBP is bacterial translocation from the gut, although multiple mechanisms have been proposed. Other factors in the pathogenesis of SBP may include the inability of the gut to contain bacteria and the failure of the immune system to clear the organisms once they have translocated. Cirrhosis can lead to intestinal bacterial overgrowth, and the intestinal permeability may be enhanced in cirrhotic patients with portal hypertension and bowel edema favoring bacterial translocation into the portal vein or lymphatics. Organisms may reach the systemic circulation from the mesenteric lymph nodes causing bacteremia. Deficiencies in the reticuloendothelial system in cirrhotic patients can lead to bacteria not being cleared from the circulation, which eventually leads to colonization of the ascitic fluid. Endogenous antimicrobial activity is diminished or nonexistent in patients with low-protein ascites, and if the immune system fails to destroy the bacteria, bacterascites (cultures from ascitic fluid are positive but the number of PMN is < 250 cells/mm³), in some cases, may progress to SBP (culture positive and PMN ≥ 250 cells/mm³).^{95,96}

Spontaneous Bacterial Peritonitis Prophylaxis

NORFLOXACIN

Because of its activity against aerobic enteric gram-negative bacilli and poor oral absorption, norfloxacin has been utilized for prophylaxis in patients at increased risk for SBP.⁹⁷ A multicenter, double-blind trial was conducted comparing norfloxacin 400 mg/day versus placebo in the prevention of SBP recurrence in cirrhotic patients ($n = 80$) with a prior episode of SBP. The results of the trial showed that the overall probability of SBP recurrence at 1 year of follow-up was 20% in the norfloxacin group and 68% in the placebo group ($p = 0.006$). Of note, in a small subset of patients ($n = 6$) who had stool cultures, norfloxacin administration produced a selective intestinal decontamination of aerobic gram-negative bacilli from the fecal flora without significant changes in other microorganisms.⁹⁸ In a prospective randomized study, selective intestinal decontamination with norfloxacin ($n = 32$) was compared with untreated controls ($n = 31$) in cirrhotic patients with low ascitic fluid total protein levels. A significantly lower incidence of infections and SBP were found (0% vs. 22.5%; $p < 0.05$) in patients receiving norfloxacin, but no significant change in mortality.^{97,99} In a randomized controlled trial conducted by Fernandez et al.,¹⁰⁰ cirrhotic patients with low-protein ascitic levels (< 1.5 g/dL) and with advanced liver failure (Child-Turcotte-Pugh score > 9 , serum bilirubin level > 3 mg/dL), or impaired renal function (serum creatinine level > 1.2 mg/dL, BUN > 25 mg/dL, or serum sodium level < 130 mEq/L) were included to compare norfloxacin ($n = 35$; 400 mg/day) with placebo ($n = 33$) in the primary prophylaxis of SBP. The trial showed a reduced incidence of SBP (7% vs. 61%; $p < 0.001$), and hepatorenal syndrome (28% vs. 41%; $p = 0.02$) in the norfloxacin group compared with placebo. There was also an improved 3-month (94% vs. 62%, $p = 0.003$) and 1-year (60% vs. 48%; $p = 0.05$) probability of survival in the norfloxacin group compared with placebo.¹⁰⁰

One concern regarding norfloxacin prophylaxis is the emergence of infections caused by *E. coli* resistant to quinolones in cirrhotic patients undergoing prophylaxis with norfloxacin. Not surprisingly, a study by Ortiz et al.¹⁰¹ showed that in cirrhotic patients with infections caused by norfloxacin-resistant *E. coli* as compared with those with norfloxacin-sensitive *E. coli*, were more likely to have received norfloxacin previously (82% vs. 22%; $p < 0.0001$).¹⁰¹

TRIMETHOPRIM-SULFAMETHOXAZOLE

Trimethoprim-sulfamethoxazole ($n = 25$; 160/800 mg/day given 5 days a week) has been compared with norfloxacin ($n = 32$; 400 mg/day) for SBP prophylaxis in patients with prior SBP and low-protein ascites. No significant difference in SBP recurrence was seen between the two groups (9.4% in the norfloxacin group and 16% in the trimethoprim-sulfamethoxazole; $p = 0.68$). Trimethoprim-sulfamethoxazole may be a reasonable alternative to norfloxacin, although the study was small. The incidences of side effects (skin rash, epigastric pain, and worsening of renal function) were higher in the trimethoprim-sulfamethoxazole group.¹⁰² A meta-analysis was conducted to assess the effect of antibiotic prophylaxis (long-term administration of quinolones or trimethoprim-sulfamethoxazole) on prevention of infections and survival rate in cirrhotic patients with GI bleeding. Antibiotic prophylaxis significantly increased the mean survival rate by 9.1%.¹⁰³ Patients with a history of SBP and those with low-protein ascites with advanced liver failure or renal impairment appear to benefit from SBP prophylaxis.^{42,97} Further studies are needed to evaluate the effectiveness of SBP prophylaxis for other subgroups of patients with low-protein ascites.^{93,104} R.W. would benefit from the addition of SBP prophylaxis because he has had a prior episode of SBP. A reasonable prophylactic regimen would be long-term administration of norfloxacin 400 mg/day to prevent recurrence of SBP. This dosage is acceptable based on his renal function (estimated CrCl 26 mL/minute).¹⁰⁵

ESOPHAGEAL VARICES

Treatment

13. C.V., a 55-year-old, pale-looking woman with known primary alcoholic cirrhosis, was admitted for a chief complaint of hematemesis. C.V. has a history of recurrent upper GI bleeding and documented esophageal varices. She has no other significant medical history. On examination, her blood pressure (BP) was 78/40 mmHg, pulse rate was 110 beats/minute, and respiratory rate was 22 breaths/minute. Her skin was cold; chest and cardiac examinations were within normal limits and abdominal examination revealed ascites and a palpable spleen. Bowel sounds were normal. Laboratory values included the following: Hgb 7 g/dL (normal, 11.5–15.5 g/dL); Hct 22% (normal, 33%–43%); albumin 3.0 g/dL (normal, 4–6 g/dL); AST 160 IU (normal, 0–35 IU); ALT 250 IU (normal, 0–35 IU); alkaline phosphatase 40 IU (normal, 30–120 IU); and creatinine 2.0 mg/dL (normal, 0.6–1.2 mg/dL; calculated creatinine clearance: 30 mL/minute). The PT was 18 seconds with a control of 12 secs (INR 1.5). Serum electrolytes were all within normal limits. An electrocardiogram (ECG) revealed sinus tachycardia. What are the immediate goals of therapy and treatment measures of the highest priority in managing C.V.'s hematemesis?

Goals of Therapy

Most patients with cirrhosis develop portal hypertension, which in turn can progress to bleeding varices (dilated veins in the upper GI tract that protrude into the esophageal or gastric lumens). Of patients with Child-Turcotte-Pugh A cirrhosis, 40% develop esophageal varices, as compared with 85% of those with Child-Turcotte-Pugh C.¹⁰⁶ Unless varices bleed, they do not cause significant complications or symptoms.

The progression and severity of varices is directly related to the severity of portal hypertension. The major sites of concern in portal hypertension are the coronary vein, draining the bottom of the esophagus and upper stomach, and the veins draining the spleen and lower GI tract. The scarring and fibrosis associated with cirrhosis initially leads to an increase in portal vein pressure (PVP). The PVP may eventually rise, causing backflow of blood supply and subsequent pressure in the veins coming off the portal vein. Hyperkinetic circulation in the branches of the portal vein raises the esophageal transmural pressure and increases the risk of upper GI bleeding. Because the veins are designed for low-pressure circulation (5–8 mmHg) and generally cannot tolerate a sustained hyperdynamic circulation, the shunting of high portal pressure blood results in gastric and esophageal varices. When PVP exceeds 12 mmHg, patients are at increased risk of variceal hemorrhage.¹⁰⁷

Varices can be visualized only during a diagnostic endoscopy. Esophageal varices are graded as small or large (>5 mm). The presence or absence of red signs (red wale marks or red spots) on varices is also noted.¹⁰⁶

Despite improvement in the management of portal hypertension, massive bleeding from esophageal or gastric varices is the leading cause of death in patients with cirrhosis.¹⁰⁸ Prevention of variceal bleeding is critical because the mortality rate remains at 32% in Child-Turcotte-Pugh classification C patients.¹⁰⁹ New varices develop at a rate of 5% to 10% per year in cirrhotic patients. Once varices develop, they enlarge by 4% to 10% each year.¹¹⁰ Acute variceal bleeding is considered a medical emergency and should be treated immediately. Treatment goals include volume resuscitation, acute treatment of bleeding, and prevention of recurrence of variceal bleeding. Approximately 10% of patients are refractory to endoscopic and medical intervention and may require life-saving portal decompressive shunt surgery or TIPS.¹¹¹

General Management

Resuscitation is the first priority in patients with acute bleeding episodes. An indwelling nasogastric tube (NG) should be placed, then saline or tap water lavage of the stomach, with suctioning of the gastric contents, should be initiated promptly to prevent airway complications such as aspiration pneumonia.^{84,112} Obtunded or unconscious patients should be intubated to maintain and protect the airway. Pharmacologic treatment should be initiated immediately to reduce bleeding and the risk of hypotension-induced renal failure. The patient should also be monitored for any abnormal electrolyte and metabolic chemistries (e.g., potassium, sodium, bicarbonate), hypoxia (e.g., PO₂, pH), serum creatinine, and decreased urinary output.¹¹²

Rebleeding is most likely to occur within the first 48 hours in patients with large varices and in patients with advanced liver disease (i.e., Child-Turcotte-Pugh class C (Table 28-2)). Factors

associated with early rebleeding include age >60 years, acute renal failure, and severe initial bleeding defined by hemoglobin <8 g/dL at presentation. Risk factors for late rebleeding are severe liver failure, continued alcohol abuse, large variceal size, renal failure, and hepatocellular carcinoma.¹¹³

Hypovolemia/Blood Loss

Care should be taken when correcting hypovolemia so as not to increase the degree of portal hypertension by overtransfusion, which can increase the risk of further bleeding. Hypovolemia should be immediately managed to maintain mean arterial pressure at 80 mmHg and the hemoglobin at approximately 8 g/dL.^{106,114} C.V.'s pallor, cold and clammy skin, rapid pulse, and a systolic BP <80 mmHg suggest significant hypotension and hypovolemia needing correction with whole blood or packed red cell transfusion along with fresh frozen plasma.^{113,115}

Patients with liver disease and elevated bilirubin frequently develop some level of vitamin K deficiency because of fat malabsorption. Prolongation of the PT owing to vitamin K deficiency usually improves within 24 hours after a 10-mg subcutaneous or oral dose of vitamin K. A prolonged PT owing to poor hepatic synthetic function is not responsive to the administration of vitamin K, because the PT prolongation results from poor synthetic function rather than vitamin K deficiency. If the INR requires rapid correction because of bleeding or a planned invasive procedure, fresh frozen plasma should be transfused. Although vitamin K is often administered in the treatment of acute variceal bleeding, there is no data to support this practice.¹¹⁶

14. Three units of whole blood and two units of fresh frozen plasma were transfused initially. C.V.'s stomach was lavaged with saline, and the gastric aspirate from the NG tube continued to be strongly positive for blood. Four hours later, her bleeding still persisted. What other pharmacologic interventions can be used to control C.V.'s bleeding esophageal varices?

Several vasoconstricting drugs have been used to control variceal bleeding. The first, and at one time the gold standard, was vasopressin (Pitressin).^{117,118} This naturally occurring hormone (also known as 8-arginine vasopressin, ADH) is produced by the posterior pituitary and was originally derived for the treatment of diabetes insipidus in persons with pituitary insufficiency. Its use to control variceal bleeding is a non-U.S. Food and Drug Administration (FDA)-labeled use that takes advantage of its intense smooth muscle and vasoconstrictive properties. Because efficacy of vasopressin for treatment of esophageal bleeding is limited and adverse effects (e.g., abdominal cramping, arrhythmias, and gangrene) are of great concern (Table 28-3), it has largely been replaced by octreotide. Nonetheless, some clinicians still prescribe vasopressin.

Octreotide

Octreotide (Sandostatin) is a synthetic analog of the somatostatin, with similar pharmacologic properties and a slightly longer half-life. Somatostatin is available in Europe, but is substituted with octreotide or vapreotide (orphan drug status) in the United States (Table 28-3).^{117,119,120} Octreotide is shown to be effective for controlling acute variceal bleeding and appears comparable in efficacy to vasopressin and balloon tamponade, with fewer side effects. Octreotide is administered as a 50- to

Table 28-3 Treatment of Acute Bleeding

| <i>Therapy</i> | <i>Mechanism</i> | <i>Side Effects and Risks</i> |
|--|--|---|
| Octreotide | Selective and potent vasoconstrictor that reduces portal and collateral blood flow by constricting splanchnic vessels | Diarrhea, hyperglycemia, hypoglycemia, constipation, rectal spasms, abnormal stools, headache, dizziness, and fat malabsorption |
| Vasopressin | Nonspecific vasoconstrictor of all parts of the vascular bed | Abdominal cramping, nausea, tremor, skin blanching, phlebitis, hematoma at the site of the infusion, worsening of hypertension, angina, arrhythmias, myocardial infarction, bowel necrosis, gangrene, and dilutional hyponatremia |
| Endoscopic band ligation (EBL) or endoscopic variceal ligation (EVL) | An elastic band is placed around the mucosa and submucosa of the esophageal area containing the varix, leading to strangulation, fibrosis, and ideally obliteration of the varix | Moderate bleeding, hypotension, gastrointestinal discomfort, esophageal ulceration, and perforation |
| Sclerotherapy | Injection of 0.5 to 5 mL of a sclerosing agent (e.g., concentrated saline: 11.5% NaCl or ethanolamine oleate [Ethamolol]) into each varix at points about 2 cm apart to induce immediate hemostasis (cessation of bleeding within 2 to 5 min) | Esophageal ulceration, stricture formation, esophageal perforation, retrosternal chest pain, and temporary dysphagia |
| Balloon tamponade | Bleeding is controlled by direct compression of the varices at the gastroesophageal junction or at the bleeding site by a Sengstaken-Blakemore tube or Linton tube (gastric varices only). The tube is passed through the mouth and into the stomach. A balloon is then inflated, which applies direct compression to the varices. | Aspiration (>10% incidence), pressure necrosis, pneumonitis, esophageal ulceration and rupture, bleeding on balloon deflation, chest pain, asphyxia (aspiration may be minimized by endotracheal intubation and continued aspiration of oropharyngeal secretions) |
| Transjugular intrahepatic portal systemic shunt (TIPS) | A conduit between the hepatic vein and intrahepatic segment of the portal vein with an expandable metal stent is placed during an angiographic procedure. This channel allows blood to return to the systemic circulation and reduces portal pressure. | Bleeding, thrombosis, stenosis, severe encephalopathy, hepatic failure, shunt occlusion and shunt migration |

100-mcg bolus followed by an infusion of 25 to 50 mcg/hour for 18 hours to 5 days. In one study, patients ($n = 68$) with portal hypertension and upper GI bleed were randomized to receive octreotide ($n = 24$), vasopressin ($n = 22$), or omeprazole ($n = 22$). Complete bleeding control was achieved in all patients receiving octreotide after 48 hours of therapy compared with 64% of vasopressin-treated patients, and 59% in the omeprazole groups ($p < 0.005$). Patients receiving vasopressin also experienced more side effects (abdominal cramps, nausea, tremor, decreased cardiac output, myocardial ischemia, and bronchial constriction) than those receiving octreotide or omeprazole ($p < 0.01$). In the patients with bleeding not controlled within 48 hours in the vasopressin and omeprazole groups, complete bleeding control was subsequently achieved by octreotide.¹²¹ In a meta-analysis of octreotide and somatostatin versus vasopressin in the management of acute esophageal variceal bleeds (6 trials; $n = 275$), octreotide and somatostatin appeared to be more effective in controlling acute bleeding (82% vs. 55%; $p = \text{NS}$) and had less adverse effects requiring discontinuation than vasopressin (0 vs. 10%; $p = 0.00007$).¹²² In general, both octreotide and somatostatin are fairly well tolerated.¹²¹ Although some centers may still initiate therapy with vasopressin, most will use octreotide as first-line therapy and reserve vasopressin for treatment failures.

Vasopressin

Vasopressin (Table 28-3) is effective in reducing or terminating bleeding in approximately 60% of patients with variceal hemorrhage.^{117,118} Of concern are reports of patients develop-

ing hypertension, angina, arrhythmias, and rarely, myocardial infarction while receiving vasopressin. Vasopressin is given as a continuous IV infusion because of its short half-life. To minimize dose-related adverse effects, the lowest effective dosage should be used. Vasopressin may be administered by peripheral IV infusion, but use of a central vein is preferred because of the risk of tissue necrosis if extravasation occurs. Most commonly, vasopressin is initiated as a continuous IV infusion of 0.2 to 0.4 unit/minute, and increased every hour by 0.2 unit/minute until control of bleeding is obtained (maximal dose 0.9 unit/minute). Approximately 12 hours after the control of bleeding, the infusion rate can be decreased by half. Higher doses should be avoided because dosages exceeding 1 unit/minute fail to control hemorrhage in patients who are unresponsive to lower dosages.¹²³ When the bleeding is controlled, it is customary to taper vasopressin over 24 to 48 hours, but tapering does not appear to decrease the incidence of rebleeding or side effects.¹¹⁷ Because of the potential for serious cardiovascular and dermatologic complications caused by nonspecific vasoconstriction, vasopressin should be used only when necessary and for a duration necessary to control bleeding. The duration of infusion should not exceed 72 hours.

Nitroglycerin can help to minimize the side effects of vasopressin. Nitroglycerin administration may also enhance the reduction in portal pressure and reduce the adverse vascular and cardiac effects. When given by IV infusion, the nitroglycerin dosage is 40 to 200 mcg/min.^{117,119,124} A randomized trial by Gimson et al.¹²⁵ was conducted to determine the efficacy of nitroglycerin when added to a vasopressin. The results of the trial found a lower rate of complications in the vasopressin and

nitroglycerin group compared with vasopressin alone. Combination therapy was also more effective in controlling variceal hemorrhage. A total of 57 patients received either vasopressin or vasopressin plus nitroglycerin, for an infusion period of 12 hours. At the end of the 12-hour period, hemorrhage was controlled in 68% receiving combined therapy versus 44% in those given vasopressin alone ($p < 0.05$). Major complications requiring cessation of therapy were less common in those given nitroglycerin compared with those given vasopressin alone ($p < 0.02$).¹²⁵ Interestingly, a meta-analysis of four randomized controlled trials ($n = 157$) comparing vasopressin for the acute treatment of variceal bleeding with nonactive treatment or placebo found no difference in mortality.¹¹⁷

Terlipressin

Terlipressin (Glypressin), a synthetic analog of vasopressin and a prodrug of lypressin (currently not available in the United States), effectively controls acute bleeding from esophageal varices in 80% of patients. Fewer cardiovascular side effects have been associated with terlipressin than with vasopressin.¹²⁶ Octreotide, vapreotide, vasopressin, and terlipressin have been shown to have efficacy in the control of acute variceal hemorrhage.^{127,128} Terlipressin, however, is the only medication for the acute treatment of variceal hemorrhage that has been shown to improve patient survival. In a meta-analysis of seven randomized, placebo-controlled trials ($n = 443$), terlipressin led to significant reductions in mortality as compared with placebo (relative risk [RR] of 0.66; 95% CI 0.49–0.88).¹²⁹

Pharmacologic therapy (somatostatin or its analogues [octreotide or vapreotide] or terlipressin) should be initiated as soon as variceal hemorrhage is suspected and continued for 3 to 5 days after diagnosis is confirmed.¹⁰⁶

Endoscopic Variceal Ligation and Sclerotherapy

15. Vasopressin and octreotide are nonspecific vasoconstrictors that require continuous IV infusion and carry a risk of systemic side effects. What are endoscopic variceal ligation, sclerotherapy, and balloon tamponade?

After successful resuscitation, endoscopy should be performed within 12 hours to establish the cause of bleeding. Fiberoptic endoscopy allows direct visualization of the esophagus and location of the bleeding sites. Those with actively bleeding varices can be treated with endoscopic variceal ligation (EVL), sclerotherapy, or balloon tamponade. EVL is a well-tolerated procedure (Table 28-3).^{127,130–134} Villanueva et al.¹³⁵ conducted a randomized, controlled trial comparing variceal ligation and sclerotherapy as an emergency endoscopic treatment added to somatostatin infusion in acute variceal bleeding. Patients admitted with acute GI bleeding and with suspected cirrhosis received somatostatin infusion (for 5 days). Endoscopy was performed within 6 hours and those with esophageal variceal bleeding were randomized to receive either sclerotherapy ($n = 89$) or ligation ($n = 90$). The authors found that the use of variceal ligation instead of sclerotherapy had a lower failure rate (4% vs. 15%; $p = 0.02$), and a lower transfusion requirement ($p = 0.05$). No statistically significant differences were found in mortality. Adverse effects (e.g., aspiration pneumonia, esophageal bleeding, ulceration, and chest pain) occurred in 28% of patients receiving

sclerotherapy and 14% with ligation (RR = 1.9, 95% CI = 1.1 to 3.5; $p = 0.03$).¹³⁵ In another similar but smaller study, Sarin et al.¹³⁶ found that the rate of rebleeding was lower in the EVL group ($n = 47$) than in the sclerotherapy group ($n = 48$) (6.4% vs. 20.8%; $p < 0.05$). EVL is the recommended form of therapy for acute esophageal variceal bleeding, although sclerotherapy may be used in the acute setting if ligation is technically difficult. Endoscopic treatments are best used in combination with pharmacologic therapy, which preferably should be started before endoscopy.¹²⁸ The AASLD Practice Guidelines Committee and the Practice Parameters Committee of the American College of Gastroenterology (ACG) on the Prevention and Management of Gastroesophageal Varices and Variceal Hemorrhage in Cirrhosis recommend that for the control and management of acute hemorrhage, the combination of vasoconstrictive pharmacologic therapy and variceal ligation is the preferred approach.¹⁰⁶

Balloon Tamponade

Balloon tamponade controls bleeding by direct compression at the bleeding site (Table 28-3). It is important to remember that balloon tamponade is only a temporary measure and can cause pressure necrosis after 48 to 72 hours. Thus, the balloon should be deflated after 12 to 24 hours. Balloon tamponade will achieve temporary control of the bleeding and allow time for other measures (e.g., EVL or sclerotherapy) to be undertaken. Also, deflation and removal of the tube can result in removal of the fibrin scab at the bleeding site, resulting in rebleeding. Balloon tamponade is only used in massive bleeding and for a maximum of 24 hours, as a temporary ‘bridge’ until definitive treatment can be instituted.^{106,127,137,138}

Alternative Treatment Modalities

16. C.V. was immediately treated with octreotide and EVL. Although the procedure was transiently successful, variceal bleeding has developed again. What alternative treatment modalities could be used?

Although the combination of pharmacotherapy (somatostatin, terlipressin, or octreotide) in combination with endoscopic procedures (EVL or sclerotherapy) has been shown to be beneficial in controlling acute bleeding, a chance exists for variceal rebleeding episodes.^{106,127} Poor responders to initial therapy may require surgical correction of the underlying portal hypertension to control the bleeding.

TRANSJUGULAR INTRAHEPATIC PORTAL SYSTEMIC SHUNT

Henderson et al.¹³⁹ conducted a prospective, randomized, multicenter trial comparing distal splenorenal shunts (DSRS) or TIPS for variceal bleeding refractory to medical treatment with β -blockers and endoscopic therapy. Patients with Child-Turcotte-Pugh class A and B cirrhosis ($n = 140$) and refractory variceal bleeding were enrolled and randomized to DSRS or TIPS with a follow-up for 2 to 8 years. No significant differences were found in survival at 2 and 5 years (DSRS, 81% and 62%; TIPS, 88% and 61%, respectively). Thrombosis, stenosis, and reintervention rates were significantly higher in the TIPS group (DSRS, 11%; TIPS, 82%; $p < 0.001$). Rebleeding, encephalopathy, ascites, need for transplantation, quality of life, and costs did not significantly differ between groups. DSRS and TIPS had similar efficacy in the control of refractory variceal

bleeding in Child-Turcotte-Pugh class A and B patients, although reintervention rates were significantly greater for TIPS compared with DSRS.¹³⁹ TIPS has the advantage of being less invasive and faster than surgical portal systemic shunts. Long-term patency of the TIPS remains problematic (Table 28-3).¹³⁰ TIPS can be used as a bridge to liver transplantation, and may be an effective option for nonsurgical patients or those with advanced cirrhosis (Child-Turcotte-Pugh Score C) with recurrent bleeding, uncontrolled by pharmacologic and endoscopic therapy.^{106,127,140,141}

SURGERY

Surgical creation of a portacaval shunt has been effective in reducing portal pressure and in preventing recurrent bleeding. These shunts, however, are associated with a high incidence of hepatic encephalopathy and may exacerbate hepatic parenchymal dysfunction by shunting blood away from the liver. Mesocaval shunts and distal splenorenal shunts are also effective in preventing variceal rebleeding and may be associated with a lower incidence of hepatic encephalopathy.¹⁴²

Infection Prophylaxis—Short-Term Antibiotics

Short-term administration of antibiotics for the prevention of bacterial infections in patients with variceal hemorrhage has shown favorable results.^{93,143,144} In a prospective, randomized trial comparing norfloxacin 400 mg BID for 7 days (n = 60) with no treatment controls (n = 59), the norfloxacin group had a significantly lower incidence of SBP (3.3% vs. 16.9%; $p < 0.05$); although, the decrease in mortality (6.6% vs. 11.8%) did not reach statistical significance.¹⁴³ Because of the emergence of infections caused by quinolone-resistant bacteria, Fernandez et al.¹⁴⁴ compared oral norfloxacin versus IV ceftriaxone in the prophylaxis of bacterial infection in cirrhotic patients with GI hemorrhage. Patients were randomly assigned to oral norfloxacin 400 mg BID (n = 57) or IV ceftriaxone 1 g/day (n = 54) for 7 days. Antibiotics were initiated following emergency endoscopy and within 12 hours of hospital admission. The probability of developing proved infections (26% vs. 11%; $p < 0.03$), and bacteremia or spontaneous bacterial peritonitis (12% vs. 2%, $p < 0.03$) was significantly higher in patients receiving norfloxacin as compared with ceftriaxone. No significant difference was seen in mortality, within the 10 days after inclusion, between treatment groups.¹⁴⁴

The AASLD and ACG consensus guidelines recommend 7 days of antibiotic prophylaxis for prevention of SBP in patients with variceal hemorrhage with oral norfloxacin (400 mg BID) or ciprofloxacin IV (400 mg BID) when oral administration is not possible. Ceftriaxone IV (1 g/day) may be a preferable option in centers with a high prevalence of quinolone-resistant organisms.¹⁰⁶ C.V. should be treated with norfloxacin 400 mg orally once daily (dose adjusted for creatinine clearance of 30 mL/minute), or ceftriaxone 1 g/day for 7 days to prevent SBP.

Primary Prophylaxis

17. All variceal hemorrhage interventions up to this point were aimed at terminating the acute bleeding episode. Could drug therapy have helped prevent the first episode of bleeding from C.V.'s esophageal varices?

Preventing the initial occurrence of variceal bleeding is referred to as *primary prevention* or *primary prophylaxis*. Pharmacologic prophylaxis is aimed at reducing the HVPG to ≤ 12 mmHg, or a decrease in baseline of $\geq 20\%$.^{145,146} In a small study by Vorobioff et al.,¹⁴⁵ none of the patients with HVPG ≤ 12 mmHg (n = 6) bled from portal hypertensive-related causes as compared to 42% in the HVPG > 12 mmHg group (n = 24). In addition, only 1 of the 6 patients with a HVPG ≤ 12 mmHg as compared with 16 in the HVPG > 12 mmHg group died during the study period ($p < 0.06$). This study suggests that patients with an HVPG ≤ 12 mmHg may have a better prognosis than those with HVPG > 12 mmHg. Escorsell et al.¹⁴⁶ has shown that a fall of HVPG by $\geq 20\%$ from baseline was associated with a decreased risk of variceal bleeding (6% vs. 45%; $p = 0.004$).

β -BLOCKERS

Nonselective β -adrenergic blockers decrease portal pressure through a reduction in portal venous inflow as a result of a decrease in cardiac output (β_1 -adrenergic blockade) and splanchnic blood flow (β_2 -adrenergic blockade). They are the most frequently studied drug class for primary prevention of bleeding. Only nonselective β -blockers have an adrenergic dilatory effect in mesenteric arterioles resulting in a decrease in portal blood circulation and pressure. Nonselective β -blockers have been studied in comparison with other modalities of treatment, such as endoscopic variceal ligation, for the primary prevention of variceal hemorrhage in patients with existing varices in a number of randomized trials.^{147,148} Usual starting dosages of propranolol are 10 mg three times a day, or nadolol 20 mg daily. Selective β -blockers (e.g., atenolol and metoprolol) have little effect on mesenteric arterioles and have not been shown to be effective in primary prophylaxis.¹⁴⁹

Propranolol or nadolol, given in dosages to reduce the resting heart rate to 55 to 60 beats/minute or by 25%, have been shown to prevent or delay the first episode of variceal bleeding.¹⁷ Nonselective β -blockers are considered first-line therapy in the prevention of variceal hemorrhage based on numerous randomized, placebo-controlled trials and meta-analyses.^{127,150} For example, Pascal et al.¹⁵¹ conducted a prospective, randomized, multicenter, single-blind trial of propranolol compared with placebo in the prevention of bleeding in patients with large esophageal varices without previous bleeding. Patients received either propranolol (n = 118) or placebo (n = 112), with the endpoints of the study being bleeding and death. The dosage of propranolol was progressively increased to decrease the heart rate by 20% to 25%. The cumulative percentages of patients free of bleeding 2 years after inclusion in the study (74% vs. 39%; $p < 0.05$) and cumulative 2-year survival (72% vs. 51%; $p < 0.05$) were higher in the propranolol group versus the placebo group.

The role of propranolol added to EVL in the prevention of first variceal bleeding has also been compared with EVL alone as primary prophylaxis. Sarin et al.¹⁵² conducted a prospective, randomized, controlled trial comparing EVL with propranolol (n = 72) with EVL alone (n = 72) in the prevention of first variceal bleeding among patients with high-risk varices. EVL was performed at 2-week intervals until obliteration of varices. Propranolol was administered at a dosage sufficient to reduce heart rate to 55 beats/minute or 25% reduction from baseline, and continued after obliteration of varices. No significant

differences were seen in the rates of bleeding and survival between groups, although more patients in the EVL alone group had recurrence of varices ($p = 0.03$).¹⁵²

Treatment with a β -blocker must be continued indefinitely. A study by Abraczinskas et al.¹⁵³ reported the outcomes of patients in whom β -blocker therapy was discontinued. Patients completing a prospective, randomized, double-blind, placebo-controlled trial of propranolol for the primary prevention of variceal hemorrhage were tapered off of propranolol and placebo and followed prospectively for subsequent events. The authors found that when propranolol was withdrawn, the risk of variceal hemorrhage increased from 4% (while on propranolol therapy) to 24% (after propranolol withdrawal), and was comparable to the risk of bleeding in an untreated population (22% in the placebo group from the previous study). The authors suggested that the protective effect of propranolol against variceal hemorrhage was no longer present. Also, patients who discontinued β -blockers experienced increased mortality compared with the untreated population (48% vs. 21%; $p < 0.05$).¹⁵³ Therefore, avoiding sudden discontinuation of β -blockers in this population is essential.

The AASLD/ACG guidelines recommend nonselective β -blockers for primary prophylaxis in patients with small varices that have not bled but are at increased risk of hemorrhage (Child B or C or presence of red wale marks on varices). Patients with medium or large varices that have not bled but are at a high risk of hemorrhage (Child B or C or variceal red wale markings on endoscopy), nonselective β -blockers or EVL may be recommended. In contrast, patients with medium or large varices that have not bled and are not at the highest risk of hemorrhage (Child A patients and no red signs), nonselective β -blockers are preferred and EVL should be considered in patients with contraindications or intolerance or noncompliance to β -blockers. The β -blocker should be titrated to the maximal tolerated dose.¹⁰⁶

ISOSORBIDE-5-MONONITRATE

Isosorbide-5-mononitrate has been evaluated as primary prophylaxis for variceal hemorrhage as monotherapy in patients intolerant or refractory to β -blockers and in combination with β -blockers in a number of trials and in prior consensus conferences.¹⁵⁴ Isosorbide-5-mononitrate in combination with β -blockers has had mixed success, however, when studied for primary prevention of bleeding in patients with cirrhosis. Also, its use as monotherapy has not proved to be effective.^{154,155} Garcia-Pagan et al.¹⁵⁵ conducted a multicenter, prospective, double-blind randomized controlled trial evaluating whether isosorbide-5-mononitrate prevented variceal bleeding in cirrhotic patients ($n = 133$) with gastroesophageal varices, who had contraindications or could not tolerate β -blockers. Patient received isosorbide-5-mononitrate ($n = 67$) or placebo ($n = 66$). No significant differences were noted in the 1- and 2-year actuarial probability of bleeding or survival between the two treatment groups.¹⁵⁵

When combined with a β -blocker, isosorbide-5-mononitrate causes a greater reduction in the hepatic venous pressure gradient than propranolol alone.¹⁵⁶ Merkel et al.¹⁵⁷ examined the value of combining nadolol and isosorbide-5-mononitrate for primary prevention of variceal bleeding. Patients in the nadolol monotherapy group ($n = 74$) received between 40 and 160 mg/day titrated to achieve a 20% to 25% decrease in rest-

ing heart rate. Patients receiving both drugs ($n = 72$) received nadolol and isosorbide-5-mononitrate 10 to 20 mg orally BID. The overall risk of variceal bleeding was 18% in the nadolol group compared with 7.5% in the combined treatment group ($p = 0.03$). A higher number of patients had to be withdrawn from the study owing to side effects in the group receiving combination therapy compared with the nadolol monotherapy group (8 vs. 4 patients).¹⁵⁷ The AASLD and ACG guidelines suggest that nitrates (either alone or in combination with β -blockers), shunt therapy, or sclerotherapy should not be used in the primary prophylaxis of variceal hemorrhage.¹⁰⁶

Secondary Prophylaxis

18. C.V.'s hepatologist would like to start treatment to prevent further variceal hemorrhage. What are the long-term objectives for the treatment of C.V.? What treatment approaches can be used to prevent a recurrence of bleeding (secondary prevention)?

Secondary prevention or *secondary prophylaxis* is the terminology used to describe therapy to prevent rebleeding once it has occurred. All patients who survive a variceal bleeding episode should receive therapy to prevent recurrent episodes. It is important that the initiation of β -blockers be delayed until after recovery of the initial variceal hemorrhage. Initiation of a β -blocker during the treatment of an acute bleed would block the patient's acute tachycardia in response to his or her hypotension, which may adversely impact survival. The benefit of nonselective β -blockers in the prevention of rebleeding episodes has been demonstrated by a number of trials.^{130,158,159} For example, a trial by Colombo et al.¹⁵⁸ studied the efficacy of β -blockers in preventing rebleeding in cirrhotic patients. Patients were randomly assigned to propranolol ($n = 32$), atenolol ($n = 32$), or placebo ($n = 30$). Randomization was made at least 15 days after the bleeding episode. Propranolol was given orally and titrated until the resting pulse rate was reduced by approximately 25%, and atenolol was given at a fixed dose of 100 mg daily. The incidence of rebleeding was significantly lower in patients receiving propranolol than in those on placebo ($p = 0.01$). Bleeding-free survival was better for patients on active drugs than for those on placebo (propranolol vs. placebo, $p = 0.01$; atenolol versus placebo, $p = 0.05$).¹⁵⁸

Eradication of varices by endoscopic procedures is also effective in preventing recurrent variceal bleeding.^{17,159} A study by de la Pena et al.¹⁵⁹ showed that nadolol plus EVL ($n = 43$) reduced the incidence of variceal rebleeding compared with EVL alone ($n = 37$). Variceal bleeding recurrence rate was 14% in the EVL plus nadolol group and 38% in the EVL group ($p = 0.006$). Mortality was similar in both groups and the actuarial probability of variceal recurrence at 1 year was lower in the EVL plus nadolol group than in the EVL alone group (54% vs. 77%; $p = 0.06$). The adverse effects in the β -blocker group were high, and led to the withdrawal of 20% to 30% of patients.¹⁵⁹ Interestingly, Gonzalez-Suarez et al.¹⁶⁰ conducted a study to compare the occurrence of SBP in cirrhotic patients treated with nadolol plus isosorbide mononitrate ($n = 115$) versus sclerotherapy or endoscopic variceal ligation ($n = 115$) for the prevention of rebleeding. They found that the probability of SBP was lower in the medication group at 1 year (6% vs. 12%; $p = 0.08$) and at 5 years (22% vs. 36%; $p = 0.08$). The probability of survival was similar in both groups.¹⁶⁰

TIPS may be an option for those patients who fail both EVL and prophylaxis with β -blocker therapy. Escorsell et al.¹⁶¹ studied 91 Child-Turcotte-Pugh class B or C cirrhotic patients surviving their first episode of variceal bleeding. Subjects were randomized to TIPS ($n = 47$) or combination therapy with propranolol and isosorbide-5-mononitrate ($n = 44$) to prevent variceal rebleeding. Rebleeding occurred in a lower percentage of patients treated with TIPS versus those treated with drug (13% vs. 39%; $p = 0.007$). The 2-year rebleeding probability was lower in the TIPS group (13% vs. 49%; $p = 0.01$). Encephalopathy was more frequent in TIPS than in patients treated with drug (38% vs. 14%, $p = 0.007$). Child-Turcotte-Pugh class improved more frequently in those treated with drug than with TIPS (72% vs. 45%; $p = 0.04$). The 2-year survival probability was identical (72%). The cost of therapy was double for TIPS treatment. Drug therapy was less effective than TIPS in preventing rebleeding; however, drug therapy caused less encephalopathy, had identical survival, and more frequent improvement in Child-Turcotte-Pugh class with lower costs than TIPS in high-risk cirrhotic patients.¹⁶¹

The AASLD/ACG guidelines suggest the use of a combination of nonselective β -blockers plus EVL for secondary prophylaxis. TIPS should be considered in patients who are Child A or B who experience recurrent variceal hemorrhage despite combination pharmacological and endoscopic therapy.¹⁰⁶

Depending on the size of C.V.'s varices on endoscopy and the risk of hemorrhage, C.V. should have been given nonselective β -blockers (propranolol or nadolol) or EVL to prevent or delay the first episode of variceal bleeding. Because C.V. has a history of recurrent upper GI bleeding, the best option to prevent further bleeding is to initiate a nonselective β -blocker and begin EVL. The β -blocker should be titrated to reduce the resting heart rate to 55 to 60 beats/minute or by 25%. EVL should be repeated every 1 to 2 weeks until obliteration with a repeat endoscopy performed 1 to 3 months after obliteration and then every 6 to 12 months to check for variceal recurrence.¹⁰⁶ If this combination fails to prevent variceal hemorrhage, then TIPS would be considered as a therapeutic option.

HEPATIC ENCEPHALOPATHY

19. R.C., a 57-year-old man, was admitted to the hospital because of nausea, vomiting, and abdominal pain. He had a long history of alcohol abuse, with multiple hospital admissions for alcoholic gastritis and alcohol withdrawal. Physical examination revealed a cachectic male patient with clouded mentation who was not responsive to questions about name and place. Tense ascites and edema were noted, and the liver was percussed at 9 cm below the right costal margin. The spleen was not palpated, and no active bowel sounds were heard. Laboratory results on admission included the following: Na 132 mEq/L; K 3.7 mEq/L; Cl 98 mEq/L; bicarbonate 27 mEq/L; BUN 24 mg/dL; SrCr 1.4 mg/dL; Hgb 9.2 g/dL; Hct 24.1%; AST 520 IU (normal, 0–35 IU); alkaline phosphatase 218 IU (normal, 30–120 IU); lactate dehydrogenase (LDH) 305 IU (normal, 82–226); and total bilirubin 3.5 mg/dL. PT was 22 seconds with a control of 12 seconds (INR 1.8).

A 60-g protein, 2,000-kcal diet was ordered. Furosemide 40 mg IV every 12 hours was ordered in an attempt to reduce the edema

and ascites. Morphine sulfate and prochlorperazine (Compazine) were ordered for his abdominal pain and nausea, respectively. Two days after admission, R.C. had an episode of hematemesis. He became mentally confused and at times nonresponsive to verbal command. An NG tube was inserted and coffee ground material was produced on continuous suctioning. Saline lavage was continued until the aspirate became clear. The next morning, R.C. was still in a confused mental state. He demonstrated prominent asterixis, and fetor hepaticus was noted in his breath. On the second day of his hospitalization, laboratory data were as follows: Hgb 7.4 g/dL; Hct 21.2%; K 3.1 mEq/L; SrCr 1.4 mg/dL; BUN 36 mg/dL; PT 22 seconds with a control of 12 seconds (INR 1.8); and guaiac positive stool. Hepatic encephalopathy and upper GI bleeding were added to the problem list.

What aspects of R.C.'s history are compatible with a diagnosis of hepatic encephalopathy?

Hepatic coma or encephalopathy is a metabolic disorder of the central nervous system (CNS), which occurs in patients with either advanced cirrhosis or fulminate hepatic failure. It is commonly accompanied by portal systemic shunting of blood. The clinical features (as seen in R.C.) include altered mental state, asterixis, and fetor hepaticus. During the early phase of encephalopathy, the altered mental state may present as a slight derangement of judgment and personality, and change in sleep pattern or mood. Drowsiness and confusion become more prominent as the encephalopathy progresses. Finally, unresponsiveness to arousal and deep coma ensue.

Asterixis, or flapping tremor, is the most characteristic neurologic abnormality in hepatic encephalopathy. This tremor can be demonstrated by having the patient hyperextend his or her wrist with the forearms outstretched and fingers separated. It is characterized by bilateral, but synchronous, repetitive arrhythmic motions occurring in bursts of one flap (twitch) every 1 to 2 seconds. Asterixis is not specific for hepatic encephalopathy and may also be present in uremia, hypokalemia, heart failure, ketoacidosis, respiratory failure, and sedative overdose.

Fetor hepaticus, a peculiar sweetish, musty, pungent odor to the breath, is believed to be caused by circulating unmetabolized mercaptans. A staging scheme for grading the severity of hepatic encephalopathy is found in Table 28-4.^{162,163} As discussed in the questions that follow, the pharmacologic management of encephalopathy is guided by both an understanding of the pathogenesis of this disorder and the stage of severity demonstrated by the individual patient. In most cases, hepatic encephalopathy is fully reversible; therefore, it is likely a metabolic or neurophysiologic rather than an organic disorder.¹⁶² Progressive hepatic encephalopathy (a plasma ammonia level $> 150 \mu\text{mol/L}$), however, can lead to irreversible brain damage caused by increased intracranial pressure, brain herniations, and death.^{164,165}

Pathogenesis

20. What is the pathogenesis of hepatic encephalopathy?

Several theories exist about the pathogenesis of hepatic encephalopathy. The most widely referenced theories involve abnormal ammonia metabolism, altered ratio of branched chain to aromatic amino acids, imbalance in brain neurotransmitters, such as γ -aminobutyric acid (GABA) and serotonin,

Table 28-4 Stages of Encephalopathy

| Physical Sign | Stage I Prodrome | Stage II Impending Coma | Stage III Stupor | Stage IV Coma | Stage V Coma |
|----------------------------|---|--|--|--------------------------------------|--------------|
| Mental status | Alert; slow mentation; euphoria, occasional depression, confusion; sleep pattern reversal | Stage I signs amplified; lethargic, sleepy | Arousable, but generally asleep; significant confusion | Unarousable or responds only to pain | Unarousable |
| Behavior | Restless, irritable, disordered speech | Combative, sullen, loss of sphincter control | Sleeping, confusion, incoherent speech | None | None |
| Spontaneous motor activity | Uncoordinated with tremor | Yawning, grimacing, blinking | Decreased, severe tremor | Absent | None |
| Asterixis | Absent | Present | Present | Absent | Absent |
| Reflexes | Normal | Hyperactive | Hyperactive + Babinski | Hyperactive + Babinski | Absent |

derangement in the blood brain–barrier, and exposure of the brain to accumulated “toxins”.¹⁶⁶ None of these are considered to be a single cause, and the pathogenesis of hepatic encephalopathy is likely to be multifactorial.

Ammonia

Ammonia is a byproduct of protein metabolism, and a large portion is derived from dietary ingestion of proteins or presentation of protein-rich blood into the GI tract (e.g., from bleeding esophageal varices). Bacteria present in the GI tract digest protein into polypeptides, amino acids, and ammonia. These substances are then absorbed across the intestinal mucosa, where they are either further metabolized, stored for later use, or used for production of new proteins. Ammonia is readily metabolized in the liver to urea, which is then renally eliminated. When blood flow and hepatic metabolism are impaired by cirrhosis, serum and CNS concentrations of ammonia are increased. The ammonia that enters the CNS combines with α -ketoglutarate to form glutamine, an aromatic amino acid. Ammonia has been considered central to the pathogenesis of hepatic encephalopathy. An increased ammonia level raises the amount of glutamine within astrocytes, causing an osmotic imbalance resulting in cell swelling and ultimately brain edema. Although high serum ammonia and cerebrospinal glutamine concentrations are characteristic of encephalopathy, they may not be the actual cause of this syndrome.^{165,167}

Amino Acid Balance

Body stores of branched chain and aromatic amino acids are affected by their rate of synthesis from protein metabolism (both in the GI tract and in the liver), their utilization in the resynthesis of new proteins within the liver, and their utilization by various tissues for energy. In both acute and chronic liver failure, the serum concentrations of aromatic amino acids significantly increase and the ratio of the branched chain to aromatic amino acids is altered as a result. The utilization of branched chain amino acids for skeletal muscle metabolism during liver failure can decrease branched chain amino acids.¹⁶⁶ At the same time, the blood–brain barrier appears to be more permeable to aromatic amino acid uptake into the cerebrospinal fluid

(CSF). Once in the CSF, some aromatic compounds can be metabolized to produce “false neurotransmitters” (e.g., tyrosine conversion to octopamine) that disrupt normal CSF neurotransmitter balance, and compete with norepinephrine for normal CNS function.¹⁶⁷

γ -Aminobutyric Acid

Schafer et al.¹⁶⁸ proposed that, in liver disease, gut-derived GABA escapes hepatic metabolism, crosses the blood–brain barrier, binds to its postsynaptic receptor sites, and causes the neurologic abnormalities associated with hepatic encephalopathy. Others hypothesize that endogenous benzodiazepinelike substances, via their agonist properties, contribute to the pathogenesis of hepatic encephalopathy by enhancing GABA-ergic neurotransmission. The role of GABA and endogenous benzodiazepines in hepatic encephalopathy is still not clearly defined and requires further clarification.^{169,170}

Of all the toxins suspected to cause hepatic coma, ammonia and certain aromatic amino acids are those most commonly studied. Other precipitating factors (Table 28-5) increase the serum ammonia or produce excessive somnolence in patients with impending hepatic coma. Excess nitrogen load and metabolic abnormalities may increase ammonia levels and precipitate an exacerbation of hepatic encephalopathy.^{171,172}

21. What are the probable precipitating causes of hepatic encephalopathy in R.C.?

The main precipitating cause of the encephalopathy in R.C. was the sudden onset of upper GI bleeding. The bacterial degradation of blood in the gut results in absorption of large amounts of ammonia and possibly other toxins into the portal system. Other important contributory factors in this case are diuretic-induced hypovolemia (BUN:Serum creatinine ratio, >20), hypokalemia (potassium, 3.1 mEq/L), and potentially metabolic alkalosis (continuous NG suctioning and furosemide). Overzealous diuretic therapy enhances hepatic encephalopathy by inducing prerenal azotemia, hypokalemia, and metabolic alkalosis. Alkalosis promotes diffusion of non-ionic ammonia and other amines into the CNS. The associated intracellular acidosis “traps” the ammonia by converting it back to ammonium ion (NH_4^+).^{173,174}

Table 28-5 Factors That May Precipitate Hepatic Encephalopathy

| <i>Excess Nitrogen Load</i> | <i>Fluid and Electrolyte Abnormalities</i> | <i>Drug-Induced Central Nervous System Depression</i> |
|--|--|---|
| Bleeding from gastric and esophageal varices | Hypokalemia | Sedatives |
| Peptic ulcer | Alkalosis | Tranquilizers |
| Excess dietary protein | Hypovolemia | Narcotic analgesics |
| Azotemia or kidney failure | Excessive diarrhea | |
| Deteriorating hepatic function | Over diuresis | |
| Infection: tissue catabolism | | |
| Constipation | Excessive vomiting | |

Sedating drugs can also precipitate hepatic encephalopathy. Drugs that have been associated with hepatic encephalopathy are opioids (e.g., morphine, methadone, meperidine, codeine), sedatives (e.g., benzodiazepines, barbiturates, chloral hydrate), and tranquilizers (e.g., phenothiazines). Encephalopathy precipitated by most drugs can be explained by increased CNS sensitivity and decreased hepatic clearance with subsequent drug and, in some cases, active metabolite accumulation. In addition, the effects of morphine, chlorpromazine, and diazepam may be increased in liver disease because of decreased plasma protein binding. Thus, the morphine and prochlorperazine that were prescribed for R.C. also may have contributed to the worsening of his hepatic encephalopathy. Although not applicable to this case, excessive dietary protein, infections, and constipation can contribute to excess nitrogen load and the genesis of hepatic coma as well (Table 28-5).

Treatment and General Management

22. What steps should be taken to manage R.C.'s hepatic encephalopathy?

After identifying and removing precipitating causes of hepatic coma, therapeutic management is aimed primarily at reducing the amount of ammonia or nitrogenous products in the circulatory system. In general, the 2006 European Society for Clinical Nutrition and Metabolism (ESPEN) recommends an energy intake of 35 to 40 kcal/kg of body weight/day and a protein intake of 1.2 to 1.5 g/kg of body weight/day is recommended for cirrhotic patients and those awaiting liver transplantation surgeries.¹⁷⁵⁻¹⁷⁸ A study conducted by Cordoba et al.¹⁷⁹ assessed the effects of the amount of protein in the diet on the evolution of hepatic encephalopathy. Cirrhotic patients admitted to the hospital for encephalopathy (n = 30) were randomized to two dietary groups, in addition to standard measures to treat hepatic encephalopathy, for 14 days. The first group followed a progressive increase in the dose of protein in the diet, and received 0 g of protein for the first 3 days, then the amount of protein was increased progressively every 3 days (12, 24, and 48 g) up to 1.2 g/kg/day for the last 2 days. The second group received 1.2 g/kg/day from the first day. Results showed that the course of hepatic encephalopathy was not significantly different between both dietary protein restriction groups. The patients in the first group, however, experienced a higher degree of protein breakdown.¹⁷⁹

23. How are lactulose and neomycin used in hepatic encephalopathy? Which agent would be more appropriate for R.C.?

Lactulose

Lactulose is broken down by GI bacteria to form lactic, acetic, and formic acids. It is believed that acidification of colonic contents converts ammonia into the less readily absorbed ammonium ion. Back diffusion of ammonia from the plasma into the GI tract may also occur. The net result is a lower plasma ammonia concentration. The absorption of other protein breakdown products (e.g., aromatic amino acids) may also be reduced. Lactulose-induced osmotic diarrhea may also decrease the intestinal transit time available for ammonia production and absorption, and may help clear the GI tract of blood. Lactulose syrup (10 g/15 mL) has been used successfully in both acute and chronic hepatic encephalopathy. For acute encephalopathy, lactulose 30 to 45 mL is administered every hour until evacuation occurs. Then, the dosage is titrated to two to four soft bowel movements per day and clear mentation. When the oral route of administration is not possible, as in the treatment of a comatose patient, it may be necessary to administer the drug through an NG tube. Alternatively, a rectal retention enema compounded with 300 mL of lactulose in 700 mL water can be prepared. The lactulose water mixture (125 mL) is retained for 30 to 60 minutes, although this may be difficult in patients with altered mental status. The beneficial clinical effect of lactulose occurs within 12 to 48 hours. Patients may need long-term administration of lactulose as maintenance therapy, especially in patients with recurring encephalopathy. For chronic encephalopathy, oral dosing of lactulose should be administered daily to four times daily titrating to two to four soft stools per day and clear mentation. The chronic administration of lactulose permits better dietary protein tolerance and is well tolerated if dosages are kept sufficiently low to avoid diarrhea.¹⁸⁰

Very limited data exist evaluating the efficacy of lactulose for the treatment of hepatic encephalopathy. Care should be taken not to induce excessive diarrhea that could lead to dehydration and hypokalemia, both of which have been associated with exacerbation of hepatic encephalopathy. Although lactulose is generally well tolerated, 20% of patients may complain of gaseous distention, flatulence, or belching. Diluting it with fruit juice, carbonated beverages, or water can reduce the excessive sweetness of the syrup.¹⁶³

Neomycin

Neomycin, at dosages of 500 mg to 1 g orally four times daily, or as a 1% solution (125 mL) given as a retention enema (retained for 30–60 minutes) four times daily, is effective in reducing plasma ammonia concentrations (presumably by decreasing protein-metabolizing bacteria in the GI tract). Approximately 1% to 3% of the neomycin dose is absorbed. Chronic use in patients with severe renal insufficiency can cause ototoxicity or nephrotoxicity. Routine monitoring of the serum creatinine, the presence of protein in the urine, and estimation of creatinine clearance are advisable for patients receiving high dosages for more than 2 weeks.¹⁸⁰ Neomycin therapy can also produce a reversible malabsorption syndrome that not only suppresses the absorption of fat, nitrogen, carotene, iron, vitamin B₁₂, xylose, and glucose, but also decreases the absorption of some drugs, such as digoxin, penicillin, and vitamin K.¹⁶³

Comparison With Lactulose

Lactulose and neomycin appear to have similar efficacy for the acute treatment of hepatic encephalopathy.¹⁸¹ In the treatment of an acute exacerbation, particularly in an acute GI bleed, lactulose may, however, produce a faster response than neomycin. Neomycin may be used in patients who do not respond to lactulose.¹⁸⁰

Interestingly, while lactulose therapy is considered the standard of practice in both acute and chronic hepatic encephalopathy, a meta-analysis evaluating the efficacy of lactulose in patients with hepatic encephalopathy questions its benefit.¹⁸² Large randomized, controlled trials are needed to determine the optimal treatment for hepatic encephalopathy management.¹⁶⁵

Neomycin in Combination With Lactulose

24. Would the combined use of neomycin and lactulose have any additive beneficial effect for R.C.?

The ACG guidelines state that combination therapy of lactulose and neomycin may be reasonable in patients who do not respond to monotherapy. Although the mechanism of additive effects is unclear, theoretically it may be that either degradation of lactulose may not be essential for reduction of ammonia level or there are other unknown mechanisms for the activity of lactulose. Lactulose should be tried first, and if satisfactory results do not occur, neomycin alone should be given a trial. If both agents fail when used as monotherapy, the two agents can then be tried in combination.¹⁸⁰ Although the combined use of lactulose and neomycin may be beneficial, lactulose alone may be more desirable for long-term use because it is potentially less toxic in patient with renal impairment. Further research is needed evaluating the efficacy of combination therapy.

25. Are there other potential treatments for hepatic encephalopathy?

Rifaximin

Rifaximin is a synthetic antibiotic structurally related to rifamycin. It displays a wide spectrum of antibacterial activity against gram-negative and gram-positive bacteria, both aerobic and anaerobic, and has a very low rate of systemic absorption.¹⁸³ It has been available for enteric bacterial conditions for more than a decade in several countries outside the

United States, and was recently introduced in the United States for the treatment of travelers' diarrhea.¹⁸⁴ Miglio et al.¹⁸⁵ conducted a randomized, controlled, double-blind study to evaluate the efficacy and tolerability of rifaximin (400 mg three times daily) in comparison to neomycin (1 g three times daily) treatment for 14 days each month over 6 months (n = 49). During the study, blood ammonia concentrations in both the rifaximin and in the neomycin groups decreased a similar amount. The advantage of rifaximin over neomycin for the treatment of hepatic encephalopathy is for patients intolerant to neomycin or those with renal insufficiency.¹⁸⁵ Bucci et al.¹⁸⁶ evaluated the use of rifaximin in a double-blind study comparing rifaximin and lactulose in patients (n = 58) with moderate to severe hepatic encephalopathy. Rifaximin was administered at a dose of 1,200 mg/day, and lactulose was administered at a dose of 30 g/day, both for 15 days. At the end of the treatment period, cognitive function test scores improved in both groups. Also, concentrations of ammonia normalized after 7 days of treatment in both groups. Rifaximin therapy was better tolerated.¹⁸⁶ Although the data reported from these and other trials suggest a benefit with rifaximin for the treatment of hepatic encephalopathy, larger trials must be conducted to determine its eventual place in therapy.

Flumazenil

Based on the theory of increased GABA-ergic neurotransmission in hepatic encephalopathy, flumazenil, a benzodiazepine antagonist, has been evaluated for its role in the treatment of hepatic encephalopathy. Several trials have demonstrated both clinical and electrophysiologic improvement in patients with hepatic encephalopathy.¹⁸⁷ In one study, 60% of patients had transient neurologic improvement after the administration of IV flumazenil 0.5 mg.¹⁸⁸ However an IV product with modest benefits in the treatment of hepatic encephalopathy is not an ideal treatment option.

Lactulose would be the preferred option to treat R.C.'s encephalopathy because it would shorten the time to clear the blood from his GI tract and, it is hoped, lead to a rapid resolution of his encephalopathy. Although neomycin is not contraindicated for R.C., the potential for worsening of his coagulopathy (by interfering with vitamin K absorption) and risk of nephrotoxicity (SrCr 1.4 mg/dL) make this a less optimal choice. If R.C.'s renal function continues to decline, neomycin may become contraindicated. Lactulose can be initiated at 30 mL every hour until diarrhea occurs; the dose can then be reduced to maintain two to four soft stools per day and improved mental status. R.C. may receive lactulose by NG tube if necessary in the early treatment period. Rifaximin 400 mg three times daily may be an option if lactulose therapy fails, because it can be used in renal insufficiency. Finally, flumazenil would not be recommended owing to its lack of evidence as a beneficial chronic therapy.

HEPATORENAL SYNDROME

26. Lactulose treatment was initiated at 30 mL every hour and titrated to effect with some improvement in R.C.'s mental status. A few days after resolution of his GI bleeding, his serum creatinine increased from 1.4 to 2.7 mg/dL and he became progressively oliguric. His BP was 85/65 mmHg, pulse rate was 70 beats/minute,

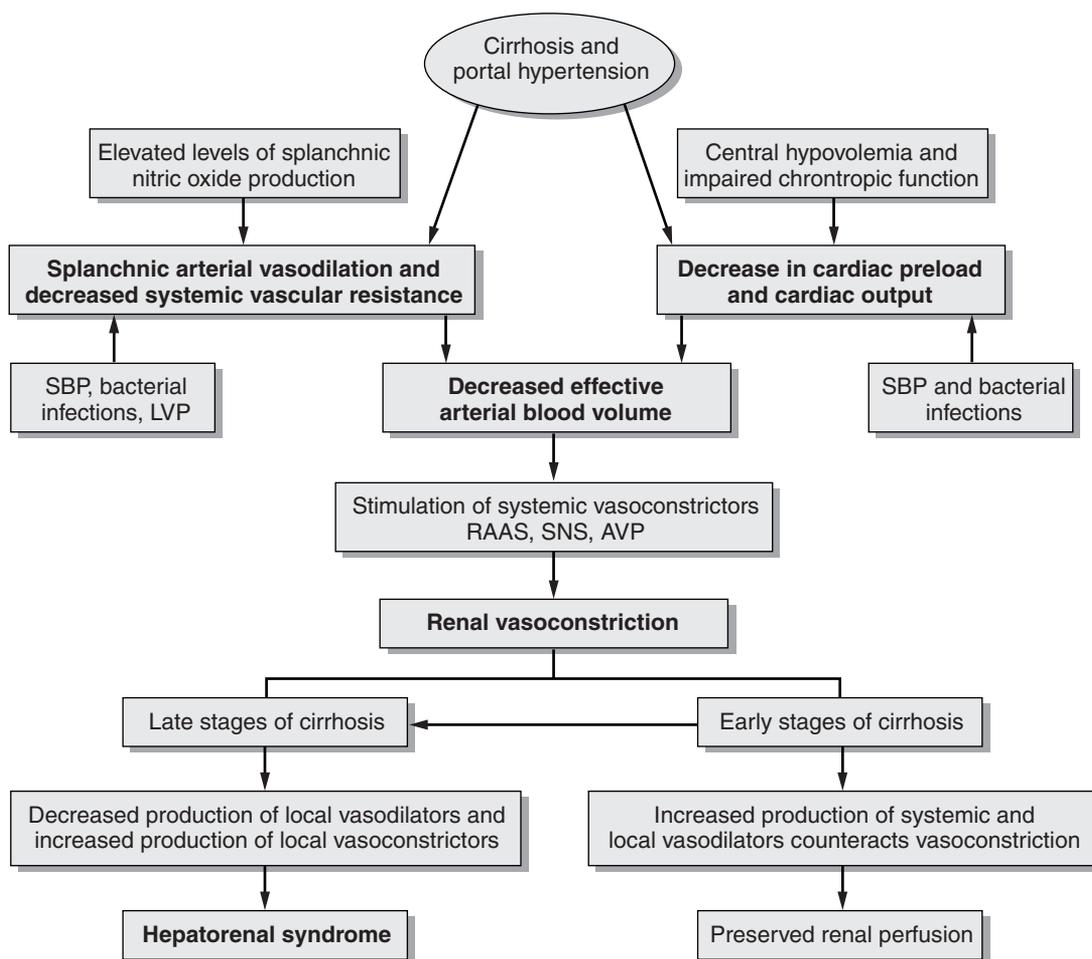

FIGURE 28-3 Pathogenesis of hepatorenal syndrome and its precipitating factors. AVP, arginine vasopressin; LVP, large-volume paracentesis; RAAS, renin-angiotensin-aldosterone system; SBP, spontaneous bacterial peritonitis; SNS, sympathetic nervous system. (Reproduced with permission from reference 190.)

and respiratory rate was 16 breaths/minute. Furosemide was discontinued, and R.C. was treated with albumin infusions to allow volume expansion and improve urine output. A renal ultrasound did not reveal any specific abnormalities. Minimal improvement occurred in his blood pressure and urine output. Laboratory results included the following: Na 123 mEq/L; K 3.6 mEq/L; Cl 98 mEq/L; bicarbonate 25 mEq/L; BUN 96 mg/dL; SrCr 2.7 mg/dL; Hgb 8.4 g/dL; Hct 27.1%; AST 640 IU (normal, 0–35 IU); alkaline phosphatase 304 IU (normal, 30–120 IU); LDH 315 IU (normal, 82–226 IU); and total bilirubin 4.1 mg/dL. PT was 22 seconds with a control of 12 seconds (INR 1.8). A 24-hour urinalysis showed protein 50 mg/day; RBC 1 to 2 per high power field (HPF); negative for WBC, glucose, and ketones. After exclusion of other possible causes of kidney disease, R.C. is diagnosed with hepatorenal syndrome.

Pathogenesis

Hepatorenal syndrome (HRS) is a complication of advanced cirrhosis. It is characterized by an intense renal vasoconstriction, which leads to a very low renal perfusion and glomerular filtration rate, as well as a severe reduction in the ability to excrete sodium and free water.¹⁸⁹ Cardenas et al.¹⁹⁰ have sum-

marized the pathogenesis and the precipitating factors of HRS (Fig. 28-3). HRS is diagnosed by exclusion of other known causes of kidney disease in the absence of parenchymal disease. The revised criteria for the diagnosis of HRS as defined by the International Ascites Club are listed in Table 28-6.^{191,192}

Table 28-6 Diagnostic Criteria for Hepatorenal Syndrome in Cirrhosis

1. Cirrhotic patients with ascites
2. Serum creatinine $>133 \mu\text{mol/L}$ (1.5 mg/dL)
3. No improvement of serum creatinine (\downarrow to a level of $\leq 133 \mu\text{mol/L}$) after at least two days along with
 - a. Diuretic withdrawal and
 - b. Volume expansion with albumin (1 g/kg of body weight per day up to a maximum of 100 g/day)
4. The absence of shock
5. No current or recent treatment with nephrotoxic drugs
6. The absence of parenchymal kidney disease as indicated by
 - a. Proteinuria $>500 \text{ mg/day}$,
 - b. Microhematuria (>50 red blood cells per high power field),
 - c. And/or abnormal renal ultrasonography

From reference 192, with permission.

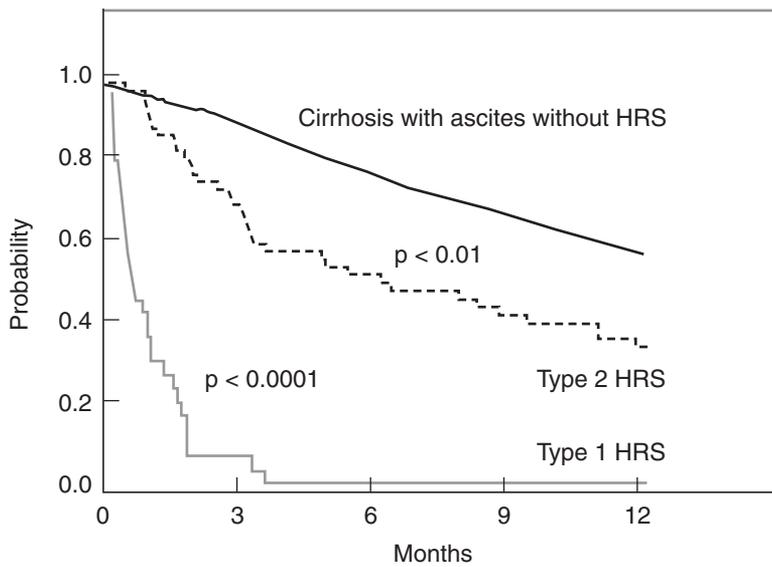

FIGURE 28-4 Actuarial probability to survive in cirrhotic patients with different renal impairments: nonazotemic patients (continuous line); patients with HRS type-2 (dotted line) and patients with HRS type-1 (red line). (Reproduced with permission from reference 192.)

Hepatorenal syndrome can be classified into two categories. Type-1 HRS is characterized by an acute and progressive kidney failure defined by doubling of the initial serum creatinine concentrations to a level >2.5 mg/dL in <2 weeks. Type-1 HRS is precipitated by factors such as SBP or large volume paracentesis, but can occur without a precipitating event. This usually occurs within the setting of an acute deterioration of circulatory function characterized by hypotension and activation of endogenous vasoconstrictor systems. It may be associated with impaired cardiac and liver functions as well as encephalopathy. The prognosis of patients exhibiting type-1 HRS is very poor (Fig. 28-4).^{192,193} In contrast, type-2 HRS is a progressive deterioration of kidney function with a serum creatinine from 1.5 to 2.5 mg/dL. It is often associated with refractory ascites, and has a better survival rate than that of patients with type-1 HRS.^{190–192}

Treatment

Treatments for HRS are still investigational. HRS is associated with a high mortality rate (within 2 weeks of diagnosis of type-1 HRS and within 6 months of type-2 HRS). The definitive treatment for type-1 and type 2 HRS is liver transplantation, which is the only treatment that assures long-term survival.⁶⁹ The main goal of pharmacologic therapy is to reverse HRS sufficiently so that appropriate candidates for liver transplantation can survive until suitable donor organs can be procured.^{191,192} Diuretics therapy must be stopped because this can worsen the kidney disease.¹⁹⁰

A small randomized study by Solanki et al.¹⁹⁴ showed that vasoconstrictor therapy using terlipressin, in conjunction with albumin, was an effective treatment for patients with type-1 HRS. Patients were randomly assigned to treatment with IV terlipressin 1 mg at 12-hour intervals ($n = 12$) or placebo at 12-hour intervals ($n = 12$). Urine output, creatinine clearance, and mean arterial pressures significantly increased in patients treated with terlipressin compared with the placebo group ($p < 0.05$). Survival was significantly higher in the terlipressin group compared with placebo (42% vs. 0%; $p < 0.05$). All survivors in the terlipressin group had a reversal of HRS.¹⁹⁴

Other nonrandomized studies suggest that vasoconstrictor therapy with norepinephrine (combined with albumin and furosemide) or midodrine (combined with octreotide and albumin), improve renal function in patients with type 1 HRS. The impact of vasoconstrictor therapy in terms of efficacy (i.e., improvement of kidney function and survival) and safety should be evaluated in large, randomized clinical trials.^{195–197} Duvoux et al.¹⁹⁷ conducted a pilot study describing the efficacy and safety of norepinephrine in combination with IV albumin and furosemide in patients ($n = 12$) with type-1 HRS. Norepinephrine was given for 10 ± 3 days, at a mean dosage of 0.8 ± 0.3 mg/hour. Reversal of HRS was observed in 83% of patients after a median of 7 days, with a reduction in serum creatinine (358 ± 161 to 145 ± 78 $\mu\text{mol/L}$; $p < 0.001$), a rise in creatinine clearance (13 ± 9 to 40 ± 15 mL/minute; $p = 0.003$), an increase in mean arterial pressure (65 ± 7 to 73 ± 9 mmHg, $p = 0.01$) and a marked reduction in active renin and aldosterone plasma concentrations ($p < 0.05$).¹⁹⁷

Type-2 HRS manifests itself as a progressive disease and, therefore, patients do not present acutely with deterioration in kidney function. No particular treatment exists for type-2 HRS. The main clinical problem in type-2 HRS is refractory ascites, which can be controlled by large volume paracentesis along with IV albumin or TIPS.^{190,195,198} Studies are needed to determine the place in therapy for vasoconstrictors and other potential treatments (e.g. TIPS) in patients with type-2 HRS.¹⁹²

Because of the poor prognosis associated with hepatorenal syndrome, R.C. should be evaluated for transplantation. It may be beneficial to enroll R.C. in investigational research studies evaluating the use of vasoconstrictor therapy in conjunction with albumin while awaiting transplantation.

27. When should liver transplantation be considered in patients with end-stage liver disease?

Liver transplantation for appropriate candidates may be the best option for end-stage liver disease and its complications. Transplantation is generally considered in patients with refractory ascites, severe hepatic encephalopathy, esophageal

or gastric varices and hepatorenal syndrome.¹⁹⁹ Because of the shortage of organs available and significant complications associated with transplantation, therapeutic alternatives should be considered to avoid the necessity for transplantation. For those patients who are transplantation candidates,

therapeutic strategies to improve outcomes after transplantation should be considered in therapeutic decision-making before transplantation (see Chapter 34, Kidney and Liver Transplantation, for further information on the indications for liver transplantation).¹⁹⁸

DRUGS REPORTED TO CAUSE CLINICALLY SIGNIFICANT HEPATIC DYSFUNCTION 29-21**INTRODUCTION**

Drug-induced liver injury (DILI) is a term that is used to describe abnormalities in liver function following exposure to a drug or noninfectious agent.^{1,2} Generally, a distinction should be made between hepatic injury and function, because when function is impaired, clinically significant liver disease usually follows. The loss of hepatic function often leads to a compromised ability to perform activities of daily living, hospitalization, or life threatening events. Before World War II, DILI was an issue of minor proportions, but with the introduction of a large number of new drugs during the ensuing 25 years, a notable increase in the instances of DILI was observed. Over the past few years, there has been a heightened awareness of DILI in the United States. DILI has been associated with nearly 1,000 agents and is the single most common reason for drug withdrawal from the market by the Food and Drug Administration (FDA). Furthermore, DILI is responsible for more than 50% of all cases of acute liver failure with acetaminophen being the principal offending agent (28% of cases in 1998, increasing to 51% of cases in 2003), accounting for 15% of all liver transplants in the United States.¹⁻³ Additional causative agents of DILI include antibacterials (especially antitubercular agents), nonsteroidal anti-inflammatory drugs (NSAIDs), and antiepileptic drugs. Thus, the widespread risk of DILI imparts a challenging task for health care professionals.

Hepatotoxicity appears to be responsible for 2% to 5% of the cases of jaundice or acute hepatitis and for even fewer cases of chronic liver disease^{1,4-23} but the true incidence is difficult to determine. The exact incidence may be much greater due to under reporting, complexities in diagnosis and detection,

and limited follow-up of exposed persons. Other data suggest that adverse drug reactions cause a larger number of liver diseases than previously reported.^{1,2,6-8} However, certain patient populations may have a greater incidence of DILI.⁹⁻¹⁶ For example, in a population-based study conducted in France from 1997 to 2000, researchers found that the crude incidence of hepatotoxicity was 13.9 cases per 100,000 patients per year; 12% of the patients were hospitalized, and 6% died.¹⁰ The agents most often responsible for hepatotoxicity in this report included antimicrobials (25%), psychotropic agents (22.5%), lipid lowering agents (12.5%), and NSAIDs (10%). The authors noted that the observed frequency of hepatotoxicity was 16 times greater than that typically reported to the drug regulatory authorities as part of the postmarketing surveillance system. Based on these findings, the authors speculated that the incidence and severity of drug-induced liver dysfunction is grossly underestimated in the general population. Additionally, investigators from a Swedish University hospital reported that DILI cases occurred more often in females and accounted for 77/1,164 (6.6%) of all referrals to an outpatient hepatology clinic.¹¹

Until recently, a paucity of data has existed with respect to the incidence and outcome of DILI or acute liver failure in the United States. This was due to the relatively rare occurrence of the condition, the variability among patient referral systems in North America, and the lack of an organized data registry.^{1,2,8,9,17} Subsequently, a consortium of liver centers was developed to prospectively define the etiologies and outcomes of patients with acute liver failure.^{1,2,5,12} This

organization, known as the Drug-induced Liver Injury Network (DILIN), was challenged with the specific aim of studying the problem of hepatotoxicity (<http://diln.dcri.duke.edu>). Over a 41-month period beginning in 1998, 308 patients (≥ 15 years) with acute liver failure from 17 tertiary care liver centers were studied.¹² Results showed that most of these patients were women (73%) with a median age of 38 years. The primary cause of acute liver failure was acetaminophen overdose (39% of cases), followed by idiosyncratic drug reactions (13%). Short-term transplant-free survival was 68% and 25% for patients with acute liver failure secondary to acetaminophen ingestion or an idiosyncratic drug reaction, respectively. Additionally, a comprehensive summary of their findings with respect to DILI was published.¹² Other data also suggest that in cases of acute liver failure, fatality rates are high and range from 10% to 50%.^{24–27}

EPIDEMIOLOGY AND RISK FACTORS

Epidemiologic reports suggest the overall prevalence of DILI is low.^{28–37} For example, the risk of liver injury secondary to NSAIDs use is 1 to 10/100,000 exposed individuals,^{20–22,28,29,37} and the combination of amoxicillin with clavulanic acid has been associated with hepatitis in 1 to 5 per 1 million exposed individuals.^{1,18,22,32,33} Isoniazid-induced liver injury may occur in as many as 100/100,000 exposed persons, possibly because of its ability to exert a metabolic type of hepatotoxicity,^{1,7,21–23} whereas the rate of acute liver failure with lovastatin is 1/1.14 million patient-treated years.³⁴ Furthermore, the incidence of significant elevation in ALT or AST associated with the use of protease inhibitors (PIs) in combination with other antiretroviral agents has been reported to be up to 9.5% in the randomized controlled registration trials.^{1,22,35,36} However, the reported rate of ADRs may be a poor indicator of risk, because it depends on case recognition and definition as well as the motivation of observers to report ADRs.

Recent methodology, such as prescription event monitoring, medical record linkage, and case-controlled studies, have better defined the true risk of an agent's association with DILI.^{2,7,31} In many circumstances, drugs are the only cause of liver injury, whereas in other cases, they may augment the relative risk for types of liver injury that could potentially occur even without drug exposure. For example, salicylates are associated with Reye's syndrome, oral contraceptives have been linked to hepatic veno-occlusive disease, and methotrexate may exacerbate hepatic fibrosis in patients with coexisting alcoholic and diabetic types of fatty liver disease.^{5,14,38}

1. C.W. is a 63-year-old female, 61 inches tall, and weighs 75 kg with a history of chronic urinary tract infections for which she had previously taken prophylactic trimethoprim-sulfamethoxazole. C.W. also has a history of generalized tonic-clonic seizures following an automobile accident 7 years ago. For the previous 18 months, her seizures have been well controlled on valproic acid 1 g Q 8 hr. Of note, C.W. has recently been initiated on venlafaxine 50 mg twice daily (BID) for treatment of depression. On a routine visit to the neurology clinic, she was noted to have ALT, 66 U/L (normal, 5–40); AST, 88 U/L (normal, 5–40); alkaline phosphatase, 85 U/L (normal, 21–91); and total bilirubin, 0.8 mg/dL

(normal, 0.1–1.2). What nonpharmacologic risk factors does C.W. have for DILI?

Several host factors affect the risk of DILI (Table 29-1). As previously described, most hepatic adverse drug reactions occur in adults rather than in children.^{1,2,6,22,38} In the adult population, the relative risk of hepatotoxicity induced by isoniazid,^{23,39} halothane,⁴⁰ erythromycin estolate and its analogues,^{5,7,22,41–43} and diclofenac⁴⁴ is greater in patients older than 40 years of age. Generally, the increased frequency of adverse reactions observed in adults may correspond with an increased exposure, ingestion of multiple agents, or altered drug disposition. Exceptions to these findings include valproic acid- or salicylate-induced hepatotoxicity, which occurs most commonly in children younger than 3 years of age.^{1,2,45,46} Although DILI is uncommon in children, it accounts for about 25% of childhood acute liver failure. Causative agents include acetaminophen, antiepileptic drugs, antineoplastic drugs, herbal supplements, and recreational drug use. Gender may also be related to risks for DILI. For example, female gender has been associated with an increased risk of hepatotoxicity, especially from agents such as halothane,⁴⁰ nitrofurantoin,⁴⁷ methyldopa,^{6,7} and sulfonamides.^{9,48}

In addition to age and gender, genetic factors may also have an impact on the ability to metabolize or eliminate drugs, encode pathways of bile excretion, and modulate the immune response. Although rarely encountered, a familial predisposition to hepatic ADRs from agents, such as halothane^{40,49} and phenytoin,⁵⁰ has been shown. Other factors that have an impact on DILI risk include a previous history of ADRs and ingestion of multiple drugs. The mechanism of DILI in the latter appears to be enhanced cytochrome P450-mediated metabolism of the second agent to toxic intermediates (i.e., acetaminophen, isoniazid, and valproic acid). Chronic excessive ingestion of alcohol may also enhance the risk of DILI from agents, such as acetaminophen, by reducing the body's stores of glutathione, which essentially lowers the dose threshold for hepatotoxicity. Other concomitant diseases or conditions, such as rheumatoid arthritis, diabetes, hyperthyroidism, obesity, pregnancy, infection with human immunodeficiency virus, hepatitis B or hepatitis C virus, or renal dysfunction, may also place patients at risk for DILI.^{1,2,22,51–60} Furthermore, drug dose, concentration, and duration of intake may be additional determinants in DILI. Environmental risk factors, such as malnutrition may also enhance the risk of DILI.²²

Thus, C.W.'s age, gender, and obesity appear to be nonpharmacologic risk factors for developing DILI. However, because C.W. is asymptomatic and does not have manifestations of DILI, her baseline laboratory values are not reported, and the current hepatic enzyme elevation is less than three times normal, she should undergo close monitoring of her liver function tests within the next 2 to 4 weeks and return to the clinic for a follow-up.

PATHOPHYSIOLOGY OF HEPATIC INJURY

Because the hepatotoxicity of drugs is often related to reactive metabolites and exposure to these intermediates is determined by genetic and environmental factors, having a general

Table 29-1 Risk Factors for Developing Drug-induced Liver Disease^{1,5,7,22,28}

| <i>Factor</i> | <i>Examples of Drugs Affected</i> | <i>Comments</i> |
|---------------------------------|--|---|
| Age | Isoniazid, nitrofurantoin, halothane Valproic acid, salicylates | Increased incidence/severity with age >60 year Higher incidence in children |
| Sex | Halothane, methyl dopa, nitrofurantoin Flucloxacillin, azathioprine | Higher incidence in females Higher incidence in males |
| Dose | Acetaminophen, aspirin Methotrexate, vitamin A | Higher-blood concentrations associated with risk of hepatotoxicity Total dose, frequency, and duration associated with hepatotoxic risk |
| Genetic factors | Halothane, phenytoin, sulfonamides, isoniazid | Numerous familial cases; defective epoxide hydrolases increase susceptibility to phenytoin and halothane associated injury; acetylator phenotype may predispose to isoniazid hepatotoxicity |
| History of other drug reactions | Valproic acid Halothane, enflurane; erythromycins; diclofenac, ibuprofen | Familial cases, correlation with mitochondrial enzyme abnormalities Rare incidence of cross-sensitivity reported between drug classes |
| Concomitant drug therapy | Acetaminophen Busulfan, azathioprine | Isoniazid, zidovudine may lower toxic dose threshold for hepatotoxicity Increased risk of hepatic veno-occlusive disease |
| Excessive alcohol use | Valproic acid Acetaminophen Isoniazid, methotrexate | Other anti-epileptic drugs increase risk of hepatotoxicity Lowered dosage threshold Increased liver injury and enhanced fibrosis |
| Other diseases | | |
| Obesity | Halothane hepatitis, methotrexate | Increased liver injury and enhanced fibrosis |
| Fasting | Acetaminophen | Increased risk of hepatotoxicity |
| Renal failure | Tetracycline, methotrexate | Increased liver injury and enhanced fibrosis |
| Preexisting liver disease | Niacin (nicotinamide), methotrexate | Increased risk of liver injury |
| Organ transplantation | Azathioprine, busulfan | Increased risk of vascular toxicity |
| AIDS | Dapsone, trimethoprim-sulfamethoxazole, oxacillin | Increased risk of liver injury; hypersensitivity |
| Diabetes | Methotrexate | Increased risk of hepatic fibrosis |

understanding of the pathophysiology and pathways is important. Thus, hepatic injury secondary to phase I mediated cytochrome P450 (toxification), phase II (detoxification) conjugation reactions, and phase III (excretion/transport), as well as biochemical mechanisms of cellular injury or death, will be reviewed in the following section.^{1,2,18,22}

The liver is an extremely resilient organ and is well equipped to resist toxic insults because of its unique cellular attributes (e.g., cell cooperation, acute-phase response, synthesis of hepatoprotective substances). Despite this resiliency, the liver is vulnerable to injury because it is frequently exposed to agents in their most reactive, thus toxic, forms. Because the liver is located between the absorptive lining of the gastrointestinal tract and drug targets within the body, orally administered drugs enter the portal circulation and undergo “first-pass metabolism,” leading to significant exposure of the drug or its metabolites to the hepatocytes. Several factors promote the close contact between hepatocytes, blood, and drugs, including (a) the structure of the hepatic sinusoids; (b) the fenestrated hepatic endothelium; and (c) the enhanced overall surface area of the hepatocytes.^{6,22,61,62} The liver may also be rapidly exposed to intravenously administered drugs because it receives approximately 25% of the cardiac output.

Hepatic uptake of drugs is thought to occur through passive diffusion, carrier-mediated uptake, facilitated transport, or active transport. After drugs have entered the hepatocytes, back diffusion out of the cells may be minimized through cytosolic transfer proteins, such as glutathione S-transferase, fatty acid-binding proteins, and 3-hydroxysteroid dehydrogenase.^{61,62} Drugs are, thereby, transferred to either the endoplasmic retic-

ulum, where they are metabolized, or to the canalicular membrane, where transporters actively secrete endogenous or exogenous substances into the bile. Because most drugs are primarily lipophilic, they are not readily excreted in the urine or bile and must be converted to a more excretable hydrophilic form. The liver is responsible for this biotransformation either through phase I mediated cytochrome P450 oxidative metabolism and formation of potentially hepatotoxic metabolites (toxification)^{62,63} or through phase II conjugation (detoxification)^{62,63} reactions.

In drugs undergoing oxidative metabolism, an activated oxygen molecule is integrated into lipophilic substrates resulting in the formation of reactive electrophiles, free radicals, and reduced oxygen compounds.^{62,63} Reactive electrophiles can bind to cellular membranes, disrupt their function, and subsequently lead to hepatocellular necrosis.^{6,63,64} Examples of causes of this type of liver injury include isoniazid and acetaminophen. Free radical formation from agents, such as carbon tetrachloride (CCl₄), may lead to peroxidative injury of membrane lipids and necrosis,^{7,62,63} whereas activated oxygen appears to be primarily associated with pulmonary injury rather than with DILI.^{62,63} Several cytochrome P450 isoenzymes exist that have different substrates and can be expressed differently based on increasing age, genetic polymorphisms, and environmental conditions.

Because cellular function is overwhelmingly disrupted through these cytochrome P450-mediated mechanisms, cellular death is a common result. This process occurs through the following mechanisms: (a) plasma membrane alteration and disruption of the cytoskeleton (e.g., loss of ionic gradients);

(b) mitochondrial dysfunction (e.g., decline in adenosine triphosphate levels and disrupting fatty acid oxidation); (c) loss of intracellular homeostasis; and (d) activation of degradative enzymes.^{62,62} Additional mechanisms causing hepatocellular death are immunoallergenic (antibody-mediated cytotoxicity or induction of direct cytolytic T-cell responses). Another response involving cytokines (e.g., interferon, tumor necrosis factor, and Fas pathways), nitric oxide, complement activation, and other immune cells (e.g., Kupffer's, thymus, sinusoidal endothelial cells) has also been postulated, which results in inflammation and neutrophil-mediated hepatotoxicity.^{5,62,63,65,66} Finally, apoptosis (programmed cellular death) may occur simultaneously with immune-mediated injury.

A second means of drug metabolism is by phase II (detoxification) conjugation reactions. Phase II reactions occur through binding drug metabolites to glutathione, glucuronate, or sulfate, which leads to the formation of nontoxic, readily excretable hydrophilic products.^{62,63,66} Subsequently, these compounds are excreted from the body in bile or urine through excretory transporters in the hepatocyte canalicular and sinusoidal membrane (phase III elimination). Inadequate detoxification due to reduced binding substance concentrations (e.g., inadequate glutathione stores) may lead to a greater concentration of a reactive metabolite. An example of phase II-induced liver injury may arise from the inability to detoxify phenytoin metabolites. In addition, the combination of phase I- and phase II-induced liver injury may occur in situations resulting in both formation of toxic metabolites and inadequate detoxification (e.g., acetaminophen).

Overall, the pathogenesis of hepatotoxic drug reactions is likely a result of a "multi-hit" process.^{5,62} Several genetic P 450 isoenzyme variants that result in toxic metabolites, the involvement of suppressor and attenuator pathways modulating the hepatotoxic effects, cell-mediated and antibody-induced immune responses, cell surface neoantigens and cytokine expression (interleukin-10 and tumor necrosis factor), inadequate detoxification pathways and individual genetic predisposition all may contribute to DILI. Ultimately, a series of events beginning with intracellular hepatocyte disruption, cellular necrosis, and apoptosis, followed by an immune inflammatory response have been proposed to cause DILI. The actual incidence and resolution of a DILI event may rely on the adaptive phenotypes of the host, which likely is a function of a genetic predisposition. The emerging field of pharmacogenomics could help predict and identify patients with aberrant gene polymorphisms or P450 alleles that affect drug concentrations leading to DILI.

Histopathologically, there are no absolute definitive features of DILI. However, certain patterns suggest a drug etiology. These include (a) zonal necrosis or fatty changes that are associated with mitochondrial injury and (b) mixed histologic manifestations of necrosis and cholestasis. The presence of neutrophils and/or eosinophils within destructive bile duct lesions is suggestive of DILI.^{5,62}

Classification of Drug-induced Liver Injury

The nature of drug-induced liver injury may mimic several known liver diseases, but classification is challenging due to overlap between categories and the fact that some drugs may be associated with more than one syndrome. Often there is discordance between the clinical and laboratory features of

the liver disease and hepatic histology. Identification of specific patterns or syndromes provides only a clue to the diagnosis of DILI; more important is the temporal relationship between drug administration and liver injury or exclusion of other causes of liver disease. Therefore, drugs are often classified as predictable or unpredictable hepatotoxins, and as a result, the terms *intrinsic hepatotoxicity* and *idiosyncrasy* have evolved to help clinically characterize the proposed drug-induced mechanism of hepatic injury. Briefly, intrinsic hepatotoxicity generally is dose dependent and has a short and consistent latency period between drug exposure and liver injury, whereas idiosyncratic reactions occur without warning, are unrelated to dose and may have a latency period from a few days to 12 months. Idiosyncratic reactions often result from a hypersensitivity reaction (immunologic) or metabolic aberration (altered drug metabolism).

However, because the aforementioned terms may not fully elucidate all forms of DILI, the nature of the hepatic injury has been further delineated based on the time frame in which it occurs (i.e., acute vs. chronic), or it may be classified based on whether the drug-induced liver insult is confined to the hepatocytes (hepatocellular injury) or involves areas such as the biliary tract, liver parenchyma, or hepatic vasculature. Finally, several types of drug-induced lesions resulting from acute or chronic administration of drugs are recognized histologically. Along with the proposed mechanism for liver injury and the time frame of occurrence, the histologic characterization of hepatic lesions is also useful in describing DILI and is reviewed next.

Intrinsic and Idiopathic Reactions to Drugs as Causes of Hepatic Injury

From a clinical perspective, the terms used for identifying and describing drug-induced hepatic injury are *intrinsic hepatotoxicity* and *idiosyncrasy* (Table 29-2). Intrinsic or true hepatotoxins (e.g., chloroform) have the inherent property of predictably injuring the liver. Idiosyncratic or unpredictable hepatotoxins (e.g., halothane) cause hepatic damage only in a small number of uniquely susceptible individuals. The major differences between these two types of drug-induced hepatic injury are listed in Table 29-3.

Table 29-2 Mechanisms of Drug-induced Hepatotoxicity^{1,2,15,22,28}

| Classification | Lesion | Incidence |
|---------------------------------|-------------------------------|-----------|
| Intrinsic Hepatotoxicity | | |
| Direct hepatotoxins | Necrosis or steatosis | High |
| Indirect hepatotoxins | | |
| Cytotoxic | Steatosis or necrosis | High |
| Cholestasis | Bile casts | High |
| Host Idiosyncrasy | | |
| Hypersensitivity | Hepatocellular or cholestatic | Low |
| Metabolic abnormality | Hepatocellular or cholestatic | Low |

Table 29-3 Characteristics of Intrinsic versus Idiosyncratic Hepatotoxins

| <i>Intrinsic</i> | <i>Idiosyncratic</i> |
|--|--|
| Distinctive histologic pattern observed for any given drug | Variable histologic pattern of lesions |
| Dose-dependent hepatotoxicity | Dose-independent hepatotoxicity |
| Elicited in all individuals | Only a small fraction of exposed individuals affected |
| Reproducible in experimental animals | Cannot be reproduced in experimental animals |
| Predictable appearance of lesions and usually a brief latent period following exposure | Appearance of lesions bears no temporal relationship to the institution of drug therapy |
| No extrahepatic manifestations of hypersensitivity | Lesions often accompanied by extrahepatic manifestations of hypersensitivity (e.g., fever, rash, eosinophilia) |

Intrinsic Hepatotoxicity

Intrinsic hepatotoxins can be subdivided into direct and indirect toxins. Direct intrinsic hepatotoxins (e.g., carbon tetrachloride) destroy hepatocytes by a physicochemical attack, mostly through the toxic effects of their metabolites. There are no known direct hepatotoxins that are used as therapeutic agents.^{5,7}

In contrast, indirect hepatotoxins (e.g., antimetabolites) induce structural changes in the hepatocytes by competitive inhibition of essential metabolites or by interference with selective metabolic or secretory processes of the hepatocytes. These changes in the hepatocytes can be due to either cytotoxic or cholestatic mechanisms. Indirect intrinsic hepatotoxins that produce cytotoxic changes include tetracycline, mechlorethamine, alcohol, acetaminophen, and mercaptopurine.^{13–15,22,28} Indirect intrinsic cholestatic hepatotoxins produce jaundice and hepatic dysfunction by interfering with mechanisms for the excretion of bile from the liver (e.g., C-17 alkylated anabolic steroids, C-17 ethinylated contraceptive steroids).^{7,22,62,63}

2. One month after her initial visit, C.W. returns to the clinic with a 1-week history of jaundice, anorexia, fever, and nau-

sea while continuing to take her valproic acid (well-controlled seizures with no change in pattern). Upon obtaining an additional medication history, C.W. states that she briefly reinitiated her trimethoprim-sulfamethoxazole for a couple of days during the last 4 weeks for a recurrence of her urinary tract infection, and increased her venlafaxine dose to 100 mg BID. Laboratory values are as follows: ALT, 164 U/L (normal, 5–40); AST, 177 U/L (normal, 5–40); alkaline phosphatase, 105 U/L (normal, 21–91); and total bilirubin, 2.3 mg/dL (normal, 0.1–1.2). What type of liver injury could C.W. have and what is the clinical significance of her elevated liver function tests?

Idiosyncrasy

Like intrinsic hepatic injuries, idiosyncratic injuries may be cytotoxic, cholestatic, or mixed.^{7,22,62,63} Most idiosyncratic drug reactions cause damage to hepatocytes throughout the hepatic lobule with various degrees of necrosis and apoptosis. Hepatic injury due to host idiosyncrasy can be caused by hypersensitivity reactions or by other mechanisms (e.g., an aberrant metabolic pathway for the drug in the susceptible patient). The liver injury may be tentatively attributed to hypersensitivity when it develops after a “sensitization” period of 1 to 5 weeks and is accompanied by systemic characteristics of rash, fever, and eosinophilia.^{7,22,62,63} These hallmarks of an immunological reaction suggest that the hepatic injury is caused by drug allergy, especially when they reappear in response to a subsequent challenge dose of the drug. Examples of drugs causing allergic hepatic dysfunctions are methyl dopa, phenytoin, *para*-aminosalicylic acid, chlorpromazine, erythromycin estolate, rarely clarithromycin, and sulfonamides.^{1,5,14,22,41} Thus, C.W.’s recent elevation of liver function tests could be explained as an apparent “idiosyncratic” reaction to her trimethoprim-sulfamethoxazole (Table 29-4). Furthermore, the second-generation nonselective serotonin reuptake inhibitor venlafaxine has also been identified as a possible cause of hepatic injury. Two cases of venlafaxine-associated “hepatitis” have been reported in the literature.^{1,22,69} The first case occurred in a 44-year-old woman receiving 150 mg/day within 7 months of initiating therapy, whereas the second case was reported in a 78-year-old man within 1 month of a dosage increase from 37.5 mg/day to 150 mg/day. In both cases, discontinuation of venlafaxine resulted in resolution of

Table 29-4 Drug-induced Hepatotoxicity^a

| <i>Drug</i> | <i>Clinical Remarks</i> |
|---|--|
| I = Incidence H = Hepatocellular (elevated ALT) M = Mixed (elevated ALP + elevated ALT) C = Cholestatic (elevated ALP + TBL) | |
| Acarbose I: Low H ¹³⁸ | Mild ALT elevation, diabetic patients receiving long-term therapy should be monitored closely. |
| Acetaminophen | See Chapter 5: Managing Acute Drug Toxicity |
| Alcohol | See Chapter 28: Complications of End-Stage Liver Disease |
| Allopurinol I: Occasional H ^{1,139} | Onset of symptoms varies from 7 days to 6 weeks, but mostly during the first month. Mild to moderate increases in alkaline phosphatase and AST have been reported in most cases. Hepatic granulomas are observed in about half the cases. Fever, rash, and eosinophilia are frequent. Incidence may be increased in those on diuretics or with decreased renal function. Death from hepatic failure occurs rarely. |

(continued)

Table 29-4 Drug-induced Hepatotoxicity^a (Continued)

| Drug | Clinical Remarks |
|---|---|
| Amiodarone I: Uncommon H ^{93,94,140–143} | Phospholipidosis is a frequent hallmark of amiodarone therapy. Serum transferase levels modestly increase in about 40% of patients. Liver disease is frequently associated with peripheral neuropathy, corneal deposits, a bluish skin discoloration, or thyroid dysfunction. Incidence and severity of these adverse effects appear to be dose and duration related. Due to the long half-life of amiodarone, liver injury may persist for months even after the drug is discontinued. In severe hepatitis, jaundice, hepatomegaly, ascites, and encephalopathy can develop. Fatal cases of amiodarone-induced hepatitis have been reported after IV loading doses. Polysorbate 80, an organic surfactant that is added to the IV solution of amiodarone, may be responsible for hepatotoxicity. |
| Amoxicillin-clavulanic acid (Augmentin) I: Low C ^{32,33,131–134} | More than 100 cases of cholestatic jaundice have been reported with this combination. Onset of symptoms range from 2–45 days. Common clinical features include jaundice, pruritus, GI distress, and eosinophilia. Although 40% of this combination is used in pediatric patients, hepatic dysfunction has largely been observed in adults >30 years, suggesting advancing age as a risk factor; male to female ratio was about 2:1. Because some patients had previous or later exposure to amoxicillin without complications, it has been suggested that clavulanic acid or the combination is the cause. |
| Androgenic steroids I: High incidence of hepatic dysfunction; cholestatic jaundice dose related C ^{1,6,144,145} | Anabolic steroids with an alkyl group in the C-17 position are more likely to cause hepatic dysfunction and jaundice than testosterone and 19-nortestosterone. Although hepatic enzymes can be increased by 10%–20%, many patients might not have clinical symptoms. However, cholestatic jaundice can develop in patients taking the drug for 1–10 months. The onset of cholestatic jaundice and the severity of hepatic dysfunction are dose dependent. The larger the daily dose, the more likely is the development of jaundice. Individual susceptibility and preexisting liver disease enhance the potential for hepatic damage. Jaundice may be preceded by nonspecific prodromal symptoms such as malaise, mild anorexia, and nausea. Pruritus may be present in about 10% of patients. Serum transferase levels usually <150 U/mL. Values for alkaline phosphatase are normal or modestly increased in most patients. Serum bilirubin levels are usually <170 mmol/L (9.9 mg/dL), but occasionally patients may reach up to 800 mmol/L (46.8 mg/dL). Recovery is prompt after cessation of the drug, but may take up to 6 months in severe cases. Anabolic-androgenic steroids have been associated with a number of cases of peliosis hepatis. Peliosis hepatis is a vascular lesion that may rupture and lead to hemoperitoneum in some patients. Hepatic adenoma and carcinoma also have been ascribed to the taking of androgens. Anabolic steroids are more likely incriminated in causing hepatic carcinoma than estrogens. The degree of risk probably relates to the type of anabolic steroid, dose, and duration of therapy. Clinically, patients with hepatocellular carcinoma may present with hepatomegaly, abdominal discomfort, pain, or jaundice. In some cases, the patients are asymptomatic with normal biochemical tests. |
| Aspirin and other salicylates I: 0.1%–0.5% C ^{1,6,146,147} | Anicteric injury may occur in 5%–50% of patients with high salicylate blood levels (>15 mg/dL). Most patients who have developed hepatic injury have had levels >25 mg/dL, although a few instances have been noted at levels as low as 10 mg/dL. The injury is manifested by increased serum transferases (10- to 40-fold) and is reversible upon withdrawal of the drug. Fatal hepatitis is very rare. Bilirubin levels are normal or moderately elevated. Children with juvenile rheumatoid arthritis or acute rheumatic fever, and adults with active RA or SLE seem to be more vulnerable. Recently, cholestatic hepatitis during low-dose (250 mg/day) aspirin therapy has been reported. Use of salicylates in children with varicella or influenza-like illnesses is reported to be strongly associated with an increased risk of Reye's syndrome, which includes liver failure as part of the syndrome. |
| Azathioprine I: Rare M ^{1,148–151} | Only a few isolated instances of cholestatic jaundice have been attributed to azathioprine. Jaundice starts 3 weeks to 6 months after initiation of therapy. Generalized pruritus, widespread abdominal pain, and hypochromic greasy diarrhea may be present. Although azathioprine has been used in the treatment of chronic active hepatitis, worsening of the hepatic disease also may occur. Azathioprine is the most common drug in the United States implicated in causing VOD. Approximately 20% of bone marrow and renal transplant patients may be affected with a mortality rate of 50%. VOD results from a nonthrombotic concentric occlusion of the lumen of small intrahepatic veins, also known as “bush tea” disease. |
| Bupropion I: Rare H, C ^{1,6,152,153} | Laboratory findings primarily show increase in ALT within 6 months of initiation of therapy. Fatal cases with autoimmune characteristics have been reported. |
| Calcium channel blockers I: Rare H ^{178–183} | Mild to marked elevations in liver function test results have been reported in <1% of patients taking diltiazem, and drug discontinuation was not required. Six case reports of hepatocellular injury, usually early in the therapy (1–8 weeks), have been published. Eight reported cases of hepatic injury have been associated with nifedipine, each producing acute hepatocellular, cholestatic, or a mixed hepatocellular picture. Three additional chronic cases have been documented beginning 9–72 months after initiation of therapy. Cases were characterized by steatosis and the presence of Mallory-like bodies. Nifedipine, a similar agent, has also been associated with hepatocellular injury. Verapamil-induced hepatocellular injury has been reported in about 6 cases. Hypersensitivity was the proposed mechanism of the injury. |

Table 29-4 Drug-induced Hepatotoxicity^a (Continued)

| Drug | Clinical Remarks |
|--|--|
| Captopril I: Rare M ^{1,119–122} | Hepatotoxicity, usually cholestatic in nature, has been reported with captopril, enalapril, and lisinopril use. Cross-sensitivity also has been reported. Jaundice was the most common finding, followed by pruritus, nausea, other GI symptoms, fever, rash, and confusion. Onset of symptoms varied from 5 days to 12 months (mean: 14 weeks; median: 1 month). Doses employed were variable. Hepatotoxicity usually resolves in 2 weeks to 9 months after ACE inhibitors are stopped, but may progress to liver failure and death if therapy is continued. |
| Carbamazepine I: <1% M ^{55,56,83,154–156} | Hepatotoxic syndrome resembles that observed with phenytoin. Onset of injury is usually within the first 8 weeks of therapy in 80% of cases. Hepatic injury is associated with modest hyperbilirubinemia, fever, rash, and eosinophilia. Morphologic features are hepatocellular, cholestatic or mixed. Fatality rates are less than those reported with phenytoin and range from 7%–12%. |
| Chlorpromazine (CPZ) I: 0.1%–0.2% C ^{157,158} | <p>The effect of age, gender, race, or other predisposing factors has not been established. In approximately 80% of cases, icterus develops between 1–5 weeks of CPZ treatment. In rare instances, jaundice has developed after the first dose. Prodromal symptoms consist of fever, itching, abdominal pain, anorexia, and nausea. Skin rash is observed only in about 5% of reported cases. CPZ jaundice often resembles extrahepatic obstructive jaundice.</p> <p>Severe pruritus is common and may be the first evidence of hepatic injury in some patients. Serum alkaline phosphatase and cholesterol levels are often markedly elevated. Serum transferase levels are increased slightly to moderately in almost all patients. Eosinophilia has been noted in 25%–50% of cases reported. The outlook for CPZ-induced jaundice is good. Cholestatic jaundice associated with CPZ often resolves within 8 weeks but occasionally may continue for a year or longer. Some of the patients with prolonged cholestasis have developed a syndrome resembling that of primary biliary cirrhosis. The clinical syndrome is characterized by itching, xanthoma, hepatomegaly, and splenomegaly. Although it has been suggested that this syndrome is frequently benign and reversible, at least two cases of irreversible cirrhosis and fatality due to CPZ have been described.</p> <p>Other phenothiazines also have been reported to cause cholestatic jaundice, but no reliable estimate of the incidence is available. Because there is a potential for cross-sensitivity between chlorpromazine and other phenothiazines, it is best to avoid using any agent in this class for patients who have had CPZ-induced jaundice. Cholestasis also has been associated with almost all other phenothiazines, and the clinical manifestations reported are similar to chlorpromazine.</p> |
| Chlorpropamide (and other sulfonylurea oral hypoglycemics) I: Rare M ^{159–163} | <p>Host factors that modify the susceptibility to hepatic injury are unknown. Onset of jaundice usually occurs between 2–6 weeks of chlorpropamide therapy. Initial symptoms are anorexia, nausea, and vomiting. Soon thereafter, dark urine, jaundice, and clay-colored stools appear. Pruritus and hepatomegaly are common. Fever, rash, and eosinophilia occur frequently but not in all cases. Complete recovery generally occurs within 1–3 months after chlorpropamide is stopped. Patients who recover from chlorpropamide-induced jaundice apparently do not relapse when given tolbutamide.</p> <p>Other sulfonylureas in clinical use (i.e., acetohexamide, tolbutamide, glibenclamide, and tolazamide) also have been reported to cause jaundice, but the incidence appears to be very low.</p> |
| Clindamycin I: Rare M ^{6,131,164} | Patients present with elevated ALP and ALT. Rarely fatal; resolution follows discontinuation of the drug. |
| Clopidogrel I: Rare C ^{1,165} | Rapid onset of elevation in ALP and TBL. Monitoring of liver function tests may be warranted. |
| Contraceptive steroids (OCs) I: Dose related 1:10,000 in Europe and North America; 1:4000 in Chile and Scandinavia 1) M ^{1,6,166–175} | <p>1) Estrogens can selectively interfere with bilirubin excretion by the liver. The importance of structural specificity of the estrogen molecule in causing hepatic dysfunction has been established. The phenolic character of ring A and the addition of an alkyl group at the C-17 position of the estrogen molecule seem to be responsible for the injury. Progesterone has little or no demonstrable adverse effect on hepatic function by itself, but may enhance the hepatic injury produced by the estrogens. Transient hepatic dysfunction occurs much more frequently and may be as high as 40%–50% of patients taking these agents but the overall incidence of jaundice appears to be much lower (i.e., 1 per 4,000–10,000). Postmenopausal women appear to be more susceptible to hepatic dysfunction induced by estrogen than younger women. Certain ethnic groups (Swedes, Chileans) seem to be more prone to develop anicteric dysfunction than others. Susceptibility to estrogen-induced cholestasis probably is related to a genetic factor because of the strong link with recurrent cholestasis of pregnancy. The jaundice usually is noted during the first 6 months of therapy and often during the first cycle. Jaundice is preceded by nonspecific symptoms including malaise, anorexia, nausea, and pruritus. Splenomegaly is not seen and hepatomegaly is infrequent. Serum concentrations of bilirubin levels are increased moderately in most cases (≥ 10 mg/dL) but values >20 mg/dL have been described. Other biochemical features resemble the jaundice produced by the C-17 alkylated anabolic steroids. Prognosis of the cholestatic jaundice is good. In most individuals, the clinical syndrome resolves completely within 1 month of discontinuation.</p> |

(continued)

Table 29-4 Drug-induced Hepatotoxicity^a (Continued)

| <i>Drug</i> | <i>Clinical Remarks</i> |
|--|--|
| 2) Adenoma, peliosis hepatis | 2) Hepatic adenoma was a very rare tumor before the widespread use of contraceptive steroids. Since then, the increase in incidence of adenoma seems to have paralleled the increased use of OCs. Women taking contraceptive steroids for periods >5 years appear to be at higher risk of developing an adenoma than those who have taken the drug <3 years. One-third to one-half of patients found to have adenoma remain asymptomatic. Approximately one-third may present with a painful, tender mass. The remaining one-fourth to one-third of reported patients often present with a sudden life-threatening intra-abdominal hemorrhage secondary to rupture of the adenoma. Prognosis is good if the adenoma can be resected before the rupture. For patients with hemoperitoneum, the outlook is fair if the diagnosis is made promptly and the tumor resected. Otherwise, death may result from hemorrhagic shock, coagulation abnormalities, and related complications. Peliosis hepatis is a rare complication from contraceptive steroids and often occurs along with the adenoma. |
| 3) Budd-Chiari syndrome | 3) Budd-Chiari syndrome is characterized by acute or subacute development of abdominal pain, hepatomegaly, portal hypertension, ascites, edema, and moderate jaundice. This syndrome is caused by thrombosis and subsequent occlusion of the hepatic veins. Although this complication is very rare, an extremely high mortality rate clearly makes it an important consideration in the use of estrogens. |
| 4) Carcinoma | 4) Several types of malignant tumors have been associated with the use of OCs. Over 100 cases have been reported, but the incidence is low when compared to the widespread use of OCs. Hepatic carcinoma may be more likely in women who have used the OCs for >8 years. |
| Cyclosporine I: Uncommon M ^{6,176,177} | Increased serum transferase, gamma-glutamyl transferase, and serum bilirubin concentrations are signs of cyclosporine hepatotoxicity. Elevated LFTs have been observed in about 4% of renal transplant, 7% of heart allograft, and 4% of liver transplant recipients, usually during the first month of cyclosporine therapy. Reduction of cyclosporine dosage usually reverses hepatotoxic effects. Several cases of cholestasis have been reported. There was a significant increased incidence of VOD among patients who received cyclosporine and methotrexate (CYC-MTX) versus those who received cyclosporine and methylprednisolone (70% vs. 18%) as prophylaxis against graft-versus-host disease for allogeneic bone marrow transplantation. Incidence of early deaths due to VOD was significantly higher in the CYC-MTX group (25% vs. 4.5%). |
| Erythromycin M ^{1,41–43,131} | Erythromycin-associated cholestasis is primarily associated with the estolate salt; less common with the ethylsuccinate and propionate derivatives. Children may be less susceptible than adults. Onset of cholestatic jaundice usually occurs 1–3 weeks after exposure; however, patients previously exposed may exhibit symptoms within 2 days. Abdominal pain occurs in about 75% of the cases. Icterus may precede or accompany GI complaints, such as anorexia, nausea, and vomiting. Fever occurs in about 60% of patients, and rash is often absent. Eosinophilia occurs frequently (45%–80%). Serum bilirubin values are generally <100 mmol/L (5.8 mg/dL). Response to a challenge dose of the same erythromycin derivative is usually prompt. The hepatic injury is reversible, and jaundice often subsides within 2–5 weeks after the drug is discontinued. Cholestatic jaundice has also been reported with clarithromycin and in seven cases of patients receiving roxithromycin. |
| Felbamate I: <1% C ^{57,184} | Twenty-three cases of hepatic failure have been reported following the use of felbamate, 13 of these were not clearly related to felbamate therapy. Of the remaining 10 cases, 5 deaths were attributable to felbamate. The overall incidence appears to be 1 per 26,000–34,000 exposed. The drug remains available; close biochemical and hematologic monitoring has been recommended. |
| Fluoroquinolones I: Rare H ^{131,185–189} | Elevations in aminotransferase, bilirubin, and alkaline phosphatase levels were observed in 1.8%–2.5% of patients who received fluoroquinolones. Sporadic cases of drug-induced hepatitis had appeared in the literature for ciprofloxacin, enoxacin, ofloxacin, and norfloxacin. Hepatic injury due to fluoroquinolones apparently is not dose related and generally is reversible when the drug is stopped. However, one fatal case of hepatic failure, apparently due to oral ciprofloxacin, was reported. The broad spectrum fluoroquinolone trovafloxacin has also been associated with more than 100 cases of hepatotoxicity, fourteen of which involved acute liver failure, with liver transplantation required in four of these. An immuno-allergenic mechanism has been suggested as an etiology. The drug remains available in the United States for very restricted indications. |
| Fluoxetine (paroxetine) I: Very low H ^{1,6,190,191} | According to three published reports of fluoxetine-induced liver disease, patients generally presented with elevated bilirubin, ALT, and AST. Patients generally required from several weeks to months before liver function tests normalized. |
| Haloperidol I: Low C ^{6,192} | Incidence has been estimated to be between 0.2% and 3% of recipients. Most reported cases of jaundice appear to be cholestatic. |

Table 29-4 Drug-induced Hepatotoxicity^a (Continued)

| Drug | Clinical Remarks |
|---|--|
| Halothane I: 1) Mild form >25% 2) Severe 1:35,000 to 1:3,500 C ^{40,49,52,54,81,193-196} | <p>Halothane exposure may be followed by two distinct types of hepatotoxicity: asymptomatic with abnormal laboratory values only or severe acute hepatitis with massive hepatic necrosis. The incidence and severity appear to be greater in females and enhanced by obesity and previous exposure to halothane or irradiation. Jaundice is rare in children and young adults <30 years. The clinical syndrome of halothane-induced liver disease often consists of a history of unexplained delayed fever postoperatively (>3 days) after halothane anesthesia. There is usually a latent period of 5–14 days between the anesthetic episode and the appearance of hepatic injury, but it may appear as early as 1 day after the operation in patients who have had multiple prior exposures to halothane. Fever with or without chills, aching, anorexia, nausea, and abdominal distress preceded jaundice in 75% of the patients. After jaundice appears, other manifestations of serious hepatocellular damage often develop rapidly. Coagulation abnormalities, ascites, renal insufficiency, GI bleeding, and encephalopathy may follow.</p> <p>Values for serum transferases are markedly elevated (≥ 3000 U/L), whereas alkaline phosphatase is increased only modestly. Eosinophilia has been observed in 20%–50% of reported cases. Rash is uncommon. Mortality rate for halothane hepatitis ranges from 14%–67%.</p> |
| Isoniazid (INH) ^{1,39,131,197,198} | <p>Serological testing for antibodies specific to halothane-altered antigens is positive in about 75% of patients and can be used as a diagnostic aid along with the drug history and clinical presentation. See Chapter 61: Tuberculosis. Fast and slow acetylators may be equally susceptible to the hepatotoxic effects of INH. It appears that specific P450 isoenzymes may be involved because of the enhanced hepatotoxicity by alcohol, other drugs (rifampicin), and advancing age.</p> |
| Irbesartan/Losartan I: Rare C (irbesartan) ¹⁹⁹ H (losartan) ²⁰⁰ Ketoconazole I: 0.03%–0.1% H ^{1,6,131,201-206} | <p>Eight cases of hepatotoxicity due to angiotensin II antagonist are reported in the literature. General presentation following initiation of therapy (1 week to 5 months) includes anorexia, and abdominal pain. Age of patients range from 41–77 years with female predominance.</p> <p>Serum transferase concentrations can be increased in 8%–12% of patients without overt clinical symptoms. Symptomatic hepatic injury is infrequent and often presents as a mixed or cholestatic jaundice. Fulminant hepatitis is also possible. Hepatitis is more common in females, especially those over 40 years of age, and usually occurs after 10 days to 26 weeks of therapy. Hypersensitivity manifestations are usually absent.</p> |
| Lovastatin I: Very rare H ^{1,34,207-211} | <p>Fluconazole, itraconazole, and voriconazole have also been implicated in cases of hepatic injury, but the overall incidence is extremely low.</p> <p>In 613 patients who received lovastatin during controlled trials, the most common laboratory abnormalities were elevations in hepatic enzymes. Serum concentrations of ALT, AST, and CPK were increased by 7.3%, 5.9%, and 5.1%, respectively. Serum aminotransferase concentrations were increased by more than threefold in about 1.9% of all patients in this study. Increased transferase levels have been reported in patients with the homozygous form of familial hypercholesterolemia and may be dose related. Hepatitis, fatty change in the liver, cholestatic jaundice, and chronic active hepatitis have been reported rarely. Liver function tests are usually reversible after a few weeks upon discontinuation, but recovery may be delayed for up to 21 months. Rechallenge can result in elevations of aminotransferases in about 50% of patients. Lovastatin should be avoided in patients who have liver disease or a history of alcohol abuse.</p> |
| Methotrexate (MTX) I: Dose, frequency, and duration related H ^{1,6,212,213} | <p>Pravastatin and simvastatin also have been reported to cause increases in aminotransferases that may lead to cessation of therapy. Simvastatin has been associated with at least five cases of presumed hepatitis.</p> <p>MTX frequently causes steatosis and portal inflammation in the liver when it is used in the acute treatment of leukemia, choriocarcinoma, and other neoplastic diseases. Overt clinical symptoms occasionally accompany these lesions. Prolonged use of MTX in patients with psoriasis may lead to hepatic fibrosis and cirrhosis but apparently not in those with RA. The likelihood of hepatic injury probably is directly related to the total dose and duration of therapy; it is inversely related to the time interval between doses. Other risk factors include age, obesity, diabetes, alcoholism, and perhaps severity of psoriasis. Biochemical changes provide insensitive reflections of MTX-induced hepatic injury. Serum concentrations of AST and ALT are usually increased for 1–2 days after a single dose of MTX; however, cirrhosis can develop insidiously without increases in the liver enzyme concentrations. Serial liver biopsies at yearly intervals are highly recommended for patients with psoriasis to facilitate the discovery of cirrhosis and its complications which can progress without overt clinical symptoms. Some of these patients may progress to hepatic failure and death. Early recognition of this syndrome can minimize irreversible hepatic damage and improve long-term survival. Preventative measures include giving intermittent rather than small daily doses of MTX. Single weekly dosing regimens of <15 mg have been successful in reducing the incidence of significant hepatic injury.</p> |

(continued)

Table 29-4 Drug-induced Hepatotoxicity^a (Continued)

| Drug | Clinical Remarks |
|---|---|
| Nonsteroidal anti-inflammatory drugs (NSAIDs) I: 1:100,000 recipients H ^{1,6,37,214–221} | Two-thirds of the cases of sulindac-induced hepatic injury had clinical hallmarks of hypersensitivity. Ratio of females to males was 3.5:1 with 69% of patients >50 years. Most commonly reported clinical features of sulindac-induced hepatitis were jaundice (67%), nausea (67%), fever (55%), rash (48%), pruritus (40%), and eosinophilia (35%). Onset ranged from 1 day to 3 years, but mostly <8 weeks. Rechallenge leads to recurrence in a few days, thus suggesting an allergic mechanism. Complete recovery occurred in all patients 2–3 weeks after drug discontinuation. Severe cholestatic hepatitis, which can progress to subacute hepatic necrosis, has been reported with piroxicam. Elderly patients >60 years seem to be more prone to piroxicam-induced cholestasis. Liver enzymes may take 3–4 months to return to normal levels after piroxicam is discontinued. Other NSAIDs, such as naproxen, diclofenac, ketoprofen, and ibuprofen, also have been implicated. Although cases of NSAID-induced hepatitis are rare, they can be fatal; serious hepatotoxicity resulted in the removal of benoxaprofen and bromfenac from the U.S. market. The majority of cases of hepatitis secondary to NSAIDs occur within the first few months of treatment. |
| Nitrofurantoin I: Rare M ^{1,91,131,222–224} | Symptoms of hepatic injury are usually abrupt with fever (60%), rash (30%), and eosinophilia (70%). Approximately two-thirds of the patients have had previous exposure to nitrofurantoin. The latent period before the development of symptoms ranges from 2 days to 5 months, but is usually within the first 5 weeks. Cholestatic jaundice is the most common acute injury observed with nitrofurantoin. Biochemical abnormalities and jaundice are generally reversible when the drug is discontinued. CAH of the “lupoid” type is rare and may be accompanied by pulmonary lesions. Most patients have a low serum albumin concentration and a high gamma globulin serum concentration. Antinuclear and/or antismooth muscle autoantibodies are found in most patients. Few cases of cirrhosis have been reported. |
| Oxacillin and its derivatives I: Low C ^{131,225–227} | Oxacillin has been associated with rare cholestatic jaundice and numerous cases of anicteric hepatic dysfunction. Liver transferase levels can be as high as 1,000 U/L in some cases. Alkaline phosphatase levels are only modestly elevated and serum bilirubin remains normal in most patients. Eosinophilia accompanies only about 25% of cases. Upon cessation of oxacillin, liver enzyme values generally return to normal within 2 weeks. Apparently there is no cross hepatotoxicity between oxacillin and other penicillins. Nafcillin or penicillin G often can be substituted without recurrence of liver injury. Cloxacillin and flucloxacillin also have been associated with severe cholestatic jaundice. Occasionally, the cholestatic injury may last for months to years even after the drug is stopped. Estimated incidence of flucloxacillin-induced liver dysfunction ranged from 1:11,000–1:30,000 prescriptions. Higher risk was associated with female sex, age, high daily doses, and duration of >2 weeks. |
| Phenytoin I: <1% M ^{1,58,59,154} | Subclinical hepatic enzyme elevation is common with phenytoin but overt hepatitis is much less common. Children seem to be less vulnerable to hepatic injury from phenytoin. Almost 80% of cases involved adults >20 years. Symptoms generally occur after 1–5 weeks of therapy. Fever, rash, lymphadenopathy, and eosinophilia followed by jaundice appear in most patients. Leukocytosis with lymphocytosis and atypical lymphocytes is common. The syndrome resembles that of serum sickness or infectious mononucleosis. Biochemical features are similar to those of severe viral hepatitis. Values for AST and ALT are very high (200–4,000 U/L), and the serum concentrations of alkaline phosphatase usually is only modestly increased. A case mortality rate of about 30% is due partly to accompanying severe hypersensitivity reactions (e.g., exfoliative dermatitis) and partly to resulting hepatic failure. A single case of phenytoin-induced chronic persistent hepatitis which was verified by histology and rechallenge was reported. |
| Propylthiouracil (PTU) I: Rare H, C ^{6,228,229} | Asymptomatic and transient elevations of liver enzymes are common in patients receiving PTU (up to 28% in one study). However, ALT levels decrease after dosage reduction and normalize in most cases. Signs and symptoms of hepatocellular damage usually appear within 2–4 weeks after initiation of the drug and often are accompanied by rash, fever, and lymphadenopathy. CAH and cholestatic jaundice secondary to PTU have been described. Fatal cases of PTU-induced jaundice have been attributed to hepatic necrosis or accompanying granulocytosis. |
| Quinidine I: Rare M ^{5,6,20} | Mild hepatic injury induced by quinidine most commonly occurs within 6–12 days of initiation of treatment and is usually anicteric. Quinidine-induced hepatitis is usually heralded by fever in association with increased AST, ALT, LDH, and ALP levels. Discontinuation of the drug usually results in rapid resolution of fever and laboratory abnormalities. Upon rechallenge with a single dose of quinidine, most patients have promptly developed fever and increased concentrations of serum transferases, thereby supporting hypersensitivity as a mechanism. |
| Risperidone I: Very rare H ^{1,230} | Atypical presentation; hepatocellular damage occurs weeks to months following exposure. Reverses upon discontinuation of therapy. |
| Rifampin ^{1,39,131} Sertraline | See Chapter 61: Tuberculosis The primary presentation is increased ALT levels between 1 and 5 months after exposure. It is likely to be an idiosyncratic mechanism. |
| I: Very rare H ^{1,231} | |

Table 29-4 Drug-induced Hepatotoxicity^a (Continued)

| <i>Drug</i> | <i>Clinical Remarks</i> |
|---|---|
| Sulfamethoxazole-trimethoprim (Co-Trimoxazole) I: Very low M ^{1,6,43,70-73,131,232,234} | Twelve cases of cotrimoxazole-induced liver injury (including fatality) have been reported. The cholestasis can be severe and might last for >12 months, even after the drug was stopped. Prominent features are pruritus, fever, skin rash, arthralgias, and eosinophilia. |
| Sulfonamides I: 0.5%–1% cholestatic jaundice M ^{1,6,131} | Clinical presentation of hepatic injury often occurs within 5–14 days, but occasionally presents as late as several months. About 25% of the patients with hepatic dysfunction have had prior exposure to sulfonamides. The reaction is characterized by fever, rash, and signs of visceral and bone marrow injury. The clinical and morphologic features of such reactions resemble those of serum sickness. Usually, the onset of symptoms is sudden, with fever, anorexia, nausea, vomiting, and sometimes rash. Jaundice appears on the third to sixth day after the onset of fever, but may be delayed for as long as 2 weeks. Dark urine and acholic stools are frequent, and hepatomegaly may be noted. Prognosis depends on the extent of cytotoxic injury. Case fatality rate is reportedly above 10%. Patients who survive generally recover slowly over a period of several weeks to months. Fatal massive necrosis has been described with pyrimethamine-sulfadoxine (Fansidar). Slow acetylators are more susceptible to sulfonamide-included hepatic injury. |
| Tetracyclines I: Low H ^{1,6,131,235,236} | Tetracycline has been reported to produce hepatic steatosis. The development of clinically significant fatty liver appears to depend on the presence of high blood levels of the drug. Large doses (>1.5 g/day) of tetracycline, especially when given IV to pregnant women or individuals with renal disease, may give rise to severe hepatic injury. Clinical manifestations usually appear 4–10 days after initiation of tetracycline therapy. Early symptoms include nausea, vomiting, abdominal pain, hematemesis, and headache. Mild jaundice then follows. Hemorrhagic complications, azotemia, hypotension, shock, and coma may develop subsequently. Tetracycline-induced massive steatosis does not differ clinically or morphologically from the spontaneous form of fatty liver of pregnancy. Mortality rate from this syndrome is 80%. This serious untoward reaction can be avoided by using safer alternative antibiotics whenever possible. |
| Tricyclic antidepressants (TCAs) (amitriptyline, imipramine, desipramine) I: Rare to infrequent C ^{1,6,237-242} | TCAs usually cause a mixed hepatitis with either the necrotic or the cholestatic component predominating depending on the agent. Jaundice appears within 1 week to 4 months. Hypersensitivity manifestations are seen in some patients. Severe hepatic necrosis and death are rare. Prolonged cholestasis and progressive hepatic fibrosis have been reported in a few cases. |
| Troglitazone I: Very low C ^{1,6,123-130} | Reports of troglitazone-associated liver failure led to the removal of this agent from the U.S. market by the FDA in 2000. However, the clinical presentation of thiazolidinedione DILI is significant because this class of agents is still routinely administered to manage type II diabetes. The clinical presentation of thiazolidinedione DILI includes significant increases in ALT (>20× upper limit of normal) between the third and several months (mean 147 days; range 17–287) following initiation of therapy. In patients who had therapy discontinued, ALT usually returned to baseline (mean, 55 days; range 8–142). Patients may not have symptoms of liver dysfunction (e.g., fatigue, nausea, and abdominal pain), yet jaundice may be present in some instances. Liver transplantation was required in some cases. Additional thiazolidinediones, such as rosiglitazone and pioglitazone, may also be associated with idiosyncratic hepatotoxicity. Two case reports describe ALT and AST elevations following initiation of rosiglitazone therapy with rapid normalization following discontinuation. |
| Valproic acid I: 0.05%–0.1% H ^{1,6,74-78,154,243} | Valproate can increase the serum transferase concentration in 6%–44% of patients without overt clinical symptoms. Numerous cases of fatal and nonfatal liver disease due to valproate have been reported. Infants and young children (<2 years) are at much higher risk than adults. Lethargy, lassitude, anorexia, nausea, vomiting, edema, facial puffiness, and a frequent change in the pattern of convulsions may precede jaundice, ascites, and hemorrhage. Severe hepatic necrosis can result in coma and azotemia. Prothrombin time is prolonged, serum ammonia concentrations are increased, and hypoglycemia may occur. The hepatotoxicity is thought to be related to an inherited or acquired deficiency in the beta oxidation of valproate resulting in increased formation of a toxic metabolite (4-envalproate). This toxic metabolic pathway seems to be cytochrome P450 enzyme-dependent and is inducible by other drugs such as phenobarbital and phenytoin. |
| Zidovudine (HAART) I: Very low H ^{1,6,35,36,244-247} | See Chapter 69: Pharmacotherapy of Human Immunodeficiency Virus Infection Patients generally present with weakness, malaise, abdominal discomfort, prolonged coagulation time, acidosis, an increase in ALT, hyperbilirubinemia, and hepatomegaly following several months of therapy. The primary injury is macrovesicular steatosis, but cholestasis has also been seen. Discontinuation of therapy may only reverse acidosis. Didanosine and nevirapine have also caused macrovesicular steatosis and have lead to several cases of fulminant hepatic failure. Of the PIs, indinavir has been reported to produce hepatic injury. |

^aACE = Angiotensin converting enzyme; ALP = Alkaline phosphatase; ALT = Alanine aminotransferase; AST = Aspartate aminotransferase; CAH = Chronic active hepatitis; GI = Gastrointestinal; IV = Intravenous; LDH = Lactate dehydrogenase; LFTs = Liver function tests; OCs = Oral contraceptives; PIs = Protease inhibitors; RA = Rheumatoid arthritis; SLE = Systemic lupus erythematosus; SR = Sustained-release; TBL = Total bilirubin; VOD = Veno-occlusive disease.

liver function tests within 5 weeks, and 4 months, respectively. Thus, C.W. should be advised to discontinue trimethoprim-sulfamethoxazole and venlafaxine, and the clinician should monitor her liver function tests closely for the next several weeks to months. Generally, the recovery from a sulfonamide-induced injury depends on the extent of the cytotoxic injury but usually occurs over a period of weeks to months.⁷⁰⁻⁷³

Idiosyncratic hepatic injury also can be caused by toxic metabolites (e.g., isoniazid, halothane, valproate, ketoconazole, methyl dopa).^{1,7,13,22} The idiosyncratic or unpredictable hepatic injury that results from a metabolic aberration rather than hypersensitivity usually develops after variable latent periods of 1 week to 12 months and usually is not accompanied by fever, rash, eosinophilia, or histologic findings of eosinophilic or granulomatous inflammation in the liver. In addition, reproduction of the hepatic injury requires administration of the drug for a period of days or weeks, rather than for only one or two doses, presumably to allow for accumulation of toxic metabolites.

Furthermore, C.W.'s clinical presentation could also be explained by her chronic ingestion of valproic acid (Table 29-4). The hepatotoxicity associated with valproic acid is thought to be related to an inherent or acquired deficiency in the β -oxidation of valproic acid, resulting in formation of a toxic metabolite (4-envalproate).^{7,22,46,74-78} However, infants and children younger than 2 years of age are at much higher risk than adults for valproic acid-induced liver disease. In addition, there appears to be a change in the pattern of the seizure frequency, which generally precedes clinical manifestations (jaundice, anorexia, fever, nausea) of valproic acid-induced liver disease. Although possible, it is unlikely that C.W.'s DILI is from valproic acid because of her age (>2 years). Thus, it should be continued with close monitoring for resolution of clinical symptoms and liver function tests as described previously.

The classification of the mechanism of hepatic injury by an individual drug into either intrinsic, predictable hepatotoxicity, or unpredictable idiosyncrasy can sometimes be impossible, and in many instances, both major types of mechanisms may have a role. Thus, toxic hepatitis may occur after large overdoses of an intrinsically hepatotoxic drug or in an idiosyncratic manner after therapeutic doses. The reasons for the unique susceptibility of some patients are still poorly understood, and both genetic and acquired factors are likely to be involved.^{5,9,18,19,22}

FORMS OF DRUG-INDUCED LIVER DISEASE

In addition to classifying DILI as a result of intrinsic hepatotoxicity or idiosyncratic reactions, the nature of the hepatic lesion can be used to categorize a specific type of liver injury. However, there are several limitations to fully differentiating the number and forms of DILI based on the nature of the hepatic lesion. These limitations may include an inability to completely analyze the histologic, clinical, and biochemical characteristics of the offending agent or the lack of recognition and confidence in implicating a potentially hepatotoxic agent due to the sporadic nature of ADR reporting. Other limitations may include the concomitant use of additional hepatotoxic agents, pre-existing hepatic diseases, and the inability to rechallenge a patient with the agent in question. Despite

these concerns, drug-induced hepatic injury continues to be classified according to the morphology of the liver injury, the presumed mechanism, or the circumstances of drug-induced damages.

Drug-induced hepatic lesions can also generally be characterized as either acute (clinical or histologic evidence present for <3 months) or chronic (clinical or histologic evidence present for >3 months). Although acute injuries have received the most attention, chronic DILI has become increasingly prevalent. Both types of injury (acute and chronic), along with the characteristic clinical patterns and lesion(s), are discussed in the following sections.

Acute Drug-induced Liver Disease

The FDA, American Pharmaceutical Manufacturers, and selected members of the American Association of the Study of Liver Diseases (AASLD) have adopted guidelines that recommend that an alanine aminotransferase level of more than three times the upper limit of normal and a total bilirubin level of more than twice the upper limit be used as a combined test to define clinically relevant abnormalities on liver tests with additional verification through analysis of available clinical data. Elevations in serum enzyme levels, including alanine aminotransferase, aspartate aminotransferase, and alkaline phosphatase, are to be considered as indicators of liver injury as opposed to increases in both total and conjugated bilirubin levels, which should be considered measures of overall liver function. Furthermore, the pattern of liver injury is important to recognize, because specific drugs elicit an injury according to one pattern or another. Thus, the pattern of DILI can be hepatocellular, mixed, or cholestatic (Table 29-5). Clinically, hepatocellular injury pertains to elevations of alanine aminotransferase, mixed patterns are manifested by an elevated alkaline phosphatase, and the cholestatic pattern is defined by an increase in both alkaline phosphatase and total bilirubin levels. Hepatocellular injury can be either cytotoxic or cytolytic, and it results in damage to the liver parenchyma. The lesions responsible for hepatocellular injury can be due to necrosis, steatosis, or a combination thereof. Most cases of DILI have a "mixed" pattern with features of both hepatocellular and cholestatic injury. Cholestatic injury depicts arrested bile flow with jaundice and is associated with minimal or no parenchymal injury.^{5,7,22,79}

Precise measures of conjugated bilirubin are infrequently obtained and the direct reacting bilirubin fraction overestimates bilirubin elevations. Thus, a concept of combining the measures of liver injury and function were developed from a clinical observation (referred to as Hy's law) that states that "drug-induced hepatocellular jaundice is a serious lesion."^{1,2,22} Furthermore mortality rates are approximately 10% in patients who have both hepatocellular injuries with jaundice, even if the offending agent is discontinued.^{1,2,22} Two surveys have supported the assertion that drug-induced hepatocellular injury with jaundice results in greater mortality or the need for liver transplantation than is cholestatic or mixed injury.^{1,2} Because C.W. has evidence of hepatic injury and compromised function, she is more likely to have a greater risk of mortality and require liver transplantation. Thus, she should be referred to an inpatient setting for additional evaluation of her liver disease.

Table 29-5 Features of Acute Drug-induced Acute Hepatic Injury ^{1,5-6,7,15,22,28}

| Lesion | Syndrome | Clinical Presentation | Biochemical Markers | | Examples of Offending Agents |
|------------------------------|----------------------|-----------------------|---------------------|----------|--|
| | | | ALT/AST | ALK/Phos | |
| Hepatocellular | | | | | |
| Necrosis | Acute hepatitis | A, N, V | 8–200× | 3× | Isoniazid, diclofenac, halothane |
| Sinusoidal beading | Pseudomononucleosis | A, N, V, L, S | 8–200× | Variable | Phenytoin, dapsone |
| Massive | Acute liver failure | A, N, V, L, S, C, E | 25–200× | <3× | Phenytoin, dapsone |
| Subacute | Prolonged hepatitis | A, N, V, J, FG | 8–25× | <3× | Propylthiouracil, diclofenac |
| Spotty | Subclinical | None | 2–5× | <3× | Isoniazid, diclofenac |
| Steatosis, microvesicular | Reye-like | N, V, E | 2–15× | <3× | Tetracycline |
| Cholestatic Injury | | | | | |
| <i>Hepatocanalicular</i> | | | | | |
| Bile casts + spotty necrosis | | | | | |
| Portal inflammation | Obstructive jaundice | A, N, J, PR, FV, R, P | 8× | >3× | Carbamazepine, erythromycin estolate, sulfonyleureas |
| <i>Canalicular</i> | Obstructive jaundice | PR, J, P | <5× | <3× | Anabolic steroids |
| Bile casts | | | | | Oral contraceptives |

A, anorexia; ALKPhos, alkaline phosphatase; ALT, alanine aminotransaminase; AST, aspartate aminotransaminase; C, coagulopathy; E, encephalopathy; FG, fatigue; FV, fever; J, jaundice; L, lymphadenopathy; N, nausea; P, pain; PR, pruritus; R, rash; S, splenomegaly; V, vomiting.

Hepatocellular Injury

NECROSIS

Drug-induced hepatocellular necrosis may primarily involve cells in a centrilobular (zonal) pattern (e.g., acetaminophen, CCl₄, enflurane, ferrous sulfate, halothane), a diffuse (nonzonal) pattern, or hepatocytes similar to that of viral hepatitis (e.g., methyl dopa), or it may affect significant portions of the entire liver (e.g., valproic acid).^{5,7,22,28} Additional agents reported to cause hepatocellular injury include trazodone, diclofenac, nefazodone, venlafaxine, and lovastatin.^{5,7,22} Serum aminotransferases are the hallmark of hepatic damage. The serum AST and ALT in patients with hepatic necrosis are elevated from 8 to 500 times the upper limit of normal, whereas values for alkaline phosphatase are usually increased modestly to no more than three times normal.^{5,13,15,22,80} Blood cholesterol concentrations are often normal or sometimes low. These biochemical patterns resemble those observed in acute viral hepatitis; thus, hepatocellular necrosis is often referred to as *drug-induced* or *toxic hepatitis*.^{1,5,7,22} Clinical features include fatigue, anorexia, nausea, and jaundice. With increasing degrees of liver cell necrosis, patients may experience manifestations of acute liver failure, such as deep jaundice, coagulopathy, ascites, hepatic encephalopathy, coma, and death.^{7,24,26,27} A final clinical presentation of drug-induced acute hepatitis may mimic infectious mononucleosis.^{6,7,22,28} In addition to hepatocellular injury, lymphadenopathy, lymphocytosis, and circulating lymphocytes may be present. This presentation has been associated with the use of phenytoin, dapsone, sulfonamides, and *para*-aminosalicylic acid.^{6,7,22,28}

STEATOSIS

A second type of acute drug-induced lesion is steatosis, which can be microvesicular or macrovesicular. In microvesicular steatosis, the hepatocytes are filled with many tiny droplets of fat that do not displace the nucleus (e.g., valproic acid, tetracycline, aspirin overdose).^{22,37,46,81-83} In macrovesicular

steatosis, the hepatocyte contains a large fat droplet that displaces the nucleus to the periphery (e.g., ethanol, glucocorticoids, methotrexate). Generally, acute toxic steatosis is likely to be microvesicular, whereas chronic steatosis is usually macrovesicular (e.g., amiodarone, tamoxifen). Although microvesicular steatosis results in enlargement of the liver, routine liver function tests often remain normal. In contrast, fatty degeneration caused by drugs such as valproic acid may result in irreversible cell damage reflected by increased AST and ALT serum concentrations of 100 to 500 U/L.^{7,22,46} Elevations in aminotransferase levels in patients with drug-induced hepatic steatosis are not as high as those reported with hepatocellular necrosis. The histologic picture of drug-induced fatty degeneration is similar to that observed with fatty liver of pregnancy or Reye's syndrome.^{1,5,6,22,28} Certain drugs (e.g., high dosages of estrogens) also can induce a form of degenerative, necrotizing liver damage known as *fatty liver hepatitis*, which can eventually result in micronodular cirrhosis.^{1,5-7,22} Fatty liver hepatitis is often asymptomatic, and the appearance of malaise, diarrhea, fever, jaundice, leukocytosis, ascites, or edema may indicate that the damage is already irreversible with a poor prognosis.

Cholestatic Injury

CANALICULAR AND HEPATOCANALICULAR

Cholestatic injury has been associated with two prominent types of lesions.^{1,5-7,22,28} These are manifested by bile stasis without inflammation and with minimal parenchymal injury (i.e., bland, pure, or steroid cholestasis) or by cholestasis with inflammation and slight parenchymal injury (i.e., cholestatic hepatitis, pericholangitis, cholangiolitic cholestasis, or sensitivity cholestasis). The former can be characterized as *hepatocanalicular* (i.e., combined with hepatocyte injury), whereas the latter is referred to as *canalicular* (i.e., portal inflammation).

Canalicular cholestasis is characterized by AST and/or ALT elevations less than eightfold above normal, normal

cholesterol, alkaline phosphatase elevations less than threefold above normal, in a patient who is jaundiced or has a serum bilirubin level >42 mmol/L. In contrast, hepatocanalicular cholestasis usually presents with AST and/or ALT levels less than eightfold elevated, increased cholesterol, and alkaline phosphatase 3- to 10-fold above normal. Patients with AST, ALT, and alkaline phosphatase levels in the canalicular range but with a serum bilirubin level <42 mmol/L are categorized as having an “indeterminate type,” because these values could reflect either minor hepatocellular injury or anicteric injury of the cholestatic type. Hepatocanalicular injury is typically seen in chlorpromazine-induced jaundice, and the canalicular type usually is observed in cases resulting from anabolic or contraceptive steroids.^{1,2,5,7,22}

Drug-induced canalicular and hepatocanalicular cholestatic injury often resembles extrahepatic obstructive jaundice both clinically and biochemically.^{1,5,13,22,28} Pruritus, jaundice, pale stools, and dark urine are the primary clinical manifestations. Other patient complaints may include upper abdominal pain or dull abdominal aching. The serum bilirubin level is increased in all cases of drug-induced cholestasis, but it usually is <170 mmol/L (normal, 2–17), although on occasion, it can be >800 mmol/L.^{1,4,5,15,22,28} The serum aminotransferase concentrations are generally only moderately increased. The serum concentrations of alkaline phosphatase are usually increased more than threefold when cholestasis is caused by oral hypoglycemic agents, some antithyroid drugs, erythromycin estolate and its derivatives, or chlorpromazine (hepatocanalicular), but they do not increase as much when the cholestasis is not accompanied by cellular injury (e.g., anabolic, contraceptive steroids).^{5,13,15,22,28}

The immediate prognosis in patients with either hepatocanalicular or canalicular injury is good. The mortality rate for pure cholestasis is much lower than when the cholestasis is accompanied by cytotoxic damage and is believed to be $<1\%$.^{5,13,22,28} However, a syndrome of chronic intrahepatic cholestasis with clinical, biochemical, and histologic features that resemble primary biliary cirrhosis (PBC) has been observed following acute drug-induced cholestasis.^{22,82,83} (Table 29-6). These cases of PBC-like disease are likely to resolve,

yet a permanent and fatal PBC-like syndrome (vanishing bile duct syndrome) has been identified.^{5,7,22,82,83}

Mixed Injury

Mixed forms of drug-induced injury can be primarily hepatocellular with significant cholestatic characteristics, or primarily cholestatic with significant hepatocellular features. They appear to be more consistent with a drug-induced etiology rather than with viral hepatitis. Biochemical markers for mixed cholestatic injury may be defined by elevations in ALT, AST (values more than eight times the upper level of normal), and alkaline phosphatase levels (values more than three times the upper level of normal).

Several drugs appear to exhibit a distinct relationship between their therapeutic class and the type of injury they elucitate.^{5,7,15,22,28} For example, some anti-epileptic drugs (e.g., phenytoin, carbamazepine) tend to produce hepatocellular or mixed hepatocellular jaundice. Most neuroleptic agents tend to produce cholestatic (hepatocanalicular) jaundice, whereas hydrazide antidepressants cause hepatocellular jaundice, and tricyclic antidepressants primarily cause cholestatic injury.

Nevertheless, most drugs do not exhibit a distinct relationship between their therapeutic class and the type of injury they induce. Specifically, some oral hypoglycemic agents such as acetohexamide produce mixed hepatocellular injury, whereas others, such as chlorpropamide, tolbutamide, and tolazamide, cause cholestatic jaundice.^{5,7,15,22,28} Second-generation hypoglycemic agents, such as glyburide and glipizide, have rarely been associated with causing cholestatic jaundice. Also, the antimicrobial agent nitrofurantoin and the NSAID sulindac may cause either cholestatic or hepatocellular injury.^{22,37} Gold compounds appear to be associated with cholestatic rather than hepatocellular jaundice, but this relationship is not consistent. Other agents that lead to mixed injury include *para*-aminosalicylic acid, sulfonamides, amoxicillin-clavulanate, cyclosporine, methimazole, carbamazepine, troglitazone (no longer available), and herbal supplements.^{5,7,22,28} The mortality rate of the mixed form seems to depend on the extent of cytotoxic injury.

Table 29-6 Drug-induced Chronic Cholestasis Compared With Primary Biliary Cirrhosis^{7,15,22,28}

| Characteristics | Drug-induced Chronic Cholestasis | Primary Biliary Cirrhosis |
|----------------------------|---|---|
| Associated disease | Irrelevant | Sicca syndrome |
| Drug intake | Phenothiazines, organic arsenicals | None |
| Clinical symptoms | Pruritus, early severe jaundice, xanthomas, hepatomegaly, splenomegaly, cirrhosis | Pruritus, latent mild jaundice, xanthomas, hepatomegaly, splenomegaly, meloderma, cirrhosis |
| Laboratory Markers | | |
| Bilirubin | 1–20 mg/dL | 1–5 mg/dL |
| ALT/AST | 2–8× | 2–8× |
| Alkaline phosphatase | 3–10× | 3–10× |
| Histologic Markers | | |
| Ductopenia | Slight | Remarkable |
| Nonsuppurative cholangitis | Absent | Present |
| Hepatic granulomas | Absent | Present |

ALT, alanine aminotransaminase; AST, aspartate aminotransaminase.

Table 29-7 Features of Drug-Induced Chronic Hepatic Injury^{5-7,15,22,28}

| Lesion | Associated Syndrome | Biochemical Markers | | Examples of Offending Agents |
|----------------------------------|---------------------------|---------------------|----------|--|
| | | ALT/AST | ALK Phos | |
| Hepatocellular | | | | |
| Necroinflammatory | Chronic hepatitis | 3–50× | 1–3× | Nitrofurantoin, minocycline, methyl dopa |
| Steatosis | Alcoholic steatosis | 1–3× | 1–3× | Methotrexate, glucocorticoids |
| Phospholipidosis | Alcoholic hepatitis | 1–5× | Variable | Amphophilic agents |
| Pseudoalcoholic | Alcoholic hepatitis | 1–5× | Variable | Amiodarone, perhexiline |
| Cholestatic Injury | | | | |
| Cholangiodestructive | Primary biliary cirrhosis | 1–3× | 3–20× | Carbamazepine, haloperidol |
| Biliary sclerosis | Sclerosing cholangitis | 1–5× | 3–20× | Floxuridine |
| Granulomatous | Hepatomegaly; hepatitis | 1–3× | 3–20× | Allopurinol, carbamazepine, hydralazine, quinine |
| Vascular Lesions | | | | |
| Peliosis | Hepatomegaly | 1–3× | <3× | Anabolic steroids, oral contraceptives |
| Budd-Chiari syndrome | Congestive hepatopathy | 2–20× | Variable | Oral contraceptives |
| Veno-occlusive | Congestive hepatopathy | 2–20× | Variable | Pyrrrolizidine alkaloids, azathioprine |
| Sinusoidal dilation | Hepatomegaly | 3× | Variable | Oral contraceptives |
| Pericellular/sinusoidal fibrosis | Noncirrhotic portal HTN | 1–3× | Variable | Vitamin A |
| Neoplasm | | | | |
| Adenoma, carcinoma | Asymptomatic hepatic mass | Variable | Variable | Oral contraceptives, anabolic steroids |

ALK Phos, alkaline phosphatase; ALT, alanine aminotransaminase; AST, aspartate aminotransaminase; HTN, hypertension.

Chronic Drug-induced Liver Disease

Chronic adverse effects of drugs on the liver generally can be categorized based on the type of lesion or on similarity to clinical syndromes (Table 29-7). These categories include parenchymal lesions secondary to chronic hepatitis, subacute hepatic necrosis, chronic steatosis, phospholipidosis (PL), or fibrosis and cirrhosis. Also included are two forms of cholestatic lesions either from chronic intrahepatic cholestasis or biliary sclerosis. In addition, vascular, granulomatous, and neoplastic lesions may also lead to chronic hepatic disease.^{5,7,22,28}

Parenchymal Disease

CHRONIC HEPATITIS

Formerly categorized as chronic active or persistent hepatitis, all chronic necroinflammatory disease of the liver is now referred to as *chronic hepatitis* (CH).⁸⁴ In addition to viral etiologies (e.g., hepatitis B virus, hepatitis C virus), autoimmune hepatitis (AIH), Wilson's disease, and cryptogenic cirrhosis, drug-induced hepatic parenchymal lesions have been reported. Drug-induced lesions appear to mimic AIH because they predominantly affect females and are accompanied by hyperglobulinemia, antinuclear antibodies, anti-single-strand DNA, and other serologic autoimmune markers.^{5,7,22,28} Drugs associated with this syndrome include dantrolene, diclofenac, fenofibrate, methyl dopa, minocycline, nitrofurantoin, sulfonamides, and drugs of abuse such as ecstasy. Acetaminophen and isoniazid also have been incriminated in causing chronic active viral hepatitis-like disease, perhaps owing to continued toxic injury rather than an autoimmune response.^{5,7,13,22} To date, at least 24 drugs have been associated with CH, and al-

though the overall presentation is not homogeneous, they have been categorized into four separate types of injury.^{13,22}

The first group (type 1) consists of drugs that induce liver injury that resembles autoimmune hepatitis.⁶ Drugs associated with this form of injury are often taken for prolonged periods and are continued beyond the initial liver insult. The overall incidence of this “type” appears to be <5%. Unique clinical features in this group includes a high incidence in women (>90% of cases reported), hypergammaglobulinemia, autoantibodies, and a chronic necroinflammation rich in plasma cells.

Type 2 drug-induced chronic hepatitis is characterized by antibody formation against isoforms of cytochrome P450 or other microsomal proteins, which apparently leads to “neoantigen” production during biotransformation.^{5,13,22,85–87} Compared with type 1, hyperglobulinemia is not a prominent feature of this entity. Only two drugs (dihydralazine and tienlic acid) have led to this type of drug-induced CH.

Drugs such as etretinate, lisinopril, sulfonamide, and trazodone make up a third form of drug-induced CH, but the serologic markers of autoimmune disease are absent.^{6,7,22} Patients with type 3 injury often have elevations in their aminotransferases with histologic evidence of chronic hepatitis.

Type 4 of drug-induced CH consists of agents, such as acetaminophen, aspirin, and dantrolene, which produce chronic toxicity rather than the chronic necroinflammatory disease that resembles chronic hepatitis.^{22,28,88,89}

Overall, the clinical picture of drug-induced CH has mixed characteristics, with features of both acute and chronic hepatic injury. Patients may first present with either features of acute hepatocellular injury or clinical evidence of cirrhosis. Physical examination often reveals a firm, enlarged liver, splenomegaly, and spider angiomas with or without ascites,

Jaundice, anorexia, and fatigue are common. Arthralgias or “arthritis” may occur. Serum transferase levels are usually moderately increased; hypoalbuminemia and coagulopathy are common.^{90,91} Recognition of drug-induced CH is extremely important because withdrawal of the responsible drug may lead to marked improvement and complete resolution of the injury within 4 weeks. However, continuation of these agents may lead to cirrhosis, fulminant hepatic failure and death.

SUBACUTE HEPATIC NECROSIS

Subacute hepatic necrosis (toxic cirrhosis) is different from acute necrosis and CH in that the clinical deterioration is slower than that seen in acute injury, yet it progresses faster than that associated with CH. Manifestations include a progressive, serious liver disease with deep jaundice and evidence of cirrhosis. Drugs that have been associated with this type of presentation include isoniazid,^{28,39} methyl dopa,^{6,90} nitrofurantoin,⁹¹ and propylthiouracil.⁹²

CHRONIC STEATOSIS

Compared with the acute microvesicular type of drug-induced steatosis, chronic steatosis is usually macrovascular and has minimal clinical manifestations. Ethanol, glucocorticoids, and a number of antineoplastic agents such as methotrexate (which all primarily lead to hepatomegaly) are agents associated with this type of insult.^{7,22} Glucocorticoid-induced steatosis appears to be benign, whereas methotrexate-induced steatosis can progress to cirrhosis. However, in some instances, the lesions seen in chronic steatosis may be microvesicular and lead to prominent hepatic disease (i.e., necrosis). This presentation has been reported with asparaginase and valproic acid. Valproic acid not only can induce microvesicular lipid deposits in the liver, but also causes fatty degeneration that can result in chronic liver failure with encephalopathy and a fatal outcome.^{7,22,74–79}

PHOSPHOLIPIDOSIS

PL occurs frequently and is caused by an amphiphilic drug (i.e., a drug that is both lipophilic and hydrophilic) that accumulates within the lysosomes. PL is usually clinically silent or causes only mild liver dysfunction. Hepatomegaly is the predominant feature of PL with or without other organ injury (e.g., PL of peripheral nerves, lungs, thyroid, and skin). Pseudoalcoholic liver disease (PALD) or nonalcoholic steatohepatitis (NASH) consisting of steatosis, focal necrosis, inflammatory aggregates, and Mallory bodies in association with PL have also been reported. These lesions have progressed to cirrhosis in several instances after long-term administration of amiodarone^{5,6,82,93,94} This clinical presentation of PALD or NASH can include hepatomegaly, ascites, spider angiomas, wasting syndrome, neuropathy, and moderate increase in aminotransferases (less than five times the upper limit of normal).

FIBROSIS AND CIRRHOSIS

CH, PL-associated PALD, chronic cholestatic injury, lesions affecting hepatic outflow, and chronic injury from methotrexate and etretinate can all lead to hepatic fibrosis and cirrhosis. Portal hypertension and its associated complications are the main characteristics in advanced cases.

Cholestatic Lesions

CHRONIC INTRAHEPATIC CHOLESTASIS

One form of drug-induced chronic intrahepatic cholestasis has features that resemble PBC, but it does not have some of the defining characteristics of PBC such as late-onset jaundice or antimitochondrial antibodies.^{5,7,82,83} Common clinical findings associated with this form of lesion are pruritus, early-onset jaundice, and elevated serum bilirubin and alkaline phosphatase levels, but only moderately increased AST and ALT levels. In advanced stages, xanthomatosis, ascites, edema, and portal hypertension may occur. Bile duct destruction and portal inflammation are less significant from chronic cholestatic-associated drug-induced injury compared with PBC, and it may lead to a unique form of the vanishing bile duct syndrome. Drugs reported to cause this syndrome include carbamazepine, haloperidol, imipramine, phenothiazines (chlorpromazine, prochlorperazine), sulfamethoxazole-trimethoprim, thiabendazole, and tolbutamide.^{5,7,82,83}

BILIARY SCLEROSIS

A second form of cholestatic cholestasis is biliary sclerosis, which has been observed in cases of bile duct injury produced by intrahepatic arterial infusion of floxuridine.⁹⁵ The incidence of injury due to floxuridine appears to be high. Clinical features include upper abdominal pain, anorexia, weight loss, and jaundice. Alkaline phosphatase levels are more than three times normal, whereas the aminotransferases are less than five times the normal limit.

Vascular Lesions

Four significant drug-induced vascular lesions have been reported, including hepatic vein thrombosis, hepatic venule occlusion, peliosis hepatitis, and hepatoportal sclerosis. Vascular injury that affects efferent blood flow (e.g., portal blood flow) to the liver leads to hepatic vein thrombosis. Budd-Chiari syndrome can be manifested by symptoms such as hepatomegaly, abdominal pain, ascites, moderate elevations in serum aminotransferases, and occasionally, jaundice.³⁸ Rapid deterioration and death may soon follow. This type of injury can be caused by oral contraceptives (OCs), and although the incidence remains low relative to the large number of women taking OCs, case-controlled studies demonstrate that women taking these agents have greater than double the risk compared with other women of developing this lesion.

Veno-occlusive disease as a result of injury and fibrotic occlusion of the terminal hepatic venules has clinical symptoms similar to those of Budd-Chiari syndrome and may result in death or can be followed by complete recovery. This type of hepatic injury has historically been associated with alkaloid derivatives (e.g., etoposide, vincristine, vinblastine), but agents such as thioguanine, azathioprine, chemotherapeutic agents (e.g., busulfan, cyclophosphamide, dactinomycin, methotrexate, mitomycin) and radiation injury serve as common etiologies.^{5,7,98} Additional etiologies of this type of injury include herbal medications or dietary supplements that are often obtained in natural food stores.⁹⁹

Peliosis Hepatitis

Peliosis hepatitis, a rarely encountered blood-filled cyst in the liver, can be caused by anabolic or contraceptive steroids, as well as related agents such as danazol.^{5,7,100} Most cases with

this type of injury are often associated with hepatic tumors or with cholestatic jaundice induced by the offending drug. Clinical manifestations include hepatomegaly, jaundice, or liver failure.¹⁰⁰ Occasionally, the cyst may rupture and result in a syndrome of hemoperitoneum.

Drug-induced portal hypertension may occur without evidence of cirrhosis.^{5,7,28} An example is hepatoportal sclerosis after chemotherapeutic or immunosuppressive therapy.^{5,7,101} Additional causes of this lesion include chronic exposure to inorganic arsenicals, copper sulfate, and vinyl chloride, as well as vitamin A intoxication.^{5,7,13,22} Clinically, splenomegaly, leukopenia, thrombocytopenia, pancytopenia, or esophageal varices may be present.

Granulomatous Hepatitis (Drug-Induced)

Granulomatous reactions are a common presentation of DILI and account for 2% to 29% of cases of granulomatous hepatitis. The clinical presentation includes fever, malaise, headache, and myalgia between 10 days and 4 months after the initiation of treatment, with splenomegaly present in up to 15% of cases. Hepatic granulomas are always noncaseating and can be surrounded by eosinophils. The granulomas can be accompanied by cytotoxic or cholestatic injury as part of a hypersensitivity reaction (e.g., allopurinol, methyldopa, penicillin, phenytoin, quinidine, sulfonamides) or without any clinical evidence of hepatic injury (e.g., gold salts).^{7,13,22,28,102} Up to 60 drugs have been associated with hepatic granulomas.^{5,7,22}

Neoplastic Lesions

Several associations between pharmacologic agents and liver tumors have been reported, but causality has been difficult to prove because of the infrequent nature of these events. Hepatocellular adenoma and carcinoma, although rare, are clearly associated with the use of OCs and anabolic (C-17 alkylated) steroids.^{5,7,103–107} Several cases of hepatic adenomas have involved women, virtually all of whom had a history of OC use. The results of two large, case-controlled studies suggest that the incidence is between 3 and 4 per 100,000 exposed persons annually. This represents a relative risk (compared with patients not receiving OCs) of approximately 20-fold in those patients ingesting OCs for <10 years and more than 100-fold in those exposed for >10 years.^{5,103} Similarly, some cases have been associated with anabolic steroid use in men.¹⁰⁴ Danazol has been associated with causing hepatocellular adenoma and carcinoma in humans, whereas griseofulvin, hycanthone, and isoniazid have been known to produce hepatocellular carcinoma in experimental animals.^{5,7,22} OCs have also been associated with causing hepatocellular carcinomas^{7,105} and possibly focal nodular hyperplasia.^{6,7,106,107}

In general, prognosis of DILI is good when the offending agent is withdrawn; however, the prognosis clearly is affected by the type of liver damage (injury vs. function as described earlier), the duration of the insult, and whether the hepatic damage is irreversible.^{5,13,14,22}

HERBAL SUPPLEMENT-INDUCED HEPATOTOXICITY

3. H.D. is a 48-year-old female with a history of chronic back pain secondary to an auto accident 3 years ago. She previously had taken oral Vicodin (hydrocodone 5 mg/acetaminophen

500 mg), 1 to 2 tablets Q 6 hr for pain relief, but recently, she discontinued the drug because of constipation; subsequently, the pain became worse. After several months of acupuncture as primary therapy, H.D. began taking the herbal supplement Jin Bu Huan per her mother's recommendation. However, after taking the herbal remedy for 2 months, H.D. began experiencing fever, fatigue, and mild abdominal pain. Her husband noticed that H.D. had also become "jaundiced" around that time; as a result, he brought her to the emergency department for treatment. Upon obtaining a careful medication history, laboratory tests revealed that H.D.'s ALT, AST, and total bilirubin were 1,378 U/L, 1,333 U/L, and 3.9 mg/dL, respectively. A biopsy was also obtained, and the results are pending. What is the association between herbal medications and hepatotoxicity?

Previous reports indicated that 3% of the population of the United States had taken herbal medications for a variety of reasons (e.g., analgesia, sedation, nutrition, weight reduction, skin disorders).^{99,108–118} Herbals used for treating these diseases can be derived from the root, stem, leaf, or seed of a plant and are available as crude and commercial products. Recent studies show that 42% of Americans take some form of complementary and alternative medicine, and that herbal medicine use is now estimated to be 12.5%. In the United States, herbal products are labeled as dietary supplements, which are not expected to meet the standards for drugs specified in the Federal Food, Drug, and Cosmetic act. Because they are exempt from the rigorous regulations that are required for drug approval in the United States, there are considerable disparities in the composition of these agents. In addition, 20% to 30% of patients attending hepatology clinics use herbal remedies on the erroneous assumption that these agents are "natural" and, therefore, safe.^{111,113} Although herbal remedies have historically been considered benign, a plethora of information has suggested that many agents are associated with toxic effects and they are not safe (Table 29-8). Some include asafetida, chaparral leaf, camphor, carp capsules, comfrey, dai-saiko-to (TJ-9), gentian, germander, greater celandine, hops, impila, isabgol, kava, mistletoe, mother wart, pennyroyal oil, senna fruit extract, skullcap, and valerian.^{99,111,113,117} Adverse effects usually manifest when the recommended threshold for toxic doses are surpassed, although the duration of therapy may also be a factor. The range of herbal-induced liver injury includes minor transaminase elevations, acute and chronic hepatitis, steatosis, cholestasis, zonal or diffuse hepatic necrosis, hepatic fibrosis and cirrhosis, veno-occlusive disease, and acute liver failure requiring liver transplantation.⁹⁹

In one representative report, seven adult patients ingesting Jin Bu Huan, a traditional herbal remedy used primarily as a sedative and analgesic, presented with fever, fatigue, nausea, pruritus, abdominal pain, jaundice, and hepatomegaly at a mean time of 20 weeks (range, 7–52 weeks) after ingestion of normal doses of this agent.^{111,113,118} Serum transaminases were increased 20- to 50-fold in most cases. One patient who had taken the agent for 12 months underwent a liver biopsy, which showed lobular hepatitis with microvesicular steatosis. Resolution of liver injury occurred within 8 weeks after the cessation of therapy. Other than a female predominance, no predisposing risk factors for developing liver disease were evident in this case series. However, it appears that concomitant agents that induce cytochrome P450 enzymes may also increase

Table 29-8 Selected Herbal Medications/Remedies Associated With Hepatic Injury¹⁰⁸⁻¹¹⁸

| Herb | Proposed Use | Toxic Ingredient | Feature of Hepatic Injury |
|--|--------------------------------|---------------------------------------|---|
| Comfrey Gordolobo yerba tea Mate tea | Health tonic | Pyrrrolizidine alkaloids | Veno-occlusive disease |
| Chinese medicinal tea | Health tonic | T'u-san-chi'i (Compositae) | Veno-occlusive disease |
| Jin bu huan | Sedative, analgesic | <i>Lycopodium serratum</i> | Hepatocellular injury: hepatitis, fibrosis, steatosis |
| Chinese herbs | Eczema, psoriasis | Many | Nonspecific hepatic injury |
| Germander (tea, capsules) | Weight reduction, health tonic | <i>Teucrium chamaedrys</i> | Hepatitis: necrosis, fibrosis |
| Chaparral leaf | Herbal remedy | <i>Larrea tridentata</i> | Hepatic necrosis |
| Mistletoe/skullcap/valerian | Herbal tonic, cathartic | Senna, podophyllin, aloin | Elevated liver function tests |
| Margosa oil | Tonic | <i>Melia azadirachta indica</i> | Reye's syndrome |
| Pennyroyal oil (squaw mint) | Abortifacient, herbal remedy | Labiatae plants (possibly diterpenes) | Elevated liver function tests |
| Oil of cloves | Dental pain | Unknown | Dose-dependent hepatotoxin |

susceptibility to developing liver disease. In summary, because herbal agents are readily available, are not subject to rigorous purity testing or regulation, and may often contain small amounts of arsenic or cadmium, it is critical for clinicians to obtain a detailed medication use history when evaluating atypical cases of liver injury. H.D. should discontinue this agent and, pending the biopsy results, be followed closely for the next few weeks for resolution of her liver injury. However, if her symptoms worsen, liver transplantation may be necessary.

PATIENT ASSESSMENT

4. K.V., a 52-year-old female with a 12-year history of type 2 diabetes is admitted with a 2-week history of nausea, anorexia, fatigue, and intense generalized pruritus. She noted dark urine, light-colored stools, and yellow pigmentation of the skin about 10 days ago, which has progressively worsened. She reports no history of fever, rash, vomiting, abdominal pain, or fatty food intolerance. She denies use of alcohol or recreational drugs and has never had a blood transfusion nor has she recently traveled to a foreign country. Her medical history includes diabetes controlled by diet and pioglitazone (for the past 18 months) and hypertension treated with hydrochlorothiazide (HCTZ) and lisinopril for the past 4 years. One month ago, K.V. was treated with a 10-day course of amoxicillin-clavulanic acid (Augmentin) for sinusitis, but her symptoms remained throughout therapy. Subsequently, she was placed on a 5-day course of telithromycin.

On admission, K.V. appears weak and icteric. Other significant findings include scratch marks and a slightly tender, but normalized, liver. Vital signs are all within normal limits. Laboratory findings show the following: serum AST, 430 U/L; serum ALT, 294 U/L; alkaline phosphatase, 1,230 U/L; conjugated bilirubin 0.8 mg/dL (range 0.0–0.2 mg/dL); total bilirubin 3.8 mg/dL (range 0.2–1.1 mg/dL); and albumin, 4.1 g/dL. All other chemistry data are within normal limits. Complete blood count (CBC) and differential count are normal. Serologic tests for hepatitis A, B, and C all are negative. Ultrasound with a subsequent magnetic resonance image (MRI) shows a normal biliary tract system with no obstruction in the bile ducts or gallbladder or near the end of the pancreas. Liver biopsy showed preserved normal liver architecture, marked centrilobular cholestasis with bile pigment in hepatocytes and canaliculi, and a mild portal inflammatory infiltrate with an excess of eosinophils.

K.V. is placed on a 1,200-calorie daily diet with no added salt and regular insulin before meals titrated to a premeal glucose level of 100 to 150 mg/dL. All other drugs are discontinued. Cholestyramine (Questran) 4 g PO TID is started for itching. By the fifth day of hospitalization, her laboratory values are as follows: AST, 85 U/L; ALT, 214 U/L; alkaline phosphatase, 288 U/L; and conjugated/total bilirubin 0.3 mg/dL and 1.8 mg/dL, respectively. Her blood pressure increased to 190/105 mmHg and HCTZ 25 mg/day is restarted with a plan to add a calcium channel blocker if this does not adequately control her blood pressure. What signs and symptoms are suggestive of DILI in K.V.?

Diagnosis

There is no single test, including a liver biopsy that can be used to diagnose DILI.^{1,2,22} Routine screening of serum aminotransferases in patients taking potentially hepatotoxic drugs generally is not recommended because the changes in laboratory tests often are delayed or erratic in onset, making detection of abnormalities difficult. Elevations of less than three times normal may reflect normal variations or spurious laboratory results. However, minor elevations that continue to trend upward on repeat evaluations or that are more than three times normal are cause for concern, especially in the presence of increased bilirubin levels. The presence of nonspecific symptoms ranging from anorexia, nausea, and fatigue to more specific symptoms, such as jaundice, in the setting of the administration of prescription or nonprescription medications or dietary supplements should direct suspicion toward drug-related hepatic injury. Other potential causes of liver injury in the diagnostic workup must also be ruled out including: (a) hepatitis A, B, and C (or hepatitis E with a history of recent travel to a developing country); (b) alcoholic or autoimmune hepatitis; (c) biliary tract disease; (d) hemodynamic insults; and (e) genetic and metabolic disorders (e.g., hemochromatosis α_1 -antitrypsin deficiency or Wilson's disease)^{1,2,22} (see Fig. 1). Thus, liver injury in the absence of another etiology could be drug-induced, but a meticulous drug history in relation to the onset of the injury is mandatory. The clinical presentation of hepatotoxicity is most evident with acute hepatocellular injury and cholestatic liver disease.

In K.V., weakness, anorexia, dark urine, light-colored stools, icterus, pruritus, hyperbilirubinemia, and a high-serum alkaline phosphatase concentration suggest cholestatic jaundice.

Table 29-9 Components and Caveats in Assessing Cause in the Diagnosis of Drug-related Hepatic Injury^{1,2}

1. Exposure to a drug must precede the onset of liver injury for diagnosis as drug-induced.
Caveat: The latent period for the onset of injury after drug use is highly variable.
2. Disease as a cause of liver injury should be ruled out before concluding that hepatotoxicity is drug related.
Caveat: Drugs taken concurrently should also be evaluated.
3. Injury may prove when administration of a drug is stopped (dechallenge).
Caveat: Liver injury may initially worsen for days or weeks. In severe cases, falling enzyme levels may indicate impending liver failure, not improvement, especially if accompanied by worsening function.
4. Liver injury may recur more rapidly and severely on repeated exposure, especially if immunological in nature. (rechallenge)
Caveat: Worsening on rechallenge may not occur if adaptive tolerance has occurred.

The slightly tender liver and the high-serum concentrations of AST and ALT suggest hepatocellular damage. K.V.'s clinical presentation is consistent with that of a mixed cholestatic-cytotoxic hepatic injury.

Etiology

5. How can the potential etiology of DILI be determined, and what was the most likely etiology in K.V.?

Drug-induced liver injury should be suspected in every patient with jaundice. Relevant elements and caveats in assessing the cause of DILI are outlined in Table 29-9. A negative history of fever, abdominal pain, and fatty food intolerance rule out gallbladder disease in K.V. She has no history of alcoholism and her viral hepatitis serologic tests are negative. In addition, negative ultrasound studies rule out the possibility of extrahepatic obstructive jaundice.

The presence of dark urine rules out unconjugated hyperbilirubinemia, which may be associated with hemolysis. AST elevations alone may be seen in injury to cardiac and skeletal muscles, but together with increased ALT, as in K.V., usually indicate hepatic origin. The presence of eosinophils in the liver biopsy, together with the rapid decline of serum aminotransferases, alkaline phosphatase, and bilirubin concentrations toward normal when all drugs are withdrawn, supports the assessment of drug-induced hepatitis in K.V.

There are several possible causes for K.V.'s drug-induced hepatitis, including telithromycin, amoxicillin-clavulanic acid, pioglitazone, hydrochlorothiazide, and lisinopril. Hydrochlorothiazide is an unlikely candidate because allergic cholestatic jaundice is very rarely associated with thiazide diuretics, and K.V. has taken the drug for 4 years. Lisinopril, like other angiotensin-converting enzyme inhibitors, can cause acute hepatocellular injury with mostly mixed hepatocellular and cholestatic injury; pure hepatocellular injury is rare. Furthermore, most cases of lisinopril-induced hepatic injury occur within the first 14 weeks of exposure.¹¹⁹⁻¹³⁷ Thus, lisinopril, which is known to cause mixed hepatocellular injury, is probably not the causative agent in K.V. based on the time frame

of the presentation of hepatic injury. Pioglitazone, on the other hand, has been reported to cause a mixed cholestatic-cytotoxic injury, but not to the same degree as its predecessor, troglitazone, which was previously withdrawn from the market due to over 90 cases of hepatotoxic effects (68 fatalities and 10 required liver transplantation).¹²³⁻¹³⁰ There are few reports of pioglitazone-associated hepatotoxicity. In one case, a 49-year-old male taking 30 mg/day for 6 months was found to have an ALT level three times the upper limit of normal, and a serum bilirubin concentration five times the upper limit of normal.^{1,22,129} Therefore, it is unlikely in K.V. because she had been taking pioglitazone for 18 months and her ALT elevation is not consistent with those previously reported. Amoxicillin-clavulanic acid, a semisynthetic penicillin-lactamase inhibitor combination drug, has been reported to cause hepatic dysfunction and jaundice in a number of patients.¹³¹⁻¹³⁴ The latent period between the initiation of the drug and onset of jaundice or hepatic dysfunction ranged from 2 to 45 days with a mean of 27 days. In review of K.V.'s recent history of amoxicillin-clavulanic acid intake and the physical and laboratory findings, amoxicillin-clavulanic acid is a probable cause of DILI.

Additionally, telithromycin, the first ketolide agent approved by the FDA, was designed to have improved antimicrobial activity and pharmacokinetics compared to macrolide antimicrobials. Although the occurrence of telithromycin related hepatotoxicity is rare (1.6%) based on clinical trials, the precise incidence is unknown. The FDA Adverse Reporting System described 10 postmarketing cases of hepatic adverse events associated with telithromycin use.^{131,135-137} The severity of the reactions ranged from serious to fatal (two deaths) and was associated with cholestatic hepatitis, abnormal aminotransferase levels, increased bilirubin levels, liver disorder, cholestatic jaundice, and hepatocellular damage. The duration of administration of telithromycin ranged from 1 to 30 days, and patients were from 35 to 85 years of age. In 2006, the FDA announced changes to the product labeling for telithromycin to warn healthcare practitioners and patients about the risk of liver injury. This was based on several reports of serious liver injury and liver failure, along with four deaths and one liver transplant. Furthermore, another case series describe similar cases of severe DILI secondary to telithromycin use resulting in death or liver transplantation. Thus, K.V.'s recent exposure to telithromycin and her laboratory and physical findings are consistent with telithromycin-induced liver injury. Nevertheless, the possibility of hydrochlorothiazide- or pioglitazone-induced hepatic injury cannot be ruled out without an inadvisable rechallenge test with one or both of these drugs.

Procedure to Determine

To determine the cause of DILI, a detailed drug history should be obtained for all patients with jaundice (Table 29.10). Special attention should be paid to the duration of exposure to a specific drug and its relationship to the onset of symptoms. A history of taking OCs, nonprescription drugs such as laxatives and vitamins, and illicit drug use should not be overlooked and obtained. Predisposing factors to drug-induced hepatitis, if any, should be noted (Table 29-1). The presumptive diagnosis of DILI requires a history of exposure to a drug, awareness of the characteristic syndromes produced by various agents,

and a search for supportive evidence. If the liver injury is accompanied by fever, rash, and eosinophilia, the likelihood of drug-induced disease increases. In some instances, these features may be associated with lymph node enlargement, lymphocytosis, and atypical circulating lymphocytes, leading to a syndrome that mimics infectious mononucleosis and serum sickness. Additional plausible systemic manifestations are listed in Table 29-7. Lack of these features, however, does not exclude the possibility of drug-induced disease.^{2,7,222,224} As described previously, differentiation of DILI from viral hepatitis involves evaluation of the epidemiologic circumstances; serologic studies to detect hepatitis A, B, or C antigens or antibodies; and determination of whether a history of receiving blood transfusions or injection with a contaminated syringe exists. Distinction between drug-induced cholestatic jaundice and extrahepatic obstructive jaundice often requires radiographic or ultrasonic studies. If liver biopsy reveals cholestasis with an eosinophil-rich portal inflammation, as observed in K.V., drug-induced causes are more likely.

Rechallenge With Offending Agent

6. Should K.V. be given a challenge dose of amoxicillin-clavulanic acid or telithromycin to confirm the cause of her DILI?

Confirmation of the cause may be obtained by giving a rechallenge dose of the incriminated drug. Recurrence of hepatic dysfunction or hyperbilirubinemia after a test dose offers valuable support for the diagnosis. Failure to develop abnormalities, however, does not preclude drug-induced dysfunction, because only 40% to 60% of patients show a recurrence of hepatic injury after a test dose.^{1,2,5,7,20} Furthermore, some drugs will produce the hepatic injury only after an extended period (1 to 12 weeks) of readministration. Testing for the effect of a challenge dose can be potentially dangerous if the drug is known to cause hepatocellular injury, whereas rechallenge is considered safe if the drug usually leads to cholestasis alone. Therefore, risk must be weighed against benefit before giving a challenge dose of an incriminated drug to a patient.

Rechallenge of K.V. with amoxicillin-clavulanic acid or telithromycin is potentially dangerous given her clinical picture consistent with hepatocellular injury. Rapid occurrence of jaundice and liver enzyme abnormalities following rechallenge with amoxicillin-clavulanic acid or telithromycin suggests an immunoallergic type of idiosyncrasy.^{1,5,7,20,22,28} Since alternative antibiotics can be used to manage K.V.'s infection, rechallenging with amoxicillin-clavulanic acid or telithromycin is not recommended, because a recurrent injury may be more severe than the initial insult.

Management

7. Was K.V. treated appropriately for her suspected drug-induced hepatic injury?

If patients present with symptoms, especially jaundice and signs of acute liver failure (e.g., encephalopathy) the administration of any potential hepatotoxic agent should be discontinued. To assess liver injury, biochemical tests should be obtained at baseline and serially; consultation with a gastroenterologist

or hepatologist is recommended. In most cases of DILI improvement occurs, but at variable rates. Worsening of DILI may occur followed by a long protracted course of recovery (weeks to months), and may be seen following discontinuation of the suspected offending agents. In K.V.'s case, all medications taken before admission were discontinued and an atypical rapid recovery was observed. The management of drug-induced jaundice is similar to the treatment of other hepatic diseases. Treatment usually includes a diet high in carbohydrates, moderately high in protein, and adequate in calories (e.g., 2,000–3,000 calories/day). However, a lower caloric diet was prescribed for K.V. because of her diabetes. Treatment of jaundice is mainly supportive. If itching is severe, the use of cholestyramine to enhance the rate of bile acid excretion may alleviate the symptoms. If possible, the use of amoxicillin-clavulanic or telithromycin acid should be avoided in K.V., and appropriate alternative drugs should be used instead. If present, ascites, esophageal variceal bleeding, and other complications are treated accordingly. The use of large doses of glucocorticoids (e.g., 1,000 mg hydrocortisone/day) in acute hepatic failure is largely empirical and may have a role in hypersensitivity related cases, but otherwise is not recommended.^{13,25–27} There was no indication of these complications in K.V.

8. What preventative measures can be taken to minimize the risk of DILI in patients like K.V.?

During the stages of drug development, opportunities to prevent hepatotoxicity occur.^{1,19,22} Preclinical animal data can help detect dose-related, predictable hepatotoxicity rather than unpredictable hepatotoxicity in humans. Phase 1 drug trials provide the initial opportunity to assess the hepatotoxic risk of drugs in humans. Generally, these trials have a small number of subjects and the duration of exposure of an agent is short at relatively low dosages. As a drug enters phase 2 trials, exposure to higher dosages occurs, but the relatively small number of patients still limits the determination of hepatotoxic risk. During phase 3 efficacy trials, more patients can be exposed to a drug and the relative likelihood of hepatotoxicity is increased. However, there are still relatively low numbers of patients enrolled in clinical trials, and to predict a true incidence of hepatotoxicity in 1 in 1,000 patients requires at least 3,000 be studied. Thus, phase 3 clinical trials may underpredict the true risk of a drug's hepatotoxic potential.

Perhaps the most significant time period for recognizing drug-induced liver injury is in the postmarketing time period.^{1,19,22} During this time, several thousand patients may be exposed to an agent and surveillance programs such as the FDA MedWatch program may help elucidate and report drug-related hepatotoxicity. This type of program is voluntary, and probably underreports the frequency and severity of DILI. Clinicians should also rely on case reports that appear in the medical literature to help guide or confirm suspicion of the risk of drug-related hepatotoxicity from prescription drugs, over the counter drugs, herbal (dietary) supplements, or other alternative medications. Additionally, patients should be educated on the recognition and symptoms of DILI and instructed to report any perceived adverse events promptly (Table 29-10). Finally, the evolving science of pharmacogenomics may help clinicians predict those at greatest risk of DILI, but currently genetic testing has not been added to

Table 29-10 Essential Guidelines in the Recognition and Prevention of Hepatotoxicity in Clinical Practice^{1,2}

| | |
|----------------------------|--|
| Do not ignore symptoms | When a drug is being used, even vague symptoms such as nausea, anorexia, malaise, fatigue, and right upper quadrant pain as well as specific symptoms such as itching or jaundice should prompt consideration of hepatotoxicity. Testing for liver injury and abnormal function should be performed. |
| Take a careful history | Elicit a detailed history of prescribed and nonprescribed over-the-counter herbal and other medications or remedies with dates and amounts. |
| Remove the causative agent | Discontinue the causative agent or agents, especially if symptoms have occurred or abnormal liver function (e.g., increased bilirubin level or prothrombin time) exists. Watch closely over time for changes and consult a hepatologist or gastroenterologist. |
| Pay attention to “Hys” Law | Jaundice that appears after drug-induced hepatocellular liver injury suggests a serious and potentially fatal liver problem, consult a specialist at once. |
| Report the injury | 1-800-332-1088 (telephone) 1-800-332-4178 (fax) http://www.fda.gov/medwatch Provide information for differential diagnosis and assessment of cause, time course of the reaction, and normal ranges of laboratory tests. |

routine patient management strategies. The ability to implement novel fields, such as proteonomics and metabonomics, may also provide insight into establishing the mechanisms of DILI.

DRUGS REPORTED TO CAUSE CLINICALLY SIGNIFICANT HEPATIC DYSFUNCTION

There are many reports of drug-related hepatitis in the literature. Most of these are reports of single cases involving one drug and are difficult to evaluate. Furthermore, hepatic drug effects that occurred early after exposure may differ in character from those that occurred later (e.g., chlorpromazine). In addition, certain drugs may cause various types of morphologic responses via different mechanisms (i.e., hepatotoxic vs. idiosyncratic). In an attempt to summarize and facilitate discussion of the vast amount of information on this subject, selected drugs that have been implicated in causing significant

liver dysfunction are listed in Table 29-4. The hepatotoxicity of acetaminophen (see Chapter 5, Managing Acute Drug Toxicity), antituberculous agents (see Chapter 61, Tuberculosis) and certain antiretrovirals (see Chapter 69, Pharmacotherapy of Human Immunodeficiency Virus Infection) are included in other chapters. The types of morphologic findings and presumed mechanisms of hepatotoxicity for each drug are presented in Table 29-4. References are listed so that more detailed information may be obtained if desired. In the column labeled “Clinical Remarks,” prominent clinical features, such as clinical presentation, dose, and duration of therapy associated with the adverse effect, pertinent laboratory data, and prognosis are summarized.

ACKNOWLEDGMENT

The author would like to acknowledge Amy Choi for her contribution to this chapter.

DEFINITION

Acute renal failure (ARF) is characterized clinically by an abrupt decrease in renal function over a period of hours to days, resulting in the accumulation of nitrogenous waste products (*azotemia*) and the inability to maintain and regulate fluid, electrolyte, and acid–base balance.¹ Many attempts have been made to objectively quantify ARF based on laboratory data, daily urine output, or the need for renal replacement therapy (RRT), but a consensus using these parameters has not been attained. Traditionally, ARF has been defined as an increase in serum creatinine (SrCr) of >0.5 mg/dL when the baseline SrCr is <2.5 mg/dL, and an increase in SrCr of >1.0 mg/dL when the baseline SrCr is >2.5 mg/dL.¹ These criteria are often inaccurate because SrCr and glomerular filtration rate (GFR) do not follow a linear relationship. Diagnosing ARF solely on creatinine concentration is problematic because many pa-

tients are in a high catabolic state as a result of their critical illness. Catabolism leads to the accumulation of creatinine and noncreatinine waste products (urea nitrogen), organic acids, water, and electrolytes. To help clarify much of this confusion, the Acute Dialysis Quality Initiative created an international expert panel, which has proposed a new classification system named “RIFLE.”² This system represents various stages of ARF, including risk, injury, failure, loss (defined as the need for dialysis at least 1 month following failure), and finally “end-stage renal disease.” Although it is too early to tell if this new classification system will provide advantages over traditional definitions, it represents a significant step forward to detect and prevent ARF. Regardless of the definitions used, the clinician should suspect ARF when the kidney is unable to regulate fluid, electrolyte, acid–base, or nitrogen balance, even in the presence of a normal SrCr concentration.

EPIDEMIOLOGY

Acute renal failure occurs almost exclusively in hospitalized patients; hallmark studies conducted in the United States and abroad indicate the incidence of *community-acquired ARF* (development of ARF before hospitalization) is just 1%; approximately 75% of these admissions result from decreased kidney blood flow, termed *prerenal azotemia*. Other less-common causes include obstructive uropathy (17%) and intrinsic renal disease (11%).³ Community-acquired ARF can usually be reversed by correcting the underlying problems of volume status or obstruction. Hospital-acquired ARF is much more common, and the incidence and severity vary based on intensive care unit (ICU) or non-ICU setting.⁴ The incidence of ARF in general medicine patients is approximately 2% to 5%, with the most common causes being prerenal azotemia, postoperative complications, or nephrotoxin exposure. These patients can experience one or more of these renal insults throughout their hospitalization. Conversely, ICU-acquired ARF is more prevalent and severe. Data suggest the incidence of ARF in patients in the ICU approaches 25%, stemming from multiple risk factors, including older age, infection, nephrotoxin exposure, male gender, multiorgan dysfunction, and the need for mechanical ventilation.⁵ Although many patients with ARF will initially require dialysis, a small percentage will develop end-stage renal disease requiring long-term dialysis.

PROGNOSIS

Despite recent advances in dialysis delivery and the development of sophisticated continuous RRT, ARF continues to have a grim prognosis. Indeed, the occurrence of ARF in critically ill patients carries at least a 50% mortality rate.⁶ Worse yet, the mortality rate increases correspondingly by 10% with each additional failed organ system. The mortality rate of ARF has declined minimally during the last 50 years. This slow decline may be explained in part by three important factors. First, patients are older when they develop ARF. Second, patients are often afflicted with serious underlying medical illnesses beyond ARF. Third, the clinical severity status of the patient is much higher now than ever before. Before the widespread availability of RRT, the most common causes of death in patients with ARF were fluid and electrolyte disorders and advanced uremia. Today, the most common causes of death are infection, bleeding, cardiopulmonary failure, and withdrawal of life support.^{7,8}

CLINICAL COURSE

Three distinct phases of ARF exist. The *oliguric phase* generally occurs over 1 to 2 days and is characterized by a progressive decrease in urine production. Urine production of <400 mL/day is termed *oliguria*, and urine production of <50 mL/day is termed *anuria*. The oliguric stage may last from days to several weeks. *Nonoliguric renal failure* (>400 mL/day of urine output) carries a better prognosis compared with oliguric renal failure, although the exact reason remains unknown. Similarly, the shorter the duration of oliguria, the higher the likelihood of successful recovery. This is probably because the

renal insults in these cases are less severe (e.g., dehydration, nephrotoxin exposure, postrenal obstruction). Strict fluid and electrolyte monitoring and management are required during this phase until renal function normalizes.

After the oliguric phase, a period of increased urine production occurs over several days; this is called the *diuretic phase*. This phase signals the initial repair of the kidney insult. The diuretic phase can result, in part, from a return to normal GFR before tubular reabsorptive capacity has fully recovered. The elevated osmotic load from uremic toxins and the increased fluid volume retained during the oliguric phase may also contribute to the diuretic phase. Despite the increased urine production, patients may remain markedly azotemic for several days. Daily modifications in the fluid and electrolyte requirements are necessary based on urine output.

The *recovery phase* occurs over several weeks to months, depending on the severity of the patient's ARF. This phase signals the return to the patient's baseline kidney function, normalization of urine production, and the return of the diluting and concentrating abilities of the kidneys.

PATHOGENESIS

The production and elimination of urine requires three basic physiologic events.

- Blood flow to the glomeruli
- The formation and processing of ultrafiltrate by the glomeruli and tubular cells
- Urine excretion through the ureters, bladder, and urethra

Many conditions can alter the above physiologic events leading to ARF. These are classified as *prerenal azotemia*, *functional*, *intrinsic*, and *postrenal* ARF (Table 30-1). It is possible for more than one of these categories to coexist.

Normal renal function depends on adequate renal perfusion. The kidneys receive up to 25% of cardiac output, which is >1 L/minute of blood flow. Prerenal azotemia occurs when blood flow to the kidneys is reduced. Major causes include decreased intravascular volume (e.g., hemorrhage, dehydration, including overdiuresis), decreased effective circulating volume states (e.g., cirrhosis or chronic heart failure [CHF]), hypotensive events (e.g., shock or medication-related hypotension), and renovascular occlusion or vasoconstriction. Because no structural damage occurs to the kidney parenchyma per se, correcting the underlying cause rapidly restores GFR. Sustained prerenal conditions can result, however, in glomerular ischemia causing acute tubular necrosis (ATN).

Functional ARF results when medical conditions or drugs impair glomerular ultrafiltrate production or intraglomerular hydrostatic pressure. Blood travels through the afferent arteriole and enters the glomerulus, where it is filtered, and exits through the efferent arteriole (Fig. 30-1). The afferent and efferent arterioles work in concert to maintain adequate glomerular capillary hydrostatic pressure to form ultrafiltrate. Many medications can drastically reduce intraglomerular hydrostatic pressure and GFR by producing afferent arteriolar vasoconstriction or efferent arteriolar vasodilation (Fig. 30-2).

Intrinsic ARF can occur at the microvascular level of the nephron, glomeruli, renal tubules, or interstitium. Vasculitic diseases (e.g., Wegener's granulomatosis, cryoglobulinemic

Table 30-1 Causes of Acute Renal Failure

| <i>Classification</i> | <i>Common Clinical Disorders</i> |
|---|--|
| <i>Prerenal Azotemia</i> | Intravascular Volume Depletion |

| <i>Postrenal Acute Renal Failure</i> | Ureter Obstruction (Bilateral or Unilateral in Solitary Kidney) |
| | Malignancy (prostate or cervical cancer) |
| | Prostate hypertrophy Anticholinergic drugs (affect bladder outlet muscles) |
| | Renal calculi |

vasculitis) involve the small vessels of the kidney. Glomerulonephritis and systemic lupus erythematosus, although relatively uncommon, result in glomerular damage. ATN is by far the most common cause of intrinsic ARF. In fact, the term *acute tubular necrosis* is often used interchangeably with *ARF*. ATN occurs in part because the renal tubules require high oxygen delivery to maintain their metabolic activity. Consequently, any condition that causes ischemia to the tubules (e.g., hypotension, decreased blood flow) can induce ATN. Moreover, the tubules may be exposed to exceedingly high concentrations of

nephrotoxic drugs (e.g., aminoglycosides). Interstitial nephritis or inflammation within the renal parenchyma, is most often associated with drug administration (e.g., penicillins).

Postrenal ARF occurs when there is an outflow obstruction in the upper or lower urinary tract. Lower tract obstruction is most common and can be caused by prostatic hypertrophy, prostate or cervical cancer, anticholinergic drugs that cause bladder sphincter spasm, or renal calculi. Upper tract obstruction is less common and occurs when both ureters are obstructed or when one is obstructed in a patient with a single

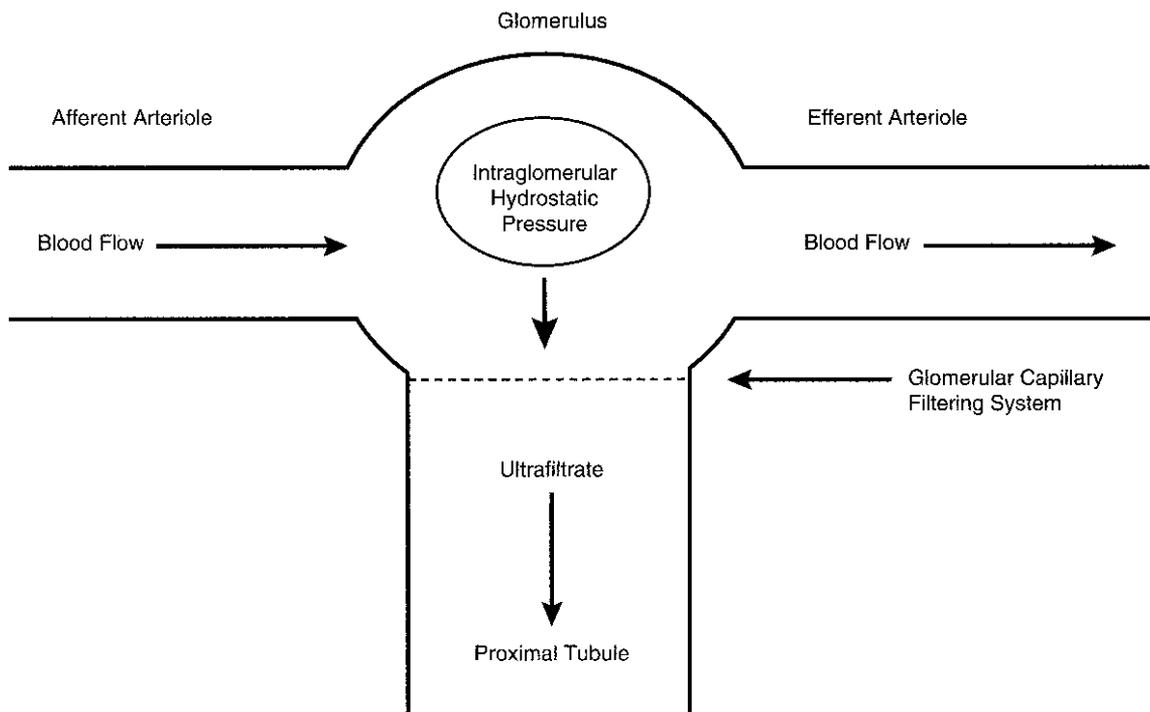

FIGURE 30-1 Schematic of renal blood flow. Blood enters the glomerulus via the afferent arteriole. The intraglomerular hydrostatic pressure leads to ultrafiltration across the glomerular into the proximal tubule. The unfiltered blood leaves the glomerulus via the efferent arteriole. In conditions of decreased renal perfusion, efferent arteriolar vasoconstriction occurs to increase intraglomerular hydrostatic pressure and maintain ultrafiltrate production. Afferent arteriolar vasodilation also occurs to improve blood flow into the glomerulus.

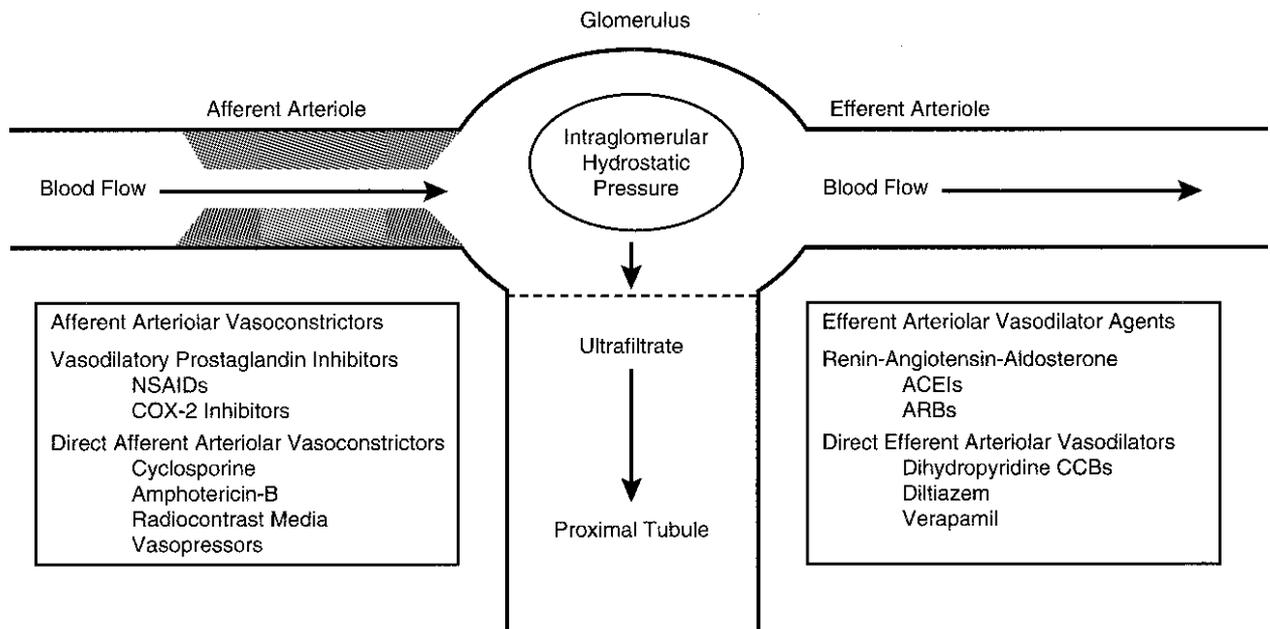

FIGURE 30-2 Drugs that alter renal hemodynamics by causing afferent arteriole vasoconstriction or efferent arteriole vasodilation. ACEIs, angiotensin-converting enzyme inhibitors; ARBs, angiotensin II-receptor blockers; CCBs, calcium channel blockers; COX-2, cyclooxygenase-2; NSAIDs, nonsteroidal anti-inflammatory drugs.

functioning kidney. Postrenal ARF usually resolves rapidly after the obstruction has been removed. Postobstructive diuresis can be dramatic (e.g., 3–5 L/day).

CLINICAL EVALUATION

History and Physical Examination

A detailed history and physical examination often reveal the cause(s) of ARF. The clinician's responsibility is to ask specific, open-ended questions regarding the patient's chief complaint; history of present illness; medical history; family, social, and allergy history; and current prescription and nonprescription medication use. Probing for pertinent information regarding recent surgery, nephrotoxin exposure, or concurrent medical conditions can aid in rapidly determining the etiology of ARF. For example, does the patient have pre-existing conditions that point toward prerenal azotemia, such as CHF or liver disease? Did the patient receive prophylactic antibiotics before surgery? Did the patient hemorrhage or have protracted hypotension during surgery? Furthermore, assessment of the vital sign flowchart for documented weight loss, hypotensive events, fluid intake, and urine output may also prove useful.

A thorough physical examination, when used in conjunction with the history, can be invaluable in confirming the cause of ARF. The patient's volume status should be evaluated first. Evidence of dehydration (e.g., syncope, weight loss, orthostatic hypotension) or decreased effective circulating volume (e.g., ascites, pulmonary edema, peripheral edema, jugular venous distention) usually indicates prerenal azotemia. The presence of edema in a patient with normal cardiac function can, however, signal the early signs of nephrotic syndrome. Concurrent rash and ARF associated with recent antibiotic exposure suggest drug-induced allergic interstitial nephritis. The clinician should suspect rhabdomyolysis in a patient with trauma or crush injuries and ARF. An enlarged prostate, painful urination, or wide deviations in urine volume can suggest obstructive ARF causes. Flank and lower abdominal pain suggest upper obstruction, whereas urinary frequency, hesitancy, dribbling, and abdominal fullness indicate lower obstruction.

Laboratory Evaluation

Quantifying Glomerular Filtration Rate

Because of the dynamic changes that occur in ARF, it is difficult to quantify renal function accurately in this population. Although equations were created decades ago to address the dynamic changes in SrCr during ARF, none have proved helpful. One of the most widely used clinical measures for estimating GFR is determination of creatinine clearance (CICr). Creatinine is produced at a relatively constant rate by nonenzymatic hydrolysis of muscle stores of creatine and phosphocreatine. An individual's muscle mass, age, and sex are predictors of creatinine production. Under steady-state conditions, the urinary excretion of creatinine equals the creatinine production rate, and the SrCr concentration remains relatively stable. Creatinine is freely filtered at the glomerulus, with about 10% to 20% eliminated by active tubular secretion. Consequently, the CICr overestimates the true GFR by 10% to 20%. As GFR declines further, tubular creatinine secretion can account for up to 50% of creatinine elimination, which may overestimate

actual GFR by as much as 100%. Commonly used drugs, such as trimethoprim, can inhibit the secretion of creatinine. Accordingly, administration of these agents can increase the SrCr and decrease CICr without affecting GFR.⁹ Various methods for determining CICr have been developed, including urine and nonurine methods. All these methods have potential limitations and pitfalls when used in patients with ARF. Clinicians commonly use nonurine methods for estimating kidney function. The Cockcroft-Gault (CG) equation is one method commonly used to estimate CICr¹⁰:

$$CICr = \frac{(140 - \text{Age}) (IBW)}{(72) (SrCr)} \quad 30-1$$

where age is in years, *IBW* is ideal body weight in kilograms [male $IBW = 50 + (2.3 \text{ height} > 60 \text{ inches})$; female $IBW = 45 + (2.3 \times \text{height} > 60 \text{ inches})$], and *SrCr* is the serum creatinine concentration (mg/dL).

For women, the CG equation is multiplied by 0.85 to account for decreased muscle mass. The CG equation should not be used to estimate GFR in patients with rapidly changing SrCr concentrations because it was derived from normal, healthy subjects with stable renal function. The CG equation produces falsely high CICr estimates in the early stages of ARF and falsely low CICr estimates when ARF is resolving. An example of this is a patient who develops ATN and anuria. Within the first few days, the creatinine level may increase slightly because it takes time for the serum creatinine concentration to achieve a new steady state. In fact, the calculated CICr may even remain in the normal range, although the true GFR is substantially lower. The converse is true with patients recovering from ATN. As the diuretic phase of ATN begins, urine output can be dramatic, but patients may remain markedly azotemic for several days. Using the CG equation in this setting will produce a falsely low CICr estimate. The CG equation is also inaccurate in populations that have little muscle mass, such as elderly, obese, or cachectic patients.

A more recent development is the acceptance of the abbreviated Modification of Diet in Renal Disease (MDRD) equation for quantifying GFR in most clinical laboratories.^{11,12} As such, clinicians are routinely provided the estimated GFR (eGFR) for their respective patients. An important point is that the results from the MDRD and CG equation are not interchangeable. For example, the MDRD equation should only be used to quantify GFR and to detect or stage the degree of chronic kidney disease; the CG equation should be used simply as a guideline for drug dosing adjustment in patients with ARF. No published data using the MDRD in cases of ARF exist.

In the past, many clinicians advocated the collection of timed urine specimens to calculate creatinine clearance in ARF. Although this may seem relatively easy, it is susceptible to serious errors, particularly the timing of the collection and assuring the patient has not voided urine in the commode. For these reasons, the practice of collecting timed urine specimens is not routinely performed.

Blood Tests

Assessment of the blood urea nitrogen (BUN) and creatinine concentrations is crucial for guiding the diagnosis, treatment, and monitoring of ARF. The BUN:SrCr ratio can delineate prerenal causes from intrinsic and postrenal causes. Urea reabsorption is inversely proportional to the urine flow rate. The

Table 30-2 Urinary Indices in Acute Renal Failure

| Component | Prerenal Azotemia | Acute Tubular Necrosis | Postrenal Obstruction |
|-------------------------------|-------------------|------------------------|-----------------------|
| Urine Na ⁺ (mEq/L) | <20 | >40 | >40 |
| FE _{Na} ⁺ | <1% | >2% | >1% |
| Urine/plasma creatinine | >40 | <20 | <20 |
| Specific gravity | >1.010 | <1.010 | Variable |
| Urine osmolality (mOsm/kg) | Up to 1,200 | <300 | <300 |

normal steady-state BUN:Scr ratio is approximately 10:1. In prerenal conditions, the BUN:Scr ratio is >20:1 because sodium and water are actively reabsorbed in the renal tubules to expand the effective circulating volume. Urea, an ineffective osmole, is reabsorbed as a result of increased water reabsorption, while creatinine is not reabsorbed. Whereas the Scr may increase owing to decreased glomerular filtration, BUN increases to a greater degree as a result of increased proximal reabsorption.

The presence of hypercalcemia or hyperuricemia can indicate a hematologic malignancy. *Tumor lysis syndrome* is a condition that occurs in patients with leukemia after chemotherapy induction. The destruction of cancerous cells results in the release of large quantities of cellular contents (e.g., potassium, uric acid) into the bloodstream, which can overwhelm the kidney's functional ability, especially in dehydrated states.

Other elevated enzymes may also aid in the diagnosis of ARF. An increased level of creatine kinase or myoglobin in the face of ARF usually indicates rhabdomyolysis. Eosinophilia may suggest acute allergic interstitial nephritis from drug exposure. High levels of circulating immune complexes in the presence of ARF suggest glomerulopathies.¹

Urinalysis

The urinalysis is an important diagnostic tool for differentiating ARF into prerenal azotemia, intrinsic, or obstructive ARF (Table 30-2). The presence of highly concentrated urine, as determined by elevated urine osmolality and specific gravity, suggests prerenal azotemia. During dehydrated states, *vasopressin (antidiuretic hormone [ADH])* is secreted, and the *renin-angiotensin-aldosterone (RAA) system* is activated. These mechanisms promote the reabsorption of water and sodium at the collecting duct of the nephron, which serves to expand the effective circulating volume in an attempt to restore renal perfusion. As a result of diminished urine volume, the urine osmolality and specific gravity increase dramatically. Patients with prerenal azotemia and oliguria often have a urine osmolality > 500 mOsm/kg. The maximal urine osmolality can exceed 1,200 mOsm/kg.

The presence of proteinuria or hematuria can indicate glomerular damage. Nephrotic syndrome is characterized by urinary protein losses >3.5 g/1.73 m²/day. Proteinuria can also result from tubular damage; however, the protein loss is rarely >2 g/day. The protein content can be used to differentiate glomerular versus tubular damage. The low-molecular-weight protein, 2-microglobulin is freely filtered at the glomerulus and reabsorbed at the proximal tubule. Therefore, the presence of excessive β_2 -microglobulin in the urine suggests a tubular source of ARF, such as ATN. Conversely, albumin is not readily filtered at the glomerulus; hence, the presence of heavy albuminuria suggests a glomerular source of ARF.

Microscopic examination of the urine provides helpful clues for determining the source of ARF (Table 30-3). Pigmented granular casts are generally seen with ischemic or nephrotoxin-induced ARF. White blood cells (WBC) and WBC casts can indicate an inflammatory process in the glomerulus, such as acute interstitial nephritis (AIN) or pyelonephritis. Red blood cells (RBC) and RBC casts can result from strenuous exercise or can indicate glomerulonephritis. Allergic interstitial nephritis can be detected by the presence of urinary eosinophils. Obstructive ARF causes, such as nephrolithiasis, can be identified by the presence of crystals in the urine. Cystine, leucine, and tyrosine crystals are considered pathologic. The presence of calcium oxalate crystals may suggest toxic ingestion of ethylene glycol.

Urinary Chemistries

Analyzing urine electrolyte concentrations and simultaneously comparing them with serum sodium and creatinine concentrations is useful for differentiating between prerenal azotemia and ATN (Table 30-2). The fractional excretion of sodium (FE_{Na}⁺) is a measurement of how actively the kidney is reabsorbing sodium, and it is calculated as the fraction of filtered

Table 30-3 Clinical Significance of Urinary Sediment in Acute Renal Failure

sodium excreted in the urine using creatinine as a measure of GFR. In normal conditions, the proximal tubule reabsorbs 99% of filtered sodium. The FE_{Na^+} formula is listed as follows: (Eq. 30-2)

$$FE_{Na^+}(\%) = \frac{(UNa)(SrCr)}{(UCr)(SNa)} \times 100\% \quad 30-2$$

where UNa is the urine sodium concentration (mEq/L), $SrCr$ is the serum creatinine concentration (mg/dL), UCr is the urine creatinine concentration (mg/dL), and SNa is the serum sodium concentration (mEq/L).

In prerenal azotemia, the functional ability of the proximal renal tubule remains intact. In fact, its sodium-reabsorbing abilities are markedly enhanced because of the effects of circulating vasopressin and activation of the RAA system. Both the FE_{Na^+} and urinary sodium concentration become markedly low (<1% and <20 mEq/L, respectively) in prerenal conditions. In contrast, these indices are elevated in ATN because the renal tubules lose their ability to reabsorb sodium; the FE_{Na^+} is >2%, and the urine sodium is >40 mEq/L. FE_{Na^+} values between 1% and 2% are generally inconclusive. The clinician should ensure that the patient is not receiving scheduled thiazide or loop diuretic therapy when the FE_{Na^+} is calculated. These diuretics increase natriuresis, thereby making the results difficult to interpret.

PRERENAL AND FUNCTIONAL ACUTE RENAL FAILURE

Congestive Heart Failure and Nonsteroidal Anti-Inflammatory Drug Use

1. A.W. is a 71-year-old white man who had a ST-segment elevation myocardial infarction (STEMI) 2 months ago. His ejection fraction is currently 15% (normal, 50%–60%). He presents today for his 2-month follow-up clinic appointment complaining of shortness of breath, dyspnea on exertion, and inability to produce much urine. His medical history is significant for longstanding hypertension, coronary artery disease, osteoarthritis, and recent-onset heart failure (HF) after his MI. His home medications include furosemide 40 mg every day, enalapril 5 mg daily, metoprolol XL 100 mg daily, digoxin 0.125 mg daily, atorvastatin 40 mg QD, and naproxen sodium 550 mg twice daily (BID), all of which are taken orally (PO). With the exception of naproxen, A.W. often forgets to take his medications. Physical examination reveals lower leg 3+ pitting edema, pulmonary crackles and wheezes, positive jugular venous distention, and an S_3 heart sound. His vital signs are significant for a blood pressure (BP) of 198/97 mm Hg and a weight gain of 4 kg since his last visit 2 months ago. Last month, his BUN and SrCr were 23 (normal, 5–20) and 1.2 mg/dL (normal, 0.5–1.2), respectively. What are A.W.'s risk factors for ARF?

[SI units: BUN, 8.2 mmol/L (normal, 1.8–7.1); SrCr, 106 mol/L (normal, 44.2–106)]

A.W.'s risk factors for ARF are CHF with poor cardiac output (ejection fraction, 15%) that resulted from his STEMI and his medication, naproxen sodium. CHF is a major cause of functional ARF.¹³ A.W.'s diminished cardiac output has resulted in decreased effective circulating volume and activation of the RAA system, which are impairing his renal perfusion. In states of decreased renal perfusion, prostaglandins

E_2 and I_2 compensate for the afferent arteriole vasoconstriction by stimulating afferent arteriole vasodilation, and thereby enhancing renal blood flow. Prostaglandin synthesis is mediated predominantly by cyclooxygenase-1 (COX-1) and perhaps cyclooxygenase-2 (COX-2). Nonsteroidal anti-inflammatory drugs (NSAID), such as naproxen, are often overlooked as causes of ARF.^{14,15} NSAID exert their pharmacologic effect by inhibiting prostaglandin synthesis, thereby negating compensatory vasodilation. NSAIDs induce abrupt decreases in GFR in at-risk patient populations, specifically those with CHF, liver disease, the elderly, or dehydrated patients. Indomethacin is associated with the highest risk of NSAIDs-induced renal ischemia, whereas aspirin appears to have the lowest risk. Naproxen, ibuprofen, piroxicam, and diclofenac are considered intermediate in their relative capacities to acutely compromise renal perfusion.^{15,16} Sulindac may offer a “renal-sparing” effect. Sulindac is a prodrug that is converted to its active sulfide metabolite by the liver and then becomes reversibly oxidized back to its parent compound in the kidney; renal prostaglandin synthesis is essentially unaltered by sulindac. Cases of sulindac-induced renal dysfunction have been reported when the drug was administered to patients with cirrhosis and ascites.

COX-2 inhibitors also inhibit prostaglandin synthesis. A study comparing the effects of rofecoxib and celecoxib to nonselective NSAIDs demonstrated similar renovascular effects.¹⁶ These data suggest that COX-2 selective agents do not offer any benefit over nonselective NSAID with regard to renovascular effects. Figure 30-2 illustrates common medications that alter renal hemodynamics by causing either afferent arteriole vasoconstriction or efferent arteriole vasodilation.

2. A.W.'s cardiologist obtains a stat digoxin level, electrolyte panel, urinalysis, and urine electrolyte panel. The digoxin level is reported as “not detectable” (target, 0.5–0.8 ng/mL). Other significant serum laboratory values include Na^+ of 140 mEq/L (normal, 135–145), BUN 56 mg/dL (normal, 5–20), and creatinine of 1.5 mg/dL (normal, 0.5–1.2). The urinalysis is significant for a urinary osmolality of 622 mOsm/kg (normal, 300–500 mOsm/kg), and specific gravity of 1.092 (normal, 1.010–1.020). The urine electrolytes are significant for Na^+ of 12 mEq/L (normal, 20–40) and creatinine of 87 mg/dL. What laboratory findings suggest functional ARF?

[SI units: sodium, 140 mmol/L (normal, 135–145); BUN, 20 mmol/L (normal, 1.8–7.1); SrCr, 132.6 mol/L (normal, 44.2–106); urine Cr, 7691 mol/L]

A.W. has classic laboratory findings associated with poor renal perfusion (Table 30-2). It is important to compare the current and previous laboratory data to assess acute changes in renal function. Compared with last month, A.W.'s renal function has deteriorated based on substantial increases in BUN and SrCr concentrations; BUN has increased nearly twofold and creatinine by 25%. The BUN:SrCr ratio is >20:1, suggesting poor renal blood flow, which is corroborated by other urinary indices such as the urinary Na^+ 12 mEq/L; specific gravity (elevated), 1.090; urine osmolality, 622 mOsm/kg; and the calculated FE_{Na^+} , 0.14%. These values reflect the ability of the renal tubules to respond to vasopressin and aldosterone in an attempt to expand effective circulating volume and restore renal perfusion.

Another consideration is furosemide-induced volume depletion; however, the nondetectable serum digoxin level

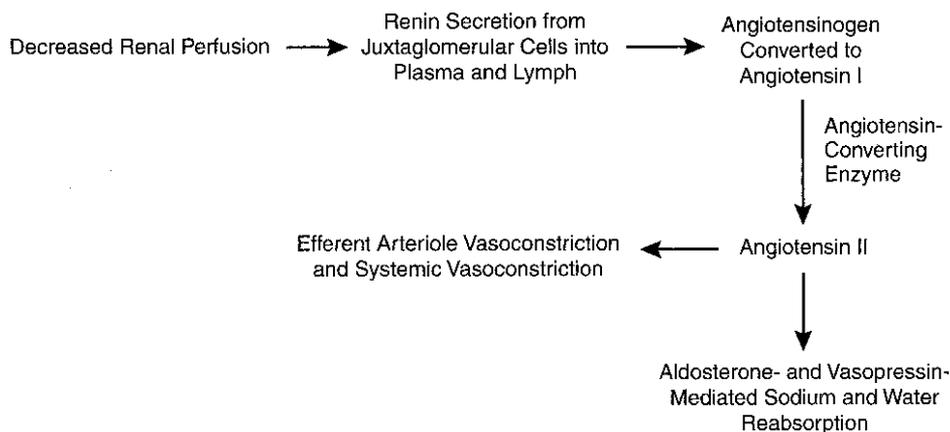

FIGURE 30-3 Compensatory hormonal mechanisms of decreased renal perfusion.

indicates likely noncompliance with his medications. A more likely explanation is poor renal perfusion because of his heart failure (i.e., low cardiac output).

3. How should A.W.'s prerenal azotemia be treated?

The presence of volume overload in the face of prerenal azotemia suggests a decreased effective circulating volume, most likely from poorly controlled HF. Restoring and improving A.W.'s cardiac output and renal perfusion will rapidly correct the prerenal azotemia. This can be achieved by (a) assuring adherence to his heart failure medications (furosemide, enalapril, metoprolol XL, and digoxin), (b) controlling BP to a goal of <135/85 mm Hg by decreasing both preload and afterload, and (c) modifying any drug therapy that has deleterious effects on the renal hemodynamics (e.g., NSAID). The specific therapies for controlling hypertension and improving cardiac output are presented in Chapter 14, Essential Hypertension, and Chapter 19, Heart Failure. Naproxen should be discontinued and substituted with acetaminophen to treat his osteoarthritis. Normal renal function should return in a few days after correction of the underlying causes.

Angiotensin-Converting Enzyme Inhibitor- and Angiotensin Receptor Blocker-Induced Acute Renal Failure

4. G.B. is a 53-year-old white woman with hypertension, coronary artery disease, peripheral vascular disease, and diabetes, for which she had been taking hydrochlorothiazide 25 mg PO daily, atorvastatin 10 mg PO daily, aspirin 81 mg PO daily, and NPH insulin 30 U subcutaneously Q morning and 15 U subcutaneously Q evening. At last week's clinic visit, she had two consecutive BP readings of 187/96 and 193/95 mm Hg, respectively, measured 20 minutes apart. At that time, G.B.'s primary care physician discontinued her hydrochlorothiazide and started her on lisinopril 5 mg PO daily. She returns to the clinic today for her 1-week follow-up appointment complaining of dizziness, very little urine production over the past week, and swelling in her ankles. Her BP is 98/43 mm Hg. A stat serum electrolyte panel is significant for a BUN of 62 mg/dL (normal, 5–20) and an SrCr of 6.1 mg/dL (normal, 0.5–1.2). Why is G.B. experiencing ARF?

[SI units: BUN, 22.1 mmol/L (normal, 1.8–7.1); SrCr, 539 mol/L (normal, 44.2–106)]

Inhibition of the RAA system in patients with compromised renal blood flow is a common cause of functional ARF. A basic understanding of the effects of the RAA system on renal hemodynamics is necessary in this situation (Fig. 30-3). When renal perfusion is impaired, the juxtaglomerular cells of the kidney secrete renin into the plasma and lymph. Renin cleaves circulating angiotensinogen to form angiotensin I (AT I), which is further cleaved by angiotensin-converting enzyme (ACE), to form angiotensin II (AT II). AT II induces two physiologic events to improve renal perfusion. First, it directly causes systemic vasoconstriction, which shunts blood to the major organs, and indirectly increases intravascular volume through aldosterone- and vasopressin-mediated activity. Second, it preferentially vasoconstricts the efferent renal arteriole to maintain adequate intraglomerular hydrostatic pressure. Under conditions of decreased arterial pressure or effective circulating volume, the RAA system is activated and plasma renin and AT II activity are increased.¹⁷

G.B. has extensive atherosclerotic disease indicated by the presence of coronary artery and peripheral vascular disease. Atherosclerosis not only affects major blood vessels, but also the macro- and microvasculature of the kidney; indeed, atherosclerosis is a major cause of renal artery occlusion and decreased renal perfusion. This activates the RAA system, which causes sodium and water reabsorption and AT II-mediated efferent arteriole vasoconstriction, in an attempt to restore normal renal perfusion and intraglomerular hydrostatic pressure.

The administration of ACE inhibitors directly inhibits the formation of AT II, which is necessary for efferent arteriole vasoconstriction. Consequently, the compensatory physiologic event that maintains G.B.'s renal blood flow is inhibited, thereby reducing her intraglomerular hydrostatic pressure and GFR. ACE inhibitors are contraindicated in patients with bilateral renal artery stenosis or unilateral stenosis in patients with a single functioning kidney.¹⁷

5. Are there other factors that predispose patients to ACE inhibitor-induced ARF?

In addition to the above situation, three other general scenarios will result in the development of ARF with ACE inhibitors. First, conditions of sodium and water depletion (e.g., dehydration, overdiuresis, poor fluid intake, low-sodium diet)

can increase the dependency of the efferent arteriole on AT II. When ACE inhibitors are given in these situations, GFR can fall dramatically, and SrCr rises. ARF can be averted by withholding the ACE inhibitor (or diuretic, or both) for a day and repleting the intravascular fluid volume with a saline-containing fluid (e.g., normal saline or 0.45% saline). The ACE inhibitor can be restarted at the same dose after adequate hydration. Second, ACE inhibitors can decrease the mean arterial pressure to such a degree that renal perfusion cannot be sustained. This is more likely to occur with long-acting agents or in situations in which the pharmacologic half-life of the ACE inhibitor is prolonged (e.g., pre-existing renal disease). Finally, ACE inhibitors may precipitate ARF in patients who are taking concomitant drugs with renal afferent arteriole vasoconstricting effects, most notably cyclosporine and NSAIDs.

6. How is ACE inhibitor-induced ARF managed?

Patients who are receiving ACE inhibitors should be monitored judiciously with regard to their serum creatinine and electrolyte concentrations. Once an ACE inhibitor is initiated, an increase in SrCr of 20% to 30% can be expected.¹⁷ This slight increase should not worry clinicians, because it typically normalizes within 2 to 3 months. SrCr rises greater than this along with reduced urine output signal ARF, however. ARF related to ACE inhibitors is usually reversible, principally because the ARF is caused by inadequate glomerular capillary pressure, which is restored as soon as sufficient AT II is produced. This normally takes 2 to 3 days to re-equilibrate. Anecdotally, ARF appears to develop more commonly in hypotensive patients or in those with intravascular volume depletion (e.g., patients with HF receiving high-dose diuretics). In these conditions, it is prudent to replete the intravascular fluid volume or temporarily discontinue diuretic therapy. ACE inhibitor therapy should be temporarily discontinued and reinstated when the patient has a normalized intravascular volume and is hemodynamically stable.

7. Do angiotensin II–receptor blockers (ARB) cause less ARF compared with ACE inhibitors?

The ARBs competitively inhibit the angiotensin II receptor. At least two subtypes of the angiotensin II receptors exist: AT I and AT II. The ARBs exert their pharmacologic effect at the AT I receptor subtype, which is responsible for most, if not all, of the cardiovascular effects of angiotensin II, such as vasoconstriction, aldosterone release, and β -adrenergic stimulation. Few differences are seen in the incidence of ARF between ACE inhibitors and ARBs,¹⁸ and one should not be interchanged with the other in an attempt to decrease ARF risk.

INTRINSIC ACUTE RENAL FAILURE

Intrinsic ARF is a general term that connotes damage at the parenchymal level of the kidney. The term *acute tubular necrosis* is often used to describe this type of ARF, but this is a histologic diagnosis that describes only one of several intrinsic disorders. Pragmatically, intrinsic ARF can be subdivided into vascular, glomerular, or tubular disorders.

Disorders involving the large renal vessels are relatively uncommon. Acute renal artery or vein occlusion can be caused by vasculitis, atheroembolism, thromboembolism, dissection, or

clamping of the ascending aorta during surgery. To affect serum BUN and creatinine, occlusion must be bilateral, or it can be unilateral in patients with concomitant renal insufficiency or one functioning kidney. Reduced blood flow to the renal microvasculature and glomeruli also can result in ARF. Common examples are rapidly progressing glomerulonephritis (RPGN) and vasculitis. If these conditions become sufficiently severe, they can cause ischemia, resulting in superimposed ATN. Any disorder that produces tubular ischemia, such as prolonged hypotension or shock syndromes, can result in ATN.

Nephrotoxic drugs are a common cause of ATN, especially when given in septic or volume-contracted patients. The various mechanisms by which drugs can cause ATN, are explained in detail later in this chapter. Although relatively uncommon, drug-induced acute interstitial nephritis (AIN) is another type of intrinsic ARF. This is a hypersensitivity reaction that results from the formation of drug–antibody complexes that subsequently deposit in the glomerular membrane.

Acute Glomerulopathies

Poststreptococcal Glomerulonephritis

8. B.M. is an 18-year-old male college freshman in otherwise good health who recently developed strep throat. He received a 10-day course of amoxicillin, which cleared the infection. He returns to the student health center after completing his 10-day course complaining of “puffy eyes,” swelling in his legs, a cough productive of clear sputum, and decreased urine output that appears “tea-colored.” Other than the amoxicillin, he is not on any medication. Baseline records from a routine physical examination 2 months ago revealed a serum BUN and creatinine of 10 mg/dL and 0.8 mg/dL (normal, 5–20 and 0.5–1.2), respectively, and a BP of 120/80 mm Hg. Today, the physical examination is significant for a BP of 176/95 mm Hg, 2+ peripheral edema, and bilateral pulmonary rales. The urinalysis is significant for gross hematuria, nephritic-range proteinuria, RBC and WBC casts, and epithelial cells. B.M.’s SrCr has increased to 7.1 mg/dL. Based on the history, physical examination, and laboratory findings, what is the most likely cause of ARF in this patient?

[SI units: BUN, 3.6 mmol/L (normal, 1.8–7.1); SrCr, 70.7 and 627.6 mol/L, respectively (normal, 44.2–106)]

B.M.’s recent history of a streptococcal infection with the development of ARF suggests poststreptococcal glomerulonephritis (PSGN), which results from the formation of antibodies against streptococcal antigens. The streptococcal–antigen immune complexes are deposited in the glomerulus, resulting in complement, cytokine, and clotting cascade activation; neutrophils and monocytes attack the glomerulus causing glomerulonephritis. The onset of PSGN is usually 7 to 21 days after the start of the pharyngeal infection. PSGN is the most common acute-onset, immune-mediated, diffuse glomerulopathy. It primarily affects children, although it can affect any age group and is more prevalent in males than in females. Only certain serologic subtypes of group A hemolytic streptococci, known as *nephritogenic* strains, cause PSGN. Strains that follow pharyngeal infections (e.g., strep throat) include types 1, 3, 4, 6, 12, 25, and 49. Type 49 is the most prevalent strain worldwide. Positive diagnosis of PSGN requires identification of a nephritogenic group A hemolytic streptococcal strain;

objective urinalysis findings suggestive of glomerular damage, such as proteinuria, hematuria, and casts; and elevated streptococcal antibody titers.

B.M. exhibits the classic physical and laboratory findings associated with PSGN. The pertinent positive physical findings include periorbital, pulmonary, and peripheral edema; tea-colored urine, hypertension, and decreased urine output. Edema is a common manifestation, with periorbital edema typically being the first to appear. Reduced GFR, proteinuria, and sodium retention by the kidney all contribute to edema formation. When protein, principally albumin, is lost in the urine, the intravascular oncotic pressure declines, causing a shift of fluid into the extravascular space. The loss of intravascular volume stimulates sodium and water reabsorption by the kidney via aldosterone and vasopressin, which often produces stage 1 to 2 hypertension.

Pertinent laboratory data in B.M. include elevated SrCr, and urinalysis positive for hematuria, proteinuria, WBC casts, and epithelial cells. Hematuria, which is found in almost all patients with PSGN, accounts for the reddish-brown, tea-colored urine. Other commonly found urine sediments include cellular casts and hyaline and granular casts. Oliguria is common in PSGN, but anuria is rare.

9. Are there other tests that can be used to confirm this diagnosis?

Given that B.M. has received a 10-day course of amoxicillin, it is unlikely that throat cultures for the nephritogenic group A hemolytic streptococcal strain will be positive. Cultures of close contacts may, however, be positive for the streptococcal strain, even if they are asymptomatic. The presence of circulating antibodies to the nephritogenic streptococcal strains indicates recent exposure. The antistreptolysin O (ASO), antihyaluronidase (AHase), antideoxyribonuclease B (ADNase B), and antinicotyladenine dinucleotidase (NADase) antibody titers can be measured clinically. ASO titers begin to rise 2 weeks after pharyngeal infection, peak at 4 weeks, and slowly decline over 1 to 6 months. No correlation exists between degree of ASO rise and nephrogenicity. In fact, ASO titers may not be elevated at all if early antibiotic treatment is initiated or in cases of streptococcal skin infections. The use of ADNase and AHase titers is more specific to detect recent infection in these situations.

The streptozyme test, which can be used clinically for rapid screening purposes, uses several antistreptococcal antibody assays. False-positive and false-negative results are common, however, because of cross-reactivity between the antibody and normal collagen.

Serial complement determinations may be of value in diagnosing PSGN. Decreased levels of C3 protein and hemolytic complement activity (CH50) are observed in nearly all patients with active PSGN. Serum C3 levels can fall by nearly 50% of normal in the first weeks of infection and return to normal within 8 weeks after infection. No correlation, however, exists between the degree of C3 depression and severity of nephritis. Circulating antibody complexes of C3 can be found in patients with acute infection.

Rarely, is renal biopsy needed, but it may be prudent in patients who present with atypical symptoms, such as anuria, prolonged oliguria, marked azotemia, hematuria for >3 weeks, or in those who have no streptococcal antibody titers.

10. What are the therapeutic goals and treatment options for PSGN?

The therapeutic goals are to minimize further kidney damage and to provide symptomatic relief for B.M. The underlying streptococcal infection should be treated with appropriate antibiotics, but as illustrated by B.M., this has no effect in preventing PSGN. Family members and close contacts of the infected patient should receive antibiotic prophylaxis as well. Restriction of protein to 0.8 g/kg/day may be beneficial in patients with marked proteinuria, and antihypertensive drugs can be used on a short-term basis to control BP. Sodium and water restriction is beneficial in reducing edema, and loop diuretics may be used as needed for symptomatic pulmonary or peripheral edema. Close monitoring of electrolytes is warranted if diuretics are used. Dialysis is rarely required.

Rapidly Progressive Glomerulonephritis

11. Are there other glomerulopathies that cause ARF?

Yes. RPGN, also called *crescentic glomerulonephritis*, is a clinical syndrome of rapid decline in renal function (from days to weeks) combined with the hallmark findings of gross hematuria, proteinuria, and the presence of extensive glomerular crescents (>50% of glomeruli) on renal biopsy. It is not uncommon for patients with RPGN to have a 50% decline in GFR in only a few weeks. RPGN is a medical emergency, and treatment success depends on how early therapy is initiated. If left untreated, progression to end-stage renal disease or death is almost certain.

Idiopathic RPGN is divided into three categories based on immunofluorescence microscopy. Type I idiopathic RPGN is characterized by linear deposition of immunoglobulins, primarily IgG, along the glomerular basement membrane (GBM) indicating anti-GBM antibodies. Type II idiopathic RPGN is identified by granular immunoglobulin and complement depositions in the glomerular microvasculature and mesangium suggesting immune complex deposition. Type III idiopathic RPGN is also called *pauci-immune* because there are no hallmark immunoglobulin or complement findings on immunofluorescence microscopy. Type III idiopathic RPGN is identified by the presence of circulating antineutrophil cytoplasmic antibodies.

Multisystem vasculitic disorders that result in glomerular capillary inflammation are the most common cause of RPGN.¹⁹ Many of these patients present with nonspecific flu-like symptoms such as fever, weight loss, myalgia, and malaise with proteinuria and hematuria.²⁰ Uremic symptoms can occur with severe disease. The presence of ARF with pulmonary congestion, cough, hemoptysis, or dyspnea suggests *Wegener's granulomatosis*. The treatment for autoimmune RPGN generally involves immunosuppressive agents, such as prednisone, azathioprine, or cyclophosphamide. A more detailed discussion of glomerulonephritis is presented in Chapter 31, Chronic Kidney Disease.

Nonsteroidal Anti-Inflammatory Drug-Induced Glomerulopathy

12. What drugs cause glomerulonephropathy?

Minimal-change disease and *membranous nephropathy* have been associated with NSAID use.²¹ The mechanism is probably related to NSAID-induced inhibition of the cyclooxygenase pathway, which leads to increased arachidonate

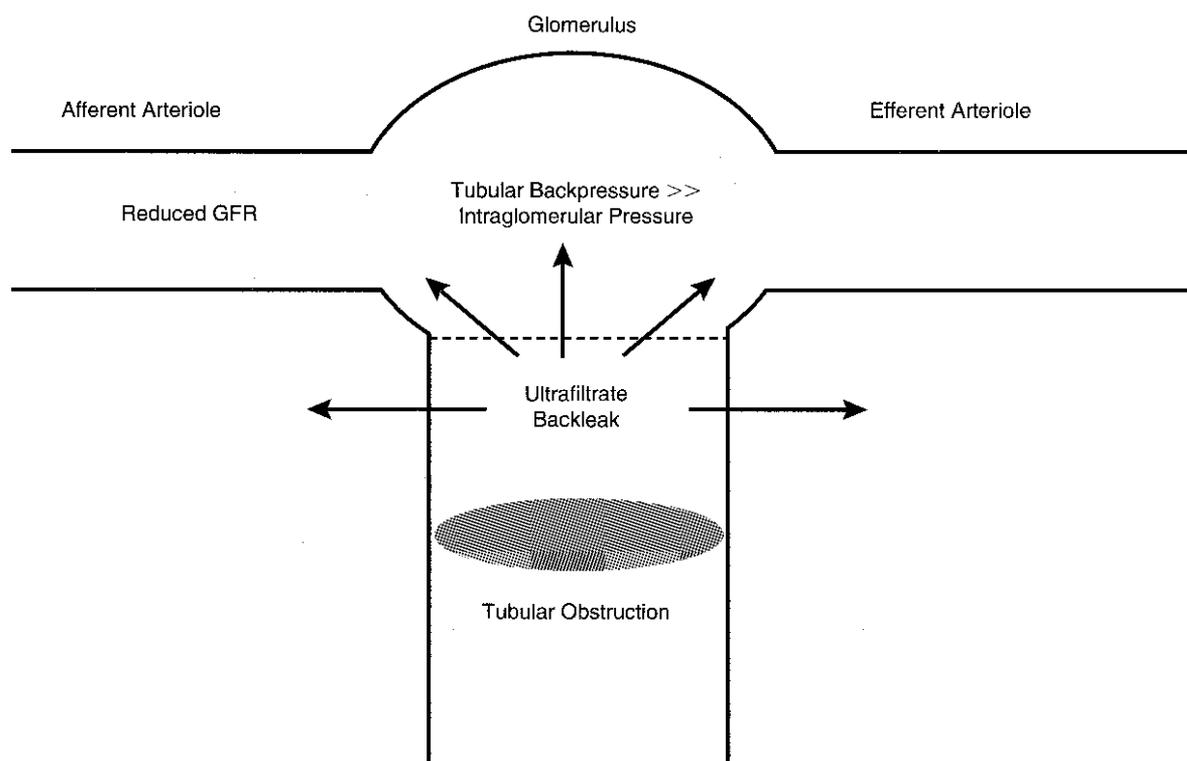

FIGURE 30-4 Schematic of acute tubular necrosis (ATN). The process is initiated by ischemia or nephrotoxin exposure that leads to tubular cell death. The cellular debris sloughs off and obstructs the proximal tubule lumen. Once the nephron is obstructed, a backleak of the glomerular ultrafiltrate occurs across the tubular basement membrane and impairment of glomerular filtration. During the recovery phase of ATN, the obstructive cellular casts are released into the urine and filtration begins to normalize. GFR, glomerular filtration rate.

catabolism and increased proinflammatory leukotriene production. The hallmark feature of NSAID-induced nephropathy is nephrotic-range proteinuria. The nephropathy resolves slowly over several months once the NSAID is discontinued.

TUBULOINTERSTITIAL DISEASES

Acute Tubular Necrosis

Acute tubular necrosis arises most often from ischemia or drug-induced causes.^{1,22} Prolonged prerenal conditions, such as hypotension, surgery, overwhelming sepsis, or major burns, can lead to ischemic ATN. Unlike prerenal azotemia, tubular cell death occurs in ATN, and immediate volume resuscitation will not reverse the damage. The pathophysiology of ATN is complex and remains unclear. It is currently thought that when tubular cells die, they slough off into the tubule lumen and contribute to cast formation. The casts completely obstruct the tubule lumen and increase intratubular pressure, which causes a back leak of ultrafiltrate across the tubular basement membrane (Fig. 30-4). The aforementioned processes are mediated by a variety of substances, including calcium, phospholipases, and perhaps growth factors as well as free radical and protease activation.

Treatment With Diuretics and Dopamine

13. Do diuretics and dopamine have a role in treating established ATN?

It is well documented that patients with nonoliguric renal failure have significantly better outcomes compared with those with oliguria. This is probably because patients who are nonoliguric have less extensive renal damage and are better able to maintain fluid and electrolyte balance. Loop diuretics are commonly used in established ATN in an attempt to convert patients with oliguria to a nonoliguric state. Numerous clinical trials, however, have failed to demonstrate improved mortality or duration of azotemia in oliguric patients who receive loop diuretics, despite improved urine output. Two large systematic reviews of the primary literature convincingly showed that diuretic therapy plays little role in altering the course of ARF, decreasing length of hospitalization, or helping recover renal function.^{23,24} These data suggest that, although patients who are nonoliguric generally have better outcomes, converting a patient from oliguria to nonoliguria through pharmacologic intervention does not improve patient outcomes. Currently, the only role that diuretic administration has in patients with established ATN is to increase urine output, which facilitates fluid, electrolyte, and nutritional support.

Another controversy that has been debated extensively in the literature is the use of dopamine in patients with established ATN. Dopamine is a catecholamine that stimulates dopaminergic receptors at low dosages (1–3 mcg/kg/minute), and α - and β -receptors at higher dosages (5–20 mcg/kg/minute). Animal and human studies have demonstrated that low-dose dopamine improves renal blood flow by inducing afferent arteriolar vasodilation. No data, however, support the use of dopamine in

the treatment of established ARF. A recent meta-analysis of 61 clinical trials including nearly 3,500 patients failed to detect any significant improvement in variables such as occurrence of ARF, need for renal replacement therapy, or mortality.²⁵ Unequivocally, dopamine has no role in preventing or treating ARF.

Radiocontrast Media–Induced Acute Tubular Necrosis

14. K.S., a 74-year-old man, presents to the emergency department complaining of chest pain. His medical history is significant for advanced type 2 diabetes mellitus, with retinopathy, peripheral vascular disease, and advanced coronary artery disease. Based on cardiac enzymes, K.S. is ruled in for STEMI. He is taken to the cardiac catheterization laboratory for a percutaneous coronary intervention. Immediately before the procedure, K.S. is given iohexol PO to enhance visualization of his cardiac arteries. His admission BUN is 37 mg/dL (normal, 5–20) and SrCr is 1.5 mg/dL (normal, 0.5–1.2). Two days later, pertinent laboratory findings include a BUN and SrCr of 60 and 2.0 mg/dL, respectively, and his urine output is 700 mL/day. Why did K.S. develop ARF?

[SI units: BUN, 13.1 and 21.3 mmol/L (normal, 1.8–7.1); SrCr, 132.6 and 176.8 mol/L, respectively (normal, 44.2–106)]

Radiocontrast media administration is one of the most common causes of drug-induced ATN. Although no set criteria exist for its diagnosis, it is generally considered when the SrCr increases by >0.5 g/dL over 2 to 5 days. Contrast-induced nephropathy (CIN) usually presents as a nonoliguric ATN. It is also differentiated from other forms of ATN in that the FE_{Na^+} is usually $<1\%$ (vs. the typical $>2\%$). Nephropathy is indicated by a progressive rise in creatinine 24 to 48 hours after contrast administration, which usually peaks within 5 days. The degree of creatinine rise and the presence of oliguria are widely variable. Because of the lack of an accepted CIN definition and differences in both clinical trial design and populations studied, estimating the true prevalence of CIN is daunting. Nevertheless, patients without risk factors prevalence have a relatively minute risk of developing CIN; for those with recognized risk factors prevalence may approach 50%.²⁶

The mechanisms by which radiocontrast media induce ARF are complex. Initially, the radiocontrast medium produces renal vasodilation and an osmotic diuresis. This, however, is followed by intense vasoconstriction in the medullary portion of the kidney, which has been demonstrated by significant decreases in medullary PO_2 after contrast administration.²⁷ The ischemia is compounded by the increased medullary O_2 consumption because of the osmotic diuresis. Consequently, disequilibrium exists between O_2 supply and demand creating ischemic ATN. Various vasoactive substances are suspected of decreasing medullary blood flow, including oxygen-free radicals, prostaglandins, endothelin, nitric oxide, angiotensin II, and adenosine. Endothelin and adenosine are potent vasoconstrictors that are directly released from endothelial cells on exposure to radiocontrast media.

15. What are the risk factors for CIN?

The documented risk factors for CIN are listed in Table 30-4. Any condition that decreases renal blood flow increases

Table 30-4 Proven Risk Factors for Developing Radiocontrast Media–Induced Acute Tubular Necrosis

| |
|---|
| Diabetic nephropathy |
| Chronic kidney disease |
| Severe heart failure |
| Volume depletion and hypotension |
| Dosage and frequency of contrast administration |

the risk of nephropathy. At-risk patient populations include individuals with underlying diabetic nephropathy or chronic renal insufficiency, CHF, volume depletion, or those receiving aggressive diuretic regimens. The use of the ionic high-osmolar or low-osmolar contrast products also increases the risk of nephropathy, as well as the previously discussed medications that markedly reduce renal perfusion (e.g., NSAIDs, COX-2 inhibitors, ACE inhibitors). Iso-osmolar contrast appears to be better tolerated.

K.S. was at high risk for developing radiocontrast-induced ATN. He was volume depleted, as evidenced by his admission BUN:SrCr ratio, which was $>20:1$. Second, it is very likely that K.S. had underlying diabetic nephropathy, as evidenced by his elevated admission SrCr. The presence of retinopathy, coronary artery disease, and peripheral vascular disease suggest long-term uncontrolled diabetes mellitus, a risk factor for nephropathy.

Prevention

16. What strategies can be performed to prevent the occurrence of CIN?

Attempts have been made to minimize or prevent CIN using a variety of approaches. Medullary vasodilation with dopamine infusions have generally had disappointing results. Volume expansion, mannitol, and furosemide have been tried as a means of “flushing” radiocontrast from the kidney. *Volume expansion* is a rational approach to prevent renal dysfunction in this population because human and animal data have revealed dehydration as a major risk factor for developing CIN. Hydration with normal saline, hypotonic saline (0.45% sodium chloride), and sodium bicarbonate in dextrose have all shown benefits in preventing CIN. Notably, sodium bicarbonate may be more beneficial in decreasing the incidence of radiocontrast nephropathy relative to other fluids because it reduces oxygen-free radicals in the renal medulla and, therefore, increases the medullary pH. Whatever fluid is given, data suggest it should be infused before and after the procedure to adequately reduce the risk of developing nephropathy. Another important point is that the administration of diuretics such as mannitol and furosemide should be avoided. These diuretics result in volume depletion and increase oxygen demand in the medullary portion of the kidney when diuresis occurs, thereby counteracting the benefits of hydration. Other therapeutic modalities for the prevention of CIN have been studied. A systematic review and meta-analysis of *aminophylline* and *theophylline* have affirmed a renoprotective effect in patients who have underlying chronic kidney disease; however, large-scale clinical trials are lacking.²⁸ Although the use of calcium channel blockers theoretically seems rational to prevent contrast-induced ATN, limited clinical data exist. Other emerging data suggest that *ascorbic acid* may be

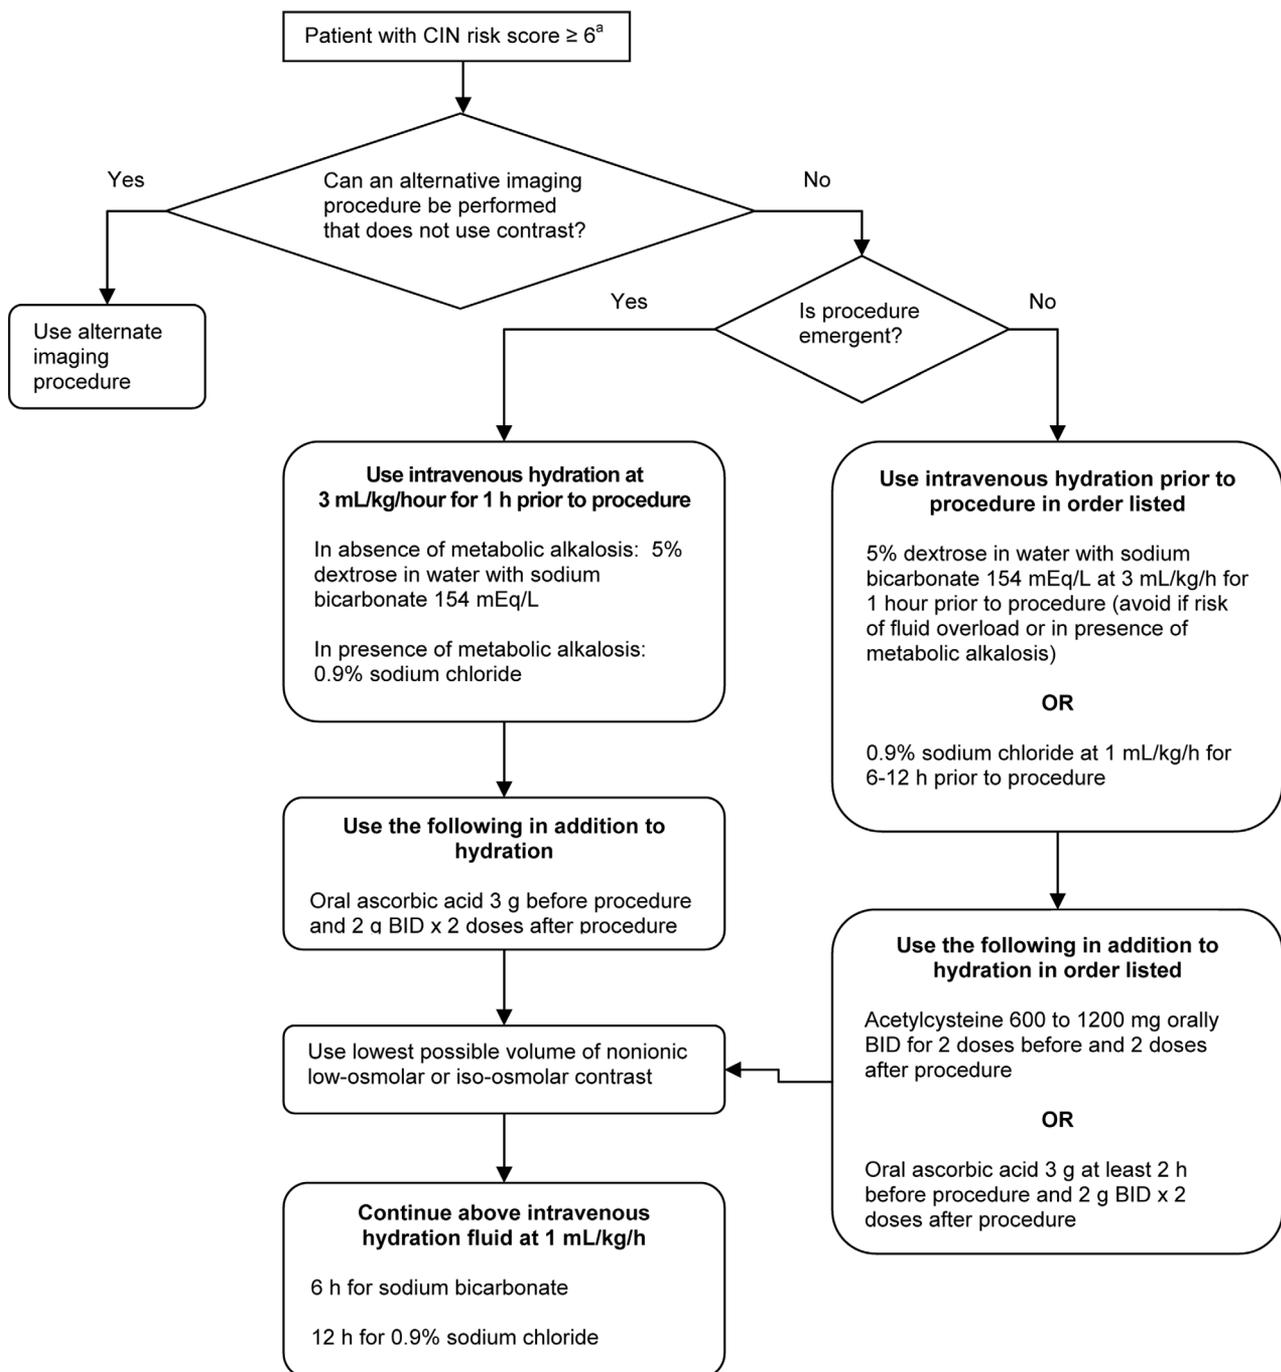

FIGURE 30-5 Preventing contrast-induced nephropathy (CIN) in high-risk populations. (From reference 26, with permission.)

beneficial in preventing contrast nephropathy given its antioxidant effects; however, large-scale prospective trials are lacking.²⁹

N-acetylcysteine (NAC) has received the most attention for its renal-sparing effects relative to radiocontrast media. Indeed, since 2001, nearly 30 primary studies and more than 10 meta-analyses have been conducted to assess its prophylactic effects.²⁶ Although much data have been generated with NAC, many of these studies have significant pitfalls, including relatively small sample size; single-center design; heterogene-

ity of patient populations; differing doses, dosage forms, and schedules of NAC therapy; and differing hydration regimens. Therefore, trying to delineate meaningful conclusions from this body of literature is daunting. At this time, recommending a specific dose of NAC is difficult. The commonly accepted regimen at many institutions is 600 mg orally twice daily pre- and postprocedure for a total of four doses along with concomitant hydration therapy.

Figure 30-5 summarizes one possible strategy to prevent CIN in high-risk populations. When possible, alternative

imaging studies that do not require radiocontrast should be attempted. If this is not practical, the lowest effective dose of nonionic, iso- or low-osmolar radiocontrast media should be used. Concomitant drug therapy that can impair renal perfusion, such as diuretics, NSAIDs, COX-2 inhibitors, ACE inhibitors, and ARBs, should be discontinued 1 day before and 1 day after radiocontrast administration. Metformin should also be discontinued before giving radiocontrast media and held for at least 48 hours because it can cause lactic acidosis if patients develop ARF. If patients are receiving calcium channel blockers for underlying cardiovascular disease, no change in therapy is warranted. All patients should be well hydrated with saline or sodium bicarbonate fluids before and after radiocontrast administration.

17. What treatment options are available for established radiocontrast-induced ATN?

Few data exist regarding treatment of existing radiocontrast-induced ATN. The acute management largely involves supportive care that includes strict fluid and electrolyte management to prevent undue sequelae. Approximately 25% of patients will require temporary dialysis therapy; patients who are oliguric generally require long-term dialysis therapy. As already noted, attempts to convert oliguria to nonoliguria with furosemide and mannitol have been largely unsuccessful.

Aminoglycoside-Induced Acute Tubular Necrosis

18. H.H. is a 43-year-old, 80-kg man being treated for gram-negative septic shock. He was admitted to the hospital 6 days ago, but he has spent the last 3 days intubated in the medical respiratory ICU because of hypotension, respiratory failure, and altered mental status. Since admission, H.H. has received ceftriaxone 2 g/day and gentamicin 140 mg IV Q 8 hr. Admission laboratory results were significant for the following: BUN, 13 mg/dL (normal, 5–20); SrCr, 0.9 mg/dL (normal, 0.5–1.2); and WBC count, 23,500 cells/mm³ (normal, 4,000–9,000) with a left shift (90% polymorphonuclear leukocytes [PMN] and 12% bands). Serial blood, urine, and sputum cultures were positive for *Acinetobacter baumannii* sensitive to ceftriaxone and gentamicin. In addition to the previously listed antibiotics, his current medication regimen includes norepinephrine IV 18 mcg/minute, pancuronium 0.02 mg/kg IV Q 3 hr, famotidine 20 mg IV Q 12 hr, and lorazepam IV 2 mg/hour. Today (hospital day 7), H.H.'s vital signs include the following: temperature, 101.5°F (38.6°C); BP, 90/40 mm Hg; pulse, 135 beats/minute; and respirations, 20 breaths/minute. Significant laboratory values are as follows: BUN, 67 mg/dL; SrCr, 5.4 mg/dL; and WBC count, 16,700 cells/mm³ with continued left shift. Over the last 2 days, H.H.'s urine output has steadily declined, and today it is 700 mL/24 hours (normal, 1,500–2,500). Urine electrolytes were obtained and reveal Na⁺, 55 mEq/L (normal, 20–40) and creatinine, 26 mg/dL (normal, 50–100). A urinalysis revealed many WBC (normal, 0–5), 3% RBC casts (normal, 0%–1%), brush-border cells (normal, negative), and granular casts (normal, negative) with an osmolality of 250 mOsm/kg (normal, 400–600). Serum gentamicin concentrations obtained with the last dose reveal a peak of 15 mg/dL (target, 6–10) and a trough of 9.1 mg/dL (target, <2.0). Given the history and laboratory data, what is the likely source of H.H.'s ARF?

Table 30-5 Risk Factors for Developing Aminoglycoside Nephrotoxicity

Patient Factors

Elderly
Underlying renal disease
Dehydration
Hypotension and shock syndromes
Hepatorenal syndrome

Aminoglycoside Factors

Aminoglycoside choice: gentamicin > tobramycin > amikacin
Therapy >3 days
Multiple daily dosing
Serum trough >2 mg/L

Concomitant Drug Therapy

Amphotericin B
Cisplatin
Cyclosporine
Foscarnet
Furosemide
Radiocontrast media
Vancomycin

[SI units: BUN, 4.6 and 24 mmol/L (normal, 1.8–7.1); SrCr, 79.6 and 477.4 mol/L (normal, 44.2–106); WBC count, 23.5 and 16.7 × 10⁶ (normal, 4.0–9.0); urine creatinine, 2,298 μmol/L (normal, 4,419–8,838)]

The source of ARF in this situation is likely multifactorial (Table 30-1). First, H.H. is experiencing diminished renal perfusion from profound hypotension and septic shock. As a result, he is receiving high-dose norepinephrine, a potent vasopressor. Consequently, the combination of these variables reduces renal perfusion further, resulting in prolonged renal ischemia. Second, H.H. has received 1 week of gentamicin, a well-known nephrotoxic antibiotic. The risk factors for developing aminoglycoside nephrotoxicity are listed in Table 30-5. The latest gentamicin trough concentration of 9.1 mg/L is far higher than the target value of <2 mg/L for a traditional three-times-daily dosing regimen. Given the laboratory data (Table 30-2) and the clinical course of prolonged hypotension, vasopressor, and aminoglycoside administration, nonoliguric ATN is the most likely diagnosis.

Presentation

19. How does aminoglycoside-induced ATN present, and what are the mechanisms of toxicity?

H.H. illustrates the typical presentation of aminoglycoside-induced nephrotoxicity. Generally, the onset occurs after 5 to 7 days of treatment and presents as a hypo-osmolar, nonoliguric renal failure with a slow rise in SrCr.³⁰ Because of the tubular necrosis that occurs, the urinalysis is often positive for low-molecular-weight proteins, tubular cellular casts, epithelial cells, WBC, and brush-border cells.³¹ H.H.'s plasma and urinary laboratory indices are consistent with those listed for ATN in Table 30-2.

The mechanism of aminoglycoside-induced ATN is complex. Approximately 5% of filtered aminoglycoside is actively reabsorbed by the proximal tubule cells. These agents are polycationic and bind to the negatively charged brush-border cells within the tubule lumen. Once attached, these agents undergo pinocytosis and enter the intracellular space, setting off complex biochemical events that result in the formation of myeloid bodies. With continued formation of myeloid bodies, the brush-border cells swell and burst, releasing large concentrations of aminoglycoside and lysosomal enzymes into the tubule lumen, thereby beginning a cascade of further tubular destruction.^{30,32} The following rank order of nephrotoxicity has been collated from human and animal data: neomycin > gentamicin = tobramycin = amikacin = netilmicin > streptomycin.³¹

Extended-Interval Dosing

20. Is “extended-interval” aminoglycoside dosing less nephrotoxic than multiple daily dosing regimens?

Extended-interval aminoglycoside dosing entails the administration of one large daily aminoglycoside dose. This dosing scheme takes advantage of the concentration-dependent killing activity and postantibiotic effect observed with aminoglycosides while minimizing time-dependent toxicity. The net effect of this dosing scheme, purportedly, is greater efficacy with reduced toxicity. Aminoglycoside nephrotoxicity is a function of drug exposure, and it might be minimized with extended-interval dosing because of saturable uptake kinetics in the proximal tubule. That is, only a maximal amount of aminoglycoside is transported into the tubule cell, no matter how much aminoglycoside is present in the tubule. Consequently, once saturation occurs, the remaining aminoglycoside concentration passes through the proximal tubule without being absorbed, and is excreted in the urine. Accumulation is therefore averted.³³ This concept is supported by studies demonstrating that continuous-rate gentamicin infusions, which produce sustained low plasma concentrations, result in greater proximal tubule uptake and nephrotoxicity than extended-interval regimens. This is probably because the achieved drug concentrations are well below those required to saturate the uptake mechanism. Extended-interval dosing results in very high peak concentrations to improve efficacy and generally undetectable trough concentrations before the next dose, thus minimizing accumulation.

Numerous clinical trials and meta-analyses have compared the efficacy and toxicity of extended-interval aminoglycoside dosing with conventional multiple daily dosing regimens. Many of these meta-analyses concluded that less nephrotoxicity was associated with extended-interval aminoglycoside dosing. Given the inherent biases of meta-analyses, these results, however, must be interpreted cautiously. For example, meta-analyses combine results from different clinical trials, which can differ in patient population, severity of illness scores, degree of underlying renal dysfunction, and dosing regimen and duration of therapy. Most of the clinical trials did not show a clinically or statistically significant difference in efficacy or toxicity between regimens. Contemporary practice suggests that patients should receive extended-interval aminoglycoside dosing unless they have specific contraindications.

In summary, extended-interval aminoglycoside dosing appears to result in similar or greater efficacy, with similar or

reduced toxicity. This dosing schedule is also less costly when considering therapeutic drug monitoring, preparation, and administration costs. Although the typical extended interval in patients with normal renal function is dosing every 24 hours, the interval may have to be prolonged to several days in patients with renal failure.

Drug-Induced Acute Interstitial Nephritis (AIN)

Drug-induced AIN accounts for approximately 1% to 3% of all ARF cases. A variety of antibiotics, such as penicillins, cephalosporins, quinolones, sulfonamides, and rifampin, as well as NSAIDs have been implicated as major causes of drug-induced AIN. The pathophysiology of this reaction is not well understood; however, it is suspected that either humoral or cell-mediated immune mechanisms or both are involved.³⁴ Humoral immune reactions occur within minutes to hours of drug exposure and involve the drug or its metabolite acting as a hapten that binds to host proteins, making them antigenic. The drug-protein antigens become lodged in the renal tubules, which initiate the inflammatory cascade. Cell-mediated injury can occur days to weeks after drug exposure and is identified by the presence of mononuclear inflammation and the lack of detectable immune complexes. This suggests a delayed hypersensitivity rather than a direct cytotoxic effect from a given drug. Both immune mechanisms probably contribute to the development of drug-induced AIN.

Penicillin-Induced AIN

21. J.S. is a 50-year-old woman who developed a cellulitis 3 days after a car door was closed on her right hand. She was admitted to the hospital, where blood and wound cultures were found to be positive for methicillin-sensitive *Staphylococcus aureus*. She received two full days of nafcillin 2 g IV Q 4 hr before being discharged to complete a 14-day course with dicloxacillin 500 mg PO four times daily (QID). Ten days after discharge, J.S. returned to the emergency department complaining of malaise, fever, diffuse rash, hematuria, and reduced urine output. The following laboratory values were significant: BUN, 39 mg/dL (normal, 5–20); SrCr, 2.3 mg/dL (normal, 0.5–1.2); and WBC count, 18,500 cells/mm³ (normal, 4,000–9,000) with 18% eosinophils. The urinalysis was positive for elevated specific gravity, WBC, RBC, eosinophiluria, and a FE_{Na+} of 3%. What objective data suggest drug-induced AIN?

[SI units: BUN, 13.9 mmol/L (normal, 1.8–7.1); SrCr, 203.3 mol/L (normal, 44.2–106); WBC count, 18.5 × 10⁶ (normal, 4.0–9.0)]

J.S.’s onset of symptoms suggests drug-induced AIN. As illustrated by this case, the median onset of penicillin-induced AIN generally occurs 6 to 10 days after drug exposure. Hallmark symptoms of AIN include fever, macular rash, and malaise. Fever is present in nearly all patients with AIN, whereas rash occurs in 25% to 50% of patients. J.S.’s objective laboratory data that suggest AIN include azotemia, elevated SrCr, proteinuria, cellular urinary sediment, eosinophilia, and eosinophiluria. Her FE_{Na+} of 3% suggests intrinsic renal disease and her eosinophiluria and eosinophilia indicate an immune-mediated allergic reaction. Drug-induced AIN is generally nonoliguric, but oliguria can develop in severe cases of AIN.

22. How should J.S.'s drug-induced AIN be treated?

The dicloxacillin should be stopped immediately because most patients recover normal kidney function once the offending agent is discontinued. General supportive measures that maintain fluid and electrolyte balance are necessary. Corticosteroids have been used with variable results to shorten the duration of ARF, but no clinical guidelines have been developed to delineate when to administer them and for how long. Some administer prednisone 1 mg/kg for 7 days and then gradually taper the dose over the next several weeks. The response to corticosteroids may be delayed or absent in some patients. Dialysis may be needed in patients who are oliguric, but it is usually not required for those who are nonoliguric. The clinician should document J.S.'s allergic reaction to penicillins because repeated exposure is likely to result in similar reactions.

POSTRENAL ACUTE RENAL FAILURE

Any condition that results in the obstruction of urine flow at any level of the urinary tract is termed *postrenal ARF*. Common causes of postrenal ARF are stone formation, underlying malignancies of the prostate or cervix, prostatic hypertrophy, or bilateral ureter strictures. Conditions that result in bladder outlet obstruction (e.g., prostatic hypertrophy) are the most common causes of postrenal ARF. The onset of signs and symptoms is generally gradual; it often presents as decreased force of urine stream, dribbling, or polyuria. Drugs can also result in insoluble crystal formation in the urine and should be included in the differential diagnosis.

Nephrolithiasis

Kidney stones are relatively common and affect approximately 10% of all people at least once in their lifetime.³⁵ A strong genetic predisposition appears to exist in this population. Epidemiologic data have found that men with stones were three times more likely to have parents or siblings with a history significant for stones.³⁶ In addition to genetics, other underlying risk factors exist for stone development (Table 30-6). Nephrolithiasis has a male:female incidence of 3:1, and whites are twice as likely as blacks to develop stones. Kidney stones generally consist of uric acid, cystine, struvite (also called magnesium ammonium phosphate or triple phosphate nephrolithiasis), and calcium salts. Of these, calcium stones are by far the most prevalent.

Calcium Stones

Calcium nephrolithiasis constitutes approximately 70% to 80% of all kidney stones,³⁶ with calcium oxalate and calcium phosphate stones making up most of these. Genetic factors appear to play an important role in the development of calcium

nephrolithiasis; the stereotypical patient is a man in his third to fifth decade of life. Other risk factors for developing calcium nephrolithiasis are low urine output, inadequate hydration (e.g., living in a hot climate and not drinking adequate fluids), hypercalciuria, hyperoxaluria, hypocitraturia, hyperuricosuria, and distal renal tubular acidosis. Generally, more than one of these conditions is present simultaneously.

Struvite Stones

Magnesium ammonium phosphate crystallization, termed *struvite stones*, represents the second most common type of nephrolithiasis (~2%–20% of cases). Struvite stones can result in significantly high morbidity and mortality because they tend to recur and can result in irreversible kidney damage.³⁷ These stones often fill the renal collecting ducts and assume a “staghorn” appearance. Struvite stones generally result when existing stones are colonized with *Proteus*, a bacterium that produces urease, an enzyme that hydrolyzes urea and alkalinizes the urine. The alkaline environment promotes the formation of insoluble crystals of ammonium, calcium, and phosphate. *In vitro*, simply alkalinizing the urine results in the immediate precipitation of amorphous struvite stones. Populations at risk for developing struvite stones include obese women, patients with frequent urinary tract infections or pyelonephritis, and patients with genitourinary tract abnormalities that promote bacterial colonization or make eradication of infection difficult. The most problematic form of stone disease develops in paralyzed patients with indwelling Foley catheters. Recurrent nephrolithiasis is one of the most common causes of death in patients with spinal cord injury. Treatment of struvite stones can consist of surgical intervention; prolonged courses of broad-spectrum antibiotics; administration of acetohydroxamic acid, which inhibits bacterial urease; or shock-wave lithotripsy.³⁷

Uric Acid Stones

Uric acid stones commonly occur in patients whose uric acid metabolism is altered because of various medical conditions. In particular, patients with gout and those receiving chemotherapy are susceptible to these stones. This topic is discussed further in Chapter 43, Gout and Hyperuricemia.

Cystine Stones

Cystinuria is a rare autosomal-recessive hereditary disorder of amino acid transport in the renal tubules that results in the urinary excretion of large amounts of cystine. These stones form when the cystine excretion rate exceeds the urinary solubility limit. The calculi form staghorns in the renal tubules and can cause urinary obstruction, infection, and ARF. Therapy of cystine stones is targeted at reducing the urinary cystine excretion while increasing its urinary solubility. This can be accomplished by diet modification, increased fluid intake, urine alkalinization, and drug therapy. Low-sodium diets decrease cystine excretion, and restriction of methionine, a cystine precursor, may reduce cystine excretion. It may also result in depletion of other important amino acids, however. To decrease the urinary cystine concentrations, urine volume should be increased by maintaining a fluid intake of >4 L/day. The solubility of cystine in urine also can be increased by alkalinizing the urine. Pharmacologic therapy is indicated when the above nondrug measures have failed. Drug therapy is targeted at increasing the urinary solubility of cystine, which can be achieved by forming

Table 30-6 Risk Factors for Nephrolithiasis

| |

| Low urine volume |
| Hypercalciuria |
| Hyperoxaluria |
| Hyperuricosuria |
| Hypercitruria |
| Chronically low or high urinary pH |

a thiol-cysteine disulfide bond. D-Penicillamine and tiopronin are the most commonly used drugs, although tiopronin appears to be better tolerated than D-penicillamine.

Presentation and Treatment

23. T.C., a 48-year-old man, presents to the emergency department complaining of sharp flank pain radiating to the groin, gross hematuria, and dysuria. He states that these symptoms have been present for 4 hours and that they are similar to previous episodes of calcium nephrolithiasis he has experienced. Serum chemistries are ordered and are significant only for a BUN of 34 mg/dL (normal, 5–20) and an SrCr of 1.5 mg/dL (normal, 0.5–1.2), which are up from his baseline values of 15 and 0.9 mg/dL, respectively. A urine sample was obtained and visualized with microscopy. It was determined that T.C. passed a kidney stone, based on the large amount of calcium oxalate crystals found in the urinary sediment. On questioning, he admits that he has not been drinking much fluid over the past week owing to a busy work schedule, and his urine volume has been markedly lower than usual. What are the common subjective and objective data that suggest nephrolithiasis, and how can this be prevented from occurring in the future?

[SI units: BUN, 12.1 and 5.3 mmol/L (normal, 1.8–7.1); SrCr, 132.6 and 79.5 mol/L, respectively (normal, 44.2–106)]

T.C. illustrates the classic presentation of nephrolithiasis: acute, severe flank pain that radiates to the groin. It is usually accompanied by gross or microscopic hematuria, dysuria, or frequency. Of symptomatic calculi, 90% pass spontaneously, as in T.C.'s case, and invasive surgical treatment is rarely necessary.³⁸ The risk factors that predispose T.C. to stone recurrence include a previous episode of nephrolithiasis, age within the fourth decade, and decreased fluid intake and urine output.

T.C. should take preventive measures to reduce the likelihood of stone recurrence. Many randomized trials have demonstrated that nondrug and pharmacologic mechanisms can prevent stone formation. The most cost-effective way to prevent stone formation is to increase fluid intake. A classic 5-year randomized study compared a high fluid intake group (>2 L/day) with one that had normal daily fluid intake (~1 L/day). The results demonstrated a significantly longer time to stone recurrence (39 vs. 25 months) in the high fluid intake group.³⁹ Dietary modifications remain controversial. Although it appears that limiting protein, calcium, and sodium intake should decrease the likelihood of recurrent nephrolithiasis, the data are conflicting.⁴⁰ In summary, a high calcium intake probably increases the risk of nephrolithiasis but only in patients with absorptive hypercalciuria and not in normal subjects.

Pharmacologic control of calcium oxalate stones has been tried with thiazide diuretics.⁴¹ Thiazide diuretics promote calcium reabsorption in the distal tubule, which decreases the concentration in the lumen. Thiazides also may decrease intestinal calcium absorption in patients with absorptive hypercalciuria, although this remains unclear. Patients receiving thiazide diuretics should be sodium restricted because excessive sodium intake negates their hypocalciuric effect. Allopurinol has been used successfully to prevent recurrent calcium oxalate nephrolithiasis, presumably by inhibiting purine and uric acid metabolism.⁴¹ Alkalinization of the urine with potassium citrate and potassium-magnesium citrate also prevents recurrent calcium oxalate nephrolithiasis.

Table 30-7 Commonly Used Drugs That Cause Crystal-Induced Acute Renal Failure

| |
|--------------|
| Acyclovir |
| Indinavir |
| Methotrexate |
| Sulfonamides |
| Triamterene |

T.C. should be instructed to drink at least 2 L of fluid (~eight 8-ounce glasses) daily. Given his busy work schedule, a thiazide diuretic probably is not the most convenient option for T.C., and noncompliance is likely. Allopurinol 200 mg orally once daily is probably the most convenient preventive strategy for T.C., and data suggest it is effective in preventing recurrent nephrolithiasis. Alternatively, urinary alkalinization with potassium citrate or potassium-magnesium citrate is likely to benefit T.C., but it may be less convenient because it needs to be administered two to four times daily.

Drug-Induced Nephrolithiasis

24. Can drugs crystallize in the urine and cause ARF?

Many commonly prescribed drugs are insoluble in urine and crystallize in the distal tubule (Table 30-7). Risk factors that predispose patients to crystalluria include severe volume contraction, underlying renal dysfunction, or acidotic or alkalotic urinary pH. In conditions of renal hypoperfusion, high concentrations of drug become stagnant in the tubule lumen. Drugs that are weak acids (e.g., methotrexate, sulfonamides) precipitate in acidic urine; drugs that are weak bases (e.g., indinavir, other protease inhibitors) precipitate in alkaline urine. Prevention of crystal-induced ARF is targeted at dosage adjustment for patients with underlying renal dysfunction, volume expansion to increase urinary output, and urine alkalinization. Similarly, for established crystal-induced ARF, the above general supportive measures of urinary alkalinization and volume expansion should be performed. Dialysis may be necessary in a small percentage of patients. With appropriate pharmacotherapy, crystal-induced ARF is usually reversible without long-term complications.

SUPPORTIVE MANAGEMENT OF ACUTE RENAL FAILURE

25. What is the supportive management of ARF?

Despite years of study, no pharmacologic “cure” for ARF exists. Therefore, supportive therapy is directed at preventing its morbidity and mortality. This is achieved by close patient monitoring; strict fluid, electrolyte, and nutritional management; treatment of life-threatening conditions, such as pulmonary edema, hyperkalemia, and metabolic acidosis; avoidance of nephrotoxic drugs; and the initiation of dialysis or continuous renal replacement therapies (CRRT).

Clinicians should closely monitor patient vital signs (e.g., weight, temperature, BP, pulse, respirations, and fluid intake and output) at least once every shift. Daily weights can forewarn the clinician of edematous weight gain. The patient's medication profile should be reviewed daily to assess for appropriate dosage adjustment in renal dysfunction. Because estimation of ClCr is difficult in patients with rapidly changing renal function, therapeutic drug monitoring should be

performed when using drugs with narrow therapeutic indices. When possible, nephrotoxic drugs should be avoided, but this may be difficult in patients who are septic or hypotensive and require nephrotoxic antibiotics and vasopressors. Preventive measures to reduce the likelihood of ARF should be used, such as ensuring adequate hydration, using dosing strategies or products that are associated with less nephrotoxicity, and avoiding drug therapy combinations that enhance nephrotoxicity (e.g., NSAID, aminoglycosides). If patients with ARF are receiving total parenteral nutrition, close monitoring of serum chemistries is needed to identify fluid and electrolyte abnormalities.

Supportive drug therapy may be used to reduce ARF symptoms. As discussed, diuretics currently have no role in preventing ARF progression or reducing mortality, but they can prevent complications, such as pulmonary and peripheral edema, and they may prevent tubular obstruction from ATN. The patient's volume status should be assessed daily, and fluids should be adjusted based on laboratory chemistries, urine output, and gastrointestinal and insensible losses. Dietary sodium restriction of 2 to 2.5 g/day should be instituted to prevent edema formation.

Diuretics for Edema in Acute Renal Failure

If edema occurs, intravenous (IV) furosemide is preferred because of its potency and pulmonary vasodilation properties. Oral furosemide therapy should be avoided because gut edema may limit its bioavailability. *Torsemide*, another loop diuretic, has excellent oral bioavailability and is unaffected by gut edema. Previously, torsemide was reserved for patients with demonstrated bioavailability problems with furosemide because of cost concerns, but a generic version of torsemide is now available. The dosage of diuretic needed is highly patient specific, especially in those with frank proteinuria, glomerulonephritis, or the nephrotic syndrome. Furosemide is highly protein bound, and thus binds to filtered protein, which negates its pharmacologic effect on the kidneys. Combinations of loop and thiazide diuretics may be needed in patients with ARF if they become diuretic resistant. This combination acts synergistically to block sodium and water reabsorption in both Henle's loop and the distal convoluted tubule. Other alternatives include continuous loop diuretic infusions, such as furosemide 1 mg/kg/hour. The infusion rate should not ex-

ceed 4 mg/minute because these rates are associated with ototoxicity, especially when given in combination with aminoglycoside antibiotics. Close monitoring of potassium, magnesium, and calcium is necessary when giving large doses of loop diuretics.

Hyperkalemia commonly occurs in patients with ARF because the kidneys regulate potassium homeostasis. Acute therapy of hyperkalemia is discussed in Chapter 12, Fluid and Electrolyte Disorders. In cases in which conventional pharmacologic treatment is not feasible, emergency hemodialysis should be performed.

Metabolic acidosis is a common manifestation of ARF because the kidneys are responsible for excreting organic acids. As GFR declines to <30 mL/minute, organic acids accumulate and clinical symptoms can occur. Severe metabolic acidosis should be corrected with dialysis, but early initiation of oral sodium bicarbonate may prolong or obviate the need for dialysis.

Extracorporeal Continuous Renal Replacement Therapy

Renal replacement therapy is not always indicated in ARF. It is reserved for patients with severe acid-base disorders, fluid overload, hyperkalemia, symptomatic uremia, or drug intoxications. RRT can be divided into intermittent hemodialysis or CRRT, such as continuous peritoneal dialysis or extracorporeal CRRT. The decision to use one over the other is most often decided by the nephrologist's experience and comfort level. Extracorporeal CRRT differs from peritoneal and hemodialysis in its mechanism of solute removal; dialysis modalities rely primarily on solute diffusion across a semipermeable membrane, whereas CRRT relies primarily on convective ultrafiltrate production. This discussion will be limited to extracorporeal CRRT therapies. (See Chapter 33, Renal Dialysis, for a complete overview of peritoneal and hemodialysis.)

Not all *extracorporeal CRRT* is alike⁴²; many variations exist and include modalities such as continuous arteriovenous hemofiltration (CAVH), continuous venovenous hemofiltration (CVVH), continuous venovenous hemodialysis (CVVHD), and continuous venovenous hemodiafiltration (CVVHDF). Differences between these modalities are illustrated in Table 30-8. Drug dosing can be difficult in patients receiving these therapies, especially in those who are undergoing both dialysis and hemofiltration modalities (i.e., CVVHDF).

Table 30-8 Comparison of Extracorporeal Continuous Renal Replacement Therapies

| Parameter | Continuous Venovenous Hemofiltration (CVVH) | Continuous Arteriovenous Hemofiltration (CAVH) | Continuous Venovenous Hemodialysis (CVVHD) | Continuous Venovenous Hemodiafiltration (CVVHDF) |
|---|---|--|--|--|
| Volume control in hypotensive patients | Good | Variable | Good | Good |
| Solute control in highly catabolic patients | Adequate | Inadequate | Adequate | Adequate |
| Blood flow rates in hypotensive patients | Adequate | Poor | Adequate | Adequate |
| Ease of drug dosing | Published recommendations | Difficult | Difficult | Difficult |
| Dialytic solute clearance | None | None | Moderate | Moderate |
| Convective solute clearance | Good | Good | Minimal | Moderate |
| Corresponding GFR (mL/min) | 15–17 | 10–15 | 17–21 | 25–26 |
| Blood pump required | Yes | No | Yes | Yes |
| Replacement fluid required | Yes | Yes | Yes | Yes |
| Pharmacy expense | High | High | High | High |

GFR, glomerular filtration rate.

Both CAVH and CVVH are modalities that rely solely on convective solute removal. Convection is simply the movement of water and solutes across a high-flux dialyzer or hemofilter. Because it does not depend on the molecular weight (MW) of a given solute, small solutes (MW, <500 D) and middle MW solutes (MW, 500–15,000 D) are removed to the same extent if they fit through the membrane pore. Drugs and solutes <15,000 D are removed very well. Most penicillin, cephalosporin, and aminoglycoside antibiotics have MW <500 D, and vancomycin's MW is 1,450 D. Continuous convective modalities are much better than dialysis for middle molecule and low-molecular-weight protein removal. CRRT is also better able to maintain a constant total body water volume. These therapies allow for a more gradual removal of large fluid volumes (3–5 L/day), which is not possible with conventional dialysis therapies.

Continuous Arteriovenous Hemofiltration

The first extracorporeal therapy, CAVH, was developed in the late 1970s. In this technique, a patient's blood is accessed

through an artery and systemic BP and cardiac output are used as the driving forces to pump it through a high-flux hemofilter. Heparin is infused prefilter to prevent clot formation within the hemofilter. Blood flow rates are modest at 90 to 150 mL/minute. The mean arterial pressure (MAP) generates a transmembrane pressure (TMP) that filters plasma water and dissolved solutes (urea, creatinine, and drugs) across the hemofilter membrane.⁴³ Most of the filtered solution, or ultrafiltrate, is replaced by a solution that contains normal electrolyte concentrations. In volume-overloaded patients, a desired volume of plasma can be maintained by adjusting the volume of replacement fluid returned to the patient. The primary disadvantage of CAVH is that arterial access is often complicated by bleeding, aneurysm, ischemia, or embolism. Second, because blood flow and ultrafiltration depend on the MAP, volume and solute control becomes difficult in patients who become hypotensive or hypercatabolic.⁴⁴ These disadvantages have been averted to a degree through the introduction of venovenous access and the addition of blood roller pumps.

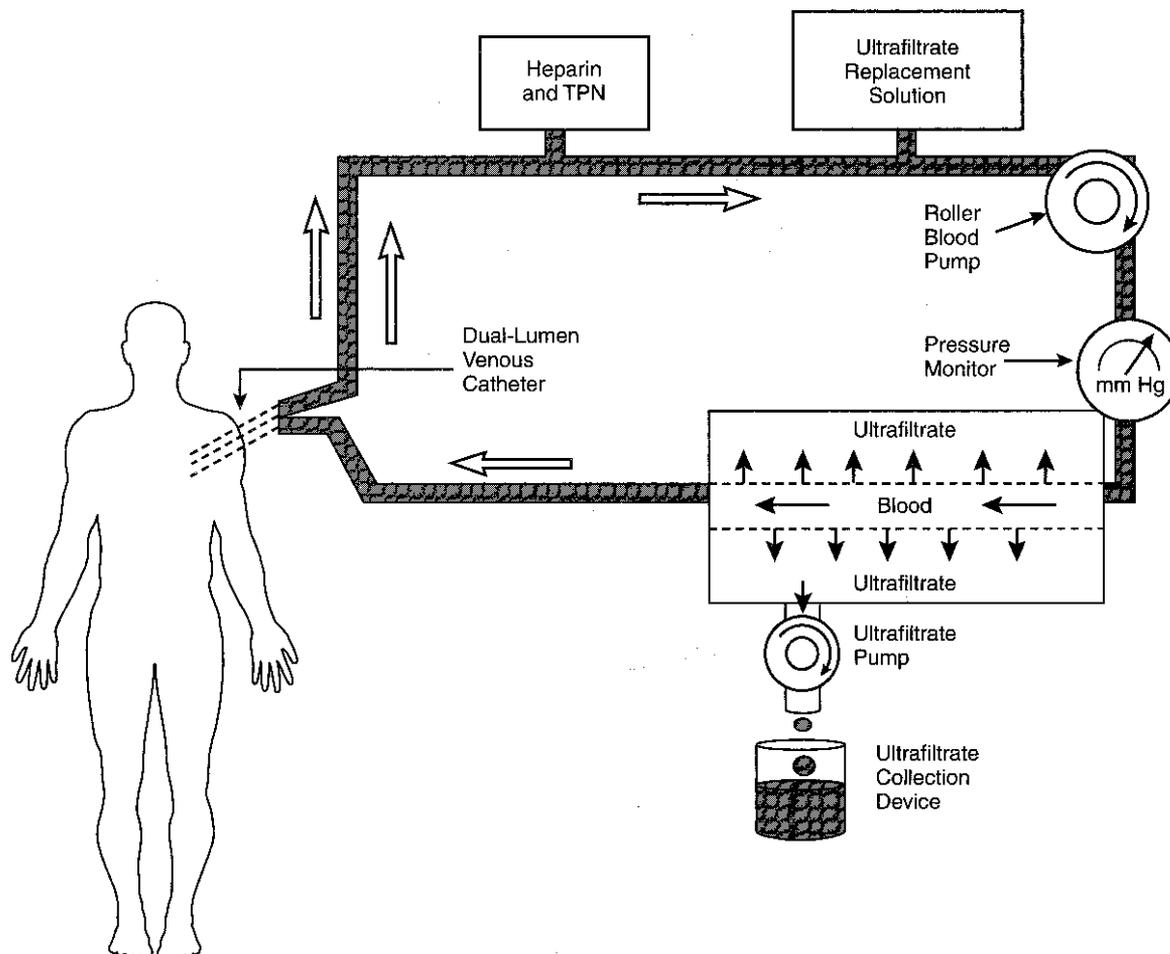

FIGURE 30-6 Schematic of continuous venovenous hemofiltration (CVVH). Blood is accessed by a dual-lumen catheter in a central vein and is pumped through the extracorporeal circuit by a roller blood pump. The blood pump maintains a constant hydrostatic pressure to create ultrafiltration, even in hypotensive conditions. Patients receiving CVVH are most often in the intensive care unit and often receive concomitant parenteral nutrition. Heparin is infused prefilter to prevent clot formation within the circuit. The ultrafiltrate replacement solution is provided back to the patient through a second venous catheter port at a rate that achieves a desired total body water volume. (From reference 45, with permission.)

Continuous Venovenous Hemofiltration

A major advancement in extracorporeal CRRT is CVVH. Venous access is obtained by inserting a dual-lumen catheter into a central vein (e.g., internal jugular or subclavian), and a roller pump provides a constant driving force for the blood to enter the hemofilter (Fig. 30-6).⁴⁵ The pressure generated by the roller pump results in continuous ultrafiltrate production. The blood flow rate is considerably increased by the roller pump, achieving rates of 100 to 200 mL/minute, which provides adequate ultrafiltrate, even in patients who are hypotensive or hypercatabolic. The ultrafiltrate production rate is generally started at 1 L/hour, which corresponds to a GFR of approximately 16 mL/minute. On exiting the hemofilter, the blood is returned through the second lumen of the venous access; a replacement solution containing normal electrolyte concentrations is also infused. As with CAVH, the patient's volume status can be controlled by adjusting the volume of replacement solution. A common example is a patient with volume overload of 20 L after surgery who develops ARF. A reasonable goal in such a patient is a net fluid loss of 5 L/day. If the CVVH ultrafiltration rate is 1 L/hour, the total daily volume of fluid removal will be 24 L/day. To achieve a net loss of 5 L/day, the volume of replacement solution needs to be 19 L. Hence, the replacement solution should be infused at 792 mL/hour. At this rate, if all variables remain constant, the patient will achieve euvolemia within 4 days.

Combined Modalities

The CRRT modalities that combine hemofiltration with dialysis (e.g., CAVHDF, CVVHDF) are technically more difficult to perform and require sophisticated equipment. Although the same ultrafiltration principles described previously apply, a dialysis component that promotes additional solute diffusion across the high-flux hemofilter is added. In the case of CVVHD, the process is initiated as for CVVH with blood flow rates of 50 to 200 mL/minute, but a dialysis solution is run counter-

current along the hemofilter at 10 to 35 mL/minute, resulting in diffusion of solutes. This makes drug dosing extremely difficult because clinicians must account for both diffusive and convective drug removal.

Estimating Drug Removal

26. Are there ways to calculate drug removal in extracorporeal CRRT modalities?

Two recent reviews provide an excellent background on dosing drugs in patients receiving CRRT.^{45,46} The principles for drug removal in hemofiltration are basically identical with those for removal in hemodialysis. For example, drugs with a small volume of distribution and low protein binding are removed readily by these modalities. The *sieving coefficient* (SC) of a drug is the non-protein-bound fraction of the drug that is in plasma. For example, an SC of 0.8 means that 80% of the drug is unbound in plasma. Drug SC can be obtained from the literature or by measuring concentrations simultaneously in the prefilter blood and ultrafiltrate. The ratio of the ultrafiltrate concentration to plasma concentration is the SC. Drug clearance can be calculated by multiplying the SC by the ultrafiltration rate. For example, if a patient is receiving CVVH at an ultrafiltration rate of 1 L/hour, and he or she is receiving vancomycin (which has an SC of 0.8) 1 g/day, the vancomycin clearance while receiving CVVH is $0.8 \times 1,000 \text{ mL/hour} = 800 \text{ mL/hour}$ or 13 mL/minute.

Calculating drug clearance is much more difficult in hemodiafiltration modalities (CAVHDF, CVVHDF) because both convection and diffusion account for drug clearance and it is difficult to predict drug clearance precisely. The use of SC can be useful for small-molecular-weight drugs, but the accuracy declines with larger drug molecules, such as vancomycin. When possible, therapeutic drug monitoring should be performed to maintain therapeutic concentrations and to maximize drug therapy.

INTRODUCTION

Chronic kidney disease (CKD) describes the continuum of kidney dysfunction from early to late-stage disease. Estimated glomerular filtration rates (eGFR) range from 90 mL/minute/1.73 m² in the early stages to 15 mL/minute/1.73 m² in the late stages of disease. The most severe stage occurs when the eGFR is less than 15 mL/minute/1.73 m² and is known as end-stage renal disease (ESRD).¹ Patients with ESRD require renal replacement therapy in the form of dial-

ysis or transplantation to sustain life. Complications associated with CKD that increase the complexity of the condition and include fluid and electrolyte abnormalities, anemia, cardiovascular disease, hyperparathyroidism, bone disease, and malnutrition. Optimal treatment of patients with CKD is best achieved using a multidisciplinary approach to address the concurrent medical problems and complex pharmacotherapeutic regimens. Alterations in drug disposition that occur with kidney impairment and the subsequent need for dosage

Table 31-1 Staging of Chronic Kidney Disease Based on eGFR

| Stage | Description | eGFR (mL/min/1.73 m ²) |
|-------|--|---|
| 1 | At increased risk Kidney damage with normal or ↑ eGFR | ≥90 (with CKD risk factors) ≥90 |
| 2 | Kidney damage with mild ↓ eGFR | 60–89 |
| 3 | Moderate ↓ eGFR | 30–59 |
| 4 | Severe ↓ eGFR | 15–29 |
| 5 | Kidney failure | <15 (or need for renal replacement therapy) |

adjustments are additional considerations when determining rational pharmacotherapy in this population.

Definitions

Chronic kidney disease is characterized by a progressive deterioration in kidney function ultimately leading to irreversible structural damage to existing nephrons. Based on the progressive nature of this condition, a staging system has been established to classify kidney disease according to the eGFR, which is estimated clinically using creatinine clearance (Cl_{Cr}) (Table 31-1).¹ Specifically, CKD is defined as kidney damage with a normal or a mildly decreased eGFR (stages 1 and 2) or a eGFR <60 mL/minute/1.73 m² for at least 3 months with or without evidence of kidney damage (stages 3 to 5). Kidney damage is indicated by pathologic abnormalities or markers of injury, including abnormalities in blood or urine tests and imaging studies.¹ The presence of protein in the urine (defined as *proteinuria*, *albuminuria*, or *microalbuminuria* based on protein type and amount) is an early and sensitive marker of kidney damage.

A substantial decline in kidney function also leads to *azotemia*, the condition resulting from accumulation of nitrogenous wastes such as urea (blood urea nitrogen [BUN]), and an increased risk for developing complications of CKD. Uremic signs and symptoms from accumulation of nitrogenous wastes and other toxins lead to a myriad of complications affecting most major organ systems. Laboratory abnormalities include azotemia, hyperphosphatemia, hypocalcemia, hyperkalemia, metabolic acidosis, and worsening anemia. Clinical signs of CKD and its associated complications, including hypertension and uremic symptoms (e.g., nausea, anorexia), and bleeding are observed as the disease advances to stages 3 through 5. Interventions to slow the progression of kidney disease and potentially reverse the disease process are critical, because patients with a decline in eGFR to <30 mL/minute/1.73 m² (stage 4), in general, will ultimately have ESRD.

Epidemiology of Chronic Kidney Disease

Incidence and Prevalence

The Third National Health and Nutrition Examination Survey (NHANES III), a national study of more than 18,000 persons 20 years of age or older conducted from 1988 through 1994, provides information on the stages of CKD in the U.S. population.² From these data, it is estimated that 8.3 million Americans have CKD stages 3 to 5. They also reported that

11.3 million Americans are at risk for developing or have mild decrease in kidney function (CKD stage 1 and 2).¹

Data describing the ESRD population are made available annually by the U.S. Renal Data System (USRDS). The reports characterize the development, treatment, morbidity, and mortality associated with ESRD in the United States and include data from patients with kidney transplants. Based on the most recent data from the USRDS, more than 472,000 patients were receiving renal replacement therapy for ESRD at the end of 2004, with approximately 104,000 new patients starting treatment during that year.³ A continued increase in incidence rates of ESRD has been observed over the past decade, although this rate has decreased to approximately 1.5% to 5% per year over the past 5 years.³ The continued increase in incidence rates of ESRD, in conjunction with a relatively stable death rate for this population, accounts for the overall increase in the prevalence of ESRD. CKD has been identified as one of the focus areas for the Healthy People 2010 national health initiative; one of the specific objectives is to reduce the number of new cases of ESRD.⁴

Populations at increased risk for developing ESRD include males and the older population, particularly patients 65 years of age and older. More than 49% of incident hemodialysis patients in 2004 were age 65 or older, a much larger percentage than for the peritoneal dialysis and transplant populations.³ Racial distribution of the dialysis population shows that the prevalence is greatest in whites (61%) and blacks (32%), followed by Hispanics (14%) and Asians (4%). Blacks and Native Americans have a three to four times greater incident rate of kidney failure than white individuals.³

Etiology

Chronic kidney disease most often results from a progressive loss of functioning nephrons caused by a primary kidney disease or as a secondary complication of certain systemic diseases, but it can also result from an acute event causing irreversible damage to the kidneys. The leading causes of ESRD in patients newly diagnosed in 2004 were diabetes mellitus (44%), hypertension (27%), and chronic glomerulonephritis (8%).³ Among Native Americans, diabetes is the predominant etiology, accounting for nearly two-thirds of the ESRD cases. Diabetes also accounts for higher rates of ESRD in blacks and Hispanics than in whites. Another of the Healthy People 2010 national health objectives for CKD is to focus on efforts to reduce the incidence of ESRD in blacks, Hispanics, and Native Americans.⁴ Hypertension remains the most common cause of ESRD among blacks, with approximately one-third of cases

attributed to this disease. A variety of causes are responsible for the remaining cases of ESRD, among which are cystic kidney disease, other urologic causes, and acquired immunodeficiency syndrome (AIDS) nephropathy.

Mortality

Advances in dialysis and transplantation have improved patient care; however, mortality rates during the first year of ESRD have not improved over the past decade (first-year adjusted death rate is 234/1,000 patient-years in the year 2003 for prevalent ESRD patients).³ Patients with cardiovascular disease on dialysis have a fivefold greater risk of all-cause mortality when compared with the general Medicare population and with patients with CKD not yet requiring renal replacement therapy. Comorbid conditions, low albumin, malnutrition, and anemia at initiation of dialysis are strong predictors of mortality. Life expectancy is 20% to 25% of that of the general population. Cardiovascular-related events, particularly cardiac arrest and myocardial infarction, are the leading causes of death in the ESRD population. This is not surprising given the high prevalence of coexisting cardiac disorders in patients with ESRD and the elevated risk for mortality associated with these conditions. The Healthy People 2010 initiative for CKD will also focus on decreasing deaths from cardiovascular disease.⁴ Infection (predominantly septicemia) and cerebrovascular disease are also substantial contributors to overall mortality in patients with ESRD.³

Drug-Induced Causes of Chronic Kidney Disease

Analgesic Nephropathy

Analgesic nephropathy is a form of tubulointerstitial kidney disease characterized by renal papillary necrosis as a primary lesion and chronic interstitial nephritis as a secondary lesion resulting from habitual ingestion of a mixture of two antipyretic analgesics and usually caffeine, codeine, or both.⁵ Analgesic nephropathy is part of the *analgesic syndrome*, including such nonrenal complications as anemia, peptic ulcer disease, urinary tract infection, and atherosclerosis.⁵ Phenacetin, an acetaminophen prodrug, was the first agent to be identified as causing this syndrome. Currently in the United States, most cases are caused by long-term use or misuse of compound analgesics containing acetaminophen and aspirin along with caffeine or codeine.⁵ Similar findings in terms of the effect on kidney function have also been observed with nonsteroidal anti-inflammatory drugs (NSAID), with both acute and chronic manifestations associated with long-term use.⁶ The cumulative amount (at least 1 to 2 kg of acetaminophen), rather than the duration of analgesic intake, is the primary risk factor for developing chronic analgesic nephropathy.⁷ Recommendations made by the National Kidney Foundation (NKF) on analgesic use have been published.⁵

Analgesic nephropathy is more prevalent in female patients, with a female-to-male ratio of 5 to 7:1. The peak incidence occurs between the fourth and the fifth decades of life.^{5,7} Patients usually complain of chronic pain syndromes and, in most cases, psychiatric manifestations indicative of an addictive behavior are observed. At presentation, patients may have a reduced eGFR and findings consistent with CKD. During acute necrosis, patients may experience flank pain, pyuria, and hematuria. As necrosis progresses, cellular debris can cause

ureteral obstruction. Kidney dysfunction is characterized as a salt-wasting nephropathy, with a substantial reduction in urine-concentrating and urine-acidifying capabilities. The exact mechanism for kidney damage is uncertain; however, it is thought that because acetaminophen accumulates in the renal medulla, its oxidative metabolite produced by the medullary cytochrome P450 enzyme system may bind to macromolecules causing cellular necrosis. Although the reduced form of glutathione in the medulla can prevent this process, agents that reduce medullary glutathione content (e.g., aspirin) may promote kidney damage. This mechanism may explain a lack of analgesic nephropathy associated with acetaminophen alone. NSAID, which attenuate prostaglandin-mediated vasodilation, may induce an ischemic state within the renal medulla, leading to papillary necrosis.⁶

Data on the adverse renal effects of selective cyclooxygenase 2 (COX-2) inhibitors is less clear. Recently, a meta-analysis of 114 randomized, double-blind clinical trials evaluated the adverse renal events of COX-2 inhibitors. The authors reported that, of the six agents evaluated, only rofecoxib was associated with adverse renal effects, defined as significant changes in urea or creatinine levels, clinically diagnosed kidney disease, or renal failure. Higher doses and longer duration of therapy were associated with higher rates of renal dysfunction.⁸ Rofecoxib was voluntarily withdrawn from the market in 2004 because of increased concern about cardiovascular events.

The long-term management of analgesic nephropathy primarily involves strict abstinence from use of NSAID and combination analgesics. If possible, patients should be encouraged to maintain a high fluid intake to prevent obstruction of the tubules with necrotic debris and to reduce the risk of urinary tract infection. If such patients develop ESRD, treatment is similar to that for those with kidney disease from other causes. For patients requiring analgesics, aspirin or propoxyphene taken alone may be reasonable alternatives. Acetaminophen as a single agent may be safe, although habitual use can contribute to progression of kidney disease as well as to liver toxicity.⁷ Patients requiring chronic analgesic therapy should use the lowest dose to control pain, avoid combination products when possible, and maintain adequate hydration.

Lithium Nephropathy

Although lithium use has been associated with alterations in kidney function secondary to acute functional and histologic changes, its role in the development of chronic changes (i.e., chronic interstitial nephritis) is less clear. Both the concentrating ability within the kidney and the eGFR may decline with long-term lithium use.⁹ In addition, chronic interstitial changes may develop in patients receiving lithium, particularly those with high serum lithium concentrations. Despite these findings, however, others have failed to implicate lithium as a chronic nephrotoxic agent.¹⁰ In patients taking lithium chronically, close monitoring of serum lithium concentrations is advised, and serum creatinine (SrCr) measurements should be obtained annually to detect changes in kidney function.

Progressive Kidney Disease Treatment Options

Treatment of patients with stage 1 to 4 CKD focuses on reducing risk factors for progression of CKD (e.g., uncontrolled hypertension and diabetes) and providing interventions that

delay progression. Management of complications of CKD, including fluid and electrolyte abnormalities, anemia, hyperphosphatemia, secondary hyperparathyroidism, metabolic acidosis, and malnutrition, is necessary once patients were in stage 3 CKD and beyond. Renal replacement therapies including hemodialysis (HD), peritoneal dialysis (PD), and kidney transplantation are treatment options for patients with ESRD. In the 1950s, a patient diagnosed with ESRD faced unavoidable death with a life expectancy of days to weeks. Continued development of treatment options for ESRD introduced in the 1960s dramatically reduced ESRD-related morbidity and mortality. At the end of 2004, 66% of patients with ESRD were undergoing HD, 29% had a functioning transplant, and 5% were receiving PD.³

Medication Use

Data regarding medication use in dialysis patients, including those having HD and PD, reveal that these patients are prescribed a total of 8 to 11 medications per patient.^{11,12} According to the USRDS, antihypertensive agents were prescribed for 75% of patients, with calcium channel blockers and angiotensin-converting enzyme (ACE) inhibitors as the most common agents. Approximately 80% of patients on dialysis were prescribed phosphate-binding agents with a similar percentage of patients requiring erythropoietin. These patterns of medication use are reflective of the prevalence of complications in the latter stages of CKD. The extent of medication use and the complexity of prescribed drug regimens contribute to nonadherence and medication-related problems (MRP) in the ESRD population. To manage MRP, some dialysis facilities have utilized a clinical pharmacist, which has been shown to be cost-effective and is associated with maintenance of health-related quality of life in patients on HD.^{13,14}

Economics

The cost of treating patients with ESRD is substantial, with most of this cost paid by the federal government. In 2004, the cost was \$18.5 billion dollars, 6.7% of the Medicare budget.³ This amount reflects a consistent increase from prior years and an increase in the percentage of the Medicare budget dedicated to ESRD care. The increase is most likely associated with the higher prevalence of ESRD, changes in the standard of care, reimbursement structure, and types of patients being treated (e.g., diabetic patients versus nondiabetic patients). Higher costs of treatment were associated with diabetes and patients with low hemoglobin values at initiation of dialysis. Out-patient pharmacy-related costs accounted for approximately \$60.1 million of the ESRD Medicare budget for 2004.³

Pathophysiology

Progression of kidney disease to ESRD generally occurs over months to years and is assessed by the rate of decline in eGFR. There are approximately 1 million nephrons per kidney, each maintaining its own single nephron eGFR. Progressive loss of nephron function results in adaptive changes in remaining nephrons to increase single nephron eGFR.¹⁵ Over time, the compensatory increase in single nephron eGFR leads to hypertrophy and an irreversible loss of nephron function from sus-

tained increases in glomerular pressure. Glomerulosclerosis (glomerular arteriolar damage) develops from prolonged elevation of glomerular capillary pressure and increased glomerular plasma flow leading to a continuous cycle of nephron destruction. Regardless of the cause, a predictable and continuous decrease in kidney function occurs in patients when the eGFR drops below a “critical” value, to approximately one-half of normal.¹⁶ The rate of decline remains fairly constant for an individual, but can vary substantially among patients and disease states. A more rapid rate of decline in kidney function has been associated with black race, lower baseline eGFR, male gender, older age, and smoking. Compared with hypertensive kidney disease, conditions associated with a faster decline include diabetic kidney disease, glomerular diseases, and polycystic kidney disease.¹ Progressive disease is typically identified by persistent proteinuria, decreasing kidney function, and the development of glomerulosclerosis. Although early changes in kidney function can be detected through routine laboratory monitoring, most patients do not develop symptoms of uremia until they have reached the more severe stages (stage 4 CKD and ESRD).

As the leading causes of ESRD in the United States, diabetes, hypertension, and glomerular diseases have been the focus of research to identify their associated mechanisms of kidney damage. Diabetes accounts for most cases of ESRD, which are caused not only by poor glycemic control, but also by concurrent hypertension.³ Excess filtration of glucose and contact with glomerular and tubular cells result in increased cellular osmotic pressure and thickening of the capillary basement membrane. The resulting glomerulopathy may or may not result in proteinuria. Systemic hypertension is a potent stimulus for the progression of kidney disease because of its association with increased single nephron eGFR.^{15,17} Coexistent diabetes and hypertension increase the risk of developing ESRD by five- to sixfold compared with persons with hypertension alone. Proteinuria, one of the initial diagnostic signs, may also contribute to the progressive decline in kidney function, with a more rapid rate of progression associated with higher protein excretion.¹⁸ Immunologic and hemodynamic mechanisms have been identified to explain the glomerular injury and increase in renal plasma flow associated with proteinuria and high protein intake. Inflammatory cytokines may be responsible for fibrosis and renal scarring ultimately resulting in loss of nephron function.

Dyslipidemias, which are common in patients with CKD, are often observed concurrently with proteinuria. Increased low-density lipoprotein (LDL) cholesterol, total cholesterol, and apolipoprotein B, as well as decreased high-density lipoprotein (HDL) cholesterol, have been observed in patients with progressive kidney disease.¹⁹ Hypercholesterolemia has been associated with loss of kidney function in patients with and without diabetes.^{20,21} Accumulation of apolipoproteins in glomerular mesangial cells contributes to cytokine production and infiltration of macrophages and has been implicated in the progression of CKD, primarily in the presence of previous kidney disease or other risk factors such as hypertension.²² LDL is thought to promote glomerular damage by initiating a series of cellular events in mesangial cells and through oxidation to a more cytotoxic derivative once within these cells. Although serum total cholesterol, triglycerides, and apolipoprotein B all correlate with the rate of decline in eGFR, it is not clear that

they directly increase the rate of progression of kidney disease, particularly when present with concomitant conditions that also cause kidney damage. Some evidence, however, suggests that treatment of hypercholesterolemia with statin therapy in patients with CKD may reduce proteinuria and progression of CKD.²³

Clinical Assessment

Evaluation of Kidney Function

The most reliable and practical means available to determine baseline kidney function and monitor progression of kidney disease over time is eGFR. The ideal marker of eGFR should be a nontoxic substance that is freely filtered at the glomerulus and not secreted, reabsorbed, or metabolized by the kidney. Inulin and exogenous radioactive markers have been used to assess eGFR because they meet these criteria; however, they are not readily available to clinicians, require intravenous (IV) administration, and are costly. Creatinine is an endogenous substance that is derived from the breakdown of muscle creatine phosphate. It is excreted primarily by glomerular filtration; thus, creatinine clearance (Cl_{Cr}) has been used as a reasonable surrogate for eGFR. There are limitations to consider when using methods to assess eGFR that incorporate creatinine. Creatinine is eliminated not only through glomerular filtration, but also via tubular secretion. As nephron function declines, tubular secretion of creatinine contributes more substantially to overall elimination of creatinine such that Cl_{Cr} overestimates true eGFR. As a result, disease progression may be underestimated. Administration of cimetidine to patients before measurement of Cl_{Cr} may provide a more accurate assessment because cimetidine blocks tubular secretion of creatinine.²⁴

Serum creatinine (SrCr) alone is used clinically as an index of kidney function; however, multiple limitations to this practice exist. In the initial stages of kidney disease, SrCr may remain within the normal range. Consequently, SrCr may be relatively insensitive in detecting early kidney disease and is not accurate for estimating the progression of the disease. Because generation of creatinine is proportional to total muscle mass, it is affected by diet (notably by the ingestion of meats), age, and gender. Generally, muscle mass declines with age and is smaller in women. Thus, a SrCr that is in the upper limit of normal (e.g., 1.2 mg/dL) for a young athletic male is likely to be associated with a high creatinine clearance, whereas the same SrCr in a 70-year-old woman could indicate compromised renal function. Use of creatinine to assess kidney function in patients with liver disease may also lead to overestimation of eGFR.²⁵ This may be attributed to decreased production of creatine, the precursor to creatinine, by the liver or increased tubular secretion of creatinine by the kidney. Also, substantial variation is seen in the calibration of SrCr among laboratories that can result in differences in measured SrCr. Although SrCr can provide a rough estimate of kidney function, other means of assessing eGFR should be used when a more accurate determination is necessary. Other markers of early kidney damage, such as proteinuria, should also be evaluated in patients at risk for kidney disease.

Several equations have been developed to calculate eGFR that incorporate SrCr and other variables (especially age and gender) for reasons described above. The most commonly used

equation is the Cockcroft-Gault equation, which provides an estimate of Cl_{Cr} in patients with stable kidney function²⁶ (see Chapter 31, Acute Renal Failure). More recently a prediction equation was developed using data from the Modification of Diet in Renal Disease (MDRD) study, a multicenter trial that evaluated the effects of dietary protein restriction and blood pressure (BP) control on progression of kidney disease.²⁷ This equation, referred to as the *MDRD equation*, may provide a better estimate of GFR based on the fact that the equation was derived using eGFR measured directly by urinary clearance of a radiolabeled marker (¹²⁵I-iothalamate) as opposed to creatinine, and included a relatively large and diverse population (>500 white and black individuals with varying degrees of kidney disease) for derivation and validation of the equation. The MDRD equation²⁷ is as follows:

$$\begin{aligned} \text{Estimated GFR (mL/minute/1.73 m}^2\text{)} &= 170 \times (\text{SrCr})^{-0.999} \\ &\times (\text{Age})^{-0.176} \times (\text{BUN})^{-0.170} \times (\text{Alb})^{+0.318} \quad \text{(31-1)} \\ &\times (0.762 \text{ if female}) \times (1.18 \text{ if African American}) \end{aligned}$$

An abbreviated version has also been developed¹:

$$\begin{aligned} \text{Estimated GFR (mL/minute/1.73 m}^2\text{)} &= 186 \\ &\times (\text{SrCr})^{-1.154} \times (\text{Age})^{-0.203} \times (0.742 \text{ if female}) \quad \text{(31-2)} \\ &\times (1.21 \text{ if African American}) \end{aligned}$$

The Schwartz²⁸ equation is used to assess eGFR in children as follows:

$$\begin{aligned} \text{Creatinine clearance (mL/minute)} &= [k \times \text{length (in cm)}] / \text{SrCr} \\ \text{where } k \text{ is dependent on age: infant (1 to 52 weeks)} \\ k &= 0.45; \text{ child (1 to 13 years)} k = 0.55; \text{ adolescent male} \\ k &= 0.7; \text{ and adolescent female } k = 0.55. \quad \text{(31-3)} \end{aligned}$$

Although historically accepted as a more accurate method, calculation of Cl_{Cr} using 24-hour urine collection methods has not been proved to be more reliable than use of the Cockcroft-Gault or MDRD equations. Problems with urine collection methods include incomplete urine collection, diurnal variation in eGFR, and variation in creatinine excretion. Despite these limitations, shorter collection times or spot untimed urine samples may be useful to determine creatinine excretion. Populations in whom estimation of GFR using a 24-hour urine collection is more reasonable include patients with variation in dietary intake of creatine sources, such as vegetarians, or persons with poor muscle mass (e.g., malnourished individuals or amputees).¹

Estimation of GFR by the MDRD equation is used to follow the progression of kidney disease. Frequent assessment of drug selection and dosage regimen design should be integral to the evaluation of a patient with progressive kidney disease. The Cockcroft-Gault equation is most commonly used to evaluate the appropriate doses of drugs that are eliminated by the kidney.

Proteinuria

In patients who have (or are at risk for) kidney disease, additional assessment of kidney function should include evaluation of urinary protein excretion, which has been shown to be predictive of disease progression. Protein is not normally filtered at the glomerulus and is present only in trace amounts in the

Table 31-2 Diagnostic Criteria for Proteinuria and Albuminuria

| | Total Protein | | | Albumin | | |
|-------------------------------------|---------------------------|-----------------------------|--------------------------------------|---------------------------|-----------------------------|--------------------------------------|
| | 24-hr Collection (mg/day) | Spot Urine Dipstick (mg/dL) | Spot Urine Protein-SrCr Ratio (mg/g) | 24-hr Collection (mg/day) | Spot Urine Dipstick (mg/dL) | Spot Urine Albumin-SrCr Ratio (mg/g) |
| Normal | <300 | <30 | <200 | <30 | <3 | <17 (men) <25 (women) |
| Microalbuminuria | NA | NA | NA | 30–300 | >3 | 17–250 (men) 25–355 (women) |

urine. With glomerular damage, proteinuria is commonly observed. Proteinuria may precede elevations in SrCr and should be considered as an early marker of kidney damage. *Microalbuminuria* is defined as an albumin excretion rate of 20 to 200 mcg/minute or 30 to 300 mg/24 hour. Specific assays with increased sensitivity relative to standard assays are required for detecting quantities of protein in the range defined as microalbuminuria. *Proteinuria* is defined as a total protein excretion rate >200 mcg/minute or >300 mg/24 hour (referred to as *albuminuria* if albumin is the only protein measured). Total protein includes albumin and other proteins, such as low molecular weight globulins and apoproteins. Assessment of albuminuria is a better indicator of early kidney disease because it is primarily indicative of glomerular damage as opposed to total protein, which is not as specific for glomerular damage. Other tests, including urinalysis, radiographic procedures, and biopsy, may also be valuable in further assessing kidney function.

Quantification of albumin can be done using timed urine samples. Typically, a 24-hour collection period is used, although a timed sample collected overnight may be more reliable because protein excretion can vary throughout the day and with postural changes (i.e., orthostatic proteinuria). Untimed or “spot” urine samples for measurement of protein- or albumin-to-creatinine ratios are often more convenient. As opposed to measuring protein or albumin in a timed collection, this method corrects for variations in hydration status and may be more accurate because protein excretion is normalized to glomerular filtration. The albumin and creatinine concentrations in the urine are measured from a spot urine sample, preferably from a first-morning urine sample, because it correlates best with 24-hour protein excretion. If a first morning urine sample is not available, a random sample is acceptable. Factors associated with proteinuria, such as ingestion of a high-protein meal and vigorous exercise, must be considered when evaluating urinary protein. Measuring urinary protein postexercise will result in a falsely elevated urine protein level as a consequence of an increase in the membrane permeability of the glomeruli to protein and a saturation of the tubular reabsorption process of filtered protein. To minimize this risk, it is recommended to wait approximately 4 hours postexercise to test for proteinuria.²⁹ Screening for albuminuria can also be done using urine dipstick testing of a spot urine sample.

Reagent strips are available from several commercial test products and differ with regard to the specified testing procedure and the sensitivity and specificity for detecting albuminuria. Patients with a positive dipstick screening test should have a subsequent quantitative assessment of the protein- or albumin-to-creatinine ratio to confirm proteinuria.

According to the NKF-Kidney Disease Outcomes Quality Initiative (K/DOQI) Clinical Practice Guidelines for CKD, persistent proteinuria is diagnosed by at least two positive quantitative tests spaced by at least 1 to 2 weeks. The American Diabetes Association (ADA) defines microalbuminuria as a positive test on at least two of three quantitative measurements performed within a 3- to 6-month period. ADA criteria specify albumin-to-creatinine ratios of 30 to 300 mcg/mg as consistent with microalbuminuria, whereas higher values are indicative of albuminuria.³⁰ The NKF-K/DOQI Guidelines for CKD provide criteria for diagnosis of proteinuria and albuminuria based on testing method and gender (Table 31-2).¹

Staging of Chronic Kidney Disease

Historically the term *chronic renal insufficiency* was used to describe patients with decreased kidney function not requiring dialysis. This included a broad range of patients from the earlier stages of the disease, with eGFR >60 mL/minute/1.73 m², as well as those patients with more severe disease, with eGFR <30 mL/minute/1.73 m². Failure to distinguish patients at these differing levels of kidney function also resulted in failure to recognize differences in management approaches required at varying levels of eGFR. Only recently has a uniform classification system been adopted to describe the various stages of kidney dysfunction, similar to the rationale for staging or classifying other chronic disease (e.g., hypertension). This staging system was developed to promote a more consistent dialogue when referring to patients with kidney dysfunction and use of terminology associated with a more objective description. Kidney disease is classified into five stages based on the eGFR (Table 31-1).¹ A patient with stage 1 or 2 CKD would have some pathologic abnormality indicative of kidney damage (See *Definitions* above), although their eGFR is relatively normal. Continued screening and interventions to delay progression are essential at these stages. Patients with stages 3 to 5 CKD are diagnosed with the disease based on eGFR alone (eGFR

<60 mL/minute/1.73 m²). At these stages, management of complications becomes a standard of care. Stage 5 is the most severe stage when the eGFR is <15 mL/minute/1.73 m² and dialysis or transplantation is necessary.

Complications

Complications begin to develop as kidney disease progresses, most often when patients reach to stage 3 CKD and the eGFR is <60 mL/minute/1.73 m². Among these complications are fluid and electrolyte abnormalities, anemia, hyperphosphatemia, hyperparathyroidism, metabolic acidosis, cardiovascular complications, and poor nutritional status. Often, these complications go unrecognized or are inadequately managed during the earlier stages of CKD, leading to poor outcomes by the time a patient is in need of dialysis therapy. Hypoalbuminemia and anemia were identified in more than 50% of a population of patients new to dialysis therapy, and these findings were associated with a decreased quality of life.³¹ Late referral to a nephrologist to manage specific kidney disorders and associated complications has also been associated with increased mortality in the ESRD population.³² These and similar reports underscore the need for early and aggressive therapy to manage complications of CKD. These complications will be presented in more detail throughout this chapter. Complications associated with dialysis therapy are discussed in Chapter 32, Renal Dialysis.

Prevention

Appropriate management of CKD includes measures to prevent or slow progression of the disease and regular evaluation of kidney function to assess changes in disease severity and to monitor therapy. This includes aggressive strategies to manage the disorders that cause kidney disease or are known to accelerate the disease process, such as diabetes, hypertension, high protein intake, and dyslipidemias (see Chapter 12, Dyslipidemias, Atherosclerosis and Coronary Heart Disease; Chapter 13, Essential Hypertension; and Chapter 50, Diabetes Mellitus).

Antihypertensive Therapy

The association between BP and kidney disease is difficult to establish because hypertension is both a cause and a result of kidney failure. Hypertension, whether the primary cause of kidney disease or a coexisting disease in the presence of other etiologies, can promote kidney damage through transmission of elevated systemic pressure to glomeruli. The result is glomerular capillary hyperperfusion and hypertension leading to progressive kidney damage as nephron destruction continues. Glomerular ischemia induced by damage to preglomerular arteries and arterioles can also occur. Antihypertensive therapy prevents kidney damage and slows the rate of progression of CKD in both diabetic and nondiabetic patients.^{30,33} The added benefit of reduced cardiovascular mortality further supports the use of antihypertensive therapy in patients at risk for progressive CKD. Despite what is known about the beneficial effects of BP control in patients with CKD, data from NHANES III indicate that only 11% of individuals with hypertension and elevated SrCr had BP measurements below 130/85 mmHg (the previous goal BP in patients with CKD) and just 27% had BP less than 140/90 mmHg.^{1,2}

The target BP for patients with or at risk for kidney disease differs from that recommended for the general population with hypertension. Evidence now exists to support lowering BP beyond the generally advocated target of <140/90 mmHg. According to the Seventh Report of the Joint National Committee on Prevention, Detection, Evaluation, and Treatment of High Blood Pressure (JNC-7) and recommendations from the NKF-K/DOQI Hypertension and Diabetes Executive Committee, the goal BP for individuals with CKD or diabetes is <130/80 mmHg.^{34,35} Results from the MDRD study showed that further lowering of BP to <125/75 mmHg (or a mean arterial pressure <92 mmHg) was more beneficial than usual BP control in patients with higher rates of urinary protein excretion (>1 g proteinuria/day).^{18,30} The benefit seen in the low-target-BP group was maintained for 7 years after the end of randomization.³⁰ The effects of more aggressive BP lowering on progression of kidney disease were also studied in the African American Study of Kidney Disease and Hypertension (AASK) trial.³⁶ In this population, some evidence was seen in support of a lower BP goal in patients with higher baseline proteinuria; however, the effect on eGFR did not reach statistical significance. Changes in eGFR over a 4-year evaluation period did not differ significantly between patients with a mean BP of 141/85 mmHg and those with stricter control to a mean BP of 128/78 mmHg.³⁶ A *post hoc* analysis of the AASK trial found that patients with proteinuria >1 g/day assigned to the low-target BP group slowed progression to ESRD.³⁷ Clearly, BP control is important to delay progression of kidney disease, and with the expanding data supporting more aggressive BP lowering in patients with more severe proteinuria, the importance of BP control in this patient population is pivotal in slowing progression of CKD.

Blood pressure reduction with any agent or combination of agents is reasonable in patients with CKD. Among the available classes of antihypertensive agents, ACE inhibitors (e.g., enalapril, captopril, lisinopril) and angiotensin receptor blockers (ARB; e.g., losartan, irbesartan, candesartan) may afford additional benefits in preserving kidney function. In conditions of decreased kidney function and eGFR, angiotensin II primarily causes compensatory vasoconstriction of the efferent arteriole, thereby increasing glomerular capillary pressure (P_{GC}) and eGFR (Fig. 31-1). This effect is beneficial in conditions of acute renal failure; however, sustained increases in P_{GC} cause hypertrophy of individual nephrons and progressive kidney disease. ACE inhibitor and ARB therapy prevents this chronic increase in glomerular pressure mediated by angiotensin II. Benefits of ACE inhibitors have been demonstrated in patients with diabetes who had some degree of proteinuria, suggesting that use of ACE inhibitors be considered in this population regardless of BP.^{33,38–40} In patients without diabetes, ACE inhibitors have been shown to reduce BP, decrease proteinuria, and slow the progression of kidney disease when compared with other agents.^{36,41–43} An initial and mild decrease in eGFR is expected with ACE inhibitor therapy; therefore, an increase in SrCr of approximately 30% within the first 2 months of therapy is acceptable.⁴⁴ Hypotension, acute kidney failure, and severe hyperkalemia are reasons to consider discontinuing therapy (also, see Chapter 18, Heart Failure.)

Angiotensin II receptor blockers offer similar benefits to ACE inhibitors based on their ability to decrease efferent arteriolar resistance by blockade of the angiotensin type 1 (AT₁)

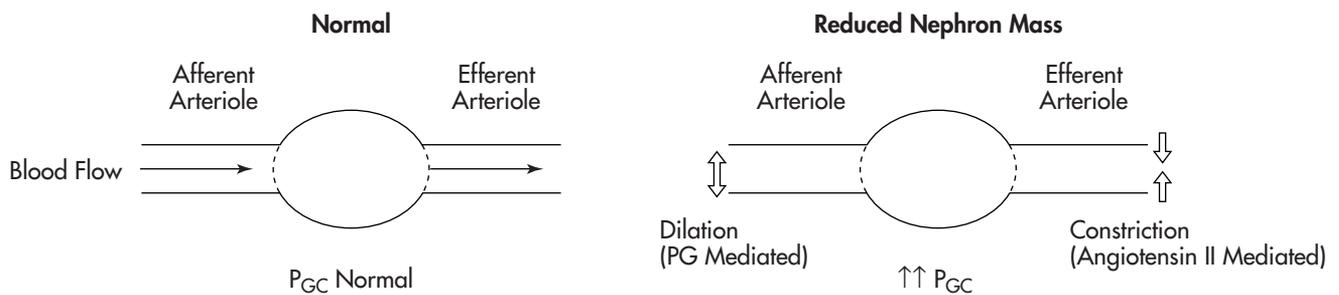

FIGURE 31-1 Renal hemodynamics are dependent on afferent and efferent arteriolar tone and glomerular capillary pressure (P_{GC}). With reduced nephron mass, afferent arteriolar vasodilation (mediated primarily by prostaglandins PGI_2 and PGE_2) and efferent arteriolar constriction (mediated primarily by angiotensin II) occur within remaining functioning nephrons to compensate. This leads to an increase in blood flow, intraglomerular capillary filtration pressure (P_{GC}), and hyperfiltration (increased single-nephron eGFR). Sustained increases in plasma flow and hydrostatic pressure lead to hyperfiltration injury and glomerular sclerosis. Over time, these changes contribute to continued loss of nephron function (i.e., progression of kidney disease). Angiotensin-converting enzymes (ACE) inhibitors and angiotensin receptor blockers (ARB) prevent vasoconstriction of the efferent arteriole and reduce the P_{GC} .

receptor. In patients with type 2 diabetes mellitus, losartan decreased the incidence of a doubling of SrCr by 25% and of ESRD by 28% when compared with placebo after a mean of 3.4 years of therapy.^{45,46} Similar effects were observed in the Irbesartan Diabetic Nephropathy Trial (IDNT) with a 23% decreased risk of ESRD observed in patients treated with irbesartan.⁴⁷ In both studies, these beneficial effects were independent of reduction in BP. Reduction in the degree of proteinuria has also been demonstrated with candesartan and valsartan.^{48,49} Combination therapy with an ARB and an ACE inhibitor may confer additional benefits than either therapy used alone, but larger clinical trials are needed to further ascertain the effect combination therapy will have on proteinuria and reducing time to HD.⁵⁰

Aliskiren is the first available agent in a new class of antihypertensives that targets the renin-angiotensin-aldosterone system (RAS) by inhibiting renin. The advantages of renin inhibition include inhibition of the rate-limiting step of angiotensin II formation, preventing compensatory RAS activation by ACE inhibitor or ARB therapy, and possible synergistic effects with other antihypertensive regimens. Potential additional advantages in the CKD population include nonrenal elimination and possible antiproteinuric effects. Clinical trials evaluating the use of aliskiren in the CKD population are lacking, therefore, its role remains undefined until further data are available.⁵¹

Calcium channel blockers have been considered for preventing progression of kidney disease because of their effects on renal hemodynamics and cytoprotective and antiproliferative properties, which prevent mesangial expansion and renal scarring. The nondihydropyridine agents (i.e., diltiazem and verapamil) have been beneficial in reducing proteinuria when compared with dihydropyridines (e.g., amlodipine), which have been found to worsen proteinuria.⁵² The NKF-K/DOQI guidelines suggest that dihydropyridine calcium channel blockers should not be used alone in nondiabetic or diabetic kidney disease with proteinuria, but can be used safely in combination with an ACE inhibitor or ARB. Combination therapy with an ACE inhibitor and nondihydropyridine agents has resulted in greater reductions in proteinuria in patients with diabetes than with either agent alone, suggesting that it may be rational to use multiple agents in this population.⁵³

β -Blockers may offer benefits in the treatment of diabetic nephropathy as demonstrated by the United Kingdom Prospective Diabetes Study, which showed similar effects of atenolol and captopril on decreasing the incidence of albuminuria in patients with diabetes.⁵⁴

Dietary Protein Restriction

Proteinuria was identified as the most significant predictor of ESRD in patients with type 2 diabetes and early CKD.⁴⁶ Evidence such as this has led to investigation of measures to decrease the degree of proteinuria. In addition to controlling the primary causes of kidney disease (e.g., diabetes, hypertension, and glomerulopathies) and using ACE inhibitor and ARB therapy, dietary protein restriction has been evaluated as a strategy for reducing proteinuria and delaying progression of kidney disease. Increases in protein ingestion are associated with a rise in eGFR, potentially because of structural changes of the glomerulus and changes in renal plasma flow with increased protein load.⁵⁵

A number of studies have investigated the effect of protein restriction on disease progression with varying results.^{56–58} These conflicting conclusions may result from differences in study design, patient populations, methods to assess kidney function, degrees of protein restriction, and dietary compliance. Evidence of the beneficial effects of protein restriction is primarily from nondiabetic patients and individuals with type 1 diabetes with protein restricted to approximately 0.6 to 0.8 g/kg of body weight per day.

In the MDRD study, the effects of protein and phosphorus restriction on progression of kidney disease were evaluated.⁵⁶ Nondiabetic patients with what is now considered stage 3 to 4 CKD (eGFR 25 to 55 mL/minute/1.73 m²) received either a normal protein (1.3 g/kg/day) or low-protein (0.58 g/kg/day) diet, whereas those with more severe kidney disease (eGFR 13 to 24 mL/minute/1.73 m²) were randomized to a low-protein or very-low-protein diet (0.28 g/kg/day). Within each protein category, patients were either maintained at a normal or low mean arterial pressure. A secondary analysis of the MDRD study, which accounted for dietary compliance, suggested that patients with severe kidney disease (eGFR <25 mL/minute/1.73 m²) could benefit from protein restriction to 0.6 g/kg/day.⁵⁷

Recently, a follow-up analysis of the above trial was published, which found that after a mean follow-up of 7.3 years, no significant difference was seen in decline in eGFR for each group.⁵⁹

The potential benefits of protein restriction in patients with CKD must be weighed against the potentially adverse effect on overall nutritional status. Malnutrition is prevalent in patients with CKD starting dialysis and is a predictor of mortality in this population.⁶⁰ The decision to restrict protein should be done with referral to a dietitian and frequent monitoring of nutritional status.

Treatment of Dyslipidemia

Lipoprotein metabolism is altered early in the course of kidney disease and becomes pronounced with more advanced disease, making hyperlipidemia common in patients with CKD. Elevated triglyceride, total cholesterol, LDL cholesterol, and decreased HDL cholesterol levels are generally observed. The predominance of triglyceride-rich apo-B lipoproteins may contribute to the progression of kidney disease and is also a risk factor for the development of cardiovascular morbidity and mortality.⁶¹

The role of antihyperlipidemic drug therapy in preventing progression of CKD is uncertain. Use of statin therapy has been associated with decreased proteinuria and preservation of eGFR in a small number of patients with CKD.^{23,62} A meta-analysis of trials, predominantly in patients with diabetes and CKD, showed that lipid-lowering therapy slowed the rate of decline in eGFR.⁶³ Despite uncertainty of therapy to delay progression, treatment of dyslipidemia should be considered, because abnormal lipid metabolism predisposes patients to cardiovascular disease. The question of whether strategies used to prevent and treat hyperlipidemia in the general population should be extrapolated to the population with kidney disease was addressed by the NKF Task Force on Cardiovascular Disease.⁶¹ This group supported application of the National Cholesterol Education Program (NCEP ATP III) guidelines to the population with kidney disease and classified these patients in the highest risk group.⁶⁴ Guidelines for management of dyslipidemias in patients with CKD have recently been made available (NKF-K/DOQI guidelines).⁶⁵ These guidelines also support classifying patients with CKD in the highest risk category for cardiovascular disease, equivalent to the risk for patients with coronary artery disease. The choice of the specific antihyperlipidemic agent should be based on the individual lipid profile. In general, NCEP guidelines should be followed, with particular consideration of the effect of such interventions on patients with CKD, such as dietary restrictions and use of agents that are renally eliminated. Hydroxymethylglutaryl-coenzyme A (HMG-CoA) reductase inhibitors, which are necessary to lower LDL cholesterol, may have added cardiovascular benefits. Fibrates should be used cautiously in patients with CKD, because all agents in this class are renally metabolized, and all are eliminated primarily via the renal route leading to a possible increase risk of myositis and increase in SrCr. Small studies have shown that excretion of gemfibrozil in renal insufficiency to be less severely compromised, therefore the NKF-K/DOQI recommends gemfibrozil as the fibrate of choice in patients with CKD and hypertriglyceridemia (see Chapter 12, Dyslipidemias, Atherosclerosis and Coronary Heart Disease).

END-STAGE RENAL DISEASE (STAGE 5 CHRONIC KIDNEY DISEASE)

Clinical Signs and Symptoms

During stages 4 and 5, patients may develop the more severe signs and symptoms associated with advanced kidney disease, often referred to as the *uremic syndrome*. The manifestations and metabolic consequences of advanced kidney disease are listed in Table 31-3. These manifestations certainly may develop in the earlier stages of CKD, underscoring the importance of early intervention, but become more prominent as the disease worsens. The pathogenesis of these disorders has been attributed, in part, to the accumulation of uremic toxins. The search for uremic toxins has led to the identification of nitrogenous compounds that are consistently observed in the serum of patients with kidney disease. A cause-and-effect relationship between these compounds and the clinical manifestations of uremia has not been clearly established, however.

Treatment

Dialysis and Transplantation

As ESRD becomes inevitable, the appropriate dialysis modality must be selected based on patient preference and options

Table 31-3 Metabolic Effects of Progressive Kidney Disease

| | |
|--|---|
| Cardiovascular | Hematologic |
| Hypertension | Anemia |
| Congestive heart failure | Bleeding complications |
| Pericarditis | Immune suppression |
| Atherosclerosis | Musculoskeletal |
| Arrhythmias | Renal bone disease |
| Metastatic calcifications | Amyloidosis |
| Dermatologic | Neurologic |
| Altered pigmentation | Lethargy |
| Pruritus | Depressed sensorium |
| Endocrine | Tremor |
| Calcium-phosphorous imbalances | Asterixis |
| Hyperparathyroidism | Muscular irritability and cramps (i.e., restless legs syndrome) |

GI, gastrointestinal.

for vascular access for HD or peritoneal access for PD. Early planning for dialysis therapy and timely initiation may lower patient morbidity and mortality. (Indications for dialysis and considerations in selection of modality are discussed in Chapter 33, Renal Dialysis.) Kidney transplantation is an option for all patients with ESRD without specified contraindications if a suitable organ match is available (see Chapter 34, Kidney, Liver, and Pancreas Transplantation).

Pharmacotherapy

Pharmacotherapy in patients with ESRD involves interventions to manage comorbid conditions and complications. The extent of medication use, including medications administered during dialysis therapy, contributes to the potential for drug interactions, adverse reactions, and nonadherence to therapy.¹² The effect of decreased kidney function on absorption, distribution, metabolism, and elimination of pharmacologic agents, in addition to the contribution of dialysis to drug removal, further complicates pharmacotherapy in this population (see Chapter 33, Dosing of Drugs in Renal Failure). Appropriate pharmacotherapeutic management includes choice of rational agents based on the indication, a regular comprehensive review of all medications, and frequent re-evaluation to adjust regimens relative to kidney function.

DIABETIC NEPHROPATHY

1. M.R. is a 32-year-old, Native American woman (weight, 63 kg; height, 5'8") with a 15-year history of type 1 diabetes mellitus. She presents to the diabetes clinic with a 1-week history of nausea, vomiting, and general malaise. She has been noncompliant with regular appointments and her blood glucose has generally remained >200 mg/dL on prior evaluations, with a hemoglobin A1C of 9.1% (goal, <7%) 2 months ago. M.R. has been treated for peptic ulcer disease for the past 6 months. The workup reveals the following pertinent laboratory values: serum sodium (Na), 143 mEq/L (normal, 135–147 mEq/L); potassium (K), 5.3 mEq/L (normal, 3.5–5.0 mEq/L); chloride (Cl), 106 mEq/L (normal, 95–105 mEq/L); CO₂ content, 18 mEq/L (normal, 22–28 mEq/L); SrCr, 2.9 mg/dL (normal, 0.6–1.2 mg/dL); BUN, 63 mg/dL (normal, 8–18 mg/dL); and random blood glucose, 220 mg/dL (normal, 140 mg/dL). Physical examination revealed a BP of 155/102 mmHg, mild pulmonary congestion, and 2+ pedal edema. Additional laboratory studies show serum phosphate, 7.6 mg/dL (goal, 3.5–4.6 mg/dL); calcium (Ca), 8.8 mg/dL (goal, 8.4–9.5 mg/dL); magnesium (Mg), 2.8 mEq/L (normal, 1.6–2.4 mEq/L); and uric acid, 8.8 mg/dL (normal, 2.0–7.0 mg/dL). Hematologic studies show hematocrit (Hct), 26% (normal, 36%–46%); hemoglobin (Hgb), 8.7 g/dL (normal, 12–16 mg/dL); and white blood cell (WBC) count, 9,600/mm³ (normal, 3,200–9,800/mm³). Red blood cell (RBC) indices are normal. Platelet count is 175,000/mm³ (normal, 130,000–400,000/mm³). M.R.'s reticulocyte count is 2.0% (normal, 0.1%–2.4%). Her urinalysis (UA) showed 4+ proteinuria, later quantified as a urinary albumin of 700 mg/24 hrs (normal, <30 mg/day). What subjective and objective data in M.R. are consistent with a diagnosis of advanced kidney disease?

[SI units: Na, 143 mmol/L (normal, 135–147); K, 5.3 mmol/L (normal, 3.5–5.0); Cl, 106 mmol/L (normal, 95–105); CO₂, 18 mmol/L (normal, 22–28); SrCr, 256 μmol/L (normal, 50–110); BUN, 22 mmol/L of urea

(normal, 3.0–6.5); glucose, 12.2 mmol/L (normal, <11 mmol/L); phosphate, 2.45 mmol/L (normal, 1.13–1.48); Ca, 2.2 mmol/L (normal, 2.1–2.38); Mg, 1.4 mmol/L (normal, 0.8–1.20); uric acid, 524 μmol/L (normal, 120–420); Hct, 0.26 (normal, 0.36–0.46); Hgb, 87 g/L (normal, 120–160); WBC count, 9,600 × 10⁶ /L (normal, 3,200–9,800); platelet count, 175 × 10⁹ /L (normal, 130–400); reticulocyte count, 0.02 (normal, 0.001–0.024), urinary albumin, 0.7 g/day (normal, <0.03)]

M.R.'s abnormal values for SrCr, BUN, serum potassium, magnesium, phosphate, uric acid, CO₂ content, hemoglobin, and hematocrit are all consistent with kidney disease and its associated complications. Assuming relatively stable kidney function (i.e., no acute changes in kidney function), her eGFR is approximately 24 mL/minute/1.73 m² based on the MDRD equation, placing her in stage 4 CKD (eGFR 15–29 mL/minute/1.73 m²). As the eGFR declines to the degree observed in M.R., normal regulation of fluids and electrolytes is impaired. Elevations in SrCr, BUN, sodium, potassium, magnesium, phosphate, and uric acid as well as signs of fluid accumulation are observed. Although potassium is mildly elevated in M.R., overall potassium balance is usually maintained within the normal range until more severe kidney disease develops (i.e., eGFR <10 mL/minute/1.73 m²). The substantial degree of proteinuria observed in M.R. is consistent with more advanced glomerular damage. Volume overload from continued intake and decreased sodium and water excretion leads to weight gain (although likely not observed in M.R. because of her recent onset of nausea and vomiting), hypertension, congestive pulmonary disease, and edema. Metabolic acidosis results from impaired synthesis of ammonia by the kidney, which normally buffers hydrogen ions and facilitates acid excretion. Anemia associated with CKD is caused primarily by decreased erythropoietin production by the kidneys, but it also can be caused by increased bleeding from uremia and her peptic ulcer disease. M.R.'s recent onset of nausea, vomiting, and malaise may be a consequence of the accumulation of uremic toxins (azotemia) from the decline in kidney function, although such symptoms are generally associated with BUN values greater than that observed in M.R.

2. What is the cause of M.R.'s advanced kidney disease?

Based on M.R.'s presentation, her kidney disease is most likely caused by diabetic nephropathy from her 15-year history of type 1 diabetes mellitus. Her history of noncompliance with regular appointments, elevated blood glucose concentration, and high hemoglobin A1C values support poor control of diabetes and diabetic nephropathy as the primary etiology. Diabetic nephropathy rarely develops within the first 10 years after onset of type 1 diabetes. The annual incidence is greatest after approximately 20 years' duration of diabetes and declines thereafter.⁶⁶ ESRD develops in 50% of patients with type 1 diabetic within 10 years and in >75% of patients within 20 years.⁶⁶ M.R. fits this pattern in that she has diabetic nephropathy after a 15-year history of diabetes, although her nephropathy was likely evident several years previously. M.R. may also be at increased risk for developing ESRD because Native Americans have a higher risk of ESRD relative to non-Hispanic whites.³

Diabetic nephropathy is a microvascular complication of diabetes resulting in albuminuria and a progressive decline in kidney function. Diabetic nephropathy develops in approximately one-third of all patients with type 1 and type 2 diabetes, with a

larger percentage of patients with type 1 diabetes developing ESRD. Because type 2 diabetes is more prevalent, however, these patients account for most of diabetic patients starting dialysis.⁶⁶ With the increased prevalence of diabetes and the increase in life expectancy of this population, it is likely that diabetic nephropathy will remain the leading cause of ESRD in the United States.^{3,4} Whereas most research has focused on the pathophysiology, prevention, and treatment of diabetic nephropathy in type 1 diabetes, it is reasonable to extrapolate available evidence on prevention of diabetic nephropathy to the population with type 2 diabetes.

The exact mechanisms leading to the development of diabetic nephropathy are not clearly defined; however, several predictive factors for the development and progression of kidney damage have been identified. These include elevated BP, plasma glucose, glycosylated hemoglobin, and cholesterol; smoking; advanced age; male gender; and potentially, high protein intake.^{67,68} Insulin deficiency and increased ketone bodies have also been proposed as contributors to the pathogenesis. Advanced glycosylation end products (AGE) that form in conditions of hyperglycemia have also been implicated as a cause of end organ damage. The accumulation of multiple AGE is associated with the severity of kidney disease in patients with diabetic nephropathy.⁶⁹ A genetic predisposition exists in that higher rates of diabetes and nephropathy, hypertension, cardiovascular events, albuminuria, and elevated BP have been observed in relatives of patients with type 2 diabetes.^{67,70} Certain genes and polymorphisms have also been associated with the development of diabetic nephropathy, and further exploration into this area may prove beneficial in identifying high-risk patients.⁷¹

3. What is the significance of M.R.'s albuminuria?

Albuminuria, the earliest sign of kidney involvement in patients with diabetes mellitus, correlates with the rate of progression of kidney disease. For most patients, eGFR begins to decline once proteinuria is established. Because of this association, annual testing for the presence of microalbuminuria is indicated in patients who have had type 1 diabetes for more than 5 years and in all patients with type 2 diabetes starting at diagnosis.⁷² The presence of albuminuria indicates irreversible kidney damage. M.R. has likely reached the point at which such damage is inevitable, because her urinary protein exceeds ranges normally observed at the earlier stages of kidney disease. M.R.'s current laboratory data suggest that she has substantial kidney disease and has developed associated complications of the disease. Although progression to ESRD is generally beyond prevention at this stage, appropriate intervention can extend the time period until M.R. will require dialysis therapy.

Management

4. How should M.R.'s kidney disease be managed?

Because reversal of M.R.'s kidney disease is unlikely, the primary goals are to delay the need for dialysis therapy as long as possible and to manage complications. The three main risk factors for the progression of incipient nephropathy to clinical diabetic nephropathy are poor glycemic control, systemic hypertension, and high dietary protein intake (>1.5 g/kg/day).

M.R.'s current random blood glucose concentration of 220 mg/dL, history of elevated glucose on prior visits, and increased hemoglobin A1C indicate poorly controlled diabetes, which will accelerate progression of her diabetic nephropathy. Thus, her blood glucose concentrations need to be maintained within target concentrations while avoiding hypoglycemia. M.R.'s elevated BP is likely the result of kidney disease and changes in intravascular volume; reduction of BP may prevent further damage to functioning nephrons. Similarly, protein intake should be less liberal in an attempt to reduce the rate of further progression, although this needs to be evaluated in the context of her overall nutritional status.

Intensive Glucose Control

Strict glycemic control is clearly indicated to reduce proteinuria and to slow the rate of decline in eGFR.⁶⁶ The Diabetes Control and Complications Trial (DCCT) was a multicenter trial in 1,441 patients, which was designed to address how rigidly blood glucose concentrations should be controlled to reduce diabetic complications.⁷³ The DCCT evaluated the effect of intensive insulin treatment for type 1 diabetes on the development and progression of long-term complications, including diabetic nephropathy. Patients were randomized to receive either conventional insulin treatment (one to two insulin doses a day) or intensive treatment (three or more insulin doses a day). The goal of the intensive regimen was to maintain fasting blood glucose concentrations between 70 and 120 mg/dL, with postprandial blood glucose concentrations <180 mg/dL. After a mean follow-up of 6.5 years, the intensive insulin regimen reduced the overall risk of microalbuminuria (defined as urine albumin ≥ 40 mg/24 hours) by 39%, and albuminuria (defined as urine albumin ≥ 300 mg/24 hours) by 54%. Stricter glycemic control was associated with an increased incidence of hypoglycemic episodes, however.⁷³ The effect of intensive glycemic control has also been studied in patients with type 2 diabetes. Over a 10-year treatment period, glucose control with either insulin or an oral sulfonylurea reduced microvascular complications, including albuminuria, when compared with conventional dietary therapy.⁷⁴

Based on this information and the need to minimize risk of hypoglycemia, the recommended goals in the adult diabetic population are a preprandial plasma glucose of 90 to 130 mg/dL, peak postprandial plasma glucose of <180 mg/dL, and an A1C <7%.⁷² M.R. will benefit from intensive insulin therapy and achievement of these goals despite her advanced kidney disease. M.R. should be counseled on appropriate techniques for insulin administration and home glucose monitoring, particularly given her history of noncompliance. Compliance with this regimen will require motivation as well as encouragement from M.R.'s family and health care providers. (See Chapter 50, Diabetes Mellitus, for a more complete discussion of intensive insulin therapy and counseling.)

Antihypertensive Therapy

Systemic hypertension usually occurs with the development of microalbuminuria in patients with type 1 diabetes and is present in about one-third of patients at the time of diagnosis of type 2 diabetes. The coexistence of these disorders further increases the risk of cardiovascular events. Hypertension may be a result of underlying diabetic nephropathy and increased plasma volume or increased peripheral vascular resistance. Regardless of

the etiology, virtually any level of untreated hypertension (either systemic or intraglomerular) is associated with a reduction in eGFR. As such, the control of systemic and intraglomerular BP is perhaps the single most important factor for retarding the progression of kidney disease and has been shown to increase life expectancy in patients with type 1 diabetes.³³

Patients with diabetes and hypertension develop elevated systemic vascular resistance and increased vasoconstriction from angiotensin II, which are in large part responsible for the glomerular damage characteristic of diabetic nephropathy. Although the management of hypertension with virtually any agent can attenuate the progression of kidney disease, ACE inhibitors, which inhibit the synthesis of angiotensin II, and ARB, which block angiotensin II AT₁ receptors, are preferred owing, in part, to the effects of these agents on renal hemodynamics (Fig. 31-1). Reductions in proteinuria and a decreased rate of decline in eGFR have been observed with ACE inhibitors and ARB in patients with type 1 and type 2 diabetes (see also the Prevention section in Progressive Kidney Disease in this chapter).^{33,38–40,45–50} As a result of these and other studies, ACE inhibitors or ARB should be considered for all patients with diabetes and microalbuminuria, even if their BP is normal.⁶⁶ Data comparing these two classes of agent are lacking. A recent trial compared the effects of the ARB, telmisartan, with the ACE inhibitor, enalapril, in patients with type 2 diabetes over 5 years. Conclusion was that the renoprotective effects of telmisartan were not inferior to enalapril, but a large dropout rate limits interpretation of the results. Additional trials may help clarify if one class of agents is superior to the other.⁷⁵

The primary goal in M.R. is to delay development of ESRD and to reduce the risk of cardiovascular complications and death. Treatment with an ACE inhibitor, such as enalapril, should be initiated, because she has substantial albuminuria (700 mg/day) and an elevated BP. An ARB (e.g., losartan) is a reasonable alternative to an ACE inhibitor in patients with ACE inhibitor-induced cough or other adverse effects that do not cross-react with an ARB. The initial product selected is generally based on tolerance to therapy and cost. A goal BP for M.R., based on the fact that she has type 1 diabetes and kidney disease, is a BP <130/80 mmHg.^{34,35} Because the beneficial effects of ACE inhibitor therapy occur over months to years, M.R. must be monitored on a long-term basis for changes in kidney function and albuminuria and for side effects of therapy, such as hyperkalemia. An increase in SrCr of up to 30% is acceptable with initiation of therapy with ACE inhibitors or ARB.⁴⁴ Contraindications for the use of ACE inhibitors and ARB include bilateral renal artery stenosis and pregnancy. The risk of hyperkalemia must also be weighed against the potential beneficial effects of these agents.

Some evidence suggests that a nondihydropyridine calcium channel blocker (e.g., diltiazem, verapamil) may be beneficial alone or in combination with an ACE inhibitor.^{52,76,77} Diuretics may be considered for patients with diabetic nephropathy and edema, depending on their degree of kidney function. For patients with kidney disease as extensive as that observed in M.R. (eGFR <30 mL/minute/1.73 m²), loop diuretics are generally preferred because, unlike thiazide diuretics, they may retain their effect at this reduced eGFR level (see Chapter 12, Fluid and Electrolyte Disorders and Chapter 13, Essential Hypertension). Other antihypertensive agents may be considered

based on response to initial therapy and changes in kidney function. Currently, clinical studies are examining the use of the aldosterone blocker, spironolactone, and the selective aldosterone blocker, eplerenone, for use in patients with diabetic nephropathy and overt proteinuria on maximal doses of both an ACE inhibitor and an ARB. These agents have antiproteinuric effects, but the potential increase risk for hyperkalemia when adding these agents to patients already as an ACE inhibitor and ARB warrants further evaluation of their use. The effect on slowing of progression of kidney disease has not been evaluated with these agents.⁷⁸

Dietary Protein Restriction

High protein consumption accelerates the progression of diabetic nephropathy, presumably because of increased glomerular hyperfiltration and intraglomerular pressure. In patients with overt albuminuria, some evidence indicates that the rate of decline in eGFR, as well as urinary albumin excretion, can be blunted by restricting protein intake to 0.6 to 0.8 g/kg/day and maintaining an isocaloric diet.^{30,57} Limited evidence indicates, however, a beneficial role of dietary protein restriction in diabetic patients with microalbuminuria. Nonetheless, given the potential benefits to delay progression of kidney disease, M.R. should be advised to maintain an isocaloric diet with a protein intake of 0.8 g/kg/day (~10% of daily calories).⁶⁶ The decision to decrease this intake even further to 0.6 g/kg/day must be based on the rate of decline in eGFR and her nutritional status. Because the typical Western diet is high in protein, some patients may have difficulty complying with such a low-protein diet because of its perceived unpalatability. Intervention by a dietitian is recommended to design a feasible dietary regimen limited in protein, yet consistent with nutritional requirements in a diabetic patient.

FLUID AND ELECTROLYTE COMPLICATIONS

Sodium and Water Retention

5. Assess M.R.'s sodium and water balance. What interventions may be used to address this problem?

As illustrated in M.R., patients in the latter stages of CKD commonly retain sodium and water. This is supported by M.R.'s elevated BP, 2+ pedal edema, and mild pulmonary congestion. Sodium and water retention also lead to weight gain, although this may not be evident in M.R. because of volume loss from her recent onset of nausea and vomiting. Early in the course of CKD, glomerular and tubular adaptive processes develop, such as an increase in the fractional excretion of sodium (FE_{Na}). These mechanisms enable patients to maintain relatively normal sodium and water homeostasis. As M.R.'s normal serum sodium concentration indicates, this value is of little use in establishing the diagnosis of total body sodium and fluid excess because retention of sodium and water usually occurs in an isotonic fashion, leaving the serum sodium concentration relatively normal. Eventually, however, patients with advanced kidney dysfunction exhibit signs of sodium and fluid retention, because sodium balance is maintained at the expense of increased extracellular volume, which results in hypertension. Expansion of blood volume, if not controlled, can cause peripheral edema, heart failure, and pulmonary edema. Thus,

management of sodium and water retention is essential. To achieve control, most patients with more advanced kidney disease will be placed on sodium restriction (~2 to 4 g/day) and fluid restriction (~2 L/day). These restrictions will depend on the current dietary intake, extent of volume overload, and urine output and should be altered according to the special needs of the patient. The primary consideration in CKD is that the kidney cannot adjust quickly to changes in sodium intake; therefore, any dietary intervention should be initiated gradually. Because M.R. has edema and hypertension, initial restriction of salt to 4 g/day, which is essentially a no-added-salt diet, is reasonable at this stage.

Because some patients with more advanced kidney disease produce normal amounts of urine, whereas others may produce less (or no urine if the patient has ESRD), fluid restrictions must be based on urine output. Diuretic therapy, usually with loop diuretics (e.g., furosemide, bumetanide, torsemide), is often required. Combination therapy with two different types of diuretics (i.e., loop and thiazide) may be successful in patients resistant to a single agent; however, limitations in efficacy of diuretics exist under certain conditions (e.g., a reduced eGFR and hypoalbuminemia), and these situations must be considered when designing a diuretic regimen. Thiazide diuretics as single agents are generally not effective when the eGFR is <30 mL/minute/1.73 m², as in M.R. The possible exception is use of the thiazidelike diuretic, metolazone, which may retain its effect at reduced eGFRs.⁷⁹ As kidney failure progresses, manifestations of excess fluid accumulation develop that are resistant to more conventional interventions, and dialysis will be required to control volume status.

Hyperkalemia

6. M.R. has a serum potassium concentration of 5.3 mEq/L. Describe the mechanisms by which potassium imbalance occurs in patients such as M.R. who have progressive CKD.

[SI unit: K, 5.3 mmol/L]

Hyperkalemia can result from a combination of factors, including diminished renal potassium excretion, redistribution of potassium into the extracellular fluid owing to metabolic acidosis, and excessive potassium intake. In M.R., all these mechanisms are likely to be contributing to hyperkalemia, although in the short-term dietary intake of potassium may not be substantial because of her recent onset of nausea and vomiting.

Potassium normally is filtered at the glomerulus and undergoes nearly complete reabsorption throughout the renal tubule. Distal tubular secretion is the primary mechanism by which potassium is excreted in the urine. A variety of factors affect this distal secretion of potassium, including aldosterone, sodium load presented to the distal reabsorptive site, hydrogen ion secretion, the amount of nonresorbable anions, urinary flow rate, diuretics, mineralocorticoids, and potassium intake.⁸⁰ Serum potassium concentrations are relatively well maintained within normal limits in patients with CKD. At eGFR >10 mL/minute/1.73m² hyperkalemia is rare without an endogenous or exogenous load of potassium. This balance is maintained despite a decreasing nephron population and an overall drop in eGFR, because the remaining nephrons undergo adaptive changes to enhance the distal tubular secretion of potassium per nephron (i.e., increased fractional excretion

of potassium, FE_K).⁸¹ Gastrointestinal (GI) excretion of potassium is also important because increased GI excretion and fecal losses may account for up to 50% of the daily potassium loss in patients with severe kidney disease. M.R.'s eGFR of 24 mL/minute/1.73 m² is above the "threshold" value for adequate potassium homeostasis. M.R. should be carefully observed for manifestations of hyperkalemia as her kidney disease progresses.

Additional factors that alter potassium homeostasis include metabolic or respiratory acidosis. Acidotic conditions can cause a redistribution of intracellular potassium to the extracellular fluid. M.R. has metabolic acidosis as indicated by a serum bicarbonate of 18 mEq/L. This condition may account for her mildly elevated potassium concentration. Correction of metabolic acidosis could lower her potassium concentration. For each 0.1-unit change in blood pH, an average corresponding opposite change of approximately 0.6 mEq/L in the serum potassium concentration occurs (see Chapter 10, Acid-Base Disorders).

M.R. is not taking any drugs that could contribute to hyperkalemia, although the influence of ACE inhibitors and ARB must be considered because they are now advocated for M.R. to delay progression of kidney disease. Potassium-sparing diuretics, such as spironolactone (Aldactone), triamterene (Dyrenium), and amiloride (Midamor), should be avoided in patients with severe CKD because they decrease tubular secretion of potassium. Some diabetic patients with only mild degrees of kidney disease develop hyperkalemia from these diuretics because they have low plasma renin activity and, as a result, lower aldosterone concentrations.

7. Is treatment of M.R.'s potassium indicated? How should severe hyperkalemia be managed?

Treatment of hyperkalemia depends on the serum concentration of potassium as well as the presence or absence of symptoms and electrocardiographic (ECG) changes. Manifestations of hyperkalemia include weakness, confusion, and muscular or respiratory paralysis. These symptoms may be absent, however, especially if hyperkalemia develops rapidly. Early ECG changes include peaked T waves, followed by a decreased R-wave amplitude, widened QRS complex, and a prolonged PR interval. These changes may progress to complete heart block with absent P waves and, finally, a sine wave. Ventricular arrhythmias or cardiac arrest may ensue if no effort to lower serum potassium is initiated. Hyperkalemic ECG changes are uncommon at potassium concentrations of <7 mEq/L, but occur regularly at concentrations >8 mEq/L.

M.R. has a mild elevation in potassium to 5.3 mEq/L; therefore, no specific treatment is required. Generally, treatment is unnecessary if the potassium concentration is <6.5 mEq/L and there are no ECG changes. Although this serum potassium concentration does not require immediate intervention, close monitoring for hyperkalemia and its manifestations is necessary. This would be particularly important after starting ACE inhibitor therapy, which can contribute to development of hyperkalemia by decreasing aldosterone production. If potassium concentrations rise above 6.5 mEq/L, and especially if they are accompanied by neuromuscular symptoms or changes in the ECG, treatment should be instituted.

Goals of therapy include prevention of adverse events related to excessive potassium and reduction of serum potassium

concentrations to a relatively normal range (4.5–5.5 mEq/L). Chronic management involves prevention of hyperkalemia by limiting potassium intake and avoiding the use of agents that could elevate potassium levels. This requires regular monitoring of potassium concentrations. Acute management involves reversal of cardiac effects with calcium administration and reduction of serum potassium. The latter can be achieved by shifting potassium intracellularly with administration of glucose and insulin, β -adrenergic agonists, or alkali therapy (if metabolic acidosis is a contributing factor) and by removing potassium using exchange resins or dialysis (see Chapter 11, Fluid and Electrolyte Disorders).

Metabolic Acidosis

8. Assess M.R.'s acid-base status. How should her acid-base disorder be managed?

M.R.'s low blood CO₂ content and high chloride concentration are consistent with metabolic acidosis. Normal buffering of hydrogen ions by the bicarbonate and carbonic acid system as well as other extracellular and intracellular buffers, including proteins, phosphates, and hemoglobin, is essential for maintaining normal acid-base balance (i.e., normal pH). Normal metabolism of ingested food produces approximately 1 mEq/kg of metabolic acid daily, which must be excreted by the kidneys (primarily as ammonium ion) to maintain acid-base balance. The kidney is responsible for reabsorption of bicarbonate and excretion of hydrogen ions through buffering by ammonia (produced by the kidney) and filtered phosphates. Reduced bicarbonate reabsorption and impaired production of ammonia by the kidneys are the major factors responsible for development of metabolic acidosis in advanced kidney disease. As nephron function declines, production of ammonia is increased to compensate for a decrease in secretion of hydrogen ions; however, once the maximal capacity for ammonia production is reached, acidosis develops. Mild hyperchloremia is generally observed in the earlier stages. As kidney disease progresses, metabolic acidosis with an elevated anion gap is observed owing to accumulation of organic acids (see Chapter 10, Acid-Base Disorders). Bone carbonate stores serve as a source of alkali, but over time cannot compensate for changes in acid-base balance. Metabolic acidosis can contribute to bone disease by promoting bone resorption, and it may also influence nutritional status by decreasing albumin synthesis and promoting a negative nitrogen balance.⁸²

M.R.'s mild acidosis should be treated with a goal of normalizing the plasma bicarbonate concentration or at least achieving bicarbonate levels near ≥ 22 mEq/L. Treatment includes use of preparations containing sodium bicarbonate or sodium citrate. Each 650-mg tablet of sodium bicarbonate provides 8 mEq of sodium and 8 mEq of bicarbonate. Shohl's solution and Bicitra contain 1 mEq of sodium and the amount of citrate or citric acid to provide 1 mEq of bicarbonate/mL. These latter agents may be used in patients who experience excessive GI distress with sodium bicarbonate from production and elimination of carbon dioxide. If a patient such as M.R. is sodium and fluid overloaded, it is important to consider that sodium bicarbonate can exacerbate this problem. Polycitra, or potassium citrate, is a possible alternative; however, the potassium content limits its use in patients with more severe kidney disease. Citrate also promotes aluminum absorption and should not be used in pa-

tients taking aluminum-containing agents. The NKF-K/DOQI guidelines do not give an exact recommendation of the amount of bicarbonate supplementation to achieve a bicarbonate ≥ 22 mEq/L. The use of two to four 650-mg sodium bicarbonate tablets per day, usually divided into two to three doses, is a typical regimen used to correct metabolic acidosis. Equations based on the serum bicarbonate level are available if an immediate correction of the metabolic acidosis is warranted.⁸³

Once dialysis therapy is initiated in patients with kidney disease, IV and oral supplementation with bicarbonate or citrate or citric acid preparations is generally not required. At this point, dialysis therapy is used to chronically manage metabolic acidosis through use of dialysate baths containing bicarbonate. Bicarbonate is added to the dialysate solution and is delivered through the process of diffusion from the dialysate bath into the plasma (see Chapter 32, Renal Dialysis). If dialysis therapy is initiated in M.R., the continued need for oral bicarbonate supplementation should be reassessed.

Other Electrolyte and Metabolic Disturbances of Chronic Kidney Disease

9. What other electrolyte and metabolic disturbances are exhibited by M.R.?

The mild degree of hypermagnesemia seen in M.R. is a common finding in patients with CKD owing to decreased elimination of magnesium by the kidney. Magnesium is eliminated by the kidney to the extent required to achieve normal serum magnesium concentrations until eGFR is < 30 mL/minute/1.73 m². Serum magnesium concentrations < 5 mEq/L rarely cause symptoms. Higher concentrations can lead to nausea, vomiting, lethargy, confusion, and diminished tendon reflexes, whereas severe hypermagnesemia may depress cardiac conduction. The risk of hypermagnesemia can be reduced by avoiding magnesium-containing antacids and laxatives and by use of magnesium-free dialysate in patients with stage 5 CKD requiring dialysis.

M.R.'s hyperphosphatemia is a result of decreased phosphorus elimination by the kidneys (see Question 17 for a more detailed discussion of hyperphosphatemia). Based on the NKF-K/DOQI guidelines for bone metabolism, patients should reduce dietary phosphorus to 800 to 1,000 mg/day while maintaining adequate nutritional needs.⁸⁴ Phosphorus-containing laxatives and enemas should also be avoided. Hyperphosphatemia is associated with low serum calcium concentrations, not a current finding in M.R.

M.R. also has mild hyperuricemia. Asymptomatic hyperuricemia frequently develops in patients with kidney disease owing to diminished urinary excretion of uric acid. In the absence of a history of gout or urate nephropathy, asymptomatic hyperuricemia does not require treatment.

ANEMIA OF CHRONIC KIDNEY DISEASE

10. What findings in M.R. are consistent with the diagnosis of anemia of CKD, and what is the etiology of this disorder?

M.R.'s hemoglobin of 8.7 g/dL and hematocrit of 26% are substantially lower than the normal range for premenopausal females (hemoglobin, 12–16 g/dL; hematocrit, 36%–46%) indicating that she has anemia.⁸⁵ Her normal RBC indices

suggest her red cells are of normal size, but the absence of an elevated reticulocyte count suggests an impaired bone marrow response for her degree of anemia. Her recent history of peptic ulcer disease may also have contributed to the observed drop in hemoglobin and hematocrit as a result of blood loss. Her complaint of general malaise is consistent with the symptoms of anemia.

Characteristics and Etiology

Anemia, which affects most patients with CKD, is caused by a decreased production of erythropoietin (EPO), a glycoprotein that stimulates red blood cell production in the bone marrow and is released in response to hypoxia. Approximately 90% of the total EPO is produced in the peritubular cells of the kidney; the remainder is produced by the liver. EPO concentrations in patients with kidney failure are lower than in individuals with normal kidney function who have the same degree of anemia and, therefore, the same stimulus for EPO production and release.⁸⁶

Anemia appears as early as stage 3 CKD and is characterized by normochromic (normal color) and normocytic (normal size) red blood cells unless a concomitant iron, folate, or B₁₂ deficiency exists. A direct correlation between eGFR and hematocrit has been demonstrated with a 3.1% decrease in hematocrit for every 10 mL/minute/1.73 m² decline in eGFR.⁸⁷ A higher prevalence of anemia occurs in the population with an eGFR <60 mL/minute/1.73 m².¹ Pallor and fatigue are the earliest clinical signs, with other manifestations developing as anemia worsens progressively with declining kidney function. A significant consequence of anemia is development of left ventricular hypertrophy (LVH), further contributing to cardiovascular complications and mortality in patients with CKD. LVH has been observed in approximately 30% of patients with eGFR 50 to 75 mL/minute/1.73 m² (stages 2 and 3 CKD) and in up to 74% of patients at the start of dialysis (stage 5 CKD).^{88,89} These findings support the need for early and aggressive treatment of anemia of CKD before the development of stage 5 CKD.

A more complete workup for anemia of CKD is recommended for patients with an eGFR of <60 mL/minute/1.73 m².^{1,85} This workup includes monitoring of hemoglobin and hematocrit, assessment of iron indices with correction if iron deficiency is present, and evaluation for sources of blood loss, such as bleeding from the GI tract. This workup should be done regularly as CKD progresses because of the association between anemia and the progressive decline in eGFR.

As discussed later in this chapter (see Question 12), the availability of recombinant human EPO to directly stimulate erythrocyte production revolutionized the treatment of CKD-associated anemia. However, iron deficiency is the leading cause of erythropoiesis stimulating agent (ESA) hyporesponsiveness and must be corrected before ESA therapy is initiated (see Question 12 for Iron Therapy). Iron deficiency can develop as a result of increased requirements for RBC production with ESA administration and from chronic blood loss owing to bleeding or hemodialysis. Identification and management of iron deficiency through regular follow-up testing and iron supplementation is essential for adequate RBC production (see Question 12 for Iron Therapy and also Chapter 86, Anemias).⁸⁵ M.R.'s iron status should be assessed at this time to determine if iron supplementation is needed.

Other factors that contribute to anemia include a shortened RBC life span secondary to uremia, blood loss from frequent phlebotomy and HD, GI bleeding, severe hyperparathyroidism, protein malnutrition, accumulation of aluminum, severe infections, and inflammatory conditions.⁸⁵ Substances present in the plasma of patients with CKD, collectively termed “uremic toxins,” may inhibit the production of EPO, the bone marrow response to EPO, and the synthesis of heme. The negative effects of these substances on RBC production are supported by improvement in erythropoiesis with dialysis, which removes these uremic toxins. This uremic environment also causes a decrease in the RBC life span, from a normal life span of 120 days to approximately 60 days in patients with severe CKD. A shortened RBC life span has been observed in uremic patients transfused with RBC from individuals with normal kidney function, whereas RBC from uremic individuals have a normal survival time when transfused into patients without kidney failure.⁹⁰

Blood loss also contributes to anemia of CKD, particularly in patients requiring HD. With each HD session, generally performed three times per week, blood loss occurs. In addition, these patients are usually administered heparin during dialysis or antiplatelet drugs to prevent vascular access clotting, which further increases the risk of bleeding. Although a stool guaiac test was not performed in M.R., many patients with uremia and CKD will have a positive guaiac reaction because of the risk of bleeding from uremia itself. M.R. also has a peptic ulcer, which increases her potential for blood loss.

Other deficiencies can contribute to anemia of CKD. Deficiency of folic acid, as evidenced by low serum folate concentrations and macrocytosis, is relatively uncommon in patients with early kidney disease, but occurs most often in patients on dialysis, because folic acid is removed by dialysis. Therefore, the daily prophylactic administration of the water-soluble vitamins, including 1 mg of folic acid, is recommended. Routine use of the fat-soluble vitamin A is discouraged, because hypervitaminosis A may develop, contributing to anemia.⁹¹ Several multivitamin preparations devoid of vitamin A (e.g., Nephro-caps) are available for patients with kidney failure. Pyridoxine (vitamin B₆) deficiency can also occur in both dialyzed and nondialyzed patients with CKD. Significant similarities are seen between this deficiency and the symptoms of uremia, which include skin hyperpigmentation and peripheral neuropathy. Current multivitamin products for patients with stage 5 CKD contain adequate amounts of pyridoxine to prevent deficiency.

Goals of Therapy

11. What are the goals of therapy for anemia of CKD in M.R.?

Target Hemoglobin and Hematocrit

NKF-K/DOQI guidelines recommend a target of ≥ 11 g/dL for hemoglobin ($\geq 33\%$ for hematocrit) in patients with CKD receiving ESA therapy.⁸⁵ It is at these targets that benefits such as increased survival, exercise capacity, quality of life, cardiac output, cognitive function, and decreased risk of LVH were observed in the CKD population.⁸⁵ Routine maintenance of hemoglobin levels ≥ 13 g/dL ($\geq 39\%$ for hematocrit) is not recommended for patients being treated with ESA secondary to increased risk for mortality and for serious cardiovascular and thromboembolic events. Two recent trials evaluated the efficacy

and safety of hemoglobin targets in patients with CKD not on HD. These trials showed no benefit on left ventricular mass index. In one study, increased mortality rates were observed in the high target hemoglobin group. Likely this is based on these recent data that the target hemoglobin will be restricted to a more narrow range in the future.^{92,93}

Hemoglobin, rather than hematocrits, should be used to evaluate anemia in this population for several reasons. Hematocrit is dependent on volume status, which can be problematic for patients with fluctuations in plasma water (e.g., dialysis, volume overload). In addition, a number of variables can affect the hematocrit value, including temperature, hyperglycemia, the size of the red blood cell, and the counters used for the test. These variables do not significantly affect hemoglobin, making it the preferred test for anemia.⁸⁵

Once M.R.'s iron status is evaluated, and corrected if necessary, ESA therapy may be started (see Treatment below).

Iron Status

Because iron deficiency is the primary cause of ESA-hyporesponsiveness, assessment of iron status is essential before initiating erythropoietic therapy. The two tests that best evaluate iron status are the transferrin saturation percent (TSAT), a measure of iron immediately available for erythropoiesis, and serum ferritin, a measure of storage iron.⁸⁵ Transferrin is a carrier protein and its concentration depends on nutritional status. The TSAT indicates the saturation of the protein transferrin with iron and is determined as:

$$\% \text{ TSat} = \frac{\text{serum iron (mcg/dL)}}{\text{TIBC (mcg/dL)}} \times 100 \quad (31-4)$$

where TIBC is the total iron-binding capacity of the transferrin protein. Serum ferritin is a marker for iron reserves, which are stored primarily in the reticuloendothelial system (e.g., liver, spleen). The goal of iron replacement therapy is to maintain the TSAT >20% and a serum ferritin >100 ng/mL for CKD stages 2 through 4 and >200 ng/mL for CKD stage 5 to provide sufficient iron for erythrocyte production.⁸⁵ Values below these targets are indicative of absolute iron deficiency. A functional iron deficiency may exist when ferritin is >500 ng/mL, TSAT is <20%, and anemia persists despite appropriate ESA therapy. In these cases, iron supplementation may lead to improved erythropoiesis. Other tests, including the percentage of hypochromic red cells, reticulocyte hemoglobin content, serum transferrin receptor, red cell ferritin, and zinc protoporphyrin, have been proposed as indicators of iron status.⁸⁵ Although some of these markers have demonstrated predictive value in

assessing iron status, either alone or in conjunction with other laboratory data, further investigation is warranted to determine their utility and to make such testing procedures readily available.

Treatment

12. Describe the options available to treat anemia of CKD and achieve the goals of therapy in M.R.

Iron Therapy

Before initiating ESA therapy, M.R.'s iron indices should be determined. If M.R. is iron deficient, as indicated by the TSAT and serum ferritin and other supporting laboratory data (see Chapter 86, Anemias), supplemental iron therapy should be administered. If iron deficiency is the cause of anemia, M.R. may benefit from iron supplementation alone (i.e., without erythropoietic therapy) to increase hemoglobin and hematocrit. Peptic ulcer disease will need to be evaluated as a source of blood loss. Given the poor bioavailability of oral iron and patient noncompliance, oral iron is usually inadequate for repletion of iron in patients receiving HD who experience chronic blood loss.⁹⁴ For the population with early CKD and for patients receiving peritoneal dialysis, an initial trial of oral iron may correct the deficiency because these patients do not have the same degree of blood loss. For some patients, however, IV therapy will be required to replete iron and meet the increased demands once erythropoiesis is stimulated with ESA therapy. Administration of IV iron requires IV access and frequent outpatient visits, which are drawbacks to therapy with IV iron in CKD stage 3 and 4. A recent trial examined an accelerated dosing regimen (500 mg given on two consecutive days) of IV iron sucrose to address these issues. This regimen was adequate to restore iron stores with only two patients experiencing hypotension related to iron therapy.⁹⁵

Common infusion-related effects associated with IV iron include hypotension, myalgias, and arthralgias. Despite the controversy over the best strategy for iron supplementation in patients with early CKD, current recommendations support reserving IV iron for patients in whom oral iron has failed.⁹⁶ Therefore, a trial of oral iron is reasonable for M.R. Oral iron supplementation with 200 mg/day of elemental iron should be started to address iron deficiency, if present, and this regimen should be continued to maintain sufficient iron status while receiving ESA therapy. Many oral iron preparations are available, and their iron content varies as will the number of tablets or capsules that must be taken per day to provide the required elemental iron (Table 31-4). Some oral formulations include

Table 31-4 Oral Iron Preparations

| Preparation | Common Brand Names | Commonly Prescribed Unit Size (Amount Elemental Iron in mg) | Number of Units/Day to Yield 200 mg Elemental Iron |
|-----------------------|---------------------------------|--|---|
| Ferrous sulfate | Slow FE, Fer-In-Sol | 325 (65) | 3 tablets |
| Ferrous gluconate | Feratab | 325 (36) | 5 tablets |
| Ferrous fumarate | Femiron, Feostat | 200 (66) | 3 capsules |
| Iron polysaccharide | Niferex, Nu-Iron | 150 (150) | 2 capsules |
| Heme iron polypeptide | Proferrin-ES Proferrin-Forte | 12 (12) | 17 tablets |

^aUnit size reflects common tablet/capsule sizes prescribed and not necessarily that of the brand names listed.

ascorbic acid to enhance iron absorption. A heme iron product, Proferrin-ES, has recently been approved. Heme iron is more readily absorbed; however, a large number of tablets are required to supply the 200 mg elemental iron (Table 31-4). M.R. should be advised to take oral iron on an empty stomach to maximize absorption, unless side effects prevent this strategy. She also should be counseled on potential drug interactions with oral iron (e.g., antacids, quinolones) and GI side effects (e.g., nausea, abdominal pain, diarrhea, constipation, dark stools). Noncompliance with therapy is a primary cause of therapeutic failure with oral iron.

If M.R.'s condition does not respond to oral therapy, as indicated by either persistent iron deficiency based on iron indices, or inadequate response to what is considered an adequate dose and duration of erythropoietic therapy, IV iron is necessary. The IV iron preparations currently available are iron dextran (In-FeD, DexFerrum), sodium ferric gluconate complex in sucrose (Ferrlecit), and iron sucrose (Venofer). The dextran products have caused anaphylactic reactions and, as a result, have a FDA mandated black box warning that requires administration of a 25 mg test dose followed by a 1-hour observation period before the total dose of iron is infused.⁹⁷ The dextran component is believed to be the cause of such reactions. The dose of IV iron recommended to correct absolute iron deficiency is a total dose of 1 g administered in divided doses or over a prolonged period to minimize the risk of adverse effects.⁸⁵ For iron dextran, the approved dose is 100 mg increments, administered over 10 dialysis sessions for patients on HD to provide a total of 1 g.⁹⁷ Larger doses of 500 mg up to the total 1-g dose have been safely administered over a longer infusion period of 4 to 6 hours.^{85,96}

Sodium ferric gluconate and iron sucrose are the most widely used iron products in the CKD population. Both the ferric gluconate and iron sucrose products have been used successfully in patients who have experienced allergic reactions to the dextran products and evidence indicates that they are safer: 8.7 adverse events per million doses for dextran versus 3.3 adverse events for gluconate.⁹⁸ To provide the recommended total dose of 1 g, ferric gluconate is administered as 125 mg (10 mL) over eight consecutive dialysis sessions for patients on HD. The dose can be administered as a slow IV injection at a rate of up to 12.5 mg/minute or diluted in 100 mL of normal saline and infused over 1 hour.⁹⁹ Administration of 125 mg over 10 minutes (without a test dose) was determined to be a safer alternative to dextran preparations in patients on HD and is an approved dosing strategy.^{99,100} Doses up to 250 mg over 1 hour have been administered safely.¹⁰¹ The flexibility of administering larger doses of iron is an important factor in achieving efficiencies in the outpatient setting for patients with early CKD and those receiving PD.

Iron sucrose (Venofer) is a polynuclear iron hydroxide sucrose complex. The recommended dose of iron sucrose is 100 mg (5 mL) over 10 consecutive HD sessions to provide the total dose of 1 g.¹⁰² The dose can be administered by a slow IV injection over 5 minutes or diluted in 100 mL of normal saline and infused over at least 15 minutes. As with sodium ferric gluconate, a test dose is not required. Iron sucrose doses of 250 to 300 mg have been safely administered over 1 hour and found to be as effective as sodium ferric gluconate administration in maintaining hemoglobin in patients receiving epoetin.¹⁰³

Smaller doses of IV iron, in increments of 25 to 200 mg, can be administered on a weekly, every 2 week, or a monthly basis, to patients without absolute iron deficiency. These doses will sustain adequate iron stores, maintain target hemoglobin values, and potentially reduce the required dose of the erythropoietic agent.^{85,104} This regimen is most convenient for patients on HD who have regular IV access and increased iron needs because of chronic blood loss. Maintenance iron therapy replaces these losses and minimizes the need for the more aggressive 1-g total doses of IV iron required for absolute iron deficiency. If HD is started in M.R. in the future, regular dosing of IV iron during dialysis is the most reasonable way to maintain adequate iron required for sustained erythropoiesis. Iron indices should be monitored at least every 3 months to guide IV iron therapy. Targeting a ferritin of ≥ 500 ng/mL is not routinely recommended because of the lack of evidence available.⁸⁵ A recent study evaluated the response to iron therapy in patients with elevated ferritin (500–1,200 ng/mL) and a low TSAT ($\leq 25\%$) found that administration of IV iron resulted in a statistically significant increase in Hgb levels and a faster Hgb response in patients receiving ESA therapy.¹⁰⁵ This strategy, however, could lead to increased exposure to free iron, which may place the patient at an increase risk of adverse effects (e.g., inflammation, oxidative stress).¹⁰⁶

Ferumoxylol, a semisynthetic carbohydrate-coated, magnetic iron oxide preparation, is in phase III clinical trials for use in patients with CKD requiring iron supplementation. A potential advantage of ferumoxylol is that higher doses can be safely administered over a shorter period (17 seconds). There is also a proposed reduced immunologic sensitivity, resulting in less risk for anaphylactic type reactions compared with the other available high molecular weight IV iron products (e.g., iron dextran).¹⁰⁷

Erythropoiesis Stimulating Agent (ESA) Therapy

Recombinant human EPO is the primary treatment option for patients such as M.R. with anemia of CKD. Regular dialysis may improve an anemic condition, but it will not restore the hemoglobin and hematocrit concentrations to normal because the primary cause of anemia is reduced EPO production by the kidneys. Although blood transfusions were once the mainstay of treatment, they are now avoided, if possible, because they are associated with a risk for viral diseases (hepatitis, human immunodeficiency virus [HIV]), iron overload, and further suppression of erythropoiesis. Transfusions may be required in certain patients with substantially low oxygen-carrying capacity, substantial blood loss, and in those patients exhibiting persistent symptoms of anemia (fatigue, dyspnea on exertion, tachycardia). M.R. is currently not a candidate for transfusions based on her hemoglobin of 8.7 g/dL (hematocrit 26%) and the absence of significant symptoms on presentation. Androgens were previously used to treat the anemia of CKD because they directly or indirectly raise EPO concentrations. Their routine use is not recommended, however, because the erythropoietic response is inconsistent, they cause many adverse effects, and recombinant EPO is now available.

HUMAN ERYTHROPOETIN-EPOETIN ALFA

Human erythropoietin or epoetin, the exogenous form of EPO, is produced using recombinant technology. Epoetin alfa is available in the United States, whereas epoetin beta is

available primarily outside the United States. Since it became available in 1989, epoetin alfa (Epoen, Procrit) has provided an effective treatment option for anemia and has substantially decreased the need for RBC transfusions. Epoetin alfa stimulates the proliferation and differentiation of erythroid progenitor cells, increases hemoglobin synthesis, and accelerates the release of reticulocytes from the bone marrow.

For patients such as M.R. who do not yet require dialysis and for patients receiving PD, epoetin alfa is generally administered by subcutaneous (SC) injection. However, patients on HD often receive epoetin alfa by IV administration because easy IV access is established. According to the NKF-K/DOQI guidelines for anemia management, SC administration is preferred because lower doses can be administered less frequently and cost is lower than with IV administration.^{85,108} Starting doses for SC administration are 80 to 120 U/kg/wk (~6,000 U/wk), whereas IV starting doses are 120 to 180 U/kg/wk (~9,000 U/wk). Based on the half-life of epoetin alfa (8.5 hours IV, 24.4 hours SC), the total weekly dose is usually divided into smaller doses, administered one to three times per week with SC administration and three times per week for IV administration in patients on HD.¹⁰⁹ For patients being converted from IV to SC administration whose hemoglobin is within the target range, the SC dose is usually two-thirds the IV dose.⁸⁵ For patients not yet at the target hemoglobin, a SC dose equivalent to the IV dose is recommended. Patients receiving epoetin alfa SC should be instructed on the appropriate administration technique, which includes rotating the sites for injection (e.g., upper arm, thigh, abdomen).

Extended dosing intervals for SC administration of epoetin alfa have been evaluated in patients with CKD who are not having dialysis.^{108,109} Doses of 10,000 U once weekly to 40,000 U once every 4 weeks have been shown to maintain target hemoglobin values for those patients with CKD not on dialysis.^{110,111} Such dosing strategies may provide more convenient therapy for these patients who are not yet on dialysis, but must come to the clinic for erythropoietic therapy.

DARBEOETIN ALFA

Darbepoetin alfa (Aranesp) was approved in 2001 for the treatment of anemia of CKD, whether or not the patient requires dialysis. Darbepoetin is a hyperglycosylated analog of epoetin alfa that stimulates erythropoiesis by the same mechanism. Instead of the three N-linked carbohydrate chains on epoetin alfa, darbepoetin has five, which increase the capacity for sialic acid residue binding on the protein. The increased protein binding slows total body clearance and increases the terminal half-life to 25.3 hours and 48.8 hours following IV and SC administration, respectively. Darbepoetin alfa's longer half-life relative to epoetin alfa offers the potential advantage of less frequent dosing to maintain target hemoglobin values.

Studies in patients with early CKD (stages 3 and 4) determined that starting SC doses of 0.45 mcg/kg administered once per week and 0.75 mcg/kg once every other week were effective in achieving target hemoglobin and hematocrit values in patients who had not previously received erythropoietic therapy.¹¹² In patients on dialysis converted from epoetin alfa to darbepoetin alfa (IV and SC), darbepoetin maintained target hemoglobin values when administered less frequently (i.e., one dose every week in patients previously receiving epoetin alfa

Table 31-5 Estimated Darbepoetin Alfa Starting Doses Based on Previous Epoetin Alfa Dose

| Previous Weekly Epoetin Alfa Dose ^{a,b} (< 2,500 U/wk) | Weekly Darbepoetin Alfa Dose (6.25–mcg/wk) |
|--|--|
| 2,500–4,999 | 12.5 |
| 5,000–10,999 | 25 |
| 11,000–17,999 | 40 |
| 18,000–33,999 | 60 |
| 34,000–89,999 | 100 |
| ≥90,000 | 200 |

^aDarbepoetin alfa should be administered weekly for patients receiving epoetin alfa two or three times per week and every other week for patients receiving epoetin alfa once per week.

^bFor patients requiring darbepoetin alfa every other week, the weekly dose of epoetin alfa should be multiplied by 2 and this dose used in the conversion chart to determine the appropriate darbepoetin alfa dose.

Adapted from Aranesp [darbepoetin alfa] package insert. Thousand Oaks, CA: Amgen Inc.; July 19, 2002, with permission.

three times per week and one dose every other week in patients previously receiving epoetin once weekly).^{113,114}

The approved starting dose of darbepoetin alfa in patients who have not previously received epoetin therapy is 0.45 mcg/kg given either IV or SC once weekly.¹¹⁵ Patients who are already receiving epoetin therapy may be converted to darbepoetin alfa based on the current total weekly epoetin dose (Table 31-5).¹¹⁵ For patients currently receiving epoetin alfa two to three times per week, darbepoetin alfa may be administered once weekly. Patients who are receiving epoetin alfa once weekly should receive darbepoetin alfa once every 2 weeks. To calculate the once every 2-week darbepoetin dose, the weekly epoetin alfa dose should be multiplied by 2 and that value used in column 1 of Table 31-5 to find the corresponding darbepoetin dose from column two in Table 31-5. For example, a patient receiving epoetin 6,000 U/wk should receive 40 mcg of darbepoetin alfa once every 2 weeks (6,000 U epoetin × 2 = 12,000 U, which corresponds to a weekly darbepoetin dose of 40 mcg).¹¹⁵

Epoetin alfa and darbepoetin alfa are generally well tolerated, with hypertension being the most common adverse event reported. Although elevated BP is not uniformly considered a contraindication to therapy, BP should be monitored closely so that changes in antihypertensive therapy and the dialysis prescription are made, if justified. Failure to elicit a response to erythropoietic therapy requires evaluation of factors that cause resistance, such as iron deficiency, infection, inflammation, chronic blood loss, aluminum toxicity, malnutrition, and hyperparathyroidism. Resistance to erythropoietic therapy has been observed in patients receiving ACE inhibitors, although data are conflicting.^{116,117} Rare cases of antibody formation to epoetin therapy have been reported.¹¹⁸ Neutralizing anti-EPO antibodies were identified in 13 patients with pure red-cell aplasia who required blood transfusions after a course of therapy with epoetin alfa or beta.¹¹⁸ Similar cases have been reported, primarily with one epoetin alfa product manufactured outside the United States, Eprex. Some evidence supports cross-reactivity of these antibodies with darbepoetin, although the information is currently limited.¹¹⁹ Although the clinical implications of antibody formation in patients receiving erythropoietic therapy

are uncertain, clinicians should be aware of these reports when evaluating response to therapy.

Treatment of M.R.'s anemia must be initiated, given the chronic nature of her kidney disease and her current hemoglobin and hematocrit. Patients with hemoglobin values <11 g/dL (hematocrit, <33%), such as M.R., are the best candidates for erythropoietic therapy. It is also important to identify and correct any iron or folate deficiency and perform a stool guaiac test to rule out active GI bleeding. Iron supplementation is indicated, not only if M.R. is iron deficient, but also to maintain iron status while receiving erythropoietic therapy (see section on iron therapy). Although administration of iron alone may improve her anemia, epoetin alfa or darbepoetin alfa will likely be required, based on the severity of her anemia and the progressive nature of her kidney disease. M.R. may start epoetin alfa at a dose of 6,000 U (~100 units/kg) administered SC once per week or divided into two weekly doses of 3,000 U, assuming her iron status is appropriate (see section on iron status). Another option would be darbepoetin alfa administered at a dose of 25 mcg (0.45 mcg/kg) SC once per week. She also should be instructed on how to administer SC epoetin alfa or darbepoetin alfa. Dose adjustments should not be made more frequently than once every 4 to 6 weeks for either agent because of the time course for response (i.e., the pharmacodynamic effects on RBC homeostasis). The time it takes to reach a new steady-state, when RBC production is equal to RBC destruction, depends on the life span of the red cell, which is approximately 60 days in patients with kidney failure. Therefore, it will take approximately 2 to 3 months to reach a plateau in measured hemoglobin/hematocrit. Dose adjustments should be made based on M.R.'s hemoglobin and hematocrit, which should be monitored every 1 to 2 weeks after initiation of therapy or following a dose change. If a rapid increase in hemoglobin/hematocrit is observed (hemoglobin >1.0 g/dL, hematocrit >3%–4%, over a 1- to 2-week period) or the target hemoglobin/hematocrit is exceeded, then doses of either agent should be decreased by approximately 25%. If response is inadequate (hemoglobin increase <1 g/dL, hematocrit increase <2%–3%, in 2 to 4 weeks), then the doses should be increased by approximately 50% for epoetin alfa and 25% for darbepoetin alfa.^{85,115} Once stable, the hemoglobin/hematocrit should be monitored every 2 to 4 weeks. If a response is not observed despite appropriate dose titration, M.R. should be evaluated for possible reasons for nonresponse (i.e., iron deficiency, bleeding, aluminum intoxication, hyperparathyroidism, infection).

In early 2007, a FDA mandated black-box warning was added to the safety labeling for all ESA products, which states that use of ESA therapy may increase the risk for death and for serious cardiovascular events when administered to achieve a hemoglobin >12 g/dL. This came as a result of four recently completed cancer trials that evaluated new dosing regimens, use of ESA in a new patient population, and use of new unapproved ESA. Since then, two trials in patients with CKD have shown that targeting Hgb levels >13 g/dL results in increase mortality and morbidity, thus observing these black-box warnings in CKD is warranted.^{92,93}

CONTINUOUS ERYTHROPOIETIN RECEPTOR ACTIVATOR (CERA)

Continuous erythropoietin receptor activator (Mircera) has completed phase III of its clinical development program and has received an approval letter from the FDA for use in patients

with CKD with anemia. CERA is twice the molecular weight of EPO because of the addition of a single 30-kd polymer chain into the erythropoietin molecule resulting in a considerably longer elimination half-life compared with EPO (130 hours vs. 4–28 hours). This allows for extended interval dosing of biweekly and once monthly. It has an efficacy and safety profile comparable to available ESA. The approved dosing of CERA is pending the release of the FDA-approved package insert. Extended interval dosing agents, such as CERA, have several advantages in patients with CKD stage 3 and 4, including improved patient compliance, less administration costs, reduced burden on patient from fewer injections given, and less outpatient visits to receive IV administration.¹²⁰

Other novel molecules that promote erythropoiesis are in phase II and III clinical trials. These include hematide (an erythropoietin-mimetic peptide) and the hypoxia-inducible factor (HIF) stabilizers. The latter are orally active agents that induce both renal and extrarenal erythropoietin production. If these investigational agents are approved, they will provide health care professionals new options to correct anemia in CKD.

CARDIOVASCULAR COMPLICATIONS

13. H.B. is a 65-year-old white man with stage 5 CKD who has just started chronic HD. He comes in today for his third HD session (dialysis scheduled three times per week, 4-hour duration). He has a history of hypertension, which has been poorly controlled over the past 4 months (BP ranges 150–190/85–105 mmHg), and he has experienced shortness of breath and a significant weight gain over the past month. His pertinent medical history includes hypertension for the past 14 years. H.B.'s current medications include metoprolol 50 mg BID, furosemide 80 mg BID, calcium carbonate 500 mg TID with meals, and Nephrocaps 1 PO QD. H.B.'s most recent predialysis BP was 175/98 mmHg, and his postdialysis BP was 158/90 mmHg. A recent ECG showed evidence of LVH.

Predialysis laboratory values were as follows: serum sodium (Na), 140 mEq/L (normal, 135–147 mEq/L); potassium (K), 5.1 mEq/L (normal, 3.5–5.0 mEq/L); chloride (Cl), 101 mEq/L (normal, 95–105 mEq/L); CO₂ content, 23 mEq/L (normal, 22–28 mEq/L); SrCr, 8.8 mg/dL (normal, 0.6–1.2 mg/dL); BUN, 84 mg/dL (normal, 8–18 mg/dL); phosphate, 5.2 mg/dL (normal, 2.5–5.0 mg/dL); Ca, 8.6 mg/dL (normal, 8.8–10.4 mg/dL); serum albumin, 3.0 g/dL (normal, 4.0–6.0 g/dL); cholesterol (nonfasting), 345 mg/dL (normal, <200 mg/dL); triglycerides, 285 mg/dL (normal, <200 mg/dL); Hct, 27% (normal, 39%–49%); and Hgb, 9.0 g/dL (normal, 13–16 g/dL). H.B. has a urine output of 50 mL/day. What conditions evident in H.B. put him at increased risk of cardiovascular complications and mortality?

[SI units: Na, 140 mmol/L (normal, 135–147); K, 5.1 mmol/L (normal, 3.5–5.0); Cl, 101 mmol/L (normal, 95–105); CO₂, 23 mmol/L (normal, 22–28); SrCr, 778 μmol/L (normal, 50–110); BUN, 30 mmol/L of urea (normal, 3.0–6.5); phosphate, 1.68 mmol/L (normal, 0.8–1.60); Ca, 2.15 mmol/L (normal, 2.2–2.6); serum albumin, 30 g/L (normal, 40–60 g/L); cholesterol, 8.9 (normal, <5.2); triglycerides, 3.2 (normal, <2.3); Hct, 0.27 (normal, 0.39–0.49); and Hgb, 90 g/L (normal, 130–160 for male patients)]

H.B. has uncontrolled hypertension that is not being adequately managed with his current drug therapy or HD.

Hypertension is associated with LVH, ischemic heart disease, and heart failure, all of which are contributing factors to overall mortality in patients with stage 5 CKD who are undergoing dialysis.³ H.B.'s ECG evidence of LVH should trigger additional evaluation to determine the extent of cardiac involvement and diagnosis of heart failure, which is associated with increased mortality in both diabetic and nondiabetic patients (see Chapter 18, Heart Failure). LVH develops early in the course of CKD and progresses as kidney disease progresses.^{88,89} H.B. is in the most severe stage of CKD and has greatest likelihood of developing LVH. Anemia contributes substantially to the development of LVH and heart failure as well. H.B.'s hemoglobin of 9.0 g/dL (hematocrit 27%) is below the target value and requires treatment with erythropoietic therapy and iron supplementation based on evaluation of his iron indices (see section on anemia).

Additional factors that increase the risk of cardiovascular complications and mortality in H.B. include the elevated cholesterol and triglycerides levels as well as hypoalbuminemia (serum albumin, 3.0 g/dL). Increased levels of homocysteine are common in patients with kidney failure and have been associated with increased risk of coronary artery disease (CAD).¹²¹ Because elevated concentrations of homocysteine have been observed in conjunction with decreased folate and vitamin B₁₂ levels, more aggressive supplementation of these vitamins in this population has been suggested. Because H.B.'s total corrected calcium (corrected for hypoalbuminemia; see Question 17 for an explanation of this correction) is 9.4 mg/dL, his calcium, calcium-phosphorus product, and use of a calcium-containing phosphate binder will need to be monitored frequently. Cardiac calcification is common in patients with kidney disease and also is associated with cardiovascular complications. It has been reported that up to 80% of patients with ESRD have detectable coronary artery calcification.¹²²

Cardiovascular disease and complications continue to be the leading cause of mortality in patients with kidney failure. According to data from a large population of patients on dialysis, cardiovascular disease increases the risk of all-cause mortality fivefold when compared with the general Medicare population without kidney disease.³ All-cause death rates are almost four times greater in patients on dialysis age 65 and older, such as H.B., than in the general Medicare population.³ For these reasons, the risk of CAD should be evaluated regularly in patients with ESRD (see Chapter 32, Renal Dialysis).

Hypertension

14. What options are available to treat H.B.'s hypertension considering his other cardiac complications and BP goal?

Dialysis

Hypertension is common in patients with CKD with a prevalence that varies depending on the cause of CKD and residual kidney function. Prevalence of hypertension has been estimated to be 80% in HD and 50% in PD populations.⁷⁹ Multiple factors are involved in the development of hypertension in the CKD population, including extracellular volume expansion from salt and water retention and activation of the renin-angiotensin-aldosterone system.¹²³ Increased sym-

pathetic tone also has been observed with an increase in norepinephrine activity.

Because H.B. is just beginning dialysis therapy, it is difficult to assess the degree to which volume removal will ultimately affect his BP. To control BP related to volume changes, dialysis therapy should be adjusted as needed to achieve H.B.'s *dry weight*, the postdialysis weight at which symptoms of hypervolemia and hypovolemia are absent. H.B. has had recent findings consistent with worsening volume status (shortness of breath, weight gain) that should be considered when modifying his dialysis prescription; further workup is needed to determine if H.B. has systolic or diastolic heart failure. It is also important to counsel H.B. on the importance of salt and fluid intake restriction between HD sessions to minimize weight gain, volume expansion, and hypertension. Restriction of salt intake to 2 to 3 g/day and fluid to 1 L/day is appropriate and will require regular follow up by a dietitian.

Antihypertensive Therapy

Antihypertensive therapy should be used in conjunction with dialysis therapy in H.B. to target a BP <140/90 mmHg pre-HD and <130/80 mmHg post-HD.⁷⁹ For some patients, initiation of dialysis alone may achieve this goal and antihypertensive therapy may be withdrawn. The BP goal in patients with stage 5 CKD should minimize cardiovascular complications, but it should not increase the risk for hypotension and its associated complications during dialysis. The choice of an agent is based on the patient's comorbid conditions, because no single agent has a proven mortality benefit in patients on HD. The complexity of managing hypertension in patients on HD is enhanced by the apparent "U"-shaped relationship between BP and mortality. A study of patients on HD found an increased risk of cardiac-related death at systolic BP <110 mmHg and at systolic BP >180 mmHg.¹²⁴ The mortality risk with a low pre-HD BP may be indicative of severe cardiac disease at the initiation of HD. If patients experience hypotensive symptoms during HD, the goal BP can be increased, but they also should be evaluated for other cardiovascular disorders. Because the BP between dialysis sessions varies owing to volume changes, the ideal time to measure BP relative to dialysis (i.e., predialysis versus postdialysis) is unclear, but predialysis BP has been favored.

Diuretics are commonly used in patients in the early stages of CKD. As previously discussed, the effectiveness of diuretics depends on the amount of sodium delivered to their site of action in the renal tubule and on the patient's kidney function. For example, a decrease in the eGFR from 125 to 25 mL/minute/1.73 m², theoretically, could result in an approximate 80% decrease in the amount of sodium filtered. Early in the course of kidney failure, thiazides or thiazidelike diuretics are effective antihypertensive agents. As eGFR is further reduced (eGFR <30 mL/minute/1.73 m²), the thiazide diuretics become essentially ineffective. Potassium-sparing diuretics are also ineffective and may increase the risk of hyperkalemia in this population. Loop diuretics (e.g., furosemide), which function more proximally, are indicated in patients with stage 4 CKD (eGFR 15–29 mL/minute/1.73 m²).¹²⁵ These drugs can be effective for BP and volume control in patients with advanced kidney disease if residual kidney function is substantial (urine output >100 mL/day). Their effect must be frequently reevaluated based on urine output and any effect on volume control.

H.B.'s urine output should be assessed to determine the rationale for continued use of furosemide and the current dose should be assessed, because doses higher than his current dose of 80 mg BID are often required in patients with this degree of kidney dysfunction. It is likely that furosemide will need to be discontinued as H.B.'s residual renal function declines.

Given the role of the renin-angiotensin system in the development of hypertension in patients with CKD, ACE inhibitors are a logical choice for antihypertensive therapy. ACE inhibitors are effective antihypertensive agents in patients with CKD and have been shown to reverse LVH.¹²⁶ They are underused in this population, however. Response must be assessed individually to determine if renin-angiotensin-aldosterone activity is a predominant etiology of hypertension. Initiating therapy with low doses is prudent to evaluate patient response and tolerance. Use of these agents in combination with other antihypertensives is often required for adequate BP control. Most of these agents can be administered once daily; however, because of the renal elimination of the parent drug or active metabolite, dosage adjustments are necessary in patients with CKD. Fosinopril is the exception, because it undergoes substantial hepatic elimination. ACE inhibitors should also be used cautiously in patients dialyzed with the polyacrylonitrile (AN69) membrane. This is because ACE inhibitors decrease the breakdown of bradykinin. Bradykinin production is increased in patients who experience systemic or immune-mediated reactions when blood comes in contact with the dialyzer, which can lead to anaphylactic reactions. Such reactions are common with AN69 because of its composition; therefore, ACE inhibitor use in combination with this dialyzer should be avoided.

Although ARB effectively lower BP in patients without kidney disease,¹²⁷ less is known about their effectiveness in patients with kidney failure. These agents may offer an alternative to ACE inhibitors in patients experiencing kinin-mediated adverse effects; however, similar side effects have been reported with ARB. The combined use of ARB with other antihypertensive agents may be rational when patients are unresponsive to other regimens. One ARB, valsartan, has been approved for use in heart failure and this may offer an advantage in patients with concurrent heart failure¹²⁸; however, this concept must be studied in a CKD population.

Calcium channel blockers are effective antihypertensives in patients with CKD. Because the nondihydropyridine agents (i.e., diltiazem, verapamil) have negative chronotropic and inotropic effects, they should be used with care in patients with heart disease. Generally, dosage adjustment is not required in patients with kidney disease.

Other agents used to treat hypertension in the CKD population include β -blockers, centrally acting agents (e.g., clonidine, methyl dopa), vasodilators (e.g., minoxidil, hydralazine), and α_1 -adrenergic blockers (prazosin, terazosin, doxazosin). β -Blockers inhibit release of renin and may be useful in hypertension associated with CKD. Risk versus benefit should be evaluated when β -blockade is considered in conjunction with other comorbid conditions such as asthma, heart failure, and lipid abnormalities. Dosage adjustment is required for the less lipophilic agents (i.e., atenolol, acebutolol, nadolol).

H.B. is currently taking the β -blocker, metoprolol, and the loop diuretic, furosemide. It is likely that his diuretic will need to be discontinued as his residual kidney function decreases and response to therapy is inadequate. Although an effective

antihypertensive, metoprolol may not be the best single agent for H.B. and its use must be reassessed based on the recent evidence of LVH and whether systolic or diastolic dysfunction is diagnosed on further workup. If changes in H.B.'s HD prescription to improve volume control and achieve his dry weight do not reduce his BP, another antihypertensive regimen should be selected. A reasonable antihypertensive regimen would include an ACE inhibitor (e.g., enalapril) with or without β -blocker therapy or a calcium channel blocker based on cardiac findings. The selection will depend substantially on follow-up results of his cardiac disease, BP control with HD, and the development of adverse effects (see Chapter 13, Essential Hypertension, and Chapter 18, Heart Failure).

Dyslipidemia

15. How should H.B.'s lipid abnormalities be treated?

H.B. has elevated serum cholesterol and triglyceride concentrations, a common finding in patients with CKD. Dyslipidemia and increased oxidative stress contribute to premature atherogenesis in these patients. Several atherogenic factors in patients with CKD have been postulated, including arterial wall injury, platelet activation and adherence, smooth muscle cell proliferation, and intra-arterial accumulation of cholesterol. Whether lowering of serum lipids will improve long-term morbidity and mortality remains to be determined, but treatment should be consistent with NCEP ATP III guidelines and the NKF-K/DOQI guidelines for treatment of dyslipidemias.^{64,65} Dietary intervention successfully reduces triglyceride and cholesterol concentrations, and many drugs are available to treat lipid abnormalities in patients with stage 5 CKD (see Chapter 12, Dyslipidemias, Atherosclerosis and Coronary Heart Disease). Statin use has been supported by recent evidence associating these agents with a decrease in cardiovascular mortality and all-cause mortality in patients on dialysis.¹²⁹ Because many β -adrenergic blocking drugs might elevate triglyceride concentrations, antihypertensive drugs with insignificant or beneficial effects on serum lipids (e.g., ACE inhibitors, calcium channel blockers, clonidine, prazosin) may be preferable.

SECONDARY HYPERPARATHYROIDISM AND RENAL OSTEODYSTROPHY

16. D.B. is a 42-year-old white woman who has a 24-year history of type 1 diabetes mellitus with complications of diabetic nephropathy, retinopathy, and neuropathy. She has hypothyroidism and was diagnosed with stage 5 CKD 4 years ago. She started HD three times weekly at that time. Her current medications include levothyroxine 0.1 mg/day, metoclopramide (Reglan) 10 mg TID before meals, insulin aspart 10 U with meals, insulin glargine 25 U QHS, docusate 100 mg QD, OsCal 500 mg PO TID with meals, EPO 5,000 U IV twice weekly, iron sucrose 100 mg IV (TIW), paricalcitol 1 mcg IV three times per week (TIW), and Nephrocaps 1 capsule QD. At a recent clinic visit, findings on physical examination included a BP of 128/84 mmHg, diabetic retinopathic changes with laser scars bilaterally, and diminished sensation bilaterally below the knees. Her laboratory values were as follows: normal serum electrolytes; a random blood glucose

of 175 mg/dL (normal, 140 mg/dL); BUN, 45 mg/dL (normal, 8–18 mg/dL); SrCr, 8.9 mg/dL (normal, 0.6–1.2 mg/dL), Hgb, 10 g/dL (goal, >11 g/dL); WBC count, 6,200/mm³ (normal, 3,200–9,800/mm³); Ca, 8.5 mg/dL (normal, 8.4–9.5 mg/dL); phosphate, 6.8 mg/dL (normal, 2.5–5.0 mg/dL); intact parathyroid hormone (iPTH), 450 pg/mL (normal, 5–65 pg/mL); total serum protein, 5.0 g/dL (normal, 6.0–8.0 g/dL); serum albumin, 3.1 g/dL (normal, 4.0–6.0 g/dL); and uric acid, 8.9 mg/dL (normal, 2.0–7.0 mg/dL). Describe the etiology of D.B.’s abnormal bone, calcium, phosphorus, and PTH findings.

[SI units: blood glucose, 9.7 mmol/L (normal, <11 mmol/L); BUN, 16.1 mmol/L of urea (normal, 3.0–6.5); SrCr, 787 μmol/L (normal, 50–110); Hgb, 100 g/L (goal, 110 g/L); WBC count, 6,200 × 10⁶ /L (normal, 3,200–9,800); Ca, 2 mmol/L (normal, 2.1–2.36); phosphate, 2.19 mmol/L (normal, 0.8–1.60); total serum protein, 50 g/L (normal, 60–80); serum albumin, 31 g/L (normal, 40–60 g/L); uric acid, 529 μmol/L (normal, 120–420)]

Etiology

Renal osteodystrophy (ROD) is the term used to describe the skeletal manifestations that occur as kidney function declines. Collectively, ROD refers to specific bone abnormalities that include osteitis fibrosa (most common pattern), osteomalacia, osteosclerosis, and osteopenia. Hyperphosphatemia, hypocalcemia, hyperparathyroidism, decreased production of active vitamin D, and resistance to vitamin D therapy are all frequent problems in CKD that can lead to the secondary complication of ROD.

The interrelationships between phosphorus, calcium, vitamin D, and PTH have been reviewed extensively.^{130,131} Retention of phosphorus and secondary hyperparathyroidism (sHPT) play a major role in the development of osteitis fibrosa or high-turnover bone disease. The “trade-off” hypothesis best describes the events leading to changes in bone metabolism.¹³⁰ As eGFR decreases, phosphorus excretion by the kidney decreases, resulting in hyperphosphatemia. Hyperphosphatemic conditions lead to a corresponding decrease in ionized calcium concentration, a primary stimulus for release of PTH from the parathyroid gland. Higher concentrations of PTH decrease renal tubular reabsorption of phosphorus and promote its excretion. Both serum phosphorus and calcium concentrations are corrected depending on the degree of remaining kidney function, but this occurs at the expense of an elevated PTH concentration (the “trade off”). As kidney disease becomes more severe (eGFR <30 mL/minute/1.73 m²), the phosphaturic response to PTH diminishes and sustained hyperphosphatemia and hypocalcemia develop. In response to hypocalcemia, calcium is mobilized from the bone, a mechanism largely controlled by PTH. Virtually all patients with kidney failure develop sHPT. Decreased PTH degradation by the kidney may also contribute to the hyperparathyroid state in patients with kidney disease.

The kidney is the principal organ responsible for vitamin D production and, as such, vitamin D metabolism is altered in the presence of uremia. Persistent hyperphosphatemia inhibits the normal conversion of 25-hydroxyvitamin D₃ to its biologically active metabolite, 1,25-dihydroxyvitamin D₃, by the enzyme 1-α-hydroxylase. This enzyme is present in proximal tubular cells of the kidney and is necessary for conversion of vitamin D to the active form. This active form of vitamin D, also

known as *calcitriol*, increases gut absorption of calcium and interacts with vitamin D receptors on the parathyroid gland to suppress PTH release. As a result of decreased calcitriol production, the absorption of dietary calcium in the gut is diminished, contributing to hypocalcemia. Decreased suppression of PTH release by vitamin D in conjunction with hypocalcemia promotes continued stimulus for mobilization of calcium from bone. Furthermore, uremic patients require a higher extracellular calcium concentration to suppress secretion of PTH. This is also described as an increase in the calcium “set point” or the concentration of calcium required to inhibit 50% of maximal PTH secretion.¹³⁰

The chronic effects of hyperparathyroidism on the skeleton lead to bone pain, fractures, and myopathy. In children, these effects may be particularly severe and usually retard growth. The metabolic acidosis of kidney disease also contributes to a negative calcium balance in the bone.

D.B.’s presentation is consistent with ROD based on the observed changes in bone architecture and abnormalities in serum phosphorus, calcium, and PTH; all can be attributed to her kidney disease.

Treatment

17. What are the goals of therapy for D.B.’s calcium, phosphorus, and PTH abnormalities? What options are available to treat these disorders?

The management objectives for D.B. are to (a) maintain near-normal serum calcium and phosphorus concentrations, (b) prevent secondary hyperparathyroidism, and (c) restore normal skeletal development without inducing adynamic bone disease (or low bone turnover). The NKF-K/DOQI guidelines for bone metabolism and disease suggest target levels for serum calcium and phosphorus, the calcium and phosphorus product (Ca-P), and intact PTH for each stage of CKD.^{84,131} These goals are best achieved with dietary phosphorus restriction, appropriate use of phosphate-binding agents, vitamin D therapy, calcimimetics, and dialysis.

Dietary Restriction of Phosphorus

In general, serum phosphorus should be maintained at near normal levels in the earlier stages of CKD (~2.7–4.6 mg/dL), with a higher range (3.5–5.5) accepted in patients with stage 5 CKD.⁸⁴ Dietary phosphorus restriction can prevent hyperphosphatemia and maintain target phosphorus concentrations. Protein restriction will also limit phosphorus intake, because high-protein foods tend to contain high amounts of phosphorus (Table 31-6).¹³² The challenge is in tailoring a diet that fulfills these criteria while providing adequate nutrition. During the early stages of kidney disease (eGFR <60 mL/minute/1.73 m²), dietary phosphorus should be reduced to 800 to 1,000 mg/day (~60% of normal) through restriction of meat, milk, legumes, and carbonated beverages to achieve normal phosphorus concentrations.^{84,133} Patients requiring dialysis have less dietary phosphorus restriction with a recommended phosphorus intake of approximately 800 to 1,200 mg/day.¹³³ While phosphorus is removed to some extent by dialysis, neither HD nor PD removes adequate amounts to warrant complete liberalization of phosphorus in the diet. Regular dietary counseling

Table 31-6 Phosphorus Content of Select High-Protein Foods

| Food | Portion Size | Phosphorus Content (mg) |
|---------------------------|------------------|-------------------------|
| Black-eyed peas, cooked | 1 cup | 288 |
| Cheese, American | 4 ounces | 1,200 |
| Cheese, cheddar | 4 ounces | 545 |
| Cheese creamed cottage | 4 ounces | 150 |
| Cheese, Swiss | 4 ounces | 800 |
| Chicken, cooked | 3.5 ounces | 190 |
| Chocolate candy | 2 ounces | 130 |
| Egg | 1 large | 100 |
| Fish, cooked | 4 ounces | 400 |
| Hamburger, ground sirloin | 3.5 ounces | 186 |
| Ice cream | 8 ounces | 163 |
| Kidney beans, cooked | 1 cup | 278 |
| Lamb | 3.5 ounces | 200 |
| Liver, chicken | 3.5 ounces | 312 |
| Milk, whole or skim | 8 ounces (1 cup) | 278 |
| Peanut butter | 2 tablespoons | 118 |
| Peanuts | 3.5 ounces | 466 |
| Pork tenderloin | 3.5 ounces | 301 |
| Salmon, canned | 3.5 ounces | 344 |
| Sardines, canned in oil | 3.5 ounces | 434 |
| Shrimp | 3.5 ounces | 156 |
| Soybeans | 1 cup | 322 |
| Steak, sirloin | 4 ounces | 282 |
| Tofu | 3.5 ounces | 128 |
| Tuna fish, canned | 3.5 ounces | 250 |
| Turkey | 3.5 ounces | 200 |
| Yogurt, plain | 8 ounces | 270 |

Data from Bowes AP, Church HN. *Bowes & Church's Food Values of Portions Commonly Used*. Philadelphia: Lippincott-Raven; 1998.

by a renal dietitian is necessary to reinforce the importance of phosphorus restriction and other dietary recommendations.

Phosphate-Binding Agents

Significant reduction of serum phosphorus may be difficult to achieve with dietary intervention alone, particularly in patients with more advanced kidney disease (eGFR <30 mL/minute/1.73 m²). For these patients, phosphate-binding agents used in conjunction with dietary restriction are necessary. Phosphate-binding agents limit phosphorus absorption from the GI tract by binding with the phosphorus present from dietary sources. Therefore, these agents must be administered with meals. Available binders include products that contain calcium, lanthanum, aluminum, or magnesium cations or the polymer-based agent, sevelamer hydrochloride (Renagel).

CALCIUM-CONTAINING PREPARATIONS

Calcium-containing preparations, especially calcium carbonate and calcium acetate, are frequently used to prevent hyperphosphatemia in patients with kidney disease. The many preparations available vary in their calcium content (Table 31-7). Correction of hypocalcemia is an added beneficial effect of the calcium-containing preparations; however, a risk exists of hypercalcemia and cardiac calcification associated with the prolonged use of these agents.¹³⁴ Compared with calcium carbonate, calcium acetate binds about twice the amount of phosphorus for the same amount of calcium salts, which may be owing to the increased solubility of calcium acetate in both acidic and alkaline environments.¹³⁵ Despite the reduction in the dose of elemental calcium required with the acetate product, the incidence of hypercalcemia does not differ.¹³⁵ Calcium citrate is a calcium salt with a phosphate-binding capacity

Table 31-7 Phosphate-Binding Agents

| Product | Select Available Agents ^a | Content of Compound | Starting Dose | |
|---|---|--|---------------------------------|--|
| Calcium carbonate (40% calcium) | Tums | 200, 300, 400 mg | 0.8–2 g elemental Ca with meals | |
| | Os-Cal-500 | 500 mg | | |
| | Nephro-Calci | 600 mg | | |
| | Caltrate 600 | 600 mg | | |
| | Calcarb HD (powder) | 2,400 mg/packet | | |
| | CaCO ₃ (multiple preparations) | 200–600 mg | | |
| Calcium acetate (25% calcium) | Phos-Lo 667 mg | 169 mg | 2–3 tablets with meals | |
| Sevelamer hydrochloride (polymer-based) | Renagel (tablet, capsule) | 400, 800 mg (tablet) | 800–1,600 mg with meals | |
| Lanthanum carbonate | Fosrenol | 250, 500, 750, 1,000 mg | 250–500 mg with meals | |
| | Aluminum hydroxide ^b | AlternaGel (suspension) | | 600 mg/5 mL |
| | | Amphojel (tablet and suspension) | | 300, 600 mg (tablet) 320 mg/5 mL (suspension) |
| | | Alu-Cap (capsule) | | 400 mg |
| | | Alu-Tab | | 500 mg |
| | | Basaljel (tablet, capsule, and suspension) | | 500 mg (tablet, capsule) |
| | | | | |
| Magnesium carbonate ^b | Mag-Carb (capsule) | 70 mg | 70 mg with meals | |
| Magnesium hydroxide ^b | Milk of Magnesia (tablet and suspension) | 300, 600 mg (tablet) | 300–400 mg with meals | |
| | | 400, 800 mg/5 mL (suspension) | | |

^aTablet unless noted otherwise.

^bNot first-line choice as a phosphate binder for chronic use.

similar to that of calcium carbonate; however, because it also increases aluminum absorption from the GI tract, its use is not recommended in patients with kidney disease.

Although calcium-containing binders have an added benefit of correcting hypocalcemia, the potential for hypercalcemia must be frequently evaluated in patients receiving these agents chronically. Simultaneous administration of vitamin D preparations and calcium also increases the risk of hypercalcemia. A “corrected” serum calcium and the “Ca-P product” (defined below) should be determined before therapy is started and at regular intervals thereafter.

Serum calcium should be maintained at near normal levels in the earlier stages of CKD. Calculating corrected calcium adjusts for the change in the ratio of free (unbound) versus protein bound calcium owing to reduced serum albumin concentrations. A narrower range is recommended in patients with stage 5 CKD (upper range of ~9.5 mg/dL) to prevent both hypocalcemia and hypercalcemia.⁸⁴

$$\begin{aligned} \text{Corrected total calcium (mg/dL)} &= \text{Total calcium (mg/dL)} \\ &+ 0.8 \times [4\text{-Serum albumin (g/dL)}] \end{aligned} \quad (31-5)$$

The calculation for Ca-P is as follows:

$$\begin{aligned} \text{Ca-P} &= \text{Corrected calcium (mg/dL)} \\ &\times \text{serum phosphorus (mg/dL)} \end{aligned} \quad (31-6)$$

The calculated Ca-P value gives some indication to when calcium and phosphate may precipitate and be deposited into soft tissue (e.g., coronary vasculature). Based on the increased risk of mortality associated with an elevated Ca-P product and the potential for cardiac calcification, the ideal Ca-P product target has been decreased to <55 mg²/dL².⁸⁴ This is much lower than the former recommendation of <65 to 70 mg²/dL² and more difficult to achieve. When the Ca-P product exceeds the target value, the patient should be switched to a non-calcium-based phosphate binder. Alternatives include sevelamer and cations, such as lanthanum carbonate, aluminum, or magnesium preparations. For patients requiring dialysis, reducing the calcium concentration of the dialysate bath may decrease the risk of hypercalcemia. Although avoiding hypercalcemia should reduce the risk of cardiac calcification, calcifications still can occur because of other contributing factors in the CKD population (e.g., hyperphosphatemia).

Nausea, diarrhea, and constipation are other side effects of calcium-containing products. Because calcium-containing binders may interact with other drugs, timing of their administration relative to other agents must be considered. Fluoroquinolones and oral iron, for example, should be taken at least 1 or 2 hours before calcium-containing phosphate binders. Importantly, if the calcium products are being used as supplementation to treat hypocalcemia or osteoporosis, they should be taken between meals to enhance intestinal absorption. This is in contrast to their administration with meals if they are being used as phosphate binders. Starting doses of common calcium-containing phosphate binders are listed in Table 31-7.

SEVELAMER HYDROCHLORIDE

Sevelamer hydrochloride (Renagel) is a nonabsorbed, polymer-based product that binds phosphorus in the GI tract.¹³⁶ The benefit of lowering phosphorus without significantly af-

fecting serum calcium has led to the increased use of sevelamer in patients with CKD, and it is now considered a first-line agent in patients with stage 5 CKD.⁸⁴ Sevelamer also lowers LDL and total serum cholesterol, a substantial benefit considering the increased risk of cardiovascular events in this population.¹³⁷ The combined use of sevelamer and calcium supplementation has been evaluated. Coadministration of calcium (900 mg/day elemental calcium) with sevelamer resulted in greater decreases in both phosphorus and PTH than either agent alone without significant increases in serum calcium.¹³⁸ This may prove to be a useful way to control phosphorus and PTH, while avoiding both hypocalcemia and hypercalcemia.

Sevelamer has a potential benefit of attenuating the progression of coronary calcification, which may be related to its LDL and total serum cholesterol-lowering effects and a benefit from reduced calcium loading. The actual benefit of sevelamer on mortality is controversial. The *post hoc* analysis of the Renagel in New Dialysis (RIND) trial showed a survival advantage with sevelamer compared with calcium acetate, however, the Dialysis Clinical Outcomes Revisited (DCOR) trial failed to show a difference in mortality between the two agents.¹³⁹ One explanation for the disparity in these results may be the difference in the population of patients on HD between the two trials. The RIND included incident patients on HD, whereas the DCOR included prevalent patients who likely would have advanced cardiovascular disease.

Sevelamer is available as a 403-mg capsule and as 400-mg and 800-mg tablets. The starting dose is variable and depends on the baseline serum phosphorus concentration (800 mg TID with meals if serum phosphorus is <7.5 mg/dL; 1,600 mg TID with meals if serum phosphorus is >7.5 mg/dL).¹³⁶ Gradual adjustments can be made at 2-week intervals, based on serum phosphorus levels. Dosing guidelines for sevelamer are also available for patients being converted from calcium acetate. Based on studies showing similar reductions in serum phosphorus, 800 mg of sevelamer is considered equivalent to 667 mg of calcium acetate (169 mg elemental calcium).¹³⁶

Data regarding drug interactions with sevelamer are limited; however, in recent evaluations, no drug interactions with digoxin, warfarin, metoprolol, and enalapril were observed.¹³⁶ The current prescribing information recommends administering sevelamer 1 hour before or 3 hours after administration of other agents with narrow therapeutic indices.¹³⁶ The administration of sevelamer to patients on HD has been associated with a lowering of serum bicarbonate. Several studies have confirmed this effect and it should be taken into account when using this agent.¹⁴⁰

LANTHANUM CARBONATE

Lanthanum carbonate (Fosrenol) is a newly approved phosphate binder that offers another option for a noncalcium, non-aluminum preparation. When ingested, it dissociates into a trivalent cation with similar binding capacity as aluminum salts, and lanthanum also has been found to be as effective and tolerable as standard treatment. Both calcium and iPTH were lower in the lanthanum group.¹⁴¹ Lanthanum is mainly excreted via the biliary route, with minimal renal elimination.

Studies have evaluated the deposition and toxicity of lanthanum in the bone, liver, and brain because of concerns of lanthanum accumulation. Although lanthanum accumulates in lysosomes in the liver, this has not been correlated with

increased liver enzymes or hepatobiliary adverse events in patients receiving lanthanum 3.75 g/day for up to 3 years.¹⁴² This is likely an excretory process through the biliary tract similar to iron and copper. A prospective trial of patients on HD receiving lanthanum for 1 year found minimal deposition of lanthanum within the bone and less likelihood of adynamic bone histology compared with patients receiving calcium carbonate.¹⁴³ Over a 2-year period, patients receiving lanthanum were not found to accelerate the natural deterioration in cognitive function seen in patients on HD.¹⁴⁴

Lanthanum is supplied as chewable tablets for oral administration in four strengths: 250, 500, 750, and 1,000 mg. The recommended initial total daily dose is 750 to 1,500 mg given with meals and dosage titration up to a maximal dosage of 3,000 mg daily should be based on serum phosphate levels. The most frequent adverse events reported in clinical trials are nausea and vomiting.¹⁴⁵

OTHER PHOSPHATE BINDERS

Aluminum preparations bind dietary phosphorus in the GI tract from both dietary sources and enterohepatic secretions and form an insoluble aluminum–phosphate complex that is excreted in the stool. Although these products were once used as first-line agents to decrease phosphorus, their use lost favor because of accumulation of aluminum in patients with CKD. Elevated serum aluminum concentrations and aluminum deposition in bone and other tissues of patients with kidney disease have been associated with osteomalacia, microcytic anemia, and a fatal neurologic syndrome, referred to as *dialysis encephalopathy*.¹⁴⁶ Treatment of aluminum toxicity requires chelation with deferoxamine. Aluminum-containing agents should only be considered on a short-term basis (up to 4 weeks) for patients with an elevated Ca-P product; however, sevelamer is generally preferred in these situations. Sucralfate, used primarily for the treatment of ulcers, also contains aluminum and should be used cautiously in patients with kidney disease.

Magnesium agents (magnesium hydroxide, magnesium carbonate) may be beneficial, but as with aluminum, their use should be limited, because at the high doses required to control serum phosphorus concentrations, severe diarrhea and hypermagnesemia invariably result. Magnesium might, however, be considered in patients whose serum phosphorus concentrations cannot be controlled adequately by other phosphate-binding agents. In this instance, a magnesium-containing phosphate binder may be added in conjunction with a reduction in the dialysate magnesium concentration (in the dialysis population). These agents should not be considered first-line therapy for control of phosphorus and careful monitoring of magnesium is warranted if therapy is started.

D.B.'s corrected calcium is approximately 9.2 mg/dL and the Ca-P product is 66 mg²/dL². More aggressive control of serum phosphorus is needed to achieve a phosphorus level <5.5 mg/dL. Currently she is receiving 1,500 mg of elemental calcium. Although presumably much of this calcium will be bound to phosphorus in the GI tract, a potential exists for calcium absorption. Because her Ca-P product is above the threshold of 55 mg/dL, she is at increased risk for cardiac calcification and adverse outcomes. The total dose of elemental calcium provided by binders should not exceed 1,500 mg/day (or 2,000 mg/day from binders and diet).⁸⁴ Sevelamer should

be started to limit her calcium exposure and decrease her phosphorus levels. The recommended starting dose is 800 mg TID with meals and titrated based on follow up of calcium, phosphorus, and Ca-P values. Adjustments should also be considered in conjunction with vitamin D therapy (see section on vitamin D below). D.B. should be instructed to take her phosphate binder with meals. This regimen should be implemented in conjunction with a restricted-phosphorus diet. Regular reinforcement of the importance of compliance is necessary, because non-adherence with prescribed dietary phosphorus restriction and drug therapy is one of the most significant factors associated with treatment failure. Use of a low-calcium dialysate may also help decrease her risk of hypercalcemia.

Vitamin D

CALCITRIOL

Vitamin D occurs naturally as ergocalciferol (vitamin D₂) and cholecalciferol (vitamin D₃), both of which are inactive precursors of active forms of vitamin D. An intermediate activation step (25-hydroxylation) occurs in the liver to produce 25-hydroxy vitamin D (25-hydroxycalciferol), which is also relatively inactive. Final activation (1-hydroxylation) occurs in the kidney, yielding calcitriol (1,25-dihydroxycholecalciferol), the active form of vitamin D. Thus, the response to vitamins D₂ and D₃ in patients with compromised renal function can vary, depending on the degree of kidney dysfunction and the ability of the kidney to metabolize 25-hydroxyvitamin D to calcitriol. For unexplained reasons, some patients in the early stages of CKD can also have decreased levels of 25-hydroxyvitamin D, reducing substrate for producing calcitriol.¹⁴⁷ Altered vitamin D metabolism that occurs in this population may warrant measurement of 25-hydroxyvitamin D and supplementation with vitamin D precursors, such as ergocalciferol.⁸⁴ Oral therapy with active vitamin D (oral calcitriol) or an analog (oral doxercalciferol) is likely warranted only when PTH remains elevated despite normal 25-hydroxyvitamin D levels.^{84,147} As the final, active metabolite of vitamin D, calcitriol is required in patients with more severe kidney disease (stage 5 CKD).

Administration of active vitamin D, in conjunction with control of serum phosphorus and calcium, is necessary in many patients with CKD to control PTH and prevent ROD. Calcitriol interacts with the vitamin D receptor (VDR) located in the parathyroid gland, intestines, bone, and kidney. It is thought to decrease PTH messenger RNA (mRNA) resulting in decreased PTH secretion. It also lowers the calcium set point for PTH release in patients with CKD with sHPT, most likely through a direct effect on calcium receptors within the parathyroid gland.¹³⁰ In addition, calcitriol stimulates calcium absorption from the GI tract to correct hypocalcemia and prevent sHPT. To avoid hypercalcemia, the lowest-effective dose should be used and the patient's serum calcium and the Ca-P product should be monitored at least every 2 weeks for 1 month and then monthly thereafter. Furthermore, control of serum phosphorus is critical before calcitriol is initiated, because this agent also increases GI phosphorus absorption.

Calcitriol is available as an oral formulation (Rocaltrol) or IV formulation (Calcijex). Administration of calcitriol by either the oral or IV route may be based on conventional dosing (usually 0.25–0.5 mcg/day) or pulse dosing (intermittent dosing of 0.5 to 2.0 mcg two to three times per week). Higher doses (e.g., 4 mcg three times per week) are generally required

to reduce PTH secretion in more severe sHPT (PTH >1,000 pg/mL). Daily dosing of 0.25 to 0.5 mcg may be preferred in patients with hypocalcemia, because this regimen primarily works to stimulate calcium absorption from the GI tract. Intermittent dosing of IV calcitriol is more routine in the HD population, because administration is coordinated with dialysis. In contrast, oral dosing is more convenient in patients with CKD who are not having dialysis and the PD population. Intact PTH and serum calcium concentrations are used to determine starting doses and dosing adjustments for calcitriol. Acceptable iPTH ranges of three to four times normal have been proposed in patients with stage 5 CKD to prevent sHPT while avoiding adynamic bone disease.^{131,147} Lower iPTH ranges of one to two times normal may be more reasonable in patients with stage 4 CKD.⁸⁴

Intact PTH (1–84 PTH) is the 84 amino acid biologically active form of this hormone. It is metabolized into smaller, less active fragments (e.g., 7–84 PTH) with activity that is not well characterized. These fragments are cleared from the circulation by the kidney and may accumulate in patients with CKD. Assays used for iPTH measure the intact structure as well as the biologically active and inactive PTH fragments. Thus, proposed ranges for iPTH in current guidelines are based on these assays. Recently, assays that measure only the biologically active form (1–84 PTH) have become available. When iPTH is measured using both methods, there is roughly a 2:1 ratio between the nonspecific and specific assay results. For example, the current guidelines for iPTH in patients with stage 5 CKD state a value of 150 to 300 pg/mL (i.e., three to four times normal); this would correspond to a 1–84 PTH concentration of approximately 75 to 150 pg/mL measured by the new methods.¹⁴⁸ These newer assays have not yet been adopted for most of the CKD population; however, they are being used in some clinical settings. Clearly, the clinician must know which assay has been used to appropriately interpret the results, establish the desired PTH range, and correctly adjust therapy.

Dose adjustments of calcitriol are generally made in 0.5- to 1.0-mcg increments every 2 to 4 weeks in the early stages of therapy until iPTH and serum calcium are maintained at target levels. If hypercalcemia develops, the decision to withhold therapy or to switch to a vitamin D analog (see section on vitamin D analogs) must be made. Serum iPTH should be monitored every 3 to 6 months, and adjustments of calcitriol doses made to maintain the goal iPTH and to prevent hypercalcemia and hyperphosphatemia.

VITAMIN D ANALOGS

The unique interactions of vitamin D with the VDR have led to the development of vitamin D analogs, which vary in their affinity for the VDR. In the case of treatment for sHPT, some were developed to retain the suppressive effect on PTH release while decreasing the potential for hypercalcemia relative to calcitriol. Currently approved agents for managing sHPT in the United States are paricalcitol (Zemplar), also referred to as 19-nor-1,25-dihydroxyvitamin D₂, and doxercalciferol (Hectorol), or 1- α -hydroxyvitamin D₂. Doxercalciferol requires conversion to the active form (1- α -,25-dihydroxyvitamin D₂) by the liver.

In patients with sHPT, paricalcitol significantly decreases iPTH without significantly increasing calcium, phosphorus, or Ca-P product.^{149,150} In one such study, a significant rise in cal-

cium concentration (within the normal range) was observed after 12 weeks of paricalcitol therapy at a maximal dose of 0.12 mcg/kg. Patients experiencing transient episodes of hypercalcemia (calcium >11 mg/dL) were evaluated with regard to their corresponding iPTH levels. An iPTH level <100 pg/mL was associated with an increase in serum calcium concentration equal to or beyond the upper limits of normal, indicating that these events were caused by inappropriate dosing and over-suppression of PTH.¹⁴⁹ Based on these data, the recommended initial dose of paricalcitol is 0.04 mcg/kg to 0.1 mcg/kg IV administered with each dialysis session or every other day.¹⁵¹ Doses can be titrated by 2- to 4-mcg increments every 2 to 4 weeks based on iPTH values. Some data have also suggested paricalcitol dosing based on initial PTH levels (paricalcitol dose = PTH/80), rather than weight, as a reasonable dosing strategy.¹⁵¹ Oral paricalcitol capsules are now available for use in CKD stages 3 and 4, and are available in three strengths (1, 2, and 4 mcg) administered daily or TIW. The starting dose should be 1 mcg daily or 2 mcg TIW if the baseline iPTH level is \leq 500 pg/mL and 2 mcg daily or 4 mcg TIW if the iPTH is >500 pg/mL. Dosage adjustments based on change in iPTH levels should occur every 2 to 4 weeks.¹⁵²

The recommended conversion ratio for calcitriol to paricalcitol is 1:4 (i.e., for every 1 mcg of calcitriol, 4 mcg of paricalcitol should be administered). This information is based on similar efficacy observed when patients treated for secondary hyperparathyroidism with calcitriol were switched to paricalcitol using this dosing strategy.¹⁴⁹ A lower ratio of 1:3 also has been proposed in patients resistant to therapy with calcitriol.¹⁵³ Although data comparing paricalcitol with calcitriol are currently limited, one study reported fewer cases of hyperphosphatemia with paricalcitol at doses that had equivalent efficacy with regard to PTH suppression. A trend was also seen toward more rapid suppression of PTH in patients treated with paricalcitol.¹⁵⁴

Doxercalciferol is another vitamin D analog that has provided an alternative to the active form of vitamin D and has been studied in patients with stage 5 CKD on dialysis.^{155,156} Intermittent oral therapy was administered to patients on HD with hyperparathyroidism (iPTH, >400 pg/mL) in a multicenter trial. In this study, 10 mcg of oral doxercalciferol was administered three times per week with HD.¹⁵⁵ Of the 99 patients completing the study, 83% achieved the target iPTH; higher doses and longer therapy was required for patients with more severe sHPT (PTH, 1,200 pg/mL). Hypercalcemia occurred in a larger percent of patients in the doxercalciferol group compared with placebo, and this was corrected by lowering the doxercalciferol dose or by reducing calcium-containing phosphate binders. In another study, intermittent IV therapy was compared with intermittent oral administration.¹⁵⁶ The doses were 4 mcg IV or 10 mcg orally three times per week with HD. Oral and IV therapy were both effective in reducing iPTH levels in patients with sHPT; however, some evidence indicated that intermittent IV therapy may result in less hypercalcemia and hyperphosphatemia than oral intermittent therapy. Comparisons with calcitriol have not been reported. The recommended starting dose of doxercalciferol for patients on dialysis is 4 mcg IV or 10 mcg orally administered three times per week with dosing titration based on changes in iPTH.¹⁵⁷

Vitamin D analogs offer an alternative for patients in whom persistent hypercalcemia develops with calcitriol therapy. Use

of these agents is increasing in clinical practice because of the concerns of hypercalcemia and its adverse consequences. Recent retrospective reports indicate a mortality benefit with vitamin D therapy. A historical cohort study of patients on HD, found that patients receiving either calcitriol or paricalcitol had lower overall and cardiovascular-related mortality rates than those not receiving vitamin D therapy.¹⁵⁸ Two trials also examined the survival advantages among the different forms of vitamin D in patients on HD.^{159,160} One report indicated that receiving paricalcitol for 36 months conferred a survival advantage starting at 12 months from initiation of therapy and increased over time compared with those receiving calcitriol.¹⁵⁹ Another study reported that patients taking either paricalcitol or doxercalciferol had a significantly lower mortality rate than patients receiving calcitriol, although when adjusted for laboratory values and clinic standardized mortality, no difference was found between the products.¹⁶⁰

Possible biologic reasons for vitamin D improving outcomes include its role downregulating the RAS and immunomodulatory properties. A prospective trial would be required to confirm a survival advantage associated with vitamin D therapy.

Calcimimetics

The discovery of extracellular calcium-sensing receptors (CaSR) has prompted research with calcimimetic agents that allosterically modulate CaSR. CaSR have been identified in the parathyroid gland, thyroid, nephron, brain, intestine, bone, lung, and other tissues. Calcimimetic agents increase the sensitivity of the CaSR to extracellular calcium ions, inhibit the release of PTH, lowering PTH levels within hours after administration. The calcimimetic cinacalcet is the first agent in this class to be approved by the FDA. Pooled data from two phase III trials of this agent demonstrated efficacy in lowering PTH concentrations and Ca-P product in patients on HD with sHPT and a higher proportion of patients achieved NKF-K/DOQI recommended targets for PTH, calcium, phosphorus, and Ca-P product.¹⁶¹ No data are found on survival rates for patients receiving cinacalcet versus those treated with vitamin D. Cinacalcet, however, offers an additional choice of agent to lower PTH when vitamin D cannot be increased because of elevated calcium, phosphorus, or calcium-phosphorus product. Current studies are also examining the role of combined therapy with cinacalcet and vitamin D therapy to improve achievement of bone metabolism and disease targets.¹⁶²

Appropriate treatment for D.B. should be based on assessment of her serum calcium, phosphorus, and PTH values. She currently has an elevated PTH, phosphorus, and calcium-phosphorus product; therefore, cinacalcet should be started in conjunction with her dietary phosphorus restriction, phosphate-binder regimen, and vitamin D therapy. Cinacalcet should be initiated at a dose of 30 mg daily with dosage titrations occurring every 2 to 4 weeks to 60, 90, 120 or a maximum of 180 mg daily to achieve target iPTH levels. Serum calcium and phosphorous levels should be drawn within 1 week after initiation or dosage increase, and plasma PTH levels drawn within 4 weeks after initiation of therapy or dosage adjustment. Nausea and vomiting are the most common adverse events associated with cinacalcet. In phase III trials, 66% of patients receiving cinacalcet experienced at least one episode of hypocalcemia (serum calcium <8.4 mg/dL), although, <1% of patients discontinued treatment.¹⁶³ The high incidence of

hypocalcemia is not solely caused by lowered PTH activity, but is also attributed to the mechanism of action of cinacalcet. It is thought that activation of CaSR in bone, intestine, and other tissues may contribute to hypocalcemia.^{164,165} Most episodes of hypocalcemia occur during the initiation of cinacalcet therapy and slowly titrating the dose reduces the risk. Seizures caused by hypocalcemia have been reported, however. Vitamin D or calcium-based binders can be increased to manage serum calcium levels between 7.5 and 8.4 mg/dL. If serum calcium falls below 7.5 mg/dL and is associated with symptoms of hypocalcemia and vitamin D cannot be increased further, cinacalcet should be withheld until serum calcium is 8.0 mg/dL or the patient is asymptomatic. Cinacalcet is a strong *in vitro* inhibitor of CYP2D6, therefore, dose adjustments of concomitant medications that are predominantly metabolized by CYP2D6 may be required. Ketoconazole has also been documented to interact with cinacalcet. Cinacalcet is a substrate of CYP3A4, and ketoconazole, a potent inhibitor of CYP3A4, has been shown to increase the area under the curve (AUC) of cinacalcet 2.3 times. Thus, other inhibitors of the CYP3A4 isoenzyme should be used in caution in patients receiving cinacalcet.¹⁶³ Short-term aluminum hydroxide may be another alternative if more aggressive lowering of phosphorus is necessary.

Parathyroidectomy

The parathyroid glands enlarge as a compensatory response to disturbances of phosphorus, calcium, and calcitriol metabolism in patients with CKD. Timely administration of vitamin D therapy to prevent parathyroid hyperplasia is crucial, because treatment with vitamin D cannot adequately reverse established hyperplasia.¹³³ Under circumstances in which severe sHPT cannot be controlled by dietary phosphorus restriction and drug therapy, parathyroidectomy is considered. Parathyroidectomy can be subtotal, total, or total with autotransplantation. One of the major complications of parathyroidectomy is the early development of postsurgical hypocalcemia. Clinical symptoms of hypocalcemia include muscle irritability, fatigue, depression, and memory loss. Patients should be monitored closely following parathyroidectomy, and all patients with signs or symptoms of hypocalcemia should be treated with calcium supplementation (see Chapter 11, Fluid and Electrolyte Disorders). In patients who have had subtotal parathyroidectomy, the remaining parathyroid tissues will start functioning adequately, so that the acute hypocalcemia is only transient, lasting only a few days. With total parathyroidectomy, however, hypocalcemia is permanent, necessitating long-term treatment with calcitriol and oral calcium supplements (1–1.5 g/day of elemental calcium).

OTHER COMPLICATIONS OF CKD

Endocrine Abnormalities Caused by Uremia

18. Does D.B.'s hypothyroidism have any relationship to her CKD? What other endocrine abnormalities are associated with uremia?

Disturbances in thyroid function are frequently encountered in patients with CKD because the kidney is involved in all aspects of peripheral thyroid hormone metabolism. Common laboratory abnormalities include reduced serum concentrations

of total thyroxine (T_4) and 3,5,3'-triiodothyronine (T_3) and a low free thyroxine index (FTI). The thyroid-stimulating hormone (TSH) concentration is usually normal, but peripheral conversion of T_4 to T_3 is reduced in uremic patients.¹⁶⁶ Despite these abnormalities, clinical hypothyroidism does not occur solely as a result of kidney disease, probably because the amount of free (unbound to protein) thyroid hormone in serum remains normal. Hypothyroidism in patients with kidney failure should be confirmed by the presence of an elevated serum TSH concentration and a low serum concentration of free T_4 .

Other endocrine abnormalities that have been observed in patients with CKD include gonadal dysfunction leading to impotence, diminished testicular size, menstrual abnormalities, and cessation of ovulation.¹⁶⁷ Decreased libido and infertility occur in both sexes. Uremic women should avoid becoming pregnant, because there is a low likelihood of successful delivery. In children with kidney disease, growth retardation occurs despite normal or elevated growth hormone. Hyperprolactinemia and altered vasoactive hormone activity are other endocrine disturbances that can occur in patients with CKD.¹⁶⁶

Altered Glucose and Insulin Metabolism

19. Other than the obvious effect of D.B.'s diabetes mellitus on blood glucose, are there any effects of kidney disease itself on glucose metabolism?

Uremia often is associated with glucose intolerance early in the course of kidney disease in nondiabetic patients and this may be referred to as "pseudodiabetes." Specifically, patients with CKD often exhibit an abnormal response to an oral glucose challenge and have sustained hyperinsulinemia.¹⁶⁸ The fasting blood glucose is typically within normal limits. Diminished tissue sensitivity to the action of insulin is also observed. Although their exact role is unclear, several uremic toxins, including urea, creatinine, guanidinosuccinic acid, and methylguanidine, have been implicated as causes for insulin resistance. Elevated concentrations of growth hormone, PTH, and glucagon also may contribute to glucose intolerance. Most nondiabetic patients with kidney disease do not require therapy for hyperglycemia, and dialysis can correct these abnormalities in glucose metabolism.¹⁶⁶

Patients with diabetes mellitus and advanced kidney disease may experience improved glucose control and decreased insulin requirements. This is because the kidney is responsible for a substantial amount of daily insulin degradation and, as the disease progresses, less insulin is cleared, and its metabolic half-life is increased.¹⁶⁶ A decreased clearance of insulin by muscle tissue also can occur in patients with uremia. Thus, in diabetic patients with progressive kidney disease, blood glucose concentrations should be monitored and insulin doses adjusted to avoid hypoglycemia. D.B. has stage 5 CKD and is receiving her insulin in the peritoneal dialysate solution. Hyperglycemia is also a concern in D.B. because the glucose present in her continuous ambulatory peritoneal dialysis (CAPD) fluid to promote fluid removal will be absorbed systemically. Insulin dosage adjustments should be made on the basis of repeated home blood glucose measurements, changes in the CAPD prescription, and glycosylated hemoglobin determinations.

Gastrointestinal Complications

20. One month before her current clinic visit, D.B. complained of nausea and vomiting of partially digested food. Metoclopramide (Reglan) was begun at that time. Could D.B.'s nausea and vomiting have been caused by her kidney failure? Was the appropriate therapy selected?

Gastrointestinal abnormalities are extremely common in patients with CKD and include anorexia, nausea, vomiting, hiccups, abdominal pain, GI bleeding, diarrhea, and constipation.¹⁶⁹ Diminished gastric motility can occur from uremia; however, this problem may improve with adequate HD. Dyspeptic complaints and gastroparesis may be more prevalent in the PD population than in the HD population and in the earlier stages of CKD.¹⁷⁰ D.B. has diabetes and diabetic neuropathy, which also contributes to the delayed gastric emptying (diabetic gastroparesis) and retention of food in the upper intestinal tract. This frequently causes distention, nausea, and vomiting. Metoclopramide is recommended to relieve these symptoms, although the risk for extrapyramidal side effects should be considered. A lower dose of 5 mg before meals may be warranted for D.B. Cisapride (Propulsid), a prokinetic agent that has restricted access, is contraindicated in patients with kidney disease because its use is associated with the development of arrhythmias in this population.

Severe uremia also causes nausea and vomiting, and these can be initial presenting symptoms of kidney failure. Although antiemetics, such as prochlorperazine (Compazine), are used, dialysis is the preferred therapy. Drug-induced nausea and vomiting always should be considered, because patients with CKD often take multiple drugs and are at risk for drug toxicity because of diminished kidney function (e.g., digitalis intoxication).

Bleeding

21. During her clinic visit, D.B. reports that her bowel movements have become black and tarry in appearance. A rectal examination reveals guaiac-positive stools. Is GI bleeding related to kidney failure?

D.B. should be evaluated for peptic ulcer disease and lower GI bleeding. Uremic patients are at risk for bleeding from mucosal surfaces such as the stomach. D.B.'s hemoglobin and hematocrit are below the target values (11–12 g/dL for hemoglobin, 33% to 36% for hematocrit), despite therapy with epoetin, and it is likely that bleeding is contributing to poor responsiveness to therapy. Angiodysplasia of the stomach and duodenum, as well as erosive esophagitis, are the most common causes of bleeding in patients with CKD.¹⁷¹ Treatment of upper GI bleeding in uremic patients usually consists of cautious use of antacid therapy and H_2 -receptor antagonists, which should be given in reduced doses according to the degree of kidney function. Proton pump inhibitors are primarily eliminated by nonrenal routes and can be administered at standard doses (see Chapter 26, Upper Gastrointestinal Disorders). Use of H_2 -receptor antagonists has generally replaced chronic antacid use for treatment of dyspepsia in patients with CKD.

Neurologic Complications

22. S.H., a 64-year-old, 72-kg, black man, went to his primary care physician because of weakness, nausea, lethargy, decreased exercise tolerance, and general malaise that has developed over the past few weeks. S.H. had not been seen by a physician for >10 years. His medical history was unremarkable, except he recalls being told approximately 5 years ago that he had borderline hypertension. He was taking no medications. The physician's examination revealed a BP of 168/92 mmHg, and fundoscopic examination showed grade III hypertensive changes. On neurologic examination, S.H. was slightly confused, appeared somnolent, and had diminished sensation to pinprick in both lower extremities; asterixis was present. Examination of the skin showed pallor and excoriations across the abdomen, legs, and arms. Pertinent laboratory values were as follows: Hct, 20% (normal, 39%–49%); Hgb, 6.7 g/dL (normal, 13–16 g/dL); WBC count, 9,100/mm³ (normal, 3,200–9,800/mm³); serum Na, 135 mEq/L (normal, 135–147 mEq/L); K, 5.8 mEq/L (normal, 3.5–5.0 mEq/L); Cl, 109 mEq/L (normal, 95–105 mEq/L); CO₂ content, 16 mEq/L (normal, 22–28 mEq/L); random blood glucose, 121 mg/dL (normal, <140 mg/dL); BUN, 199 mg/dL (normal, 8–18 mg/dL); SrCr, 19.8 mg/dL (normal, 0.6–1.2 mg/dL); Ca, 8.5 mg/dL (normal, 8.8–10.4 mg/dL); phosphate, 11.1 mg/dL (normal, 2.5–5.0 mg/dL); intact PTH, 830 pg/mL (normal, 5–65 pg/mL); uric acid, 11.9 mg/dL (normal, 2.0–7.0 mg/dL); and albumin, 3.0 g/dL (normal, 4.0–6.0 g/dL).

Renal ultrasonography revealed no obstruction and small kidneys bilaterally. Subsequent kidney biopsy showed chronic glomerular scarring. S.H. was diagnosed with stage 5 CKD, likely caused by chronic, untreated hypertension. What is the likely explanation for S.H.'s altered mental status? What treatment, if any, is indicated for his neurologic findings?

[SI units: Hct, 0.20 (normal, 0.39–0.49); Hgb, 67 g/L (normal, 130–160); WBC, 9,100 × 10⁶/L (normal, 3,200–9,800); Na, 135 mmol/L (normal, 135–147); K, 5.8 mmol/L (normal, 3.5–5.0); Cl, 109 mmol/L (normal, 95–105); CO₂, 16 mmol/L (normal, 22–28); blood glucose, 6.7 mmol/L (normal, <11 mmol/L); BUN, 71.0 mmol/L of urea (normal, 3.0–6.5); SrCr, 1,750 μmol/L (normal, 50–110); Ca, 2.12 mmol/L (normal, 2.2–2.6); phosphate, 3.58 mmol/L (normal, 0.8–1.60); uric acid, 708 μmol/L (normal, 120–420); and albumin, 30 g/L (normal, 40–60)]

Disorders of the central nervous system (CNS) that occur in patients with untreated kidney disease and in those receiving dialysis are referred to collectively as *uremic encephalopathy*. Symptoms generally occur when the eGFR is <10% of normal. Although S.H.'s altered neurologic function is most likely caused by uremia, a careful drug history should exclude the possibility of drug effects. Symptoms of uremic encephalopathy include alterations in consciousness, thinking, memory, speech, psychomotor behavior, and emotion. Patients or their family members may note fatigue, daytime drowsiness, insomnia, diminished cognitive abilities, slurred speech, vomiting, and emotional volatility. The patient also may complain of being cold, having “restless legs,” or “burning feet.” The encephalopathy may progress to ataxia, vertigo, nystagmus, coma, and convulsions. Electroencephalograms (EEG) of patients with CKD usually show diffuse abnormalities.

Evidence supports PTH as a major contributing factor to the altered neurologic status of patients with ESRD; however, other uremic toxins can play a role in this disorder. PTH may enhance the entry of calcium into the brain and peripheral nerves, but it also may be directly neurotoxic. In all likelihood, S.H.'s altered mental status will improve with dialysis and correction of his hyperparathyroidism, although additional factors, such as his advanced age, must be considered.

The peripheral nervous system also shows abnormal function in many patients with advanced CKD, as illustrated by S.H., who has loss of sensation in his legs by pinprick examination. Typically, the peripheral neuropathy will be slowly progressive, distal, and symmetric, usually first involving sensory function. The abnormalities seen usually are indistinguishable from other types of neuropathy, especially diabetic neuropathy. Nerve conduction studies often reveal abnormalities preceding clinical symptoms. Treatment generally consists of measures to alleviate symptoms with agents, such as tricyclic antidepressants (e.g., amitriptyline) and anticonvulsants (e.g., phenytoin, gabapentin). Increasing the intensity of dialysis does not seem to affect the neuropathy; however, successful renal transplantation may ameliorate nerve dysfunction.

Abnormalities of the autonomic nervous system also have been observed in patients with kidney failure and present as postural hypotension, impotence, impaired sweating, and alterations in gastric motility. HD may be more likely to correct autonomic dysfunction in nondiabetic patients.

Dermatologic Complications

23. Why does S.H. have excoriations on his skin? What therapy would be useful?

Several dermal abnormalities have been observed in patients with CKD, including hyperpigmentation, abnormal perspiration, skin dryness, and persistent pruritus. Of these, *uremic pruritus* can be the most bothersome for the patient and may lead to repeated scratching and skin excoriation. Hyperparathyroidism, hypervitaminosis A, and dermal mast cell proliferation with subsequent histamine release have been suggested as causes of pruritus.¹⁷²

Treatment of pruritus often is a frustrating experience for the patient and clinician. Although many therapies have been advocated, few have provided sustained benefit. A trial-and-error approach is recommended. Efficient dialysis therapy relieves pruritus in some patients and pharmacologic therapy may be avoided.¹⁷³ When necessary, initial pharmacologic treatment usually consists of oral antihistamines (e.g., hydroxyzine). Topical emollients or topical steroids may provide benefit if antihistamine therapy is not completely successful. If pruritus is still present, other treatment options can be tried. These include cholestyramine, ultraviolet B (UVB) phototherapy, and oral administration of activated charcoal. Control of calcium and phosphorus concentrations and prevention of secondary hyperparathyroidism are also advocated to reduce pruritus in patients with CKD.

GLOMERULAR DISEASE

Glomerular diseases lead to many complications that result from disruption of normal glomerular structure and function.

Several clinical syndromes of glomerular disease exist; however, glomerulonephritis, characterized as proliferation and inflammation of the glomerulus, is observed most frequently. According to the most recent USRDS report, glomerulonephritis as a broad category remains the third leading cause of ESRD in the United States, accounting for approximately 8.4% of new cases and a higher proportion of the PD population (14.6%) when compared with the HD population (8%).³ In developing countries, glomerulonephritis is more common as a cause of kidney failure because various infectious processes responsible for glomerulonephritis are more common.

Nephrotic Syndrome

Nephrotic syndrome is characterized by proteinuria >3.5g/day, hypoalbuminemia, edema, and hyperlipidemia. In more severe conditions, hypercoagulable conditions may be present because of loss of hemostasis control proteins, including antithrombin III, protein S, and protein C. This syndrome can occur with or without a change in glomerular filtration rate. Nephrotic syndrome may be caused by a primary disease, such as membranous glomerulopathy, which is characterized by deposition of immune complexes, or other systemic diseases including diabetic glomerulosclerosis and amyloidosis. Elevated serum cholesterol and triglycerides are observed in patients with this degree of proteinuria (>3.5 g/day). This hyperlipidemic condition also predisposes patients with nephrotic syndrome to accelerated atherosclerosis. Hyperlipidemia itself can also contribute to progression of kidney disease. Because nephrotic syndrome is associated with numerous causes, further evaluation of the patient for systemic causes is required to then determine the course of therapy and prognosis.

Chronic Glomerulopathies

Glomerulonephritis can occur as a primary disease that is idiopathic in origin (focal segmental glomerulosclerosis [FSGS]) or as a secondary manifestation of other systemic disease (lupus nephritis [LN]), Wegener's granulomatosis). Renal biopsy is often required for definitive diagnosis. Glomerular lesions associated with glomerulopathies are characterized as diffuse, focal, or segmental, depending on the extent of involvement of individual glomeruli. Pathologic changes are characterized as proliferative, membranous, and sclerotic based on the pattern observed. Proliferative changes usually involve an overgrowth of the epithelium or mesangium, whereas membranous changes are typically described as a thickening of the glomerular basement membrane. Signs and symptoms of glomerulonephritis include hematuria, proteinuria, and decreased kidney function. An autoimmune reaction is the predominant pathogenic process leading to most forms of primary and secondary glomerulonephritis. Although a number of autoantibodies are associated with glomerulonephritis, their exact role in the pathogenesis of glomerulonephritis is still unclear. Nonetheless, analysis of autoantibodies in the clinical setting can aid in early diagnosis of glomerulonephritis.¹⁷⁴

Glomerular damage generally occurs in two phases: acute and chronic. During the acute phase, immune reactions occur within glomeruli that stimulate the complement cascade, ultimately resulting in glomerular damage. Nonimmune mechanisms that occur in response to loss of nephron function and

hyperfiltration of remaining nephrons are characteristic of the chronic phase.

Glomerulonephritis often causes acute renal failure. Patients with damage to >50% of glomeruli in the presence of rapid loss in kidney function (over days to weeks) are classified as having *rapidly progressive glomerulonephritis* (RPGN).¹⁷⁴ If kidney involvement is severe, signs and symptoms of uremia may develop. RPGN may be classified based on the immunopathogenic etiology of the glomerular damage: (a) immune complex deposition (e.g., LN), (b) nonimmune deposit-mediated mechanism (e.g., Wegener's granulomatosis), and (c) sclerotic lesions of the glomerulus (e.g., FSGS).¹⁷⁴ This chapter focuses on the treatment of the more common forms of chronic glomerulonephritis (i.e., LN, Wegener's granulomatosis, FSGS).

Lupus Nephritis

Systemic lupus erythematosus (SLE) is a multisystem autoimmune disease characterized by abnormalities in cell-mediated immunity, such as B-cell hyperresponsiveness and defective T-cell-mediated suppressor activity. In certain predisposed individuals, SLE can lead to the development of LN, a secondary form of glomerulonephritis. LN is the prototypical immune complex-mediated kidney disease, characterized by deposition or in situ formation of autoantibody-antigen complexes along the glomerular capillary network. LN remains an important cause of mortality. Up to 60% of adults with SLE have some degree of kidney involvement later in the course of their disease, discernible from clinical evidence of kidney damage: heavy proteinuria, hematuria, decreased eGFR, and hypertension. Early in the disease, laboratory abnormalities indicative of kidney involvement are seen in approximately 25% to 50% of patients.

24. C.W., a 34-year-old black woman with a 7-year history of SLE, presents to the nephrology clinic for follow up of her LN. Pertinent laboratory values are as follows: serum Na, 146 mEq/L (normal, 135–147 mEq/L); K, 4.2 mEq/L (normal, 3.5–5.0 mEq/L); Cl, 100 mEq/L (normal, 95–105 mEq/L); CO₂ content, 25 mEq/L (normal, 22–28 mEq/L); SrCr, 2.0 mg/dL (normal, 0.6–1.2 mg/dL); BUN, 20 mg/dL (normal, 8–18 mg/dL); and WBC count, 9,600/mm³ (normal, 3,200–9,800/mm³). RBC indices were normal. Platelet count is 175,000/mm³ (normal, 130,000–400,000/mm³). Her 24-hour urine contained 2.3 g of albumin (normal, <30 mg/day), and her urine analysis shows 12 RBC/high-power field (HPF) (normal, 0–3). Compared with her visit of a week ago, C.W.'s kidney function and urinary indices (proteinuria, hematuria) show substantial worsening of her nephritis. C.W. was hospitalized, and a kidney biopsy showed inflammation of 40% of the glomeruli. What subjective and objective data in C.W. are consistent with a diagnosis of LN, and what is the stage of her nephritis?

[SI units: Na, 146 mmol/L (normal, 135–147); K, 4.2 mmol/L (normal, 3.5–5.0); Cl, 100 mmol/L (normal, 95–105); CO₂, 25 mmol/L (normal, 22–28); SrCr, 177 μmol/L (normal, 50–110); BUN, 7.14 mmol/L of urea (normal, 3.0–6.5); WBC, 9,600 × 10⁶/L (normal, 3,200–9,800); platelet count, 175 × 10⁹/L (normal, 130–400); urinary albumin, 2.3 g/day (normal, <0.03)]

C.W. has clinical evidence of kidney damage as demonstrated by her proteinuria, hematuria, and increased SrCr

Table 31-8 2003 International Society of Nephrology/Renal Pathology Society Classification of Lupus Nephritis

| Class | Histologic Characterization | Usual Clinical Presentation |
|-------|--|---|
| I | Minimal mesangial lupus nephritis | Mild proteinuria |
| II | Mesangial proliferative glomerulonephritis | Mild proteinuria and urine sediment abnormalities |
| III | Focal and segmental proliferative glomerulonephritis A: Active lesions; A/C: active and chronic lesions; C: chronic lesions | Proteinuria and hematuria |
| IV | Diffuse proliferative segmental (S) or global (G) glomerulonephritis A: Active lesions; A/C: active and chronic lesions; C: chronic lesions | Heavy proteinuria; active sediment; hypertension; renal failure |
| V | Membranous glomerulonephritis | Proteinuria; often nephrotic syndrome |
| VI | Advanced sclerosing glomerulonephritis | Proteinuria; renal failure; nephrotic syndrome |

Data from reference 175.

concentration. Glomerular damage is most evident by the presence of RBC or red cell casts in the urine, a finding observed in C.W.

CLASSIFICATIONS

The International Society of Nephrology and the Renal Pathology Society (ISN/RPS) classification system was developed in 2003 to replace the previous classification system published by the World Health Organization. (Table 31-8).¹⁷⁵ This classification scheme provides a reasonable correlation among histopathology, outcome, and response to treatment. C.W. has proteinuria, hematuria, and inflammation of <50% of her glomeruli, and she is diagnosed as having class III/A (focal proliferative) glomerulonephritis.

TREATMENT

25. Should C.W.'s LN be treated?

Unlike nonrenal manifestations of SLE, serologic markers of disease correlate poorly with LN. Therefore, elevations in SrCr and worsening of proteinuria and hematuria, as seen in C.W., are used as primary markers of disease activity.

Treatment of LN must address both management of the acute disease process and maintenance therapy for the more stable chronic disease process. A general consensus is that patients, such as C.W., who present with focal or diffuse proliferative glomerulonephritis (class III or IV), should be treated aggressively, with the primary goal of preventing irreversible kidney damage. The prognosis of kidney function in patients with SLE has improved. The likelihood of developing ESRD or dying within 10 years of diagnosis has decreased from >80% to <20%; however, the prognosis is worse in blacks when compared with the white population treated for SLE.¹⁷⁶ Elevated serum creatinine, heavy proteinuria, anemia, and disease onset during childhood or in those >60 years of age are other predictors of a worse prognosis. Advances in pharmacologic therapy (i.e., safer immunosuppressive regimens, and antihypertensives) have improved the prognosis for the population as a whole.

The treatment of LN is primarily empiric but is based, to some extent, on histologic findings. Although appropriate treatment can improve patient outcomes, vigorous attempts to suppress SLE activity may lead to serious drug-related complications. Because the primary strategy in the treatment of LN involves suppression of the immune system with corticosteroids and cytotoxic agents, such as cyclophosphamide (CYC), azathioprine (AZA), and mycophenolate mofetil

(MMF), clinicians need to be aware of the potential complications associated with therapy. Therefore, careful monitoring of patients is essential in determining the indication for treatment and improving prognosis. Toxicities associated with immunosuppressive agents depend on both the dose and the duration of therapy. Abnormalities in hematopoiesis, such as neutropenia and thrombocytopenia, are the most common adverse effects associated with cytotoxic agents. Immunosuppression, in general, increases a patient's susceptibility to a vast array of infections and to lymphocytic malignancies. In addition, the alkylating agent CYC can cause nausea and vomiting, gonadal toxicity, hemorrhagic cystitis, and alopecia. The antimetabolite azathioprine AZA can cause pancreatitis and abnormalities in liver function. The selective inhibitor of inosine-monophosphate-dehydrogenase MMF, although relatively benign compared with the other agents, can cause GI disturbances.

Induction Therapy

Therapy for LN is usually not indicated in patients with normal renal function and proteinuria <2 g, regardless of class, because these patients have a good prognosis. Corticosteroids represent the cornerstone of therapy in patients with a mild form of LN. Low-dose prednisone should be initiated for patients with stable LN. In patients with a more severe form (class III and IV), prednisone 1 to 2 mg/kg/day for 4 to 8 weeks, as a single morning dose, may be initiated. Gradual tapering of prednisone to a low-dose regimen of 0.2 to 0.4 mg/kg/day must be attempted once glomerulonephritis has stabilized. For the treatment of acute exacerbations of LN, high-dose pulse therapy with methylprednisolone may be warranted. Given that C.W.'s LN has worsened, she should receive 3 days of therapy with pulse methylprednisolone (0.5 to 1 g IV, not to exceed 1 g) for 3 days in an attempt to reduce the degree of proteinuria and improve kidney function.¹⁷⁶ Although generally well tolerated, rapid methylprednisolone injections can cause transient tremor, flushing, and altered taste sensation. To reduce the risk of adverse effects associated with the rate of injection, C.W. should receive methylprednisolone over 30 minutes. After a course of pulse methylprednisolone therapy, oral prednisone at a dose 10 to 20 mg daily may be initiated.¹⁷⁶ Suppression of C.W.'s active LN should be demonstrated by a reduction in proteinuria and hematuria and an increase in her eGFR.

The addition of cytotoxic agents is reserved for patients who do not respond to corticosteroids alone, or those who have unacceptable toxicity to corticosteroids, worsening renal function, severe proliferative lesions, or evidence of sclerosis

on renal biopsy. Induction therapy with six monthly pulse doses of IV CYC (0.5–1 g/m²) or six doses of CYC given every 2 weeks at a dose of 0.5 g/m² along with steroid therapy was shown to have improved renal outcomes with less flares and relapses.^{177,178} Before, and for 24 hours after initiating IV CYC, the patient must be well hydrated to prevent bladder toxicity. Recently, MMF (2,000–3,000 mg/day times 6 months) has been proven to be as effective as CYC in the induction treatment for LN.¹⁷⁹ Given the significant toxicities associated with CYC (e.g. gonadal toxicity, hemorrhagic cystitis), the anti-inflammatory properties of MMF resulting in a possible retardation of atherosclerosis and the lower side effect profile with MMF, the option to use MMF as an alternative agent in LN seems promising, but its use in LN is still unclear. Studies are currently ongoing to determine the optimal dosing and duration of therapy with MMF, as well as, which patient population would benefit the most from this therapy in the induction therapy for LN.

Maintenance Therapy

Once the acute flare resolves (generally in up to 12 weeks), low-dose, maintenance steroid therapy with 5 to 15 mg/day of prednisone can be initiated in combination with cytotoxic therapy, as indicated, based on severity of LN. In a meta-analysis assessing the efficacy of therapeutic agents used to treat LN, improved outcomes (total mortality and ESRD) were associated with use of oral prednisone in combination with IV CYC. As a result, the National Institutes of Health (NIH) recommends the use of IV CYC pulse therapy (0.5 to 1 g/m²) every 3 months for up to 2 years for maintenance therapy of LN.¹⁸⁰ An additional benefit of combination therapy with immunosuppressive agents is their steroid-sparing effect and, potentially, lower risk of steroid toxicity.

Studies have evaluated other immunosuppressive agents (AZA, MMF) for maintenance therapy in light of the toxicities associated with CYC. The most recent trial compared maintenance therapy with AZA (1 to 3 mg/day) and MMF (500–3,000 mg/day) with CYC along with steroids after induction with CYC in patients with severe LN. Patients receiving AZA had a lower mortality rate than with CYC and the MMF treatment group had fewer relapses than the CYC treatment group.¹⁸¹ Until results from long-term trials with AZA and MMF are available, CYC is still considered first-line therapy for most classes of LN. MMF and AZA may be indicated in patients resistant to CYC therapy or with a more severe type of LN (class III and IV). The addition of CYC, AZA, and MMF, along with corticosteroid therapy, should be considered in C.W. once the acute lupus flare resolves. Once suppression of C.W.'s LN is documented, initiation of either AZA or MMF and steroids are indicated because of the severity of her LN (class III). The duration of therapy is dictated by the individual's response, but typically patients will require up to 2 years of maintenance therapy.

Alternative Agents

Exploration of alternative therapies for LN are also being studied. Rituximab, a monoclonal antibody that inhibits B-cell production, is being studied because B-cell hyperactivity is one of the major pathophysiologic mechanisms of LN. Small studies in patients with LH resistant to therapy have shown rituximab to be of benefit.¹⁸⁰ Cyclosporine, in doses of 5 mg/kg/day, may

also provide an alternative therapy to treat lupus in the maintenance phase in patients unresponsive to treatment.¹⁷⁶

Wegener's Granulomatosis

26. J.M. is a 42-year-old white man who presents to the clinic with a 1-month history of cough, nasal congestion, facial pain with headache, fever, and lethargy. Over the past week, he has noted bright red blood in his phlegm, which has worsened in the past 3 days. Pertinent laboratory values are as follows: serum Na, 143 mEq/L (normal, 135–147 mEq/L); K, 5.1 mEq/L (normal, 3.5–5.0 mEq/L); Cl, 102 mEq/L (normal, 95–105 mEq/L); CO₂ content, 24 mEq/L (normal, 22–28 mEq/L); SrCr, 2.8 mg/dL (normal, 0.6–1.2 mg/dL); BUN, 41 mg/dL (normal, 8–18 mg/dL). This compares with last year's physical checkup visit when his SrCr and BUN were within the normal range. Hematologic studies reveal an Hct of 35% (normal, 8–18 mg/dL); an Hgb of 11.7 g/dL (normal, 13–16 g/dL); mean corpuscular volume (MCV) 69 mm³ (normal, 76–100 mm³); mean corpuscular Hgb (MCH) concentration 24% (normal, 33%–37%); and reticulocyte count 1.8% (normal, 0.1%–2.4%). RBC indices are normal. Platelet count was 175,000/mm³ (normal, 130,000–400,000/mm³). His 24-hour urine contains 3.8 g of albumin (normal, <30 mg) and his eGFR is calculated to be 27 mL/minute/1.73 m². His urine also contains many RBC casts and 16 RBC/HPF (normal, 0–3 RBC/HPF). Chest radiograph shows alveolar shadowing spreading from the hilar region. The result of J.M.'s cytoplasmic-staining, antineutrophil cytoplasmic antibody (c-ANCA) is positive. Based on his subjective and objective data, which of the chronic glomerulopathies is J.M. likely to have?

[SI units: Na, 143 mmol/L (normal, 135–147); K, 5.1 mmol/L (normal, 3.5–5.0); Cl, 102 mmol/L (normal, 95–105); CO₂, 24 mmol/L (normal, 22–28); SrCr, 247 μmol/L (normal, 50–110); BUN, 14.6 mmol/L of urea (normal, 3.0–6.5); Hct, 0.35 (normal, 0.39–0.49); Hgb, 11.7 g/L (normal, 130–160); MCV, 69 fL (normal, 76–100); MCH, 0.24 (normal, 0.33–0.37); reticulocyte count, 0.019 (normal, 0.001–0.024); eGFR, 0.40 mL/second]

Wegener's granulomatosis is a primary systemic vasculitis characterized by granulomatous inflammation of the upper and lower respiratory tract and secondary glomerulonephritis. Primary systemic vasculitic syndromes, such as Wegener's granulomatosis, often cause glomerulonephritis. Although vasculitis involves inflammation of blood vessels of any size, the small- and medium-size vessels are most commonly affected.¹⁸² The etiology of Wegener's granulomatosis is unclear; however, an autoimmune response is suspected for two reasons. First, Wegener's granulomatosis is a systemic inflammatory disease without a known infectious etiology. Second, good treatment response can be obtained with immunosuppressive therapy.

The clinical features of Wegener's granulomatosis include upper airway disease, such as sinusitis, epistaxis, and nasopharyngitis, as well as otitis media caused by blockage of the eustachian tube. Constitutional symptoms include fever, night sweats, arthralgia, anorexia, and malaise. After a few months, weakness may progress, severely limiting physical activity. Although the lungs are invariably affected, most patients remain asymptomatic; however, cough and hemoptysis may be present. J.M.'s presenting symptoms are consistent with the above clinical features. The laboratory signs also are non-specific and indicate the presence of a systemic inflammatory process. They include an elevated erythrocyte sedimentation

rate in virtually all patients, anemia of chronic disease, and thrombocytosis.¹⁸² Hematuria and proteinuria can be prominent features of Wegener's granulomatosis and are present on initial presentation in 80% of patients. The presence of severely diminished kidney function, seen in approximately 10% of patients, is an ominous sign, with nearly one-third of these patients progressing to ESRD. All patients with Wegener's granulomatosis are at risk for developing irreversible, rapidly progressive kidney failure. Renal histologic findings are nonspecific, with most patients exhibiting necrotizing crescentic glomerulonephritis.¹⁸²

Wegener's granulomatosis is diagnosed primarily by the presenting signs and symptoms. According to the American College of Rheumatology 1990 classification, a person is diagnosed with Wegener's granulomatosis if any two of the following four criteria are present: (a) nasal or oral inflammation, (b) abnormal chest radiograph, (c) microhematuria (>5 RBC/HPF) or RBC casts in the urine sediment, or (d) granulomatous inflammation on biopsy.¹⁸² J.M. has satisfied three of the four criteria for diagnosing Wegener's granulomatosis.

TREATMENT

27. How should J.M.'s Wegener's granulomatosis be treated?

The discovery of c-ANCA and its strong association with Wegener's granulomatosis has permitted a more certain diagnosis. Because of the substantial rise in titer that commonly precedes relapse of Wegener's granulomatosis, the c-ANCA test is best used to follow the course of disease activity and guide induction of therapy. Treatment with CYC and corticosteroids results in improvement in kidney function in approximately 80% to 85% of patients, versus 75% with pulse steroids alone.¹⁸³ The main predictive factors for treatment success are the extent of kidney damage before therapy starts and how long therapy is delayed after symptoms develop.

Cyclophosphamide

Because Wegener's granulomatosis is considered an autoimmune inflammatory disease, immunosuppressive therapy is the mainstay of treatment. Therapy is generally indicated for 6 months if remission occurs and up to 12 months in resistant cases.¹⁸³ J.M. should be initiated on oral CYC 2 mg/kg/day, as a single morning dose to prevent irreversible glomerular scarring. With a more fulminate form of the disease, higher doses (4–5 mg/kg/day) may be used, although the potential for toxicities must be carefully considered. High fluid intake (>3 L/day) reduces the risk of hemorrhagic cystitis. Regular urinalysis should be performed (every 3–6 months) to detect hematuria caused by hemorrhagic cystitis.

Induction treatment with pulse IV boluses of CYC is not satisfactory because of high relapse rates and increased toxicity. However, the two conditions for which IV CYC may be considered are (a) patients whose conditions have not responded to conventional treatment and (b) patients in whom severe kidney dysfunction developed initially, including those requiring dialysis. In the former, IV CYC 1 g/m² in 150 mL of saline can be administered over 60 minutes. The dose must be reduced by 25% in patients with a eGFR <10 mL/minute/1.73 m². This regimen may be administered monthly for 6 months, after which a dosage reduction may be attempted.¹⁸⁴

Corticosteroids

The main role of corticosteroids is to induce remission of the disease. J.M. should receive prednisone 1 mg/kg/day in addition to cyclophosphamide. The combined regimen should be continued for 2 to 4 weeks until the immunosuppressive effect of CYC becomes evident. Then, over the next 2 months, the prednisone dose can be tapered to 60 mg every other day to reduce the risk of infection. Then, the dose can be tapered by 5 mg/week to discontinue prednisone over 3 to 6 months. For patients with a more fulminate form of the disease, pulse methylprednisolone 1 g/m²/day for three doses is administered. The dose can be repeated in 1 to 2 weeks if disease progression is uncontrolled.

Azathioprine

Because of its poor efficacy, AZA should not be used as a first-line agent to treat active Wegener's granulomatosis. If remission is induced with CYC and the patient cannot tolerate long-term treatment with that agent, AZA 2 mg/kg/day may be substituted.

Alternative Agents

Other agents have been studied as alternatives to CYC. Use of trimethoprim-sulfamethoxazole over 1 year was evaluated for patients in remission or after treatment with CYC and prednisolone.¹⁸⁵ A reduction in relapse rate was demonstrated compared with placebo. Subgroup analysis indicates, however, that only patients with upper respiratory tract disease had a lower relapse rate, but not in those with renal or lung involvement.¹⁸⁵ Methotrexate may be beneficial for patients with milder disease, although one study demonstrated high relapse rates in patients treated initially with weekly methotrexate and daily prednisone; disease was controlled in only select patients.¹⁸⁶

Focal Segmental Glomerulosclerosis

28. A.G. is a 37-year-old morbidly obese (BMI 40 kg/m²), black woman who presents to the clinic with complaints of increased swelling in her extremities over the last 2 weeks, decreased urine output, and pink-colored urine. Her medical history is significant only for hypertension, which is well controlled with amlodipine 5 mg PO QD. She takes no other prescription or over-the-counter (OTC) medications. Pertinent laboratory values are as follows: SrCr 2.1 mg/dL (normal, 0.6–1.2 mg/dL), a spot albumin-to-creatinine ratio of 1,200 mg/g (normal, <30 mg/g), her UA showed 18 RBC/HPF (normal, 0–3), and eGFR of 34 mL/minute/1.73 m². The nephrologist schedules a biopsy to obtain a definitive diagnosis for her new onset kidney disease. Biopsy results are as follows: light micrograph shows a moderately large segmental area of sclerosis with capillary collapse on the upper left side of the glomerular tuft; the lower right segment is relatively normal. Electron micrograph shows diffuse epithelial cell foot process fusion with occasional loss of the epithelial cells. The other major finding is massive subendothelial hyaline deposits under the glomerular basement membrane. The pathologist's impression is FSGS. What is the relevance of FSGS and what are the management strategies for FSGS?

[SI units: SrCr, 185 μmol/L (normal, 50–110)]

Focal segmental glomerulosclerosis is characterized by sclerotic lesions of the glomerulus, which can be either focal

or segmental in nature. The development of FSGS may be idiopathic (primary) or secondary to other diseases (i.e., morbid obesity, sickle cell disease, congenital heart disease, AIDS). Currently, FSGS is the leading cause of idiopathic nephrotic syndrome and accounts for 15% to 20% of the cases. Black patients are two to four times more likely to develop idiopathic FSGS than white patients and they have a higher incidence of ESRD caused by FSGS.¹⁸⁷

Most all patients with FSGS will present with proteinuria, but only about half of them will initially present with nephrotic syndrome. Patients with nephrotic syndrome will also likely present with hypertension, increased serum creatinine levels, and hematuria. During the early stages of FSGS, the symptoms may be indistinguishable from minimal-change nephropathy, a glomerulopathy characterized by similar lesions within the glomeruli. A renal biopsy is necessary for diagnosis. Predictors of increased risk of progression to ESRD include massive proteinuria (>10 g/day), higher serum creatinine level (>1.3 mg/dL), and black race.¹⁸⁷

TREATMENT

Corticosteroids

A.G. should be placed on steroids, in addition to an ACE inhibitor or ARB and a loop diuretic, because she has FSGS and nephrotic syndrome.¹⁸⁸ A course of high-dose steroids (1–2 mg/kg) over 3 to 4 months with tapering of the dose over 3 months is recommended. The higher remission rates associated with this high-dose regimen compared with low-dose regimens have led to this regimen. The median time to remission is 3 to 4 months, with most patients achieving complete remission by 5 to 9 months. Patients whose proteinuria does not respond after a 4-month trial of therapy should be considered resistant to steroids and be rapidly tapered off over 4 weeks.¹⁸⁷

Cytotoxic Agents

The addition of cytotoxic agents (CYC, AZA, chlorambucil) may be considered for A.G. if she is steroid resistant, intolerant of long-term steroid therapy, severely nephrotic, frequently relapsing, or steroid dependent. The data supporting the use of these agents in FSGS are limited. Retrospective studies have

shown that use of cytotoxic drugs can produce complete remission in 50% of cases. Length of therapy of these agents may predict the remission rates of FSGS. Recent prospective studies are supporting a longer duration of therapy. Patients who received either chlorambucil or CYC up to 75 weeks obtained a higher complete remission rate (30%–47%). The duration of use of these agents is limited by their toxicities (gonadal toxicity, malignancies). Cumulative doses of 300 mg/kg of CYC and 10 mg/kg of chlorambucil have been shown to increase the risk of developing these toxicities, thus limiting the exposure to these agents is important.¹⁸⁷

Cyclosporine

Evidence supporting the efficacy and safety of cyclosporine in FSGS is minimal, but therapy with doses of 5 mg/kg/day for 6 to 12 months has been found to be effective and can result in remission rates of up to 69% in patients resistant to steroid and cytotoxic therapy.^{189,190} Limitations of cyclosporine therapy include high relapse rate (23%–100%), side-effect profile (nephrotoxicity, hypertension), and resistance to therapy. The former two limitations may be overcome by prolonged treatment with a slow tapering and targeting lower doses of cyclosporine. The exact dose and duration of cyclosporine therapy should be determined by the response of the patient's proteinuria and serum creatinine. Further studies will determine the role cyclosporine therapy has in certain types of patients with FSGS.

Mycophenolate Mofetil

Mycophenolate mofetil has the least available studies evaluating its use in FSGS. Recently, a small study of patients with FSGS resistant to steroids, cytotoxic agents, or both and cyclosporine received MMF for 6 months. At the end of 6 months, 44% of patients had improved proteinuria, but no patient achieved complete remission.¹⁹¹ Other studies examining MMF therapy at doses of 1,500 to 2,000 mg/day have found no clinically significant reduction in proteinuria or have little effect on remission rates.¹⁸⁹ Treatment with MMF in FSGS is very limited and well-designed, prospective, randomized trials are necessary to determine its role, if any, in FSGS.

The prevalence of end-stage renal disease (ESRD) in the United States at the end of 2004 was nearly 472,000 people. Of these, 71.2% (336,000) were treated by dialysis (3.4% greater than in 2003) and the remainder had received a kidney transplant.¹ Prevalence in both populations has more than doubled since 1988, with the rate of growth slightly higher in the transplant group. Although the incidence of ESRD continues to increase each year, the rate of increase has fallen from approximately 10% to less than 2% over the past 20 years. The reasons for this decline are unknown but may be owing to reporting or to a true change in the incidence rate. Patients age 45 to 64 years account for the largest segment of the ESRD population. In 2004, 94,891 new patients with ESRD began therapy with hemodialysis, 6,686 were placed on peritoneal dialysis, and 2,200 received a transplant. The shortage of donor kidneys and the existence of patients with ESRD who are unacceptable transplant recipients sustain the demand for dialysis. Kidney transplantation is further discussed in Chapter 34, Kidney, Liver, and Pancreas Transplantation.

The two primary modes of dialysis therapy are *hemodialysis* (HD) and *peritoneal dialysis* (PD). Variations of PD include *continuous ambulatory peritoneal dialysis* (CAPD) and *automated peritoneal dialysis* (APD), an increasingly common modality that permits greater patient flexibility with dialysis. Among the nearly 335,000 dialysis patients in the United States, 92% undergo HD.¹ Most of these patients receive dialysis three times a week in a center designed primarily for stable, ambulatory patients at either a hospital-based or a free-standing dialysis facility. Home HD accounts for <1% of dialysis patients. Patients having PD also are managed through dialysis centers for routine care, although less often than patients on HD. Several factors are considered in the selection of the type of dialysis for each patient. Often, the overriding consideration is the suitability of the procedure for the patient's lifestyle. A patient who needs flexibility and freedom from a rigid sched-

ule may prefer PD over HD to avoid the necessity of being at a dialysis center three times weekly for a 3- to 4-hour dialysis treatment. Other considerations include the availability of a vascular access site for HD, or a patient's ability to perform self-care for dialysate exchanges with PD.

Without dialysis or transplantation, patients with ESRD will die of the metabolic complications of their renal failure. Overall morbidity and mortality are generally similar for both HD and PD; however, the first-year death rate is higher for HD than PD, and is reported to be 280 versus 249 deaths per 1,000 patient years. Second-year death rates are similar, at 268 and 286 deaths per 1,000 patient years for HD and PD, respectively.² The length of time on dialysis (HD and PD) influences the mortality rate. Since 1985, the mortality rate for patients who have been on dialysis less than 2 years has fallen 25%, from 289 deaths per 1,000 patient years to 216. In patients on dialysis 5 or more years, however, the mortality rate has risen to a plateau of 8% since 2001.¹

Patient characteristics and comorbid conditions influence the death rate, including age (increased with increased age), race (increased in white patients), and primary cause of ESRD (increased with diabetes and hypertension compared with glomerulonephritis).³ The expected survival of a patient having chronic dialysis compared with the average life expectancy in the United States is significantly reduced. For example, at 60 years of age, the average survival is approximately 4 years for a patient on dialysis compared with 21 years for the average population. Among patients on dialysis, those with diabetes (the most common cause of ESRD) or hypertension have a higher mortality rate than patients without these conditions. The all-cause mortality rates are 370 and 382 deaths per 1,000 patient years, for diabetes and hypertension, respectively, compared with 311 and 215 for patients with chronic nephritis and cystic kidney disease.² Over the past 15 years, however, deaths caused by heart disease, cerebrovascular disease, or septicemia, have

fallen most dramatically among dialysis patients with diabetes from a peak of 36% to 7.5% in 2004.¹ Other factors associated with mortality include body mass index (BMI) (decreased with increased BMI) and serum albumin (decreased with increased albumin).² Summary reports and analysis of survival and mortality are included as part of the annual report of the United States Renal Data System (USRDS).¹

The demographic characteristics of the ESRD population are based primarily on data from the Centers for Medicare and Medicaid Services (CMS), because patients with ESRD are eligible for Medicare benefits. Coverage for ESRD began in 1973, when Congress enacted the End-Stage Renal Disease Program as an amendment to Medicare.⁴ Total Medicare expenditures in 2004 were \$299.6 billion, of which \$20.1 billion, or 6.7%, were for the ESRD program. This represents an increase in the fraction expended for ESRD from 4.5% in 1991. The total per person per month (PPPM) costs for dialysis fell 2.1% from 2003 and 2004 to \$1,135.80; however, the costs for erythropoiesis stimulating agents (ESA), parenteral (intravenous [IV]) iron, and IV vitamin D rose 11% to 13%.¹

The rapid growth of the number of patients having dialysis calls attention to the need for practitioners who understand the processes and therapies for these patients. Both HD and PD were developed as methods for the removal of metabolic waste products across a semipermeable membrane. HD is an extracorporeal (dialysis membrane is outside of the body) process, whereas PD uses the patient's peritoneal membrane for the clearance of water and solutes. This chapter addresses the fundamental clinical aspects of both HD and PD, including principles, complications, and management. Throughout the chapter, reference will be made, when appropriate, to the clinical practice guidelines developed by the National Kidney Foundation, originally published in 1997, and updated in 2000 and 2006.⁵⁻⁸ The initial guidelines focused on dialysis issues, the Dialysis Outcomes Quality Initiative (DOQI), and included four workgroups: Hemodialysis Adequacy,⁹ Peritoneal Dialysis Adequacy,¹⁰ Vascular Access,¹¹ and Anemia.¹² The updated clinical practice guidelines have been renamed the Kidney Disease Outcomes Quality Initiative (K/DOQI) to reflect the broader nature and impact of renal impairment. Additional clinical practice guidelines developed under K/DOQI include Nutrition of Chronic Renal Failure¹³ and Chronic Kidney Disease: Evaluation, Classification, and Stratification.¹⁴ The latter guideline is addressed in Chapter 31, Chronic Kidney Disease.

HEMODIALYSIS

Principles and Transport Processes

Dialysis is a process that facilitates the removal of excess water and toxins from the body, both of which accumulate as a result of inadequate kidney function. During HD, a patient's anticoagulated blood (circulated to the dialyzer from a vein in the arm) and an electrolyte solution that simulates plasma (dialysate) are simultaneously perfused through a dialyzer (artificial kidney) on opposite sides of a semipermeable membrane. Solutes (e.g., metabolic waste products, toxins, potassium, and other electrolytes) are removed from the patient's blood by diffusing across concentration gradients into the dialysate. The rate of removal (flux) of various solutes from the blood is a function of blood and dialysate flow rates through the dialyzer, relative

concentration of each solute in the blood and dialysis solution (thus determining their concentration gradients across the membrane), physical characteristics of the dialysis membrane (e.g., total available surface area, thickness, and pore size), and properties (e.g., molecular size in daltons, molecular weight, volume of distribution, and protein binding) of the solute being removed. Because blood and dialysate flow in opposite directions through the dialyzer, the concentration gradient for each solute across the membrane is amplified (Fig. 32-1). This principle is defined in greater detail in the section labeled "dialyzer characteristics."

Solutes from the blood are removed through diffusion and convection. *Diffusion* is the process whereby the molecule moves across its concentration gradient by passing through pores in the dialysis membrane.^{15,16} Once the concentration of a solute reaches equilibrium on both sides of the membrane, the net movement is zero because the rate of movement from the blood to dialysate compartment is equal to the rate from the dialysate to the blood compartment. For most substances, equilibrium is not achieved, either because the blood and dialysate flow rates are too rapid, or the molecule is too large to easily move through the pores.

Convection is the process that removes toxins during dialysis through the ultrafiltration of plasma water from the blood compartment.^{15,16} A controlled pressure difference across the semipermeable membrane permits water movement through the membrane pores, which carries with it solute into the dialysate, thereby further enhancing solute removal. The removal of solutes by convection during ultrafiltration generally is small relative to their elimination through diffusion.

Dialyzer Characteristics

Dialyzers are characterized by many factors, such as membrane composition, size, and ability to clear solutes. Their primary component is the dialysis membrane, made of cellulose (e.g., cuprammonium cellulose), substituted cellulose (e.g., cellulose acetate, cellulose triacetate), cellulosynthetic (e.g., HemoPhan), or synthetic polymer (e.g., polysulfone, polyacrylonitrile [PAN], polymethylmethacrylate [PMMA]).¹⁷ Membranes differ not only by composition, but also by surface area, thickness, and configuration within the dialyzer. The most common configuration is the hollow fiber dialyzer, whereby the membrane is formed as thousands of hollow fibers that run the length of the dialyzer. Blood flows through the fibers and the dialysate flows in the space surrounding the fibers within the dialyzer cartridge. The result is an extremely large surface area for diffusion, which is functionally increased further by the movement of blood and dialysate in opposite directions so that equilibrium is never fully achieved. Another, less common design is the parallel-plate configuration, whereby blood and dialysate flow between alternating sheets of the membrane.

Functionally, dialysis filters can be differentiated based on their ability to remove solutes and water. Dialyzers are characterized as low-flux or high-flux based on pore size and ability to remove small versus large molecules. One method of categorizing and comparing efficiency (flux) of dialyzer units is their relative *in vitro* and *in vivo* clearance rates of marker solutes of varying molecular size. This information is usually printed on the outside of the dialyzer or in the package insert (specification chart) for the dialyzer. For example, urea (molecular size 60 Da) is a marker of small-molecule transport

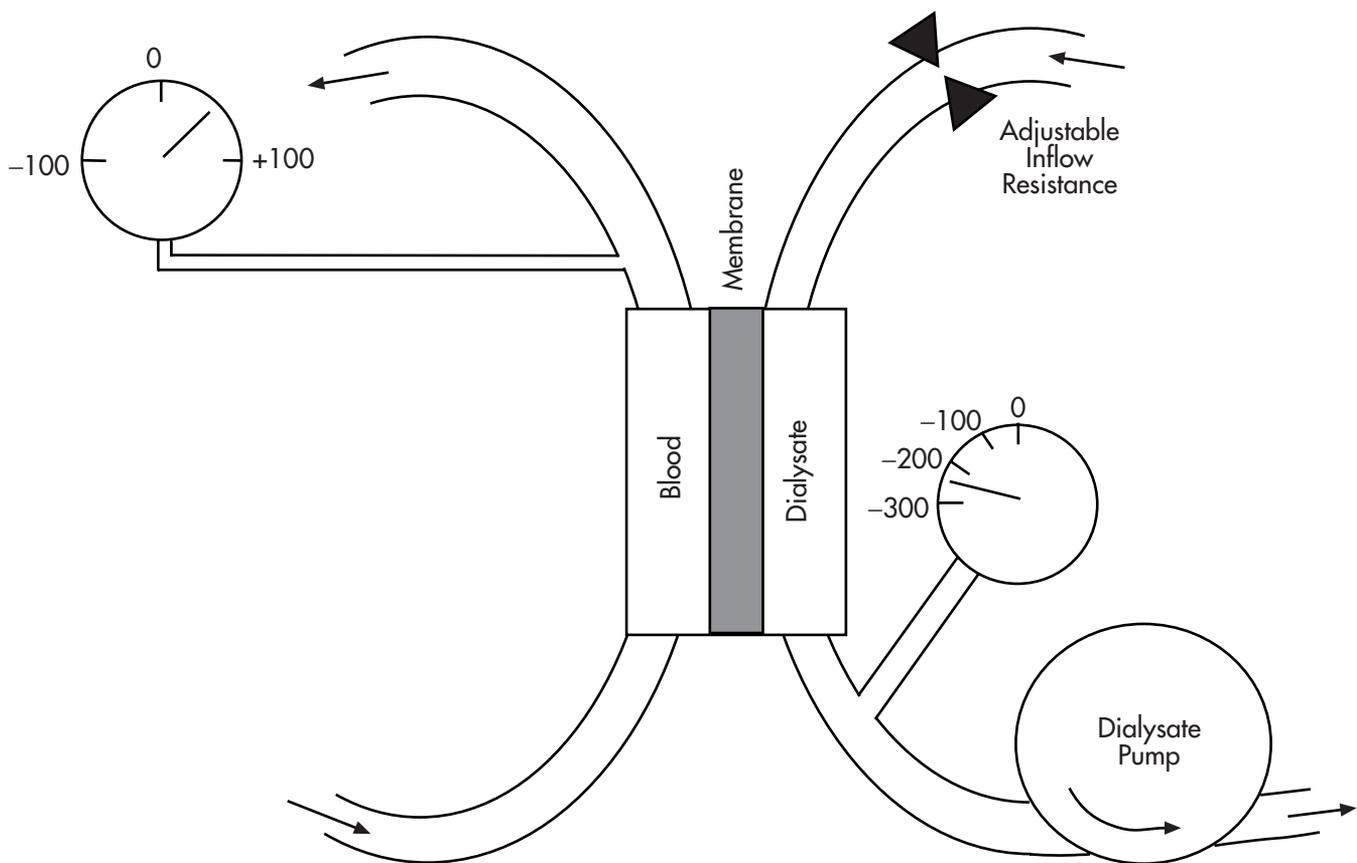

FIGURE 32-1 Representation of hemodialysis with blood flowing in one direction and dialysate in the opposite, separated by a semipermeable membrane. Note pressure monitors and dialysate pump with variable inflow resistance to create negative pressure for ultrafiltration from the blood compartment. (Reproduced from reference 18.)

across the dialysis membrane. Urea (found in the blood as blood urea nitrogen [BUN]) distributes freely throughout body water and is cleared rapidly by HD, even when using standard low flux dialyzers.^{18–21} Because the pore size of most dialyzer membranes is large enough to allow this small molecule to freely diffuse, the rate-limiting step for the removal of urea is blood flow through the dialyzer. A larger-molecule, vitamin B₁₂ (1,355 Da), also has been used as a measure of dialysis efficiency. Because vitamin B₁₂ is too large to easily cross through the pores of conventional dialysis membranes, its dialysis clearance is less dependent on blood flow than on urea. Instead, the overall removal of vitamin B₁₂ depends more on the type of membrane (i.e. thickness and pore size) and the duration of dialysis. More recently, the clearance of β_2 -microglobulin, an even larger molecule than vitamin B₁₂ (11,800 Da), has been used to characterize the flux of a dialyzer.^{5,17} High-flux dialyzers are defined as providing β_2 -microglobulin clearances of at least 20 mL/minute.⁵ High-flux membranes have larger pores and are able to clear larger molecules (e.g., middle molecules such as β_2 -microglobulin and leptin) and drugs (e.g., vancomycin or vitamin B₁₂, with molecular weights in the range of 1,000–5,000) more effectively than low-flux membranes with smaller pores. High-flux membranes also have a greater permeability to water, as reflected in a K_{Uf} value (to be defined later) of >10 mL/hour/mmHg. Importantly, β_2 -microglobulin is not

only a surrogate marker for middle molecule dialysis clearance, but it has also been found to be predictive of mortality.²² It also plays a role in the pathogenesis of amyloidosis (see section on Amyloidosis, for further discussion). β_2 -microglobulin clearance, however, is not consistently reported in all dialyzer specification charts.

Similarly, molecular weight of drugs is a predictor of dialysis clearance. At a molecular weight of <500 (e.g., aminoglycosides and theophylline) dialyzability is expected to be high. For these drugs, the actual amount dialyzed will vary based on protein binding (i.e., amount of unbound drug available to cross the dialysis membrane), volume of distribution (V_d) (i.e., a large V_d indicates a relatively small amount of drug will be available in the blood for dialysis), blood flow rate through the dialyzer, dialysis flow rate, and dialyzer surface area. Drugs with a molecular weight between 500 and 100 (e.g., morphine and digoxin) are less well dialyzed. For digoxin, a greater problem is its large V_d and relatively low serum concentrations. Even if the drug in the blood is effectively removed, tissue-bound drug will quickly redistribute back into the blood as soon as dialysis is completed, a phenomenon known as *rebound*. Finally, large molecular weight drugs, such as vancomycin, are poorly dialyzed by conventional dialyzers, but may be removed using high-flux techniques described later in this chapter.

The efficiency of a dialyzer is also a function of its surface area. High-efficiency membranes generally have a large surface area and are able to clear large quantities of small molecules, such as urea. High-efficiency dialyzers can also have small or large pores resulting in low or high clearance of larger molecular weight solutes. Membranes also differ in their degree of biocompatibility. Free hydroxyl groups on unsubstituted cellulose membranes when in contact with blood evoke complement response and cytokine release, which can lead to hypotension, fever, and platelet activation in patients.²³ Use of these membranes is discouraged.⁵ The free hydroxyl groups can be substituted with other chemical structures, such as acetate, to improve biocompatibility. Complement activation and cytokine release occur to a much lesser extent with substituted cellulose or cellulose-synthetic membranes, and least of all with synthetic membranes made from plastics. Dialyzers coated with antioxidants, such as vitamin E, to minimize oxidant stress and to improve biocompatibility, are under investigation.²⁴

Synthetic, high-flux membranes are more expensive than conventional cellulose, but when reuse systems in which the filter is cleansed and sterilized are put in place, the cost per dialysis session is reduced substantially.²⁵ Standards for dialyzer reuse are set by the Association for the Advancement of Medical Instrumentation. Both manual and automated systems are used to reprocess dialyzers. These systems include rinsing of blood and clots from the dialyzer, cleaning with agents such as dilute sodium hypochlorite (bleach), testing of dialyzer performance, and sterilization. Among all membranes, reuse of high-flux synthetic membranes is associated with a lower risk of mortality, particularly when exposed to bleach.²⁶ The average number of times a dialyzer is reused depends on quality control standards within the dialysis center, but generally it is 10 or more times for a patient. Universal precautions should be used to handle dialyzers. Controversial issues regarding reuse programs include safety of disinfectants, dialyzer efficiency after processing, contamination and risk of infection, and pyrogenic reactions. The potential benefits and risks of dialyzer reuse have not adversely affected morbidity or mortality.^{25,26} One study, however, reported a survival advantage when patients were switched from reuse to single use dialyzers.²⁷ As a result of declining prices and the decision of a major dialysis manufacturer to discontinue reuse, single use dialyzers may become more commonplace.⁵

A typical package insert for a dialyzer will provide information on the clearance of various molecules (e.g., urea, creatinine, phosphate, and vitamin B₁₂). Urea clearance has become a common measure of comparison for membranes; however, clearance also depends on other factors, such as blood and dialysate flow rates.^{15,16} A more standard measure for comparison is KoA_{urea}, the mass transfer area coefficient for urea. Based on the urea clearance data from the package insert, KoA_{urea} can be estimated based on blood flow. Using this information, the dialysis prescription can be individualized to provide a specified dose of dialysis for the patient.

Patients having chronic HD typically are dialyzed for 3 to 4 hours, three times a week, either Monday-Wednesday-Friday or Tuesday-Thursday-Saturday. During the interdialytic period, fluids ingested and produced through metabolic processes are retained in the patient. Although patients generally are on fluid-restricted diets, accumulation of 1 to 5 L of fluid (translating

into 1- to 5-kg weight gain) between sessions is common and must be removed during the dialysis treatment.

Blood and Dialysate Flow

Although small-molecule clearance is highly dependent on blood flow, the relationship is not strictly linear. Increased blood flow yields a less than proportional response in urea clearance.¹⁸ This is likely because of an insufficient time for equilibration to occur between the blood and dialysate compartments as well as a greater membrane resistance to diffusion from an increased stagnant layer. A typical blood flow rate for dialysis is 400 to 500 mL/minute but is dependent on the vascular access site and the cardiovascular status of the patient. Some patients are not able to tolerate this rate, and a lower blood flow rate may be necessary. Dialysate flow rates generally are 500 mL/minute and can be increased to 800 mL/minute for high-flux dialysis, which will increase urea clearance by approximately 10%.²⁸

1. R.W., a 55-year-old man with a 25-year history of hypertension and kidney insufficiency, presents to the renal clinic for reassessment of his kidney function. He is 70 inches tall and weighs 70 kg. Since his last visit 3 months ago, his creatinine clearance (Cl_{Cr}) has decreased from 22 to 12 mL/minute (normal, 75–125 mL/minute) and the BUN has increased to 89 mg/dL (normal, 8–18 mg/dL). The serum potassium (K) is 4.5 mEq/L (normal, 3.5–5.0 mEq/L) and HCO₃ is 17 mEq/L (normal, 24–30 mEq/L). He has selected HD as his form of therapy until a suitable donor kidney is available and is expected to begin dialysis within the next 1 to 3 months. When he begins dialysis, he will be dialyzed three times a week for 4 hours each treatment, using a Fresenius F-60S dialyzer, with blood and dialysate flows of 400 and 500 mL/minute, respectively, and bicarbonate-containing dialysate. What characteristics of the Fresenius F-60S dialyzer make it a good choice for R.W.? What determines the composition of the dialysate?

[SI units: Cl_{Cr}, 0.37 and 0.2 mL/second, respectively (normal, 1.24–2.08); BUN, 31.8 mmol/L (normal, 3–6.5); K, 4.5 mmol/L (normal, 3.5–5)]

The Fresenius dialyzer is a high-flux dialyzer as described in the introduction.¹⁷ This polysulfone membrane is a synthetic membrane with larger pore sizes than conventional cellulose membranes. The F-60S has a KUf, the ultrafiltration coefficient (volume of water removed/mmHg across the membrane per hour of dialysis), of 40 mL/mmHg/hour, indicating a high ultrafiltration capability; an in vitro KoA_{urea} (the urea mass transfer area coefficient) of 709, a measure of dialyzer efficiency for urea removal; urea clearance of 185 mL/minute at a blood flow of 200 mL/minute; and a surface area of 1.3 m². This information can be located in the product literature from the manufacturer or summary tables from common dialysis references.¹⁷ These data are used to individualize the dialysis prescription for a patient.

Dialysate Composition

Dialysate composition usually is standardized within certain limits of electrolyte content, yet allows for individualization as necessary. Water is obtained through the public water system, which then undergoes treatment by reverse osmosis, followed by ion exchange with activated charcoal to remove contaminants, such as aluminum, copper, and chloramines, as well as bacteria and endotoxins.²⁹ The dialysate solution does not

Table 32-1 Electrolyte Composition of Hemodialysis and CAPD Dialysate Solutions

| Solute | Hemodialysis (mEq/L) | CAPD (mEq/L) |
|-------------|----------------------|--------------|
| Sodium | 135–145 | 132 |
| Potassium | 0–4 | 0 |
| Calcium | 2.5–3.5 | 3.5 |
| Magnesium | 0.5–1.0 | 1.5 |
| Chloride | 100–124 | 102 |
| Bicarbonate | 30–38 | |
| Lactate | | 35 |
| pH | 7.1–7.3 | 5.5 |

CAPD, continuous ambulatory peritoneal dialysis.

require sterilization because the dialysis membrane separates the blood and dialysate compartments. Nevertheless, pyrogen reactions may occur, and a greater risk may exist with high-flux membranes because of the increased pore size.

The final dialysate solution is prepared in the dialysis machine by proportioning a dialysate concentrate with the purified water, resulting in a final product, which typically contains those elements listed in Table 32-1. By adjusting electrolyte concentration in the dialysate, the efficiency of dialysis for particular chemicals can be manipulated. For example, if the patient is hyperkalemic, the dialysate contains a low concentration of potassium. On the other hand, if the patient is normokalemic at the start of dialysis, the potassium concentration of the dialysate is set at a normal physiologic concentration to minimize flux of this electrolyte across the membrane. If the concentration of a solute is higher in the dialysate than in the blood, the net movement will be into the blood, not out.

Before delivery, the dialysate is heated to 37°C to maintain body temperature and avoid hemolysis, which can occur with excessive heating. Metabolic acidosis, which is associated with ESRD because of an inability to excrete the daily obligatory load of acid, is controlled with the addition of bicarbonate buffer to the dialysate solution.¹⁷ Precipitation of calcium carbonate previously was a problem with the addition of bicarbonate to the dialysate, which led to the use of acetate to control acidemia instead. Acetate enters the blood compartment by diffusion from the dialysate and is metabolized to bicarbonate in vivo. Acetate, however, is associated with hypotension and cardiac instability during HD and is no longer used.³⁰ Improvements in delivery systems that provide for special mixing methods prevent precipitation and allow for the resumption of bicarbonate dialysis. Liquid bicarbonate concentrate and reconstituted bicarbonate-containing dialysate, however, can support the growth of gram-negative bacteria, filamentous fungi, and yeast.¹⁵ Use of dry bicarbonate cartridges or membrane filters at the point where the dialysate leaves the machine before entering the patient's dialyzer obviates the problem of bacterial growth and contamination of the final dialysate solutions.^{15,31}

Vascular Access

2. To achieve a sufficient blood flow for dialysis, R.W. must have a vascular site for chronic access. What are the options for chronic vascular access in R.W.?

A permanent vascular access site provides easy access to high blood flow, which cannot be achieved through routine venipuncture of superficial veins. Different types of vascular access are available: arteriovenous (AV) fistula, AV graft composed of expanded polytetrafluoroethylene (PTFE), double-lumen or tunneled catheters, and catheters with subcutaneously implanted access ports. AV fistulas and grafts are placed in the nondominant arm. Ideal vascular access delivers blood flow rates necessary for chronic HD, has a long period of use, and has a low rate of complications (e.g., infection, stenosis, thrombosis, aneurysm, and limb ischemia).

An AV fistula is preferred because of its longer survival of approximately 75% at 3 years (compared with 30% for the AV graft) and low rates of complications.³² An AV fistula is created surgically by subcutaneous anastomosis of an artery to an adjacent vein. The K/DOQI guidelines for vascular access advocate placement of a fistula at the location of the wrist (radial-cephalic), or secondarily the elbow (brachial-cephalic), as the preferred vascular access sites. If neither of these is feasible for the patient, insertion of an arteriovenous graft or creation of a transposed brachial basilica vein fistula is recommended. During the dialysis procedure, one needle or catheter is placed into the fistula site to deliver blood to the dialyzer. This is often referred to as the “arterial line” to the dialyzer. Blood exiting the dialyzer is returned back to the patient's fistula site through a second catheter and needle, referred to as the “venous line” from the dialyzer.

Central venous catheters are discouraged for chronic vascular access. Although preferred, the AV fistula may not be suitable for patients with poor vasculature, such as elderly patients or those with diabetes, atherosclerosis, or small vessels. The fistula should preferably be created 3 to 4 months before its intended use to allow the vein to mature. The graft can be used soon after insertion, although 2 weeks will allow for healing at the anastomosis sites and may prolong patency. If R.W. has adequate vasculature, a fistula should be created for chronic access based on the higher long-term graft survival. Vascular access is critical for chronic HD and often has been labeled the “Achilles' heel” of dialysis therapy. Complications associated with vascular access are a significant problem in patients having chronic HD. The most common is thrombosis, usually the result of venous stenosis.⁷ If not treated, thromboses will result in loss of the access. Access-related complications are a major cause of hospitalization and, therefore, attention to these problems is important clinically and economically.

Anticoagulation

3. Recommend a reasonable anticoagulation regimen for R.W. with the initiation of his HD. What are alternatives for patients at high risk for bleeding?

Most patients having HD are anticoagulated with IV heparin during the dialysis treatment. Anticoagulation is necessary to prevent blood from clotting in the extracorporeal circuit for patients having HD. Several methods have been used in an attempt to provide adequate anticoagulation without increasing the risk of bleeding. Approaches include the administration of heparin in adequate quantities to anticoagulate the patient during the dialysis procedure either by intermittent bolus injections or an initial bolus followed by a continuous infusion.³³ Modern HD delivery systems have incorporated heparin infusion

devices that can be programmed to provide the desired infusion rate during dialysis.

With no evidence of a bleeding disorder, recent surgery, or other risk factors for heparin anticoagulation, therapy should be initiated with a 2,000-unit bolus of IV heparin 3 to 5 minutes before initiation of dialysis, followed by an infusion of 1,200 units/hour.³³ The target activated clotting time (ACT) is 40% to 80% above the average baseline for the dialysis unit (e.g., 200–250 seconds, for normal values of 120–150 seconds). The clinician should monitor for signs of bleeding and measure the ACT at 1-hour intervals during dialysis. Heparin should be discontinued 1 hour before the end of dialysis to prevent excessive bleeding following dialysis. Using these standard doses, the estimated elimination half-life for heparin is approximately 50 minutes and it should have a linear dose-response relationship within the target ACT.³³

Patients at increased risk of bleeding include those who have had recent surgery, retinopathy, gastrointestinal (GI) bleeding, and cerebrovascular bleeding. For these patients, the goal is to prevent clot formation within the dialysis circuit as well as to minimize the risk of active bleeding. This may be accomplished by using “minimal-dose” heparin (tight ACT control), or even heparin-free anticoagulation. The minimal dose heparin approach individualizes therapy to achieve ACT values 40% above baseline following an initial bolus of 750 units.^{33,34} The ACT is measured 3 minutes after the bolus dose, which should allow for vascular distribution of the heparin to be complete. If the goal ACT level is not achieved, repeat bolus doses of heparin can be administered at a dose that is adjusted based on the expectation of a linear response. For example, if the first dose of 750 units reaches 75% of the ACT goal, an additional 250 units would be appropriate for the second dose. Similarly, the initial heparin maintenance infusion rate of 600 units/hour can be modified by monitoring the ACT at 30-minute intervals. Adjustments in the infusion rate should be proportionate to the bolus dose needed to maintain the ACT at 40% above baseline. Samples collected for determination of ACT should be obtained from the arterial line into the dialyzer, before the infusion of heparin, to reflect systemic anticoagulation effects.

An alternative to heparinization for patients having dialysis with high blood flow rates is heparin-free dialysis.^{33,35} This approach requires priming the hemodialysis circuit and dialyzer with heparin 3,000 units/L in normal saline to coat the extracorporeal surfaces. The heparin-containing priming fluid is allowed to drain by filling the circuit with either the patient's blood or normal saline alone at the outset of dialysis. Next, hemodialysis is set at a high blood flow rate of 400 mL/minute, if tolerated. During dialysis, the dialyzer is flushed with normal saline every 15 to 30 minutes to rinse away microclots that may have formed. The incidence of clotting with this approach is approximately 5%.

Enoxaparin and dalteparin are two low-molecular-weight heparins (LMWH) that are commercially available, but not yet approved by the U.S. Food and Drug Administration (FDA) for hemodialysis. In a randomized, crossover study comparing the safety and efficacy of enoxaparin with standard heparin, a dose of 1.0-mg/kg body weight of enoxaparin produced less minor fibrin or clot formation in the dialyzer, but more frequent minor hemorrhage between dialyses. Dosage reduction of enoxaparin to 0.75 mg/kg body weight resulted in similar efficacy and eliminated the minor hemorrhage.³⁶ Differences in

body weight were found to influence maximal concentrations of dalteparin. Therefore, weight-based dosing of dalteparin in patients having hemodialysis is under investigation.³⁷ Tinzaparin also has been shown to be effective as an anticoagulant during HD, using an IV dose of 75 IU/kg just before dialysis.³⁸

Because LMWH undergo renal elimination, dose adjustments are necessary in patients with ESRD, accompanied by careful patient monitoring. While LMWH inhibit factor Xa, factor XIIa, and kallikrein, measurement of antifactor Xa activity is the only available laboratory monitoring parameter for these factors. Because active heparin metabolites that are not detected by the factor Xa assay can accumulate in dialysis patients, the clinical utility of this test is unclear.^{39–41}

Another concern with LMWH is that patients on dialysis exhibit greater sensitivity to their effect than healthy volunteers.⁴¹ Furthermore, LMWH administered at fixed-weight doses and without monitoring show unpredictable anticoagulant effects in patients with stage 4 and 5 chronic kidney disease. In a case series of patients on HD treated with LMWH for acute coronary syndrome, two patients who received as few as two to three doses of LMWH developed dialysis access site bleeding, hematuria, and massive melena. Another subject who received 10 doses developed hemorrhagic pericardial effusion resulting in death. Only one patient in the series, who received a total of five doses, did not develop hemorrhagic complications.⁴² Based on these findings, it is recommended that unfractionated heparin, rather than LMWH, should be used in patients on dialysis for prophylaxis and treatment of thromboembolic disease.⁴³

Another class of agents with potential use in patients requiring anticoagulation during HD are the direct thrombin inhibitors, argatroban and lepirudin (Refludan). Their use is especially attractive in individuals who experience heparin-induced thrombocytopenia (HIT). This complication is reported to occur in 0% to 12% of patients on HD receiving heparin for anticoagulation. Argatroban is a synthetic derivative of L-arginine, which is approved by the FDA for use in patients susceptible to thrombosis who also have a history of HIT. Most dosage regimens for argatroban consist of an initial bolus dose followed by a continuous infusion during dialysis. Because it is eliminated by nonrenal routes, argatroban dosing in patients with renal failure is the same as for patients with normal kidney function.⁴⁴ Similarly, dialysis clearance of argatroban during high-flux hemodialysis is clinically insignificant, making dose adjustments in patients on dialysis unnecessary.^{45,46} Murray et al.⁴⁵ evaluated three argatroban regimens in patients having high-flux hemodialysis. Anticoagulation was more consistently achieved (ACT >140% of baseline) when a continuous infusion of 2 mcg/kg/minute with or without a bolus of 250 mcg/kg was used. The infusion was discontinued 1 hour before the end of the HD session. Argatroban therapy provided adequate, safe anticoagulation throughout HD. No thrombosis, bleeding, or other serious adverse events occurred.⁴⁵

Another antithrombin product, lepirudin, is produced through recombinant DNA technology. It is biologically similar to hirudin, which is isolated from the saliva of leeches. Unlike argatroban, lepirudin is significantly cleared by the kidneys and requires individualized dosage adjustment based on the patient's residual renal function.^{44,47} No established dosage regimens exist, because elimination is substantially delayed; monitoring should be performed using a target activated partial

thromboplastin time (aPTT) of 2.0 to 2.5 times baseline. Further studies are necessary to define the role of these newer agents in patients having chronic HD.

The regional administration of trisodium citrate through the arterial line is an alternative to systemic anticoagulation. It binds free calcium, which is necessary for the coagulation process. The calcium citrate complex is removed by the dialysate and, based on plasma calcium values, calcium chloride is administered on the venous side to replace the citrate-bound calcium to prevent hypocalcemia or hypercalcemia. Some of the administered citrate is returned to the patient and is metabolized to bicarbonate, leading to metabolic alkalosis in some cases. Regional citrate anticoagulation is reserved for patients who are at risk for bleeding and requires additional monitoring to adjust the dual infusions.³³ In a prospective study of 1,009 consecutive high-flux dialysis procedures in 59 patients, long-term citrate anticoagulation achieved excellent anticoagulation (99.6%) with rare (0.2%) adverse effects on ionized calcium levels, electrolytes, and acid-base balance.⁴⁸

Dialysis Prescription

Individualization of the “prescription” to quantify the desired “dose” of dialysis to be delivered to a particular patient on any given day has undergone several advances during the past decade. In 1981, the report of the National Cooperative Dialysis Study (NCDS) showed a relationship between the degree of dialysis delivered to the patient and morbidity.^{19,20,49} Average serum urea concentrations during hemodialysis, expressed as time-averaged serum urea concentrations (TAC), were determined as an index of dialysis adequacy. Four groups of patients were randomized to different combinations of time-averaged serum urea concentrations (low TAC (50 mg/dL) or high TAC (100 mg/dL)) and length of dialysis (2.5–3.5, or 4.5–5.0 hours). No differences were found in mortality during the 1-year study; however, patients with higher urea exposure (high TAC) experienced a greater withdrawal rate from the study and more hospitalizations compared with patients with lower urea concentrations. These data suggested that urea kinetics could be used to model dialysis therapy and that urea could be used as a surrogate marker for the adequacy of dialysis. Because it is well recognized that other uremic toxins also contribute to the overall morbidity among these patients, surrogate markers of their removal by dialysis have been used in an attempt to better define the adequacy of dialysis. For example, creatinine (MW 113 D), which is slightly larger than urea, has been explored as a marker, but it offers no additional predictive benefit. As described in the introduction to this chapter, vitamin B₁₂ is a marker for the class of “middle molecules” that are thought to be responsible for many of the complications of uremia. Because vitamin B₁₂ is a larger molecule than urea or creatinine, it is not easily cleared by membranes with smaller pores, although it is more effectively cleared by high-flux membranes. Nonetheless, the utility of vitamin B₁₂ as a surrogate for dialysis adequacy has not been established.¹⁵

Further analysis of the NCDS data by Gotch et al.²⁰ using a pharmacokinetic-like term, Kt/V, demonstrated a relationship between morbidity and Kt/V. The Kt/V term is based on the predialysis and postdialysis BUN values, distribution of urea, and duration of dialysis. K is the urea clearance (mL/minute), t is time (minutes), and V is distribution volume for urea (mL).

The term has no units and represents the quantity of dialysis delivered to the patient, or the total volume of blood cleared of urea, relative to the urea distribution volume in a given patient. Its basic relationship depends on the first-order elimination of urea, as seen in the following general equations:

$$\begin{aligned} \text{BUN}_{\text{post}} &= \text{BUN}_{\text{pre}} (e^{-Kt/V}) \\ \text{Kt/V} &= -\ln(\text{BUN}_{\text{post}}/\text{BUN}_{\text{pre}}) \end{aligned}$$

Patients with a Kt/V < 0.9 had a 54% failure rate, defined as death, hospitalization, or withdrawal from the study for medical reasons, whereas those with a Kt/V > 0.9 had a 13% failure rate on dialysis. Based on these data, it was recommended that patients receive a dialysis “dose” of Kt/V > 1.0 when having dialysis three times weekly.

Several refinements of the Kt/V relationship have been made to better approximate the actual observations in patients on HD. These include corrections for ultrafiltration of fluid during dialysis; access and cardiopulmonary recirculation, which result in dilution of the arterial urea concentration in vivo; single-pool, variable volume model for urea (spKt/V); using body water volume in the denominator, so the clearance expression is reduced from a flow to a fractional removal rate (rate constant), and adding residual renal urea clearance to compute an “adjusted” or “total” Kt/V. Failure to account for residual renal clearance could lead to excessive dialysis that would compromise quality of life. On the other hand, omission will protect patients from underdialysis when residual kidney function is lost.⁵ Timing of blood sample collection is very important to avoid diluted samples and postdialysis rebound of the plasma urea concentration.¹⁸ Redistribution of urea can occur for 30 to 60 minutes after dialysis treatment, and the greatest change will be evident in the first few minutes following dialysis. The effect of redistribution on Kt/V is a reduction in the apparent dose of dialysis provided to the patient.⁵

Observations after the NCDS were implemented suggest a discrepancy between the prescribed dialysis and actual delivered dialysis, with conclusions that some patients are not receiving adequate dialysis.⁵⁰ The K/DOQI clinical practice guidelines for HD adequacy address the issue in detail and recommend formal urea kinetic modeling to determine the appropriateness of the patient’s dialysis prescription. The minimal delivered dose of dialysis should be a Kt/V of at least 1.2 per dialysis, which corresponds to an average urea reduction ratio (URR, the percent reduction of plasma urea following an HD treatment) of 65%. To achieve this delivered dose, the guidelines further recommend that the prescribed dose be based on a Kt/V of 1.4 per dialysis or a URR of 70%.⁵

The National Institutes of Health supported the HEMO study, a multicenter, prospective, randomized trial to assess the impact of the dialysis prescription on morbidity and mortality in hemodialysis patients.⁵¹ In this study (N = 1,846), subjects were randomized to standard-dose hemodialysis with a goal Kt/V of 1.3 or to high-dose hemodialysis with a goal Kt/V of 1.7. Patients were also randomized to dialysis with either a low-flux or high-flux filter. Neither a higher dose of dialysis or use of high-flux filters significantly improved survival or reduced morbidity. No major benefit in the primary outcome of mortality or in secondary outcomes relating to various causes of hospitalizations (e.g., cardiac causes, infection) combined with mortality was observed in the high-dose group. The

results of the HEMO study provided little evidence to support increasing the dialysis prescription beyond the K/DOQI recommendations.

4. What are the variables that determine the Kt/V for R.W.?

Based on a target Kt/V of 1.4 and known characteristics of the dialysis system, it is possible to develop a dialysis prescription to achieve that value.^{5,17} The operative variables include the type and size of dialysis membrane with known urea removal characteristics, blood and dialysate flow rates, and duration of treatment. The membrane usually is determined based on the type of dialysis delivery equipment in the facility and economic factors. The size of the filter to be used is determined by the size of the patient, with larger patients generally being dialyzed using membranes with larger surface area. Blood flow rate is maximized based on the type of equipment and pump capability, as well as the ability of the patient's cardiovascular system to tolerate a high blood flow. High-flux dialysis usually is carried out with a blood flow rate of 400 to 500 mL/minute and rapid- and high-efficiency dialysis blood flow rates of 300 to 500 mL/minute.^{15,16} The last variable—time—is important to consider in providing adequate dialysis therapy to the patient. Longer dialysis sessions allow for greater Kt/V values, and it is unknown whether an upper limit exists for ideal therapy. With the introduction of high-flux membranes, dialysis treatment times were initially reduced to provide therapy to patients in a more cost-efficient manner. The total removal of urea was considered to be similar with higher urea clearance and shorter dialysis sessions, thereby allowing for reductions in personnel to manage the center and the ability to dialyze more patients.

Concern regarding increased morbidity and mortality in the United States in the early 1990s, compared with other industrialized nations, resulted in an examination of dialysis practices. Many factors were thought to contribute to this situation, including an older dialysis population, patients with more comorbid conditions being accepted to dialysis programs, and a shorter dialysis duration. Independent of the use of high-flux membranes and higher blood flow rates, the duration of dialysis appears to be a very important factor. This may be related to the clearance of uremic toxins other than urea and the removal of fluid which, if not removed, contributes to hypertension. An international study of 22,000 patients on HD in the Dialysis Outcomes and Practice Patterns Study (DOPPS) found that longer treatment time (>240 minutes) and higher Kt/V were independently and synergistically associated with lower mortality.⁵² Every 30 minutes longer on HD was associated with a 7% lower relative risk of mortality (RR = 0.93; $P < 0.0001$). One dialysis center in Tassin, France, reported improved patient survival with dialysis sessions of 8 hour/day, three times weekly. The mean Kt/V was 1.67, and the survival rate was 87% at 5 years, 75% at 10 years, and 55% at 15 years.⁵³ Although these data are promising, a major dilemma in U.S. centers is insufficient funding for prolonged dialysis and the unwillingness of many patients to commit the time required for more prolonged dialysis treatment on a chronic basis. Newer approaches for longer, slow dialysis are under investigation, including overnight HD in the home.⁵⁴ A systematic review of available evidence revealed improvements in blood pressure control and hemoglobin levels after conversion from traditional intermittent hemodialysis to nocturnal hemodialysis (defined as dialysis occurring at least 5 nights per week and at least

6 hour/night).⁵⁵ No differences in these values, however, were noted when compared with controls. Moreover, the impact of nocturnal hemodialysis on mortality is not yet known.

Fluid Removal

In addition to solute removal, the artificial kidney must be used to maintain fluid balance in the patient without renal function. Most patients will become anuric once stabilized on HD, requiring control of ingested fluids between treatment sessions. Fluid removal during dialysis then is necessary to achieve the “dry weight,” or weight below which the patient could become symptomatic from volume depletion. The dry weight for R.W. has been set at 69.1 kg. Below this weight, R.W. exhibited symptoms of orthostasis. Achieving the dry weight is accomplished by ultrafiltration, through adjustment of the transmembrane pressure. Negative pressure on the dialysate side of the membrane results in movement of fluid across the membrane from the blood compartment.^{15,16} Dialysate membranes are characterized by their water permeability, or Kuf. Most membranes have values in the range of 2.0 to 8.0 mL/mmHg/hour, although high-flux membranes may have values as high as 60 mL/mmHg/hour. Adjustment of the transmembrane pressure will provide the desired ultrafiltration rate, based on the amount of fluid to be removed (predialysis weight + IV saline + ingested fluids during dialysis – dry weight). For patients undergoing dialysis three times weekly, weight gains of 1 to 5 kg are common between sessions. For membranes with Kuf values >10 mL/mmHg/hour, volumetric circuitry in newer dialysis machines should be used to avoid errors in rates of fluid removal based on transmembrane pressure. Modern hemodialyzers have built-in functions to adjust the transmembrane pressure and remove fluid at a predetermined rate.

Complications

Hypotension

5. The dry weight for R.W. is 69.1 kg. During his most recent dialysis session, he complained of nausea and light-headedness 3 hours into the procedure. His diastolic pressure had dropped from 85 to 60 mmHg. Ultrafiltration was discontinued, and he recovered without further event. His postdialysis weight was 69.9 kg. What are possible etiologies for his hypotension?

Many complications can occur in patients having HD. The most common is intradialytic hypotension (IDH), which can produce a variety of clinical signs and symptoms, including nausea and vomiting, dizziness, muscle cramps, and headache. The reported incidence of hypotension is 10% to 30%, and even higher in patients with specific risk factors, such as autonomic dysfunction with diabetes and cardiac disease. It primarily is caused by excessive fluid removal from the vascular compartment at a rate exceeding mobilization of fluid stores.⁵⁶ As a consequence, patients with an inadequate hemodynamic response to intravascular volume depletion will develop a decrease in blood pressure and other symptoms. An ultrafiltration rate >10 mL/hour/kg was found to be associated with higher odds of IDH (odds ratio = 1.30; $P = 0.045$) and a higher risk of mortality (RR 1.02; $P = 0.02$).⁵² It may be necessary to adjust the dry weight upward if the patient is volume depleted and symptomatic following dialysis. Another cause

of hypotension is related to excessive heating of the dialysate, which can produce vasodilation. Cooling of the dialysate to slightly below body temperature may correct this problem, although many patients are uncomfortable and do not tolerate the cooling effect. The use of acetate as the buffer in the dialysate has been associated with hypotension because of its direct vasodilating effects, but it is no longer used. Antihypertensive therapy before dialysis may exacerbate hypotensive episodes as well; in some patients, these drugs may need to be withheld until after the dialysis session. Immediate treatment of the hypotensive episode can be accomplished by placing the patient in the Trendelenburg position (bed positioned with legs raised and head lowered), administering a small (100 mL) bolus of normal saline into the venous blood line, and reducing the ultrafiltration rate.

Several pharmacologic agents have been proposed for the management of IDH, including ephedrine, fludrocortisone, caffeine, vasopressin, L-carnitine, sertraline, and midodrine. Perazella⁵⁷ reviewed these agents for their potential use in the treatment of IDH and concluded that only midodrine, sertraline and L-carnitine have shown potential benefit in patients. Midodrine is an oral prodrug that is converted to desglymidodrine, a selective α_1 -agonist. Doses of 10 to 20 mg, 30 minutes before dialysis are effective for most patients, but the presence of active myocardial ischemia is a major contraindication.⁵⁷ Sertraline is a selective serotonin reuptake inhibitor that has shown promise in IDH at daily doses of 50 to 100 mg/day. The mechanism is proposed to be through attenuation of paradoxical sympathetic withdrawal. L-carnitine has also been shown to have potential benefit for treatment of IDH with IV doses of 20 mg/kg at dialysis. Its mechanism of action is not known but it may be related to improvements in vascular smooth muscle and cardiac functioning.⁵⁷

Because the volume status of R.W. is associated with his weight, another consideration is a change in his lean mass. R.W. has noted an improvement in his appetite lately and, as a result, added a few extra pounds. It is important to consider “real” weight changes when assessing the dry weight and volume status. Without appropriately increasing the dry weight goal to compensate for his real weight gain, R.W. became volume depleted and hypotensive. His dry weight should be adjusted upward to the point at which he no longer is symptomatic (to ~70 kg).

6. What other hemodialysis related complications must be watched for and how can they be treated?

Muscle Cramps

Perhaps also related to fluid shifts, muscle cramps developing during dialysis may be induced by excessive ultrafiltration resulting in altered perfusion of the affected tissues. Several treatments have been attempted, including reduced ultrafiltration and infusion of hypertonic saline or glucose to improve circulation.^{58,59} Exercise and stretching of the affected limbs also may be beneficial. Long-term therapy may be directed at prevention with the use of vitamin E 400 IU at bedtime.⁶⁰ Vitamin E in combination with vitamin C 250 mg daily has been found to be more effective than either therapy alone.⁶¹ Vitamin C therapy, however, is known to produce hyperoxaluria, oxalate-containing urinary stones, and renal damage. Therefore, the long-term safety of vitamin C in hemodialysis patients needs to be evaluated. Quinine sulfate is no longer

available for use in leg cramps. It is associated with a number of serious adverse events, some of which are potentially fatal. In February 2007, the FDA ordered the manufacturing of unapproved quinine to cease.

Hypersensitivity

Reports of anaphylactic reactions to dialyzer membranes, particularly on initial exposure, may be directly related to the membrane itself, or to ethylene oxide, which is commonly used to sterilize the dialyzer.^{62,63} Membranes most commonly responsible for reactions are unsubstituted cellulose membranes (bioincompatible) or the high-flux polyacrylonitrile membrane when used in conjunction with angiotensin-converting enzyme (ACE) inhibitors.⁶⁴ This latter reaction is thought to be related to the inhibition of bradykinin metabolism by ACE inhibitors, resulting in an anaphylactoid reaction.

Dialysis Disequilibrium

Dialysis disequilibrium is a syndrome that has been recognized since the initiation of HD more than 30 years ago. Its etiology is related to cerebral edema, and patients new to HD are at a greater risk because of the accumulation of urea.⁶⁵ Rapid removal of urea from the extracellular space lowers the plasma osmolality, thereby leading to a shift of free water into the brain. Lowering of intracellular pH, as can occur during dialysis, has also been suggested as a cause. Clinical manifestations occur during or shortly after dialysis and include central nervous system (CNS) effects, such as headache, nausea, altered vision, and in some cases, seizures and coma. Treatment is aimed at prevention by initiating dialysis gradually by using shorter treatment times at lower blood flow rates in new patients. Direct therapy can be provided in the form of IV hypertonic saline or mannitol.⁶⁵

Some of the long-term complications associated with HD include thrombosis or infection of the access site, aluminum toxicity, and amyloidosis.

Thrombosis

Access loss is most often the result of thrombosis, which is usually a consequence of venous stenosis. Prospective monitoring of access function (e.g., intra-access flow; static or dynamic venous pressures; measurement of access recirculation; and physical findings, such as swelling of the arm, clotting of the graft, prolonged bleeding after needle removal, or altered character of the pulse or thrill) is paramount to the prevention of thrombosis. Fistula patency generally is much greater than synthetic graft patency; yet, thrombosis and loss of function may occur in both.^{7,66} The stenosis may be corrected by percutaneous transluminal angioplasty (PCTA) or, if necessary, surgical revision of the access site. Successful correction is effective as a means to prevent thrombosis. Once it occurs, thrombosis is managed by surgical thrombectomy or with pharmacomechanical or mechanical thrombolysis. Thrombolytic therapy, administered by pulse spray technique of urokinase or streptokinase, combined with mechanical thrombectomy is as effective as surgical thrombectomy.⁶⁷ The pulse spray technique involves rapid pulse injections of small aliquots of highly concentrated thrombolytics directly into the clot. More recently, because of the potentially life-threatening adverse events associated with streptokinase and the nonavailability of urokinase, clinicians have evaluated the use of alteplase as an alternative

thrombolytic agent.⁶⁸ Alteplase and reteplase appear to be effective for thrombomechanical lysis of the vascular access site.^{68,69} Thrombolytic therapy should be avoided in those patients with an increased risk of bleeding.

Anticoagulants and antiplatelet agents have been evaluated in the prevention of graft thrombosis. In two separate randomized, placebo-controlled trials, therapy with low-dose warfarin to achieve a target international normalized ratio (INR) of 1.4 to 1.9 or combination therapy with clopidogrel and aspirin in patients with PTFE grafts showed no benefit in the prevention of thrombosis or prolongation of graft survival.^{70,71} In both studies, patients receiving active treatment experienced a significantly increased risk of bleeding.

Infection

Access infections, usually involving grafts to a greater extent than a native fistula, are predominantly caused by *Staphylococcus aureus* or *S. epidermidis*. Infections with gram-negative organisms as well as *Enterococcus* occur with a lower frequency.⁷ Access infections can lead to bacteremia and sepsis with or without local signs of infection. Treatment usually is initiated with vancomycin, administered as a single, 1-g dose, repeated as necessary, depending on the type of dialysis being used, or cefazolin 20 mg/kg three times weekly, and gentamicin 2 mg/kg with appropriate serum concentration monitoring.⁷² High-flux dialysis results in greater removal of vancomycin than conventional dialysis and, therefore, more than a single dose may be necessary for adequate treatment.^{73,74} Vancomycin can be given either during or after high-flux dialysis. A vancomycin postdialysis dosing algorithm using fewer vancomycin concentrations for patients receiving thrice-weekly high-flux dialysis was developed by Pai et al.⁷⁵ The algorithm achieved predialysis vancomycin concentrations comparable to those found with more frequent monitoring. Cost savings was realized because of a 70% reduction in the number of drug concentrations. Intradialytic dosing of vancomycin is a convenient mode of drug administration in patients receiving high-flux dialysis. It avoids the need for additional intravenous access, longer stays in the hemodialysis unit, or home antibiotic administration. Two studies have shown that vancomycin dosing in the last 1 to 2 hours of high-flux hemodialysis achieves adequate predialysis plasma concentrations of 5 to 20 mcg/mL depending on the administered dose.^{76,77} K/DOQI clinical practice guidelines for vascular access also advocate surgical incision and resection of infected grafts. Fistula infections are rare and should be treated as subacute bacterial endocarditis with 6 weeks of antibiotic therapy.⁷

Aluminum Toxicity

Aluminum accumulation in patients having HD was a significant problem before water sources were adequately treated to remove aluminum.²⁹ Major complications of aluminum toxicity include dementia, aluminum bone disease, and anemia. Aluminum accumulation still occurs in patients treated with aluminum-containing antacids as binding agents for phosphate in the GI tract, although not to the degree associated with water supplies.⁷⁸ Aluminum toxicity is diagnosed by clinical signs and symptoms associated with the aforementioned conditions, and a serum aluminum concentration of >200 ng/mL or a deferoxamine-stimulated serum aluminum concentration increase of >200 ng/mL.⁷⁹ Deferoxamine chelates with serum

aluminum and the shift in equilibrium results in movement of aluminum from tissue storage sites. The complex can be removed by dialysis (600 Da), and high-flux membranes are capable of removing the complexed aluminum in a single dialysis session, minimizing systemic exposure to deferoxamine and its potential adverse effects. The latter include mucormycosis, a fungal infection caused by a rhizopus that grows avidly in iron media, as well as ocular, auditory, and neurologic toxicity.^{80,81} Deferoxamine generally is continued until the stimulated aluminum concentration is <50 ng/mL, which may require 1 year of therapy.⁸²

Amyloidosis

Amyloidosis is caused by the deposition of β_2 -microglobulin-containing amyloid in joints and soft tissues over prolonged periods.⁸³ The incidence of amyloidosis is approximately 50% after 12 years of dialysis and nearly 100% after 20 years. β_2 -Microglobulin (MW 11,800 Da) normally is eliminated by filtration and metabolism in the intact nephron. Renal failure leads to reduced elimination and accumulation of this substance even during dialysis. High-flux membranes are more effective than conventional membranes for the removal of β_2 -microglobulin, but they have not been in use long enough to evaluate their role in preventing amyloidosis. Carpal tunnel syndrome, manifested as weakness and soreness in the thumb from pressure on the median nerve, is the most common symptom. Bone cysts also appear along with joint deposition of amyloid, which can impair mobility.⁸³ The type of membrane used for dialysis also has been implicated in increasing the rate of production of β_2 -microglobulin, in that some types seem to cause more rapid amyloid deposition. Biocompatible membranes are proposed to stimulate production to a lesser degree, but prospective studies demonstrating their long-term benefit have not been conducted.⁸⁴

Malnutrition

Chronic kidney disease produces a catabolic state in patients and, along with the multifactorial complications of ESRD, leads to malnutrition. Serum albumin concentrations <3.0 g/dL are associated with an increased mortality rate compared with higher values. Inadequate dietary intake and losses of amino acids by dialysis contribute to protein malnutrition, which in turn can lead to additional complications, such as impaired wound healing, susceptibility to infection, and others (see Chapter 31, Chronic Kidney Disease, for further discussion).

L-CARNITINE

L-Carnitine supplementation has been advocated in patients with ESRD to relieve intradialytic symptoms. It is a metabolic cofactor that facilitates transport of long-chain fatty acids into the mitochondria for energy production. This cofactor is found in both plasma and tissue as free carnitine, the active component, or bound to fatty acids as acylcarnitine. The primary source of carnitine is dietary intake, primarily from red meat and dairy products. Patients with renal failure may have what appear to be normal or elevated total carnitine concentrations but low levels of free carnitine. Accumulation of acylcarnitine, decreased carnitine synthesis, reduced dietary intake, and dialytic losses may account for the normal to elevated total concentrations in this population.^{85,86}

Carnitine is a small water-soluble molecule that is freely dialyzed, thus its levels are reduced in hemodialysis. The potential benefits of correcting this relative carnitine deficiency have been primarily studied in patients having chronic HD. Recommended doses of carnitine are 10 to 20 mg/kg IV after each HD treatment. Although some have suggested that carnitine supplementation benefits muscle cramps and hypotension during dialysis, as well as minimizing fatigue, skeletal muscle weakness, cardiomyopathy, and anemia resistant to large doses of erythropoietic therapy, no evidence supports its routine use in patients undergoing chronic HD.¹³

PERITONEAL DIALYSIS

Peritoneal dialysis is performed using several different modalities, including the most common, continuous ambulatory peritoneal dialysis. Development of specialized devices to facilitate the exchange process and improve patient convenience has led to processes referred to as automated peritoneal dialysis, including continuous cycling peritoneal dialysis (CCPD) and nocturnal intermittent dialysis (NIPD). CAPD is the most common method for chronic PD, but the APD methods are rapidly growing. The number of patients with ESRD having treatment with PD in the United States increased from approximately 10,000 in 1985 to a peak of about 32,000 in 1995 and has been on the decline, with 27,000 in 2000 and 25,765 in 2005.^{1,2}

Principles and Transport Processes

Continuous ambulatory peritoneal dialysis is performed by the instillation of 2 to 3 L of sterile dialysate solution into the peri-

toneal cavity through a surgically placed resident catheter. The solution dwells within the cavity for 4 to 8 hours, and then is drained and replaced with a fresh solution. This process of fill, dwell, and drain is performed three to four times during the day, with an overnight dwell by the patient in his or her normal home or work environment⁸⁷⁻⁸⁹ (Fig. 32-2). Conceptually, the process is similar to HD in that uremic toxins are removed by diffusion down a concentration gradient across a membrane into the dialysate solution. In this case, the peritoneal membrane covering the abdominal contents serves as an endogenous dialysis membrane, and the vasculature embedded in the peritoneum serves as the blood supply to equilibrate with the dialysate. A primary difference is that because the dialysate solution is resident, the result is a very slow dialysate flow rate of approximately 7 mL/minute when 10 L of fluid is drained per day. Solute loss occurs by diffusion for small molecules, and through convection for larger, middle molecules.

Blood and Dialysate Flow

Hemodialysis provides constant perfusion of fresh dialysate, thereby maintaining a large concentration gradient across the dialysis membrane throughout the dialysis treatment. During a typical dwell period for CAPD, urea and other substances increase in the dialysate relative to unbound plasma concentrations. For a daytime dwell period of 4 hours, urea achieves nearly equal concentrations with plasma; therefore, the rate of elimination can become very small (Fig. 32-3). Instillation of fresh dialysate solution will re-establish the diffusion gradient leading to an increased rate of urea removal. For a patient making four exchanges of 2 L each per day, assuming the urea

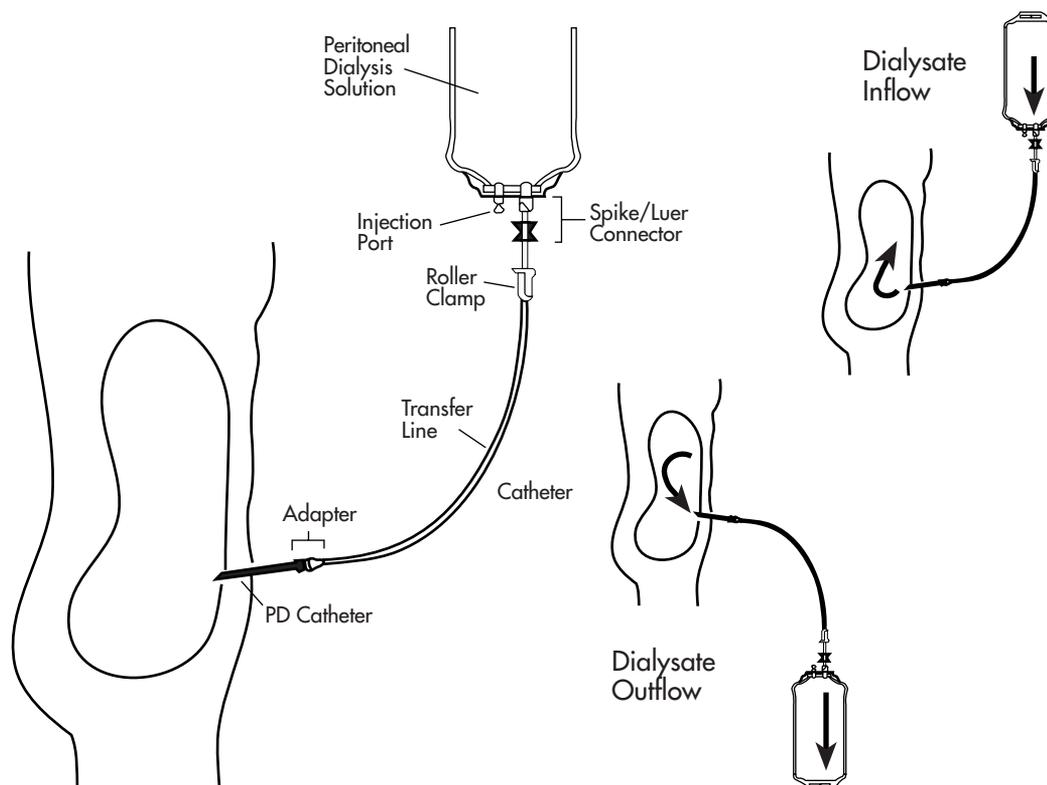

FIGURE 32-2 Schematic representation of CAPD components and techniques of inflow and outflow. (From Schoenfeld P. Care of the patient on peritoneal dialysis. In: Cogan MG, et al., eds. *Introduction to Dialysis*. 2nd ed. New York: Churchill Livingstone; 1991:200, with permission.)

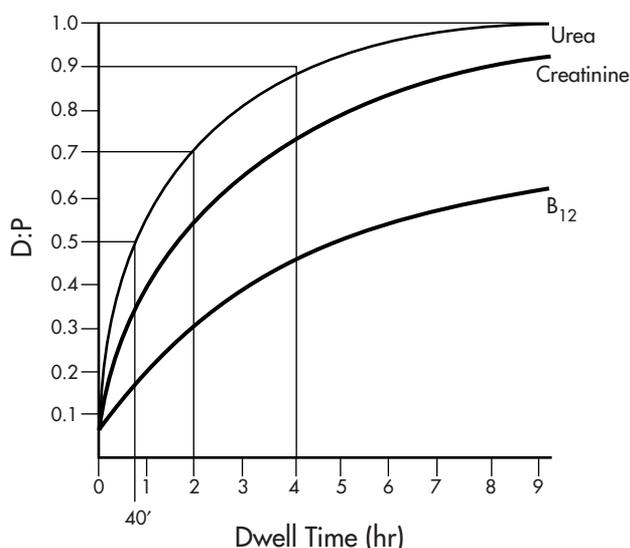

FIGURE 32-3 Rate of entry into peritoneal dialysate of urea, creatinine, and vitamin B₁₂. The y-axis indicates the ratio of dialysate to plasma concentration (D:P). (From Blake PG et al. Physiology of peritoneal dialysis. In: Daugirdas JT et al., eds. *Handbook of Dialysis*. 4th ed. Philadelphia: Lippincott Williams & Wilkins; 2007:332, with permission.)

dialysate concentration equals the plasma concentration, and 2 L are removed by ultrafiltration, the urea clearance would be approximately 7 mL/minute. This is substantially lower than urea clearances achieved with HD; therefore, CAPD must be performed continually throughout the week to achieve adequate urea removal. Clearance depends on blood flow; dialysate flow; and peritoneal membrane characteristics, such as size, permeability, and thickness. Dialysate flow, the only easily adjusted variable to alter clearance, has been used effectively in acute PD to achieve relatively high clearances with 30- to 60-minute dwell periods in a cycling system. CCPD uses this concept of shorter dwell periods during the sleeping hours with automatic fill, dwell, and drain periods, leaving a high-dextrose dialysate in the peritoneal cavity throughout the day until the next cycling session. NIPD is similar, with nightly exchanges, but the peritoneum is left unfilled, or dry, during the daytime. As a result, urea clearance is lower with NIPD, but may be suitable for many patients, and preferable to the volume load in the peritoneal cavity throughout the day with CCPD.⁸⁷ Electrolyte concentrations in the dialysate solution are near physiologic concentrations to prevent substantial shifts in serum electrolyte levels (Table 32-1). A potential advantage of PD compared with HD is the continuous dialysis of larger, middle molecules that may exert toxic effects. These molecules are cleared through convection and follow water as it is removed through ultrafiltration. Clearance of these molecules depends less on flow and more on duration of dialysis. The continuous process of PD, albeit associated with low clearance values, provides for a more physiologic condition in patients, rather than the intermittent treatment provided with HD.

Fluid Removal

Fluid is removed by ultrafiltration through adjustment of the transmembrane pressure during HD. Because this pressure is not easily adjusted in PD, fluid is removed by altering the os-

motric pressure within the dialysate. This is accomplished by the addition of dextrose monohydrate to the dialysate in varying concentrations, depending on the degree of fluid removal necessary in the patient. Concentrations of dextrose in commercially available solutions include 1.5%, 2.5%, and 4.25%, with net fluid losses during a 4-hour dwell period of 200 and 400 mL for the 1.5% and 2.5% solutions, respectively, and approximately 700 mL for the 4.25% solution following an overnight dwell.⁹⁰ As the dwell time persists, the dextrose is absorbed and is diluted by the movement of fluid from the vascular space, so that most ultrafiltration occurs early during the dwell period.

Acid-base balance is achieved through the absorption of lactate from the dialysate, which subsequently is metabolized to bicarbonate in vivo. Bicarbonate is not compatible with the calcium and magnesium in the dialysate and can lead to precipitation.

Access

Delivery of dialysate into the peritoneal cavity is accomplished through an indwelling catheter inserted through the abdominal wall. The most common design is the Tenckhoff catheter, made of silicone rubber or polyurethane; it consists of a tube, straight or curved, with many holes in the distal end for fluid inflow and outflow.⁹¹ The catheter also has a single or double cuff, which serves to anchor it to the internal and external attachment sites by promoting fibrous tissue growth; this also serves as a barrier to bacterial migration. Several modifications to the original catheter have appeared on the market, mostly in an attempt to overcome problems related to outflow of dialysate. Maintaining an unobstructed outlet port is essential for successful PD.

Delivery of dialysate through the catheter is accomplished in several modes. A straight transfer set uses tubing attached to the catheter at one end, and to the bag of dialysate at the other, via a spike. The transfer set usually is changed every 1 to 2 months in the dialysis clinic. For each dialysate exchange, the patient attaches a bag of fresh dialysate, warmed to body temperature, to the transfer set and infuses the solution. The tubing is clamped and rolled up with the attached bag and placed into a pouch carried on the patient. The primary purpose for maintaining the connection is to prevent contamination and the development of peritonitis. Following the dwell period, the patient unrolls the bag and tubing, places it on the floor, unclamps the tubing and awaits drainage of the fluid, usually 5 to 15 minutes. Using aseptic technique, the patient changes the dialysate bag and infuses fresh solution to repeat the process. This process is used rarely today and has been replaced by Y sets and double bag systems. The Y transfer set employs three limbs, with fresh dialysate attached to the upper arm of the Y, an empty bag to the lower arm, and the stem connected to the catheter.⁹¹ Clamping the inflow arm and opening the stem and outflow arm allow dialysate to drain from the peritoneum into the empty bag. Reversing the clamps then permits infusion of the fresh dialysate solution after a small rinse of the line is performed with the fresh solution. Clamping of the catheter allows removal of the Y transfer set and bags from the patient. The double bag system employs preattached bags to both limbs and the patient and makes only a single connection to the catheter. Use of the Y transfer set has reduced episodes of peritonitis from approximately 1 for every 9 to 12 patient-months to 1 for

every 24 to 36 patient-months.⁹² PD performed with the cyclor involves only two disconnections of the system, compared with four for CAPD.

Dialysis Prescription

The initial CAPD prescription for most patients consists of three exchanges during the day with 1.5% dextrose and a fourth, overnight exchange with 4.25% dextrose. This would be expected to achieve fluid removal of approximately 1,300 mL, based on 200 mL from each daytime exchange and 700 mL overnight. Based on assessment of the patient's fluid status, it may be necessary to increase or decrease the dialysate prescription to achieve fluid balance. Fluid retention is solved by increasing the dextrose content of the daytime exchanges, beginning with 2.5% in place of one of the 1.5% solutions. This is expected to result in an additional removal of 200 mL, and therapy can be further adjusted as necessary. For patients with excessive fluid removal, it may be possible to decrease the number of exchanges per day as long as adequate solute removal is present. If four exchanges are needed, the fluid intake can be liberalized to maintain adequate hydration.

Cyclor machines automatically cycle dialysate into and out of the peritoneal cavity. Patients having CCPD will generally need three to five exchanges, each lasting approximately 2 hours, using a cyclor while the patient sleeps. During the daytime hours, the patient maintains a reservoir of dialysate in the peritoneal cavity resulting in a long dwell. The cyclor process repeats at night. Six to eight exchanges are performed every night for patients having NIPD. The peritoneum is left dry and patients do not continue dialysis during the day. Nightly dwell times are generally 1 to 2 hours for each exchange, resulting in a higher clearance for small molecules because of the increased dialysate flow rate.⁸⁷

Dextrose is the dextrorotatory form of glucose. Glucose is a small molecule that rapidly diffuses across the peritoneal membrane. As glucose is absorbed, the osmotic gradient of the dwell progressively dissipates reducing ultrafiltration. Toward the end of the long dwell, more dialysate fluid may be absorbed than ultrafiltered, resulting in a negative net ultrafiltration volume where the drained volume is less than the infused volume. A negative net ultrafiltration volume is undesirable. Greater ultrafiltration and fluid management are predictors of survival.⁹³ An alternative to dextrose as the osmotic agent in the dialysate solution is icodextrin (Extraneal). It is approved for use in the United States in patients having CAPD or APD during the long dwell period. It is a starch-derived, water-soluble, glucose polymer that is approximately 40% absorbed and subsequently metabolized to maltose oligosaccharides. Unlike glucose, icodextrin does not readily diffuse across the peritoneal membrane, but is slowly removed from the peritoneal cavity via convective uptake into the peritoneal lymphatics.⁹⁴ It is superior to 1.5%, 2.5%, and 4.15% dextrose solutions for ultrafiltration.^{95,96} Its use may be most beneficial in those patients characterized as high average to high transporters.

7. M.J., a 27-year-old woman, has a 14-year history of insulin-dependent diabetes mellitus. She is 5 feet 5 inches tall and weighs 60 kg. One complication of her diabetes is ESRD necessitating dialysis. She has been undergoing CAPD for 1 year and, until now, has done well without any complications. Her dialysis pre-

scription consists of three exchanges with 1.5% dextrose during the day and a fourth, overnight exchange with 4.25% dextrose. She has a double-cuff Tenckhoff catheter and uses a Y transfer set for her exchanges. Her blood pressure is controlled and she shows no evidence of edema. She has no residual renal function. Her most recent serum laboratory results showed the following: calcium (Ca) 10.9 mg/dL (normal, 8.8–10.2 mg/dL) and K 3.2 mEq/L (normal, 3.5–5.0 mEq/L). Calculate the prescribed amount of dialysis for M.J.

[SI units: Ca, 2.7 mmol/L (normal, 2.2–2.6); K, 3.2 mmol/L (normal, 3.5–5)]

Residual renal clearance and greater urine volume, rather than peritoneal clearance, have been shown to be significant and important predictors of patient survival.^{97,98} The 2006 K/DOQI clinical practice guidelines for PD adequacy recommend that total small-molecule clearance should be measured as Kt/V_{urea} and is based on a 24-hour collection of urine (kidney Kt/V_{urea}) and a 24-hour collection of effluent for CAPD and APD (peritoneal Kt/V_{urea}).⁶ In the new guidelines, the target Kt/V_{urea} has been revised downward to at least 1.7 week from the previous Kt/V_{urea} of 2.0/wk because levels above this range have not been shown to improve outcomes. Renal and peritoneal Kt/V can be added to achieve the target.

Determining the number of exchanges needed for solute removal is based on the clearance of urea as a surrogate for uremia. Based on dialysate urea achieving 90% of plasma urea at the end of the dwell period, and four exchanges per day, the fluid removal would be approximately 9,300 mL/day, or a urea clearance of 59 L/week. For M.J., body water content (urea distribution volume) is approximately 33 L (0.55 L/kg); therefore, the dialysis prescription would provide a weekly Kt/V of 1.79. Based on her dialysis prescription, M.J. should achieve the target dose. The evidence for a Kt/V 1.79 is based on the assumptions that the patient has no residual renal function, there is full equilibration between dialysate and plasma with respect to urea, the target urea concentration is 60 mg/dL, and the normalized protein catabolic rate (nPCR) is between 1.0 and 1.2 g/kg/day, indicating adequate nutrition. Larger patients may need a larger volume for each exchange (up to 3 L) or an additional exchange per day to achieve the target Kt/V . The increased volume is preferable because of the inconvenience of an additional exchange.

M.J. also is noted to have an elevated serum calcium concentration of 10.9 mg/dL, probably as a result of her calcium carbonate requirements to serve as a binder of dietary phosphate. Dialysate preparations with a low calcium concentration (2.5 mEq/L) compared with the standard concentration of 3.5 mEq/L can help control hypercalcemia associated with increased oral calcium intake. Potassium is not present in the dialysate solution but can be supplemented in patients who are not able to maintain potassium within the normal range. M.J. has a somewhat low serum potassium concentration of 3.2 mEq/L. Therefore, providing a dialysate concentration of 4 mEq/L will sustain normal concentrations and prevent hypokalemia. This is particularly important for patients receiving digitalis preparations.

Assessment of Dialysis Adequacy

8. Assess the actual dialysis provided to M.J., based on a 24-hour collection of 9,130 mL dialysate with a urea concentration of 54 mg/dL and serum urea concentration of 60 mg/dL.

Following stabilization of the patient on the new dialysis prescription, it is necessary to assess the adequacy of the delivered dialysis dose. According to the 2006 K/DOQI clinical practice guidelines for PD adequacy, Kt/V should be measured within 1 month of initiating peritoneal dialysis and every 4 months thereafter.⁶ This is accomplished by taking into account both the peritoneal and residual renal clearance of urea, and comparing these with the target Kt/V. Dialysis urea clearance is determined by collecting and measuring the dialysate, as well as urine output, for a 24-hour period.^{10,99} Clearance is calculated by standard methods: rate of elimination divided by average plasma concentration. The sum of the two urea clearances then is multiplied by 7 to determine the volume cleared per week, and then it is divided by the urea distribution volume (estimated from total body water content). This value then is compared with the target weekly Kt/V value for assessment and adjustment of the prescription. For M.J., the urea clearance was 5.7 mL/minute, or 57.5 L/week. Based on her estimated urea distribution volume of 33 L, her weekly Kt/V is approximately 1.74, near the target of 1.7, not accounting for any residual renal function that may be present.

Another test of peritoneal function is the peritoneal equilibration test (PET).¹⁰⁰ It is a standardized semiquantitative test of peritoneal membrane transport function, and is useful to assess membrane function over time as well as to provide guidance for the appropriate mode of PD for a patient. Based on the ratio of dialysate to plasma concentration of a solute at 2 hours into a 4-hour dwell, the patient is characterized as a high, high-average, low-average, or low transporter. Glucose absorption also is assessed by comparing the dialysate concentration at 2 hours with the baseline. High transporters are those who equilibrate rapidly, and would benefit from NIPD therapy with rapid overnight exchanges. Low transporters can be treated with standard CAPD, as long as the Kt/V is sufficient to meet their needs.

Complications

9. M.J. now presents to the dialysis clinic with complaints of abdominal tenderness and cloudy effluent. Examination of the dialysate reveals a white blood cell (WBC) count of 330 cells/mm³ with 62% neutrophils. Gram stain is positive for gram-positive cocci. Her diabetes has been controlled by the addition of 10 units of regular insulin to each daytime bag and 15 units to the overnight bag. How should M.J.'s infection be treated?

[SI unit: WBC, 0.33×10^9 cells/L (normal, $<0.05 \times 10^9$)]

Peritonitis

The most significant complication among patients having PD is peritonitis, which is frequently caused by coagulase-negative staphylococci, including *S. epidermidis* (30.6%) or *S. aureus* (17.5%).^{71,101} The patient usually presents with abdominal pain, nausea and vomiting, and fever with or without a cloudy effluent. Bacterial peritonitis generally is accompanied by an elevated dialysate WBC count $>100/\text{mm}^3$ with $>50\%$ neutrophils. A positive Gram stain should be followed by culture, with therapy initiated in the interim. For lower cell counts or negative Gram stain, a culture should be obtained followed by treatment for positive cultures and continued observation for

negative results. Specific consensus recommendations of the Advisory Committee on Peritonitis Management of the International Society for Peritoneal Dialysis (ISPD) are located at <http://www.ispd.org>.¹⁰² These guidelines were first published in 1983 and revised in 1989, 1993, 1996, 2000, and 2005. The initial focus of the ISPD recommendations was the treatment of peritonitis and exit-site infections. The most recent guidelines stress the importance of prevention.

Empiric antibiotics must cover both gram-positive and gram-negative organisms.¹⁰² The increasing prevalence of vancomycin-resistant organisms has resulted in a shift in empiric therapy away from vancomycin, toward first-generation cephalosporins: cefazolin or cephalothin. Without a Gram stain, therapy should be initiated with a combination of cefazolin or cephalothin (to cover gram-positive organisms) and ceftazidime (to cover gram-negative organisms), coadministered in the same dialysate solution at a dose of 1 g/bag for both drugs, once daily, given intraperitoneally.¹⁰³ Separate syringes must be used to add the antibiotics to dialysis solutions. An aminoglycoside can be used in place of ceftazidime, but it is not recommended initially, in an attempt to preserve residual renal function. Gentamicin, tobramycin, or netilmicin are given at doses of 0.6 mg/kg/bag, once daily, and for amikacin, 2 mg/kg/bag once daily. Antibiotics should be allowed to dwell for at least 6 hours.¹⁰² In addition to antibiotics, heparin 500 to 1,000 units/L may be added to each exchange to prevent the formation of fibrin clots, which can result in catheter failure.¹⁰³ Subsequent antibiotic therapy should be based on culture and sensitivity results, incorporating specific dosage regimens based on the treatment guidelines.¹⁰³

This is M.J.'s first episode of peritonitis. The most likely pathogen, a *Staphylococcus* species, is consistent with the positive Gram stain. Her treatment should consist of cefazolin or cephalothin alone. Vancomycin should not be used for empiric therapy. Instead, it should be reserved for methicillin-resistant *Staphylococcus aureus* (MRSA) infections or methicillin-resistant *S. epidermidis* (MRSE) if M.J. does not respond to empiric therapy. Heparin 1,000 units/L should be added to the dialysate to prevent fibrin clots from forming and obstructing outflow from the peritoneal cavity. Her blood glucose should be monitored, because infection causes insulin resistance and peritonitis will increase glucose and insulin absorption. Inability to control the blood glucose concentration may require temporary discontinuation of the intraperitoneal (IP) insulin and administration by another route.

For patients having APD, the choice of first-line antibiotics is the same as for CAPD because the likely organisms are similar. Drug dosage regimens, however, can differ because patients having CCPD or NIPD undergo PD only during the night-time hours, and those having NIPD do not have residual peritoneal fluid during the day. For aminoglycoside antibiotics, once daily dosing is preferred for the foregoing reasons, as well as their longer duration of action because of the post-antibiotic effect (see Chapter 32, Chronic Kidney Disease). Vancomycin and other glycopeptides can be administered intermittently because of their prolonged elimination half-life in patients with ESRD. Because of the lack of clinical trials with other antibiotics in patients having APD, extrapolation from the CAPD literature may be necessary. A review addresses the current knowledge and issues surrounding the pharmacokinetics of antibiotics in patients with peritonitis undergoing APD.¹⁰⁴

Exit-Site Infection

Prevention of catheter exit-site infections (and thus peritonitis) is the primary goal of exit-site care.¹⁰² Several preventative measures are important: adequate catheter placement, dedicated postoperative catheter care, and routine daily care of the exit site. Dressing changes of a newly placed catheter are done by a dialysis nurse using sterile technique until the exit site is well healed, which can take up to 2 weeks. Once the exit site is well healed, the patient is educated and trained to do routine exit-site care. Routine care consists of thorough handwashing with antibacterial soap before touching the exit site. Antiseptics that contain at least 60% ethanol or isopropyl alcohol can be used to augment handwashing.¹⁰⁵ The exit site is then washed daily with antibacterial soap, although use of an antiseptic (e.g., povidone iodine or chlorhexidine) is a reasonable option.¹⁰² Hydrogen peroxide should be avoided as a routine antiseptic because it causes drying. After daily cleansing, antimicrobial creams (e.g., mupirocin, gentamicin) are applied around the catheter exit site using a cotton swab. Mupirocin ointment, not the cream, can cause structural damage to polyurethane catheters, and should be avoided in patients with these catheters.¹⁰² Catheter exit-site infections are most often caused by *S. aureus* and *Pseudomonas* species.⁹⁹ In a randomized, double-blind trial, gentamicin sulfate 0.1% cream was found to be as effective as mupirocin 2% cream in preventing *S. aureus* infections.¹⁰⁶ Gentamicin cream was also highly effective in reducing *P. aeruginosa* and other gram-negative catheter infections, whereas mupirocin cream was not. A longer time to first catheter infection and a reduction in peritonitis, particularly gram-negative organisms, was also seen with gentamicin use. For these reasons, daily gentamicin cream at the exit site is considered to be the prophylaxis of choice in patients having PD.¹⁰⁶ Finally, the catheter should be immobilized with a small gauze dressing and tape to prevent pulling and trauma to the exit site, which may lead to infection.

Empiric therapy for exit-site infections may be started immediately, and should always cover *S. aureus*. Oral antibiotic therapy has been shown to be as effective as IP therapy.¹⁰² Local erythema alone can be treated with topical agents, whereas purulent drainage indicates more significant infection and the need for systemic antibiotics.¹⁰³ Hypertonic saline

dressings, as well as oral antibiotic therapy, can be used for especially severe exit-site infections.¹⁰² Hypertonic saline is prepared by adding 1 tablespoon of salt to 1 pint (500 mL) of sterile water. The solution is then applied to gauze and wrapped around the catheter exit site for 15 minutes, once or twice a day. Gram-positive organisms are treated with first-generation oral cephalosporins, a penicillinase-resistant penicillin, or trimethoprim-sulfamethoxazole (TMP-SMX). A 1-week course of rifampin may be added at 600 mg/day orally (in single or split dose) for nonresponding infections with positive cultures after 1 week of appropriate therapy. Rifampin monotherapy treatment of *S. aureus* should be avoided. In areas where tuberculosis is endemic, rifampin should also be avoided in the treatment of *S. aureus* to reserve this drug for treatment of tuberculosis.¹⁰² Oral quinolone antibiotics are recommended as first-line agents in the treatment of *P. aeruginosa* exit-site infections. *P. aeruginosa* infections are difficult to treat and often require prolonged therapy with two antibiotics.¹⁰² If the infection is slow to resolve or if in cases of a recurrence, a second antipseudomonal drug can be added (e.g., ceftazidime IP). Gram-negative organisms can be treated with ciprofloxacin 500 mg orally twice daily.¹⁰³ Scheduling of the quinolone dose is important so that coadministration with foods or other drug therapies that may chelate the quinolone in the gut is avoided. Potentially chelating agents include calcium products, iron, multivitamins, antacids, zinc, sucralfate, and dairy products. Antibiotic therapy should be continued for a minimum of 2 weeks until the exit site appears entirely normal.

Weight Gain

Dextrose is present in dialysate solutions primarily to serve as an osmotic agent for the removal of fluid during each exchange. Higher concentrations are expected to result in greater fluid removal. Approximately 500 to 1,000 kcal/day are absorbed as glucose from PD solutions, which can lead to weight gain in patients. Some patients may require modification of oral caloric intake to avoid excessive weight gain. Insulin requirements generally are increased in patients with diabetes as a result of the additional calories and, when administered IP, usually are two to three times the normal subcutaneous dose because of their reduced bioavailability of 20% to 50% by this route.

SUMMARY 33.24

BASIC PRINCIPLES

An increasing amount of information is available on the disposition of drugs in renal disease. It is important to design specific pharmacotherapeutic regimens for patients with renal impairment. Many patients are treated with multiple medications, which may require dosage adjustment. Without careful dosing and therapeutic drug monitoring for select agents in these patients, accumulation of drugs or toxic metabolites can occur, resulting in serious adverse effects.

In addition to altered drug elimination, a number of factors associated with kidney disease predispose patients to the potential for drug toxicity. Renal disease can affect the pharmacokinetic disposition as well as the pharmacodynamic effect of drugs. For example, the physiologic changes associated with uremia can alter drug absorption, protein binding, distribution, or elimination. These physiologic changes can alter drug concentrations in the plasma or blood, and at the targeted tissue site of activity, thereby affecting drug efficacy and toxicity.

Little is known about the effect of renal disease on drug pharmacodynamics. Pharmacodynamics (or “what the drug does to the body”) quantitatively describes the pharmacologic or toxicologic effects of drugs relative to the drug concentration. Patients with renal disease may have a different response to a given drug concentration than a patient with normal renal

function. Data in the area of pharmacodynamics and renal disease are limited. Patients with renal disease can be more sensitive to some drugs, and can experience an increased frequency of adverse drug reactions, with or without dosing modifications.

Figure 33-1 illustrates the relationship between pharmacokinetics and pharmacodynamics. The dose of drug produces a drug concentration, which results in a pharmacologic or toxic effect. Figure 33-2 illustrates how different components of drug disposition influence the ability of a drug to exert its pharmacologic effect at the site of action.

Effect of Renal Failure on Drug Disposition

Bioavailability

Although several factors can affect drug absorption in patients with kidney disease, only limited data are available that definitively document altered bioavailability. The absorption of drugs in patients with renal disorders could be inhibited by gastrointestinal (GI) disturbances present with uremia (e.g., nausea, vomiting, diarrhea), uremic gastritis, and pancreatitis. Edema of the GI tract, which can occur in patients with nephrotic syndrome, can cause impaired absorption. Gastric and intestinal motility as well as gastric emptying time can be

FIGURE 33-1 Relationship between pharmacokinetics and pharmacodynamics and the relationship of these two scientific principles to drug dose and concentration, and drug concentration and effect.

altered by the neuropathy that is commonly associated with uremia. Uremia also can increase gastric ammonia, leading to an increased gastric pH. Drugs that require an acidic environment for absorption, such as ferrous sulfate, may be less bioavailable.¹ Calcium-containing antacids that often are used by patients with renal failure for GI symptoms and hyperphosphatemia will neutralize hydrochloric acid in the stomach and increase gastric pH. Patients with end-stage renal disease often take oral phosphate binders, such as sevelamer, which can impair the absorption of other medications.

The bioavailability of orally administered drugs also depends on the extent to which the drug is eliminated by first-pass (presystemic) metabolism. In an early study, the first-pass hepatic metabolism of oral propranolol was found to be reduced in patients with renal disease, leading to increased bioavailability.² Subsequent studies, however, have attributed these observed increased concentrations of propranolol in renal failure to a significant increase in the blood-to-plasma ratio.³ Not only can decreased first-pass metabolism contribute to increased bioavailability, but intestinal P-glycoprotein activity may be decreased as well.⁴ Additional drugs exhibiting increased bioavailability in renal disease include cloxacillin, propoxyphene, dihydrocodeine, encainide, and zidovudine (AZT). For example, the area under the curve (AUC) of dihydrocodeine is increased by 70% in those patients with impaired renal function.⁵

Protein Binding and Volume of Distribution

The extent to which a drug exerts its pharmacologic effects is related to the amount of free or unbound drug available for distribution to the target tissues. Patients with renal failure often have alterations in plasma protein binding, which can increase the amount of unbound drug.⁶ Although this generally is true for acidic drugs, the binding of basic drugs is usually unchanged or possibly decreased in renal disease. Clinically, this is most important for highly protein-bound drugs (>80%). Decreased protein binding of these drugs results in increases in the free fraction of drug. This leads to an increase in the apparent

volume of distribution (Vd), and plasma clearance for drugs with a low-extraction ratio. A simultaneous increase in both the Vd and clearance results, however, in little or no change in the elimination half-life ($t_{1/2}$) of these drugs. Alternatively, the Vd of high-extraction ratio drugs can increase without a concomitant change in clearance. In this situation, the elimination half-life would increase, based on the relationships:

$$K_d = Cl/V_d$$

$$t_{1/2} = 0.693 \times V_d/Cl$$

In patients with renal failure, the accumulation of uremic toxins may alter protein binding. When the free fraction of drugs that are highly protein bound changes, the interpretation of the total drug concentration must also be considered. That is, with increasing free fraction, the total drug concentration necessary to exert the desired pharmacologic effect is lower than that needed under normal conditions.

Hypoalbuminemia is a common complication of renal failure. Because acidic rather than basic drugs are bound to albumin, their protein binding tends to be altered in patients with renal failure (Table 33-1).⁷ Patients with uremia accumulate acidic byproducts that may inhibit binding, or displace acidic drugs from albumin binding sites. This is supported by the observed improvement in protein binding following removal of uremic byproducts by hemodialysis. Finally, the conformation or structural arrangement of albumin is altered in renal disease, which may reduce the number and affinity of binding sites for drugs. Studies have demonstrated differences in the amino acid composition of albumin between healthy people and patients with uremia.⁸

The anticonvulsant, phenytoin, is a classic example of a drug whose protein binding is altered in renal disease.⁹ This is discussed in more detail later in this chapter.

Renal disease can change the Vd of various drugs. The Vd or “apparent volume of distribution” is the “volume” or size of a compartment necessary to account for the total amount of drug in the body if it were present throughout the body at the same concentration as that found in plasma. A decrease in the plasma protein binding of highly protein-bound drugs, such as phenytoin, leads to an increase in the apparent Vd.

Drugs that are not highly protein bound (e.g., gentamicin, isoniazid) have little change in their Vd in renal disease. Digoxin is a unique exception in that its Vd is decreased in renal disease. This is attributed to a decrease in myocardial tissue uptake of digoxin, leading to a decrease in the myocardial- or tissue-to-serum concentration ratio.¹⁰

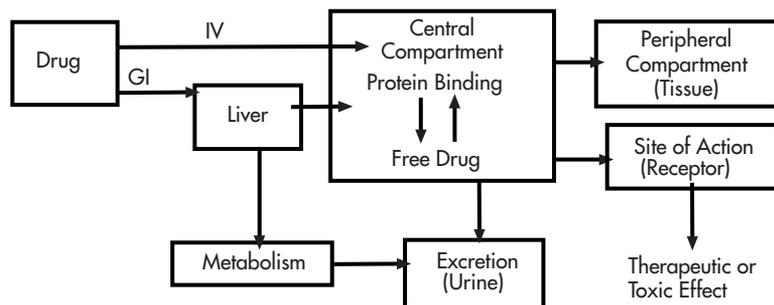

FIGURE 33-2 Factors influencing drug disposition and therapeutic or toxic effects. Following drug administration, a number of factors can influence pharmacokinetic parameters, such as bioavailability, volume of distribution, clearance, and target tissue binding. These factors may include first-pass metabolism, protein binding, and renal and liver function.

Table 33-1 Plasma Protein Binding (%) of Acidic Drugs in Renal Failure

| Drug | Normal | Renal Failure |
|------------------|--------|---------------|
| Cefazolin | 85 | 69 |
| Cefoxitin | 73 | 25 |
| Clofibrate | 97 | 91 |
| Diazoxide | 94 | 84 |
| Furosemide | 96 | 94 |
| Pentobarbital | 66 | 59 |
| Phenytoin | 88–93 | 74–84 |
| Salicylate | 87–97 | 74–84 |
| Sulfamethoxazole | 66 | 42 |
| Valproic acid | 92 | 77 |
| Warfarin | 99 | 98 |

Elimination

The extent to which renal disease affects the elimination of a drug depends on the amount of drug normally excreted unchanged in the urine and the degree of renal impairment. As kidney disease progresses, the kidney's ability to excrete uremic toxins diminishes. Consequently, the ability to eliminate certain drugs that are renally excreted also decreases. If the dose of these drugs is not modified for patients with renal dysfunction, these drugs will accumulate, leading to an increase in the pharmacologic effect and the potential for toxicity.

The kidney eliminates drugs primarily by filtration or active secretion. Characteristics of a drug that determine its ability to be filtered include its affinity for protein binding and its molecular weight. Drugs with low protein binding or those that are displaced from proteins in the setting of renal disease (e.g., phenytoin) are filtered more readily. Molecules with a high molecular weight (>20,000 Da) are not readily filtered because of their large size. The reasons for how renal disease selectively alters the process of glomerular filtration or tubular secretion of specific drugs are not well understood. The renal elimination of drugs in patients with renal disease usually is estimated by measuring the ability of the kidney to eliminate substances such as creatinine (i.e., creatinine clearance [Cl_{Cr}]) (see Chapter 31, Acute Renal Failure).

Renal disease can also have an important impact on the elimination of drugs that are primarily metabolized by the liver.¹¹ Metabolic processes, such as hydroxylation and glucuronidation, often produce inactive, more polar compounds that can be eliminated by the kidney. The metabolites of some drugs (e.g., meperidine, morphine, procainamide) are pharmacologically active or toxic. In patients with renal disease, these metabolites may accumulate, leading to an increase in pharmacologic activity and adverse effects.^{12,13} For example, the central nervous system (CNS) toxicity observed in renal disease has been attributed to accumulation of the morphine metabolite, morphine-6-glucuronide. Therefore, careful dosing modifications or avoidance of these drugs are warranted in patients with renal impairment. Metabolic enzymes have been found within renal tissue, and may play a role in the metabolism of some of these drugs.^{14,15} For example, the nonrenal clearance of drugs (e.g., acyclovir) decreases in patients with renal impairment, and is believed to be caused by a decrease in "renal" metabolism.¹⁶

Although renal and hepatic dysfunction may alter the metabolism and excretion of many drugs, the disposition of excipients used to formulate medications should also be considered. The pharmacokinetics of itraconazole and voriconazole are not significantly altered in the setting of renal dysfunction. The parenteral formulations of itraconazole and voriconazole contain the solubilizing agent, β -cyclodextrin. Cyclodextrin is rapidly eliminated by glomerular filtration, but can accumulate in patients with renal impairment, causing GI disturbances.¹⁷

Drug Removal by Dialysis

The effect of dialysis on the removal of a specific drug must be considered when using medications in patients undergoing dialysis. Patients may need supplemental doses of a medication after a dialysis session or alteration in their dosage to maintain therapeutic drug concentrations. Dialysis also can be initiated to hasten drug removal from the body in some cases of drug overdose.

When using dialysis to manage a drug overdose, patients may respond clinically to factors unrelated to dialysis of the drug. For example, declining plasma concentrations may be caused by concurrent drug elimination by hepatic metabolism or renal excretion, which is independent of the dialysis procedure itself. Furthermore, clinical improvement may result from removal of active metabolites by dialysis rather than the parent compound.

The primary literature should be used to determine if any information is available about the ability of dialysis to remove drug. The application of data from the literature to a specific clinical situation often is difficult, however, and information pertaining to the dialysis of a specific drug may be limited. Anecdotal case reports in the primary literature seldom provide quantitative information. The effectiveness of dialysis is often based on a positive clinical outcome rather than on objective measurements of drug concentrations in the plasma and dialysate.

When applying information from the primary literature to a specific patient, the specifics of the dialyzer (e.g., type of machine, membrane surface area, pore size, and blood and dialysis flow rates) must be considered (see Chapter 32, Renal Dialysis). Furthermore, patient-specific information (e.g., time of drug ingestion, liver and renal function) from case reports in the literature also should be evaluated appropriately. The method used to calculate dialysis clearance also should be considered. In addition, clinical investigators often use predialysis and postdialysis serum drug concentrations for estimating drug dialyzability without considering the contributing effects of drug metabolism and excretion on drug elimination.

Drug-Specific Properties

The physical and chemical characteristics of drugs can be used to predict the effectiveness of dialysis on drug removal.^{18–20} Low-molecular-weight (MW) compounds are more readily dialyzed by conventional hemodialysis procedures because they can pass with greater ease across the dialysis membrane. Using cuprophane dialysis membranes, compounds with a MW ≤ 500 are more likely to be significantly dialyzed than compounds with a high MW (e.g., vancomycin, MW $\approx 1,400$). Newer high-flux dialyzers using polysulfone membranes more effectively remove large chemical compounds (see High-Flux

Hemodialysis below and Chapter 32, Renal Dialysis). In addition, the water solubility of a compound can also help predict drug dialyzability because water-soluble drugs are removed more readily than lipid-soluble compounds.

Pharmacokinetic characteristics (e.g., V_d , protein binding) also can affect drug dialyzability. A drug with a large V_d that distributes widely into the peripheral tissues resides minimally in the plasma and therefore is not substantially removed by dialysis. This is particularly true for highly lipid-soluble drugs such as digoxin ($V_d = 300\text{--}500\text{ L}$), and amiodarone ($V_d = 60\text{ L/kg}$). In addition, drugs that are highly protein bound, such as warfarin (99%) and ceftriaxone (83%–96%), are not significantly removed by dialysis because the large protein–drug complex is unable to pass through the dialysis membrane.

The plasma clearance of a drug should also be compared with the dialysis clearance. Clearance values are additive. Dialysis clearance must contribute substantially to the patient's own clearance to enhance drug elimination. For example, zidovudine (AZT) has a large plasma clearance in patients with severe renal disease ($\approx 1,200\text{ mL/minute}$). Therefore, despite a hemodialysis clearance of 63 mL/minute , the contribution of dialysis to AZT removal is negligible.

High-Flux Hemodialysis

High-flux hemodialysis utilizes higher blood and dialysate flow rates compared with conventional methods. The enhanced efficiency of high-flux dialysis and the larger pore size of the polysulfone membranes allow for small- and mid-MW compounds (e.g., vancomycin) to be partially removed. Drugs such as gentamicin and foscarnet, which are removed by conventional dialysis, are also efficiently removed by high-flux hemodialysis.^{21,22} In many cases, the net amount of drug removed during a high-flux dialysis session is greater than the amount removed during conventional dialysis because of the use of higher blood flow rates. The principal difference is the greater efficiency and the ability to clear drugs of larger MW compared with conventional dialysis.

Continuous Ambulatory Peritoneal Dialysis

Continuous ambulatory peritoneal dialysis (CAPD) uses the patient's peritoneum as the dialysis membrane. Patients maintained with CAPD undergo infusion of a dialysate solution via a catheter inserted into the peritoneal cavity; the solution is allowed to dwell in the cavity for several hours. The accumulated fluid and uremic byproducts diffuse from the blood into the dialysate solution, which is exchanged every 4 to 8 hours (see Chapter 32, Renal Dialysis).

Some drugs, such as antibiotics, can be administered intraperitoneally in patients on CAPD by directly adding it to the dialysate solution. This is particularly useful for patients with peritonitis who require high intraperitoneal concentrations of antimicrobial agents to treat this infection. Following intraperitoneal administration of drugs, such as the aminoglycosides, plasma and intraperitoneal drug concentrations will eventually reach equilibrium. Despite systemic absorption of these drugs from the peritoneal fluid, peritoneal dialysis usually is inefficient at removing drugs from the plasma.²³ Because CAPD contributes little to the overall elimination of most drugs, dosage modifications are not always necessary in patients having this procedure.

Continuous Renal Replacement Therapies

Continuous arteriovenous hemofiltration (CAVH) and continuous venovenous hemofiltration (CVVH) are forms of continuous renal replacement therapy (CRRT) used in the critically ill patient with acute renal failure. These therapies are typically reserved for patients who are unable to tolerate hemodialysis because of hemodynamic instability. As with hemodialysis, this procedure removes fluid, electrolytes, and low- and mid-MW molecules from the blood. Using a hollow fiber that is made of a semipermeable membrane, water and solutes are filtered by hydrostatic pressure. A countercurrent dialysate can be added to the circuit to improve solute removal (CAVHD or CVVHD).

Limited data are available on the effect of CAVH or CVVH on the removal of drugs. Drugs that have a high sieving coefficient (permeability of a drug through a semipermeable membrane), such as the aminoglycosides, ceftazidime, vancomycin, and procainamide, are readily removed by CAVH or CVVH.^{24–26} Data concerning the removal of drugs by hemodialysis cannot be extrapolated to CAVH or CVVH because of differences in the membranes used, blood flow rates, ultrafiltration rate, dialysate flow rate, and the continuous nature of the procedure compared with intermittent hemodialysis. A way does exist to estimate CVVH clearance and determine the appropriate dosage regimen based on the pharmacologic characteristics of a specific drug (see Question 8).

Hemoperfusion

Hemoperfusion is another method of drug removal that may be used to facilitate the elimination of a drug in the setting of an overdose.^{27,28} During the hemoperfusion procedure, blood is passed through a column of adsorbent material (e.g., activated charcoal or resin) to bind toxins and drugs. Hemoperfusion can be particularly useful for removing large-MW compounds or highly protein-bound drugs that are not removed efficiently by hemodialysis. Large compounds and drug–protein complexes are adsorbed onto the high-surface-area resin as blood passes through the adsorbent column. Hemoperfusion can also be used to remove lipid-soluble drugs not easily removed by hemodialysis. Lipid-soluble drugs often have a large V_d . Removal of drugs by hemoperfusion is of limited value because a significant amount of these lipophilic compounds reside in peripheral tissues.

Pharmacodynamics and Renal Disease

Few studies have investigated the pharmacodynamics of drugs in patients with renal disease. Clinical observations report that patients with renal disease are more sensitive to various drugs. For example, morphine has been associated with increased neurologic depression in patients with renal failure.^{29,30} The ability of morphine to potentiate the CNS depressant effects of uremia may result from an alteration in the permeability of the blood–brain barrier that results in higher CNS levels of morphine and morphine-6-glucuronide.

Another example of altered drug response in uremia is that of nifedipine, which, at similar unbound plasma concentrations, has an increased antihypertensive effect in patients with renal disease.³¹ The mean maximal effect change in diastolic blood pressure (E_{max}) values in the control group and in patients with severe renal failure were 12% and 29%, respectively.

Therefore, the dose of nifedipine needs to be adjusted in patients with renal disease because of changes in drug effects rather than pharmacokinetic alterations.

The pharmacokinetics of warfarin is not significantly altered in renal failure. Patients with renal failure who are prescribed warfarin have a higher incidence of hemorrhagic complications, likely because of platelet dysfunction from uremia, and drug–drug interactions from concomitant medications.^{32,33}

PHARMACOKINETICS AND PHARMACODYNAMICS OF SPECIFIC DRUGS IN RENAL FAILURE

Ceftazidime

Dosage Modification: Factors to Consider

1. G.G., a 31-year-old, 70-kg woman with a 3-year history of systemic lupus erythematosus (SLE), presents to the emergency department (ED) with a 5-day history of fatigue, weakness, and nausea as well as worsening of her facial rash and a fever of 40°C. Her SLE had been moderately controlled until this acute flare. Her admission laboratory workup now reveals the following pertinent values: potassium (K), 6.0 mEq/L (normal, 3.6–4.8 mEq/L); sodium (Na), 142 mEq/L (normal, 135–144 mEq/L); serum creatinine (SrCr), 3.4 mg/dL (normal, 0.6–1.3 mg/dL); and blood urea nitrogen (BUN), 38 mg/dL (normal, 7–20 mg/dL). Complete blood count (CBC) reveals a hematocrit (Hct) of 32% (normal, 35%–45% [females]) and a hemoglobin (Hgb) of 9.2 g/dL (normal, 11.8–15.4 g/dL [females]). The platelet count is 50,000/mm³ (normal, 140,000–300,000) and her erythrocyte sedimentation rate (ESR) is 35 mm/hr (normal, 0–20). Physical examination is significant for a blood pressure (BP) of 136/92 mm Hg and 2+ pedal edema. Prednisone is started at a dose of 1.5 mg/kg/day.

Two weeks into her hospital course, G.G.'s condition worsens and signs of sepsis develop. *Pseudomonas aeruginosa* is cultured from her urine. Therapy with ceftazidime is initiated at a dose of 1 g Q 8 hr, a dose commonly used for patients with good renal function. Considering that G.G.'s renal function has remained stable and that she has an estimated Cl_{Cr} of 27 mL/minute, what factors should be considered before modifying her dose? What would be an appropriate dose of ceftazidime for G.G.?

[SI units: K, 6.0 mmol/L (normal, 3.6–4.8); Na, 142 mmol/L (normal, 135–144); SrCr, 300.56 μmol/L (normal, 53.04–114.92); BUN, 13.57 mmol/L urea (normal, 2.5–7.14); Hct, 0.32 (normal, 0.35–0.45); Hgb, 92 g/L (normal, 118–154); platelet count, 50 × 10⁹/L (normal, 140–300); ESR, 35 mm/hour (normal, 0–20)]

Before modifying the dose of any drug, its route of elimination should be established. The elimination of most drugs that primarily are cleared by the kidneys will be decreased in the setting of renal impairment. The degree to which renal impairment affects elimination depends on the percentage of unchanged drug that is excreted by the kidney. For many drugs that are cleared by the kidneys, relationships between some measurement of renal function (e.g., Cl_{Cr}) and some parameter of drug elimination (e.g., plasma clearance or half-life) have been established to help the clinician determine the appropriate dosing modifications in patients with renal disease.

In contrast, the clearance of drugs that are eliminated primarily by nonrenal mechanisms (e.g., hepatic metabolism) is not altered significantly in patients with renal disease. Lim-

ited data indicate, however, that the kidney may play a role in drug metabolism. Enzymes with metabolic capacity have been found within renal tissue (see Question 12). The clinical importance of this elimination pathway is unclear.

Of clinical significance is the role of the kidney in eliminating pharmacologically active or toxic metabolites. Despite the metabolism of the parent drug and the lack of renal elimination of unchanged drug, the formation of active, more water-soluble metabolites that may accumulate with renal dysfunction warrants dosage adjustment or avoidance of the drug entirely (e.g., meperidine; see Question 22).

Another factor important to consider is the “therapeutic window” for a given drug. The therapeutic window is the range of drug concentrations thought to be most effective. Drug concentrations below this range are usually subtherapeutic, whereas concentrations above this range can lead to a greater incidence of adverse effects. For drugs with a wide therapeutic window, the difference between toxic and therapeutic concentrations is large. Drugs that are cleared primarily by the kidney may require dosing modifications in patients with renal dysfunction. Aggressive dose reduction may not be necessary, however, for drugs with a large therapeutic window, particularly if the adverse effects of the drug (e.g., fluconazole) are relatively mild. This is in contrast to drugs (e.g., aminoglycosides, vancomycin, or foscarnet), which are eliminated primarily by the kidney and have narrow therapeutic windows. For these drugs, the toxic plasma concentrations are very close to the therapeutic drug concentrations, with little room for dosing error. Table 33-2 summarizes the pharmacokinetics and dosing guidelines for drugs commonly used in patients with renal failure.

Ceftazidime is a cephalosporin that has excellent activity against most strains of *Pseudomonas* sp. As with most cephalosporins, ceftazidime primarily is cleared by the kidneys, with little nonrenal or hepatic elimination. The correlation between the clearance of ceftazidime and Cl_{Cr} in mL/minute is represented by the following equation³⁴:

$$Cl_{\text{ceftaz}} (\text{mL}/\text{min}) = (0.95)(Cl_{\text{Cr}}) + 6.59 \quad (33-1)$$

Using Equation 33-1, the clearance of ceftazidime in G.G. is estimated to be 32 mL/minute compared with an average normal clearance of approximately 100 mL/minute. Because her drug clearance is approximately one-third of normal, she would require about one-third of the normal daily dose (i.e., 1 g every 24 hours). As with other cephalosporins, ceftazidime has a large therapeutic window.³⁷ Failure to reduce the dose from a normal dose of 1 g every 8 hours might, however, lead to accumulation of ceftazidime, predisposing G.G. to seizures and other adverse effects associated with toxic β-lactam antibiotic plasma levels.^{35,36} This is in contrast to the aminoglycosides, which must be dosed based on specific pharmacokinetic calculations. Therefore, more generalized or empirical dosage modifications can be made with ceftazidime.

Aminoglycosides

2. G.G.'s medical team decides that the addition of an aminoglycoside antibiotic is now necessary to treat her infection. Considering that her renal function has remained stable, how should the gentamicin be dosed in G.G.? Is it best to alter the dose or the dosing interval for this drug?

Table 33-2 Pharmacokinetics and Dosing Guidelines for Drugs Commonly Used in Renal Failure¹⁵²

| Drug | Oral Availability (%) | Protein Binding (%) | V _d (L/kg) | Metabolism and Excretion | t _{1/2} (hr) | Normal Dose Cl _C > 50 mL/min | Dose Change With Renal Failure Cl _C (mL/min) | Effect of Dialysis |
|----------------|-----------------------|---------------------|-----------------------|---|--|--|--|------------------------------------|
| Acyclovir | 15–30 | 15 | 0.7 | 76%–82% excreted renally; 14% hepatic | Normal: 2.1–3.2 Anephric: 20 | 5 mg/kg Q 8 hr | 10–50: 5 mg/kg Q 12–24 hr <10: 2.5 mg/kg Q 24 hr | Dialyzed; 80 mL/min |
| Adefovir | 59 | <4 | 0.35–0.39 | 45% excreted in urine | 5–7 | 10 mg QD | 20–49: 10 mg Q 48 hr 10–19: 10 mg Q 72 hr HD: 10 mg Q 7 days | Moderately dialyzed |
| Allopurinol | 90 | 0 | 0.6 | Metabolized to active oxypurinol metabolite, which is excreted renally; 6%–12% excreted unchanged renally | Normal: 1.1–1.6 Anephric: No change; 7 days oxypurinol | 300 mg QD | 10–50: 200 mg QD <10: 100 mg QD | Oxypurinol; moderately dialyzed |
| Amikacin | Parenteral | <5 | 0.2–0.3 | 94%–99% excreted renally | Normal: 2–3 Anephric: 3.6–8.2 | See section on aminoglycoside pharmacokinetics | See section on aminoglycoside pharmacokinetics | Dialyzed; 22–38 mL/min |
| Amphotericin B | Parenteral | 90–95 | 4 | 95%–97% hepatic metabolism or inactivation in body tissue; 3.5%–5.5% excreted unchanged renally | Normal: Initial: 24–48; Terminal: 15 days Anephric: No change | 0.3–1 mg/kg Q 24 hr | 10–50: 100% Q 24 hr <10: 100% Q 24–48 hr (to minimize azotemia) | Not dialyzed; large V _d |
| Ampicillin | 32–76 | 29 | 0.3 | 73%–92% excreted renally; 12%–24% hepatic metabolism or biliary elimination | Normal: 0.8–1.5 Anephric: 20 | 1–2 g Q 4–6 hr | 10–50: 1–1.5 g Q 6 hr <10: 50% 1 g Q 8–12 hr | Moderately dialyzed |
| Argatroban | Parenteral | 54 | 0.174 | 16% excreted in urine | 0.65–0.85 | 2 mcg/kg/min adjusted to appropriate aPTT | No change | 20% removed by dialysis |
| Atenolol | 50 | <5 | 1.2 | 75% excreted renally; 10% hepatic; 10% feces | Normal: 5–6 Anephric: 42–73 | 50–100 mg QD | 10–50: ↓ 50% and titrate <10: ↓ 50% and titrate | Moderately dialyzed |
| Aztreonam | Parenteral | 50–60 | 0.15–0.38 | 60%–70% excreted renally; 12% hepatic | Normal: 1.3–2.2 Anephric: 6–9 | 1–2 g Q 6–8 hr | 10–50: 1–2 g Q 8–12 hr <10: 1 g Q 12–24 hr | Moderately dialyzed |
| Captopril | 65 | 30 (↓R) | 0.7 | 36%–42% excreted renally; 50% hepatic | Normal: 1.7–1.9 Anephric: 21–32 | 6.25–12.5 mg Q 8–12 hr | 10–50: No change <10: ↓ 25% and titrate | Moderately dialyzed; 80–120 mL/min |
| Cefazolin | Parenteral | 84–92 | 0.2 | >95% excreted renally; 3–5% hepatic | Normal: 1.8–2.6 Anephric: 12–40 | 1–2 g Q 8 hr | 10–50: 0.5–1.5 g Q 12 hr <10: 0.5–1 g Q 24 hr | Moderately dialyzed |

| | | | | | | | | |
|--------------|---------------------------------------|---------------------------------|-----------|--|--|---|--|------------------------------|
| Cefepime | Parenteral | 20 | 0.23 | >80% renally excreted | Normal: 2 Anephric: 13-18 | 1-2 g Q 8-12 hr | 30-60 mL/min = 1-2 g Q 12-24 hr 10-29 mL/min = 0.5-2 g Q 24 hr <10 mL/min = 0.25-1 g Q 24 hr | Moderately dialyzed |
| Cefixime | 50 | 69 | 0.1-1.0 | 20%-40% excreted renally; 50% excreted by nonrenal mechanisms | Normal: 3.5 Anephric: 12-15 | 200-400 mg Q 12-24 hr | 10-50: No change <10: 50% Q 12-24 hr | Not dialyzed |
| Cefoperazone | Parenteral | 87-93 | 0.16 | 70%-85% excreted unchanged in bile; 15-30% excreted renally | Normal: 1.6-2.6 Anephric: 2.5 | 1-2 g Q 8-12 hr | 10-50: No change <10: ↓ with concurrent hepatic disease | Slightly dialyzed |
| Cefotaxime | Parenteral | 38 | 0.22-0.36 | 40%-60% hepatic (desacetyl active metabolite; 25% activity of parent compound); 40%-65% excreted renally | Normal: 0.9-1.1 Anephric: 2.3-3.5, 12-20 (metabolite) | 1-2 g Q -12 hr | 10-50: 1-2 g Q 12 hr | Moderately dialyzed |
| Cefotetan | Parenteral | 75-91 | 0.13 | 50%-88% excreted renally; 12% excreted in bile | Normal: 3-4.2 Anephric: 13 | 1-2 g Q 12 hr | 10-50: 1-2 g Q 24 hr <10: 0.5-1 g Q 24 hr | Slightly/moderately dialyzed |
| Cefoxitin | Parenteral | 65-79 | 0.27 | 85% excreted renally; up to 15% biliary and/or hepatic | Normal: 0.7-0.8 Anephric: 12-24 | 1-2 g Q 6-8 hr | 10-50: 1-2 g Q 12-24 hr <10: 0.5-1 g Q 24 hr | Moderately dialyzed |
| Ceftazidime | Parenteral | 20-30 | 0.2-0.3 | 73%-84% excreted renally | Normal: 1.6-2 Anephric: 13-25 | 1-2 g Q 8 hr | 10-50: 1-2 g Q 12-24 hr <10: 0.5 g Q 24 hr | Dialyzed |
| Ceftizoxime | Parenteral | 17-25 | 0.2-0.4 | 78%-92% excreted renally | Normal: 1.4-1.7 Anephric: 19-30 | 1-2 g Q 8-12 hr | 10-50: 1-2 g Q 12-24 hr <10: 0.5 g Q 24 hr | Moderately dialyzed |
| Ceftriaxone | Parenteral | 83-96 (concentration dependent) | 0.1 | 40%-67% excreted renally; 40% excreted in bile | Normal: 6.5-8.9 Anephric: 12 | 1-2 g Q 12-24 hr | 10-50: 1-2 g Q 24 hr <10: 1-2 g Q 24 hr | Not dialyzed |
| Cefuroxime | Parenteral and 40-50 (as axetil salt) | 33 | 0.19 | 90%-95% excreted renally | Normal: 1.1-1.7 Anephric: 15-17 | 0.75-1.5 g Q 6-8 hr | 10-50: 50-75% Q 8-12 hr <10: 25-50% Q 24 hr | Moderately dialyzed |
| Cephadrine | 90-100 | 6-20 | 0.25-0.33 | 80%-95% excreted renally; 5%-20% hepatic metabolism or biliary/fecal elimination | Normal: 0.7-0.9 Anephric: 8-15 | 250-500 mg Q 6 hr | 10-50: 250-500 mg Q 12 hr <10: 250-500 mg Q 24 hr | Moderately dialyzed |
| Cimetidine | 62 | 20 | 0.9-1.1 | 40%-80% excreted renally; some metabolism | Normal: 1.5 Anephric: 3.3-4.6 | PO: 400 mg Q 12 hr IV: 300 mg Q 8 hr | 10-50: ↓ 25% <10: ↓ 50% | Slightly dialyzed |

Table 33-2 Pharmacokinetics and Dosing Guidelines for Drugs Commonly Used in Renal Failure¹⁵² — cont'd

| Drug | Oral Availability (%) | Protein Binding (%) | V _d (L/kg) | Metabolism and Excretion | t _{1/2} (hr) | Normal Dose Cl _C > 50 mL/min | Dose Change With Renal Failure Cl _C (mL/min) | Effect of Dialysis |
|------------------------|--------------------------|---------------------|-----------------------|---|-----------------------------------|---|---|------------------------------|
| Ciprofloxacin | 50–85 | 22 | 2.2 | 62% excreted renally; the rest cleared hepatically, in the bile and via intestinal mucosa | Normal: 4 Anephric: 8.5 | 250–750 mg Q 12 hr (PO) | 10–50: 250–500 mg Q 12 hr <10: 250–750 mg Q 24 hr | Slightly dialyzed |
| Clindamycin | 50 | 94 | 0.6 | 85% hepatic to active and inactive metabolites; 10% excreted renally; 5% feces | Normal: 2–4 Anephric: 1.6–3.4 | 600–900 mg Q 6–8 hr | 10–50: No change <10: No change | Not dialyzed |
| Codeine | 40–70 | 7 | 3–4 | Hepatic with some active metabolites; little renal elimination (5%–17%) | Normal: 2.9–4 Anephric: 19 | No change | 10–50: ↓ 25% and titrate <10: ↓ 50% and titrate | ? |
| Cyclosporine | <5–89 | >96 | 3.5 | Extensively metabolized to active and inactive metabolites; <1% excreted renally | Normal: 6–13 Anephric: 16 | No change | 10–50: No change <10: No change | Not dialyzed |
| Daptomycin | Parenteral | 90–93 | 0.1 | 78% renally eliminated | Normal: 9 Anephric: 29 | 4–6 mg/kg Q 24 hr depending on indication | 4–6 mg/kg Q 48 hr depending on indication | Minimally dialyzed |
| Digoxin | 70 | 25 (↓ R) | 5–8 (↓ R) | 70% excreted renally | Normal: 36–44 Anephric: 80–120 | No change | 10–50: ↓ 50% <10: ↓ 75% | Not dialyzed |
| Emtricitabine | 93 | <4 | N.D. | 86% excreted in urine | 10 | 200 mg QD | 30–49: 200 mg Q 48 hr 15–29: 200 mg Q 72 hr <15 or HD: 200 mg Q 96 hr | Moderately dialyzed |
| Enalapril ^a | 36–44 | <50 | 1 | 61% excreted renally; 33% excreted in feces | Normal: 5–11 Anephric: 36 | No change | 10–50: ↓ 50% and titrate <10: ↓ 50% and titrate | Slightly/moderately dialyzed |
| Ertapenem | Parenteral | 85–95 | 0.12 | 80% excreted in urine | 4 | 1 g QD | <30: 500 mg QD | Moderately dialyzed |
| Erythromycin | 30–65 (varies with salt) | 84–90 | 0.9 | 85%–95% hepatic to inactive metabolites; 5–15% excreted renally | Normal: 1.4–2 Anephric: 4 | 0.25–1 g Q 6 hr | 10–50: No change <10: No change | Slightly dialyzed |
| Ethambutol | 75–80 | <5 | 1.6 | 65%–80% excreted renally and 20% in feces; 8–15% hepatic | Normal: 3.1 Anephric: 18–20 | 15 mg/kg Q 24 hr | 10–50: 7.5–10 mg/kg Q 24 hr <10: 5 mg/kg Q 24 hr | Slightly dialyzed |

| | | | | | | | | |
|--------------|------------|-------|-----------|--|--------------------------------------|---|--|------------------------|
| Fluconazole | >85 | 11-12 | 0.8 | 70% excreted renally; some hepatic metabolism | Normal: 20-50 Anephric: 98 | 100-200 mg Q 24 hr <10: 50-100 mg Q 24 hr | 10-50: 50-200 mg Q 24 hr <10: 50-100 mg Q 24 hr | Moderately dialyzed |

Table 33-3 Advantages and Disadvantages of General Approaches to Dosing Adjustments in Renal Disease

| Method | Advantages | Disadvantages |
|---|---|--|
| Variable Frequency Use the same dose but ↑ the dosing interval | Same $C_{p_{ave}}$, $C_{p_{max}}$, $C_{p_{min}}$ Normal dose | Levels may remain subtherapeutic for prolonged periods in patients requiring dosing intervals >24 hr |
| Variable Dose With Fixed $C_{p_{ave}}$ ↓ dose to maintain a target $C_{p_{ave}}$; keep the dosing interval the same | Same $C_{p_{ave}}$ Normal dosing interval | ↓ peak levels, which may ↑ be subtherapeutic; ↑ trough levels, which may ↑ potential for toxicity |

$C_{p_{ave}}$, average plasma concentration; $C_{p_{max}}$, maximum plasma concentration; $C_{p_{min}}$, minimum plasma concentration.

Alteration of Dose versus Dosing Interval

The aminoglycosides (e.g., tobramycin, gentamicin, amikacin) are effective in the treatment of serious systemic infections caused by gram-negative organisms such as *Pseudomonas* sp. Unlike the cephalosporins and penicillins, however, the aminoglycosides have a relatively narrow therapeutic window. Using pharmacokinetic principles, a dose regimen can be designed to produce specific peak and trough serum concentrations. Peak serum concentrations ($C_{p_{peak}}$) (e.g., gentamicin or tobramycin 5–8 mg/L) correlate best with therapeutic efficacy, whereas toxicity tends to correlate with elevated trough levels ($C_{p_{trough}}$), which reflects prolonged exposure to high drug concentrations. To minimize the risk of toxicity, trough levels of <2 mg/L should be maintained. In patients with normal renal function, these target serum aminoglycoside concentrations are usually obtained following standard doses (e.g., 1.5 mg/kg) administered every 8 hours. For most patients, peak and trough levels are usually measured once steady state is achieved, which is typically within 24 hours.^{38–41}

Many clinicians now utilize once-daily dosing of the aminoglycosides (e.g., 5 mg/kg every 24 hours) for patients with normal renal function in an attempt to minimize aminoglycoside accumulation and nephrotoxicity. The rationale for this regimen is based on the aminoglycosides' concentration-dependent killing and post-antibiotic effect. This approach is not recommended for patients with renal impairment, however. When once-daily dosing is used, peak concentrations are less helpful; however, trough concentrations should be monitored, and are usually below the limit of analytic detection (<1 mg/L). The discussion regarding aminoglycoside dosing in renal impairment that follows is based on the traditional an every 8-hour dosing regimen.

Aminoglycosides are almost completely eliminated by the kidneys; thus, the clearance of these drugs essentially is equal to the glomerular filtration rate (GFR). The pharmacokinetic properties of gentamicin and tobramycin are similar. A close correlation exists between Cl_{Cr} and gentamicin total body clearance. As renal function deteriorates, aminoglycoside doses must be modified to maintain the desired peak and trough plasma concentrations. Failure to appropriately adjust the dosage of aminoglycosides in renal insufficiency can lead to high drug plasma levels that can result in ototoxicity and nephrotoxicity.

In many cases, the aminoglycoside dose can be modified by extending the dosing interval rather than simply reducing the dose. This permits maintenance of adequate peak plasma concentrations to ensure efficacy, while allowing for sufficient

elimination between doses to produce trough levels <2 mg/L. The advantages and disadvantages of adjusting the dosing interval versus reducing the dose are summarized in Table 33-3.

Figure 33-3 illustrates the effect of increasing the dosing interval in a patient such as G.G. with renal function that is 30% of normal. Although this is the preferred method for adjusting the dose of aminoglycosides, for many other drugs requiring dose adjustments in renal disease, simple dosage reduction is sufficient (Table 33-2).

Determination of Appropriate Dose

A number of methods have been developed to determine the appropriate aminoglycoside dose for patients.⁴² One method is Bayesian forecasting, in which pharmacokinetic data obtained in the individual patient are integrated with population parameters. Initially, a dose is used that is based on population parameter values adjusted for characteristics such as increased SrCr. Drug concentrations for the individual patient are measured at specific times (e.g., peak and trough measurements) and these are compared with the expected values from the population data. Individualized pharmacokinetic parameter estimates are

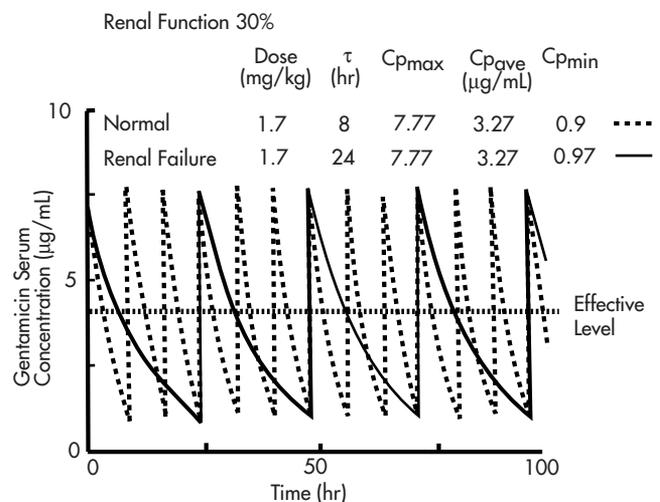

FIGURE 33-3 Serum concentration versus time profile for a patient with renal function 30% of normal in whom the interval of drug administration has been extended for dose adjustment. Advantages to this method are summarized in Table 33-3. [From Brater DC. *Drug Use in Renal Disease*. Sydney: ADIS Health Science Press; 1983, with permission.¹⁵³]

subsequently derived using Bayes' theorem to calculate a more patient-specific dosing regimen.⁴³

Because of the wide interpatient variability in aminoglycoside pharmacokinetic parameters and the therapeutic index for these drugs is narrow, doses should be adjusted based on pharmacokinetic principles (e.g., Bayesian calculations or methods described later in this chapter) and plasma concentrations that are specific for this patient.

PATIENT-SPECIFIC METHODS

Sawchuk and Zaske developed a method to derive patient-specific estimates of Vd and clearance (Cl) based on the patient's size and estimated Cl_{Cr}.⁴⁰ These parameters can be used to calculate a specific dose for G.G. that will produce the desired gentamicin peak and trough concentrations. If steady-state serum concentrations of gentamicin are known, they can be used to calculate even more specific parameters. To initiate gentamicin therapy, pharmacokinetic parameters should first be estimated from population values.

The clearance of gentamicin (Cl_{gent}) can be calculated based on G.G.'s Cl_{Cr}. Using the Cockcroft and Gault equation,⁴⁴ the Cl_{Cr} can be estimated as follows:

$$Cl_{Cr} \text{ (males)} = \frac{(140 - \text{age})(\text{IBW})}{(\text{SrCr})(72)} \quad (33-2)$$

$$Cl_{Cr} \text{ (females)} = \frac{(140 - \text{age})(\text{IBW})}{(\text{SrCr})(72)} (0.85) \quad (33-3)$$

where IBW is ideal body weight in kg, age in years, and SrCr is serum creatinine in mg/dL.

With a SrCr of 3.4 mg/dL, an ideal body weight of 70 kg, and an age of 31, G.G.'s estimated Cl_{Cr} is 27 mL/minute.

For practical purposes, Cl_{gent} is usually considered equivalent to Cl_{Cr}. Therefore, Cl_{gent} also is approximately 27 mL/minute or 1.6 L/hour. The Vd of gentamicin (Vd_{gent}) is approximately 0.25 L/kg in patients with normal or impaired renal function.^{40,44,45}

The Vd_{gent} will be different in obese patients or those who with fluid overload. Although G.G. does have some fluid retention, this is minimal and should not affect her Vd_{gent} significantly. Therefore, the Vd_{gent} for G.G. is as follows:

$$\begin{aligned} Vd_{gent} &= (0.25 \text{ L/kg})(\text{Body Weight}) \\ &= (0.25 \text{ L/kg})(70 \text{ kg}) \\ &= 17.5 \text{ L} \end{aligned} \quad (33-4)$$

The loading dose of gentamicin can be determined using the following equation:

$$LD_{gent} = (Vd_{gent})(\text{desired } C_{p\text{peak}}) \quad (33-5)$$

For treatment of infections caused by *Pseudomonas* sp., a peak level of approximately 6 to 8 mg/L is desired:

$$\begin{aligned} LD_{gent} &= (17.5 \text{ L})(7 \text{ mg/L}) \\ &= 122.5 \text{ mg or round off to } 120 \text{ mg} \end{aligned} \quad (33-5A)$$

Using Cl_{gent} and Vd_{gent}, the elimination rate constant (Kd) and half-life for gentamicin can be estimated as follows:

$$\begin{aligned} Kd &= \frac{Cl_{gent}}{Vd_{gent}} \\ &= \frac{1.6 \text{ L/hr}}{17.5 \text{ L}} \\ &= 0.091 \text{ hr}^{-1} \end{aligned} \quad (33-6)$$

$$\begin{aligned} t_{1/2} &= \frac{0.693}{Kd} \\ &= \frac{0.693}{0.091 \text{ hr}^{-1}} \\ &= 7.6 \text{ hr} \end{aligned}$$

For the aminoglycosides, the dosing interval (τ) is determined by doubling the half-life because by the end of two half-lives, 75% of the drug will have been eliminated. This will usually lead to a desired trough level of <2 mg/L. Therefore, gentamicin should be administered at least every 16 hours. For convenience, an interval of 24 hours can be used, which also will achieve the desired trough concentration.

Gentamicin is usually infused over 30 minutes. To determine the peak gentamicin concentration, serum samples are drawn 30 minutes after the infusion has been completed. Because the estimated elimination half-life of gentamicin in G.G. (7.6 hours) is much longer than the infusion time (0.5 hours), the intravenous bolus model can be used to calculate an appropriate maintenance dose.

To achieve the peak concentration of 7 mg/L, the following equation can be used:

$$\begin{aligned} \text{Dose} &= \frac{(C_{p\text{peak}})(1 - e^{-Kd t})(Vd_{gent})}{(e^{-Kd t_{\text{sample}}})} \\ &= \frac{(7 \text{ mg/L})(1 - e^{-(0.091 \text{ hr}^{-1})(24 \text{ hr})})(17.5 \text{ L})}{(e^{-(0.091 \text{ hr}^{-1})(1 \text{ hr})})} \\ &= 119.2 \text{ mg} \\ &= \text{or round off to } 120 \text{ mg} \end{aligned} \quad (33-7)$$

where t_{sample} usually equals 1 hour (30 minutes following a 30-minute infusion).

The expected trough level in G.G. can now be estimated by the following equation:

$$\begin{aligned} C_{p\text{trough}} &= (C_{p\text{peak}})(e^{-Kd t_{\text{sample}}}) \\ &= (7 \text{ mg/L})(e^{-(0.091 \text{ hr}^{-1})(24 \text{ hr})}) \\ &= 0.8 \text{ mg/L} \end{aligned} \quad (33-8)$$

Although not the case for G.G., patients with normal renal function may eliminate a significant amount of gentamicin during the 30-minute infusion. In these patients, the intermittent infusion model should be used to account for this loss of drug, where t_{in} is the duration of the infusion:

$$\text{Dose} = \frac{(Cl_{gent})(C_{p\text{peak}})(1 - e^{-Kd t})(t_{\text{in}})}{(1 - e^{-Kd t_{\text{in}}})(e^{-Kd \tau})} \quad (33-9)$$

Revised Parameters

3. After 72 hours of gentamicin therapy, G.G.'s peak and trough levels are 7.6 and 2.6 mg/L, respectively. Her physician attributes this to a gradual decline in renal function. (Her most recent SrCr is 4.8 mg/dL.) How would you revise G.G.'s dosing regimen based on these levels?

A gentamicin trough level of >2 mg/L suggests that G.G.'s dosing interval is too short. Although her peak concentration is within the normal range of 5 to 8 mg/L, her trough concentration indicates that she is at a potentially toxic level. Her

pharmacokinetic parameters can be revised based on these values, and a new K_d can be estimated from the equation:

$$K_d = \frac{\ln\left(\frac{C_{p1}}{C_{p2}}\right)}{\Delta t} = \frac{\ln\left(\frac{7.6 \text{ mg/L}}{2.6 \text{ mg/L}}\right)}{23 \text{ hr}} = 0.047 \text{ hr}^{-1} \quad (33-10)$$

Because little change in G.G.'s $V_{d_{\text{gent}}}$ is expected, a new Cl_{gent} (Cl_{revised}) can be estimated from her revised elimination constant (if necessary, a revised $V_{d_{\text{gent}}}$ could be calculated, keeping Cl_{gent} constant, although the clearance is more likely to change than the volume of distribution):

$$\begin{aligned} Cl_{\text{revised}} &= (V_{d_{\text{gent}}})(K_d) \\ &= (17.5 \text{ L})(0.047 \text{ hr}^{-1}) \\ &= 0.82 \text{ L/hr} \end{aligned} \quad (33-11)$$

These revised values for K_d and Cl can now be used to calculate a revised maintenance dose to maintain the $C_{p_{\text{trough}}}$ at $<2 \text{ mg/L}$ using Equation 33-7:

$$\begin{aligned} \text{Dose} &= \frac{(7 \text{ mg/L})(1 - e^{-(0.047 \text{ hr}^{-1})(48 \text{ hr})})(17.5 \text{ L})}{e^{-(0.047 \text{ hr}^{-1})(1 \text{ hr})}} \\ &= 115 \text{ mg} \\ C_{p_{\text{trough}}} &= (7 \text{ mg/L})(e^{-(0.047 \text{ hr}^{-1})(48 \text{ hr})}) \\ &= 0.73 \text{ mg/L} \end{aligned} \quad (33-11A)$$

The revised dose is now 115 mg (or $\sim 110 \text{ mg}$) every 48 hours.

4. What are some limitations in calculating G.G.'s Cl_{Cr} based on her SrCr? Can this estimate safely be used to predict gentamicin clearance?

The level of kidney function is best estimated by the glomerular filtration rate (GFR). The GFR cannot be directly measured. Prediction equations such as the Modification of Diet in Renal Disease (MDRD) study include variables, such as serum creatinine, age, body weight, race, and gender, in the estimation of GFR.⁴⁶ Although the MDRD equations are a good measure of GFR, they have not been validated for the dosing of drugs in the setting of renal dysfunction.^{47,48}

The creatinine clearance is a widely used estimation of renal function in patient care settings. The creatinine clearance is often used to assess the degree of renal impairment and develop rational drug dosing recommendations.⁴⁹ For patients with stable renal function, Cl_{Cr} can be estimated from SrCr using the Cockcroft and Gault equation (see Equations 33-2 and 33-3). In a patient such as G.G., however, whose renal function has diminished during the hospital course, estimation of renal function based on her increasing SrCr becomes more difficult. Because her SrCr does not reflect a steady-state level, the previous equations can no longer be used to accurately estimate her renal function. Because G.G.'s SrCr has increased rapidly from 3.4 to 4.8 mg/dL over the past few days, her Cl_{Cr} is probably much lower than that estimated using the Cockcroft and Gault method. A rising SrCr may represent a decline in renal function manifesting as an accumulation of creatinine.

Effect of Hemodialysis

Conventional Dialysis GENTAMICIN

5. G.G.'s renal function continues to deteriorate to the extent that she requires hemodialysis. What additional alterations in her gentamicin dosing regimen are necessary when she is having dialysis?

Gentamicin has a molecular weight of about 500 and is significantly removed by conventional hemodialysis.⁴¹ Gentamicin has a relatively low V_d , averaging 0.25 L/kg, and is about 10% bound to proteins. The dialysis clearance of gentamicin using conventional methods depends on the actual filter used as well as the blood and dialysate flow rates. Dialysis clearance averages 45 mL/minute compared with an average plasma clearance of 5 mL/minute in patients with end-stage renal disease (ESRD).^{50,51} Therefore, G.G.'s gentamicin dose must be adjusted to compensate for the amount of drug that will be removed by dialysis. Because drug removal represents a combination of drug elimination by the body and dialysis, the following equation can be used:

$$Cl_{\text{total}} = Cl_{\text{dial}} + Cl \quad (33-12)$$

where Cl_{total} is the total clearance of the drug during dialysis, Cl_{dial} is the clearance by dialysis, and Cl is plasma clearance. If dialysis clearance is high relative to plasma clearance, drug removal will be enhanced by the dialysis procedure. The total clearance of gentamicin in a patient with severe renal dysfunction during dialysis is 50 mL/minute (45 mL/minute + 5 mL/minute) or 10 times the clearance while off dialysis. Plasma clearance and dialysis clearance are related to the elimination half-life by the following equation:

$$t_{1/2} = \frac{(0.693)(V_d)}{Cl_{\text{dial}} + Cl} \quad (33-13)$$

Thus, assuming a constant V_d of 17.5 L (i.e., 0.25 L/kg \times 70 kg), the elimination half-life on dialysis is approximately 4 hours compared with 40 hours off dialysis. In addition, the extent (fraction) of drug removal (FD) during a timed dialysis run can be predicted from the following equation:

$$FD = 1 - e^{-(Cl + Cl_{\text{dial}})(t/V_d)} \quad (33-14)$$

where t is the duration of dialysis. Therefore, the fraction of gentamicin removed (FD) during a 4-hour conventional dialysis procedure is approximately 50%. If specific data are not available for dialysis and plasma clearance, the following equation will predict fraction removed using the elimination half-life data alone obtained during dialysis:

$$FD = 1 - e^{-(0.693/t_{1/2_{\text{on}}})(t)} \quad (33-15)$$

The estimated value of 50% removal is consistent with literature values indicating that 50% to 70% of a dose of gentamicin is removed during a 4-hour dialysis procedure. A limitation of this equation, however, is that it does not consider the redistribution of drug from the tissues back into the plasma following the dialysis procedure.

These data suggest that one-half the dose of gentamicin should be given to G.G. following each dialysis session.

It generally is difficult to calculate an appropriate maintenance dose for patients having hemodialysis that will

maintain peak and trough concentrations similar to patients with normal renal function, in part because of the large variability found in aminoglycoside pharmacokinetic parameters.^{51,52} Sustained plasma concentrations >2 mg/L can increase the risk of toxicity; however, dosing gentamicin to achieve trough concentrations of <2 mg/L may lead to prolonged periods of subtherapeutic concentrations. Therefore, in patients receiving hemodialysis, gentamicin doses are given to achieve a predialysis trough concentration of approximately 3 mg/L. A maintenance gentamicin dose of 1 mg/kg after each dialysis session commonly is used to achieve this desired concentration.

CEFTAZIDIME

6. Why does the dose of ceftazidime in G.G. have to be adjusted because of her hemodialysis when this drug has such a large therapeutic window?

Because only 21% of ceftazidime is protein bound and its Vd is 0.2 L/kg, it should be readily removed by hemodialysis. The mean dialysis clearance of ceftazidime is 55 mL/minute, with 55% of the drug removed during 4 hours of conventional hemodialysis.⁵³ A supplemental dose of ceftazidime should be given to G.G. following each hemodialysis session to maintain a therapeutic concentration. Half of the daily ceftazidime dose should be administered after each dialysis session.

High-Flux Hemodialysis

7. G.G.'s physician is considering changing her from a conventional dialysis system to a high-flux system that uses high efficiency polysulfone membranes. How does the dialyzability of gentamicin and ceftazidime differ with high-flux hemodialysis compared with conventional hemodialysis?

High-flux hemodialysis is more effective than conventional dialysis at removing certain pharmacologic agents (see Chapter 32, Renal Dialysis) because the membranes are more efficient and the blood flow through the dialyzer is increased. Although limited data are available, a greater fraction of drugs, such as aminoglycosides, ceftazidime, and vancomycin, are removed by high-flux versus conventional hemodialysis.^{54,55} Approximately 50% to 70% of gentamicin is removed during a 2.5-hour, high-flux dialysis session.^{56,57} The clearance of ceftazidime by high-flux dialysis is 75 to 240 mL/minute compared with 55 mL/minute for conventional hemodialysis.⁵⁴ Thus, further dosage adjustments for gentamicin and ceftazidime may be necessary if she is converted from conventional hemodialysis to high-flux hemodialysis.

Continuous Venovenous Hemofiltration

8. What changes would be necessary in G.G.'s gentamicin dosing if she were to start a continuous renal replacement therapy such as CVVH?

Because of the continuous nature of CVVH and CAVH, the extent of drug eliminated by continuous renal replacement therapies will differ from intermittent modes such as hemodialysis. The clearance of a drug in a patient receiving CVVH can be described in a fashion similar to Equation 33-12, where Cl_{dial} is replaced with Cl_{cvvh}.

$$Cl_{\text{total}} = Cl + Cl_{\text{cvvh}} \quad (33-16)$$

In G.G., the Cl_{revised} from Equation 33-11 can be used for the plasma clearance (Cl). The clearance by CVVH can be described by Equation 33-17:

$$Cl_{\text{cvvh}} = Fu \times UFR \quad (33-17)$$

where Fu is the fraction of drug unbound, and UFR is the ultrafiltration rate. Gentamicin exhibits low plasma protein binding (Fu = 0.95). Typical ultrafiltration rates for CVVH are approximately 1 L/hour, but can vary.

$$\begin{aligned} Cl_{\text{cvvh}} &= Fu \times UFR \\ &= 0.95 \times 1 \text{ L/hr} \\ &= 0.95 \text{ L/hr} \end{aligned} \quad (33-17A)$$

$$\begin{aligned} Cl_{\text{total}} &= Cl_{\text{revised}} + Cl_{\text{cvvh}} \\ &= 0.82 \text{ L/hr} + 0.95 \text{ L/hr} \\ &= 1.77 \text{ L/hr} \\ &= 29.5 \text{ ml/min} \end{aligned} \quad (33-17B)$$

Because the clearance of gentamicin approximates that of creatinine clearance, G.G.'s total clearance is approximately one-third the normal clearance of 100 mL/minute. Therefore, the gentamicin dose should be approximately one-third of the normal dose. G.G. should be given 1.5 mg/kg/day or 100 mg of gentamicin as a single daily dose (normal dose is ~5 mg/kg/day). Gentamicin trough concentrations should be monitored, and her dose adjusted to maintain a trough concentration of <2 mg/L.

Continuous Ambulatory Peritoneal Dialysis

9. J.J., a 24-year-old man with ESRD, is maintained with CAPD. He presents to the ED with a fever of 38.2°C and complains of severe abdominal pain. He also reports that his peritoneal dialysate has become cloudy over the past few days. All these symptoms are consistent with peritonitis, a frequent complication of CAPD. His culture results reveal *Escherichia coli*, sensitive to gentamicin. How should gentamicin be dosed in this patient?

Management of dialysis-related peritonitis can vary from one institution to another. Antibiotics often are administered intraperitoneally with or without systemic antibiotic therapy. For less severe cases, intraperitoneal (IP) administration is often considered sufficient. With IP administration, the goal is to deliver a concentration of drug similar to the desired plasma concentration for the treatment of systemic infections. Therefore, 8 mg of gentamicin into each liter of dialysate (or 16 mg into a 2-L bag of dialysate) is recommended. Once equilibrium or steady state is achieved, the dialysate concentration will be comparable to the concentration of gentamicin in the plasma. Despite a more rapid transfer of drug into the plasma because of increased permeability of the peritoneal membrane in patients with peritonitis, there will still be a substantial lag time before steady state is reached. For more serious cases of peritonitis, concomitant systemic antibiotics should be given.

10. Is gentamicin eliminated by CAPD?

In general, most drugs are not well removed via CAPD. This is particularly true for drugs that are highly protein bound or for drugs with a large Vd. Gentamicin and other aminoglycosides, on the other hand, are effectively removed by CAPD because

they have low protein binding and a small Vd. It is estimated that 10% to 50% of gentamicin is removed by CAPD.⁵⁸

Acyclovir

Renal Clearance

11. D.M., a 28-year-old man with acquired immune deficiency syndrome (AIDS), presents with a severe herpetic infection requiring intravenous (IV) acyclovir. Because of other complications associated with his human immunodeficiency virus (HIV) infection, D.M. has developed renal insufficiency during his hospital course. His SrCr is 4.5 mg/dL (normal, 0.6–1.4 mg/dL), and his Cl_{Cr} is 20 mL/minute (normal, 80–110 mL/minute). What are important considerations for dosing acyclovir in D.M. now, and if he requires dialysis?

[SI units: SrCr, 397.8 μmol/L (normal, 53.04–123.76); Cl_{Cr}, 0.33 mL/sec (normal, 1.33–1.83)]

Acyclovir is used to prevent or treat a variety of viral infections, such as those caused by herpes simplex and varicella zoster viruses.⁵⁹ Acyclovir is cleared primarily by the kidneys, with approximately 70% to 80% excreted unchanged in the urine. Dosage adjustment is necessary in patients with renal disease.^{16,60} Renal tubular secretion in addition to filtration contributes to the elimination of acyclovir, which explains why the renal clearance of acyclovir is about three times greater than the estimated Cl_{Cr}.

Acyclovir also can precipitate in the renal tubules and exacerbate D.M.'s renal failure. This is more likely to occur when high doses are infused too rapidly to patients with renal dysfunction.⁶⁰ To minimize nephrotoxicity, the patient should be adequately hydrated to maintain good urine flow, and the acyclovir dose should be infused over 1 hour. Nephrotoxicity is usually reversible on discontinuation of the drug or reduction of the dose.

In addition, acyclovir-associated neurotoxicity correlates with elevated plasma concentrations, and further underscores the need for adequate dosage adjustments in patients with renal dysfunction.⁶¹

The clearance of acyclovir correlates with the Cl_{Cr} according to the following relationship:

$$\begin{aligned} \text{Cl}_{\text{acyclovir}} \text{ in mL/min/1.73 m}^2 & \quad (33-18) \\ = (3.4)(\text{Cl}_{\text{Cr}} \text{ in mL/min/1.73 m}^2) + 28.7 \end{aligned}$$

In patients with normal renal function, the clearance of acyclovir ranges from 210 to 330 mL/minute; in patients with ESRD, the clearance is 29 to 34 mL/minute.^{16,60,62} Although this change in clearance primarily results from decreased renal clearance of the drug, nonrenal clearance of acyclovir also decreases in these patients.^{16,62} As a result, the elimination half-life increases significantly from approximately 3 hours in patients with normal kidney function to 20 hours in patients with ESRD. Therefore, doses should be reduced proportionately from a normal daily dose of 15 mg/kg body weight (5 mg/kg given every 8 hours) for serious herpes simplex infections to doses as low as 2.5 mg/kg/day (given as a single daily dose) in patients with ESRD.⁶³ Because D.M. has a Cl_{Cr} of 20 mL/minute and an estimated Cl_{acyclovir} of 97 mL/minute (approximately one-third of normal), a single daily dose of

5 mg/kg (one-third of normal) would be appropriate to treat this infection (see Table 33-2).

Dialysis

Acyclovir is moderately removed by conventional hemodialysis, with plasma concentrations decreasing by 60% after 6 hours of dialysis.⁶⁴ The elimination half-life on and off dialysis is 6 and 20 hours, respectively, whereas the dialysis clearance averages 80 mL/minute. Therefore, a supplemental dose of 2.5 mg/kg following dialysis is recommended to replace the amount of drug removed by hemodialysis. No data are available on the removal of acyclovir by high-flux hemodialysis.

Effect of Renal Dysfunction on Metabolism

12. Does D.M.'s renal dysfunction affect the metabolism of acyclovir? Are there other drugs that are affected similarly?

Approximately 20% of acyclovir is cleared by nonrenal mechanisms.^{16,62} The only significant metabolite that has been isolated is 9-carboxymethoxymethylguanine, which accounts for 9% to 14% of an administered dose. It is believed that this metabolite is a product of hepatic metabolism; however, the kidney may also play an important role.¹⁶ Whether renal dysfunction alters hepatic metabolism or metabolic enzymes are present within the kidney is unclear. Studies have shown that renal tissue contains many of the same metabolic enzymes found in the liver. Mixed-function oxidases have been found in segments of the proximal tubule, whereas other metabolic processes, such as glucuronidation, acetylation, and hydrolysis, also occur within the kidney.^{14,15}

Several studies have examined the effect of renal failure on hepatic metabolic enzyme activity.^{65,66} Most of these investigations were carried out in animals that had diminished microsomal, mitochondrial, and cytosolic enzyme activities. Renal dysfunction substantially alters the nonrenal clearance of certain cephalosporins, such as ceftizoxime and cefotaxime,^{67–69,70} as well as the benzodiazepines, diazepam, and desmethyldiazepam.^{71,72}

Zidovudine (AZT)

Dosage Adjustment

13. D.M. also is being treated with AZT for his HIV disease. Will his AZT doses need to be adjusted?

Zidovudine was the first drug approved for treatment of HIV infection and is still used as part of combination antiretroviral regimens. Because it has potent bone marrow-suppressive effects,⁷³ the dose of AZT may require adjustment based on the patient's clinical response and the development of toxicity.

AZT is metabolized primarily by the liver to the inactive glucuronide metabolite, GAZT, which is eliminated by the kidneys. Only 18% of AZT is eliminated unchanged by the kidneys. Little change in AZT clearance and elimination half-life occurs in patients with renal failure. Two studies report only slight increases in the elimination half-life (from 1.0–1.4 hours, and from 1.4–1.9 hours in patients with renal failure),^{74,75} whereas another case report measured a half-life of 2.9 hours in a single patient with renal impairment.⁷⁶

Although GAZT accumulates in renal disease, this is not clinically important.⁷⁴

Despite little change in AZT plasma levels, patients with renal failure are predisposed to bone marrow suppression because their kidneys produce less erythropoietin. In addition, their white blood cell (WBC) counts are also decreased. Therefore, AZT should be used more cautiously in these patients (see chapter 69, Pharmacotherapy of Human Immunodeficiency Virus Infection).

Hemodialysis

14. Is AZT significantly removed by dialysis?

A number of reports describe the removal of AZT by dialysis.^{74–76} Based on the chemical characteristics, AZT would be expected to be dialyzable: it has a low MW of 267, a relatively small Vd (1–2.2 L/kg), and low protein binding (34%–38%). The dialysis clearance of AZT is minimal, however, when compared with its plasma clearance in patients with renal failure. Clearance by dialysis averages 63 mL/minute compared with a plasma clearance (following oral administration) of approximately 1,200 mL/minute. Little change occurs in the AZT plasma levels during dialysis; however, the elimination of GAZT may be enhanced.⁷⁴

Penicillin

Dosage Adjustment

15. T.H., a 57-year-old, 85-kg man with chronic renal failure secondary to poorly controlled hypertension, presents to the ED with a 24-hour history of fever (39°C), altered mental status, nausea, and vomiting. On physical examination he was found to have nuchal rigidity and a positive Brudzinski sign. Laboratory analysis revealed the following: WBC count, 22,000/mm³ with 89% neutrophils; BUN, 45 mg/dL; and SrCr, 4.4 mg/dL. A lumbar puncture revealed cerebrospinal fluid (CSF) with a WBC count of 2,000/mm³ (90% polymorphonuclear neutrophils), a glucose concentration of 36 mg/dL, and a protein concentration of 280 mg/dL. Gram-positive diplococci were seen on CSF smear. A diagnosis of meningococcal meningitis was made, and potassium penicillin G was ordered. What dose should be used?

[SI units: count, $2.2 \times 10^9/L$ and $0.2 \times 10^9/L$, respectively; BUN, 16.065 mmol/L urea; SrCr, 388.96 $\mu\text{mol/L}$; glucose, 1.998 mmol/L; protein, 2.8 g/L]

Meningococcal meningitis can be treated with 20 to 24 MU (million units) of IV penicillin G in patients with normal renal function. As with many β -lactam antibiotics, penicillin is primarily excreted unchanged in the urine with little or no evidence of hepatic metabolism. Thus, the elimination half-life, which averages <1 hour in patients with normal kidney function, increases to 4 to 10 hours in patients with ESRD.^{77–79}

Methods to modify the dose of penicillin in renal insufficiency have been developed by numerous investigators. The clearance of penicillin correlates closely to Cl_{Cr} according to the following equation⁷⁹:

$$\text{Cl}_{\text{pen}} \text{ in mL/min} = 35.5 + 3.35 \text{ Cl}_{\text{Cr}} \text{ in mL/min} \quad (33-19)$$

This correlation is based on data from patients with varying degrees of renal impairment.

An equation to estimate the total daily dose for patients with renal failure to achieve serum levels similar to those produced by high-dose penicillin (20–24 MU/day) in patients with normal renal function has been developed for patients with an estimated Cl_{Cr} of <40 mL/minute. The dose for T.H. should be given in equal divided doses at 6- or 8-hour intervals:

$$\text{Dose}_{\text{pen}} \text{ in MU/day} = 3.2 + (\text{Cl}_{\text{Cr}}/7) \quad (33-20)$$

Using the Cockcroft and Gault method, T.H.'s Cl_{Cr} is approximately 20 mL/minute. Therefore, his daily dose of penicillin should be 6 MU. A dose of 2 MU every 8 hours would be appropriate for T.H.

As is true for many agents, these dosing recommendations are empiric and based on pharmacokinetic principles for patients in renal failure. These recommendations have not been subjected to carefully designed clinical trials that establish therapeutic efficacy. Therefore, other factors that can influence host response also should be considered when designing an individualized therapeutic regimen. These include the host's immune status, the presence of other medical conditions, microbial sensitivity patterns, and changes in pharmacokinetic disposition (e.g., concomitant liver disease, fluid overload, dehydration).

Penicillin-Induced Neurotoxicity

16. The medical intern fails to consider T.H.'s renal dysfunction when he prescribes penicillin, and begins a dose of 4 MU Q 4 hours. Four days later, T.H. is encephalopathic (confused, disoriented, and difficult to arouse), with some twitching that is noted on the right side of his face. Are these toxic symptoms associated with high-dose penicillin? What predisposing factors may contribute to this neurotoxicity?

T.H. is experiencing signs of neurotoxicity that are consistent with elevated penicillin concentrations in the plasma and CSF. Penicillin usually produces few serious adverse effects. When large doses are used in patients with renal impairment, toxic symptoms such as those exhibited by T.H. can result. Signs and symptoms of penicillin-induced CNS toxicity include myoclonus, complex or generalized seizure activity, and encephalopathy progressing to coma.^{35,36}

PREDISPOSING FACTORS

T.H.'s renal dysfunction predisposes him to penicillin-induced neurotoxicity. In a review of 46 cases of penicillin-associated neurotoxicity, decreased renal function was present in 35 patients.³⁶ Several possible explanations for this observation exist. First, penicillin accumulates in patients with renal failure. Second, the binding of acidic drugs (such as penicillin) to albumin is decreased, resulting in an increased fraction of "free" or active drug that can pass into the CSF. Third, an alteration in the blood–brain barrier has been observed in uremic patients, which can lead to further increases in CSF drug levels.³⁵ Finally, high plasma concentrations of penicillin *per se* may contribute to changes in the blood–brain barrier permeability of this drug.³⁵ All these factors, together with the increased sensitivity of patients with renal failure to centrally acting agents, make CNS toxicity more likely. As with penicillin, the carbapenem antibiotic combination, imipenem–cilastatin, is associated with a higher incidence of seizures in patients with renal dysfunction.^{80,81}

Antipseudomonal Penicillins

Piperacillin

17. M.H., a 44-year-old, 70-kg woman with acute nonlymphocytic leukemia, is admitted to the oncology ward for placement of a Hickman catheter for her chemotherapy. Seven days following treatment with cytarabine (Ara-C) and daunorubicin, her temperature spiked to 39.4°C. Other physical findings consistent with sepsis included a BP of 109/70 mm Hg, pulse rate of 102 beats/min, and a respiratory rate of 27 breaths/minute. M.H. is neutropenic with a WBC count of 1,400/mm³ (3% polymorphonuclear leukocytes, 70% lymphocytes, and 22% monocytes). Her platelet count is 16,000/mm³. M.H. also has renal dysfunction as reflected by an SrCr and BUN of 2.6 and 38 mg/dL, respectively. Empiric therapy for sepsis is started with tobramycin, piperacillin/tazobactam, and vancomycin. How should piperacillin/tazobactam be dosed in M.H.?

[SI units: platelet count, 16 × 10⁹/L; SrCr, 229.84 μmol/L; BUN, 13.566 mmol/L urea]

Piperacillin is an antipseudomonal penicillin that is often used with an aminoglycoside to treat serious infections caused by gram-negative organisms.⁸² Piperacillin is commonly given as a combination with tazobactam, a β-lactamase inhibitor.⁸³ In patients with normal renal function, piperacillin is primarily excreted unchanged by the kidney with a clearance of 2.6 mL/minute/kg, and a half-life of approximately 1 hour.^{84,85} Doses of piperacillin/tazobactam can be as high as 4.5 g every 6 hours for the treatment of serious *Pseudomonas* sp. infections. In patients with ESRD, mean piperacillin clearance and half-life values are 0.7 mL/minute/kg and 3.3 hours, respectively.^{84–86} Although these parameters are significantly different, they are less than those expected for a drug primarily cleared by the kidneys, suggesting that some other compensatory mechanism for elimination must be present. Piperacillin is partially cleared by biliary excretion, a route of elimination that is increased in patients with renal failure.^{86,87} Therefore, aggressive dosage reductions in M.H. are unnecessary. An appropriate dose of piperacillin/tazobactam for M.H. would be 3.375 g every 8 hours (Table 33-2).

Vancomycin

Pharmacokinetic Dosage Calculations

18. In addition to the aforementioned regimen, vancomycin therapy is initiated at 500 mg Q 24 hr to cover the possibility of an infection resistant to antistaphylococcal penicillins, such as nafcillin. Is this an appropriate dosing regimen for M.H.?

Vancomycin is a bactericidal antibiotic with excellent activity against most gram-positive organisms such as methicillin-resistant *Staphylococcus aureus* (MRSA) and *Streptococcus* sp., including some isolates of *Enterococcus faecalis*. It is used empirically in the febrile neutropenic patient, because the incidence of infection secondary to resistant organisms is much greater in this patient population. However, cases of vancomycin-resistant enterococci (VRE) have emerged at rates as high as 50%, raising concern and reducing its empiric use.⁸⁸

Vancomycin is poorly absorbed by the oral route and must be administered intravenously when used to treat systemic in-

fections. As with many other antibiotics, vancomycin primarily is cleared by the kidneys.⁸⁹ Significant toxicities have been associated with elevated serum concentrations, making careful dosing modification in renal failure necessary.⁹⁰

As with the aminoglycosides, pharmacokinetic calculations can be used to individualize a dosing regimen to produce the desired peak and trough plasma levels. Unlike the aminoglycosides, the therapeutic range for vancomycin is less clear. Normally, doses are designed to achieve peak levels of 25 to 40 mg/L and trough levels of 10 to 15 mg/L.^{91,92} The correlation between vancomycin toxicity (e.g., ototoxicity) and plasma levels is not well defined. Some clinicians have suggested, however, that plasma levels ≥ 80 mg/L may correlate with auditory dysfunction.

Vancomycin has an elimination half-life of 3 to 9 hours in patients with normal renal function.⁹³ This increases to 129 to 189 hours in patients with ESRD.^{94–96} Using pharmacokinetic principles and considering that the plasma clearance of vancomycin is approximately 60% to 70% of Cl_{Cr}⁹¹ and the Vd averages 0.7 L/kg,^{91,93,97} the estimated Vd_{vanco} and Cl_{vanco} can be calculated using the following equation:

$$Cl_{Cr} = 30.5 \text{ mL/min (calculated from Eq. 34-3)}$$

$$\begin{aligned} Cl_{vanco} &= (0.65)(Cl_{Cr}) \\ &= (0.65)(30.5 \text{ mL/min}) \\ &= 19.8 \text{ mL/min or rounded off to 1.2 L/hr} \end{aligned} \quad (33-21)$$

$$\begin{aligned} Vd_{vanco} &= (0.7 \text{ L/kg})(\text{Body Weight}) \\ &= (0.7 \text{ L/kg})(70 \text{ kg}) \\ &= 49 \text{ L} \end{aligned} \quad (33-22)$$

Based on estimated values for Cl_{vanco} and Vd_{vanco}, the elimination rate constant can be calculated using the following equation:

$$\begin{aligned} Kd &= \frac{Cl_{vanco}}{Vd_{vanco}} \\ &= \frac{1.2 \text{ L/hr}}{49 \text{ L}} \\ &= 0.024 \text{ hr}^{-1} \end{aligned} \quad (33-23)$$

$$\begin{aligned} C_{p\text{peak}} &= \frac{\text{Dose}}{1 - e^{-Kd\tau}} \\ &= \frac{500 \text{ mg}}{1 - e^{-(0.024 \text{ hr}^{-1})(24 \text{ hr})}} \\ &= 23 \text{ mg/L} \end{aligned} \quad (33-24)$$

$$\begin{aligned} C_{p\text{trough}} &= C_{p\text{peak}}(e^{-Kd\tau}) \\ &= 23 \text{ mg/L}(e^{-(0.024/\text{hr}^{-1})(24 \text{ hr})}) \\ &= 13 \text{ mg/L} \end{aligned} \quad (33-25)$$

Because M.H.'s estimated peak concentration is <40 mg/L and her trough falls within the range of 10 to 15 mg/L, the starting dose of 500 mg every 24 hours is appropriate for M.H.

Routine monitoring of plasma vancomycin concentrations in patients with normal renal function is controversial because

the likelihood that toxicity will develop in this group is relatively low. However, in patients with renal failure, such as M.H., it is advisable to measure vancomycin levels several days after initiation of therapy to ensure that they are within an acceptable range.^{93,95,96,98} This is prudent if an extended course of therapy is anticipated. Vancomycin is usually infused over 60 minutes. Because there is a distribution phase, plasma samples should be drawn at least 30 minutes after the end of the infusion.

Hemodialysis

19. M.H.'s renal function begins to deteriorate, however, so that she requires hemodialysis. How should her regimen now be altered?

Patients with ESRD may have measurable vancomycin levels for up to 3 weeks following a single dose despite conventional hemodialysis.⁹⁶ This suggests that the ability of these patients to eliminate vancomycin is minimal and that little of the drug is removed by conventional hemodialysis. The elimination half-life for vancomycin in these individuals averages 5 to 7 days, which is consistent with a residual vancomycin clearance of 3 to 4 mL/minute.^{94–96} Only about 5% of vancomycin is metabolized hepatically in patients with normal renal function.

Conventional hemodialysis removes about 7% of vancomycin during a typical 4-hour dialysis run.⁹⁹ The elimination half-life on and off dialysis, and plasma levels of the drug before and after hemodialysis do not differ significantly. The poor removal of vancomycin by conventional hemodialysis is owing to its large MW of 1,400.

Patients receiving conventional hemodialysis are typically given a single, 1-g dose every 7 to 10 days.^{93,96,98} Based on M.H.'s estimated Vd of 49 L, this dose will produce an initial peak plasma level of ~20 mg/L. If vancomycin is administered weekly, steady-state peak and trough levels of 40 and 16 mg/L, respectively, would be predicted.

Vancomycin is removed to a greater extent by high-flux hemodialysis than by conventional hemodialysis. As a result, more frequent dosing is necessary to maintain therapeutic vancomycin concentrations. High-flux dialysis clearance of vancomycin using the Fresenius polysulfone dialyzer is 45 to 160 mL/minute and varies with membrane surface area.^{55,100} Up to 50% of a dose of vancomycin is removed over 4 hours by high-flux hemodialysis compared with 6.9% using conventional dialysis. A rebound phenomenon following dialysis suggests that the total amount of drug removed may be less than initially reported.^{101,102} In any case, the efficiency of high-flux procedures in removing vancomycin is greater than that of conventional dialysis. Therefore, plasma levels should be monitored carefully in these patients, and the necessity for postdialysis replacement doses of around 500 mg (~10–15 mg/kg) should be anticipated.

Amphotericin

Dosing

20. M.H. continues to be febrile despite her triple antimicrobial regimen. Amphotericin therapy is started empirically for a potential fungal infection. In addition, pentamidine is begun to cover

Pneumocystis carinii pneumonia. How should amphotericin be administered in patients such as M.H. with renal dysfunction?

Amphotericin is an antifungal agent used to treat serious infections, such as invasive Aspergillosis and cryptococcal meningitis. The exact mechanism of elimination for this drug is unclear, but it may involve hepatic metabolism or inactivation in body tissues. Small amounts of amphotericin are gradually excreted in the urine for several weeks following its discontinuation.¹⁰³ This slow elimination may be owing to the extensive distribution of amphotericin into peripheral tissue and its large Vd (4 L/kg).^{103,104} The drug appears to bind to cholesterol-containing cytoplasmic membranes of various tissues, resulting in a very long elimination half-life of 15 days. Pharmacokinetic studies report no significant change in the disposition of amphotericin in patients with renal or liver disease. Therefore, no dosage adjustments are required in patients with renal dysfunction.

Amphotericin is associated with acute tubular necrosis (ATN), which is believed to be dose dependent.^{105–107} To prevent exacerbation of nephrotoxicity, lower doses often are administered to patients with decreased renal function. Administration of amphotericin every other day often is suggested for patients with renal failure. In addition to conventional amphotericin, a liposomal (liposomal amphotericin) or lipid-based formulation is available.¹⁸ Lipid-based formulations have reduced distribution to the kidneys, and they are associated with a lower incidence of nephrotoxicity.¹⁰⁸ Triazole antifungal agents (e.g. fluconazole, voriconazole) or an echinocandin class (e.g. anidulafungin, caspofungin, micafungin) are alternative choices that are not potentially nephrotoxic, nor do they need to be dose adjusted in the setting of renal dysfunction (with the exception of fluconazole). The oral formulation of voriconazole should be used in renal dysfunction or for patients with a $Cl_{Cr} < 50$ mL/minute to prevent accumulation of SBECD (sulfphobutylether beta cyclodextrin), the solvent vehicle found in the IV formulation.¹⁰⁹

Hemodialysis

Amphotericin is not removed significantly by hemodialysis because it is a very large compound and distributes widely into peripheral tissues. Therefore, little drug remains in the plasma to be removed by dialysis. Studies have found that <5% of amphotericin is removed during a 4-hour conventional hemodialysis period.

Phenytoin

Protein Binding

21. R.S., a 24-year-old man with ESRD from rapidly progressive glomerulonephritis, is treated by hemodialysis three times weekly. He has a 7-year history of generalized tonic-clonic seizures and has been treated with phenytoin. He presents to the ED after having had a seizure lasting about 5 minutes. His mother states that he ran out of phenytoin 4 weeks ago. Because his plasma phenytoin concentration on admission was <2.5 mg/L, R.S. is given an IV loading dose of phenytoin: 15 mg/kg over 30 minutes. Additional admission laboratory work includes the following: SrCr, 8.6 mg/dL (normal, 0.6–1.4); BUN, 110 mg/dL (normal, 7–20); potassium, 5.4 mEq/L; calcium, 9 mg/dL; and albumin,

2.9 g/dL. Eight hours after administration of phenytoin, his level is 5 mg/L. Is this level subtherapeutic?

[SI units: phenytoin, <10 and 19.82 $\mu\text{mol/L}$, respectively; SrCr, 760.24 $\mu\text{mol/L}$ (normal, 53.04–123.76); BUN, 39.27 mmol/L urea (normal, 2.5–7.14); potassium, 5.4 mmol/L; calcium, 2.24 mmol/L; albumin, 29 g/L]

R.S. has severe renal disease, which will affect how the total (bound plus free) phenytoin concentrations are measured. Decreased plasma protein binding will result in lower measured total phenytoin concentrations, and the calculated apparent volume of distribution may increase. In patients with normal renal function, approximately 90% of the measured phenytoin is bound to albumin, and 10% is free. The free fraction of phenytoin is increased to about 20% to 25% in patients with uremia.^{9,110–114} Because the free fraction for phenytoin is increased in patients with uremia, lower plasma concentrations will produce therapeutic effects that will be equivalent to those produced by higher phenytoin concentrations in patients with normal renal function.^{6,115} Phenytoin is an acidic drug that is bound primarily to albumin. A number of mechanisms have been proposed that account for the decreased binding, including (a) decreased albumin concentration, (b) accumulation of uremic byproducts that displace acidic drugs from their binding sites, and (c) alteration in the conformation or structure of albumin in uremic patients, resulting in a reduced number of binding sites or decreased affinity for drugs (see Chapter 54, Seizure Disorders). Other acidic drugs with altered protein binding in renal disease are listed in Table 33-1.

Figure 33-4 illustrates changes in phenytoin levels when uremic and nonuremic patients are given equivalent doses.¹¹⁶

The following equation should be used to correct for R.S.'s altered binding owing to his renal dysfunction and hypoalbuminemia.¹¹³

$$C_{p\text{Normal Binding}} = \frac{C_p'}{(0.48)(1 - \alpha) \left(\frac{P'}{P_{NL}} \right) + \alpha} \quad (33-26)$$

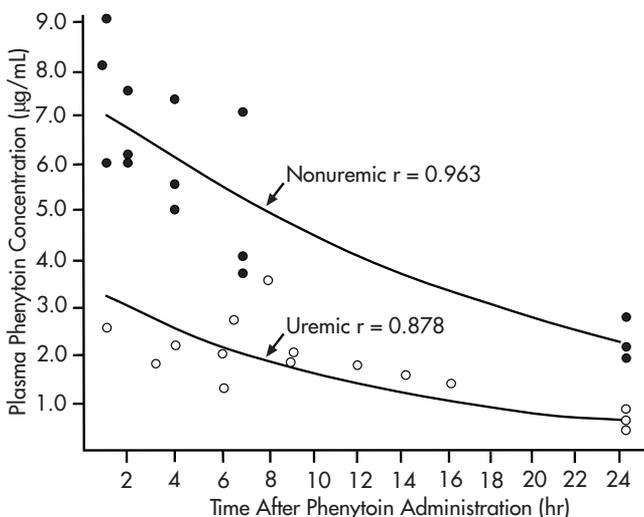

FIGURE 33-4 Plasma phenytoin concentrations in uremic (o) and nonuremic (•) patients following 250 mg of intravenous (IV) phenytoin. (From Letteri JM, et al. Diphenylhydantoin metabolism in uremia. *N Engl J Med* 1971;285:648, with permission.¹¹⁶)

where C_p' is the measured plasma concentration reported by the laboratory, and $C_{p\text{Normal Binding}}$ is the corrected plasma concentration that would be seen if the patient had normal renal function and normal albumin. α is the normal free fraction (0.1), P' is the patient's serum albumin, and P_{NL} is normal albumin (4.4 g/dL). The factor 0.48 was derived from patients on hemodialysis and represents the decreased affinity of phenytoin for albumin.

For R.S., 5 mg/L is comparable to 12 mg/L in a patient without renal failure. Because this falls within the phenytoin's therapeutic range of 10 to 20 mg/L, his measured level is not subtherapeutic.

The factor 0.48 should be used only to estimate changes in protein binding for patients with ESRD receiving hemodialysis. Data for patients with moderate renal disease are limited, and it is unclear what changes exist in the binding of phenytoin to albumin.¹¹¹ For patients with normal or moderate renal impairment, the following equation should be used only if the serum albumin is low; the factor 0.48 should be omitted:

$$C_{p\text{Normal Binding}} = \frac{C_p'}{(1 - \alpha) \left(\frac{P'}{P_{NL}} \right) + \alpha} \quad (33-27)$$

EFFECT OF RENAL FAILURE ON METABOLIZED DRUGS

Meperidine

22. F.G., a 56-year-old woman, is admitted for a cervical laminectomy. She has a history of chronic renal insufficiency (Cl_{Cr} = 20 mL/minute) and arrhythmias that are treated with procainamide. Her admission laboratory values are as follows: SrCr, 4.4 mg/dL (normal, 0.6–1.3 mg/dL); BUN, 66 mg/dL (normal, 7–20 mg/dL); Hct, 34%; and Hgb, 12.6 g/dL.

Following surgery, she complains of severe pain and is treated with meperidine 50 to 100 mg IM Q 3 to 4 hr. Three days postoperatively, F.G. experiences a generalized tonic-clonic seizure. She has no history of seizures. What might be responsible for this sudden event?

[SI units: SrCr, 388.96 $\mu\text{mol/L}$ (normal, 53–114.92); BUN, 23.6 mmol/L urea (normal, 2.5–7.14); Hct, 0.34 l; Hgb, 126 g/L]

Meperidine is a narcotic analgesic commonly used to control acute pain. It is metabolized hepatically via *N*-demethylation to normeperidine, a metabolite known to accumulate in renal insufficiency.^{12,117} Although meperidine has both CNS excitatory and depressant properties, normeperidine is a very potent CNS stimulant that can cause seizures in patients with renal failure who are receiving multiple doses of the parent drug.¹¹⁸ In a study of 67 cancer patients treated with meperidine, 48 developed neurologic adverse effects; 14 of these 48 patients had renal dysfunction defined as a BUN >20 mg/dL.¹¹⁸ Because the renal clearance of normeperidine correlates significantly with Cl_{Cr} , renal dysfunction can lead to its accumulation, resulting in neurologic toxicity. In another study, the normeperidine-to-meperidine plasma concentration ratio was consistently higher in patients with renal failure, averaging 2.0 compared with a mean of 0.6 for patients with good renal function.¹¹⁸ Table 33-4 lists examples of additional drugs

Table 33-4 Drugs With Active or Toxic Metabolites Excreted by the Kidney

| Drug | Metabolite |
|----------------------|--|
| Acetohexamide | Hydroxyhexamide |
| Allopurinol | Oxypurinol |
| Cefotaxime | Desacetylcefotaxime |
| Chlorpropamide | Hydroxy metabolites |
| Clofibrate | Chlorphenoxyisobutyrate |
| Cyclophosphamide | 4-Ketocyclophosphamide |
| Daunorubicin | Daunorubicinol |
| Meperidine | Normeperidine |
| Methylodopa | Methyl-o-sulfate- α -methylodopamine |
| Midazolam | Alpha-hydroxymidazolam |
| Morphine | Morphine-3-glucuronide Morphine-6-glucuronide |
| Phenylbutazone | Oxyphenbutazone |
| Primidone | Phenobarbital |
| Procainamide | <i>N</i> -acetylprocainamide (NAPA) |
| Propoxyphene | Norpropoxyphene |
| Rifampicin | Desacetylated metabolites |
| Sodium nitroprusside | Thiocyanate |
| Sulfonamides | Acetylated metabolites |

that have active or toxic metabolites that may accumulate in renal disease.

Narcotic Analgesics

23. Are the pharmacokinetics or pharmacodynamics of other narcotic analgesics altered in patients with renal insufficiency?

Morphine

The pharmacokinetic disposition of morphine does not appear to be altered in patients with renal failure¹¹⁹; however, its active metabolite, morphine-6-glucuronide as well as its principal metabolite, morphine-3-glucuronide, do accumulate in renal disease. The elimination half-life of morphine-6-glucuronide increases from 3 to 4 hours in normal subjects to 89 to 136 hours in subjects with renal failure.¹²⁰ This metabolite penetrates the blood–brain barrier more readily, has a greater affinity for CNS receptors, and has analgesic activity that is 3.7 times greater than morphine.¹²¹ Therefore, accumulation of morphine-6-glucuronide may be responsible for the morphine-induced narcosis reported in patients with severe renal disease.^{29,30}

Codeine

Other analgesics that have been associated with CNS toxicity in patients with renal failure include codeine, propoxyphene, and dihydrocodeine.¹¹⁷ The disposition of orally administered codeine does not appear to be altered in renal failure; however, two cases of codeine-induced narcosis have been reported.¹²² Although the dose of codeine did not exceed 120 mg/day, CNS and respiratory depression persisted for up to 4 days after discontinuation of codeine, and naloxone administration.

Guay et al.¹²³ reported a prolonged terminal elimination half-life for intravenous codeine in patients on chronic hemodialysis of 18.7 ± 9 hours versus 4 ± 0.6 hours in

subjects with normal renal function. Although the total body clearance was not significantly decreased, the Vd for codeine was approximately twice as large in the dialysis group. The clinical significance of these alterations is not known.

Propoxyphene

Propoxyphene and its metabolite, norpropoxyphene accumulate in renal insufficiency. Norpropoxyphene is eliminated by the kidneys, and its elimination half-life is prolonged in patients with renal failure; however, the half-life of propoxyphene remains unchanged. Accumulation of propoxyphene is thought to result from decreased first-pass metabolism or systemic clearance. Similar pharmacokinetic changes have been observed in patients experiencing dihydrocodeine-associated narcosis.^{124,125} The accumulation of these compounds may be associated with CNS and cardiac toxicities in subjects with renal failure, especially after multiple doses.¹²¹ Therefore, these drugs also should be avoided in patients with renal failure.

Hydromorphone

Hydromorphone is metabolized in the liver to hydromorphone-3-glucuronide, dihydroisomorphone, dihydromorphine, and small amounts of hydromorphone-3-sulfate, norhydromorphone, and nordihydroisomorphone.¹²⁶ All metabolites that are eliminated are excreted by the kidneys. Hydromorphone can be used in patients with renal failure, however, smaller initial doses may be warranted.¹²⁷

Procainamide

24. F.G.'s procainamide level is 9 mg/L (normal, 4–8 mg/L) and her *N*-acetylprocainamide (NAPA) level is 34 mg/L (normal, 10–20 mg/L). How is the disposition of procainamide affected in patients with renal disease?

[SI units: procainamide level 38.24 mmol/L (normal, 17–34)]

The pharmacokinetics of procainamide in patients with renal insufficiency is complex. Of the parent drug, 50% to 70% is excreted unchanged in the urine, and it can accumulate in patients with renal disease because plasma clearance values are reduced by as much as 70%.¹²⁸ Procainamide (PA) is also partially acetylated to NAPA, which has antiarrhythmic properties similar to procainamide and is primarily excreted by the kidneys.^{129,130} Figure 33-5 summarizes the elimination of procainamide and NAPA. The half-life of NAPA is longer, especially in patients with renal impairment, increasing from 6 hours in control subjects to as long as 40 hours in patients with ESRD.^{128,129} Because significant cardiac toxicity has occurred in some patients with NAPA levels >30 mg/L, plasma level monitoring of both NAPA and procainamide is recommended. When procainamide is used in patients with renal failure, appropriate dosage reduction of procainamide may be necessary. It also is important to realize that the time required to reach steady state for NAPA in patients with renal failure may be as long as 5 days. Therefore, plasma levels measured early in therapy must be interpreted carefully, because these concentrations may be considerably lower than those that will be achieved under steady-state conditions.

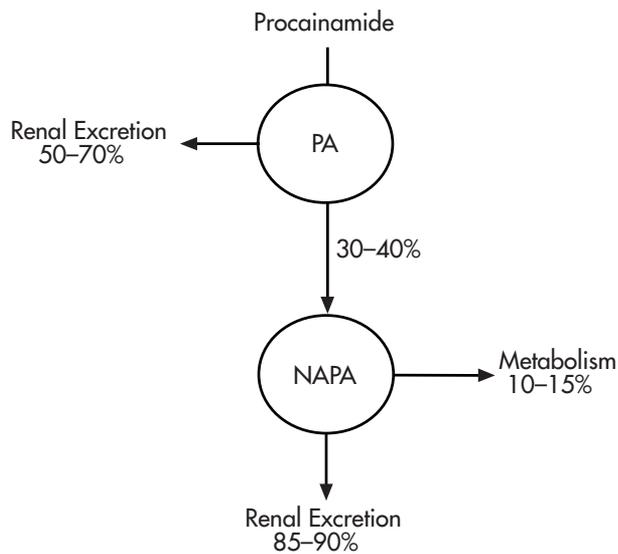

FIGURE 33-5 Elimination of procainamide (PA) and *N*-acetylprocainamide (NAPA) in subjects with normal renal and liver function.

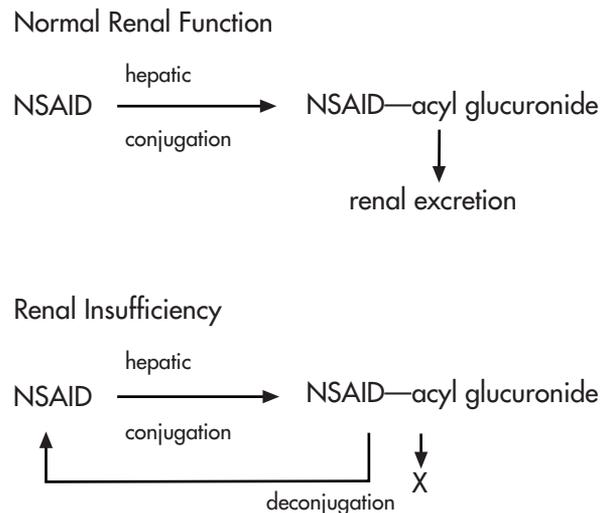

FIGURE 33-6 Schematic representation of pathways of elimination of acyl-glucuronide metabolites or arylpropionic nonsteroidal anti-inflammatory drugs. (From Brater DC. Renal disease. In: Williams R, et al., eds. *Rational Therapeutics*. New York: Marcel Dekker; 1990, with permission.¹⁵⁴ Copyright © 2001 Massachusetts Medical Society. All rights reserved.)

Nonsteroidal Anti-Inflammatory Drugs

25. F.G.'s physician would like to manage her pain with ibuprofen 400 mg Q 6 hours PRN. What factors should be considered when treating renal failure patients with nonsteroidal anti-inflammatory drugs (NSAID)?

Because NSAID have been associated with nephrotoxicity, they should be used cautiously in patients with renal disease.¹³¹ The clinical features of nephrotoxicity are variable, and can present acutely or chronically with or without oliguria. Pathologic changes caused by these drugs also are variable and range from interstitial nephritis to acute tubular necrosis.^{131,132} Mechanisms for NSAID-induced nephrotoxicity include inhibition of renal prostaglandin synthesis, leading to altered renal blood flow and ischemia.^{133,134} Renal impairment may more likely occur in patients who have abnormally high plasma levels of vasoconstrictor hormones (e.g., angiotensin II and catecholamines).¹³² Because a compensatory increase in the synthesis of vasodilatory renal prostaglandins to counteract the vasoconstriction occurs, blockade of this increase by an NSAID can lead to ischemic changes and acute renal failure (see Chapter 30, Acute Renal Failure).

A second proposed mechanism involves an autoimmune response that is triggered by changes in cell-mediated immunity.^{135,136} These changes are caused by similar alterations in prostaglandin synthesis by NSAID. Although data are limited, sulindac is an NSAID believed to have renal-sparing effects. Unlike other NSAID, studies suggest that this drug does not inhibit synthesis of renal prostaglandins.¹³⁷

The NSAID accumulate in renal insufficiency, an interesting finding because renal elimination is negligible for these drugs.¹³⁸ These compounds primarily are metabolized to an acyl-glucuronide metabolite that accumulates in patients with renal failure. This metabolite is unstable, and can deconjugate, leading to increased levels of parent drug. This phenomenon is represented in Figure 33-6. Of additional impor-

tance is fact that many of the NSAID are available as racemic mixtures, with the pharmacologic activity residing primarily with the S-enantiomer. The R-enantiomer can convert selectively to the S-enantiomer, particularly at elevated levels, leading to even greater pharmacologic activity in patients with renal dysfunction.^{139,140} This reconversion phenomenon also has been reported for clofibrac acid.¹⁴¹

Enoxaparin

26. Because F.G. is not ambulating well after her surgery, her physician would like to initiate deep vein thrombosis prophylaxis with enoxaparin. Are there any dosing considerations for enoxaparin in this patient?

Enoxaparin is a low-molecular weight heparin (LMWH) that is used to prevent and treat various thromboembolic disorders, such as deep venous thrombosis, unstable angina, and non-Q-wave myocardial infarction. The kidneys play a major role in the clearance of enoxaparin,¹⁴² and a higher incidence of bleeding complications is associated with the use of enoxaparin in patients with renal dysfunction.¹⁴³ The elimination half-life of enoxaparin is prolonged in patients with ESRD, although the other pharmacokinetic parameters are similar to those in healthy subjects.^{144,145} The increased incidence of bleeding complications cannot be completely attributed to pharmacokinetic changes, but may also be related to the effects of enoxaparin on anti-factor IIa and antithrombin III, as well as the effects of uremia on hemostasis.¹⁴⁶

Enoxaparin should be used cautiously in patients with a Cl_{Cr} < 30 mL/minute. Although monitoring the anticoagulant effect by anti-Xa activity is not necessary in clinically stable patients, it may be warranted in patients with renal dysfunction as well as those who have other factors that may increase the risk of bleeding complications.

Direct Thrombin Inhibitors

27. A.H. is a 55-year-old woman with a history of chronic renal failure (SrCr 3.7) who is diagnosed with a pulmonary embolus. While being administered anticoagulation with a heparin infusion, her platelet count drops from a baseline of $135 \times 10^3 / \text{mm}^3$ to $40 \times 10^3 / \text{mm}^3$. A positive heparin-platelet factor 4 antibody result confirms the diagnosis of heparin-induced thrombocytopenia. What options are available for the therapeutic anticoagulation of A.H. in the setting of heparin-induced thrombocytopenia?

Argatroban and lepirudin are direct thrombin inhibitors that are U.S. Food and Drug Administration (FDA) approved for the management of heparin-induced thrombocytopenia.¹⁴⁷ Lepirudin is a recombinant hirudin that inhibits the catalytic site of thrombin. The primary route of elimination of lepirudin is by the kidneys, with about 35% excreted unchanged in the urine. The dose of lepirudin should be reduced in the setting of renal dysfunction, and its use should be avoided when the creatinine clearance is $< 15 \text{ mL/minute}$.¹⁴⁸ Argatroban is primarily removed by the liver, with about 15% eliminated unchanged by the kidneys. Argatroban is preferred in patients with renal

dysfunction.^{149,150} The dose of argatroban, however, needs to be adjusted in patients with hepatic dysfunction.¹⁵¹

SUMMARY

The kidneys play a vital role in maintaining homeostasis by regulating the excretion of water, electrolytes, and metabolic byproducts. In addition, the kidneys are the primary route of elimination for many drugs. Pharmacokinetic changes, such as altered bioavailability, protein binding, drug distribution, and elimination, can occur with many drugs in patients with renal failure. Pharmacodynamic changes, such as altered sensitivity or response to medications, can also occur in this patient population. Renal replacement therapies, such as hemodialysis, continuous ambulatory peritoneal dialysis, and continuous arteriovenous hemofiltration, will aid both in the removal of fluid, electrolytes, and metabolic byproducts in drugs as well. Data from clinical trials provide valuable information about the disposition of drugs in patients with renal failure. Pharmacokinetic principles should be applied when appropriate to determine the optimal dose of drugs for patients with renal failure.

 Pre-emptive Therapy 34-35

Solid organ transplantation is a well accepted therapeutic option for patients with end-stage kidney, liver, heart, and lung disease. For many of these patients, it is the only option. One-year patient survival for these major organs is between 85%

and 98%. One-year graft survival approaches these figures as well.¹ Pancreas or combined pancreas–kidney transplantation is available as a treatment for diabetic patients with end-stage renal failure. Intestinal transplantation is performed

but in a limited number of patients. Pediatric and elderly patients are transplant candidates, increasing the pool of potential recipients. Surgical techniques involving multiorgan transplantation (e.g., heart with lung, liver, kidney), pancreatic islet cell and liver cell transplantation, intestinal transplantation, living-related and unrelated and segmental human organ transplantation (e.g., kidney, liver, lung, pancreas), domino heart and heart–lung transplantation, along with improvements in mechanical assist devices (e.g., for heart transplant candidates), have made the transplantation of organs an increasingly viable treatment option. Research continues in overcoming the immunologic barriers associated with xenotransplantation (animal to human).

Despite these approaches, many more patients are in need of transplantation than there are organs available. In 2005, about 27,000 organ transplants were performed, whereas 90,000 people were waiting for organs. Consequently, a significant number of candidates die while waiting for a transplant.¹

During the 1960s, drugs such as azathioprine, prednisone, antilymphocyte serum, and antilymphocyte globulin (ALG) made possible the success of kidney transplantation. In the late 1970s, the introduction of cyclosporine created a new era in solid organ transplantation, and in the 1980s the first monoclonal antibody approved for human use, OKT3, was introduced.

Since the mid-1990s a number of new agents have been approved. These include tacrolimus, mycophenolate mofetil, mycophenolate sodium, sirolimus (formerly rapamycin); monoclonal antibodies, such as daclizumab and basiliximab; and a polyclonal antibody, anti-thymocyte globulin (rabbit). More recently, several agents, such as intravenous immunoglobulins (IVIG), alemtuzumab, and rituximab have also been incorporated into transplant protocols. Several new agents are undergoing investigation. These provide more individualized, specific, and selective therapies for solid organ transplant recipients.

Although transplantation has had a significant positive impact on the quality of life in most patients with end-stage disease, issues such as retransplantation because of graft failure or recurrence of disease, donation source (living-related and unrelated-neonatal organs, animal organs), and costs to individuals, insurers, and society continue to be discussed vigorously. Costs during the initial transplantation period range from \$30,000 for kidney transplants up to \$250,000 for heart, liver, or lung transplants. In addition, routine follow-up monitoring and drug therapy for the first year can cost \$5,000 to \$60,000. The ability of transplant recipients, particularly those who are years out from their transplant, to pay for their medications is a major issue. Also, the cost-effectiveness and adverse effects of new immunosuppressive agents are important issues.

The goal of immunosuppressive therapy is to prevent organ rejection, prolong graft and patient survival, and improve quality of life. Short-term (i.e., 1–2-year) survival after transplantation has improved dramatically. Long-term survival also has improved, but not to the same degree.² The current immunosuppressive regimens have not produced a permanent state of tolerance (i.e., when the transplanted organ is seen as “self”). Limited data suggest that some selected patients may not require lifetime immunosuppression; these are in a minority, and more definitive studies must be done. As patients live longer after transplantation, the focus of therapy has shifted toward survival and management of long-term complications. Current

immunosuppressive drug therapies are associated with significant long-term complications. These include nephrotoxicity, hypertension, hyperlipidemia, osteoporosis, and diabetes, as well as graft loss secondary to infection, malignancy, recurrence of primary disease, and nonadherence. Although rates of acute rejection are significantly lower, this remains a problem, along with chronic rejection. The search for safer and more effective immunosuppressive regimens continues, along with a better understanding of long-term immunosuppression. This chapter addresses the immunology of transplantation and rejection, indications for solid organ transplantation, appropriate use of immunosuppressive agents, and the management of postoperative and long-term complications in the patient who receives a solid organ transplant. Many of these issues are similar for the various types of solid organ transplantations, but there can be significant differences. This chapter addresses some of these issues as they relate to kidney and liver transplantation.

TRANSPLANTATION IMMUNOLOGY

Successful organ transplantation has come from a greater understanding and application of pharmacology, microbiology, molecular and cellular biochemistry and biology, genetics, and immunology. Suppression of the host’s immune system and prevention of rejection are vital for host acceptance of the transplanted organ. The ultimate goal is permanent acceptance or tolerance, a situation in which the new organ is seen as “self” by the host’s immune system. In general, the currently used immunosuppressive drugs provide a nonpermanent form of tolerance. A basic understanding of the immune system and the mechanisms of rejection is key to the effective use of immunosuppressive drugs in organ transplantation.

Major Histocompatibility Complex and Human Leukocyte Antigen

The degree to which allogeneic grafting (i.e., a transplanted organ from a genetically different donor of the same species) is successful depends on the genetic similarities or differences between the organ of the donor and the immune system of the recipient. The recipient recognizes the transplanted graft as either self or foreign. This recognition is based on the host’s reaction to alloantigens or antigens (i.e., substances that initiate an immune response that can lead to rejection of the transplanted organ). These substances, also known as histocompatibility antigens, play a very important role in organ transplantation. Another group of substances that also plays an important role is the ABO blood group system of red blood cells. In general, the donor and recipient must be ABO compatible; otherwise, immediate graft destruction occurs because of antibodies directed against the ABO antigens.

Histocompatibility antigens are glycoproteins that are located on the surface of cell membranes. These are encoded by the major histocompatibility complex (MHC) genes located on the short arm of chromosome 6. In humans, the MHC is called the *human leukocyte antigen* (HLA). The gene products encoded on the HLA are divided into classes I, II, and III based on their tissue distribution, antigen structure, and function. Class I antigens (HLA-A, HLA-B, and HLA-C) are present on all nucleated cell surfaces and are the primary targets for cytotoxic T-lymphocyte reactions against transplanted

cells and tissues. The three class II antigens (HLA-DR, HLA-DQ, HLA-DP) have a more limited distribution and are found on macrophages, B lymphocytes, monocytes, activated T lymphocytes, dendritic cells, and some endothelial cells, all of which can act as antigen-presenting cells (APC). Individual HLA loci are extensively polymorphic. Each one possesses two A, B, and DR antigens, one from each parent. This is called a *haplotype*. Recognition of these polymorphic loci by host T lymphocytes appears to account for rejection events seen in vivo. Class III antigens (C4, C2, and Bf) are part of the complement system and do not play a specific role in the graft rejection process.

Rejection of a transplanted organ is the outcome of the natural response of the immune system to a foreign substance, or antigen, and is a complex process, the understanding of which continues to evolve. This process, in some cases segmental and simultaneous, involves an array of interactions between foreign antigens, T lymphocytes, macrophages, cytokines (soluble mediators secreted by lymphocytes, also called *lymphokines*, *interleukins*), adhesion molecules (also referred to as *costimulatory molecules*), and membrane proteins expressed on a wide variety of cells that enhance binding of T cells, and B lymphocytes. This process of organ rejection ultimately can involve all elements of the immune response, but it is predominantly T-cell-mediated. This process can be divided into several important steps, which include antigen presentation as well as T-cell recognition, activation, proliferation, and differentiation of the various components of the immune response (Fig. 34-1).

For foreign antigens to interact with recipient T cells and B cells, they must be prepared for presentation by APC. These APC (Fig. 34-1) usually are recipient macrophages (indirect pathway of allorecognition), although donor cells—referred to as *dendritic cells* or *passenger leukocytes* and *graft endothelial cells*—also can serve as APC (direct pathway of allorecognition). This phase takes place within the blood, lymph nodes, spleen, and the transplanted organ (Fig. 34-2).

The next step (signal one) involves T-cell recognition of the HLA molecules presented on the surface of the APC. The primary site for this to occur is at the CD3-T-cell receptor complex (TCR) on recipient T lymphocytes. This step involves the binding of the antigen, MHC, and TCR for T-cell activation. These T lymphocytes also express other molecules (clusters of differentiation [CD]) on their surfaces that, along with CD3, recognize and respond to different types of antigens. These T cells are known as *CD4+ cells* (T_H , helper or inducer T cells) and *CD8+ cells* (T_C , cytotoxic or suppressor T cells). *CD4+ cells* interact with class II antigens. *CD8+ cells* interact with class I antigens.

In addition, proteins known as adhesion molecules or costimulatory molecules promote T-cell signaling and activation (signal two). For T-cell activation to occur, binding of these costimulatory molecules as well as binding of the TCR with the presented antigen and MHC is required. Examples of these molecules include intercellular adhesion molecule (ICAM)-1 on APC, which bind with lymphocyte function-associated antigen (LFA) expressed on the surface of T cells; ICAM-1 and -3 on APC with CD2 on T cells; B7 (now called CD80 and CD86) on APC with either CD28 or CTLA4 on T cells; CD40 on APC with CD40 ligand (now called *CD154*) on T cells.

The binding of these molecules are critical to T-cell activation. Without this costimulation, T cells undergo abortive activation or programmed T-cell death (apoptosis). These cos-

timulatory molecules have become important targets for investigational drugs (e.g., CTLA4Ig, anti-CD40, anti-CD154) designed to try to prevent acute and chronic rejection and to promote long-term tolerance with minimal immunosuppression or none at all.

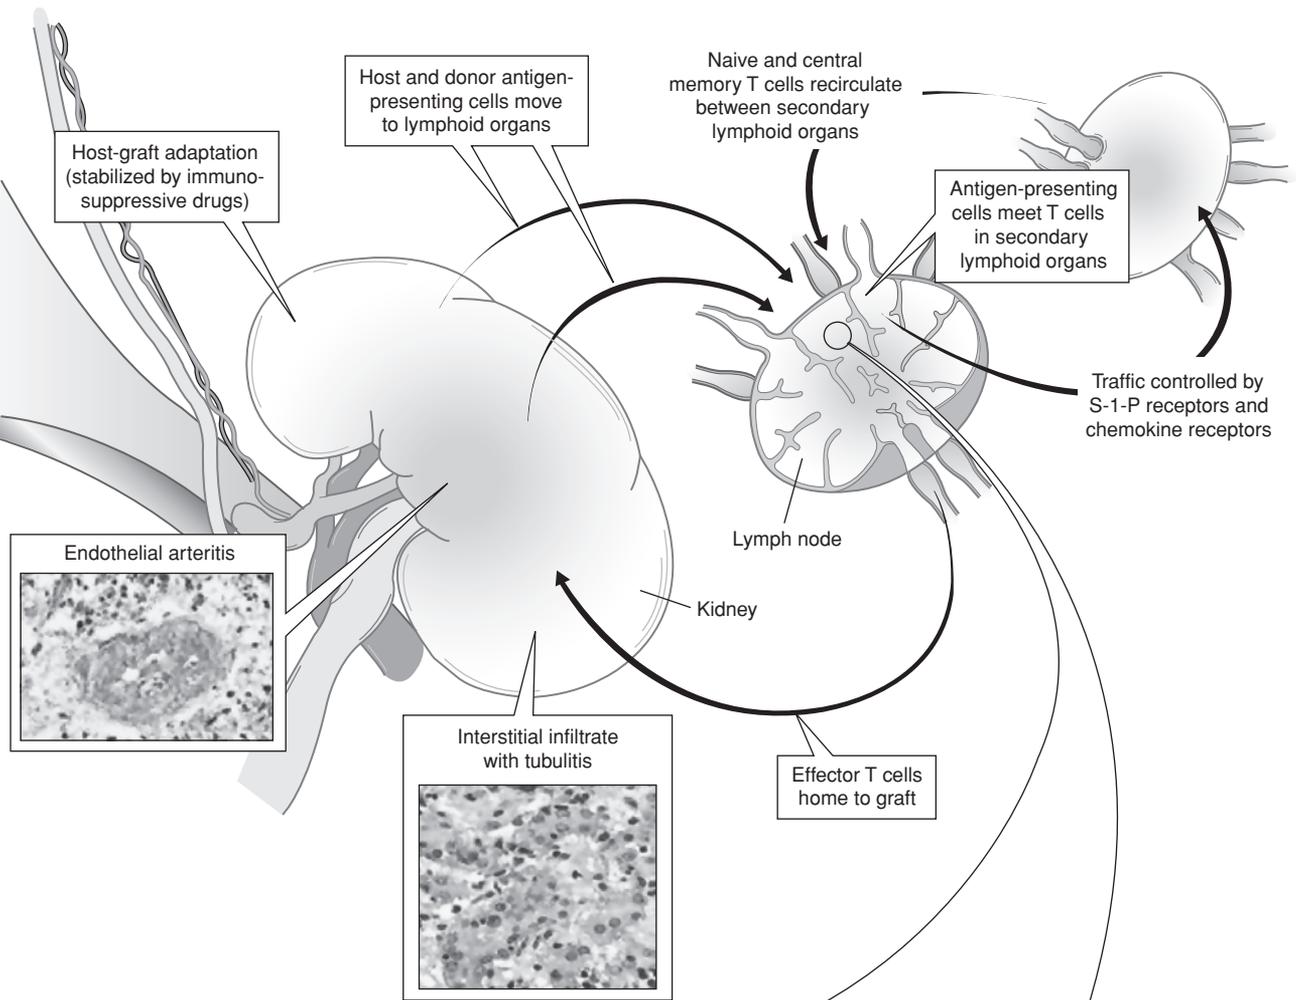

Once recognition occurs, T-cell activation and proliferation are initiated. After interacting with class II antigens and stimulation from IL-1 secreted from macrophages, T_H cells produce and secrete cytokines (e.g., interleukin [IL]-2 and interferon- γ). T_H cells are classified according to their cytokine-secretion pattern into either T_{H1} or T_{H2} cells. T_{H1} cells secrete IL-2, interferon (IFN), and tumor necrosis factor (TNF), which stimulate T_C cells. T_{H2} cells secrete IL-4, IL-5, IL-6, IL-10, and IL-13, which stimulate B cells. T_H cells, along with T_C cells, are stimulated to express cell-surface receptors specific for IL-2 (IL-2R) and other cytokines. Once the T_C cells express IL-2R, they bind to IL-2 and other cytokines, which leads to signal transduction that results in proliferation, division and stimulation of T cells (signal 3). These committed T_C cells bind directly to allogeneic cells and produce cell lysis. T_H -secreted cytokines recruit other T cells, which results in further cytotoxicity. During this process, T_H cells also produce cytokines that trigger a cascade of events involving B cells and antibody production, complement fixation, increased macrophage infiltration, neutrophil involvement, fibrin deposition, platelet activation and release, prostaglandin release, and inflammatory response at the graft site. These delayed-type hypersensitivity and humoral responses occur in conjunction with one another and are not mutually exclusive. This results in cellular and tissue graft destruction (Fig. 34-1).

The antibodies produced by plasma cells, which are transformed B cells under the influence of cytokines, bind to the target antigenic cells. This leads to local deposition of complement and results in immune complexation and injury to the graft (complement-mediated cell lysis). The newly formed antibodies cause a series of interactions to occur with T cells, which lead to cytotoxicity (antibody-dependent, cell-mediated cytotoxicity). These cell-mediated and humoral immunologic events can impair organ function so significantly that without therapeutic intervention, complete organ graft dysfunction may occur. Under certain circumstances, which are not clear, the T_C cells can actually downregulate the immune response to alloantigen. These cells are known as *suppressor T cells*, which express $CD8+$.³

Human Leukocyte Antigen Typing

The genetic compatibility between donor and recipient can have an impact on graft survival. For example, in kidney transplantation, the closer the HLA matching is between recipient and donor, the better the outcome, particularly over the long term. To determine this compatibility, a number of laboratory tests, including serologic, flow cytometric, genetic DNA based, and cellular assessments of donor and recipient serum and lymphocytes, are performed before organ transplantation. This process is referred to as *tissue typing*.⁴ Lymphocytes are typed for HLA-A, HLA-B, and HLA-DR. Typing for HLA is performed using the donor and recipient lymphocytes for serology-based techniques and any tissue or fluid containing nucleated cells.

The panel reactive antibodies (PRA) test is commonly used to assess organ compatibility because recipients may have HLA

T-cell activation through three signals

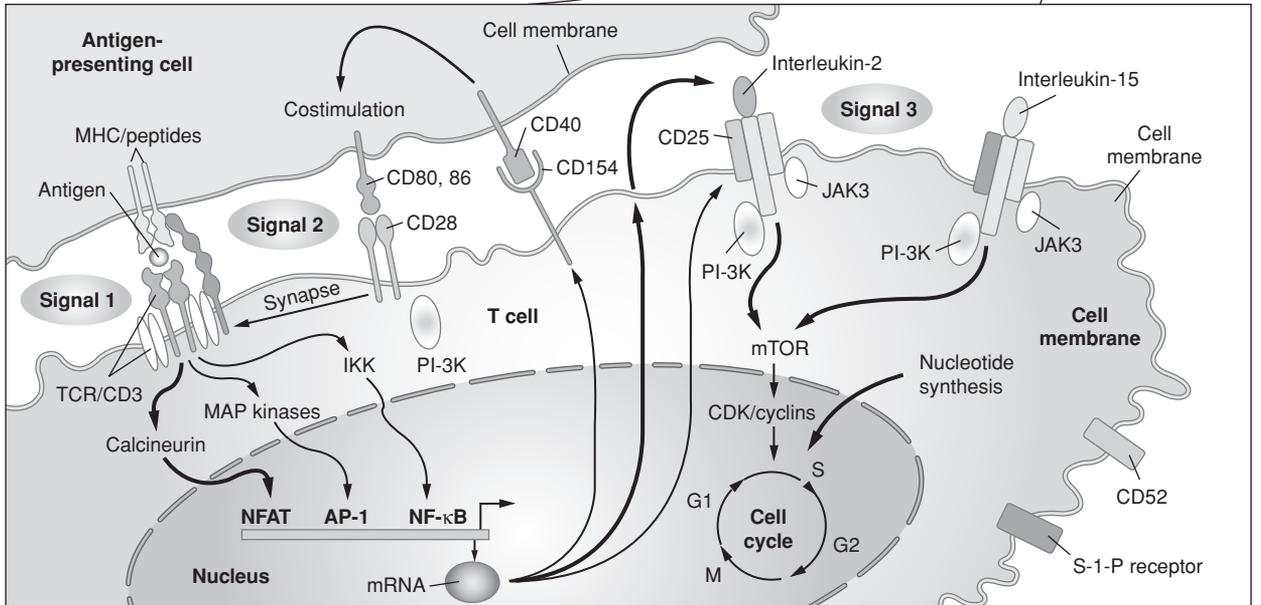

FIGURE 34-1 T-Cell activation.

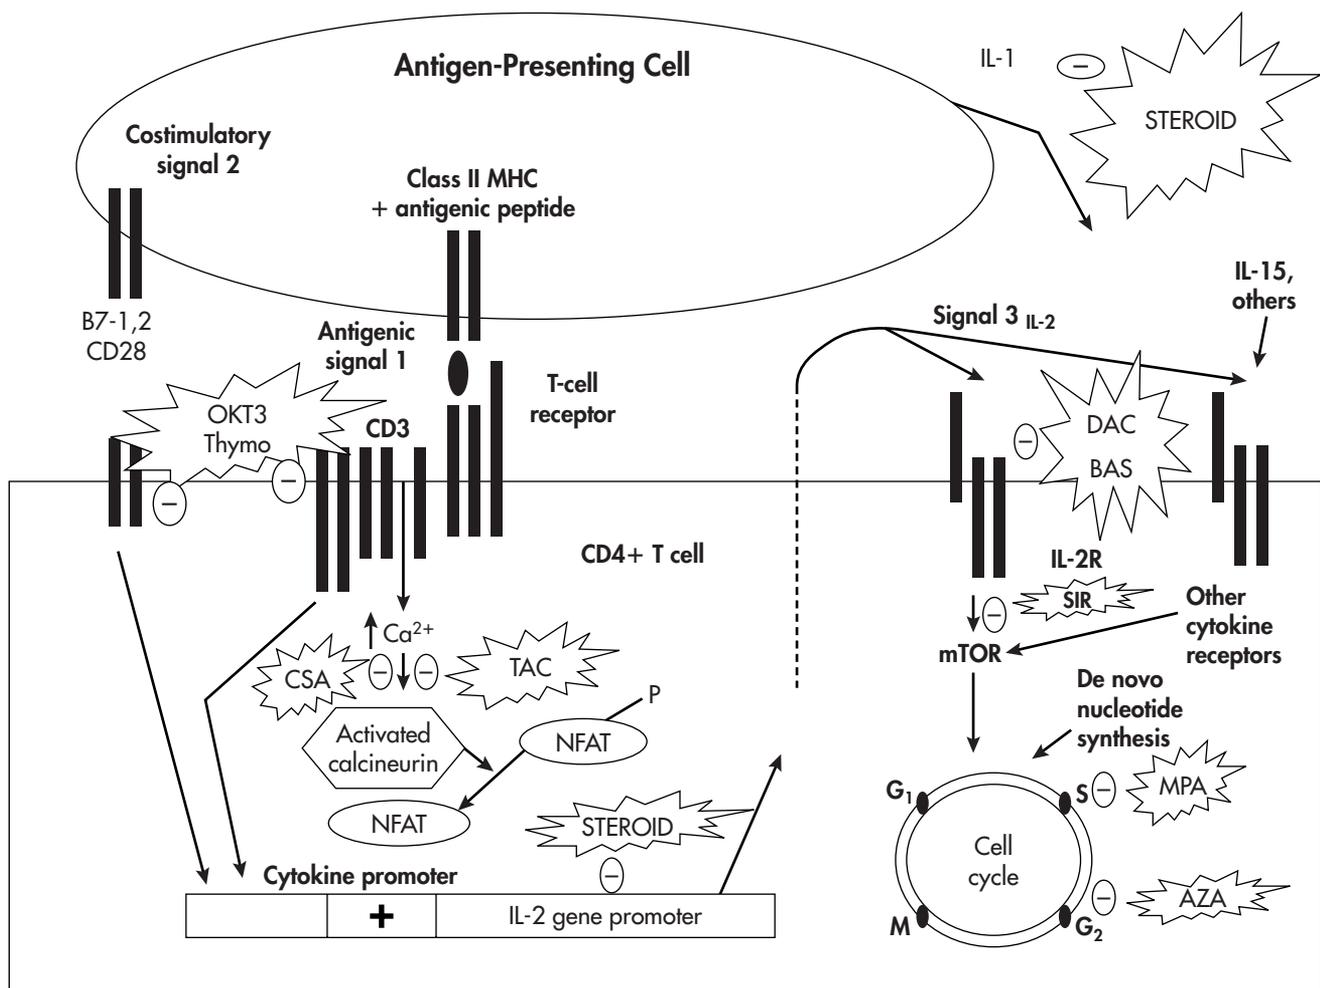

FIGURE 34-2 Schematic representation summarizing the mechanisms of action of approved and investigational immunosuppressive agents. AZA, azathioprine; BAS, basiliximab; CSA, cyclosporine; DAC, daclizumab; TAC, tacrolimus; IL, interleukin; MPA, mycophenolic acid; SIR, sirolimus.

antibodies from previous exposure to antigenic stimuli (e.g., blood transfusions, previous transplantation, pregnancy). In this test, the recipient's serum is tested against a cell panel of known HLA specificities that are representative of possible donors in the general population. The percentage of cell reactions (recipient with donor) determines a recipient's PRA.⁴ It is done periodically on patients on the waiting list to determine their immunologic reactivity. The potential recipient with a higher percentage of PRA (>20%–>50%) is at higher risk for rejection.

A lymphocyte cross-match is also performed. In this case, the potential recipient's serum is cross-matched to determine whether preformed antibodies to the donor's lymphocytes are present. A positive cross-match indicates the presence of recipient cytotoxic IgG antibodies to the donor. In solid organ transplantation, this positive cross-match is often considered a strong contraindication, although in some kidney transplants therapeutic approaches involving the use of IVIG, plasmapheresis and rituximab before and after transplant appear to be successful.⁵ In liver transplantation, a positive cross-match is not an absolute contraindication because the need is urgent and because the liver appears to be more resistant immunolog-

ically to this type of reaction. These liver transplant recipients can, however, develop significant complications and experience early acute rejection.

ABO blood typing is one of the most critical of all evaluations when determining the genetic compatibility for all solid organ transplants. Transplantation of an organ with ABO incompatibility would result in a hyperacute rejection and destruction of the graft, although in kidney transplant therapeutic approaches are being studied to minimize this outcome.⁶

IMMUNOSUPPRESSIVE AGENTS

Improvements in surgical techniques, better postoperative care and monitoring, and more effective immunosuppressive agents have all played significant roles in the success of solid organ transplantation. The use of these immunosuppressives, based on an improved understanding of their mechanisms of action and the mechanisms of rejection, has had the most significant impact on patient and graft survival. The number of currently approved immunosuppressives has significantly increased (Table 34-1), and a significant number of newly developed, more selective and potentially less toxic immunosuppressive

Table 34-1 Currently Used Immunosuppressive Agents

| <i>Drug (Brand Name)</i> | <i>Usual Dose (How Supplied)</i> | <i>Therapeutic Use(s)</i> | <i>Adverse Effects</i> |
|---|---|---|---|
| Alemtuzumab (Campath-H1) | 0.3 mg/kg or 30 mg × 1 dose | Prevention of acute rejection; steroid-free protocols | Lymphopenia, leukopenia, infection |
| Azathioprine (Imuran) | 1–3 mg/kg/day (50-mg tab; 100-mg vial for injection) | As maintenance agent to prevent acute rejection | Leukopenia, thrombocytopenia, hepatotoxicity, nausea and vomiting, diarrhea, pancreatitis, infection |
| Antithymocyte globulin, equine (Atgam) | 10–20 mg/kg/day (250 mg/5 mL ampule for injection) | Treat acute rejection (including severe or steroid-resistant forms); as induction agent in high-risk patient to prevent acute rejection | Anemia, leukopenia, thrombocytopenia, arthralgia, myalgias, nausea and vomiting, diarrhea, fevers, chills, hypotension, tachycardia, anaphylaxis, infection |
| Antithymocyte globulin, rabbit (Thymoglobulin) | 1.5 mg/kg/day (25 mg/5 mL vial for injection) | Treat acute rejection (including severe or steroid-resistant forms); as induction agent in high-risk patient to prevent acute rejection | Fever, chills, nausea and vomiting, hypotension, neutropenia, flushing, rash, itching, joint pain, myalgias, thrombocytopenia, infection |
| Basiliximab (Simulect) | 20 mg; 2 doses 10 mg; 2 doses for children if <35 kg (10- and 20-mg vial for injection) | As induction agent to prevent acute rejection | Abdominal pain, dizziness, insomnia, hypersensitivity reaction (rare) |
| Cyclosporine (Sandimmune) | Oral 5–10 mg/kg/dose BID IV 1.5–2.5 mg/kg/dose (100 mg/mL oral solution; 25- and 100-mg cap; 250 mg/5 mL ampule for injection) | As maintenance agent to prevent acute rejection | Nephrotoxicity, hypertension, neurotoxicity, hair growth, gingival hyperplasia, hyperglycemia, hyperkalemia, dyslipidemia, hypomagnesemia, infection, neoplasm |
| Cyclosporine (Neoral, Gengraf, various others) | 4–8 mg/kg/day BID (100 mg oral solution; 25-, 50-, and 100-mg cap) | As maintenance agent to prevent acute rejection; conversion agent from tacrolimus in patients with intolerance or inefficacy | Same as above |
| Daclizumab (Zenapax) | 1 mg/kg; 5 doses (25 mg/5 mL vial for injection) | As induction agent to prevent acute rejection | Headache, infection, hypo- or hypertension |
| Methylprednisolone sodium succinate (Solu-Medrol, various others) | 10–1,000 mg/dose (40-, 125-, 250-, 500-, 1,000- and 2,000-mg vial for injection) | As induction and maintenance agent to prevent acute rejection; to treat acute rejection | Hyperglycemia, psychosis, euphoria, impaired wound healing, osteoporosis, acne, peptic ulcers, gastritis, fluid, electrolyte disturbances, leukocytosis, cataracts, cushingoid state, infection, insomnia, irritability |
| Mycophenolate mofetil (CellCept) | 1.5–3.0 g/day BID (250-mg cap; 500-mg tab; 200 mg/mL oral suspension; 500-mg vial for injection) | As maintenance agent to prevent acute rejection; conversion agent from azathioprine and sirolimus in patients with intolerance or poor response | Diarrhea, nausea and vomiting, neutropenia, dyspepsia, ulcers, infection, thrombocytopenia |
| Mycophenolate sodium (Myfortic) | 360–720 mg BID | As maintenance agent to prevent acute rejection. Alternative to MMF | Similar side effect profile as MMF |
| OKT3 (Orthoclone) | 2.5–5 mg/dose (5 mg/5 mL ampule for injection) | Treat acute rejection (including severe or steroid-resistant forms); as induction agent in high-risk patients to prevent acute rejection | Pulmonary edema, fever, chills, hypotension, weakness, fatigue, muscle, joint pain, aseptic meningitis, altered mental status, infection |
| Prednisone (Deltasone, others) | 5–20 mg/day (1-, 2.5-, 5-, 10-, 20-, 50-, and 100-mg tab) | As maintenance agent to prevent acute rejection | See methylprednisolone |
| Sirolimus (Rapamune) | 2–10 mg/day (1- and 2-mg tab; 1 mg/mL oral solution) | As maintenance agent to prevent acute rejection; conversion agent from CNI or mycophenolate or azathioprine in patients with intolerance or poor response | Dyslipidemia, thrombocytopenia, neutropenia, anemia, diarrhea, impaired healing, mouth ulcers, hypokalemia, arthralgias, infection |
| Tacrolimus (Prograf) | Oral 0.15–0.3 mg/kg/day BID IV 0.025–0.05 mg/kg/day as continuous infusion (0.5-, 1-, and 5-mg cap; 5 mg/mL ampule for injection) | As maintenance agent to prevent acute rejection; conversion agent from cyclosporine in patients with intolerance | Nephrotoxicity, hypertension, neurotoxicity, alopecia, hyperglycemia, hyperkalemia, dyslipidemia, hypomagnesemia, infection, neoplasm |

BID, twice daily; CNI, calcineurin inhibitor; IV, intravenous; MMF, mycophenolate mofetil.

agents are under investigation. Sites of action of the currently used agents, along with some of the investigational agents, are represented in Figure 34-2.

Azathioprine

Azathioprine is a prodrug of 6-mercaptopurine (6-MP). Azathioprine and 6-MP are purine antagonist antimetabolites. The introduction of cyclosporine, tacrolimus, mycophenolate, and sirolimus has led to a significant reduction of azathioprine use or its elimination altogether in immunosuppressive protocols, especially in the United States. It may, however, be useful in some cases because it is available generically, or in patients who cannot tolerate other agents. It continues to be used in other countries.

Azathioprine, a nonspecific immunosuppressive agent, affects both cell-mediated (i.e., T cell) and antibody-mediated (i.e., B cell) immune responses. Because it inhibits the early stages of cell differentiation and proliferation, azathioprine is useful for preventing rejection, but it is ineffective for the treatment of acute rejection. Active metabolites of 6-MP are incorporated into DNA and RNA, thereby interfering with the intracellular formation of thioguanine nucleotides (TGN). 6-MP is intracellularly converted by hypoxanthine phosphoribosyl transferase (HPRT) to thioinosinic acid and then to thioguanine nucleotides. 6-MP may have two separate immunosuppressive effects: inhibition of cellular proliferation and cytotoxicity. A decrease in the levels of intracellular purine ribonucleotides decreases cellular proliferation, and incorporation of TGN into DNA mediates cytotoxicity.⁷

Azathioprine can be given intravenously (IV) or orally. Oral absorption is rapid but incomplete. The usual dose is 1 to 3 mg/kg/day. Although the mean bioavailability of azathioprine in renal transplant recipients is approximately 50%, oral doses usually are not doubled when converting from IV to oral route.

The half-lives for azathioprine and 6-MP are estimated to be 10 to 12 minutes and 40 to 60 minutes, respectively. Major metabolic conversion of azathioprine to 6-MP is via nucleophilic attack by glutathione. The liver and red blood cells are thought to be major tissue sites for this metabolic conversion. The 6-MP formed by this reaction can be metabolized further to thiopurine ribonucleosides and ribonucleotides. Azathioprine pharmacokinetics are not affected by renal dysfunction, but there are higher 6-TGN metabolite concentrations. In contrast, azathioprine's immunosuppressive activity is absent in patients with severe hepatic dysfunction.⁸

The most common adverse effect of azathioprine is bone marrow suppression, which presents as leukopenia or, less commonly, as thrombocytopenia and megaloblastic anemia. Myelosuppression is dose dependent and typically observed after 7 to 14 days of therapy. Bone marrow suppression may be related to a genetic deficiency of the enzyme, thiopurine methyltransferase (TPMT). Low activity of this enzyme is rare but does lead to greater availability of 6-MP, elevated 6-thioguanine levels, and susceptibility to myelosuppression. Low levels of TPMT and specific genetic polymorphisms of this enzyme have been associated with severe azathioprine myelotoxicity and reduced efficacy in some transplant recipients and testing for this polymorphism has been advocated.⁹ Hepatitis, cholestasis, and reversible and irreversible liver damage have been reported with azathioprine use. The irreversible

liver damage appears histologically compatible with central vein phlebitis and occlusion, fibrosis, lobular necrosis, and biliary stasis.¹⁰

The white blood cell (WBC) count should be maintained at $>5,000/\text{mm}^3$. If it decreases to 3,000 to 5,000/ mm^3 , the azathioprine dosage should be reduced by 50%. If the dose reduction fails to keep the WBC count above 3,000/ mm^3 , azathioprine should be discontinued and reinstated at the lower dose when the leukopenia is resolved, if needed. A similar approach should be taken if thrombocytopenia occurs. If hepatotoxicity or other serious side effects occur, azathioprine is discontinued.

Pancreatitis has been associated with azathioprine. Long-term azathioprine administration also has been associated with the occurrence of non-Hodgkin's lymphoma, squamous cell skin cancer, primary hepatic tumors, fever, rigors, rash, headache, myalgia, tachycardia, hypotension, polyarthritis, and acute hypersensitivity reactions. Anorexia, nausea, and vomiting also occur.

Mycophenolate Mofetil and Mycophenolate Sodium

As a result of several comparative trials in kidney transplant recipients, mycophenolate mofetil (MMF) has replaced azathioprine in many transplantation protocols, especially in the United States. Studies in other transplantation populations have shown positive results as well. MMF is used as adjunctive therapy in combination with cyclosporine or tacrolimus, prednisone, sirolimus, and monoclonal and polyclonal antibodies to prevent acute rejection. It is also used as rescue therapy when patients have not responded to, or cannot tolerate, the side effects of other immunosuppressive agents.¹¹

Mycophenolate mofetil, as with azathioprine, can be classified as an antiproliferative antimetabolite in that it also inhibits purine synthesis, but in a more selective manner. Unlike azathioprine, MMF interferes with the *de novo* pathway for purine synthesis. MMF is the morpholinoethyl ester prodrug of mycophenolic acid (MPA), which is the active component. MPA selectively, noncompetitively, and reversibly blocks an enzyme known as inosine monophosphate dehydrogenase (IMPDH) found primarily in actively proliferating T and B lymphocytes. T and B lymphocytes rely on this enzyme and the *de novo* purine pathway to produce purine nucleotides for DNA and RNA synthesis. Thus, MPA interferes with T- and B-cell proliferation. MPA also may affect cytokine production. Other secondary effects include inhibition of B-lymphocyte antibody production, decreased adhesion molecule expression, decreased smooth muscle proliferation and recruitment, and infiltration of neutrophils.¹²

Mycophenolate mofetil is rapidly converted to MPA on IV or oral administration. It is well absorbed. MPA is metabolized almost entirely by the liver to MPA-glucuronide (MPAG), which undergoes enterohepatic recirculation and is ultimately excreted renally as MPAG. MPA is highly protein bound to albumin and renal dysfunction can lead to an increase in free fraction.¹³

A new formulation of MPA, enteric-coated mycophenolate sodium (Myfortic), has been FDA approved to prevent rejection in kidney transplantation, when used in combination with a calcineurin inhibitor (CNI) and corticosteroids. The original purpose of designing the enteric-coated formulation was

to reduce or prevent the gastrointestinal side effects commonly seen with MMF. All the compelling data currently published indicates, however, that the efficacy rates and side effect profiles of MMF and mycophenolate sodium are nearly identical. These two agents are *not* bioequivalent; because a 1-g dose of MMF is equivalent to 720 mg of mycophenolate sodium¹⁴ (see Question 35).

Corticosteroids

Prednisone, methylprednisolone, and prednisolone—all synthetic analogs of hydrocortisone—are the primary corticosteroids used to prevent and treat rejection of transplanted organs. Although an important part of immunosuppression, a goal of most transplantation programs, is to minimize, eliminate, or avoid corticosteroid use because of their numerous and significant side effects.¹⁵

Corticosteroids have multiple effects on most cells and tissues of the body, but it is their anti-inflammatory and, more importantly, their immunosuppressive properties that serve as the basis for their use in organ transplant recipients. These effects are exerted through specific intracellular glucocorticoid receptors. The corticosteroids bind with these receptors and interfere with RNA and DNA synthesis as well as transcription of specific genes. Cell function is altered, resulting in suppression or activation of gene transcription. Corticosteroids also affect RNA translation, protein synthesis, production and secretion of cytokines, and protein and cytokine receptor expression.

Even after a single dose, corticosteroids cause marked lymphocytopenia by redistribution of circulating lymphocytes to other lymphoid tissues, such as the bone marrow, rather than by cell lysis; they also transiently increase the number of circulating neutrophils. Corticosteroids inhibit IL-1 and IL-6 production from APC, a number of events associated with T-cell activation, and IL-2 and IFN γ production. They interfere with the action of IL-2 and IL-2R on activated T cells, resulting in the inhibition of T helper 1 (T_{H1}) function. They can enhance IL-10 regulatory function and enhance T_{H2} cell function. Moderate- to high-dose corticosteroids also inhibit cytotoxic T-cell function by inhibiting cytokine production and lysis of T cells. They can inhibit early proliferation of B cells but have a minimal effect on activated B cells and immunoglobulin-secreting plasma cells. The corticosteroids affect most cells and substances associated with acute allograft rejection and inflammatory reactions. They inhibit accumulation of leukocytes at sites of inflammation; inhibit macrophage functions, including migration and phagocytosis; inhibit expression of class II MHC antigens induced by interferon- γ ; block release of IL-1, IL-6, and TNF; inhibit the upregulation and expression of costimulatory molecules and neutrophil adhesion to endothelial cells; inhibit secretion of complement protein C3; inhibit phospholipase A₂ activity; and decrease production of prostaglandins.¹⁶

The plasma half-lives of prednisone and methylprednisolone are much shorter than their biologic half-lives. Prednisone is a prodrug that is rapidly converted to its active form, prednisolone. Bioavailability in transplant recipients is rapid and complete and similar to healthy subjects. In transplant recipients, plasma half-lives are approximately 2.5 to 4 hours for prednisolone and methylprednisolone. Prednisolone is metabolized extensively. Prednisolone and methylprednisolone are

70% to 90% protein bound. Clearance of the unbound fraction is reduced in renal and liver transplant recipients. These agents usually are given in fixed doses or dosing is based on body weight (mg/kg) with little regard for pharmacokinetic differences, despite the significant variability that exists.^{17,18}

Calcineurin Inhibitors

Cyclosporine

The introduction of cyclosporine as an immunosuppressive agent has been the single most important factor in the current success of organ transplantation. Its use has increased patient and graft survival, reduced morbidity associated with rejection and infection, and extended the types and numbers of organ transplantations performed. Cyclosporine or tacrolimus are the primary agents used in almost all transplant recipients. In contrast to azathioprine and mycophenolate, cyclosporine has relatively nonmyelotoxic, immunosuppressive effects. It has been considered the prototype for agents such as tacrolimus and sirolimus, as well as some investigational immunosuppressive drugs.

Cyclosporine is an 11-amino acid undecapeptide metabolite extracted from a soil fungus, *Tolypocladium inflatum* Gams. The activity of cyclosporine is mediated through a reversible inhibition of T-cell function, particularly helper T cells. Its major effect is inhibiting the production of IL-2 and other cytokines, including interferon- γ . These actions result in an inhibition of the early events of T-cell activation, sensitization, and proliferation. Cyclosporine has little effect on activated mature cytotoxic T cells. Therefore, it has little usefulness in the treatment of acute rejection. Its site of action is within the cytoplasm of T cells after antigenic recognition and signaling occurs. Cyclosporine binds to an intracellular protein (immunophilin) called *cyclophilin*. Although binding to cyclophilin is required, it is not sufficient for immunosuppression. This cyclosporine–cyclophilin complex binds to a protein phosphatase, calcineurin. This is thought to prevent activation of nuclear factors involved in the gene transcription for IL-2 and other cytokines, including IFN.¹⁹ Also, because of this inhibition, cyclosporine indirectly impairs the activity of other cells, macrophages, monocytes, and B cells in the immune response. Cyclosporine has no effect on hematopoietic cells or neutrophils. Cyclosporine is metabolized extensively in the liver to >25 metabolites. Two of these metabolites, AM1 (formerly M17) and AM9 (formerly M1), can elicit an immunosuppressive effect in vitro, but they have much lower activity than cyclosporine. The role of these metabolites in the development of toxicity with cyclosporine is unclear²² (see Questions 15–17, 19–20).

Tacrolimus

Tacrolimus (formerly FK506) is isolated from a soil fungus, *Streptomyces tsukubaensis*. It is a macrolide with a different molecular structure than cyclosporine. Tacrolimus is as effective as cyclosporine in liver, kidney, kidney–pancreas or pancreas, heart, and lung transplantation recipients as the primary immunosuppressant in combination with corticosteroids or mycophenolate, azathioprine, sirolimus, and antibodies. It also is effective as rescue treatment in liver, kidney, kidney–pancreas or pancreas, heart, and lung transplant recipients

experiencing acute or chronic rejection resulting from failure of standard immunosuppressive therapy. Tacrolimus has become the preferred CNI over cyclosporine in many transplant centers.^{23,24}

The activity of tacrolimus is similar to that of cyclosporine, but the concentrations of tacrolimus needed to inhibit production of IL-2, which is its major effect, are 10 to 100 times lower than those of cyclosporine. Tacrolimus also inhibits production of other cytokines, including IL-3, IL-4, and interferon- γ , TNF, and granulocyte-macrophage colony-stimulating factor (GM-CSF). It has variable effects on B-cell response and also has anti-inflammatory effects. The action of tacrolimus on T cells is more difficult to reverse than cyclosporine. As with cyclosporine, tacrolimus binds to an intracellular, although different, protein: FK binding protein 12 (FKBP12). This protein, which interacts with calcineurin, inhibits gene transcription of cytokines and interferes with T-cell activation.²⁰ Further pharmacologic and pharmacokinetic descriptions of tacrolimus are presented in Questions 28–32.

Sirolimus

Sirolimus, formerly known as *rapamycin* (Rapamune), is an FDA-approved agent for prevention of acute rejection and for withdrawal of cyclosporine in kidney transplantation. It was isolated from soil samples in Rapa Nui (Easter Island) and is a macrolide, structurally related to tacrolimus. In multicenter clinical trials, sirolimus combined with cyclosporine and prednisone significantly reduced acute rejection episodes in kidney transplant recipients when compared with a combined regimen of cyclosporine, azathioprine, and prednisone. The rejection rate was decreased from approximately 30% to 40% to <20%. Positive results for sirolimus also have been observed in other transplantation populations; in situations in which it is used in combination with other agents, including antibodies, tacrolimus, and mycophenolate; and when it has been used for rescue therapy. Its major use appears to be primarily in calcineurin reduction or elimination protocols.²¹

Unlike tacrolimus and cyclosporine, which work earlier in the T-cell activation cycle and inhibit cytokine production, sirolimus is an inhibitor of late T-cell activation. It does not block cytokine production; rather, it inhibits signal transduction, which blocks the response of T cells and B cells to cytokines such as IL-2.

As with tacrolimus, sirolimus binds to intracellular proteins. Specifically, sirolimus binds to the same immunophilin bound by tacrolimus, *FK binding protein* (FKBP). This complex interferes with the action of certain enzymes or proteins. Both cyclosporine and tacrolimus inhibit calcineurin, whereas sirolimus influences a protein called the *mammalian target of rapamycin* (mTOR). Sirolimus also inhibits an enzyme called *P7056 protein kinase*, which is involved in microsomal protein synthesis. These effects result in cell-cycle arrest, blockage of messenger RNA (mRNA) production, and blockage of cell proliferation. Early in its development, in vitro studies indicated that tacrolimus and sirolimus were antagonistic. Clinical studies indicate that this is not true. Sirolimus and cyclosporine or tacrolimus appear to work synergistically. Sirolimus also inhibits proliferation of smooth muscle cells and may, although it is too early to tell, reduce the development of chronic rejection²¹ (see Question 18).

Antithymocyte Globulins

Before monoclonal antibody preparations were developed to prevent and treat acute rejection, polyclonal antilymphocyte preparations, such as antilymphocyte globulin (ATG), were available. Products used today are administered IV and include equine (Atgam, lymphoglobulin) and rabbit (Thymoglobulin) globulin, which is considered the polyclonal antibody of choice.

The ATG preparations made in goats and sheep also have been synthesized for investigational study. However, the following discussion is limited to the products produced in horses (Atgam) and rabbits (Thymoglobulin). Regardless of the species from which they are produced, all ATG products have similar pharmacologic effects. Their potency and antibody specificity vary, however, from batch to batch and between products.²² The production of polyclonal equine or rabbit antibody begins with the injection of homogenized human spleen or thymus preparations into the animals. This injection induces an immune response in the animals directed against human T lymphocytes; serum containing antibodies to T cells is collected from the animals and purified. Other antibodies to human cells are produced as well, however. These antibodies bind to all normal blood mononuclear cells in addition to T lymphocytes and B lymphocytes, resulting in depletion of lymphocytes, platelets, and leukocytes from the peripheral circulation. The mechanism of action of these agents is thought to be linked to lysis of peripheral lymphocytes, uptake of lymphocytes by the reticuloendothelial system, masking of lymphocyte receptors, apoptosis, and immunomodulation. These agents contain antibodies to a number of cell-surface markers on lymphocytes, including CD2, CD3, CD4, CD8, CD11a, CD25, CD44, CD45, HLA-DR, and HLA class I antigens. They also interfere with leukocyte adhesion and trafficking and also have effects against CD20+ B cells. ATG preparations can produce a rapid and profound depletion of circulating T cells, often within 24 hours of the initial dose. The duration of the effect can last several weeks after a course of therapy, particularly with Thymoglobulin. Antibodies can be produced to these products as well. This, however, does not appear to influence clinical outcomes.²³ The clinical use of Thymoglobulin is described further in Question 5.

Murine Monoclonal Antibody

Muromonab-CD3 (Orthoclone OKT3), the first therapeutic murine monoclonal antibody approved for use in humans, was developed to suppress T-cell-mediated rejection. It is used for induction therapy (prophylaxis) or to treat acute graft rejection.²⁴ With the introduction of Thymoglobulin, dactinomycin, and basiliximab, the prophylactic use of OKT3 has significantly declined, although some centers still use it but in lower doses. With the introduction of Thymoglobulin for treatment of acute rejection, OKT3 is used if a patient is unresponsive.

Murine monoclonal antibodies are formed by immunizing a mouse with a specific antigen (in this case, human T lymphocytes). After the mouse produces B lymphocytes against the injected antigen, it is killed and the spleen is removed. All the lymphocytes derived from the spleen are suspended and mixed with mouse myeloma cells, a tumor cell line that can

grow indefinitely in culture. The two cell types are mixed with polyethylene glycol (PEG), which allows the cells to fuse. This mixture of mouse spleen cells, myeloma cells, and hybridomas (fused spleen and myeloma cells) is grown in a medium that allows only hybridomas to grow. Hybridoma colonies that are producing the desired antibody are cloned, and the antibodies they produce are harvested from cell supernatants. Another method used to produce large amounts of monoclonal antibody is to inject the appropriate hybridoma into the peritoneum of a mouse. After 10 to 21 days, the ascitic fluid, which contains secreted antibodies, is harvested and purified to obtain the desired monoclonal antibody.

OKT3, an IV administered IgG_{2a} immunoglobulin, binds to the CD3 (cluster of differentiation 3) structure on CD3+ T lymphocytes located near the T-cell receptor complex. All mature T cells express CD3 and either the CD4 or CD8 surface antigen. Once OKT3 is bound to the CD3 region of T cells, it is thought to be opsonized and removed from the circulation by the reticuloendothelial system of the liver and the spleen. This removal occurs within minutes after IV administration. The first one to two doses, however, activate T cells thereby producing significant adverse effects known as the *cytokine release syndrome*. OKT3 also can modulate the antigen-recognition complex of T cells, which alters normal T-cell function. The third mechanism involves blocking killer T cells attached to the allograft. This occurs when high levels of OKT3 are achieved and the killer T cells are coated and rendered inactive. Once therapy is stopped, CD3+ cells return to measurable levels quickly, often within 24 hours.

CD3+ cell counts of <25/mm³ represent an appropriate response in most patients. Adequate response to OKT3 is delayed by up to 5 to 7 days after a second course, which is owing to a neutralizing antibody against OKT3.²⁴ Patients sometimes require two to three times the initial dose, or it may be contraindicated if anti-OKT3 antibody level is too high (see Questions 12–14).

Interleukin-2 Receptor Antagonists

Daclizumab and Basiliximab

Daclizumab (Zenapax) and basiliximab (Simulect) are two monoclonal antibodies approved for use in combination with other immunosuppressives to prevent acute cellular rejection in kidney transplantation. They are not considered treatment for acute rejection. Daclizumab is a humanized monoclonal antibody, which contains 90% human and 10% murine antibody sequences. Basiliximab is a chimeric antibody that contains both murine and human antibody sequences. In contrast to daclizumab, it contains higher amounts of murine antibody sequences.²⁵ These agents prevent episodes of acute rejection in kidney transplant recipients. Their use in combination with other agents is being studied in other transplant populations. Comparative studies between these agents or with other antibodies, such as Thymoglobulin, are being conducted. Advantages over these older agents include ease of administration, minimal side effects, low immunogenicity, no greater infections or malignancy rates, and fewer required doses. Both are well tolerated, although there are rare reports of anaphylaxis. These agents appear to be most effective in immunologically low-risk patients, whereas in high-risk patients, their use may

be limited. These agents, as with other antibodies, are expensive. To date, the only perceived clinical difference between daclizumab and basiliximab is the dosing regimen. Daclizumab is given as 1 mg/kg on day 0 of the transplant and then every 2 weeks for four more doses. This regimen creates issues related to compliance, outpatient administration, and reimbursement. Basiliximab is given as a 20-mg dose on days 0 and 4 after transplantation. Several reports, however, have evaluated daclizumab regimens of one, two, or three doses given over the first few days after transplant.²⁵ Both daclizumab and basiliximab appear to have similar mechanisms. They bind to the α -subunit of the IL-2R, also known as CD25 or the *TAC subunit*, which is expressed only on the surface of activated T cells; this subunit is critical to IL-2 activation of T cells in the acute rejection process. Daclizumab and basiliximab prevent the IL-2R from binding with IL-2, thereby blocking T-cell activation.²⁵

Differences exist in the elimination half-life and duration of receptor saturation with these two agents, the significance of which remains to be determined. Daclizumab has a terminal half-life of 11 to 38 days, whereas that of basiliximab is 4 to 14 days. Daclizumab, using the approved five-dose regimen, saturates the IL-2R for about 120 days. Basiliximab, with the two-dose regimen, saturates the receptor for 36 days. Duration of IL-2 saturation was also found to be shorter in liver transplant recipients than that reported in kidney transplant recipients. The half-life and clearance of daclizumab and basiliximab have been shown to be shorter and faster, respectively, in liver transplant recipients. Total body clearance correlates positively with the volume of postoperative blood loss; basiliximab also is cleared through postoperative ascitic fluid.²⁶

Alemtuzumab

Alemtuzumab (Campath-1H) is a humanized monoclonal antibody against CD52 proteins on the surface of T and B cells, natural killer cells, macrophages, and monocytes. It is approved for use in certain types of leukemias, but not in organ transplant. Because it causes a profound reduction or depletion in lymphocytes, especially T helper lymphocytes, a number of studies are evaluating its effect as induction therapy to prevent acute rejection after kidney transplant. Several studies are investigating its use in steroid avoidance or withdrawal regimens and calcineurin avoidance or withdrawal regimens. Short-term studies have indicated a role for this agent in these situations. Most protocols with this agent give a single 30 mg IV dose in the operating room. With this dose, significant neutropenia and lymphopenia can still occur, lasting for months to years in some patients. This single dose regimen has been successful in reducing the incidence of fungal and viral infections as compared with multiple dose regimens.²⁷

Investigational Agents

A number of agents are in various stages of development. These include everolimus (SDZ-RAD), belatacept (LEA29Y), FTY720, deoxyspergualin, brequinar, mizoribine, leflunomide, FK-778, and AEB-071. These agents have more specific activity directed at T-cell and B-cell function and some interfere with costimulatory proteins. Everolimus is an analogue of sirolimus.²⁸ Belatacept is a CTL4-Ig, which blocks the costimulatory pathway of CD28 or CTLA-4: CD80/CD86 binding interactions. CTLA4-Ig binds to CD80/CD86 to a greater

degree than CD28, resulting in inhibition of costimulation and T cell activation. Belatacept, which is given IV, once every few weeks in combination with other agents, is currently undergoing phase III trials as a replacement for CNI.²⁹ FTY720 interferes with lymphocyte migration from the lymph nodes. Leflunomide and its analogs, FK778, belong to a class of agents called malanitriloamides and target pyrimidine synthesis. Mizoribine and brequinar are inhibitors of DNA synthesis. Deoxyspergualin inhibits cell activation and maturation. In addition, a number of monoclonal antibodies and peptides have been developed and are undergoing investigation. The targets of these antibodies and peptides are antigen-binding sites, adhesion molecules, cytokines and enzymes such as tyrosine kinase.³¹

KIDNEY TRANSPLANTATION

Indications and Evaluation

1. G.P. is a 52-year-old, 72-kg black man with end-stage renal disease (ESRD) secondary to non-insulin-dependent diabetes mellitus, hypertension and hyperlipidemia. He has been undergoing hemodialysis three times a week for 4 years. Other medical problems include anemia, hypocalcemia, and hyperphosphatemia. G.P.'s medications include amlodipine 10 mg daily, ramipril 10 mg twice daily (BID), Lipitor 20 mg daily, Tums two tablets three times daily (TID) with meals, at bedtime, and in between meals, NPH insulin 30 U BID, regular insulin 8 U BID, and erythropoietin 8,000 U IV three times weekly. He has been on the kidney transplant waiting list for 2 years. He is called by the transplant coordinator and admitted for a possible deceased donor (formerly called cadaveric) kidney transplant. G.P. has the same blood type as the donor. His most recent PRA is 10%. Cross-match is negative, and HLA typing reveals a three-antigen match (A1, A2, B35) between donor and recipient. On admission to the hospital, his laboratory values are as follows: Na, 141 mEq/L (normal, 135–145); potassium (K), 4.7 mEq/L (normal, 3.4–4.6); Cl, 102 mEq/L (normal, 95–105); bicarbonate (HCO₃), 23 mEq/L (normal, 22–28); blood urea nitrogen (BUN), 44 mg/dL (normal, 8–18); serum creatinine (SrCr), 13.9 mg/dL (normal, 0.6–1.2); calcium (Ca), 7.8 mEq/L (normal, 8.8–10.3); phosphorus, 6.2 mg/dL (normal, 2.5–5.0); glucose, 225 mg/dL (normal, 65–110); WBC count, 8.4 cells/mm³ (normal, 4,000–10,000); hemoglobin (Hgb), 10.8 g/dL (normal, 14–18); and hematocrit (Hct), 32% (normal, 39%–49%). His serology is negative for HIV, hepatitis B surface antigen, hepatitis C, and cytomegalovirus (CMV), and is positive for anti-HBs. What are the indications for and potential benefits of kidney transplantation in G.P.?

[SI units: Na, 141 mmol/L (normal, 135–145); K, 4.7 mmol/L (normal, 3.4–4.6); Cl, 102 mmol/L (normal, 95–105); HCO₃, 23 mmol/L (normal, 22–28); BUN, 15.7 mmol/L (normal, 3.0–6.5); SrCr, 1,228.8 μmol/L (normal, 50–110); Ca, 1.95 mmol/L (normal, 2.20–2.58); P, 2.0 mmol/L (normal, 0.77–1.45); glucose, 12.5 mmol/L (normal, 3.9–6.1); WBC count, 8.4 × 10⁶ cells/L (normal, 4,000–10,000); Hgb, 108 g/L (normal, 115–155); Hct, 0.32 (0.39–0.49)]

All patients with ESRD are potential candidates for kidney transplantation unless contraindicated. The contraindications (absolute or relative) are determined by the individual transplant center. Absolute contraindications include current malignancy, active infection, active liver disease, HbsAg-positive,

severe or symptomatic cardiac or pulmonary disease, specific renal diseases with an accelerated recurrence rate, substance abuse, and abnormal psychosocial and noncompliant behavior. Relative contraindications for the recipient of a kidney transplant include chronic liver disease, active infection, positive for hepatitis C, HIV-positive, morbid obesity, current positive cross-match, and age >70 years.³⁰ The relative contraindication for the elderly with ESRD is controversial because approximately 40% of the ESRD population is >65 years and an increasing number of these patients are undergoing kidney transplantation. Patients with ESRD need not wait until they are receiving dialysis before being considered for a kidney transplant because transplantation is associated with lower cost, better quality of life and longer survival than patients on dialysis awaiting transplantation. The primary diseases leading to ESRD and transplant are diabetes, glomerulonephritis, polycystic kidneys, and arterionephrosclerosis.

In G.P., diabetes and hypertension would be the most likely causes of his ESRD. For G.P., a renal transplant should return his renal function to near normal, improve his quality of life, and correct the complications of renal dysfunction such as anemia, hypocalcemia, and hyperphosphatemia, but not diabetes or hypertension or hyperlipidemia.

When evaluating a patient for any organ transplantation, the risk-to-benefit ratio must be considered. In general, kidney transplants are performed to improve the quality of life and avoid the complications and outcomes associated with dialysis and renal failure. It is also more cost effective than dialysis. In contrast, patients who are candidates for heart, lung, and liver transplantations will die if these vital organs fail. Therefore, the criteria established for organ transplantation must be evaluated carefully before it is offered to any patient.

Donor and Recipient Matching

2. What criteria are important in determining a good match between the donor and G.P.?

G.P. had a series of serologic tests to determine his genetic compatibility with the donor. He had a negative cross-match and low PRA of 10%, indicating that he is not already sensitized to this donor's antigens, which should result in a more favorable post-transplantation course. HLA matching also indicated a three-antigen match between G.P. and the donor. Matching of donor and recipient at the HLA-A, HLA-B, and HLA-DR loci is associated with better graft survival and longer half-lives for both living-related and deceased donor kidney transplants. Half-lives are longer with living donors (13–15 years) compared with deceased donors (8–20 years). For a group of recipients with a match similar to G.P., the 1-year and 3-year graft survival for a first deceased donor transplant is projected to be >90% and >80%, respectively. These positive factors may be offset, however, by his ethnicity. Patient and graft survival after kidney transplantation is reduced in the black population compared with others because of immunologic, medical, pharmacologic, pharmacokinetic, and socioeconomic reasons.³¹ Along with black race, other risk factors associated with decreased survival include advanced donor age, recipient age <15 and >50 years, retransplantation, a high PRA (>20%–>50%), and delayed graft function. Recipients who fall into these categories are referred to as high-risk patients.³²

Because of a limited number of donors, this pool has been expanded to include what are called expanded criteria donors (ECD). These are deceased donors (DD) who are either older, and have evidence of some pre-existing hypertension, higher serum creatinine, or death caused by cerebrovascular disease than the standard criteria DD. Survival appears to be somewhat lower in recipients of organs from ECD. G.P.'s donor was a standard criteria DD donor.

Immunosuppressive Therapy

3. Before the transplant procedure, G.P. receives MMF 1 g orally (PO) and cefazolin 1 g IV. During surgery, just before reperfusion of his new kidney, he received methylprednisolone 500 mg IV and Thymoglobulin 100 mg IV. He is also given furosemide 100 mg IV after the kidney has been transplanted. Methylprednisolone 250 mg IV is to be given on the day after surgery. The methylprednisolone dose is to be decreased to 100 mg IV on the second postoperative day for one dose. Prednisone 60 mg (1 mg/kg/day) PO is to be given on the subsequent day for one dose and tapered by 0.3 mg/kg/day to 20 mg daily by day 7 after surgery. Tacrolimus nasogastric (NG) or orally (PO) 0.1 mg/kg/day or 3 mg Q 12 hr will be started within 12 hours after surgery if renal function improves. The dosage will be adjusted according to tacrolimus whole blood trough concentrations. MMF will be continued at 1g PO BID. He will also continue with antibody induction with Thymoglobulin 100 mg IV on days 1 and 3 after surgery. Why is G.P. being treated with this immunosuppressive regimen?

The major goal of immunosuppressive therapy is to prevent rejection and infection with minimal adverse side effects and to ensure long-term patient and graft survival. Overall acute rejection rates are <20% during the first year after kidney transplantation. Most of these episodes respond to acute antirejection therapy.

No consensus exists on the best immunosuppressive regimen, and the numerous dosing regimens in use primarily depend on the program and the specific organ to be transplanted. Although a number of studies have attempted to evaluate the superiority of various regimens, comparisons are influenced by variables such as differences in donor selection and condition, organ preservation and procurement, organ ischemic (cold and warm) time, recipient's pretransplant conditions, comorbid and high or low risk factors, surgical procedures and individual surgical techniques, postoperative management and monitoring, and length of follow-up. Another important consideration is that many of the newer agents show significant effects during the first year, but fail to show a significant impact on long-term effects such as chronic rejection and graft survival.² The choice of a particular regimen generally depends on the risk factors present at the time of transplantation. During this early time period, the number of agents and doses used are higher than later on after transplantation.

Most starting immunosuppressive drug regimens for the management of solid organ transplantations rely on three to four agents, although mono-or-dual therapy has been used, depending on organ type and risk factors. These combination regimens include a CNI (cyclosporine or tacrolimus) and MMF or sirolimus; or azathioprine and prednisone with or without a monoclonal antibody (alemtuzumab, basiliximab, daclizumab,

OKT3); or polyclonal antibody (Atgam, Thymoglobulin). Several regimens are being studied that avoid the use of steroids and CNI; or use a short course in the early transplantation period, or are withdrawn sometime, usually several months, after transplantation in an attempt to avoid the long-term side effects of these agents.³³

With DD kidney transplants, quadruple or triple therapy is used. The most commonly used regimen is one that contains an antibody with tacrolimus, MMF and prednisone. Cyclosporine or tacrolimus are the foundation of this type of regimen. Tacrolimus is used in >70% of new kidney transplant recipients.²⁰ In HLA-identical, living-related kidney transplants, conventional dual therapy (e.g., azathioprine or mycophenolate and prednisone) gives excellent results; however, acute rejection can still occur, and some programs may use dual therapy that contains either cyclosporine or tacrolimus. Combination therapy is used to take advantage of different mechanisms of action and to reduce drug toxicity by using sequential therapy and smaller doses of multiple agents rather than larger doses of any agent used alone. These multidrug combinations can lead, however, to increased drug costs, compliance issues, a higher incidence of infection and malignancy, and difficulty in assessing adverse effects.

In G.P., triple or quadruple therapy would be used. In many centers, an antibody such as Thymoglobulin, alemtuzumab, basiliximab, or daclizumab would be added to his current triple therapy, because G.P. is considered a high-risk recipient because he is black. Black recipients generally have a higher rate of acute rejection and graft loss than other ethnic groups after transplant.³⁴

After the initial transplantation period, drug dosages are reduced over time and maintained at a stable dose for 6 months to 1 year. In G.P., tacrolimus, MMF, or the corticosteroid may be discontinued. Although the discontinuation of a drug may reduce adverse effects, it must be counterbalanced against the risk of acute rejection and graft loss. Monotherapy, generally with tacrolimus or cyclosporine, may be achieved in kidney, liver, and heart transplant recipients at some point after transplantation. Most patients, however, require lifetime immunosuppression.

4. What is induction therapy?

Induction therapy after transplantation refers to the use of an antibody, typically during the first week after transplant. Acute rejection can occur in the early transplant period and also delayed graft function (DGF). Both of these have a negative impact on graft survival. Antibodies, such as Thymoglobulin and OKT3, reduce the incidence of acute rejection and delayed graft function and have typically been used in immunologically high-risk patients. Their use in patients at low to moderate risk is increasing, however, often as a means of reducing or avoiding the use of CNI and steroids. The newer antibodies (e.g., basiliximab, daclizumab, and alemtuzumab) are playing a bigger role in these situations because they are easier to give and have a less severe adverse effect profile.²⁸ Recent data indicate that about 70% of all kidney transplants during 2004 to 2005 received induction therapy, with Thymoglobulin making up about 40%.²⁰

Thymoglobulin and Antithymocyte Globulin (Atgam)

5. How would Thymoglobulin be administered and monitored in G.P.?

Dosing and Administration

Both Thymoglobulin and antithymocyte globulin are effective as induction therapy or as treatment of acute rejection. In general, Thymoglobulin appears to be more effective than antithymocyte globulin and has replaced Atgam as the polyclonal antibody of choice. Thymoglobulin, when used for induction, also has been reported to result in improved survival, fewer side effects, and less infection compared with OKT3. The dose of Thymoglobulin is 1.5 mg/kg/day, and the dose of antithymocyte globulin is 10 to 20 mg/kg/day. These drugs can be diluted in 0.9% sodium chloride for injection and administered over 4 to 6 hours. Both are usually infused into a high-flow central vein to reduce pain, erythema, and phlebitis at the injection site. Peripheral administration has been used successfully with Thymoglobulin by adding heparin and hydrocortisone to the IV solution.²⁵ Skin testing is recommended before horse-derived antithymocyte globulin use, but not rabbit-derived Thymoglobulin. Patients previously sensitized to horse serum are at risk for an anaphylactoid reaction, but the prevalence of anaphylaxis has diminished with improved purification of this product. Patients with a positive pretherapy skin test could undergo desensitization, but alternatives, such as Thymoglobulin and OKT3, are available.

Dose Regimen and Duration of Therapy

The first dose of Thymoglobulin is usually given intraoperatively rather than after transplant. Intraoperative administration of Thymoglobulin has been shown to reduce the incidence and severity of DGF as compared with postoperative administration.³⁴ Duration of therapy with Thymoglobulin and antithymocyte globulin ranges from 3 to 10 days for induction therapy. Protocols used to treat rejection commonly use a 7- to 14-day course of therapy.²⁰ In patients such as G.P., a three-dose regimen has been shown to be as effective as a daily regimen.³⁵

Adverse Effects

A number of adverse effects have been related to the use of Thymoglobulin or antithymocyte globulin. Local phlebitis and pain usually can occur. Anaphylaxis is rare. Chills and fever, erythema, rash, hives, pruritus, headache, leukopenia, and thrombocytopenia are commonly encountered. Fever, chills, nausea, and vomiting may be caused by the release of cytokines, such as TNF and IL-6, from lysed lymphocytes. These symptoms can be minimized by premedication with acetaminophen and diphenhydramine before each dose. Methylprednisolone, up to 500 mg, is given 1 hour before Thymoglobulin for the first two doses to minimize infusion reactions. Serum sickness leading to acute glomerulonephritis, hypotension, and acute respiratory distress also has been associated with these agents. It may not be evident until the seventh day of therapy or within 2 weeks of discontinuation.³⁶ Opportunistic viral, (CMV and Epstein-Barr virus [EBV]), and fungal infections are the predominant delayed side effect. Susceptibility to malignancy, such as post-transplantation lymphoproliferative disease (PTLD) is also a

concern (see Chapter 35, Questions 15–16). Because of the increased risk of CMV infection, patients are often given oral valganciclovir or IV ganciclovir during therapy, and then oral valganciclovir, which is continued up to several months after induction.

Monitoring

Vital signs should be monitored hourly during infusion, and WBC and platelet counts should be monitored daily. If the patient's WBC count drops to $<3,000$ cells/mm³ or if the platelet count drops to $<100,000$ cells/mm³, the dose of drug is decreased by 50% or held entirely until the counts return to desired levels. The decision to decrease or hold the dose is based on the status of the patient's rejection and the degree of thrombocytopenia and leukopenia.

Dosages also can be adjusted based on absolute lymphocyte counts or lymphocyte subsets as a way of maximizing efficacy and minimizing infectious complications. For example, the dose can be adjusted by using a target absolute T-lymphocyte count (CD2 or CD3) of <25 to 50 cells/mm³. This latter approach results in a lower dose, less frequent dosing (e.g., every other day instead of daily), lower costs, and a lower rate of viral infection. Thymoglobulin produces a more profound and longer duration of effect on lymphocytes than antithymocyte globulin, but this does not result in a greater risk for infection and malignancy.²⁰

6. Could daclizumab or basiliximab be used as an alternative to Thymoglobulin?

Daclizumab and basiliximab are agents approved for use as induction therapy in kidney transplantations. Although they are approved for use in kidney transplantations only, they are being used and studied in other organ transplant recipients. Studies with these agents have been in combination with cyclosporine or tacrolimus and steroids with or without an antimetabolite, such as azathioprine or MMF or sirolimus. These agents are well tolerated and have a better adverse event profile than Thymoglobulin or OKT3.²⁵ These agents have a limited role in high-risk populations, such as G.P. who is black, or patients with high PRA or long ischemic times, delayed graft function, patients who have received a previous transplant, and children. In these patients, induction with polyclonal antibodies is used in most centers. The large initial trials with these IL-2R antibodies included very few high-risk patients or excluded them altogether. More potent agents, such as Thymoglobulin, are still preferred in high-risk patients. A prospective study comparing Thymoglobulin with basiliximab in high-risk kidney transplants demonstrated that acute rejection rates were lower in patients receiving Thymoglobulin.³² IL-2R antibodies can be used for low- to intermediate-risk patients and in patients where CNJ minimization or steroid avoidance is implemented.²⁵

Postoperative Course and Delayed Graft Function

7. G.P. is admitted to the transplant ward for initial post-transplantation management. His urine output during the next 3 hours has decreased from 300 to 40 mL/hour. He is receiving IV fluids at a rate equivalent to his urine output. He received 3 L of fluids in the operating room (OR). His blood pressure (BP)

is 140/83 mmHg, heart rate is 87 beats/minute, and temperature 36.9°C; he has no signs of dehydration. His BUN is 56 mg/dL (normal, 8–18), and his SrCr is 12.8 mg/dL (normal, 0.6–1.2). Another dose of furosemide 100 mg IV increased his urine output to 140 mL/hour, but his urine output returned to <40 mL/hour in a few hours. Fluids and IV furosemide were given again with similar results. Renal ultrasound indicates no urine leaks, fluid collections, or ureteral obstruction. A DPTA (diethylenetriamine penta-acidic acid) renal scan indicates good perfusion, but decreased accumulation and clearance. Over the next 2 days, G.P.'s BP is 150/93 mmHg, weight is 76 kg (4 kg higher than before the transplantation), urine output has fallen to <200 mL/day, and relevant laboratory values are as follows: BUN, 85 mg/dL; SrCr, 13.2 mg/dL; and K, 5.8 mEq/L (normal, 3.4–4.6). The decision is made to institute hemodialysis. What has happened to G.P.'s renal function? What is the most likely diagnosis?

[SI units: BUN, 20 mmol/L, 30.3 mmol/L (normal, 3.0–6.5); SrCr, 1,131.5 μ mol/L, 1166.9 μ mol/L (normal, 50–110); K, 5.8 mmol/L (normal, 3.4–4.6)]

After kidney transplantation, recipients require management and monitoring for fluid and electrolyte imbalance (potassium, magnesium, phosphorous and calcium), BP and blood glucose changes, surgical complications, gastrointestinal (GI) complications, infection, rejection, immunosuppressive dosing and toxicity, and, most important, kidney function. If all goes well, recipients should be discharged from the hospital within 3 to 5 days after transplantation. The initial renal function after kidney transplantation can reflect excellent, moderate, or slow graft function or DGF. In recipients with excellent function, a good diuresis begins immediately and continues; the serum creatinine rapidly declines to <2.5 mg/dL within the first few days after transplantation. Most living-related transplants and between 30% to 50% of DD transplants generally experience this excellent graft function pattern. Kidney transplant recipients with moderate or slow graft function usually experience a slower decline in serum creatinine, which stabilizes within the first week. Recipients with DGF usually experience anuria or oliguria, require dialysis in the early period, and take days to weeks to recover. DGF is most common in recipients of organs from deceased transplant donors, occurring in between 2% to 50% (average 25%) of cases.³⁷

The diagnosis of DGF is based on clinical, laboratory, and diagnostic criteria that may vary among centers. DGF has been defined simply as the need for dialysis in the early transplantation period, whereas at others, the definition may be based on both a lack of improvement in the serum creatinine (e.g., it does not fall below 2.5 to 4 mg/dL or by 25%–30% from pre-transplantation) and the presence of anuria or oliguria within the first 6 to 24 hours after other causes of acute tubular necrosis (ATN) are ruled out. Slow graft function (SGF) is another term that has been used to describe a lag in improvement and does not involve dialysis. DGF is influenced by conditions affecting the donor (age, condition of organ, prolonged ischemic time), intraoperative conditions (hypotension, fluid imbalance, ischemia or reperfusion injury), and recipient (prior transplantation, postoperative hypovolemia or hypotension, and nephrotoxic drugs).³⁷

In G.P., poor urine output in the first hours after transplantation and subsequent oliguria, the exclusion of other causes

of ATN, the results of the renal scan, the lack of improvement in BUN and serum creatinine, and the need for dialysis are indicative of DGF. DGF reduces kidney long-term graft survival, increases the risk of acute rejection, and influences a patient's early management by requiring dialysis, increasing the length of hospital stay, and increasing the costs of therapy. It also may make the assessment of acute rejection more difficult because the patient already has impaired renal function. In DGF, a renal biopsy is obtained if no improvement in serum creatinine is seen by day 7.³⁷

8. What adjustments should be made in G.P.'s immunosuppressive regimen at this time?

The adverse renal effects of CNI can contribute to the onset of DGF as well as prolong its duration. Therefore, tacrolimus should be discontinued temporarily or its dose significantly reduced. Because of this effect, induction and sequential immunosuppressive protocols do not include CNI, or they use them only in low doses generally for the first week after a renal transplantation until renal function improves. These protocols include antibodies and provide more intense immunosuppression early after transplantation when the risk of acute rejection is highest. Thymoglobulin or OKT3 is used in patients with DGF because they have shortened the duration of DGF and the need for dialysis when compared with the CNI. These agents have an early positive impact on DGF but have failed to show a positive effect on long-term graft survival compared with standard therapies, such as CNI.³⁵ Another potential option would be to use one of the new IL-2R inhibitors, daclizumab or basiliximab, which have been shown to reduce acute rejection rates and extend the time to first rejection. They have been used primarily in low to moderate risk patients. Their use in high-risk patients (blacks, retransplantations, high PRA, prolonged ischemic time, DGF) is based primarily on single-center and retrospective studies with encouraging results, but their effectiveness in prospective studies in preventing acute rejection has not always been equal to other antibodies such as Thymoglobulin.³⁸ Another concern with use of the anti IL-2R agents is that a CNI may be required sooner than with Thymoglobulin because these agents do not provide as long a duration of protection from rejection.

In G.P., Thymoglobulin would be administered for between 5 to 10 days, depending on improvement in his SrCr and urine output, along with his current regimen of prednisone and mycophenolate. A typical dose would be 1.5 mg/kg/day or every other day, depending on his CD3+ level, and WBC and platelet counts. His tacrolimus could be held for a few days to a week and reintroduced at a lower dose of 0.025 mg/kg twice a day. Afterwards, a tacrolimus dosage of 0.05 mg/kg orally twice a day would be reasonable in G.P. with a goal of achieving whole blood trough concentrations of 8 to 12 ng/mL after transplant.

Rejection

9. G.P. was started on Thymoglobulin 1.5 mg/kg as a 6-hour IV infusion with further dosages to be adjusted to maintain CD3+ cell counts of <25/mm³ and lymphocyte counts of <20 cells/mm³ for a total of 7 days. He received this along with his prednisone

taper and MMF. He received three doses of Thymoglobulin, on days 1, 3, and 5 after transplant. Tacrolimus PO 3 mg BID was initiated on day 4 of Thymoglobulin therapy. G.P.'s urine output has increased gradually to ~1,600 mL/day 1 week after stopping Thymoglobulin. His weight has decreased to 73 kg, BP is 142/84 mmHg, heart rate is 82 beats/minute, temperature is 36.7°C, BUN is 23 mg/dL (normal, 8–18), SrCr is 2.3 mg/dL (normal, 0.6–1.2), and K is 4.6 mEq/L (normal, 3.4–4.6). He is on a regular diet and taking all oral medications. His current medications include MMF 500 mg BID, prednisone 10 mg daily, tacrolimus 5 mg BID, ranitidine 150 mg at bedtime, dioctyl sodium sulfosuccinate 100 mg BID, amlodipine 10 mg daily, metoprolol 50 mg PO BID, NPH insulin 28 U BID, regular insulin 10 U BID, valganciclovir 450 mg daily, and trimethoprim-sulfamethoxazole (TMP-SMX) DS, one tablet on Mondays, Wednesdays, and Fridays. Fifty days after stopping Thymoglobulin, G.P.'s weight increased to 74.6 kg, and his BP was 160/94 mmHg, heart rate was 98 beats/minute, temperature was 37.6°C, BUN was 30 mg/dL, SrCr was 3.4 mg/dL, K was 4.8 mEq/L, trough whole blood tacrolimus concentration was 5 ng/mL, and urine output decreased over the last 24 hours to 850 mL. He feels tired and has a decreased appetite, but his fluid intake has been adequate over the past day. What evidence is consistent with rejection in G.P.?

[SI units: BUN, 8.2 mmol/L, 10.7 mmol/L (normal, 3.0–6.5); SrCr, 212.2 μmol/L, 300.6 μmol/L (normal, 50–110); K, 4.6 mmol/L, 4.8 mmol/L (normal, 3.4–4.6)]

Although significant improvements in reduction in acute rejection and improved graft survival have occurred over the past decade, certain types of acute rejection and chronic rejection continue to be a major reason for graft loss in kidney transplants. Rejection episodes in all solid organ transplantations can be categorized as hyperacute, accelerated, acute, or chronic. Kidney biopsy is considered the gold standard for making the diagnosis of rejection after kidney transplant. Approved criteria are used to classify and grade the type of rejection.³⁹

Hyperacute Rejection

Hyperacute rejection, which occurs within minutes to hours after transplantation of the allograft, is the result of preformed cytotoxic antibodies against donor-specific class I antigens. This type of rejection is rare because of ABO matching and improved HLA typing before transplant, but it remains associated with a poor prognosis. Clinically, the patient presents with anuria, hyperkalemia, hypertension, metabolic acidosis, pulmonary edema and, in some cases, disseminated intravascular coagulopathy (DIC). Diagnostic scan of the kidney would indicate no uptake. If other causes of anuria are excluded and this diagnosis is made, then the transplanted kidney must be removed.

Accelerated Rejection

Accelerated rejection usually occurs within a few days after organ transplantation. This is a result of prior sensitization to antigens that are similar to those of the donor and newly developed donor-specific antibodies. Accelerated rejections of transplanted kidneys occur primarily in recipients who have had prior transplantation, multiple pregnancies, or blood transfusions. These patients usually maintain good renal function

for a few days before developing acute renal failure. Accelerated organ rejections generally are more resistant to pharmacologic therapy.

Acute Rejection

Acute rejection is the most common type of kidney rejection in transplant recipients and most episodes respond to therapy. Most episodes of acute rejection are T-cell mediated (cellular), although some can be B-cell (antibody or humoral) mediated, whereas others are a combination of both. Acute rejection of a transplanted kidney significantly reduces the half-life and survival of both living and DD transplants. The half-life refers to the time it takes for half of the grafts that survive the first year eventually to fail. Acute rejection can occur in the first week to months after kidney transplantation. The prophylactic use of antibody preparations may, however, delay the onset for several weeks, as illustrated by G.P.'s case. If acute rejection occurs, its onset is almost always within the first year, with most episodes occurring within the first 60 days after transplantation. Acute rejection can, however, also occur at any time after transplant and can be a result of patient nonadherence (also called non-compliance) to medications and monitoring. The clinical presentation of patients with acute rejection of a kidney ranges from an asymptomatic patient with mild renal dysfunction as indicated by an elevated serum creatinine, which is common, to patients presenting with a flulike illness and acute oliguric renal failure.⁴⁰

G.P. presents with subjective complaints of malaise or tiredness and lack of appetite. Such nonspecific complaints occur often in patients with rejection and can be accompanied by myalgias as well as pain and tenderness at the graft site in some cases. Objectively, G.P.'s fever, increased weight, hypertension, decreased urine output, and increase in serum creatinine are consistent with acute kidney rejection. In addition, the tacrolimus concentration and mycophenolate doses are low, suggesting inadequate immunosuppressive coverage. Acute rejection of a transplanted kidney must be distinguished from CNI nephrotoxicity, and infections (e.g., pyelonephritis, CMV) also must be ruled out. Although the clinical evidence in G.P. probably represents an acute rejection, a kidney biopsy is the gold standard for establishing the diagnosis. Biopsy results usually are available within 6 to 8 hours. If there is acute rejection, the renal biopsy will show an interstitial infiltration of mononuclear cells with tubulitis or intimal arteritis in more severe cases. The severity of acute rejection would be classified and graded according to standardized pathologic criteria and can determine treatment. Less severe grades would receive high-dose steroids, whereas more severe grades would often receive Thymoglobulin or OKT3.⁴⁰

Antibody-Mediated Rejection

Antibody-mediated (also called humoral) rejection can be either acute or chronic rejection mediated by antibodies. It differs histologically from acute cellular rejection in that there is no lymphocyte infiltration on biopsy. Presence of positive staining for the complement component C4d suggests antibody-mediated rejection. Humoral rejection can occur in hours to years after transplantation. Antibody-mediated rejection often is associated with hemodynamic compromise and is more

resistant to drug therapy. In addition to standard therapy, such as steroids and Thymoglobulin, plasmapheresis, IVIG, and rituximab may be required to treat acute rejection episodes.⁴¹

Chronic Rejection

Chronic rejection is a major cause of long-term kidney graft loss after the first year. It can be either cellular or humorally mediated. It occurs slowly in most cases over several years. Because no specific treatment exists, therapy is supportive (e.g., dialysis in the case of a kidney transplantation). Ultimately, retransplantation is needed. Some data suggest that some patients may benefit from some of the newer agents, such as mycophenolate and sirolimus, which are considered non-nephrotoxic, but this requires further study. The diagnosis of chronic rejection is determined by clinical signs and biopsy findings indicative of obliterative fibrosis of hollow structures and vessels within the graft. The chronic rejection of a kidney must be distinguished from chronic CNI nephrotoxicity, chronic infection, and recurrence of the original kidney disease.⁴²

Chronic Allograft Nephropathy

Chronic allograft nephropathy (CAN) is a term that has been used, generally, as a diagnosis of exclusion that indicates a slow deterioration of renal function over months to years after kidney transplant, with the exact cause unknown. Immunologic and nonimmunologic mechanisms play a role in CAN, a term that has been used to describe this overall process of graft deterioration. Another term, chronic renal allograft dysfunction (CRAD) is the functional result of CAN. It is a slow, insidious process that usually manifests as an increase in serum creatinine after about 1 year, although it can occur as early as 3 months after transplantation. The characteristic signs of chronic rejection are hypertension, proteinuria, and a progressive decline in renal function leading to renal failure. Immunologic factors that increase the likelihood of chronic rejection include a history of acute rejection, inadequate immunosuppression, noncompliance with immunosuppressive therapy, and previous infection, such as CMV. Nonimmunologic factors are donor related (age, hypertension, diabetes), increased ischemic times, recipient hypertension, hyperlipidemia, CNI nephrotoxicity, and elevated body mass index (BMI). CRAD is irreversible and unaffected by increased immunosuppressive therapy. Most recently, it has been recommended that the term CAN be eliminated from the pathologic diagnostic criteria for renal dysfunction because it is nonspecific and the end result of a number of different processes.⁴⁵

Acute Rejection Treatment

10. A biopsy of G.P.'s transplanted kidney shows grade 1A, moderate acute rejection. G.P. is started on methylprednisolone 500 mg daily IV for three doses. His maintenance oral prednisone is discontinued, but his other medications are maintained. He will be placed on a high-dose oral prednisone tapering regimen after his IV doses. Why is methylprednisolone therapy of G.P.'s first acute episode of rejection appropriate?

High-dose or "pulse" IV methylprednisolone, IV OKT3, IV Thymoglobulin, IV ATG, or oral prednisone are several of the options used to treat acute rejection in all types of solid organ transplants. A high-dose corticosteroid (usually IV

methylprednisolone) is considered first-line therapy because it works very quickly in decreasing lymphocyte responsiveness, is easy to administer, and reverses at least 75% of acute rejection episodes. Thymoglobulin and OKT3 are usually reserved for steroid-resistant rejection or more severe grades of rejection. IVIG has also been used as an alternative for resistant rejection.⁴³ The ideal corticosteroid dosage, route, and regimen are unknown, and the number of corticosteroid protocols is as varied as the number of transplantation programs. IV methylprednisolone and oral prednisone are equally effective in reversing rejection, but oral corticosteroids are given for a longer period and have been associated with a higher incidence of adverse effects. Although as little as 50 mg of IV methylprednisolone has a similar lymphocyte suppressive effect as a 1-g IV dose of this drug, most programs use methylprednisolone 250 to 1,000 mg, most commonly 500 mg, IV every day for three doses and adjust the prerejection oral prednisone regimen accordingly. An example of an oral prednisone regimen is 100 to 200 mg/day tapered over 1 to 3 weeks to baseline maintenance dose.⁴⁴

For G.P., IV methylprednisolone is appropriate because corticosteroids are considered first-line therapy for acute rejection of a transplanted kidney, and first rejection episodes (such as G.P.'s) are very responsive. In addition, G.P. has received a prophylactic course of Thymoglobulin recently. Thymoglobulin, ATG, or OKT3 therapy is associated with a higher risk of CMV infection and malignancy; it is more difficult to administer, requires more intensive monitoring, is more expensive, and usually is held in reserve for corticosteroid-resistant or more severe forms of rejection.

Nevertheless, high-dose corticosteroids are not without risk. They increase the risk of infection, and long-term therapy can induce ocular, bone, cardiovascular, and endocrine abnormalities. Although G.P. will be receiving high-dose IV methylprednisolone for only 3 days, because he is diabetic, he should be monitored for hyperglycemia and a change in his insulin requirements because corticosteroids can significantly alter glucose metabolism. Short-course methylprednisolone also can mask signs of infection (e.g., fever, changes in WBC counts, pain associated with inflammation) and delay the diagnosis. Insomnia, nervousness, euphoria, mood shifts, acute psychosis, and mania also can occur with short-term corticosteroid use. If this methylprednisolone regimen is effective in reversing the acute rejection of G.P.'s transplanted kidney, his serum creatinine concentration should decline within 2 to 5 days and his urine output should increase.

In addition, it would be appropriate to increase G.P.'s tacrolimus dosage to 7 mg twice a day because the concentration is low and a relationship exists between concentration and effect. Because small changes in tacrolimus dose can increase levels disproportionately, a trough whole blood concentration should be re-evaluated in 2 to 3 days. The mycophenolate dose could be increased to 1 g BID, because this dose in combination with a CNI has reduced acute rejection in black patients. If G.P. had been on cyclosporine, another option would be to change cyclosporine to tacrolimus, which has been shown to reduce future episodes of acute rejection.⁴⁵ Another important aspect for prevention of future rejection would be to assess G.P.'s adherence with, and understanding of, his medication regimen. Nonadherence is a cause of acute rejection and graft loss.⁴⁶

11. After receiving three doses of IV methylprednisolone, G.P.'s serum creatinine did not decrease and his urine output continued to be low. What is going on? Could this represent a steroid resistant acute rejection? If so, could muromonab (OKT3) be used if G.P.'s acute rejection is steroid resistant?

OKT 3

Because of no improvement in his renal function, based on his serum creatinine and urine output, it appears that G.P. has steroid resistant rejection. Although most centers would generally treat steroid resistant rejection with Thymoglobulin, OKT3 is also an effective agent in this situation. OKT3 is a monoclonal antibody that binds to the CD3 receptor and effectively clears the body of T cells. It is indicated to prevent and treat rejection and is effective to treat severe rejection and steroid-resistant rejection. A typical regimen would be 5 mg IV daily for 5 to 10 days.

Cytokine Release Syndrome

12. One hour after receiving his first 5-mg IV dose of OKT3, G.P. began to experience chills, nausea, and severe muscle and joint aches. His temperature rose from 100.8°F to a maximum of 102.1°F, and his BP dropped to 100/50 mmHg. Which of these effects is consistent with OKT3 administration?

OKT3 produces many adverse effects, which occur with higher frequency after the first and second doses. G.P.'s adverse reaction after his first dose of OKT3 is consistent with this finding. This complex of symptoms is referred to as the *cytokine-release syndrome*. Flulike symptoms (e.g., fever, chills, myalgia, joint pains) are the earliest signal of this syndrome, but they can be accompanied by less common, but more specific, symptoms that reflect the involvement of various organ systems. For example, central nervous system (CNS) symptoms, such as seizures, headaches, photophobia, confusion, and hallucinations, have been reported, as have aseptic meningitis and encephalopathy. Acute reversible renal dysfunction, as evidenced by a rise in the serum creatinine concentration and a decrease in urine output over the first few days of therapy, also may occur. This renal dysfunction usually resolves with continued therapy. Intrarenal graft thrombosis has been reported after high doses (i.e., 10 mg) of OKT3. Patients with evidence of fluid overload on chest radiograph (or >3% over their base weight) should receive furosemide and some may require dialysis before initiating OKT3, because of the possible risk of rapid pulmonary edema and respiratory distress that are caused by cytokine-induced increases in capillary permeability. Anaphylaxis is rarely reported.²⁴

A proposed cause is the release of cytokines, tumor necrosis factor- γ (TNF- γ), IL-2, and IFN- α by T cells after their initial binding with OKT3. OKT3 stimulation of cytokine production is another proposed explanation for the cause of these adverse effects. This effect is independent of cell lysis. The serum concentration of cytokines becomes acutely elevated within 1 to 4 hours after the first and second doses of OKT3, and these high concentrations correlate in time with the onset of the initial symptoms, which usually resolve in 4 to 6 hours. Furthermore, these cytokines have been associated with similar adverse effects in other patient populations.

Cardiovascular effects, including hypotension, hypertension, and tachycardia, can occur in heart transplant recipients and present as a biphasic response. The fever, hypertension, and tachycardia are followed by hypotension, hypoxemia, and decreased vascular resistance 5 to 7 hours later. The cardiopulmonary effects are secondary to a series of events involving a number of mediators, including TNF- α , leukotrienes, prostaglandins, thromboxane A₂, and arachidonic acid metabolites produced and released by endothelial cells, neutrophils, and muscle cells.²⁴

Dosing Protocol

13. What special procedures should be followed in G.P. when using OKT3 therapy?

The high incidence of side effects associated with OKT3 therapy, especially after the first two doses, has prompted strict dosing protocols in most medical institutions. If G.P. had not had a chest radiograph within the last 24 hours, it would be ordered and reviewed before initiation of OKT3 therapy. If he had evidence of pulmonary edema, a dose of IV furosemide appropriate for the patient (commonly, 40 mg in an adult) or dialysis, if appropriate, would have been administered before the first OKT3 dose. G.P. should receive a dose of methylprednisolone 7 to 8 mg/kg (~500 mg) IV 60 minutes before the first dose of OKT3 and 4 mg/kg before the second dose to significantly reduce the amount of cytokine released after administration. Acetaminophen 650 mg orally or rectally (10 mg/kg in children) and diphenhydramine 50 mg orally or IV (1 mg/kg in children) also are administered before the first two doses of OKT3. Prophylactic IV ganciclovir (2.5 mg/kg/day) or oral valganciclovir (both adjusted for renal dysfunction) to prevent CMV infection also has been advocated.

Some transplant centers monitor peripheral T-lymphocyte populations, such as CD3+ T cells, during OKT3 therapy to determine dosing and effectiveness. The effectiveness of OKT3 can be evaluated by monitoring for the presence of CD3+ cells among T lymphocytes in the peripheral circulation. In some transplant centers, the number of soluble CD3+ cells is kept to <10 cells/mL, whereas others are willing to accept 20 to 50 CD3+ cells/mL. Anti-OKT3 titers, and CMV polymerase chain reaction (PCR) blood levels are monitored for at least 3 weeks after discontinuation of OKT3 therapy.

Antibodies to OKT3

14. Why would doses of G.P.'s immunosuppressive drugs need to be adjusted during OKT3 administration?

When OKT3 is administered, antibodies against OKT3 can be formed. These antibodies can be anti-idiotypic, anti-isotype, or both, in most cases. Anti-isotype antibodies are formed against the murine proteins of OKT3, and anti-idiotypic antibodies are formed against the specific CD3 region. In one study of renal transplant recipients, 60% had an anti-idiotypic response and 44% had an anti-isotype response. Overall, an antibody response was detected in 75% of patients. A reduction in the dose of azathioprine, mycophenolate, and prednisone or a reduction in the dose of cyclosporine or tacrolimus while receiving OKT3 has lowered the titers of antibody against OKT3. Anti-idiotypic OKT3 antibodies have the potential to decrease

the effectiveness of repeated courses of the drug. Multiple courses of treatment with OKT3 have been successful, however, particularly if antibody titers are low ($<1:100$).²⁴

When treatment of G.P.'s acute rejection is initiated with OKT3, his tacrolimus dose should be reduced by 50% or temporarily held, his MMF should be held temporarily or decreased by 50%, and his prednisone dose should remain the same. On day 5 to 7 of his OKT3 treatment, his tacrolimus dose should be increased to the dose that he was taking before OKT3 therapy was initiated, and his MMF should be reinstated or increased. He should be tested for an anti-OKT3 antibody titer 2 to 4 weeks after the end of OKT3 treatment, when the maximal anti-OKT3 antibody level is present, in the event that OKT3 would be required at a later time.

Cyclosporine

15. B.B. is a 27-year-old, 60-kg black man who received a deceased donor kidney transplant. Within 12 hours of the transplantation, his immunosuppression consisted of modified cyclosporine (Neoral) 300 mg PO BID, MMF 1.5 g PO BID, and prednisone. He was taking other medicines for hypertension and infection prophylaxis. Describe the pharmacokinetic characteristics of cyclosporine. Based on this information, is B.B.'s cyclosporine regimen appropriate?

Pharmacokinetics

Cyclosporine pharmacokinetic parameters (e.g., absorption, distribution, metabolism) exhibit significant inpatient and outpatient variability, resulting in poor dose-response relationships. A number of factors are known to influence its pharmacokinetic behavior. These include age, transplant type, underlying disease, time after transplantation, GI metabolism and motility; biliary and liver function; metabolism, body weight, cholesterol, albumin, red blood cell mass; and drug interactions and formulation.⁴⁷ These factors can change cyclosporine's absorption, distribution, metabolism, and excretion and can influence therapeutic concentrations and, ultimately, outcomes.^{48,49} For example, children, blacks, and patients with cystic fibrosis tend to have reduced absorption, increased clearance of cyclosporine, or both. Patients who are obese or who have decreased liver function will have reduced clearance. Oral absorption of cyclosporine, which has been characterized as slow, incomplete, and highly variable, is the parameter that is most significantly affected. Absorption can depend on the type of transplant, time after transplantation, presence of food and its composition, intestinal function (e.g., diarrhea, ileus), small bowel length, and presence or absence of external bile drainage.⁵⁰ The mean absorption of the original cyclosporine product (Sandimmune) in adults with relatively normal liver function after a liver transplantation is 27%, which is comparable to that observed in recipients of kidney (27%), heart (35%), and bone marrow (34%) transplants. Bioavailability ranges from $<5\%$ to 90%.⁵¹ In most transplant recipients, cyclosporine absorption increases over time.

Dosing

Because cyclosporine (Sandimmune) absorption is so poor and erratic, it is given IV for the first few days after transplantation, particularly after liver transplantation. Cyclosporine is given IV as a continuous infusion (2–3 mg/kg/day) or intermittently

(2.5 mg/kg/day) over 2 to 6 hours two times a day. As the trough cyclosporine levels begin to rise, the IV dose is decreased gradually, while the oral dose is maintained or increased. This route may still be required in some patients with cystic fibrosis after lung transplantation.

B.B. was given modified cyclosporine (Neoral), a readily absorbed cyclosporine formulation in a solubilized microemulsified state. Neoral's bioavailability is better than that of Sandimmune, so less inpatient and outpatient variability is seen in transplant recipients. Furthermore, Neoral absorption is much less dependent on bile and thus can be used in most liver transplant recipients early after transplant without the need for IV administration. However the doses used are initially higher (10–15 mg/kg/day) than those used after kidney and heart transplantation (5–10 mg/kg/day).⁴⁹

Neoral and Sandimmune are not bioequivalent and, therefore, not interchangeable. Neoral produces a shorter time to C_{max} (T_{max}), higher maximum concentration (C_{max}), and higher area under the concentration-time curve (AUC) than Sandimmune. It has significantly less intrasubject and intersubject pharmacokinetic variability, and a better correlation exists between single doses and trough concentrations and AUC than seen with Sandimmune. The bioavailability of Neoral is approximately 20% higher than that of Sandimmune (absolute bioavailability is 10%–89%). When converting patients on Sandimmune to Neoral, a 1:1 dosage ratio is used unless patients are taking >10 mg/kg/day of Sandimmune. Trough concentrations are initially obtained within the first 4 to 7 days, and dosage adjustments are made accordingly. Most patients tolerate conversion well, although some develop concentrated-related headaches, tremors, or elevated serum creatinine levels that resolve with dose adjustment. In most patients, the Neoral dose is 10% to 20% lower than Sandimmune dose, but as much as a 50% difference can be seen in patients taking large doses (>10 mg/kg/day) of Sandimmune.⁴⁹

The first generic cyclosporine, SangCya, is no longer available. SangCya was bioequivalent to Neoral but not Sandimmune. Three other capsule forms are now available, which are also AB-rated bioequivalent to Neoral (Gengraf from Abbott and modified cyclosporine from Eon and Sidmak). Neoral and Sandimmune are available as both capsule and liquid.

Cyclosporine is extensively distributed into red blood cells, about 60%, whereas in plasma it is highly bound to lipoproteins, about 90%. It is extensively metabolized by both the gut and liver P450 3A4 enzymes and transported by P-glycoprotein. The average half-life is about 15 to 20 hours.^{47–49}

B.B. was started on Neoral 8 mg/kg/day BID. Because he is black, he may require even higher doses, because the absorption of cyclosporine has been reported to be reduced in this population.⁵⁰ His blood concentration will have to be monitored closely and adjusted if necessary. He should be watched closely for signs of rejection and toxicity.

Adverse Effects

16. What are some of the adverse effects associated with cyclosporine?

Cyclosporine can cause a number of adverse effects, of which acute or chronic nephrotoxicity is the most frequent and worrisome. Other major effects include hypertension, hyperlipidemia, tremors, headaches, seizures, paresthesias, hypomagnesemia, hypo- or hyperkalemia, hyperuricemia,

hyperglycemia, gout, gingival hyperplasia, hirsutism, hemolytic-uremic syndrome, and hepatotoxicity. If these occur, they generally respond to a reduction in dose or discontinuation of cyclosporine.⁴⁹

Therapeutic Drug Monitoring

17. B.B.'s cyclosporine levels are being measured by whole blood TDx[®] assay. How should cyclosporine levels be used to optimize his therapy?

Cyclosporine concentrations are monitored to prevent toxicity, optimize efficacy, and assess patient compliance to the prescribed regimen. Most institutions monitor trough cyclosporine levels. During the early postoperative period, cyclosporine levels should be measured daily, keeping in mind that these may not reflect steady-state concentrations, and that dosage changes should be made every few days. Once B.B. is home, cyclosporine monitoring can occur less frequently and eventually every 1 to 2 months. The target trough therapeutic concentration of cyclosporine during the first 2 months is 150 to 400 ng/mL with the monoclonal whole blood TDx assay. About 1 to 6 months after transplantation, the cyclosporine trough concentration target is lowered to 150 to 250 ng/mL. After 6 months, the targeted cyclosporine trough concentration is lowered even further to 50 to 150 ng/mL. These ranges may differ among institutions and also depend on the transplant type, time after transplantation, and other agents used. For example, lung and heart transplant recipients may require higher trough concentrations than kidney and liver transplant recipients. The range is reduced over time, given that less immunosuppression is required after transplantation and that the pharmacokinetics change over time.^{47,48}

A number of assay methods are used to measure cyclosporine concentrations, and most institutions use the method that is most familiar to their transplant physicians. The type of cyclosporine assay used by a particular institution significantly influences interpretation of results because there are significant differences between methodologies. These issues have contributed to the debate on the value of monitoring cyclosporine concentrations. The pharmacologic effects of cyclosporine metabolites and whether the concentrations of these metabolites should be monitored individually, or in combination with cyclosporine, also need to be determined.⁵²

Assays currently in use include high-performance liquid chromatography (HPLC), radioimmunoassay with polyclonal or monoclonal antibodies, enzyme immunoassay (EMIT)[®], and fluorescence polarization immunoassay. Cyclosporine concentrations can be measured in either whole blood or plasma, but plasma cyclosporine levels can differ by as much as 50% if the plasma temperature is 21°C or 37°C; whole blood cyclosporine concentrations are recommended. The most commonly used assay is the whole blood monoclonal TDx.⁵²

No assay appears to be superior in its ability to correlate cyclosporine trough levels with clinical events. Although many studies have attempted to correlate the clinical events of acute rejection or nephrotoxicity to trough concentrations of cyclosporine in recipients of solid organ transplants, results from these studies are conflicting. It may be that the ability to correlate a single blood level during the course of a day with a clinical event that takes place over a longer time period is influenced by too many other variables (e.g., other immunosuppressives, time since transplant, dosage regimen, route, transplant type, assay

method, sample matrix, donor–recipient interaction). Nevertheless, most transplant programs, if not all, use cyclosporine concentrations to guide therapy decisions.

Because of the limitations of using a single cyclosporine level and the poor correlation between AUC and trough concentration, some programs use a more intensive sampling procedure (e.g., 6–10 samples collected over 12–24 hours) when cyclosporine concentrations are expected to be at steady state. The AUC and average steady-state concentrations are calculated and used to guide cyclosporine dosage adjustments. A more limited sampling strategy involving one to three samples (1–4 hours after a dose at steady state) collected over a dosing interval has also been advocated.^{53–55} The more sophisticated pharmacokinetic monitoring programs have developed better correlations between the AUC and dose or AUC and rejection than correlations based on cyclosporine trough levels only. A number of studies have advocated the use of what is known as C₂ monitoring of cyclosporine levels. This level is obtained 2 hours after the Neoral dose. In studies conducted in kidney and liver transplant recipients, a much better correlation was seen with AUC 0 to 4 hour, used as surrogate marker for AUC 0 to 12 hour for Neoral, compared with any other time point, including a C₀ or trough levels. These studies indicate that C₂ level is a more sensitive predictor of acute rejection and toxicity than C₀ or trough values.⁵⁴ The limitation to this approach however, is that it requires training and re-education of staff and patients, potentially more personnel, modification of procedures, and a narrower window for timing of dose and sampling. Also, the concentrations ranges would be higher and different for kidney and liver transplant recipients with this approach.⁵⁵ Extrapolation to other populations, such as children, blacks, and patients with cystic fibrosis or diabetes will require further study.

As in all cases, pharmacokinetic data must be interpreted in conjunction with the patient's clinical condition. In addition, deference always must be given to trends established by multiple cyclosporine levels over that of a single level. Single levels may be erroneous because of variability in dose administration, incorrect sampling techniques (e.g., not being obtained at the correct time if drawn from an IV catheter in which IV cyclosporine had been infused), or assay error.

Sirolimus

18. B.B., developed GI intolerance to MMF and cannot take it anymore. A decision is made to use sirolimus instead. Describe the pharmacokinetic characteristics of sirolimus. What would be the appropriate regimen and monitoring parameters for this agent?

Pharmacokinetics

Pharmacokinetic data are derived primarily from kidney transplant recipients. Sirolimus, as with cyclosporine and tacrolimus, exhibits significant pharmacokinetic variability. It is rapidly absorbed after oral administration of the liquid with a median time to maximum concentration (T_{max}) of about 1 hour. Its average bioavailability is 15%; C_{max} and AUC are linear over a wide range of doses. Sirolimus is extensively distributed, with a mean apparent volume of distribution of 12 L/kg. It distributes primarily into red blood cells and is highly plasma protein bound, approximately 92%. It also binds to

lipoproteins. Sirolimus is extensively metabolized in the gut and liver by CYP 3A4 isoenzymes, and it is a substrate for P-glycoprotein. Its drug interaction profile is very similar to that of cyclosporine and tacrolimus. Renal elimination accounts for only 2% of a dose. The terminal half-life generally ranges from 57 to 63 hours and the time to reach steady state occurs in 10 to 14 days. In children, it can be shorter.⁵⁶

Dosing

Sirolimus can be used in the early transplantation period, although reports of impaired wound healing in kidney transplantations, hepatic artery thrombosis after liver transplantations, and bronchial anastomotic dehiscence in lung transplants during this time period have required reconsideration of its use in this capacity. In the case of liver or lung transplantations, its use is contraindicated in the early post-transplantation period. Sirolimus can be added later, as is the practice in many centers, as replacement for or minimization of cyclosporine, tacrolimus, steroids, or mycophenolate doses.⁵⁷ An initial loading dose is given followed by a once-daily maintenance dose. The starting maintenance dose range is 2 to 5 mg. The typical loading dose is 6 mg followed by 2 mg every day. In high-risk patients, such as blacks, a 15-mg loading dose and 5-mg daily dose is recommended along with cyclosporine. Other centers have used loading doses of 10 to 15 mg, followed by 5 to 10 mg/day for the first week with target levels of 10 to 15 ng/mL for the first month, and 5 to 10 ng/mL thereafter when used with tacrolimus.⁵⁸ Sirolimus is often given 4 hours after the morning dose of cyclosporine. If administered at the same time, sirolimus concentrations were, on average, 40% higher, than cyclosporine concentrations.⁵⁹

Adverse Effects

As with other immunosuppressives, sirolimus is associated with a number of side effects, including oral ulcerations, diarrhea, arthralgias, epistaxis, rash, acne, leukopenia, thrombocytopenia, nausea and vomiting, lymphocele, hypokalemia, anemia, hypertension, and infection. The most concerning side effects are dose-related hypertriglyceridemia and hypercholesterolemia. This occurs within the first few weeks of therapy and is sufficiently significant to require intervention with lipid-lowering agents, although it will respond to dosage reduction to some degree.⁵⁷ Recently, there have been reports of sirolimus causing proteinuria in renal transplant recipients. The exact mechanism is unknown, but many transplant centers are now routinely monitoring for proteinuria in patients on sirolimus therapy.⁶⁰

Therapeutic Drug Monitoring

Monitoring of blood concentrations plays an important role in the dosing of sirolimus. Trough concentrations are obtained and correlate well with sirolimus AUC. Because it has a longer half-life than the CNI, concentrations are obtained less frequently and only 5 to 7 days after a dose change. The target concentration range appears to be between 5 and 15 ng/mL; however, this continues to be refined with more experience. Early studies often achieved concentrations >15 ng/mL, especially if used without a CNI, which were associated with a higher degree of immunosuppression and adverse events.⁶¹ Because sirolimus appears to work synergistically with the

CNI, their target concentrations are reduced as well when these agents are used together. Target tacrolimus trough targets are 5 to 10 ng/mL, and the cyclosporine trough targets are 75 to 100 ng/mL.⁶²

B.B. could be started on sirolimus at a loading dose of 6 mg, followed by 2 mg daily. Sirolimus blood trough concentration should be obtained 5 to 7 days after initiation. B.B.'s tacrolimus may need to be reduced if concentrations exceed 10 ng/mL. Monitoring parameters should include a fasting lipid panel, complete blood count (CBC), chemistries, and electrolytes.

CNI-Induced Nephrotoxicity

19. C.C. is a 60-year-old man who received a DD kidney transplant 3 years ago. His serum creatinine at 1 year after transplant was 1.8 mg/dL; at 2 years, it was 2.0 mg/dL; now it is 2.3 mg/dL. He says he feels fine. His BP is well controlled and urinalysis is negative for protein. A kidney biopsy conducted at this time indicates that he has no signs of acute or chronic rejection, but has evidence of CNI nephrotoxicity. His current regimen is cyclosporine 275 mg BID, MMF 500 mg BID, and prednisone 5 mg daily. Prednisone was reinstated at 20 mg daily. His current cyclosporine blood concentration is 120 ng/mL (target 100–150 ng/mL). Why does C.C. have CNI nephrotoxicity?

With CNI nephrotoxicity, the rise in the serum creatinine concentration is more gradual and not as high as that seen with rejection. CNI concentrations may be elevated, although some patients may experience CNI nephrotoxicity even with levels below or within the targeted therapeutic range. Two forms of CNI nephrotoxicity have been identified: functional or acute renal dysfunction and chronic nephrotoxicity.⁶³

Acute CNI nephrotoxicity is more likely to occur in the first months after transplantation in most patients receiving therapeutic doses because CNI doses and levels are highest and are being adjusted at this time, whereas chronic toxicity usually takes longer. Functional renal dysfunction, the most common form of renal dysfunction, is characterized by rapid reversal when the CNI dosage is held or reduced. This syndrome typically is not associated with histopathologic abnormalities, which suggests that it is related to severe vasoconstriction of the renal afferent arterioles. Repeated episodes of transient acute renal dysfunction can result in protracted acute renal dysfunction. Recovery of renal function after repeated episodes usually is not complete even when CNI is withdrawn. Protracted acute renal dysfunction can be associated with the development of thrombosis of glomerular arterioles or diffuse, interstitial fibrosis. Alternatively, cyclosporine may exacerbate intravascular thrombus formation or may serve as a stimulus to interstitial cell proliferation. Another syndrome is a chronic, usually irreversible, nephropathy, which often is associated with mild proteinuria and tubular dysfunction. Renal biopsies in allograft patients with chronic cyclosporine-related nephropathy showed tubulointerstitial abnormalities, sometimes with focal glomerular sclerosis.

Nephrotoxicity, one of the most common adverse effects associated with CNI, occurs to some degree in all patients. The pathophysiology of cyclosporine or tacrolimus-induced transient acute renal failure is not understood completely, but seems to be related to its effects on renal vessels. For example, CNI

can induce glomerular hypoperfusion secondary to vasoconstriction of the afferent glomerular arteriole, thereby reducing glomerular filtration. One possible explanation for these effects is that cyclosporine alters the balance of prostacyclin and thromboxane A₂ in renal cortical tissue. Increased thromboxane A₂ results in renal vasoconstriction. Endothelin release from renal vascular cells stimulated by CNI also may contribute to this acute effect through its potent vasoconstrictive properties. CNI also can cause a reversible decrease in tubular function. The alterations in tubular function reduce magnesium reabsorption and decrease potassium and uric acid secretion. This may be a result of direct tubular toxicity and possibly the result of thromboxane A₂ stimulation of platelet activation and aggregation. A chronic nephropathy, usually seen after >6 months of therapy, can also occur and may become irreversible. In this situation, renal function progressively declines to a point that dialysis is required.⁶⁴

Concern for chronic nephropathy has led to the development of cyclosporine or tacrolimus withdrawal or substitution protocols, using agents, such as mycophenolate or sirolimus, or protocols using low doses of cyclosporine or tacrolimus.⁶⁵ G.P.'s rise in serum creatinine and hypertension in conjunction with a high cyclosporine level suggests acute cyclosporine toxicity as the most likely cause of his findings. In this case, the total cyclosporine dose should be lowered by approximately 25% to 225 mg twice a day, and G.P. should be monitored closely for resolution of the symptoms or worsening if rejection results from lowering the dose. His elevated potassium, uric acid, and low magnesium should correct themselves with this dose reduction if it is acute CNI toxicity. In any case, magnesium should be replaced to maintain a level >1.5 mEq/L. If the nephrotoxicity is caused by cyclosporine, a decrease in the serum concentration of creatinine may be evident when the cyclosporine dose is reduced. If no such reduction occurs or if the serum concentration of creatinine continues to increase, then a renal biopsy is needed to rule out rejection, nephrotoxicity, or other causes.

CNI Avoidance, Withdrawal, or Minimization

20. Would it be appropriate to withdraw cyclosporine in C.C.? If attempted, how could this be accomplished?

Cyclosporine and tacrolimus are associated with a number of metabolic, cardiovascular, neurologic and cosmetic side effects but the most concerning is nephrotoxicity, which contributes to graft loss. The potential benefit of withdrawing cyclosporine would be to reduce toxicity, but this has to be weighed against the risk for rejection, graft loss, and toxicities of replacement agents.

IL-2R antibodies, sirolimus, and mycophenolate, which are not associated with nephrotoxicity, are being evaluated in protocols that attempt to avoid, minimize, or withdraw CNI. Alternative regimens that have included sirolimus, mycophenolate, and steroids; sirolimus and steroids; and daclizumab, mycophenolate, and steroids have been compared with cyclosporine-based regimens or historical data. Studies, which were usually done in low-risk populations, generally produced reduced serum creatinines and CNI-induced toxicities, but were associated with high rates of acute rejection

(30%–50%). More recent trials in small numbers of patients that compared combinations of Thymoglobulin or basiliximab, sirolimus, mycophenolate, and steroids with either cyclosporine- or tacrolimus-containing regimens have shown equal effectiveness with acute rejection rates of <15%.⁶⁶

In the case of cyclosporine withdrawal, a 10% to 20% increased risk of acute rejection appears to exist, but no change in graft survival. Several protocols are being developed that either withdraw the CNI or at least reduce the dose to a minimal level. Many are attempting to do this earlier after transplantation in the hope that the nephrotoxic effects can be reversed before significant chronic damage occurs. These approaches add mycophenolate, sirolimus, or both as the CNI is withdrawn or reduced in dose. Most protocols have been tested in small numbers of low-risk patients. A few larger studies have used a low-risk population.⁶⁷ In one of these, all patients received cyclosporine, sirolimus, and corticosteroids as their initial immunosuppressant regimen. In one arm, at 3 months after transplantation, cyclosporine was decreased and withdrawn over 6 to 8 weeks while sirolimus and steroids were maintained. In the other arm, cyclosporine, sirolimus, and corticosteroids were continued throughout the study period. Acute rejection rates were 9.8% in the CNI withdrawal group compared with 4.2% in the nonwithdrawal group. Renal function was better and BP lower, in the withdrawal group. In the withdrawal group, however, side effects associated with sirolimus, such as thrombocytopenia, hypokalemia, hyperlipidemia, and elevated liver function tests (LFT), were more frequent and many patients dropped out of the study. In a mycophenolate-based study, in which cyclosporine was withdrawn, improvements were seen in patients who did not develop acute rejection. Acute rejection episodes occurred in 10% in the withdrawal group with no graft loss and lower lipid profiles.⁶⁸ Usually, when sirolimus is added to the CNI regimen, the CNI dose is reduced by 50% initially and in some cases slowly withdrawn altogether over several weeks to months. Improvement in serum creatinine may be seen initially, which may be attributed to the diminution of the CNI vasoconstrictive effects.

This approach may not reverse the nephrotoxicity observed in C.C.'s biopsy, but it may slow the rate of deterioration of his renal function. Because C.C. is currently receiving mycophenolate, one approach would be to continue to reduce his cyclosporine, increase his mycophenolate and maintain steroids. Another approach would be to replace the mycophenolate with sirolimus, maintain steroids, and reduce or withdraw the cyclosporine. The best regimen for someone such as C.C. has not been established, since the long-term consequences of these changes are not known. If this approach is attempted, C.C. should be watched carefully for acute rejection, and side effects of these agents and infections should be closely monitored. In addition, BP control as well as control of hyperlipidemia and hyperglycemia could improve with reduction or withdrawal of cyclosporine and could also be important in minimizing renal injury.⁵²

Steroid Avoidance or Withdrawal

21. D.T., a 60-year-old white woman, will receive a DD kidney transplant today because she has a negative cross-match to this donor and her previous PRA was <10%. She will be given one

dose of alemtuzumab 30 mg IV and 1 dose of methylprednisolone 500 mg IV intraoperatively. After transplant, she will be started on tacrolimus 0.025 mg/kg BID, adjusted to trough levels of 8 to 12 ng/mL for the first 3 months, along with MMF 750 mg BID. Methylprednisolone IV will be given as 250 mg IV on postoperative day (POD) 1, 125 mg IV on POD 2 and 3, and then discontinued. Is D.T. a good candidate for steroid avoidance or withdrawal?

Another important issue after kidney transplantation is the role of short- and long-term steroid use. Most transplant protocols incorporate steroid therapy, although an increasing number of protocols use steroids only in the early postoperative period.²⁰ The concept of either avoiding or discontinuing corticosteroids is appealing because they cause significant adverse effects such as diabetes, cataracts, infection, hypertension, hyperlipidemia, osteoporosis, and avascular necrosis, and have psychiatric, neurologic and cosmetic effects. Steroid withdrawal or avoidance, however, could increase the risk of acute rejection, compromise long-term graft function, and necessitate higher doses of the other immunosuppressives.¹⁵

Steroid avoidance is defined as either no steroid use or steroid use only for the first few days after transplant. Preliminary studies suggest no adverse impact on short-term graft survival exists and no need is seen for higher doses of other immunosuppressives when corticosteroids are not included in maintenance regimens. These protocols have included regimens such as alemtuzumab; daclizumab, basiliximab, or Thymoglobulin; mycophenolate or sirolimus; and cyclosporine or tacrolimus.^{15,30,52,53}

Steroid withdrawal in the era of cyclosporine (Sandimmune)- and azathioprine-based regimens was associated with a high rate of acute rejection and late graft loss. With the introduction of newer agents, steroid avoidance or withdrawal has been viewed with renewed interest. Steroid withdrawal has been successful in at least 50% of kidney transplant recipients—resulting in reductions in BP and lipid levels. Some protocols have withdrawn corticosteroids within the first few days to weeks after the initial transplantation period, whereas others attempt to withdraw them 3 to 6 months or later after transplantation. The rate of success depends not only on the immunosuppressives used, but on the population (high risk vs. low risk) and timing of withdrawal. Regimens that appear most successful include an antibody with cyclosporine or tacrolimus, mycophenolate, or sirolimus. In terms of population, blacks, pediatric patients, patients who have retransplants, highly sensitized patients, and patients with a high serum creatinine (>2.5 mg/dL) those who have had a recent rejection episode are more difficult to withdraw from steroids. This is particularly true early (<3 months) after transplantation. Withdrawal in these cases is associated with a higher rate of rejection. Later withdrawal may be attempted, but the benefits in terms of side-effect profile may not be as great. Low-risk populations are candidates for steroid avoidance or early withdrawal. First-time transplantation, living-donor, well-matched transplantation, older age, and stable graft function without rejection are factors associated with a positive response to steroid withdrawal.⁶⁹

D.T. would be considered a low-risk patient because of her low immunologic activity evidenced by a low PRA, her age, and ethnicity. Therefore a steroid avoidance protocol, such as

the one indicated above, would be appropriate. As with other transplant recipients, she must be closely monitored for rejection and adverse effects.

BK Polyomavirus Infection

22. K.T., a 45-year-old white man, is now 16 months post-transplant. His post-transplantation course has been complicated by two rejection episodes. The first was severe and required Thymoglobulin therapy; the second was a mild rejection several weeks later that was adequately treated with three pulse-doses of 500 mg of IV methylprednisolone. His current immunosuppressant regimen consists of tacrolimus 8 mg PO BID, MMF 1 g PO BID, and prednisone 10 mg PO daily. In addition, he is receiving amlodipine 10 mg PO daily, benazepril 10 mg PO daily, pravastatin 40 mg PO at bedtime, and calcium with vitamin D 500 mg PO BID. Today, he is in the transplant clinic for a routine follow-up visit. He has no complaints and says he has been feeling “great,” although he has noticed some blood in his urine over the past couple of weeks. Because of this, a urinalysis is ordered in addition to the standard laboratory values. The results are as follows: Na, 145 mEq/L (normal, 135–145); K, 4.2 mEq/L (normal, 3.4–4.6); Cl, 104 mEq/L (normal, 95–105); HCO₃, 26 mEq/L (normal, 22–28); BUN, 32 mg/dL (normal, 8–18); SrCr, 2.7 mg/dL (normal, 0.6–1.2); Ca, 10.1 mEq/L (normal, 8.8–10.3); phosphorus, 4.5 mg/dL (normal, 2.5–5.0); glucose, 110 mg/dL (normal, 65–110); amylase, 50 U/L (normal, 27–150); lipase, 32 U/L (normal, 10–50); WBC count, 7.7 cells/mm³ (normal, 4,000–10,000); Hgb, 10.4 g/dL (normal, 14–18); and Hct, 31% (normal, 39%–49%); tacrolimus trough level of 9 ng/mL; urinalysis, color yellow (normal, clear–yellow); specific gravity, 1.013 (normal, 1.003–1.030); pH, 7.0 (normal, 5.0–7.0); protein 100 mg/dL (normal, negative–trace); glucose, negative (normal, negative); ketones, negative (normal, negative), bilirubin, negative (normal, negative), blood, moderate (normal, negative); nitrite, negative (normal, negative) leukocyte, negative (normal, negative); squamous epithelial cells, 3 cells/high power field (HPF) (normal, 0–5 cells/HPF); bacteria, negative (normal, negative). Urinalysis revealed “decoy” cells and plasma BKV PCR was >10⁴. Because of the increasing serum creatinine, a percutaneous kidney biopsy is performed. The pathologist reviews the histology of the tissue sample and determines that it is consistent with BK virus nephritis. What is BK polyomavirus? How is it diagnosed and what are its clinical manifestations?

BK virus is a human polyomavirus, first isolated in 1971. Polyomaviruses are small, nonenveloped viruses with a closed, circular, double-stranded DNA sequence. Little is known about the transmission or about the primary infection of BK virus. It is believed that viremia during the initial exposure results in systemic seeding and subsequently into a latent infection. The kidney is the main site of BK virus latency in healthy people. More than 50% of the general population express BK virus antibodies by age 3. Immunosuppression after transplantation probably leads to the reactivation of the virus, but other factors, such as organ ischemia and coinfection with other pathogens, may contribute to reactivation. Reactivation inevitably leads to viruria or viral shedding into the urine. Asymptomatic viruria occurs in approximately 10% to 45% of renal transplant recipients.⁷⁰

Diagnosis of BK virus nephritis is made by careful review of clinical, laboratory, and histologic findings. Patients are often asymptomatic, although hematuria has been noted in some

patients. Clinically, BK virus nephritis mimics acute rejection very closely. Increases in serum creatinine often lead clinicians to perform a tissue biopsy. Tissue histology is very similar in cases of acute rejection and BK virus nephritis, with mononuclear infiltration as the predominant finding. The abundance of plasma cells, prominent tubular cell apoptosis, collecting duct destruction, and absence of endarteritis are features that may distinguish BK virus nephritis from acute cellular rejection. Although BK virus has been implicated in up to 5% of all cases of interstitial nephritis (of which 30% go on to graft failure), it is still unclear whether asymptomatic biopsy findings in the kidney transplant recipient is a prognostic indicator. Decoy cells in the urine and BKV-PCR in blood are used as screening tools. Blood or plasma BKV-PCR is a more sensitive and stable test and correlates better with renal dysfunction.⁵⁷

Most cases of BK nephritis occur within the first 3 months after transplantation, although a number of cases have been reported as long as 2 years after transplantation. The major risk factor for the development of BK nephritis and subsequent graft dysfunction or loss is the degree of immunosuppression. In addition, accelerated graft loss has been demonstrated in patients who received antilymphocyte antibodies in the presence of BK virus nephritis misdiagnosed as an acute rejection episode. Because K.T. has received higher doses of immunosuppression recently to treat two acute rejection episodes, he is at higher risk for developing BK virus nephritis.

Treatment

23. K.T. is told to stop taking MMF and to reduce his tacrolimus dose to 4 mg PO BID with target trough levels <6 ng/mL. Why was K.T.'s immunosuppressive regimen significantly reduced?

Because BK virus reactivation and BK nephritis are strongly associated with the degree of immunosuppression, reduction in, or removal of, immunosuppressant agents is considered first-line therapy. Beneficial clinical responses have been demonstrated in some patients when the dose of CNIs is reduced. Not all patients, however, respond to this maneuver. In addition, reduction in immunosuppression puts patients at higher risk for an acute rejection episode. Close clinical follow-up after reduction of immunosuppression is important to ensure adequate response and to make sure the patient does not develop an acute rejection episode. In K.T.'s case, an improvement of renal function can be expected, as seen by a reduction in serum creatinine over time. Also, monitoring viral loads both from the urine and serum have been shown to correlate with clinical disease.⁵⁷

Antiviral Therapy

24. Over the next 2 weeks, K.T.'s serum creatinine remains unchanged, and his serum and urine viral loads also remain approximately the same. Are there any additional treatment options for K.T.'s BK nephritis at this time?

Cidofovir (Vistide), an antiviral agent indicated for the treatment of CMV retinitis, inhibits polyomavirus replication in vitro; however, to date, no well-conducted clinical trials have proved this agent to be effective in treating or preventing BK virus nephritis in the transplant population. In a small number of case reports and case-series, this agent was beneficial, but the appropriate dose and frequency are still undetermined. Most re-

ports have used very small doses (0.25–1.0 mg/kg/dose) given IV either weekly or every other week; cidofovir was continued until renal dysfunction resolved and a decrease in the viral load occurred.

Cidofovir is associated with a high incidence of nephrotoxicity, especially at much higher doses; therefore, patients usually receive pre- and postdose hydration with 0.9% NaCl boluses. Close clinical monitoring of the patient is advised if this treatment option is used. Because the doses of cidofovir currently used are approximately 5% to 10% of the standard dose used to treat CMV (5 mg/kg/dose), use of probenecid as a premedication to prevent nephrotoxicity is not advocated. Other therapies that have been tried with or without success are IVIG and leflunomide in place of the discontinued antimetabolite, such as mycophenolate, and fluoroquinolones. Retransplantation has also been conducted with some success.⁷¹

New Onset Diabetes After Transplant (NODAT)

25. J.F. is a 28-year-old black man who received a kidney transplant 6 weeks ago secondary to focal segmental glomerulosclerosis (FSGS), a glomerulonephritis of unknown etiology. His medical history is significant for hypertension and nephrotic syndrome. Before the transplant, he was taking lisinopril 20 mg PO daily, amlodipine 10 mg PO daily, and valsartan 160 mg PO daily. After the transplant, J.F. was started on tacrolimus, with his current dose being 12 mg PO BID, mycophenolate mofetil 1 gm PO BID, and a corticosteroid taper. He is currently receiving 20 mg PO BID of prednisone, and will be tapered down over the next 6 weeks to 10 mg PO daily. J.F.'s tacrolimus trough concentrations have been between 10 and 14 ng/L. Over the next 12 weeks, he will be maintained on a dose of tacrolimus to achieve trough concentrations between 8 and 12 ng/L. J.F. currently weighs 108 kg and is 6 feet tall. His BMI is 32 kg/m². After transplant, he has required a sliding-scale regular insulin regimen to maintain a blood glucose level between 120 and 180 mg/dL.

What post-transplant complications are common and what is J.F. at risk of developing?

Post-transplantation diabetes mellitus (PTDM), or now more commonly referred to in the transplant literature as new onset diabetes after transplant (NODAT), is another common problem that appears to be on the increase in transplant recipients, similar to the increase in diabetes mellitus in the general population. Diabetes significantly affects morbidity and mortality in transplant recipients. It is often a pre-existing condition in renal transplant recipients and a cause of ESRD. In recipients of other organs, such as livers, diabetes is common as well, both as a pre-existing condition and as a post-transplantation complication. The definition of NODAT varies among studies. It has been based on symptoms and plasma glucose, oral glucose challenge results, or the need for insulin or oral antidiabetic drugs after transplantation.⁷² Reported rates range from 3% to >40%, with most cases of NODAT occurring within the first year after transplantation. Risk factors, besides pre-transplantation diabetes, include advanced age, family history, CMV infection, certain HLA phenotypes, race (black or Hispanic), increased BMI, and infection with hepatitis C in the liver transplant population.⁷³

One of the most critical factors in the development of NODAT is the immunosuppressive regimen. Cyclosporine,

tacrolimus, sirolimus, and prednisone are all diabetogenic through a multitude of mechanisms. The CNI appear to have a direct toxic effect on the pancreatic beta cells leading to decreased insulin synthesis and secretion; this effect seems to be dose related and generally reversible.^{74,75} Although still debated by a few clinicians, the literature now clearly suggests that tacrolimus is more likely to cause NODAT than cyclosporine.⁷⁴ Additionally, conversion from tacrolimus to cyclosporine has been useful in some patients with NODAT.⁷⁶ In evaluating these studies, other factors, such as CNI drug concentrations, steroid doses, black race, transplant type, and time lapsed following transplantation, must be considered.⁷⁷

As with diabetes in the general population, a similar intensive approach in controlling blood glucose should be undertaken. Also, other conditions (e.g., hypertension and hyperlipidemia) should be managed aggressively. Another step includes reducing or withdrawing diabetes-inducing immunosuppression as much as possible without jeopardizing graft function or using agents that are nondiabetogenic, such as mycophenolate.^{60,63} One important aspect of post-transplant diabetes management is to realize the differences in pharmacologic management in this patient population, as compared with patients who are not transplant recipients. Often, in the immediate post-transplant period, because of the rapidly changing organ function, and the dramatic tapering of corticosteroids, patient's antidiabetic medicines may need frequent adjustment. During this first 3 to 4 weeks post-transplant, insulin is the agent of choice owing to the ability to use sliding-scales and rapidly change dosing strategies. Once patients are stabilized on their immunosuppressant regimen, and their organ function has also stabilized, the use of oral agents can be introduced or restarted. Because of metformin's contraindications, it is usually not recommended for use in transplant recipients.⁷²

J.F. is requiring insulin post-transplant. By some clinicians' definitions, he would be classified as having NODAT. Other definitions would wait to see if J.F. still required insulin after his immunosuppressant regimen was tapered to lower levels. In either regard, because J.F. is obese and is black, he is considered at high risk for the development of NODAT. At this point, J.F.'s diabetes should continue to be controlled on a sliding-scale insulin regimen. Once J.F.'s immunosuppression regimen is stable, he can be switched to oral antidiabetic agents if needed. J.F. should be counseled on diet and exercise to help control his blood glucose level. Other pharmacologic interventions that may help prevent long-term diabetes in J.F. is changing his tacrolimus to cyclosporine and reducing or withdrawing his prednisone. The risks and benefits of changing immunosuppressant regimens must always be weighed in patients such as J.F. For instance, changing his tacrolimus to cyclosporine may reduce his blood glucose level or prevent NODAT, but it also will put J.F. at higher risk of developing acute rejection. Additionally, reducing or removing J.F.'s steroids may also prevent NODAT, but will likely put J.F. at higher risk of acute rejection.

Post-Transplantation Osteoporosis

Rapid bone loss with the subsequent development of osteopenia or osteoporosis is another common post-transplantation disorder that must be evaluated, prevented, and treated. Osteoporosis, a silent disease, is characterized by low bone mass and microarchitectural deterioration of bone tissue, which in-

creases bone fragility and eventually leads to fracture. Various epidemiologic and cross-sectional studies estimate that 7% to 11% of nondiabetic kidney transplant recipients, 45% of diabetic kidney transplant recipients, 18% to 50% of heart transplant recipients, and 24% to 65% of liver transplant recipients develop atraumatic fractures resulting from osteoporosis in the post-transplantation period.⁷⁸

RISK FACTORS

Osteoporosis risk factors for transplant recipients, which are similar to those in the general population, include menopausal status, family history, smoking, alcohol use, lack of physical activity, poor nutritional status, and use of various medications, such as corticosteroids, phenytoin, thyroxine, heparin, warfarin, and loop diuretics.⁷⁸ Additional factors responsible for bone loss in organ transplant recipients depend on the underlying disease state and the particular organ system transplanted. For example, patients with ESRF commonly have at least some evidence of renal osteodystrophy, which includes hyperparathyroidism, osteomalacia, osteosclerosis, and adynamic or aplastic bone disease. Hypogonadism can also be present. Many renal transplant recipients have already been exposed to medications that can affect bone and mineral metabolism, such as corticosteroids, cyclosporine for immune complex disease, loop diuretics, or aluminum-containing phosphate binders.⁷⁹ Low bone mass and abnormal mineral metabolism are common in patients with several forms of chronic cholestatic liver disease, such as biliary cirrhosis. Therefore, liver transplant recipients are susceptible to this problem.⁸⁰

Drugs used to prevent organ rejection predispose patients to osteoporosis, especially the corticosteroids.⁸¹ Most transplant recipients, however, require steroids in combination with other immunosuppressive agents to prevent rejection. As noted, efforts are underway among transplant centers to develop corticosteroid-free or rapid-taper corticosteroid immunosuppressant regimens to help prevent post-transplant bone disease. Corticosteroids reduce net intestinal calcium absorption, increase urinary calcium excretion, increase parathyroid hormone, decrease production of skeletal growth factors, and decrease androgen and estrogen synthesis in the gonads and adrenal gland. They also decrease bone formation by osteoblasts and increase bone resorption.⁸¹ The most dramatic reduction in bone loss after transplantation occurs within the first 3 to 6 months, when high doses of steroids are tapered to prednisone doses equivalent to 7.5 to 10 mg every day. Areas of the skeleton rich in trabecular or cancellous bone, such as the ribs, vertebrae, distal ends of long bones, and the cortical rim of the vertebral body, are most at risk for osteoporotic fracture because (a) a greater degree of bone remodeling or bone turnover occurs in these areas and (b) this is a target of corticosteroid activity.⁷⁸ Most studies suggest a minor effect from CNI on bone. Other currently used agents appear to have little or no effect.⁷⁹

TREATMENT

Because rapid bone loss and fractures can occur during the first few months postoperatively, strategies to prevent bone loss and fractures should be initiated immediately after transplantation and if possible before transplantation. Most recommendations are based on the American College of Rheumatology's (ACR) guidelines for the prevention

and treatment of corticosteroid-induced osteoporosis.⁸² These recommendations focus on providing calcium (1,500 mg elemental calcium three times a day) and vitamin D (various dosing depending on kidney and liver functions) to patients who will be receiving continuous corticosteroid therapy. If patients are diagnosed with low bone mineral density (osteopenia) or even osteoporosis with bone mineral density scans using dual energy x-ray absorptiometry (DXA) scans, calcium and vitamin D analogs are recommended in conjunction with either a bisphosphonate or calcitonin.⁸¹

Clinical trials have demonstrated that bisphosphonates and vitamin D analogs have had the best results in preventing and treating post-transplant bone disease. Because of their lack of size and short follow-up time, these studies have failed, however, to show a significant improvement in meaningful outcomes, including reduction in bone fracture rates, bone pain, or immobility owing to bone disease. Most studies show that these agents can minimize the loss of bone post-transplant, as demonstrated by stabilization of DXA scans.⁸³

Although J.F. is young and likely does not have severe bone disease, a DXA scan should still be performed, and he should be given calcium and vitamin D because he is receiving steroids (unless he has a contraindication to this therapy, such as hypercalcemia). Based on the results of J.F.'s DXA scan, he may need to receive either a bisphosphonate or an activated vitamin D analog, such as calcitriol, and continue calcium supplementation. A repeat DXA scan should be performed in 1 to 2 years. J.F. should be carefully counseled on how to take his medicine correctly to minimize adverse effects and he should be monitored for hypo- or hypercalcemia.

LIVER TRANSPLANTATION

Indications

26. E.P., a 58-year-old, 78-kg man, with an 18-year history of chronic liver disease secondary to hepatitis C infection, arrives at the emergency room with a 2-day history of confusion, fever up to 102.2°F, and worsening jaundice, with scleral icterus. Because the patient has severe abdominal distention, a paracentesis is performed, and 7 L of fluid is drained from his peritoneal cavity. A diagnosis of spontaneous bacterial peritonitis is made.

E.P.'s clinical status over the next several days gradually worsens, and he is moved to the intensive care unit for closer monitoring and better supportive care. E.P. continues to be severely jaundiced, with worsening Liver Function Test (LFT). He becomes progressively more confused, and eventually comatose, requiring intubation. Within 3 days of admission into the intensive care unit (ICU), a suitable liver donor, matched for size and ABO blood group, is found, and E.P. receives an orthotopic liver transplant with a choledochocholedochostomy (duct-to-duct anastomosis). Cytomegalovirus (CMV) serology for E.P. is negative, and the donor liver is CMV-positive.

After the transplantation, E.P. is started on fluid maintenance with 45% NS; nystatin suspension 5 mL four times daily (QID); tacrolimus 2 mg NG/PO BID; and high-dose methylprednisolone with a rapid taper: 50 mg IV Q 6 hours for four doses, 40 mg IV Q 6 hr for four doses, 30 mg IV Q 6 hours for four doses, 20 mg IV Q 6 hr for four doses, 20 mg IV Q 12 hours for two doses, then 20 mg IV daily; famotidine 20 mg IV Q 12 hr; and

ganciclovir 150 mg IV daily. Ampicillin sulbactam 1.5 g IV Q 6 hr for 48 hours was begun just before transplantation. An order also is written to limit all pain medications and sedatives. E.P. returned from surgery with three abdominal Jackson-Pratt (J-P) drains, an nasogastric (NG) tube. Foley catheter, and Swan-Ganz central venous catheter. What was the indication for E.P. to receive a liver transplant?

E.P. was diagnosed with end-stage hepatic failure (cirrhosis) caused by chronic hepatitis C infection. The most common indication for liver transplantation in adults is cirrhosis from various causes. Each transplantation center varies with respect to the most common disease states that indicate transplantation, but nationwide, hepatitis C and alcohol-induced disease are the number one and two reasons for patients requiring liver transplantation. Indications for liver transplantation in adults include cholestatic liver disease (e.g., primary biliary cirrhosis and primary sclerosing cholangitis), hepatocellular liver disease (e.g., chronic viral hepatitis B or C, autoimmune, drug-induced, cryptogenic cirrhosis), vascular disease (e.g., Budd-Chiari), hepatic malignancy, inherited metabolic disorders, and fulminant hepatic failure (e.g., viral hepatitis, Wilson's disease, drug or toxin induced). Controversial indications include alcohol-induced disease and some types of hepatic malignancies. The concern with these indications is either recurrence of disease, as in the case of hepatic malignancies, or recidivism in the case of alcoholics.^{84–86}

Contraindications to transplantation have decreased in numbers over the past few years. Current contraindications to liver transplantation include malignancy outside the liver, cholangiocarcinoma, active infection outside the biliary system, patients with alcoholic liver disease who continue to abuse alcohol, psychosocial instability and noncompliance, severe neurologic disease, and advanced cardiopulmonary disease. Patients with active infections are considered candidates after the infection has been eradicated.⁸⁶ HIV infection is not considered an absolute contraindication to transplantation.⁸⁷

E.P. was within the age limitations for transplantation; he had severe progressive disease and was at risk for death if he had not received a liver transplant. Because he did not have any of the listed contraindications, a liver could be transplanted emergently. His anticipated survival after transplantation at 1 year is >80%; at 5 years it is >70%.⁸⁴

Patient Monitoring

27. How should E.P. be monitored in the initial postoperative period?

A typical course is as follows. E.P. should be awake and alert within 12 to 24 hours after the operation, transferred from the ICU to a regular bed in 1 to 3 days, and discharged home within 7 to 14 days if he has a standard postoperative course with no severe complications. Because function of the transplanted liver is essential for the survival of the patient, extensive clinical, laboratory, and radiologic monitoring are necessary. E.P. has three J-P abdominal drains that must be monitored for output production. The serum concentrations of BUN, creatinine, LFT, albumin, potassium, sodium, magnesium, calcium, phosphate, and glucose should be monitored every 6 hours on the first postoperative day.⁸⁸ The surgical transplantation of a liver has been associated with coagulopathies and bleeding. Therefore,

platelets, prothrombin time, fibrinogen, and factors V and VII also must be monitored and deficiencies rapidly corrected.⁸⁹

Initial LFT results are highly variable; they can either increase for the first day or two after transplantation because of ischemic damage to the allograft, or they can decrease because of initial dilution by high-volume blood replacement. If the liver is functioning well, the LFT, bilirubin, and prothrombin time all should begin to trend toward normal within 4 to 5 days after the operation.

Magnesium, phosphate, and calcium levels may fall in the early postoperative period and should be monitored closely. Ionized calcium serum concentrations are monitored rather than total calcium because most patients have low serum albumin concentrations. Hypocalcemia can occur because these patients may receive large amounts of citrate through blood transfusions, which can lower serum calcium concentrations. Magnesium deficiency is common in patients with end-stage liver disease and may be exacerbated in the early post-transplantation period by tacrolimus or diuretics. Why patients develop hypophosphatemia is unclear, but increased demand for phosphate for incorporation into adenosine triphosphate is a possible explanation. Hypokalemia or hyperkalemia can occur, depending on renal function and fluid status. Electrolyte serum concentrations should be followed and electrolytes replaced if needed (see Chapter 11, Fluid and Electrolyte Disorders).

Hyperglycemia, which is a good indication of a properly functioning liver in this early period, may need to be controlled with a continuous IV infusion of insulin, initially, and then subcutaneous insulin dosed on the basis of periodic glucose measurements. In contrast, persistent hypoglycemia indicates a poorly functioning liver. Hypertension, which is multifactorial, also is seen during this time and usually is treated with calcium channel blockers, nitroglycerin, nitroprusside, or β -blockers. Renal dysfunction and neurologic complications also can occur.^{88,90} Neurologic complications, including those that are drug induced, include oversedation, acute psychosis, depression, tremor, headaches, peripheral neuropathy, cortical blindness, paresthesias, paresis, and seizures.⁹⁰

Other complications that can occur within the first 3 days to 3 weeks include respiratory distress, intra-abdominal hemorrhage, biliary tract leaks and strictures, hepatic artery thrombosis, and primary graft nonfunction. Because infection is another early postoperative concern, E.P. should be monitored for bacterial, fungal, and viral infections.

Tacrolimus

Pharmacokinetics

28. Seven days after his liver transplantation, E.P.'s J-P abdominal drains, Foley catheter, and NG drain have been removed. Current medications include tacrolimus (Prograf) 2 mg PO Q 12 hours; prednisone 20 mg PO daily; nystatin suspension 500,000 U to swish and swallow QID; amlodipine 5 mg PO daily; TMP-SMX SS, one tablet every Monday, Wednesday, and Friday; and valganciclovir 900 mg PO daily. E.P.'s current laboratory values include the following: BUN, 27 mg/dL (normal, 8–18); SrCr, 0.9 mg/dL (normal, 0.6–1.2); AST, 170 U/L (normal, 0–35); ALT, 154 U/L (normal, 0–35); γ -glutamyl transferase (GGT), 320 U/L (normal, 0–30); total bilirubin, 3.4 mg/dL (normal, 0.1–1.0); and tacrolimus 9.4 ng/dL (whole blood by mass spectrometry). What

important pharmacokinetic factors should be considered when using tacrolimus after transplantation?

[SI units: BUN, 9.6 mmol/L (normal, 3.0–6.5); SrCr, 79.6 μ mol/L (normal, 50–110); AST, 170 U/L (normal, 0–35); ALT, 154 U/L (normal, 0–35); GGT, 320 U/L (normal, 0–30); total bilirubin, 58.14 μ mol/L (normal, 2–18)]

Tacrolimus is a very lipophilic compound that is absorbed rapidly after oral administration in most patients. Peak blood concentrations are achieved in about 0.5 to 1 hour. Some patients have slower absorption or have a lag time of up to 2 hours in their absorption profiles. Oral bioavailability is usually poor, highly variable, and ranges from 4% to 89% (mean 25%). Protein binding is approximately 75% and is mainly to erythrocytes. Whole blood concentrations are significantly higher than serum concentrations for this reason. Tacrolimus has a large volume of distribution and accumulates in high concentrations in tissues, including the lungs, spleen, heart, kidney, brain, muscles, and liver. Tacrolimus is predominantly metabolized in the liver through the cytochrome P450 3A4 isoenzyme system and is primarily eliminated from the body as several inactive metabolites. Less than 1% of tacrolimus is eliminated as the parent compound in the urine, and renal dysfunction does not alter the pharmacokinetics of this agent. The elimination half-life ranges from 5.5 to 16.6 hours, with a mean of 8.7 hours, and plasma clearance averages 143 L/hour. Varying degrees of liver dysfunction, including cirrhosis and severe cholestasis, may have dramatic effects on the metabolism and excretion of tacrolimus. Pediatric patients appear to clear tacrolimus more rapidly and have a shorter half-life and larger volume of distribution compared with adults.⁹¹ Black patients may require higher dosages.⁹²

Dosing

29. How would you initiate the dosing of tacrolimus for E.P.?

Although tacrolimus can be administered as a continuous IV infusion through a central or peripheral infusion after transplantation (initial dose 0.025–0.05 mg/kg/day), it is preferable to give it via an NG tube or orally because adverse effects, such as headache, nausea, vomiting, neurotoxicity, and nephrotoxicity, occur more commonly with IV administration. If tacrolimus is given IV, patients should be converted as soon as possible to oral therapy (initial doses of 0.1–0.3 mg/kg/day in adults and 0.15–0.3 mg/kg/day in children divided into 12-hour intervals). Pediatric patients require two to three times the adult doses of tacrolimus.

In E.P., the initial starting dose was approximately 0.15 mg/kg/day given orally or through the NG tube every 12 hours. Oral tacrolimus should be administered on an empty stomach or taken consistently in relation to meals. Most institutions extemporaneously prepare an oral solution for NG tube administration because it is not commercially available.

30. How would you convert a patient from cyclosporine to tacrolimus?

Although E.P. was initiated on tacrolimus without prior exposure to cyclosporine, many patients are converted from cyclosporine to tacrolimus either because of a poor response (as evidenced by recurrent acute rejection episodes) or intolerance (as evidenced by persistent adverse drug reactions, most commonly gingival hyperplasia or unwanted hair

growth). When switching from cyclosporine to tacrolimus, the cyclosporine should be discontinued 24 hours before initiating tacrolimus therapy or longer if cyclosporine concentrations are elevated. The concomitant administration of cyclosporine and tacrolimus has been accompanied by increases in the serum concentrations of creatinine and urea nitrogen, which decline after the discontinuation of cyclosporine. Thus, combination therapy with cyclosporine and tacrolimus is not recommended because of the additive or synergistic risk of nephrotoxicity.

Therapeutic Drug Monitoring

31. E.P.'s tacrolimus concentrations are being measured by whole blood IMx[®] immunoassay. Why is it important to monitor E.P.'s tacrolimus concentrations and how should his tacrolimus therapy be monitored?

Because of the large inter- and inpatient variability, the narrow therapeutic index, and the large number of potential drug interactions associated with this agent, tacrolimus concentrations should be monitored in all patients receiving therapy. Concentrations are monitored to prevent toxicity, optimize efficacy, and assess patient compliance to the prescribed regimen. A relationship does appear to exist among concentration, efficacy, and toxicity.⁹³ The primary monitoring parameter used clinically is the trough concentration because, unlike cyclosporine, trough concentrations correlate well with overall total body exposure (AUC).⁹⁴ Because of accuracy in measuring the tacrolimus parent compound (without measuring inactive metabolites) and a rapid turnaround time (within hours), the microparticle enzyme immunoassay (IMx[®]) assay method for tacrolimus that uses whole blood is the one most commonly used. The target range is 10 to 20 ng/mL for the first 3 months and 5 to 10 ng/mL thereafter, but this can vary with each transplantation center's protocols. More centers are now switching to using mass spectrometry to monitor all immunosuppressant concentrations. Mass spectrometry is a more reliable method of analysis that does not cross-react with metabolites.⁹⁵

As in all cases, pharmacokinetic data must be interpreted in conjunction with the patient's clinical condition. In addition, deference always must be given to trends established by multiple tacrolimus concentrations over that of a single concentration.

Adverse Drug Reactions

32. What are the major adverse effects associated with tacrolimus and what clinical parameters should be monitored in E.P.?

Nephrotoxicity, which usually is the limiting adverse effect of tacrolimus, has been reported in >50% of patients in some studies.^{96,97} This may have been related to the higher dosages used in earlier trials because dose reduction usually reverses the nephrotoxicity. The clinical presentation of tacrolimus-induced nephrotoxicity is similar to that of cyclosporine. Because IV administration of tacrolimus during the first week has been associated with acute renal failure in 20% of patients, very few centers use this route or rapidly convert to oral therapy. Presumably, liver recipients with poor graft function are unable to metabolize tacrolimus rapidly and are at a greater risk for acute renal failure.⁹⁶ In a multicenter study involving 529 patients, the efficacy and toxicity of tacrolimus was compared

with cyclosporine in liver transplant recipients. Both agents increased serum creatinine and decreased glomerular filtration rate comparably.⁹⁷ Thus, E.P.'s renal function should be monitored closely.

Major neurologic toxicities (e.g., confusion, seizures, dysarthria, persistent coma) occur in approximately 10% of patients. Minor neurologic toxicities occur in approximately 20% to 60% of patients and include tremors, headache, and sleep disturbances.⁹⁷ Hypertension (40%) is another common finding in patients treated with tacrolimus. A greater number of tacrolimus-treated patients, however, are able to discontinue or limit their use of antihypertensives as compared with cyclosporine. Other adverse effects include diarrhea, nausea, vomiting and anorexia, hypomagnesemia, hyperkalemia, hemolytic anemia, hemolytic uremic syndrome, alopecia, increased susceptibility to infection and malignancy, and hyperglycemia. Hyperglycemia is reported to occur often with tacrolimus. This is most likely to be seen in patients with higher tacrolimus levels or higher steroid doses and in blacks. With reduction in tacrolimus and steroid doses, hyperglycemia appears to decrease. Hirsutism and gingival hyperplasia, in contrast to that which occurs with cyclosporine, are not complications of tacrolimus.

Rejection

33. E.P. was discharged from the hospital. He went to stay with his brother and was followed up with laboratory tests obtained three times a week. The following laboratory values were obtained 2 weeks later: AST, 36 U/L (normal, 0–35); ALT, 52 U/L (normal, 0–35); GGT, 65 U/L (normal, 0–30); and total/direct bilirubin, 1.0/0.3 mg/dL (normal, total 0.1–1.0, direct 0–0.3); and another week later: AST, 158 IU/L; ALT, 322 U/L; GGT, 321 U/L; and bilirubin, T/D 3.6/3.2 mg/dL.

E.P. was readmitted to the transplantation center because his LFT findings suggested liver dysfunction, and a percutaneous needle liver biopsy was obtained to determine the cause. On admission, he complained of tiredness, severe headaches, a mild tremor, and some pain over the area of the transplanted liver. E.P. also stated that he had not felt like eating for the last 2 to 3 days. The pathologist interpreted the liver biopsy as moderate rejection, and E.P. was given a 1-g IV bolus of methylprednisolone followed by rapidly tapered doses. This regimen used the following IV doses of methylprednisolone: 50 mg every 6 hours for four doses; 40 mg every 6 hours for four doses; 30 mg every 6 hours for four doses; 20 mg every 6 hours for four doses; 20 mg every 12 hours for two doses; then back to the pretapered oral prednisone dose. Three days into the recycle, E.P.'s liver enzyme values had not improved and Thymoglobulin therapy was initiated. Laboratory values after 10 days of Thymoglobulin IV 1.5 mg/kg/day were as follows: AST, 35 IU/L; ALT, 108 U/L; GGT, 169 U/L; and bilirubin, T/D 1.0/0.6 mg/dL. The 12-hour tacrolimus trough level at the end of the treatment course was 15.2 ng/mL by IMx immunoassay. E.P. was discharged and sent home with the following medications: tacrolimus 5 mg PO BID; prednisone 20 mg PO daily; clonidine 0.3 mg PO BID; felodipine 10 mg PO daily; furosemide 20 mg PO daily; co-trimoxazole one tablet daily Mondays, Wednesdays, and Fridays; and valganciclovir 900 mg PO daily. What subjective and objective evidence of liver rejection is present in E.P.?

[SI units: AST, 36 U/L, 158 U/L, 35 U/L (normal, 0–35); ALT, 52 U/L, 322 U/L, 108 U/L (normal, 0–35); GGT, 65 U/L, 321 U/L, 169 U/L (normal,

0–30); bilirubin, 17.1/5.13 $\mu\text{mol/L}$, 61.56/54.72 $\mu\text{mol/L}$, 17.1/6.2 $\mu\text{mol/L}$ (normal, 2–18)]

Rejection episodes in liver transplant recipients can be categorized as acute or chronic. Hyperacute rejection rarely occurs with liver transplantation. Treatment is supportive and retransplantation is needed.⁹⁸ Unlike other organs, however, the liver may function adequately, but survival is lower when the transplanted organ is incompatible.⁹⁹

Acute Liver Rejection

Although acute liver rejection can occur at any time after the transplantation, it is most commonly experienced within the first week to 6 weeks in approximately 30% to 50% of patients treated with either cyclosporine or tacrolimus and prednisone.⁹⁸ Early data in patients treated with tacrolimus, mycophenolate, and prednisone indicate lower rejection rates up to 6 months after transplantation.^{100,101} Late acute rejections often are a result of either a reduction in dose or a discontinuation of immunosuppressive agents. These rejection episodes, although common, rarely lead to graft loss.

E.P. presented with some of the common subjective complaints of patients experiencing rejection of their transplanted liver. Commonly, patients feel poorly and complain of anorexia, abdominal discomfort, and headache. Other symptoms, such as a low-grade fever, back pain, or respiratory distress, may occur. Objective evidence for rejection in E.P. included an abrupt rise in serum concentrations of transaminases and bilirubin and a liver biopsy that was interpreted as “moderate rejection” by the pathologist. These observations, in conjunction with the subjective signs, pointed to a diagnosis of rejection. Acute rejection is associated with mononuclear cell infiltration of the graft, edema, and parenchymal necrosis. Rejection should be diagnosed by biopsy using histologic criteria. Areas most commonly damaged are the bile ducts, veins, and arteries.¹⁰²

Chronic Liver Rejection

Chronic liver rejection, also called *ductopenic rejection*, usually develops months to years after the transplant in about 5% of recipients. Characteristics of chronic liver rejection include occlusive arterial lesions, destruction of small intrahepatic bile ducts (often referred to as *vanishing bile duct syndrome*), intense cholestasis, accumulation of foamy macrophages within the portal sinusoids, and fibrosis, which can lead to the development of cirrhosis. Chronic rejection is irreversible and unaffected by increased immunosuppressive therapy. Retransplantation has been considered the only viable alternative. Some patients with ductopenic rejection unresponsive to cyclosporine-based therapy have responded to tacrolimus.¹⁰³

Treatment of Rejection

34. Was the treatment of E.P.’s rejection of his transplanted liver appropriate?

E.P. was receiving maintenance immunosuppression with tacrolimus and prednisone. Double or triple therapy with tacrolimus or cyclosporine and prednisone commonly is used as chronic immunosuppressive therapy in liver transplant recipients. E.P.’s tacrolimus trough whole blood concentration was in the low normal therapeutic range (*Note:* normal values

for therapeutic range vary with the institution). Although E.P.’s tacrolimus concentration appeared adequate, he was treated with a bolus dose of IV methylprednisolone because of clinical evidence that supported a diagnosis of graft rejection. This treatment decision was reasonable because high-dose corticosteroids can reverse acute rejection episodes of a transplanted liver.⁹⁸ The decision to monitor E.P.’s response to the initial bolus steroid dosage and the severity of rejection by biopsy also was appropriate before proceeding with further treatment. E.P. had experienced moderate rejection of his transplanted liver, and the subsequent initiation of another cycle of corticosteroids was reasonable because the mainstay for treatment of acute liver rejection is increased immunosuppression.
