Adult liver transplant recipients usually are treated with 200 mg to 1,000 mg/day of IV methylprednisolone and tapered rapidly, as described for E.P. When patients fail to respond to recycle corticosteroid therapy, several options are available. E.P. was begun on Thymoglobulin therapy; other options include the use of OKT3 or potentially alemtuzumab. Most centers use Thymoglobulin as a second-line agent if there is no response to high-dose corticosteroids or it is used first-line if the rejection is severe. The typical dose is 1.5 mg/kg per day given as an infusion over 4 to 6 hours. Therapy is continued for 7 to 14 days. Treatment of corticosteroid-resistant rejection with Thymoglobulin is effective in about 70% to 80% of liver transplant recipients. Other adjustments in immunosuppression could include the addition of mycophenolate or possibly sirolimus.

Mycophenolate Mofetil

35. Following the rejection episode, E.P. is started on MMF. Describe MMF’s pharmacokinetic characteristics and adverse effects. How will these characteristics affect the dosing and monitoring of MMF in this patient?

Mycophenolate mofetil is an alternative to azathioprine. In most transplantation centers, MMF has replaced azathioprine as the antiproliferative agent used in combination with antibodies, CNI, and prednisone. Several studies have shown significant reductions in acute rejection rates during the first year after liver transplant as compared with azathioprine. Results with longer follow-up, at 3 years, indicate no difference in survival, however.⁹¹

Pharmacokinetics

Mycophenolate mofetil is a prodrug for the active form, MPA. MMF is well absorbed (bioavailability 94%) and is rapidly hydrolyzed to MPA after absorption. The C_{max} for MPA occurs between 1 and 3 hours, and it is hepatically metabolized via glucuronidation to inactive MPAG, which is eliminated by the kidney and excreted into the bile. Once MPAG is excreted into bile, it undergoes enterohepatic recycling in the GI tract, where it is deconjugated to MPA, which is reabsorbed back into the systemic circulation. Because of this recycling, a second peak occurs 6 to 12 hours after dosing. MPA has an elimination half-life of 17 hours on average; the volume of distribution is 4 L/kg, and it is highly protein bound to albumin (98%). Protein binding correlates well with albumin and free MPA concentrations correlate with the immunosuppressive effect. Studies indicate that protein binding changes over time after

transplantation, with the free fraction decreasing and total MPA concentrations increasing over time. Renal impairment, liver dysfunction, and elevated MPAG concentrations in transplant recipients can reduce protein binding. This may be a function of low albumin concentrations seen in these patients.¹⁰⁴

Adverse Effects

The most commonly reported side effects for MMF are GI (anorexia, nausea, vomiting and diarrhea, gastritis), hematologic (leukopenia, thrombocytopenia, anemia), and infectious in nature. GI side effects are common, and all side effects are more common with higher dosages. If a patient complains, try giving the dose without other medications, giving smaller doses more frequently, or lowering the dosage and titrating upward as tolerated.¹⁰⁵ If the WBC count is <3,000 or absolute neutrophil count (ANC) is <1.3, the MMF dose should be reduced or discontinued.

Dosing

The usual starting dose in adults is 1 to 1.5 g twice daily. Some advocate the higher dosage in high-risk patients (e.g., patients receiving another transplant, patients with a high PRA, blacks). Excluding the early post-transplantation period, 1 g two times a day is the recommended regimen in patients with a glomerular filtration rate <25 mL/minute. In heart transplant recipients, the 1.5 g twice daily regimen is used. In children, 300 to 600 mg/M² two times a day or 23 mg/kg/day two times a day has been recommended.

Therapeutic Drug Monitoring

Monitoring MPA serum concentrations is controversial and not generally recommended at this time because of so much inpatient and outpatient pharmacokinetic variability. Some studies, however, have shown a relation between effect and concentrations.¹⁰⁶

Data in heart transplant recipients indicate that an MPA trough level of >2.5 mg/L is required for therapeutic effect. In kidney transplant recipients, AUC has been shown to correlate with acute rejection. Another approach is to measure free concentrations, but the primary limitation to using serum concentrations is the lack of a simple, commercially available assay. The preceding studies used an HPLC assay, but there are ongoing investigations with an EMIT immunoassay.¹⁰⁷

Once started on MMF, the patient should be monitored for GI and hematologic side effects, as well as for any signs and symptoms of infection and rejection.

Drug Interactions With Immunosuppressives

36. C.C. is a 42-year-old woman who underwent a liver transplantation 5 days ago. She was noted to be febrile, with an elevated WBC. Cultures were obtained, and her J-P drainage grew *Candida albicans*. C.C. was started on fluconazole 400 mg daily. Her other medications included tacrolimus 3 mg BID, prednisone 20 mg daily, mycophenolate 500 mg BID, valganciclovir 450 mg daily, one-half TMP-SMX DS tablet daily, and esomeprazole 20 mg every night (QHS). The tacrolimus trough level is 11 ng/mL. What drugs interact with immunosuppressive agents? Will the initiation of fluconazole require any adjustments in current medication doses?

Because the immunosuppressants have complex and highly variable pharmacokinetic profiles with relatively narrow therapeutic indexes, drug–drug interactions represent a significant clinical problem. These drug interactions can be separated into two main categories: pharmacokinetic and pharmacodynamic. Pharmacokinetic drug interactions occur when one medication alters the absorption, distribution, metabolism, or elimination of the immunosuppressant agent.^{108–110} Table 34-2 displays the most clinically relevant pharmacokinetic drug interactions that are likely to be encountered in transplant recipients and how to manage these interactions when they do occur. These include drugs that alter either the absorption or metabolism of the immunosuppressants. This table is not comprehensive.

Pharmacodynamic drug interactions with the immunosuppressant agents represent another significant problem in transplantation. These interactions occur when one medication either potentiates an adverse effect or alters the pharmacologic effects of the immunosuppressant agent.¹⁰⁸ An example of this would be the use of CNI (cyclosporine and tacrolimus) in combination with ACE inhibitors. Because both classes of agents can cause hyperkalemia and potentially can decrease renal function, toxicity may be more pronounced when these classes are given in combination.¹¹¹ Pharmacodynamic drug interactions are usually more difficult to identify and require a thorough knowledge of the pharmacologic effects of the agents being used. Often, little or no information in the literature on these types of interactions exists to guide the clinician in determining whether this drug interaction will occur. As a general rule, if an agent is known to cause a particular toxicity that is similar to a toxicity associated with the immunosuppressant agent, then there is a high likelihood that a pharmacodynamic interaction will occur. Another example is an interaction between metoclopramide and MMF. Both agents are known to cause diarrhea and a higher incidence or severity of diarrhea likely occurs when these agents are used together.¹⁰⁸ It is important to be alert for drugs with pharmacologic effects that may alter the efficacy of an immunosuppressant.¹¹² For example, a drug with immunosuppressant properties, such as cyclophosphamide, could lead to overimmunosuppression of the transplant recipient and a higher incidence or severity of opportunistic infections. Conversely, a drug with immunostimulant properties, such as the herbal medication echinacea, may reduce the efficacy of the immunosuppressant agent and increase the risk of rejection in the transplant recipient.^{108,113} Although agents that have pharmacodynamic drug interactions with the immunosuppressants are not absolutely contraindicated, transplant recipients should be closely monitored for either increased risk of drug toxicity or decreased drug efficacy when these agents are used in combination with the immunosuppressants. When a transplant recipient adds any new medication—whether prescription, over-the-counter, or herbal—it should be thoroughly researched to determine whether there is a potential interaction with the immunosuppressant regimen.

In C.C., the addition of fluconazole will lead to a pharmacokinetic drug interaction and significantly increase (on average double) tacrolimus concentrations. This interaction is usually evident within 2 days, and a maximal effect is seen within a week of initiating fluconazole. Therefore, C.C.'s tacrolimus dose should be reduced by 50% when fluconazole is started. Tacrolimus blood levels should be monitored, as should signs and symptoms of toxicity and rejection. Fluconazole could also

Table 34-2 Immunosuppressant Drug Interactions

| Immunosuppressant (IS) | Interacting Drugs | Mechanism | Consequence | Clinical Management | References |
|--|--|---|--|---|-----------------------|
| Calcineurin inhibitors (cyclosporine and tacrolimus) and sirolimus | Clarithromycin, ^a erythromycin, ^a telithromycin, ^a ketoconazole, ^a itraconazole, ^a fluconazole, voriconazole, ^a fluoxetine, fluvoxamine, citalopram, nefazodone, ^a diltiazem, ^a verapamil, ^a delaviridine, ^a ritonavir, ^a cimetidine, ^a grapefruit juice, ^a amiodarone, saquinavir, nelfinavir, indinavir, amprenavir, chloramphenicol ^a | Inhibit CYP450 3A4 isoenzyme in the liver and intestines. | Increase the concentration and total AUC of the IS. | Either prospectively decrease the IS dose or monitor trough concentrations more closely and adjust doses accordingly. | 85, 86, 87, 246 |
| Calcineurin inhibitors (cyclosporine and tacrolimus) and sirolimus | Carbamazepine, ^a dexamethasone, phenobarbital, ^a phenytoin, ^a St. John's Wort, ^a rifampin, ^a rifabutin, ^a efavirenz ^a , nevirapine, ^a nafcillin, clindamycin | Induce CYP450 3A4 isoenzyme in the liver and intestines. | Decrease the concentration and total AUC of the IS. | Either prospectively increase the IS dose or monitor trough concentrations more closely and adjust doses accordingly. | 86, 87, 245, 246, 247 |
| Calcineurin inhibitors (cyclosporine and tacrolimus), sirolimus, mycophenolate mofetil, and mycophenolate sodium | Cholestyramine, colestipol, probucol, sevelamer, antacids (magnesium and aluminum containing), ^b iron containing products ^b | Bind to IS and prevent absorption. | Decrease the concentration and total AUC of the IS. | Avoid concomitant administration with IS and monitor trough concentrations. | 86, 87, 248, 249, 250 |
| Azathioprine | Allopurinol | Inhibits metabolism by inhibiting xanthine oxidase. | Increases the concentration and total AUC of azathioprine. | Avoid use together or prospectively reduce azathioprine dose to one-third or one-fourth normal dose and monitor for increased toxicity. | 86, 251 |

AUC, area under the concentration-time curve.

^aIndicates potent inhibitor or inducer.

^bOnly occurs with mycophenolate mofetil and mycophenolate sodium.

influence steroid metabolism, but specific recommendations are not available. In general, drug interactions can be managed and, in some cases, may require only separate administration times. In other cases, an alternative agent can be used within a pharmacologic class that does not interact with these agents.

Infection Prophylaxis

37. S.C. is a 20-year-old man who underwent liver transplantation for end-stage liver disease secondary to chronic hepatitis B. Besides his immunosuppressives, he received ampicillin sulbactam 1.5 g Q 8 hours for 24 hours perioperatively. After transplantation, he also was started on TMP-SMX one tablet Mondays, Wednesdays, and Fridays; nystatin 5 mL TID; lamivudine 100 mg daily; and valganciclovir 900 mg PO daily. Hepatitis B immunoglobulin (HBIG) 10,000 U was started intraoperatively and given every day for 8 days after transplantation. What is the rationale for all the aforementioned agents? Should other measures be considered to prevent infection?

Infection continues to be a major source of morbidity and mortality. Transplantation recipients have the same risk of infection from transplant surgery as any other immunocompromised patient having a surgical procedure. The percentage of transplantation recipients who develop infections has de-

creased since the advent of cyclosporine. Infection rates, however, remain high—50% in transplant recipients.¹¹⁴

Prophylactic antimicrobial therapy can decrease the risk of surgical infections in patients having transplantation surgery. As with other therapies in transplantation, prophylactic regimens and antibiotic therapies are highly institution dependent.¹¹⁵ Kidney transplant recipients typically receive a first-generation cephalosporin, such as cefazolin, to cover uropathogens and staphylococci, both perioperatively and, in some cases, for 2 to 5 days postoperatively. Pancreas transplant recipients usually receive an antibiotic that covers both the skin flora and GI flora, such as ampicillin-sulbactam (Unasyn), because both are breached during the surgical procedure. In addition, because *Candida* is often within the GI flora and because postpancreas transplantation candidal infections occur frequently, prophylaxis with an antifungal such as fluconazole for 3 to 7 days is commonly used. Liver transplantations are associated with the highest rate of life-threatening bacterial infection. Ampicillin-sulbactam (Unasyn) commonly is used to cover staphylococci, enterococci, and *Enterobacteriaceae*. Heart transplant recipients routinely receive a first-generation cephalosporin, such as cefazolin, at anesthesia induction and for 48 hours postoperatively. Cefuroxime or vancomycin is an alternative for resistant organisms. For lung transplant candidates, common practice is to culture the patient's sputum

Table 34-3 Common Opportunistic Infections After Transplantation

| Organisms | Time of Onset After Transplantation |
|---------------------|-------------------------------------|
| CMV | 1–6 months |
| HSV | 2 weeks–2 months |
| EBV | 2–6 months |
| VZV | 2–6 months |
| Fungal | 1–6 months |
| Mycobacterium | 1–6 months |
| PCP | 1–6 months |
| <i>Listeria</i> | 1 month–indefinitely |
| <i>Aspergillus</i> | 1–4 months |
| <i>Nocardia</i> | 1–4 months |
| <i>Toxoplasma</i> | 1–4 months |
| <i>Cryptococcus</i> | 4 months–indefinitely |

CMV, cytomegalovirus; EBV, Epstein-Barr virus; HSV, herpes simplex virus; PCP, *Pneumocystis carinii* pneumonia; VZV, varicella-zoster virus.

before transplantation, individualize the prophylactic regimen to reflect the resident flora, and include an antipseudomonal drug. Duration of therapy in these patients is individualized, based on the patient's postoperative recovery, but usually lasts 7 to 14 days.

Infections can occur at any time after transplantation, but there are predictable time patterns for certain kinds of infections.¹¹⁴ The time of highest risk for infection in transplant recipients is during the first 6 months, because they are receiving the highest doses of immunosuppressive agents during this period. Another time of high risk is during and after treatment of acute rejection with high-dose immunosuppression. Patients can acquire new infections (*Pneumocystis carinii* pneumonia [PCP], CMV), reactivate old infections (e.g., CMV, BK virus), or develop recurrence of underlying disease (hepatitis B or C). Opportunistic infections are common during this time, as shown in Table 34-3. Because the infections shown in Table 34-3 occur at such a high rate, it is routine to provide specific prophylaxis for many of them. For example, nystatin suspension 500,000 U by “swish and swallow” (S&S) three to four times a day or fluconazole 100 mg every day are used to reduce fungal colonization of the GI tract; acyclovir, ganciclovir, valganciclovir, and immunoglobulins can be used for CMV and herpes virus infections; and TMP-SMX is used for *Pneumocystis* prophylaxis. For patients with sulfa allergies, alternatives, such as dapsone 50 to 100 mg PO daily or inhaled monthly doses of pentamidine 300 mg are used. These generally are given for the first 3 to 6 months after transplantation and, in some cases, up to 1 year or even for life.¹¹⁶ In S.C., certainly a need exists for prophylaxis with TMP-SMX, valganciclovir, HBIG, and lamivudine or adefovir.

Hepatitis B

Another major concern for S.C. would be recurrence of hepatitis B in his new liver. Hepatitis B recurs and is associated with a poorer outcome.¹¹⁷ Strategies that have been effective are the use of lamivudine, adefovir, entecavir, and telbivudine preoperatively and HBIG, with or without oral antiviral therapy, postoperatively.^{118–121} S.C. was started on lamivudine

and HBIG postoperatively because monotherapy with HBIG is associated with recurrence in 10% to 50% patients, whereas HBIG with lamivudine has been associated with development of resistance in 15% to 30% per year. In patients who develop a resistant form of hepatitis B to lamivudine, adefovir, entecavir, and telbivudine have been shown to be effective.¹²⁶ The combination of an antiviral with HBIG is currently preferred. After the first week of HBIG, S.C. will continue to receive 10,000 U IV as a 1- to 2-hour infusion weekly for 4 weeks, then 10,000 U monthly for the first 6 to 12 months after transplantation. During this time, anti-HBs titers are monitored and kept >500 U/L. Because HBIG is incredibly expensive to give in this regimen (up to \$50,000 per patient per year), some transplantation centers now use lower titers (>100 U/L) and HBIG doses of 1,500 units intramuscularly (IM) every 3 to 4 weeks with lamivudine.¹¹⁹

Hepatitis C

Another virus that is a major cause for concern is hepatitis C. Hepatitis C is currently the most common reason for liver transplantation, and recurrence of hepatitis C viral replication after transplantation is universal.¹²² Immunosuppression, especially overimmunosuppression, can have a significant detrimental effect on this disease after transplantation. Epidemiologic studies indicate that patient survival rates may be significantly lower at 5 years after transplant compared with patients who received liver transplants for nonhepatitis C causes.¹²³ Strategies to improve outcomes in hepatitis C-positive liver transplants include using antiviral therapies early post-transplant or waiting later until viral recurrence with pathologic changes on the transplanted liver can be documented. All strategies have varying degrees of efficacy, but the ideal regimen has not been elucidated.^{124,125} In all cases, patients should be closely monitored for signs and symptoms of viral reactivation. If this does occur, a liver biopsy may be warranted to determine the severity of liver damage caused by the virus. In aggressive cases, the need for antiviral therapy and reduction in immunosuppression may be warranted.

Immunization

Another important element of S.C.'s care is the need for immunization. Although immunosuppression can blunt the response to some immunizations, the benefits outweigh the risks. At least 6 months after transplantation, he should receive a yearly flu vaccine. He also should receive the pneumococcal and hepatitis A vaccines if he has not yet done so. Live vaccines should be avoided.¹²⁶

Treatment of infection in transplantation recipients should be based on principles established for other immunocompromised patients (see Chapter 68, Prevention and Treatment of Infections in Neutropenic Cancer Patients). One major difference between transplant recipients and other immunocompromised hosts is that the immunocompromised condition of transplant recipients is iatrogenic, secondary to their immunosuppression. Therefore, when a transplant recipient develops a life-threatening infection, the doses of immunosuppressants are usually decreased or, in some cases, discontinued. After the patient has recovered from the infection, immunosuppression can be restored to preinfection levels.

Cytomegalovirus

38. A.A., a 58-year-old, 76-kg man with end-stage liver disease caused by alcoholic cirrhosis, received an orthotopic liver transplant 16 weeks ago. He presents to the transplantation clinic with a 3-day history of generalized malaise, fatigue, nausea, vomiting, diarrhea, fever, and anorexia. At the time of transplantation, the liver he received was positive for CMV, but he had negative CMV serology. His postoperative immunosuppressant regimen included oral prednisone and tacrolimus 5 mg PO BID, with adjustments made to his dose to maintain a 12-hour trough concentration between 10 and 15 ng/mL. He was also given valganciclovir 450 mg PO daily for 3 months.

His postoperative course was complicated by an acute rejection episode on postoperative day 8, which was treated successfully with a pulse and taper of steroids. At that time, MMF 1 g PO BID was added to his immunosuppressant regimen. He was discharged from the hospital on postoperative day 12, with instructions to return to the transplant clinic in 4 days. Since then, he has done fairly well with no complaints until now, 4 months later. On admission to the hospital, a physical examination was remarkable for an oral temperature of 38.8°C, a BP of 112/79 mmHg, a heart rate of 104 beats/minute, a respiratory rate of 22 breaths/minute, and a mild tremor. All other findings on his examination were benign. Pertinent laboratory findings include the following: WBC count, 3,400 cells/mm³ (normal, 4,000–10,000); platelet count, 34,000 cells/mm³ (normal, 150,000–450,000); BUN, 29 mg/dL (normal, 5–22); SrCr, 1.4 mg/dL (normal, 0.6–1.1); total bilirubin, 2.2 mg/dL (normal, 0.0–1.2); AST, 62 U/L (normal, 14–38); ALT, 126 U/L (normal, 15–48); CMV PCR 184,000 copies/mL (normal <500 copies/mL); and 12-hour tacrolimus concentration, 18.3 ng/dL (normal, 5–15). His current medications include tacrolimus 6 mg PO BID; prednisone 10 mg PO daily; TMP-SMX 80 mg PO Mondays, Wednesdays, and Fridays; calcium carbonate 1.25 g PO TID; vitamin D 800 U PO daily; enteric-coated aspirin 325 mg PO daily; and nizatidine 150 mg PO BID. What is the most likely diagnosis for A.A.?

A major concern in A.A. at this time after transplantation is CMV infection, an infection that is commonly encountered within 1 to 6 months after both solid organ and bone marrow transplantation. It is a ubiquitous virus belonging to the herpes virus group. In healthy immunocompetent adults, infection with the virus is usually asymptomatic, whereas in immunocompromised patients, CMV can cause significant morbidity and mortality. CMV can potentiate the risk for developing both bacterial and fungal infections and induce chronic injury to the transplanted organ (arteriosclerosis in the heart, obliterative bronchiolitis in the lungs, vanishing bile duct syndrome in the liver, and chronic arteriopathy in the kidneys).¹²⁷

Etiology

Cytomegalovirus infection in transplant recipients usually occurs when latent viruses from a seropositive donor organ are reactivated owing to immunosuppression. Transmission of CMV from a positive donor to a negative recipient leads to an 80% to 100% infection rate and a 40% to 50% disease rate; a positive donor to a positive recipient leads to a 40% to 60% reactivation rate and a 20% to 30% disease rate; and a negative donor to a negative recipient leads to a 0% to 5% infection rate. Transplant recipients at highest risk for developing the disease are (a) those who are or have serologically donor +/recipient –

(D+/R–) at the time of transplant, (b) elderly, (c) those who received large amounts of perioperative blood transfusions, (d) those who received antilymphocyte antibodies, (e) those who received a retransplantation because of acute rejection, and (f) those who received larger amounts of immunosuppressive agents.¹²⁷ A.A. is at high risk because his CMV serology is D+/R–.

Diagnosis

Diagnosis of CMV is based on both clinical and laboratory findings. CMV may be detected by culturing body fluids, such as bronchoalveolar lavage, urine, blood, and tissue biopsies. CMV is contained within the host's leukocytes, which appear to have large intranuclear inclusion bodies. CMV PCR is now a readily available method for measuring viral loads in the patient's blood. Most transplant centers have the capability of performing this test at their site, with a turnaround time of hours. Documented viral shedding is not, however, diagnostic for active disease without clinical signs and symptoms.^{127,128} A.A. certainly has laboratory criteria for the diagnosis of CMV infection: viral shedding, as indicated by the CMV PCR of 184,000 copies/mL, leukopenia, and thrombocytopenia.

Clinical Manifestations

In healthy immunocompetent adults, the CMV-infected patient is usually asymptomatic but may present with mild complaints of malaise, fever, and myalgias, as well as abnormal liver enzymes and lymphocytosis. More severe reactions are rare.¹²⁸ CMV may, however, be life threatening in the immunocompromised patient and is the most common opportunistic infection associated with solid organ transplantation. Evidence indicates that CMV infection is associated with graft rejection and that graft rejection in the setting of immunosuppression facilitates CMV infection. It often is unclear which comes first. The actual CMV course may be limited to fever and mononucleosis, or it may extend to organs presenting as pneumonia, hepatitis, gastroenteritis, colitis, disseminated infection, encephalopathy, or leukopenia.

A.A.'s clinical presentation meets the criteria for CMV disease: viremia with clinical signs and symptoms. At this time, it is unclear whether or not A.A. has any end-organ involvement. His liver enzyme concentrations are elevated and he is having numerous GI symptoms, which may be indicative of CMV hepatitis, CMV gastroenteritis, or CMV colitis, respectively. Alternatively, the increased total bilirubin and serum transaminases may be caused by acute rejection, and his GI problems may be a side effect he is experiencing from his medications (e.g., MMF). To fully differentiate among CMV hepatitis, CMV gastroenteritis, CMV colitis, acute rejection, and medication side effects, tissue biopsies should be obtained.

Treatment

39. What are the treatment options for A.A.'s diagnosed CMV disease? What doses should be used, and how should the effects of these drugs be monitored?

GANCICLOVIR

Before ganciclovir was available, CMV infection was "treated" by reducing the level of immunosuppression. This may be one of the explanations for an increased prevalence of rejection associated with CMV infections. Graft loss in kidney or pancreas recipients is undesirable; yet, it is not immediately

life threatening. Reducing immunosuppression in liver, heart, or lung transplant recipients, however, could result in the patient's death owing to graft loss. Treatment has been attempted with acyclovir, adenine-araboside, and immune globulin, all of which have been largely unsuccessful. At present, ganciclovir is the first-line agent used for the treatment of CMV disease in solid organ transplant recipients, bone marrow transplant recipients, and patients with acquired immunodeficiency syndrome (AIDS). Although ganciclovir is highly efficacious in this regard, there is still a potential 20% relapse rate of CMV after ganciclovir therapy in liver transplant recipients.

Ganciclovir, a antiviral agent, is a nucleoside analog that is phosphorylated in infected cells to its active form and is then incorporated into replicating viral DNA. Although ganciclovir-resistant strains of CMV have been isolated, their occurrence is far more common in patients with HIV; currently, ganciclovir-resistant CMV in solid organ transplantation is not a large concern.¹²⁹ A.A. should receive ganciclovir IV; oral ganciclovir should not be used because its bioavailability is <10%. Because relapses of CMV disease after IV ganciclovir are still a concern, some suggest that patients should be placed on maintenance therapy with either oral ganciclovir, valganciclovir, or oral acyclovir after the IV course is completed.^{129,130}

Dosing

The usual dose of ganciclovir in patients with normal renal function is 5 mg/kg/dose every 12 hours for 14 to 21 days. Dosage adjustment is necessary for patients with renal dysfunction: 2.5 mg/kg/dose every 12 hours for creatinine clearances 50 to 79 mL/minute; 2.5 mg/kg/dose every 24 hours for creatinine clearances 25 to 49 mL/minute; and 1.25 mg/kg/dose every 24 hours for creatinine clearances <25 mL/minute. Because A.A. has an estimated creatinine clearance of 60 mL/minute, he should receive 2.5 mg/kg/dose (190 mg) IV every 12 hours for 2 to 3 weeks, followed by either low-dose IV ganciclovir (2.5 mg/kg every day), valganciclovir, or oral ganciclovir for 2 to 4 weeks.

The most common adverse effect associated with ganciclovir therapy is neutropenia, which is seen in up to 27% of patients being treated with this drug.¹²⁹ Neutropenia is defined as an absolute neutrophil count of <500 to 1,000 cells/mm³. The neutropenia usually resolves with a decrease in dosage or discontinuation of the drug, but colony-stimulating factors may help correct it.¹³¹ Because CMV disease has a propensity to cause neutropenia as well, it is often difficult to distinguish the cause. If laboratory findings and clinical signs and symptoms of CMV disease are resolving and the patient remains neutropenic, the most likely cause is ganciclovir. Thrombocytopenia occurs in approximately 20% of ganciclovir recipients. Patients with initial platelet counts <100,000/mm³ appear to be at greatest risk. Other adverse effects include CNS effects, fever, rash, and abnormal LFT findings.¹²⁹ A.A.'s WBC and platelet counts should be assessed every 3 to 4 days during therapy, and ganciclovir should be held if neutrophils fall to <500/mm³ or platelets fall to <25,000/mm³. To monitor either the regression or progression of A.A.'s CMV disease, a weekly CMV antigen test should be obtained.

IMMUNE GLOBULINS

The use of immunoglobulins to treat CMV disease in solid organ transplantation is controversial. Immunoglobulins provide passive immunization by potentiating an antibody-

dependent, cell-mediated cytotoxic reaction. Basically, the immunoglobulins modify the immunologic response that damages host tissue. Some evidence suggests that immunoglobulins may have synergistic or additive effects with current antiviral drugs in the treatment of CMV disease.¹³² Both unselective immunoglobulins and CMV hyperimmune globulin have been studied in combination with ganciclovir. CMV hyperimmune globulin is prepared from high-titer pooled sera that have a fourfold to eightfold enrichment of CMV titers compared with unselected immunoglobulin.

Most of the literature involving combination therapy for CMV disease is in bone marrow transplant recipients. Initial response rates appear to favor the combination therapy in this group. In solid organ transplantation, the data are scarce. Most of the literature is in the form of case reports or small retrospective studies. It appears, however, that the combination of CMV immunoglobulin and ganciclovir may be more efficacious than ganciclovir alone in severe CMV disease (e.g., hepatitis, pneumonitis).¹³² Although it is controversial, many clinicians would use combination therapy in patients with severe disease, as indicated by end-organ involvement, or in those who are refractory to monotherapy with ganciclovir.

Cytomegalovirus immunoglobulin may be given as 100 mg/kg/dose every other day for 14 days. This is the dose recommended for treatment of CMV when used in combination with ganciclovir. The most common adverse effects associated with the administration of immunoglobulins appear to be infusion related and include fever, chills, headache, myalgia, light-headedness, and nausea and vomiting.

FOSCARNET

Foscarnet is a antiviral pyrophosphate analog that inhibits DNA synthesis; however, unlike ganciclovir, no phosphorylation is required for activation. Because this drug has a high nephrotoxicity propensity and because most transplant recipients are already receiving drugs that are nephrotoxic, experience with the use of foscarnet in solid organ transplantation is limited. In most centers, foscarnet is a second- or third-line agent to be used only if intolerance or resistance develops with ganciclovir therapy.

The usual dosage of foscarnet is 60 mg/kg/dose every 8 hours for 14 to 21 days. The dosage should be adjusted downward in patients with renal dysfunction. The most serious adverse effect with foscarnet is nephrotoxicity, which occurs in up to 50% of patients and is probably induced by acute tubular necrosis. Therefore, prehydration is suggested to help minimize or avoid nephrotoxicity. GI effects, a decrease in hemoglobin and hematocrit, an increase in LFTs, and alteration of serum electrolyte concentrations are other side effects of foscarnet. All of these appear to be reversible on discontinuation of the drug. SrCr should be monitored daily during therapy.¹²⁸

Prophylaxis

40. Is there any way to prevent CMV in high-risk patients, such as A.A.?

Because of its significant consequences, efforts should be made to prevent CMV disease in the transplantation population. One way to prevent primary CMV infections is to use seronegative donors and seronegative blood products, which should greatly reduce the risk. This solution is difficult if not

impossible to implement because the availability of donor organs is insufficient. Therefore, CMV status is not considered in the donor-matching process. Many studies have tried to ascertain the easiest, most cost-effective regimen to prevent CMV disease. These studies have focused on the combined use of different agents as well as IV followed by oral therapies. Trials have also targeted high-risk patients.^{129,132–138}

GANCICLOVIR

The use of both the IV and oral formulations of ganciclovir to prevent CMV disease has been studied in lung, heart, liver, kidney, and pancreas transplant recipients.¹²⁷ Very few relatively large trials have been conducted and most of the data in the solid organ transplantation population are from small uncontrolled trials. Another difficulty lies in that large discrepancies exist between the trials with regard to the terminology used to define prophylaxis and high-risk patients. Until the recent introduction of valganciclovir, ganciclovir has been the most widely used prophylactic agent.

Both oral and IV ganciclovir have been studied in lung transplant recipients to prevent CMV disease.^{127,133} Although these studies had very small numbers of subjects, it does appear that both formulations can prevent CMV disease when used in the first 90 days after transplantation. The populations targeted in these trials were patients who were considered at risk for the development of CMV disease because of their serologic status or because antilymphocyte antibodies had been used as induction therapy. Long-term follow-up in these patients, however, revealed no difference in CMV disease rates when compared with placebo. This may indicate that, although ganciclovir therapy is effective in delaying CMV early in the post-transplantation period, it does not prevent the disease.

Studies using prophylactic IV ganciclovir in heart transplantation have found it to be both effective and ineffective as prophylaxis. Oral ganciclovir has been compared with other drug combinations and shown to be more effective.^{134,135} Studies conducted in heart transplantation focused on patients at high risk for developing CMV disease. Most patients received antilymphocyte antibody induction therapy and were in the serologic high-risk groups as well (D+/R–, D+/R+, or D–/R+).^{134,135}

The prophylactic use of ganciclovir in liver transplantation recipients has been evaluated as well. Trials have shown that oral ganciclovir, given for an average of 3 to 4 months after transplantation, significantly decreases the rates of CMV disease in this population. In addition, comparative trials have concluded that oral ganciclovir is more effective than oral acyclovir. Ganciclovir prophylaxis seems most effective when used in D+/R– patients.^{136,137}

When ganciclovir prophylaxis, either oral or IV, is used in high-risk renal transplant recipients, it appears to reduce the incidence of CMV disease.^{137,138} As in the liver transplantation population, ganciclovir is superior to oral acyclovir. In most studies, prophylaxis is continued for approximately 12 weeks after transplantation. As seen in A.A., CMV can, however, occur once prophylaxis is discontinued.

VALGANCICLOVIR

Valganciclovir was developed because oral ganciclovir has a very low bioavailability (<10%). Valganciclovir is the L-valyl ester of ganciclovir, which is a prodrug that is rapidly and

completely converted into ganciclovir by hepatic and intestinal esterases once absorbed across the GI tract. The absolute bioavailability of valganciclovir is approximately 60%, so that a 900-mg single dose given with food has an AUC equivalent to a 5 mg/kg IV dose of ganciclovir. This is roughly twice the AUC achieved by 1,000 mg of ganciclovir given orally TID.¹³⁹ Valganciclovir is currently FDA approved for the treatment of HIV-associated CMV retinitis, and to prevent CMV disease in heart, lung, kidney, and pancreas transplantation.^{140–141} Valganciclovir is not FDA approved for prevention of CMV disease in liver transplantation, although it is often utilized in such cases.¹⁴² Several small studies have demonstrated that valganciclovir is effective in treating CMV infection preemptively and potentially preventing CMV disease.^{143,144}

Similar to ganciclovir, valganciclovir is predominantly eliminated from the body through the kidney, and dosage adjustment is required in renal impairment. The incidence of adverse drug reactions is similar to IV ganciclovir and they include headache, neutropenia, nausea, diarrhea, and anemia. The incidence of neutropenia is significantly higher than oral ganciclovir, and dosage reduction or temporary withdrawal of the agent is recommended in patients with an ANC less than 1,000 cells/mm³.^{139,140,145}

ACYCLOVIR

Acyclovir is ineffective in the treatment of established CMV disease, but it does appear to have a beneficial preventive role. Since the introduction of oral ganciclovir, several trials have compared the prophylactic efficacy of high-dose acyclovir with oral ganciclovir.^{137,138} As already noted, oral ganciclovir appears to be more effective in preventing CMV disease, especially in the D+/R– subgroup. Because of this, most consider oral acyclovir to be second-line therapy to IV or oral ganciclovir or valganciclovir as a CMV prophylactic agent.

CMV HYPERIMMUNE GLOBULIN

The role of CMV hyperimmune globulin in preventing CMV disease is controversial. Many studies have combined this agent with either oral acyclovir or ganciclovir, but because of its cost and IV route, its use as a prophylactic agent has decreased. In addition, in patients who are D+/R–, results have been mixed.^{127,146}

VALACYCLOVIR

One recently published meta-analysis of 12 trials that included 1,574 patients evaluated valacyclovir as a prophylactic agent in transplant recipients.¹⁴⁷ Valacyclovir was found to be more effective than acyclovir in preventing herpes viruses, including CMV. Most transplantation centers, however, do not use valacyclovir for routine prophylaxis of CMV.

41. Should A.A. have received prophylactic therapy and, if so, which agent should be used?

A.A. has several risk factors that predispose him to developing CMV disease. At the time of transplantation, A.A. was CMV D+/R–, which means that he has about an 80% chance of developing CMV infection and a 40% chance of developing CMV disease. In addition, A.A. had an early acute rejection episode, which means he received higher doses of immunosuppression, also putting him at higher risk for developing CMV disease. Because of these risk factors, A.A. should have

(and did) receive CMV prophylaxis for at least 3 months after transplantation. Immediately postoperatively, IV ganciclovir, at a dose of 5 mg/kg every day, should be used. Once A.A. is tolerating oral medications, he can be switched to oral valganciclovir at a dose of 900 mg daily with food. Because A.A. has renal insufficiency, his oral valganciclovir dose was adjusted to 450 mg daily.¹⁴⁵ As illustrated by A.A.'s case, a patient who has received prophylactic therapy does not preclude the development of CMV disease after the prophylaxis is withdrawn or, in rare instances, during prophylactic therapy. The incidence of CMV disease while receiving valganciclovir is significantly lower when compared to oral ganciclovir, probably because drug exposure is approximately two times higher.^{140,141}

PRE-EMPTIVE THERAPY

Because of recent advances in the laboratory tests used to identify and quantify CMV; because prophylactic therapy is not always effective; and because it is often toxic and very expensive, pre-emptive therapy has been used in an attempt to prevent CMV disease. The technique involves withholding prophylactic therapy and monitoring laboratory tests to identify presymptomatic CMV viremia, usually by utilizing the CMV PCR. Once a patient develops viremia (CMV PCR viral load >2,000 copies/mL), he or she usually receives treatment with IV ganciclovir or oral valganciclovir. This strategy has been prospectively studied and is as effective as universal prophylaxis, with some potential cost advantages.¹⁴⁸

INTRODUCTION

A general introduction to solid organ transplantation is provided in Chapter 34. This chapter addresses the indications for heart and lung transplantation, the appropriate use of immunosuppressive agents, and the management of postoperative and long-term complications. Although many of these issues are similar for all solid organ transplantations, unique issues exist for each organ.

HEART TRANSPLANTATION**Indications**

1. M.S., a 60-year-old, 65-kg man (body mass index [BMI] 25 kg/m²) with end-stage ischemic heart disease in stage D heart failure with functional class IV symptoms (according to New York Heart Association [NYHA]), is in the coronary intensive care unit, where he has been receiving continuous inotropic therapy for 1 month. He is on the heart transplant waiting list (status 1B). He had an acute myocardial infarction (MI) in 1995, coronary artery bypass graft in 1996 and 2003 along with several admissions for exacerbation of heart failure (HF) over the past year and an episode of sudden cardiac death 1 month ago. His most recent multiple gated acquisition (MUGA) scan to evaluate left ventricular function reveals a left ventricular ejection fraction (LVEF) of 14%, and echocardiography shows extensive anterior, septal, lateral, and apical akinesia, and severe mitral regurgitation. Right-sided heart catheterization shows mild pulmonary hypertension with a pulmonary vascular resistance of 2.8 Wood units. VO₂ (oxygen uptake via cardiopulmonary exercise testing) is 8 mL/kg/minute. Medical history also includes hypertension and hypercholesterolemia. He currently is being treated with dobutamine intravenous (IV) infusion, carvedilol 25 mg twice daily (BID), valsartan 80 mg daily, warfarin 2.5 mg daily, furosemide 80 mg BID, potassium chloride (KCl) 10 mEq BID, spironolactone 25 mg daily, digoxin 0.125 mg daily, and simvas-

tatin 20 mg daily. His vital signs are as follows: blood pressure (BP), 122/82 mmHg; heart rate (HR), 70 beats/minute; respiratory rate (RR) 24 breaths/minute; and temperature, 36.6°C. His laboratory values are as follows: Na, 136 mEq/L (normal, 135–145); K, 4.3 mEq/L (normal, 3.4–4.6); Cl, 94 mEq/L (normal, 95–105); CO₂, 32 mEq/L (normal, 24–30); blood urea nitrogen (BUN), 23 mg/dL (normal, 8–18); serum creatinine (SrCr), 1.1 mg/dL (normal, 0.6–1.2); total bilirubin, 1.7 mg/dL (normal, 0.1–1.0); aspartate aminotransferase (AST), 40 U/L (normal, 0–35); alanine aminotransferase (ALT), 16 U/L (normal, 0–35); lactate dehydrogenase (LDH), 267 U/L (normal, 50–150); alkaline phosphatase, 100 U/L (normal, 30–120); 24-hour creatinine clearance (Cl_{Cr}), 60 mL/minute (normal, 75–125); cholesterol, 225 mg/dL (normal, <200); triglycerides, 99 mg/dL (normal, 1–249); high-density lipoprotein (HDL), 71 mg/dL (normal, 28–71); and low-density lipoprotein (LDL), 134 mg/dL (normal, <130). His other laboratory tests are negative for hepatitis B, human immunodeficiency virus (HIV), and Epstein-Barr virus (EBV), but positive for cytomegalovirus (CMV) and toxoplasmosis. What makes M.S. an appropriate candidate for heart transplantation?

[SI units: Na, 136 mmol/L (normal, 135–145); K, 4.3 mmol/L (3.4–4.6); Cl, 94 mmol/L (normal, 95–105); CO₂, 32 mmol/L (normal, 24–30); BUN, 8.2 mmol/L (normal, 3.0–6.5); SrCr, 97.2 μmol/L (normal, 50–110); total bilirubin, 29.1 μmol/L (normal, 2–18); AST 0.67 μkat/L (normal, 0–0.58); ALT, 0.27 μkat/L (normal, 0–0.58); LDH, 4.45 μkat/L (normal, 0.82–2.66); alkaline phosphatase, 1.67 μkat/L (normal, 0.5–2.0); Cl_{Cr}, 1.0 mL/sec (normal, 1.24–2.08); cholesterol, 5.82 mmol/L (normal, <5.20); triglycerides, 1.12 mmol/L (normal, 0.01–2.8); HDL, 1.83 mg/dL (normal, 0.72–1.83); LDL, 3.47 mmol/L (normal, 0.26–3.34)]

The success of heart transplantation has had a significant impact on the survival of patients with end-stage heart disease (ESHD). The 1- and 5-year survival rates are 85% to 90% and approximately 75%, respectively, with a graft half-life of 9.9 years. In contrast, the 1-year survival rate for patients with severe ESHD without transplant is 20% to 40%. Nonischemic cardiomyopathy and coronary artery disease account for 46%

and 42% of those having transplantation. Patients >50 years of age are the fastest-growing segment of the population having heart transplantation.^{1,2}

The best candidates for heart transplantation are those who are least likely to survive without a transplant; that is, those with a low life expectancy and a high likelihood of a good quality of life after transplantation. The criteria for the selection of patients for heart transplantation varies from center to center, but general criteria for selection of appropriate candidates include NYHA functional class III or IV, having intolerable symptoms despite maximal medical and surgical management, lack of reversible factors, and a 1-year life expectancy of <50%. An ejection fraction of <20% alone is not an indication for transplantation. Secondary comorbid conditions also affect the selection of suitable patients for heart transplantation (e.g., irreversible renal, hepatic, or pulmonary disease; severe cerebrovascular or peripheral vascular disease; active infection; current malignancy; acute pulmonary embolus or pulmonary infarction; active gastrointestinal [GI] disease; insulin-dependent diabetes mellitus with end-organ damage; coexisting illness with poor prognosis; morbid obesity; severe osteoporosis; substance abuse; acute psychological disorder; noncompliance). One hemodynamic exclusion criterion specific for heart transplant is an elevated pulmonary vascular resistance >5 Wood units or a transpulmonary gradient >16 mmHg that does not reverse with treatment, indicating severe irreversible pulmonary hypertension. Patients with this characteristic are excluded as candidates for heart transplantation because they generally experience a poor outcome in the immediate post-transplantation period. These patients could be candidates for heart-lung transplant or, more commonly, the placement of a ventricular assist device as destination therapy, which also can be offered patients who do not qualify for heart transplant for other reasons.^{3,4}

M.S. has considerable evidence of a progressively failing heart. His increasing number of admissions for HF exacerbations, an admission for sudden cardiac death, his need for chronic IV inotropic support, and his poor LVEF and VO_2 provide clear indications for heart transplantation. The status of his organ function and his negative infectious serology should clear the way for placement on the waiting list for transplantation. The placement of M.S. into the appropriate status category (1A, 1B, 2 or 7) for heart transplant is mainly dependent on his severity of illness including current medical management. Status is defined by United Network for Organ Sharing (UNOS) policy and bylaws. A 1A patient is considered to have the highest medically urgent need for a heart transplant. Qualifiers include continuous infusions of dobutamine at 7.5 mcg/kg/minute or higher, or milrinone at 0.5 mcg/kg/minute, or multiple inotropic infusions, all with a pulmonary artery catheter in place or continuous mechanical ventilation. Patients on mechanical assist devices automatically receive 30 days of 1A time once they are considered stable for listing and then they are downgraded to a 1B status. If they have a device complication, they may remain a 1A. Maintenance of 1A status requires recertification every 7 to 14 days, depending on the qualifier. The patient classified as a 1B has a mechanical assist device in place and has used up their 30 days of 1A status or is on continuous dobutamine or milrinone infusions at doses lower than those mentioned above. A status 2 patient does not meet the qualifiers for 1A or 1B, whereas the status 7 patient is

considered temporarily inactive and unable to receive a heart transplant at this time.⁵

POSTOPERATIVE COURSE

2. M.S. receives oral (PO) mycophenolate 1 g, vancomycin 1 g IV, and cefepime 2 g IV before surgery. During reperfusion of his new heart, methylprednisolone 500 mg IV was given, and IV infusions of dopamine, nitroglycerin, dobutamine, and isoproterenol were started. A temporary pacemaker was placed in the new heart. M.S. is placed in the cardiac surgery ICU for post-transplantation care. The following medications were given IV: vancomycin 1 g every 12 hours, cefepime 1 g every 12 hours for 48 hours, pantoprazole 40 mg IV daily, methylprednisolone 125 mg every 8 hours × three doses and then a prednisone taper, mycophenolate 1g IV BID, thymoglobulin 1.5 g/kg IV × one subsequent dosing based on CD3 counts, tacrolimus 2 mg PO BID starting when SrCr was below 1.3 and ganciclovir 150 mg IV BID. He also is maintained on continuous IV infusions of nitroglycerin, dobutamine, and milrinone. Why would M.S. require vasopressor and inotropic therapy perioperatively and postoperatively?

Most heart transplant recipients recover rapidly from the transplantation procedure; they are extubated and taken off vasopressor or inotropic support within 24 to 48 hours. During the early postoperative period, however, the cardiac, respiratory, fluid, and electrolyte status of the patient must be monitored intensively. The transplanted heart is denervated such that contractility and sinus node function are temporarily impaired to varying degrees based on the condition of the donor heart, quality of preservation, ischemic time, surgical technique, myocardial depletion, and elevated pulmonary artery pressure. Soon after transplantation, both left and right ventricular dysfunction can present with elevated right and left heart filling pressures. For the first few days after transplantation, the heart depends on direct stimulation from exogenously administered catecholamines for inotropic and chronotropic support. At this time, the heart is especially sensitive to β -agonists, such as isoproterenol or dobutamine, because β -adrenergic receptors are upregulated.⁶ Therefore, inotropic and chronotropic therapy should be guided by hemodynamic monitoring results (see Chapter 21, Shock). In addition, low-dose dopamine, diuretics, or both may be needed to maintain adequate fluid balance and urine output.

For recipients such as M.S., inotropic and chronotropic agents usually are started in the operating room when the new heart is being reperfused and cardiopulmonary bypass is being discontinued. The choice of agent or combination of agents is based on the aforementioned hemodynamic parameters. The patient is eventually weaned off these agents. Isoproterenol and epinephrine are the primary agents used to maintain a heart rate between 110 and 130 beats/minute to maximize cardiac output (CO). The inotropic effects of dobutamine or milrinone are used to increase CO, reduce left ventricular dysfunction, and reduce systemic vascular resistance. Dopamine, at low dosages, could improve renal blood flow. Nitroglycerin or nitroprusside reduces pulmonary arterial pressure and afterload. Temporary atrial pacing may be used to maintain the heart rate as well. If elevated pulmonary artery pressures are unresponsive to the above agents, leading to sustained right ventricular failure, sildenafil, inhaled nitric oxide, IV prostaglandin E_1 , and

norepinephrine may be required. If these interventions fail, insertion of a mechanical assistance device may be effective.^{7,8}

Sinus Node Dysfunction

3. Two days later, M.S. is extubated and hemodynamically stable. Vasopressors are discontinued, and IV medications are switched to oral formulations. On day 9, his heart rate has decreased to 50 to 60 beats/minute. A continuous IV infusion of isoproterenol was restarted because M.S.'s temporary pacemaker had been removed 2 days earlier, resulting in a heart rate of 80 to 110 beats/minute. Theophylline extended release 150 mg BID is started and the dosage adjusted. Why is this appropriate therapy of M.S.'s bradycardia?

Sinus node dysfunction, which presents as nodal or sinus bradycardia and episodes of sinus arrest, is common in the early postoperative period. The donor sinus node serves as the heart's pacemaker, but because it is denervated, the transplanted heart cannot respond to cholinergic or vagal stimulation. Therefore, atropine, which commonly is used to treat bradycardia, is not effective. In most patients, the bradycardia is transient, and temporary use of isoproterenol or a pacemaker is needed. If resistance to vagal stimulation persists (as it does in ~5%–20% of patients), placement of a permanent pacemaker has been the traditional approach. The insertion of a permanent pacemaker may increase the risk of infection and interfere with the endomyocardial biopsy (EMB) procedure that is used to assess the status of rejection. Ultimately, up to 70% of patients with a permanent pacemaker return to normal sinus rhythm within 12 months.⁹

Theophylline has been associated with a restoration of normal vagal response, fewer days of temporary pacing and days of hospitalization, and a decreased need for a permanent pacemaker. It may antagonize the negative chronotropic and dromotropic effects of adenosine and increase catecholamine levels. The catecholamines stimulate the transplanted heart because of its increased sensitivity.¹⁰

Because M.S.'s temporary pacemaker was removed a few days earlier, the use of IV isoproterenol, followed by theophylline, is appropriate as long as he is hemodynamically stable. Although no specific dosing guidelines exist for this situation, oral theophylline extended release 150 mg every 12 hours or aminophylline IV infusion at 0.5 mg/kg/hour if the patient cannot take drugs orally are appropriate starting regimens. These regimens should be adjusted based on heart rate and achievement of therapeutic theophylline serum concentrations (10–15 mg/mL). A response should be evident within 4 days; if supraventricular tachyarrhythmias occur, the dosage of theophylline should be reduced and the drug may have to be discontinued. Terbutaline dosed three times daily PO is an alternative agent.

Cardiac Denervation

4. What is the effect of denervation on the physiology of the heart and what are the pharmacodynamic effects of cardiac medications after heart transplantation?

Although the transplanted heart usually functions very well, physiologic changes result in different responses to various

stimuli when contrasted to the normal innervated heart. The transplanted heart has a higher resting heart rate than normal because of vagal tone loss. Therefore, as already noted, drugs that work via the parasympathetic pathway (e.g., atropine) will be ineffective. The transplanted heart also accelerates more slowly during exercise, usually taking several minutes to reach a maximal heart rate, which is still less than a normal innervated heart during exercise. Acute reflex changes in heart rate do not occur in response to increases or decreases in BP in the denervated transplanted heart, and the ability to feel anginal pain is lost. Therefore, the clinical response to antianginal medications is masked. CO and BP usually are normal in the nonrejecting heart.⁶ Because the adrenergic system remains intact in the transplanted denervated heart, drugs such as isoproterenol, milrinone, epinephrine, norepinephrine, dopamine, phenylephrine, glucagon, and β -blockers still exert cardiac effects. The indirect chronotropic effect of digoxin on the sinus and atrioventricular nodes will not be manifested in the denervated heart, but the inotropic effect will be maintained. The usual increase in heart rate secondary to nifedipine-lowered BP usually is muted as well, and responses of the denervated heart to verapamil, diltiazem, quinidine, and disopyramide also may be altered.⁹ Because the effect of nonprescription sympathomimetics on the transplanted heart has not been determined, these agents should be used cautiously.¹¹ Reinnervation has been reported in some patients.

Immunosuppression

5. What was the justification for using quadruple immunosuppressive therapy (i.e., thymoglobulin, tacrolimus, methylprednisolone, and mycophenolate) in M.S.? What is the appropriate therapeutic drug monitoring scheme for this regimen in M.S.?

After heart transplantation, immunosuppressive therapy with three or four drugs is administered aggressively during the early transplantation period when the risk of organ rejection is greatest. Calcineurin inhibitors (CNI) remain the mainstay of therapy, with tacrolimus being used a bit more frequently than cyclosporine; mycophenolate mofetil (MMF) 1 to 1.5 g BID is the antiproliferative agent of choice and corticosteroids are used as the third maintenance agent. Historically, regimens of azathioprine with prednisone or azathioprine, prednisone, and antithymocyte globulin were associated with survival rates of 50% and 60%, respectively. The addition of cyclosporine increased the rate of organ survival by 80% to 90%. Regimens containing oral tacrolimus (initial regimen of 0.05 mg/kg BID) are similar in efficacy to cyclosporine modified based regimens in regards to rejection episodes and graft survival, but with less hypertension and hyperlipidemia.^{1,2,12,13} Long-term follow-up indicates that there may be less acute rejection, or acute rejection of lower severity, which may explain why more patients are receiving tacrolimus-based immunosuppressive therapy.^{14,15} Because MMF is associated with lower rejection rates and improved survival, it has replaced azathioprine in heart transplantation at most U.S. centers.^{16–18} Furthermore, data in patients converted from MMF to azathioprine late after transplant show a high rate of acute rejection.¹⁹ Enteric-coated mycophenolate sodium 720 mg BID has been shown to be bioequivalent to MMF 1 g BID for mycophenolic acid in kidney

transplant recipients and has a developing role in cardiac transplant recipients.²⁰

The 20 times higher cost of MMF keeps azathioprine in use in the United States and extensively outside of North America. The active components of azathioprine are the 6-thioguanine nucleotides, which are metabolized by thiopurine methyltransferase (TPMT). The TPMT enzyme is polymorphically expressed, with heterozygous variants making up about 10% of the population and homozygous variants occurring in <1% of patients. If TPMT activity is decreased, 6-thioguanine nucleotides accumulate and exert their antiproliferative activity on white blood cells (WBC). Reports of excessive leukopenia in transplant recipients who are heterozygous for TPMT continue to appear in the literature.²¹ Although the homozygous variant is rare, these patients would be at extreme risk of neutropenia and sepsis. The U.S. Food and Drug Administration (FDA)-approved information on azathioprine recommends TPMT genotyping before therapy.

The adverse effect profile of CNIs has led to an increased use of sirolimus (inhibitor of late T-cell function).¹ Sirolimus as a replacement for CNIs in patients with renal failure showed mixed results.²² When tacrolimus and sirolimus were used as initial therapy, an increase was seen in fungal infections, diabetes and nephrotoxicity.²³ Recently, tacrolimus or sirolimus or cyclosporine-modified, plus MMF and steroids were compared head to head. No difference was found in rejection at 6 months, whereas at 12 months an advantage was seen in the tacrolimus and sirolimus arms. When looking at other endpoints, however, sirolimus was associated with more fungal infections and wound healing issues. The authors concluded that the most advantageous initial maintenance regimen at this time includes tacrolimus, MMF, and a steroid.²⁴

The use of antilymphocyte antibodies or antithymocyte globulin or IL-2 receptor (IL-2R) antagonists as induction therapy is increasing, with 50% of heart transplant recipients receiving one of the aforementioned agents, whereas OKT3 use continues to decline (<5%).¹ Induction therapy remains a controversial topic; some centers may choose induction therapy for every patient because it delays the onset of acute rejection. Others are more selective, using these agents only for patients who have pre- or postoperative renal insufficiency, which limits the early initiation of CNI, (as in M.S.'s case) or for sensitized patients (elevated panel reactive antibodies [PRA]) who are considered to have a higher risk of rejection.²⁵ Induction therapy also may allow for a more rapid discontinuation of maintenance corticosteroids.^{26–28} IL-2R antagonists decrease the acute rejection rate when compared with placebo.^{29–32} For basiliximab, patients receive two doses (perioperative and postoperative day 4), whereas daclizumab is labeled for five doses (1 mg/kg preoperative then every 2 weeks); however, two-dose therapy has been studied with no deleterious effects.^{33,34} When IL-2R antagonists have been compared with antithymocyte globulins (also known as antilymphocyte antibodies) in head to head clinical trials, the results are mixed regarding acute rejection rates, and the long-term effects on chronic rejection rates and graft loss are not known.^{35–37} The antithymocyte globulins are polyclonal immunoglobulins that contain antibodies that affect a variety of immune cell activities, including T-lymphocytes and B-lymphocytes, making them unable to generate a response to an immune stimulus. Thus, they can be used for both induction and rejection therapy. Their mecha-

nism of action creates a profound immunosuppressed state that may lead to an increased rate of infection, adverse effect profile (cytokine release syndrome), and a higher risk of malignancy long term. Antithymocyte globulin rabbit (Thymoglobulin) is dosed at 1 to 1.5 mg/kg/day, whereas antithymocyte globulin horse (ATGAM) is dosed at 10 to 15 mg/kg/day for 3 to 10 days. Studies have shown, however, that doses that are adjusted based on CD3 counts have a similar efficacy, with decreased total dose, length of stay, and lower costs. Overimmunosuppression may be avoided as well.^{38,39} At U.S. transplant centers antithymocyte globulin rabbit has greater use. If muromonab-CD3 (OKT3), a murine monoclonal antibody to the CD3 receptor of the T-lymphocyte is used, the usual dose is 5 mg/kg IV daily for 7 days.

The corticosteroid could be discontinued within the first year depending on M.S.'s clinical course. Several reports have indicated that steroid withdrawal, generally begun >6 months after transplant, is possible in many patients who are considered low risk, such as whites with fewer and less severe acute rejection episodes.^{40,41} A risk of late rejection always exists, and the impact of steroid discontinuation on long-term survival has not been thoroughly evaluated. Recent registry data indicate that ~75% of patients are still on prednisone therapy 12 months after transplant.¹ Corticosteroid withdrawal is particularly important in pediatric heart transplant recipients, because they decrease growth. Corticosteroids are substrates for the membrane transporter P-glycoprotein, which is very active in T cells. The genotype for higher P-glycoprotein pumping has been associated with the inability to wean pediatric heart transplant recipients off of corticosteroids 1 year after transplantation.⁴²

Therapeutic drug monitoring for M.S. will include tacrolimus whole blood levels. The therapeutic range is 10 to 20 ng/mL early after transplant and 8 to 12 ng/mL once the patient is stabilized on the drug. The genotype of cytochrome P450 3A5 affects the dosage of tacrolimus required to achieve blood concentrations in heart and lung transplant recipients, with enzyme expressors requiring more drug to achieve the same levels as nonexpressors.^{43,44} The availability of tacrolimus concentrations, however, negates the value of CYP3A5 genotyping in transplant recipients.⁴⁵ Although some centers measure mycophenolic acid plasma concentrations, most give an arbitrary MMF or mycophenolate sodium dosage and adjust doses as clinically indicated. Mycophenolic acid is very highly bound to albumin in plasma, so concentration measurement in the early postoperative period for heart or liver transplant recipients may be misleading until albumin concentrations stabilize.⁴⁶

Transplant recipients older than 65 might experience lower rejection rates and higher rates of infections, malignancy, and toxicities. Although this requires further study, centers may target lower drug levels and doses of maintenance medications in this population.

Acute or Chronic Rejection

6. M.S. is discharged after 20 days in the hospital and returns for a routine clinic visit and scheduled EMB. Current medications include tacrolimus 3 mg PO BID; prednisone 20 mg daily; mycophenolate 1.5 g BID; valganciclovir 900 mg daily;

trimethoprim-sulfamethoxazole (TMP-SMX) double strength one tablet on Monday Wednesday, and Friday; diltiazem CD 180 mg daily; omeprazole 20 mg at bedtime; theophylline extended release 200 mg BID; pravastatin 40 mg daily; nystatin swish four times daily (QID) and aspirin 81 mg daily. M.S.'s BP readings, which he monitors at home, range from 140–150/85–90 mmHg. Laboratory test results are as follows: Na, 134 mEq/L (normal, 135–147); K, 4.3 mEq/L (normal, 3.5–5.0); Cl, 103 mEq/L (normal, 95–105); CO₂, 26 mEq/L (normal, 22–28); BUN, 16 mg/dL (normal, 8–18); SrCr, 1.4 mg/dL (normal, 0.6–1.2); tacrolimus trough level 10 ng/mL; and theophylline level, 14 mg/mL. His vital signs are as follows: HR, 105 beats/minute; BP, 155/84 mmHg; and temperature, 36.8°C. Biopsy results indicate a mild grade 1R rejection of his transplanted heart. His tacrolimus dose is increased to 3 mg every morning and 4 mg every afternoon. A repeat EMB 1 week later now shows a grade 2R moderate rejection. What signs and symptoms indicate that M.S. is experiencing acute rejection of his transplanted heart?

[SI units: Na, 134 mmol/L (normal, 135–147); K, 4.3 mmol/L (normal, 3.5–5.0); Cl, 103 mmol/L (normal, 95–105); CO₂, 26 mmol/L (normal, 22–28); BUN, 5.7 mmol/L (3.0–6.5); creatinine, 173.3 μmol/L (normal, 50–110)]

Organ rejection can be classified as hyperacute, accelerated, acute, vascular, and chronic. (See Chapter 34 Question 9). Current data indicate that acute rejection rates are <30% after heart transplantation. Approximately 50% of these occurred within the first 6 weeks and 90% within the first 6 months, although rejection can occur at any time.⁷ Acute rejection of a transplanted heart accounts for approximately 12% of deaths after transplantation.¹ Risk factors for acute rejection include younger recipient age, female gender (donor and recipient), donor heart ischemic time, number of human leukocyte antigen (HLA) mismatches, and retransplantation.

Most rejection episodes are asymptomatic. If clinical signs are present, however, they can include nonspecific signs of fatigue, malaise, and a low-grade temperature. In some cases, dyspnea and weight gain are seen. Heart transplant recipients do not experience cardiac chest pain because of denervation. When patients with a heart transplant present with significant hemodynamic cardiovascular symptoms, such as hypotension, increased jugular venous distention, S₃ sounds, and rales, it may indicate advanced severe rejection. Patients experiencing an acute rejection of a transplanted heart also may present with new-onset arrhythmias and congestive heart failure (CHF), although these usually occur late in the rejection process.⁷ Therefore, acute rejection of a transplanted heart must be determined by an internal jugular transvenous EMB, the gold standard for diagnosis. A set of histologic criteria has been developed to standardize the severity of rejection. A grading scale of 0 to 3R is used to describe the degree of damage to cardiac tissue.⁴⁷

Vascular or humoral rejection, which is an antibody-mediated process, also may occur.⁴⁸ This form of rejection is associated with a higher incidence of cardiac allograft vasculopathy and an increased mortality rate and is more difficult to treat. Because this rejection is antibody (B-lymphocyte) mediated, there have been several case reports of successful treatment using an anti-CD20 monoclonal antibody, rituximab.^{49–51}

M.S. is asymptomatic, which is consistent with most patients who have biopsy-proved evidence of acute rejection

but do not present with clinical symptoms. Although patients with mild, grade 1 rejection often are asymptomatic, 20% to 30% can go on to develop moderate, grade 2 to 3 rejection.⁵² When rejection of a transplanted heart is detected, the EMB should be repeated within 1 week. A number of other non-invasive electrophysiologic, echocardiographic, immunologic, radioisotopic, and biochemical methods are being investigated for their value in detecting acute rejection of a transplanted heart.

A genomic test is being used to monitor heart transplant recipients for acute rejection, based on a study comparing a messenger RNA (mRNA) microarray of the peripheral blood to heart biopsy results.⁵³ Stable patients can now have a blood sample taken instead of having to undergo a heart biopsy. If the score of this test, called Allomap (XDx, Brisbane, California), suggests that the patient may be having acute rejection, then a heart biopsy is taken. This form of monitoring may be expanded in the future to include monitoring for renal dysfunction or adverse drug effects.

Chronic rejection of a transplanted heart is called *cardiac allograft vasculopathy* (CAV) and is sometimes referred to as *transplant coronary artery disease* (TCAD), *accelerated CAD*, or *graft arteriosclerosis*. It is a leading cause of death after the first year in many heart transplant recipients.¹ Despite immunosuppressive therapy, approximately 10% of patients experience chronic rejection of a heart transplant within the first year, and this increases to at least 50% within 8 years.¹ The clinical presentation is insidious, nonspecific, and similar to the clinical presentation associated with acute rejection. The first presenting signs may be CHF, arrhythmias, MI, or sudden death.⁵⁴ Therefore, patients must undergo routine coronary angiography or intravascular ultrasound, which is more sensitive, shortly after heart transplantation and every year subsequently. On angiography, chronic rejection of a transplanted heart diffusely affects both arteries and veins. The pathogenesis of this condition, which results in endothelial damage and a cascade of other related events, is unknown. However, a number of immunologic (acute rejection),^{55,56} infectious (CMV), and nonimmunologic factors (graft ischemia, hyperlipidemia, hypertension, glucose intolerance, smoking, obesity), along with donor factors (age, male gender, hypertension [HTN], previous blood transfusion) are associated with its development.^{54,57}

Pharmacologic therapy has been directed toward prevention of this condition. Antiplatelet agents, such as the aspirin used by M.S., are used routinely, but have not been shown to alter progression to CAV.⁵⁸ Diltiazem, which M.S. also is receiving for hypertension, inhibits progressive coronary obstruction as well.⁵⁹ Other maneuvers include diet modification and BP and lipid control.⁶⁰ Pravastatin and simvastatin initiated in the first days to weeks, decrease coronary artery disease and improve survival after transplantation, such that (HMG-CoA) reductase inhibitors are now considered as standard of care.^{61–63} Sirolimus and everolimus (investigational in the United States) inhibit smooth muscle or fibroblastic cellular growth, which has been shown to delay the onset and slow the progression of CAV.^{64–67} When these agents are added to therapy, the CNI dose is decreased or discontinued, or the MMF or azathioprine therapy is removed. Although the preceding pharmacologic interventions hold some promise, retransplantation is the only effective therapy for chronic rejection.

Treatment of Acute Rejection

7. What approach should be taken in the treatment of M.S.'s grade 1 acute cardiac rejection?

Rejection grade helps to form the basis for selecting pharmacologic management. Although the individual drugs usually are given at high doses over a short period, the doses, routes, and regimens vary from program to program. High-dose corticosteroids are the primary agents used to treat moderate to severe rejection, and IV methylprednisolone 1 g every day for 3 days is effective in 85% of the initial episodes of acute cardiac rejection.⁶⁸

When M.S. was asymptomatic and had a grade 1R mild rejection, no treatment was indicated because many of these episodes resolve without intervention. An adjustment in maintenance immunosuppression is appropriate, and the increase in M.S.'s tacrolimus dose is reasonable, especially because his blood concentration was lower than desired. Nevertheless, some programs treat mild rejection because of the concern for progression to a more severe grade. As was done with M.S., a follow-up EMB, usually within 1 week of the initial diagnosis, should be performed. In M.S.'s case, the grade 1R (mild acute rejection) of his transplanted heart progressed to grade 2R. In this situation, high-dose methylprednisolone 500 to 1,000 mg IV or 10 mg/kg every day for 3 days would be given. Also, his maintenance prednisone regimen may be adjusted. Patients who were off of prednisone may have it reinstated. Alternatively, a high-dose prednisone regimen with a gradual dosage reduction could be instituted after the 3-day IV course of methylprednisolone was completed.⁶⁹ Oral prednisone 50 mg twice a day for 2 to 5 days and tapered over 7 to 14 days to the previous maintenance dose is another alternative because M.S. already is on prednisone, and hemodynamic compromise is not evident.⁷⁰

After a course of high-dose methylprednisolone, M.S. should be monitored for any hemodynamic and functional changes that might indicate further progression of rejection, and the biopsy should be repeated. If M.S. develops severe rejection, he may receive another regimen of IV methylprednisolone, or therapy could be initiated with Thymoglobulin, ATG, or OKT3. When these antilymphocyte antibodies are used for patients unresponsive to corticosteroids, the treatment is known as *rescue therapy*. Thymoglobulin, ATG, and OKT3 are equally advantageous in this situation. A typical regimen is Thymoglobulin 1 to 1.5 mg/kg/day or ATG 10 mg/kg IV every day for 7 to 10 days and both could also be dosed using CD3 monitoring. OKT3, 5 mg IV every day for 7 to 10 days, can also be given.

In some patients, the acute rejection episode is refractory to high-dose corticosteroids, ATG, and OKT3. Treatment for refractory or recurrent rejection includes replacing cyclosporine with tacrolimus or azathioprine with mycophenolate.⁷¹ Other therapies for this type of rejection include the addition of sirolimus,⁷² methotrexate, or cyclophosphamide.

Hypertension

8. T.L., a 35-year-old woman, 15 months post heart transplant secondary to valvular cardiomyopathy, has noted an increase in her home blood pressure readings. Her blood pressures

have been ranging from 145–160/90–95 mmHg. T.L.'s current medication regimen includes tacrolimus 2 mg PO BID, sirolimus 2 mg daily, prednisone 2.5 mg daily, calcium and vitamin D 500 mg twice daily, famotidine 20 mg PO BID, atorvastatin 20 mg daily, aspirin 81 mg PO daily, and multivitamin PO daily. T.L. has no other comorbid conditions. In clinic, her BP is 150/85 mmHg, HR 90, BMI 23 kg/m², Na, 138 mEq/L (normal, 135–145); K, 4 mEq/L (normal, 3.4–4.6); Cl, 100 mEq/L (normal, 95–105); CO₂, 27 mEq/L (normal, 24–30); BUN, 30 mg/dL (normal, 8–18); SrCr, 1.3 mg/dL (normal, 0.6–1.2). What is the appropriate blood pressure regimen to institute in T.L.?

[SI units: Na, 136 mmol/L (normal, 135–145); K, 4.3 mmol/L (3.4–4.6); Cl, 94 mmol/L (normal, 95–105); CO₂, 32 mmol/L (normal, 24–30); BUN, 8.2 mmol/L (normal, 3.0–6.5); SrCr, 97.2 μmol/L (normal, 50–110)]

The prevalence of hypertension (HTN) increases following transplantation of all organs. Kidney and heart transplant recipients have a higher rate secondary to pre-existing HTN, which may have led to end-stage organ failure. Post-transplant HTN is a risk factor for the development of end-stage renal disease, cardiovascular morbidity and mortality, and decreased graft and patient survival.⁷³ Immunosuppressive medication is a confounding factor, because HTN is a side effect of many CNIs and corticosteroids. The target BP should be <140/90 mmHg, following published recommendations. Nonpharmacologic therapies (weight loss, low sodium diet, cessation of cigarette smoking) also play a role in treatment.

Selecting an appropriate antihypertensive must take into account the potential for significant drug interactions. Dihydropyridine calcium channel blockers (CCB), such as amlodipine (5 mg daily), have been considered first-line treatment. Amlodipine can ameliorate some of the CNI vasoconstrictive effects on the kidney allowing for both a reduction HTN and improvement in renal function with minimal effects on drug levels. Lower extremity edema and proteinuria can occur. In contrast, non-dihydropyridine CCBs (verapamil/diltiazem) have negative inotropic effects and can significantly elevate CNI levels as does nicardipine.

Angiotensin-converting enzymes inhibitors (ACEI) and angiotensin receptor blockers (ARB) may also be beneficial, especially when the patient also has diabetes, heart failure, proteinuria, or erythrocytosis.⁷⁴ They should be started cautiously because of their effects on renal perfusion, but they are not contraindicated. Studies in renal and cardiac transplant hypertensive populations show that CCB, ACEI, or ARB response rates are below 50% with monotherapy.^{74–77} Thus, most transplant recipients, as with the general population, will require treatment with more than one antihypertensive agent. ACEIs and CCBs also decrease intimal thickening.^{78,79}

β-blockers are important for patients with known coronary artery disease; however they can worsen post-transplant dyslipidemias, depression, and recognition of hypoglycemic symptoms; they also have negative chronotropic effects. Carvedilol may increase cyclosporine levels via P-glycoprotein inhibition.⁸⁰ Diuretic use is reasonable if there are signs of fluid overload; however, electrolytes and uric acid levels should be monitored. Difficult-to-treat HTN may require the use of vasodilators such as hydralazine or minoxidil.

In T.L., it is reasonable to start amlodipine 5 mg daily or a once-daily ACEI, while avoiding over aggressive titration which can lead to hypotension and compromised organ

perfusion. Nonpharmacologic therapies should be strongly encouraged as well.

Hyperlipidemia

9. J.T., a 57-year-old black man, 22 months postorthotopic heart transplant, is seen in the clinic for follow-up of an abnormal lipid panel, HDL 40 mg/dL, LDL 170 mg/dL, triglycerides (TG) 300 mg/dL, and total cholesterol of 350 mg/dL. Other laboratory findings include an A1C of 8%, and an SrCr of 1.3 mg/dL. Current comorbid conditions include HTN, post-transplant diabetes, gout, and a BMI of 32 kg/m². His medications include cyclosporine-modified 150 mg PO BID, sirolimus 2 mg daily, prednisone 2.5 mg every other day, aspirin 81 mg daily, atorvastatin 10 mg daily, insulin glargine 15 U BID, correctional scale insulin aspart, calcium + D 500 mg BID, allopurinol 300 mg daily, amlodipine 10 mg daily, and quinapril 10 mg daily. How should his lipids be managed?

Cardiovascular disease after transplant is a major cause of morbidity and mortality. After heart transplant, use of HMG-CoA reductase inhibitors (statins) is a standard of care for most heart transplant centers as a way to decrease cardiac allograft vasculopathy.⁸¹ Patients who develop concurrent hyperlipidemia, however, will need to have their therapy adjusted. The presence of confounding factors (e.g., concomitant diseases, medications, diet, and lack of physical exercise) can worsen the hyperlipidemia. J.T.'s risk factors for hyperlipidemia include male gender, ethnicity, obesity, and diabetes, along with the following medications: sirolimus, cyclosporine modified, and prednisone.

Several treatment options exist for hyperlipidemia including diet, physical activity, tight diabetes control, and lipid-lowering pharmacotherapy. A low-fat diet along with exercise may not be sufficient to control lipids in patients after transplant, and drug therapy is often needed. Drug therapy choices include fibric acid derivatives, niacin, bile-acid binders, statins, and cholesterol absorption inhibitors. Fibric acid derivatives, such as fenofibrates and gemfibrozil, primarily decrease TG levels rather than LDL. They also can affect the absorption of statins and increase their myotoxic effects when used concurrently with statins. Niacin can lower lipid levels; however, in J.T. it may worsen glucose control and precipitate a gout attack. Colestipol and cholestyramine, bile acid derivatives, have been reported to increase TG and may alter the absorption of cyclosporine. Ezetimibe, a cholesterol absorption inhibitor, reduces lipid levels as a single agent and in combination with statins.^{82,83} Statins remain the mainstay of therapy for the treatment of dyslipidemias in transplant recipients with the following considerations. All statins—except pravastatin—are metabolized via CYP3A4 (minimal for fluvastatin) and may affect calcineurin inhibitor and sirolimus levels. The concurrent use of statins with CNIs and sirolimus may affect statin metabolism, leading to an increased risk of myotoxicity. Monitoring should be done for hepatotoxicity (liver function tests), myopathies (muscle cramps or pain, elevation in creatinine kinase). The use of statins in combination with other lipid-lowering agents may increase the occurrence of these side effects.

For J.T. the following may be considered: the cyclosporine modified can be changed to tacrolimus, although it is unclear

whether its effects on dyslipidemia differ. Sirolimus is known to increase TG, especially when it is initiated. J.T.'s blood glucose levels should be more tightly controlled. His atorvastatin dose can be increased to at least 20 mg daily with close monitoring for side effects. Lastly, J.T.'s weight should be reduced with diet and exercise. If these measures do not result in significant changes, then the addition of ezetimibe therapy, 5 to 10 mg a day, could be considered.

LUNG TRANSPLANTATION

Postoperative Course

10. B.U., a 33-year-old, 54-kg man with a 12-year history of cystic fibrosis (CF), is admitted for bilateral lung transplantation. He had been doing reasonably well until 2 years ago. Since that time, he has been hospitalized five times for acute pulmonary exacerbations caused by *Pseudomonas aeruginosa*. In addition, he has been hospitalized twice in a 6-month period over the past year for hemoptysis secondary to pulmonary infarcts. He now requires continuous oxygen at 3 L/minute via nasal cannula for daily living. Other medical problems include diabetes mellitus, gastroesophageal reflux disease, pancreatic insufficiency, and sinusitis. His current medications are deoxyribonuclease (DNase) 2.5 mL BID, albuterol BID, 4 mL 7% sodium chloride BID, tobramycin 300 mg BID (with monthly holiday), all given via a nebulizer; ADEK vitamin one tablet BID, omeprazole 20 mg daily, insulin glargine 10 U BID, correctional scale insulin aspart, calcium supplement BID, and pancreatic enzymes with meals and snacks. While on 3 L/minute of oxygen, his oxygen saturation is 100%, forced expiratory volume in 1 second (FEV₁), 1.11 (22% predicted), forced vital capacity (FVC), 2.04 (34% predicted). His vital signs are as follows: temperature, 36.5°C; BP, 120/90 mmHg; RR, 20 breaths/minute; and HR, 96 beats/minute. His laboratory results are as follows: Na, 137 mEq/L (normal, 135–147); K, 4.2 mEq/L (normal, 3.5–5.0); Cl, 100 mEq/L (normal, 95–105); CO₂, 28 mEq/L (normal, 22–28); BUN, 24 mg/dL (normal, 8–18); SrCr, 1.2 mg/dL (normal, 0.6–1.2); glucose, 104 mg/dL (normal, 80–120); Ca, 9.0 mg/dL (normal, 8.8–10.3); protein, 8.3 g/dL (normal, 6.0–8.0); albumin 3.9 g/dL (normal, 4.0–6.0); bilirubin, 0.3 mg/dL (normal, 0.1–1.0); AST, 40 U/L (normal, 0–35); ALT, 46 U/L (normal, 0–35); WBC count, 8,000 (normal, 4,000–10,000); Hct, 30% (normal, 39%–49%); Hgb, 9.5 mg/dL (normal, 14.0–18.0); platelets, 340,000 (normal, 130,000–400,000); prothrombin time, 11.6 sec (normal, 9–12); and partial thromboplastin time, 26.4 seconds (normal, 22–37). He is CMV antibody negative.

In the operating room, B.U. was given preoperative mycophenolate mofetil 1,000 mg IV, tobramycin 350 mg IV, piperacillin/tazobactam 4.5 g IV with daclizumab 2 mg/kg IV and methylprednisolone 500 mg IV × 2 during the surgery. B.U. underwent a 12-hour surgery for double-lung transplantation. During the procedure, he received 8 L of fluids and dopamine to correct hypotension. He was admitted to the ICU on a ventilator, where he received tacrolimus 1 mg sublingual (SL) BID, mycophenolate 1 g BID IV, methylprednisolone 125 mg IV every 8 hours then transitioned to prednisone 20 mg daily by postoperative day (POD) 4, D₅1/2 normal saline at a rate to keep the vein open, insulin infusion, dopamine 3 mg/kg/minute IV, epidural and patient-controlled analgesia (PCA) morphine, tobramycin 350 mg

daily IV, piperacillin/tazobactam 4.5 g every 6 hours IV, pantoprazole 40 mg IV daily, ganciclovir 125 mg IV BID, CMV immune globulin × 1 on POD 1, cotrimoxazole daily, and albuterol nebulizer QID. The donor was CMV-positive. What complications can occur in B.U. during the early postoperative period?

[SI units: Na, 137 mmol/L (normal, 135–147); K, 4.2 mmol/L (normal, 3.4–4.6); Cl, 100 mmol/L (normal, 95–105); CO₂, 28 mmol/L (normal, 22–28); BUN, 8.6 mmol/L (normal, 3.0–6.5); SrCr, 106.1 (μmol/L (normal, 50–110); glucose, 5.8 mmol/L (normal, 3.9–6.1); Ca, 3.7 mmol/L (normal, 2.2–2.5); protein, 83 g/L (normal, 60–80); albumin, 39 g/L (normal, 40–60); bilirubin, 5.13 μmol/L (normal, 2–18); AST, 40 U/L (normal, 0–35); ALT, 46 U/L (normal, 0–35); WBC count, 4 × 10⁹ cells/L (normal, 4,000–10,000); Hct, 0.3 (normal, 0.39–0.49); Hgb, 95 g/L (normal, 140–180); platelets, 340 × 10⁸/L (normal, 130–400)]

Lung transplantation is a therapeutic option for end-stage pulmonary disease; >1,500 lungs worldwide are transplanted each year. The 1- and 5-year survival rates are approximately 78% and 49% with a median half-life of 5 years. Chronic obstructive pulmonary disease (COPD) and idiopathic pulmonary fibrosis (IPF) are the primary indications for a single-lung transplant (SLT). Cystic fibrosis and α₁-antitrypsin deficiency are the primary indications for bilateral lung transplant (BLT); however, the aforementioned diseases for SLT are also receiving more BLT.^{2,8} Recently, the allocation of lungs has changed from time-on-the-list as priority (considering blood type, geographic location) to a lung allocation score (LAS) for recipients above the age of 12. The LAS score ranges from 0 to 100 (highest priority). Indications that a patient with CF should be evaluated for lung transplant include an FEV₁ below 30% or significant rapid decline and frequent antibiotic treated exacerbations. The use of oxygen, development of pulmonary hypertension, and increasing CO₂ indicate the need for listing.⁸⁴

B.U.'s CF-associated pancreatic and GI problems will not be corrected by the double-lung transplantation. His pulmonary function should improve significantly, however, reaching normal levels within 3 to 12 months. After the transplant, B.U. should no longer require oxygen, achieve normal exercise capacity, and return to a good quality of life.

Patients such as B.U. usually leave the operating room under mechanical ventilation and should be extubated within 24 to 48 hours. In the early postoperative period, the transplanted lung(s) is susceptible to pulmonary edema, hemorrhage, dehiscence at the anastomotic sites, airway leaks, infection, and rejection. Hemorrhage, ischemic or reperfusion injury, and dehiscence have decreased as a result of improved donor preservation and surgical techniques. The most common serious complications are airway complications, reperfusion ischemic pulmonary edema, acute rejection, and infection. Significant incisional pain, which occurs in all patients, also can affect how quickly B.U. recovers. Altered GI function, such as gastroparesis, also is a typical problem in the initial period.

Immunosuppression

B.U. is on the most commonly used regimen for immunosuppression of lung transplants, which consists of tacrolimus, MMF, and steroids. Currently approximately 45% of lung transplant recipients receive induction therapy primarily with an anti-IL2R antibody (daclizumab or basiliximab). Thy-

moglobulin and ATG are also used, with minimal use of OKT3.^{8,85,86} The anti-IL2R antibodies reduce acute rejection compared with placebo, but when compared with antithymocyte globulin the data are mixed. These drugs have little impact on chronic rejection. A decreased risk of infection may be seen, but is variable in CMV mismatched patients.^{87–90} Tacrolimus and cyclosporine have similar effects on graft survival, but tacrolimus is associated with fewer episodes of acute rejection and treated acute rejection and may slow the development of chronic rejection.^{91,92} Early, low-dose prednisone (0.5 mg/kg/day tapered to 0.15 mg/kg/day) is used. B.U.'s tacrolimus regimen would be adjusted to maintain a whole blood concentration of 10 to 20 ng/mL (by monoclonal TDx).⁹³ Tacrolimus must be diluted before continuous IV administration. Because it is less stable in PVC containers and could leach out phthalates, it should be stored in glass or polyethylene containers and PVC tubing should not be used. To simplify administration when patients cannot take medications orally or have absorption problems (as in CF), some centers are giving tacrolimus sublingually. This route avoids the first-pass metabolism and has produced acceptable drug levels and rejection rates in small studies, but no prospective randomized trials have been conducted. Initial doses are 0.03 mg/kg/day.⁹⁴ MMF, instead of azathioprine, is used in approximately 50% of lung transplant recipients.^{8,95} The role of sirolimus is increasing; however, use before 3 months postoperatively is avoided because it interferes with wound healing and can lead to weakened airway anastomosis.

Acute Rejection

11. At his 3 month visit, B.U. has his scheduled protocol biopsy. That afternoon, the transplant team is notified that he has an A1B2 rejection. What is the appropriate regimen to treat this rejection episode?

Rejection, both acute and chronic, occurs in all lung transplant recipients. Acute rejection is common in the early postoperative period, with up to 50% of patients having at least one treated episode within the first year.⁸ Nevertheless, acute rejection can occur at any time.⁹⁶ The diagnosis of acute rejection is made using clinical and histologic criteria. Standardized criteria have been established for histologic grading of tissue from transbronchial biopsies (TBBX), which are scheduled routinely.⁹⁷ Clinical signs of acute rejection include fever, cough, dyspnea, rales, wheezes, infiltrates, and a decline in FEV₁. The FEV₁ and FVC are assessed daily by the patient using a hand-held spirometer. As little as a 10% decline in pulmonary function (i.e., FEV₁, FVC) can be significant in the absence of other causes of respiratory decline, particularly infection. Treatment for acute rejection can be initiated based on clinical signs only, although they are not always accurate. If clinical evidence of acute rejection is present, a TBBX is needed to firmly establish the diagnosis of rejection. The diagnosis of lung transplant rejection still can be established even in the face of a negative TBBX if other causes are ruled out.⁹⁷

The primary treatment for acute rejection is methylprednisolone 500 to 1,000 mg/day IV or 10 to 15 mg/kg/day every day for 3 days. The dose of oral prednisone also can be increased to 1 mg/kg/day and then tapered down to the maintenance dose over 2 to 3 weeks. More than 90% of acute

rejection episodes of transplanted lungs respond to corticosteroid therapy, with clinical response seen within 2 days in most patients.⁹⁸ OKT3, ATGAM, Thymoglobulin, tacrolimus, and experimental aerosolized cyclosporine have been used for refractory cases.^{99–101}

Pharmacogenetic factors may play a role in resistance to treatment for acute rejection in lung transplant recipients. The homozygous and heterozygous ABCB1 genotypes that are associated with higher P-glycoprotein pumping had more persistent acute rejection that was resistant to drug therapy than the homozygous variant genotype.¹⁰² The same association has been made between acute rejection in kidney transplant recipients and the ABCB1 high pump genotype.

Chronic Rejection

12. B.U. is 36 months post transplant and is noticing a slight increase in shortness of breath when he exercises. His pulmonary function testing over the last two clinic visits has demonstrated a sustained change in his FEV₁. The FEV₁ has declined by 30% from his highest value post-transplant. The transplant team believes B.U. has chronic rejection. What is the appropriate management?

Chronic rejection is referred to as bronchiolitis obliterans (OB) or bronchiolitis obliterans syndrome (BOS). OB is a histologic finding of a fibroproliferative process in the small airways, which leads to progressive airway obstruction. The diagnosis of OB is based on clinical, physiologic, and histologic features.¹⁰³ Pulmonary function and exercise capacity progressively decline as a result of inflamed small airways and destruction of bronchioles. OB is found in 9% of patients at 1 year and in 45% at 5 years.⁷ BOS represents the clinical description, defined as an otherwise unexplained and sustained fall in FEV₁ that is 20% or greater of the peak value after transplantation. This lung dysfunction is uncommon during the first 6 months after transplantation, but it can occur as early as 3 months after transplantation. The BOS staging system indicates that B.U. has BOS-2.¹⁰⁴ Once diagnosed with BOS or OB, patients may rapidly decline and experience early death. Alternatively, the decline in FEV₁ may stabilize or the patient may have alternating periods of decline and stabilization. Many proposed risk factors exist for the development of BOS or OB, including both immune and nonimmune factors.¹⁰⁵

No evidence indicates superiority of one drug treatment over another for OB or BOS. The primary treatment of chronic rejection relies on short courses of high-dose corticosteroids, ATG, or OKT3 to stabilize and improve the patient's condition for a short time. Therapy generally stabilizes and slows down this process, but does not reverse it. Inhaled cyclosporine, antibodies, tacrolimus, mycophenolate, and methotrexate also have been used.¹⁰³ Only aerosolized cyclosporine has been shown to have an effect on lung transplant recipient survival in a placebo-controlled trial,¹⁰⁶ but the drug is not available for commercial use. Sirolimus has been used in a small number of patients with little effect, but with a significant number of side effects.¹⁰⁷ Azithromycin (250 mg PO every Monday, Wednesday, and Friday) may have an impact on the rate of progression of BOS and can be added to CNI therapy with minimal effect on CNI levels.^{108–110} For B.U., a trial of short-course, high-

dose IV methylprednisolone with the addition of azithromycin to his maintenance therapy may be considered.

Chronic rejection in lung transplant recipients has been associated with a genotype of the profibrotic cytokine, transforming growth factor- β .¹¹¹ A similar observation has been made for interferon- γ , but genotyping patients for these cytokines is not practical until chronic rejection in lung transplant recipients is better understood and treated.

Infection

13. B.U. has been talking to his fellow organ transplant recipients on the floor while awaiting discharge from his initial transplant episode, and he asks the transplant team why he is on more antimicrobials than some of the other patients? His regimen includes valganciclovir 900 mg daily, CMV immune globulin infusions until 16 weeks postoperative, TMP-SMX double strength (DS) every Monday, Wednesday, and Friday, clotrimazole troches 10 mg after meals and at bedtime, nebulized lipid complex amphotericin B 50 mg daily until discharge, and tobramycin nebulized 300 mg BID.

Risk

A patient's overall infection risk depends on their net state of immunosuppression, the environment, and the surgical procedure. The first few months after transplant can be considered the period of highest risk. There is a temporal pattern to the infection type and how infections present in transplant recipients. Infection is the leading cause of death in the first 60 days after lung transplantation and contributes significantly to the number of deaths thereafter. There are several reasons for this problem. These patients may be colonized with organisms along the upper airways and sinuses; the donor lung may contain organisms at the time of transplantation; and the transplanted organ may have ischemic damage. After lung transplantation, patients lack a cough reflex because of denervation. Consequently, pulmonary secretions that accumulate can serve as a medium for bacterial growth. Furthermore, the transplanted lung's mucociliary clearance may be impaired; alveolar macrophages may not function properly; and patients are immunocompromised. Most infections present as bacterial sepsis or pneumonia, primarily associated with *Pseudomonas aeruginosa*, *Enterobacter*, other gram-negative organisms, and staphylococci. In patients with CF, *Candida* and *Aspergillus* infections also are common. Patients with CF still have a CF airway above their anastomosis site and should continue their pretransplant nebulized antibiotic regimen to prevent colonization of the new lungs. Besides bacterial infections, viral and fungal infections are a concern. Most transplant centers adopt universal prophylaxis protocols in the early transplant period. At least 50% of lung transplant recipients develop infections despite prophylaxis. The most common infections for which patients receive prolonged prophylaxis are CMV (see Chapter 34 Kidney and Liver Transplant) *pneumocystis jiroveci* pneumonia, thrush, and other fungal infections.

Pneumocystis jiroveci (PJP)

Pneumocystis jiroveci (formerly called *Pneumocystis carinii*), an opportunistic pathogen, can cause pneumonia in immunocompromised patients. The incidence of PJP is highest in thoracic organ recipients. The first 6 months after transplant is

the period of highest risk for nonlung transplant recipients. Prophylaxis is very effective; life-long treatment is used for lung transplant recipients or others deemed to have an increased risk.¹¹² TMP-SMX given as a daily single strength or double strength tablet is the agent of choice; three times a week prophylaxis has also been used.¹¹³ Nebulized pentamidine 300 mg every month, dapson 100 mg daily, and atovaquone 1,500 mg daily are alternatives for patients intolerant or allergic to TMP-SMX.^{114,115} For documented infection, the primary agent is TMP-SMX (20 mg/kg/day of TMP); however, the above alternatives may be used with pentamidine given IV instead of nebulized at 2 to 4 mg/kg/day.

FUNGAL INFECTIONS

The use of fungal prophylaxis is based on a patient's presumed risk, considering type of transplant, center patterns, colonization, or previous infection status, and the patient's overall state of immunosuppression.¹¹⁶ Prophylaxis to prevent the occurrence of thrush may include nystatin or clotrimazole troches or oral triazoles that can cover other fungal organisms, including nonalbicans *Candida*, and *Aspergillus*. The timeline for fungal infections ranges from *Candida* in the early postoperative period along with some *Aspergillus*, then opportunistic infections for the next 6 months. After 6 months, infections are caused by other fungal organisms, including cryptococcus, zygomycetes, and endemic mycoses along with the previous mentioned organisms.¹¹⁷ Drug interactions between the triazole antifungal agents, CNI, and sirolimus create challenges for prophylaxis. Triazole antifungals, such as fluconazole, itraconazole, voriconazole and posaconazole, are inhibitors of CYP3A4, resulting in supertherapeutic immunosuppressive levels. Because voriconazole use with sirolimus has resulted in a ninefold elevation of sirolimus levels, the FDA label contraindicates the use of the combination. Transplant recipients may still receive this drug combination, especially if the patient is infected with *Aspergillus*, but close monitoring of sirolimus levels is obviously required. Echinocandins are not used for long-term prophylaxis because no orally bioavailable product exists. These agents are used because they have fewer effects on immunosuppressive drug levels, especially micafungin and anidulafungin. Commonly, these agents may be used in combination with triazole antifungals in the treatment of invasive *Aspergillus* infections.¹¹⁸ Intravenous amphotericin B in the conventional or lipid-based formulations would be used to treat fungal infections, but not for prophylaxis. Nebulized amphotericin B (or lipid based formulations) has been used, however, for prophylaxis in lung transplant populations because it allows for delivery of the antifungal agent to an area of high risk lung tissue without the systemic complications associated with IV therapy. Nebulized lipid complex amphotericin B was better tolerated in one lung transplant population than the conventional product.¹¹⁹ Zygomycosis infections remain a challenge to treat; however, posaconazole with its spectrum of activity may have a role, keeping in mind that this agent requires administration with high fat meals for best absorption.

Cyclosporine Bioavailability

14. M.R. a 30-year-old woman status post bilateral lung transplant 5 years ago for interstitial pulmonary fibrosis (IPF) has called the transplant clinic because the cyclosporine she picked

up from her local pharmacy does not look like the capsules she has received in the past. She reads the label to the pharmacist as Apotex cyclosporine 100 mg capsules. Reviewing the chart, M.R.'s cyclosporine is listed as GenGraf (generic Neoral) 125 mg BID. M.R. is asked to come to the clinic to clarify her medications.

Cyclosporine was initially introduced as a non-microemulsified product branded as Sandimmune, which demonstrated great interpatient variability in absorption and drug levels. Neoral, a microemulsion of cyclosporine, improved the absorption characteristics resulting in more predictable cyclosporine concentrations in lung transplant recipients. In general, the time to C_{max} (T_{max}) for Neoral is shorter, the maximum concentration (C_{max}) is higher, and the AUC is greater.¹²⁰ The two branded agents are not interchangeable; however, they both are available as generics. M.R. has received the generic for Sandimmune instead of her usual generic of GenGraf, the generic for Neoral, and is at risk for subtherapeutic cyclosporine levels. To rectify the situation, M.R. needs to have her local pharmacy dispense GenGraf instead. To minimize this inappropriate interchange, the clinician should specifically indicate the cyclosporine type on prescriptions.

SECONDARY MALIGNANCY

POST-TRANSPLANTATION LYMPHOPROLIFERATIVE DISORDER

Risk Factors

15. A.L., a 17-year-old, 42-kg girl with CF, had a double-lung transplant 1 year ago. She now presents with low-grade fever, malaise, pain, redness and swelling at her Port-A-Cath site, and a 1-week history of decreased appetite. She has experienced four episodes of rejection that were treated with 1 to 2 g of methylprednisolone each time. She also received ATG, azathioprine, prednisone, and cyclosporine after transplantation and has been on the latter three agents chronically along with ketoconazole, TMP-SMX, lactulose, and pancreatic enzymes. She has just finished the last of two courses of IV ganciclovir (6 weeks) for CMV infection. The donor was CMV-positive and she is CMV-positive. Her EBV IgG-VCA (viral capsid antigen) titer is now elevated, although at the time of transplantation it was negative (<1:40). On physical examination, she was noted to have mediastinal adenopathy. She denies chills, sweats, nausea, vomiting, or diarrhea. A chest computed tomography (CT) scan revealed a mediastinal mass. Vital signs and all laboratory tests are within normal limits. Her cyclosporine level is 221 ng/mL. Seven days after admission, a biopsy of this mass shows a thoracic lymphoproliferative lesion identified as a thoracic immunoblastic lymphoma adherent to the right side of the heart. Ten days later, she developed tachy/brady syndrome and a pacemaker was implanted. Given the location of her lymphoma and symptoms, surgery and radiation therapy are not viable options, and chemotherapy is started the next day. What clinical signs and risk factors in A.L. are associated with lymphoma?

A.L. has developed a post-transplantation lymphoproliferative disorder (PTLD), one of many types of malignancies that have been reported after solid organ transplantation. The exact etiology of this condition is unclear and probably multifactorial. The presentation of PTLD varies significantly. Patients can present asymptotically, with mild mononucleosis-like symptoms or with multiorgan failure. A.L. presents with fever,

lymphadenopathy, malaise, and lack of appetite. Although these symptoms are consistent with PTLD, they also are consistent with infection and episodes of rejection. Because PTLD can involve various organ systems, patients can present with organ-specific symptoms (e.g., acute abdominal pain, perforation, obstruction, bleeding if a tumor is in the GI tract). Depending on its location, a tumor can impinge on the function of other organs as seen in A.L.¹²¹

Besides immunosuppression, two factors that have been strongly associated with PTLD are the presence of EBV and the age of the patient. Children have a higher incidence of PTLD.¹²² A.L. seroconverted from a negative to a positive EBV titer, indicating that she had been exposed to this virus at the time of transplantation or afterward. EBV also can be transmitted from the donor lung and blood products. Also, EBV-positive recipients at the time of transplantation can experience reactivation of this virus as a result of immunosuppression.

A.L. received a significant amount of immunosuppression. This could lead to an inability to suppress an active viral infection by cytotoxic T cells and result in uncontrolled B-cell proliferation and polyclonal and monoclonal expansion. In addition to this T-cell defect, an imbalance or alteration in cytokine production in response to EBV, which infects B lymphocytes, may contribute to the exaggerated B-cell expansion and transformation; most are classified as non-Hodgkin lymphomas primarily of B-cell origin. Small percentages are of T-cell origin, however, and are harder to treat.¹²³

The incidence and detection of PTLD has increased. Newer, more potent agents used in different combinations, increased numbers of transplantation procedures, and closer monitoring certainly contributes to this phenomenon. When cyclosporine-based regimens were compared with azathioprine-based or cyclophosphamide-based regimens, lymphomas made up 26% and 11% of all cancers, respectively. The lymphomas occurred, on average, within 15 months in the cyclosporine group versus 48 months in the azathioprine group. One-third of these malignancies occurred in the first 4 months in the cyclosporine group compared with only 11% in the latter group.¹²³

The incidence of PTLD increases with ATG, Thymoglobulin, and OKT3 therapy and appears to be related to a cumulative dose and multiple courses. PTLD is not caused by any single agent but probably reflects the intensity of immunosuppression with multiple agents. Chronic antigenic stimulation by foreign antigens, repeated infections, genetic predisposition, and indirect or direct damage to DNA are other variables that might affect the development of PTLD.¹²³ A.L. had two recent CMV infections, which also could have contributed to this process.

As a percentage of all malignancies, PTLD occurs more commonly in thoracic than in renal transplant recipients and is even more common in children.¹²² Lymphomas develop in about 1% of renal transplantations, 2% of liver transplantations, 2% to 10% of heart transplantations, and 5% to 9% of lung transplantations. These tumors often appear early and progress rapidly. The overall prevalence of malignancies in the transplantation population averages about 6%, and the risk of cancer increases with time after a transplantation. Major organ transplant recipients are 100 times more likely to have cancer than the general population.¹²⁴ Furthermore, the most common types of cancer observed in transplant recipients (e.g., lymphomas, cancer of the skin and lips) are uncommon in the general population. The development of skin and lip cancers

in the transplant population has been attributed partially to exposure to sunlight and sensitization of skin to sunlight by an azathioprine metabolite, methylnitrothioimidazole.¹²⁵

TREATMENT AND OUTCOMES

16. What are the therapeutic maneuvers and outcomes that would be expected in A.L.?

Treatment of a PTLD depends on timing, presentation, symptoms, extent of involvement, histologic type, and transplant type. Early experiences with PTLD indicated that reduction or discontinuation of immunosuppression led to regression of the cancer. Therefore, the first step in treating PTLD is to consider the discontinuation of all immunosuppressives. This course of action is not feasible for A.L., however, because her transplanted lungs are essential for her life. The discontinuation of immunosuppressive therapy also is not an option for heart and liver transplants, but immunosuppressive drugs can be discontinued in kidney transplant recipients because dialysis is available. A.L. will need chemotherapy for her cancer. Therefore, her azathioprine probably should be discontinued to minimize the potential for severe bone marrow toxicity. If her cyclosporine levels were high, a reduction in dose could be attempted, but her cyclosporine concentration of 221 ng/mL is in the lower range for this type of transplantation, and prednisone is reduced to the lowest dose possible. If her immunosuppressive drug therapy is diminished, she should be monitored closely for rejection of her transplanted lungs.

Antiviral therapy with IV acyclovir or ganciclovir has been used to inhibit EBV replication in an effort to treat PTLD. Response is variable and may depend on the type and extent of PTLD. A.L. already has received ganciclovir for 6 weeks during which time she presented with PTLD. Surgery, radiation therapy, and chemotherapy are used to treat PTLD depending on the situation. Interferon and immune globulin have been effective in a few cases that appeared unresponsive to other therapies. Monoclonal or immunoblastic, disseminated, rapidly progressive PTLD responds poorly to traditional therapy and has a mortality rate as high as 70%.¹²⁶ Rituximab (an anti-B-cell, anti-Cd20 antibody) is considered first-line therapy for CD20-positive B-cell PTLD along with reduction or withdrawal of immunosuppression if possible. Patients usually get 375 mg/m² weekly for 4 weeks; some groups have used prolonged therapy.^{127–129} Patients may have relapse or disease progression that may respond to chemotherapy regimens such as cyclophosphamide, adriamycin, vincristine, prednisone or dexamethasone (CHOP), CHOP plus rituximab (CHOP-R), cyclophosphamide, doxorubicin, etoposide, prednisone, cytarabine and bleomycin (PROMACE-cytaBOM).^{130,131} Transplant recipients have a higher risk of myelotoxic side effects, depending on their maintenance immunosuppression.¹³² A.L.'s prognosis is poor given the type and extent of her PTLD, which would have been more responsive to therapy if it had been diagnosed early before it had metastasized. Polyclonal PTLD responds well to reduction or discontinuation of immunosuppression and high-dose acyclovir or ganciclovir therapy for several weeks to months. The roles of prophylactic antivirals, immunoglobulins, and EBV polymerase chain reaction (PCR) monitoring in the prevention of PTLD are currently under study.^{133,134}

Enteral nutrition refers to nutrition provided via the gastrointestinal (GI) tract. However, as the term is commonly used, enteral nutrition (EN) is synonymous with delivery of nutrients into the GI tract by tube (e.g., nasogastric or jejunostomy feeding). Tube feeding allows continued use of the GI tract when one or more steps in the normal process of obtaining nutrients from oral intake is disrupted. Chewing or swallowing may be completely disrupted but some digestive and absorptive function must remain for tube feeding to be a viable option.

Patient Selection

Patients generally are considered at risk of nutrient depletion and associated increased morbidity and mortality when intake is inadequate to meet nutritional requirements for 5 to 7 days or when weight loss exceeds 10% of pre-illness weight within a 6-month period.^{1,2} For adequately nourished patients, specialized nutrition support is generally not warranted when support

will only be needed for fewer than 10 days.³ Nutrition screening is used to identify patients who may be at nutritional risk. Parameters, such as weight, height, diagnosis, recent weight loss, and serum albumin, are evaluated. Nutrition assessment expands screening by including other data (hemoglobin [Hgb], hematocrit [Hct], creatinine, cholesterol, nitrogen balance, total iron-binding capacity [TIBC], prealbumin [transthyretin]), calculation of energy requirements, dietary history, and medical history. Completion of nutrition assessment helps identify potential candidates for EN. (See Chapter 37, Adult Parenteral Nutrition, for further information on nutrition assessment.)

Routes of nutrition intervention may include modified oral diet including oral supplements, EN by tube, or parenteral nutrition (PN). Tube feeding is considered the route of choice in patients with a functional GI tract whose oral nutrient intake is insufficient to meet estimated needs.^{1,3}

Table 36-1 lists functional anatomic units of the GI tract along with major steps occurring in preparing nutrients for

Table 36-1 Functional Units of the GI Tract

| Functional Unit | Major Steps | Conditions/Diseases |
|--------------------------------|---|---|
| Mouth and oropharynx | Chew and lubricate food; swallow | Amyotrophic lateral sclerosis, muscular dystrophy, severe RA, CVA, end-stage Parkinson's disease, paralysis, coma, anorexia due to other disease: cardiac or cancer cachexia, renal failure and uremia, liver failure, neurologic disease |
| Esophagus | Transport food to the stomach | Esophageal disease: ulcer, cancer, obstruction, fistula, esophagectomy, CVA |
| Stomach | Hold food for mixing and grinding; add acid and enzymes; release chyme to small bowel; osmoregulation | Severe gastritis or ulceration, gastroparesis, gastric outlet obstruction, gastric cancer, severe gastroesophageal reflux |
| Duodenum | Osmoregulation; neutralize stomach acid | Severe duodenal ulcer, duodenal fistula, cancer: gastric, pancreatic |
| Small bowel: jejunum and ileum | Digestion; absorption | Enterocutaneous fistula, severe enteric infection, malnutrition, malabsorption, Crohn's disease, celiac disease, ileus and dysmotility syndrome |
| Pancreas | Secretion of digestive enzymes | Pancreatitis, pancreatic cancer, pancreatic injury, pancreatic fistula |
| Colon | Absorb fluid; ferment soluble fiber and unabsorbed carbohydrate; absorb water | Ulcerative colitis, Crohn's disease, colon cancer, colostomy, colovaginal fistula, diverticulitis, colitis of any etiology, colon surgery |

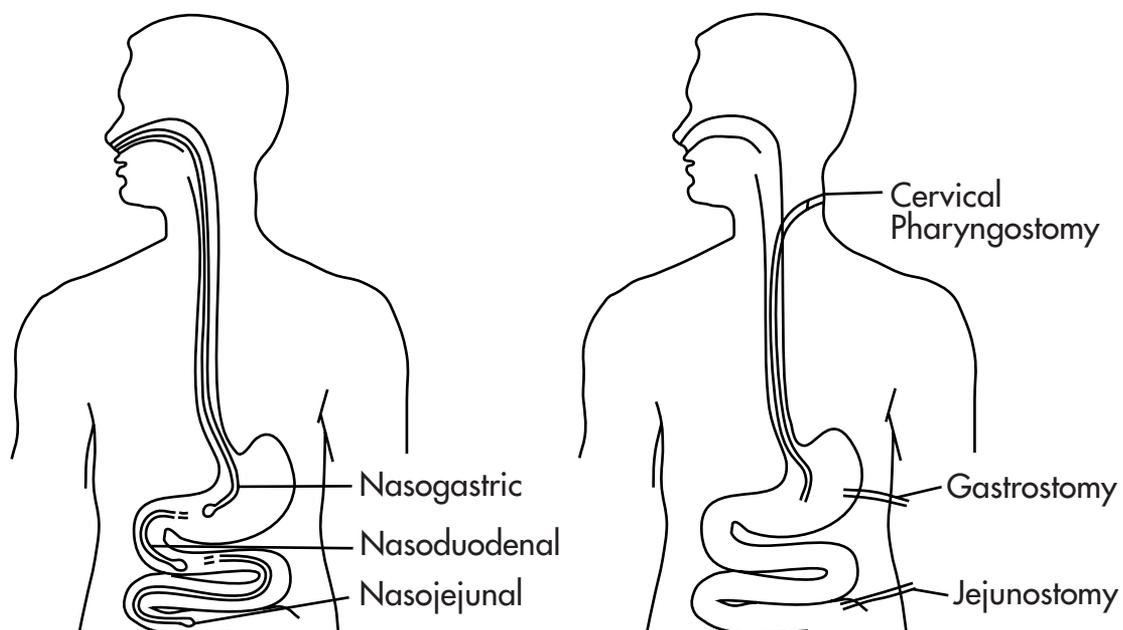

CVA, cerebrovascular accident; GI, gastrointestinal; RA, rheumatoid arthritis.

absorption and it provides examples of conditions potentially impairing each region. EN may be appropriate for patients with the disorders listed, depending on the extent to which normal intake, transport, digestion, and absorption of nutrients is impaired. Clinical circumstances, not specific diagnoses, should be the determining factor for initiating tube feeding. EN should be used with caution in patients with severe necrotizing or hemorrhagic pancreatitis, distal high-output enterocutaneous fistulae, hypotension with significant inotropic support, GI ischemia, and partial bowel obstruction.^{1,3} Contraindications to EN generally include diffuse peritonitis, complete bowel obstruction, paralytic ileus, intractable vomiting or diarrhea, severe malabsorption, severe GI bleed, inability to access the GI tract, and when aggressive intervention is not warranted or desired. Frequent reassessment is recommended because patients may become candidates for EN as the condition improves or

resolves. With advances in GI access and formula composition over the past decade, many patients once requiring PN are now treated successfully with EN.

Route of Tube Feeding

The route for EN is determined by the anticipated duration of tube feeding, disrupted region or process in the GI tract, and the risk of aspiration. Figure 36-1 illustrates the two basic types of tube placement—nasal versus ostomy—and the sites available for formula delivery (i.e., gastric, duodenal, or jejunal). The name of the feeding route usually includes both the type of tube placement and the site of formula delivery. For example, *nasogastric* (NG) indicates nasal placement with gastric delivery of formula, whereas *gastrostomy* indicates ostomy placement with gastric delivery of formula.

**FIGURE 36-1** Nasoenteric and enterostomy feeding sites.

Tube Placement

NASAL

Nasal tube placement is preferred for short-term use in patients expected to resume oral feeding and without obstruction of nasal, pharyngeal, or esophageal passages. Clinically evident injury from nasal intubation is very low, but patients may suffer mucosal trauma in the nasopharynx.⁴⁻⁶ Perforation of the hypopharynx, esophagus, or stomach is a rare complication.^{7,8} Pharyngitis, sinusitis, otitis media, and incompetence of the lower esophageal sphincter are associated with nasal tubes, especially large-bore tubes. The incidence of inadvertent pulmonary placement of small-bore feeding tubes is 4% or less.⁴ Radiographic confirmation of tube placement is mandatory to rule out pleural perforation and pulmonary intubation in unconscious patients and remains the standard to ensure correct tube placement in all patients. Tube displacement is a potential complication occurring in 25% to 41% of cases.⁴

FEEDING OSTOMIES

Feeding ostomies (tube enterostomies) generally are reserved for long-term EN, interpreted as anywhere from 4 weeks to 6 months, depending on clinical circumstances and the type of tube enterostomy placed. Nasal tubes are seldom tolerated for more than 6 weeks in alert patients. Access for enterostomies can be achieved through open surgery, laparoscopy, or percutaneously. Most surgical enterostomies require general anesthesia for placement.⁴

Percutaneous access is usually performed under local anesthesia or conscious sedation by endoscope (percutaneous endoscopic gastrostomy [PEG] or jejunostomy [PEJ]) or by radiography (PRG or PRJ), including fluoroscopy, ultrasound, or computed tomography (CT).^{4,9,10} The major advantage of radiographic compared with endoscopic placement is reduced contamination of the puncture site by oral pharyngeal microorganisms, which are implicated in the 5.4% to 30% incidence of site infections.⁷ Most patients requiring long-term EN receive a PEG, with 216,000 procedures reported annually.¹¹ Endoscopic placement is contraindicated when obstruction prevents passage of the endoscope but radiographic placement may be possible in such cases. Relative contraindications to percutaneous feeding tube placement include inability to see the endoscopic light through the abdominal wall (e.g., morbid obesity, massive ascites), peritoneal dialysis, coagulopathy, gastric varices, portal hypertension, hepatomegaly, and neoplastic or infiltrative disease of the gastric or jejunal wall.^{4,5,7,9,10,12} Prior total or subtotal gastrectomy prevents percutaneous gastrostomy placement, but percutaneous jejunostomy may be possible. Major advantages of percutaneous access are shorter procedure time and lower cost, because morbidity and mortality appear to be similar to surgical feeding tube access.^{5,12} Major complications, such as aspiration, peritonitis, hemorrhage, gastrocutaneous fistula formation, necrotizing fasciitis, gastric perforation, and migration of the tube through the gastric wall, are generally low but have been reported in up to 2.5% of patients.^{4,13}

SITE OF DELIVERY

The preferred site for formula delivery is the stomach because this is the most physiologically normal feeding site. Stimulation of normal digestive processes and hormonal responses associated with eating occur with gastric feeding. The stomach

serves as a reservoir, typically allowing tolerance of bolus, and intermittent or continuous feeding. Gastric feeding, either by NG tube or gastrostomy, requires adequate gastric motility to prevent accumulation of formula in the stomach. Patients with gastric outlet obstruction, gastroparesis, gastric distention, or gastroesophageal reflux are poor candidates for gastric feeding.

Transpyloric feeding into the duodenum or jejunum may be appropriate when gastric dysfunction or disease is present, when risk of aspiration is high, or for early postoperative feeding when gastric emptying may be impaired. In healthy volunteers, negligible reflux to the stomach occurs with dye infused into the fourth portion of the duodenum or proximal jejunum (beyond the ligament of Treitz), suggesting insignificant risk of aspiration with feeding tube placement in these positions.¹⁴ Nevertheless, despite widespread use of postpyloric feeding tube placement, evidence of reduced aspiration remains controversial.¹⁵ Tube migration from the duodenum into the stomach and equal risk of aspiration between postpyloric and intragastric tube placement has been observed.¹⁶ Critically ill patients are at risk for aspiration and ventilator-associated pneumonia, with a 25% to 40% incidence of aspiration in patients with long-term nasoenteric feeding.^{17,18} Tube placement beyond the ligament of Treitz may be best for patients at risk of tube migration and aspiration; however, rigorous randomized trials comparing feeding sites are lacking. Poor differentiation between aspiration of oral secretions and aspiration of feedings may result in erroneously high rates for aspiration of postpyloric feedings.

FORMULA SELECTION

Polymeric Formulas

Enteral formula selection is based on nutrient requirements, fluid restrictions, and the extent of impaired digestion and absorption. Many enteral formulas are available but few are typically necessary on the formulary to meet patient needs. Categorizing formulas as listed in Table 36-2 simplifies the formula selection process.

Polymeric formulas are most common. Use of whole (i.e., intact) proteins in these formulas requires that patients have full digestive capability for proteins. Carbohydrate and fat sources also require full digestive function. Osmolality is decreased and palatability increased with use of relatively intact nutrients. Administration of approximately 1.5 to 2 L of most polymeric formulas provides 100% of Dietary Reference Intakes (DRI) for vitamins and minerals; thus, these formulas sometimes are called “complete” formulas. Polymeric formulas tend to be the least expensive, although prices can vary considerably based on specific nutrient content (e.g., omega-3 [Ω -3FA] fatty acids, fiber). Table 36-3 provides a relative cost summary for enteral formulas.

Nutrient Source

Enteral products are typically *lactose-free* and these formulas are the standard for tube-fed patients owing to presumed lactose intolerance in many hospitalized patients.^{19,20} Reduced disaccharidase production during fasting, malnutrition, and various GI tract diseases contribute to lactose intolerance in hospitalized patients.²¹ In addition, most ethnic groups, except northern Europeans, have reduced lactase production in adulthood,

Table 36-2 Generic Groups and Subgroups of Enteral Formulas

| Polymeric Formulas | |
|--|--|
| <i>Nutrient Source</i> | |
| Blenderized | |
| Lactose free | |
| <i>Fiber Content</i> | |
| Fiber-free | |
| Low fiber (1–9 g/1,000 kcal) | |
| Moderate fiber (9.1–13.9 g/1,000 kcal) | |

leading to lactose intolerance. Lactose can cause bloating, flatulence, abdominal cramps, and watery diarrhea in patients with permanent or transient lactose intolerance. Milk protein concentrate does not contain lactose. Lactose-free formulas leave little residue in the colon and their viscosity is low unless fiber is added.

Table 36-3 Relative Cost of Enteral Formulas^a

| <i>Type of Formula</i> | <i>Relative Cost (dollars)</i> |
|--|--------------------------------|
| Polymeric Formulas | |
| Lactose free, standard caloric density, standard nitrogen content plus | |
| Fiber free for oral supplement or tube feeding ^b | 1 |
| Low to moderate fiber (1–8 g/1,000 kcal) | 1.5 |
| Moderate to high fiber (>8 g/1,000 kcal) | 1.7 |
| Lactose free, standard nitrogen content, fiber-free plus | |
| Standard caloric density (1–1.2 kcal/mL) ^b | 1 |
| Moderate density (1.5 kcal/mL) | 1.3 |
| Calorically dense (1.8–2 kcal/mL) | 1.3 |
| Lactose free, standard caloric density, fiber-free plus | |
| Low nitrogen (6%–10% of kcal as protein); low electrolyte | 3 |
| Standard nitrogen (11%–15% of kcal as protein) ^b | 1 |
| High nitrogen (16%–25% of kcal as protein) | 1.3 |

^bIndex product; given a relative value of 1.

^cBCAA, branched-chain amino acids; AAA, aromatic amino acids.

Fiber Content

Fiber content provides a second criterion for subdividing polymeric formulas. Fiber has potential physiologic benefits, including increased fecal bulk, decreased transit time in patients susceptible to constipation, increased transit time in patients with diarrhea, reduction of serum cholesterol, and improved glycemic control in patients with diabetes. Recommended fiber intake for healthy Americans is 21 to 25 g for women and 30 to 38 g for men, with the lower end of these amounts for people 51 years of age or older.^{22,23} Adequate intake is determined by calorie intake and fiber intake observed to protect against coronary artery disease (14 g/1,000 calories). Optimal fiber intake for ill persons has not been determined. *Fiber-supplemented formulas* vary considerably in fiber content. There is no standardized terminology for low-, moderate-, and high-fiber content. Fiber intake to protect against coronary artery disease is typically considered a high-fiber diet; thus, fiber at 14 g or higher per 1,000 calories is considered high fiber. Diets providing 9 g fiber or less per 1,000 calories generally requires excessive calories to meet recommended fiber intake and are

Table 36-4 Fiber Amount and Sources for Selected Enteral Formulas

| Formula Name | Total Dietary Fiber (g/L) | Kcal to Provide 25–38 g Dietary Fiber Daily | Insoluble Fiber | Soluble Fiber | FOS |
|---------------------------|---------------------------|---|-----------------|---------------|-----|
| Ensure with fiber | 12 | 2,083–3,167 | x | x | x |

| Peptamen AF | 5.2 | 4,808–7,307 | | x | |

FOS, fructo-oligosaccharides.

considered low-fiber diets. EN formulas with 9 g or less per 1,000 calories are considered low-fiber formulas, and fiber content above 9 g but below 14 g per 1,000 calories is classified as moderate fiber content.

Fiber is added to enteral formulas primarily to reduce the rapid intestinal transit associated with fiber-free formulas.²⁴ Insoluble fiber is associated with changes in fecal bulk and transit time, whereas soluble fiber tends to be responsible for effects on cholesterol and glycemic control. Enteral formulas may contain one or both types of fiber, as indicated in Table 36-4. Soluble fibers, such as pectin, psyllium, and certain gums, tend to form gels and are seldom used as a single fiber source.

The most common fiber source for enteral formulas is soy polysaccharide, or soy fiber. Benefits associated with both soluble and insoluble fibers have been noted with soy fiber despite its primarily insoluble fiber content.²⁵ Although soy polysaccharide demonstrates beneficial effects in healthy subjects and patients non-critically ill, studies do not provide clear evidence of improved bowel function in critically ill patients.²⁶ Given the current data, stable patients on long term EN appear most likely to benefit from fiber-supplemented formulas. Some patients on short-term EN without GI pathology who experience altered stool consistency may benefit from fiber supplementation. The effect of fiber on patients with bowel pathology is less clear, however, and it may be detrimental in the hypotensive patient with subclinical ischemia.²⁷

Addition of fiber to enteral formulas creates some potential problems. Fiber tends to increase formula viscosity, which may necessitate a pump for administration through feeding tubes. GI symptoms from fiber can include increased gas production and abdominal discomfort.^{24,28} Gradual introduction of fiber may help reduce these symptoms. Bezoar formation also has been reported in a patient receiving fiber-containing tube feedings and medications that suppressed GI motility.²⁶ Caution is advised for the use of fiber-containing formulas in patients with poor GI motility, underlying GI dysfunction, or those who are critically ill.^{24,27,28} Inadequate fluid intake may also contribute to the risk of bezoar formation and intestinal blockage with fiber.

Fructo-oligosaccharides (FOS) are naturally occurring sugars that are added to some enteral formulas (Table 36-4). Glycosidic linkages between fructose units and glucose in the FOS are not split by GI enzymes but can be fermented to short-chain

fatty acids by *Bifidobacterium* in the colon.^{26,29} Soluble fibers also are fermented to short-chain fatty acids by colon bacteria; they stimulate colonic blood flow, enhance fluid and electrolyte absorption, and provide a trophic effect in the colon. This may account for the association between soluble fibers and beneficial effects on colonocytes (e.g., regulation of cell growth and adhesion, including inhibition of neoplastic cell growth). Improvement in constipation has been noted with FOS administration; however, intake of >45 g/day may cause diarrhea.³⁰ Use of FOS in enteral formulas has increased over the past several years as FOS appear to offer the benefits of soluble fiber without the same physicochemical limitations.

Caloric Density

Caloric density is another method of subdividing polymeric enteral formulas. The standard caloric density is 1 to 1.2 kcal/mL. Moderate density formulas contain approximately 1.5 kcal/mL, and calorically dense formulas contain 2 kcal/mL. Increased caloric density increases formula osmolality. Gastric emptying can be reduced when osmolality exceeds 800 mOsm/kg and this may result in feeding intolerance.³¹ GI intolerance (e.g., nausea, flatulence, abdominal discomfort) also can occur if the capacity of intestinal enzymes is overwhelmed by infusion of a calorically dense formula. The risk of dehydration increases with increasing caloric density; however, standard caloric density formulas can result in fluid overload in patients with congestive heart failure, renal failure, or other fluid-sensitive conditions.

Protein Content

The fourth method of subdividing polymeric formulas is by protein content, either as a percentage of calories from protein or as the nonprotein calorie:nitrogen ratio (NPC:N). Grams of protein times 4 equals protein calories, and grams of protein divided by 6.25 equals grams of nitrogen, assuming protein is 16% nitrogen. Protein needs increase disproportionately to caloric needs during injury and critical illness. High-nitrogen enteral formulas, designed to supply this increased protein requirement provide approximately 16% to 25% of calories from protein. The NPC:N ratios in these formulas range from 75:1 to 130:1. Standard protein content is 11% to 15% of calories, with NPC:N approximately 140:1 to 200:1. Low-nitrogen formulas with 6% to 9% of calories from protein and a ratio >250:1 are available for patients requiring protein restriction.

Oligomeric Formulas

Oligomeric formulas, also called *predigested*, *monomeric* or *chemically defined formulas*, require minimal digestive function and produce little residue in the colon. Pancreatic enzyme activity is required for digestion of oligosaccharides and fats. Brush-border disaccharidase activity also is required. Minimal digestion is required, however, for the hydrolyzed protein and medium-chain triglyceride (MCT) components. These formulas can be used for patients with pancreatic insufficiency, reduced mucosal absorption, or reduced hydrolytic capability. Patients most likely to benefit from oligomeric formulas are those with severe pancreatic insufficiency or short bowel syndrome.¹ Although the Canadian Clinical Practice Guidelines for Nutrition Support in Mechanically Ventilated, Critically Ill Adult Patients (CCPG) noted patients with these and other GI complications may benefit from oligomeric formulas, insufficient data were available to make recommendations regarding use of such formulas.³² Pancreatic enzyme supplementation with polymeric formulas may be tried before oligomeric formulas for some patients with pancreatic insufficiency (e.g., cystic fibrosis).

Two subgroups of oligomeric formulas can be differentiated based on the protein source. True “elemental” formulas contain free amino acids, whereas “peptide-based” formulas contain oligopeptides plus dipeptides, tripeptides, and free amino acids from hydrolysis of protein. Amino acids require no digestion, but the sodium-dependent active transport mechanism appears to be somewhat slow and inefficient with only about one-third of dietary protein absorbed as free amino acids; the remaining two-thirds are absorbed as di- and tripeptides.^{30,31,33,34} Specific carriers for di- and tripeptides absorption located in small bowel mucosa do not compete with the free amino acid transport system. Peptides longer than three amino acids require further hydrolysis within the lumen of the small bowel before they are absorbed. Most peptide-based formulas contain a significant portion of peptides that require hydrolysis before absorption.

Some data suggest enteral diets high in peptides stimulate protein synthesis and tissue recovery better than free amino acids; however, the clinical relevance is unclear.³⁵ No well-designed, randomized, controlled trials have clearly delineated clinical differences in elemental (free amino acid) versus peptide-based formulas. Elemental formulas generally have the lowest fat content (10% f.a.a. (see Table 36-5)). Peptide formulas typically contain one-fourth to one-third of calories from fat, but provide 20% to 70% of the fat as MCT to minimize the risk of malabsorption. Crucial, Optimental, Peptamen products, and Perative are examples of formulas containing peptides.

Oligomeric formulas are typically hypertonic owing to their partially digested nature, although peptide-containing formulas tend to be only slightly hypertonic. Osmotic diarrhea can occur because of the hyperosmolality; however, the CCPG meta-analysis found no difference in diarrhea occurrence between patients receiving intact protein and those receiving peptide-rich formulas.³² Taste and cost are disadvantages of oligomeric formulas. Flavoring packets are available and newer formulas may be better accepted, but patients commonly complain of a bitter taste when these formulas are taken orally. In gen-

eral, patients do not tolerate adequate oral consumption of an oligomeric formula to meet daily requirements. As shown in Table 36-3, oligomeric formulas tend to cost several times more than polymeric formulas.

Specialized Formulas

Specialized formulas are designed for specific disease states or conditions, but their use and clinical benefits are controversial. Formulas generally have a good theoretic basis for use, yet lack conclusive clinical evidence of improved efficacy compared with standard formulas. Well-designed studies showing a difference in outcome between specialized and standard enteral formulas providing equal nitrogen and equal calories are difficult to find. Given the high cost of most specialized formulas, it often is difficult to justify their use without evidence of improved clinical efficacy compared with standard formulas.

Renal Failure

Specialty enteral formulas designed for patients with renal failure have enriched essential amino acid content. Theoretically, recycling of urea nitrogen for nonessential amino acid synthesis reduces the accumulation of blood urea nitrogen (BUN).^{19,35,36} Clinically significant recycling of nitrogen and incorporation into nonessential amino acids does not appear to occur, however. Essential amino acid formulas may be appropriate for patients with chronic renal failure with glomerular filtration rates <25 mL/minute/1.73 m² who are receiving very-low-protein diets and for whom dialysis is not an option.^{1,35} Use should be limited to no more than 2 to 3 weeks, because hyperammonemia and metabolic encephalopathy have been associated with longer use. These formulas are not appropriate for patients in acute renal failure or for those receiving dialysis. The NPC:N is generally $>300:1$ in these formulas. Appropriate vitamin and mineral supplements must be provided with essential amino acid formulas because the formulas themselves are incomplete. Renalcal contains higher-than-normal essential amino acids in combination with nonessential amino acids.

Polymeric enteral formulas designed for renal failure or renal insufficiency are now the standard for patients with impaired renal function. A systematic review, however, found data were insufficient to complete a meta-analysis comparing outcomes with renal versus standard enteral formulas in patients on chronic dialysis.³⁷ These formulas are not enriched with essential amino acids and use a lower NPC:N ratio (e.g., 140:1 or 160:1) than essential amino acid-enriched formulas. Lower-than-normal concentrations of potassium, phosphorus, and magnesium, as well as higher caloric concentrations (1.8–2 kcal/mL) are used in these formulas to minimize fluid and electrolyte problems. Polymeric enteral formulas meet 100% of the DRI with $<2,000$ mL/day. Examples of intact protein renal formulas include Suplena, Nepro, and Nutren Renal.

Hepatic Failure

Hepatic failure formulas contain 45% to 50% of protein as branched-chain amino acids (BCAA), compared with 15% to 20% in standard formulas, and lower-than-normal concentrations of aromatic amino acids (AAA), especially phenylalanine. Theoretically, increasing BCAA and decreasing AAA

improves hepatic encephalopathy by reducing inhibitory and false neurotransmitter formation.^{19,35,36} Prospective, randomized, controlled trials comparing BCAA-enriched formulas with comparable enteral formulas containing standard protein sources are limited. Most studies have not shown a clear advantage for hepatic failure formulas, especially with respect to mortality, and most patients with liver disease tolerate formulas with standard protein sources.^{1,19,35} NutriHep is a ready-to-use high BCAA formula containing appropriate vitamin content for patients with end-stage liver disease. Hepatic-Aid II is a powder that must be mixed with water; supplementation of vitamins, minerals, and electrolytes is necessary because it contains negligible amounts of these nutrients.

Stress or Critically Ill

Specialized *stress formulas* designed for critically ill, hypercatabolic patients generally contain a NPC:N ratio of <100:1 (i.e., high nitrogen content) and >35% of protein content as BCAA, without reduced AAA concentrations. Thus, stress and hepatic failure formulas are not therapeutically interchangeable. The theory behind stress formulas is as follows: BCAA are used preferentially for energy production in skeletal muscle of critically ill patients and exogenous BCAA reduces skeletal muscle breakdown and improves protein synthesis.^{19,35,36} Studies evaluating the effectiveness of BCAA in stressed patients have primarily involved parenteral BCAA, although results for both parenteral and enteral administration are conflicting and controversial, with no significant improvement in clinical outcome, including morbidity and mortality. Objective criteria for defining critical illness and determining entry into studies may contribute to the inconclusive and controversial results when these studies are viewed as a group.

Enteral formulas having a NPC:N ratio of $\leq 125:1$, but without BCAA supplementation, are commonly marketed as stress or critical care formulas. Several of these formulas, as listed in Table 36-5, also contain arginine, glutamine, or nucleic acid supplementation, a modified fat component, or both. Such formulas are often referred to as “immune-modulating” formulas based on their proposed beneficial modulation of biologic responses to stress. Study formulas frequently contain varying portions of potentially immune modifying components making it difficult to determine the effect of any given component. In addition, effects of immunonutrition in critically ill patients are difficult to isolate from other effects of critical illness and studies are not conclusive for the role of these formulas in most cases. Properties of each of the main immunonutrition substrates are discussed below.

Arginine. The postulated role of arginine in critical illness is related to protein synthesis, cellular growth, and lymphocyte blastogenesis. Arginine is a nonessential amino acid synthesized by the urea cycle during detoxification of ammonia and it is normally available in sufficient quantities for growth and tissue repair. Endogenous synthesis may, however, become inadequate during metabolic stress, making it conditionally essential. Studies in healthy and elderly volunteers have shown beneficial effects from arginine supplementation on T-lymphocyte response and collagen deposition in artificial wounds used as markers of wound healing.^{38–40} In burn patients, reduced wound infections, hospital length of stay (LOS), and mortality have been demonstrated with supplementen-

tal arginine.⁴¹ Arginine supplementation at two to seven times normal dietary intake (~5.4 g/day in the United States) was suggested as safe for nonseptic burn patients in a review, but further study was considered necessary in septic patients.^{40,42} Few studies with surgery and critically ill patients have used arginine alone and results with arginine plus other immune modulating components, most commonly Ω -3FA, nucleotides, glutamine, and antioxidants, are controversial. A recent meta-analysis found no difference in clinical outcomes (e.g., infectious complications, ventilator days, LOS) and mortality for critically ill patients receiving immunonutrition versus standard EN.⁴³ This meta-analysis was heavily weighted by the results of a large multicenter trial that showed no difference in the outcome parameters of 597 critically ill patients randomized to isonitrogenous high protein, isocaloric formulas, and study formula that contained 9 g/L arginine, 13 g/L glutamine, high Ω -3FA, antioxidants, and low-fiber content.⁴⁴ Several earlier meta-analyses and systematic reviews indicated improved clinical outcomes but no difference in mortality with combined immune-modulating components.^{19,40,42,45} Inclusion of multiple prospective, double-blind, randomized controlled studies in patients with upper GI cancers undergoing major surgery likely contributed to these results.⁴⁰ One meta-analysis suggested high arginine (>12 g/day) was associated with potential enhanced immune function and reduced infections in patients having elective surgery, yet advised of potential harm in some subpopulations of critically ill patients, particularly septic patients.⁴⁵

Arginine produces some of its versatile physiologic effects through a nitric oxide (NO) dependent pathway. The synthesis of NO, a potent vasodilating agent, requires arginine as a substrate. Although NO production increases during sepsis (thereby creating a negative arginine balance), the exact role of this effector molecule remains controversial. Many believe that excess NO is part of an adaptive response directed toward limiting infection, ischemia, coagulation, inflammation, and tissue injury.⁴² One study indicates that a population of septic patients, mostly with pneumonia, receiving a high-arginine-containing, immune-enhancing formula (>12 g/L) had significant decreases in the incidence of bacteremia and decreased mortality.^{45,46} On the other hand, a number of other studies and subgroup analysis of higher quality studies reveal that arginine supplementation in the critically ill patient population may be detrimental owing to an enhanced systemic inflammatory response and hemodynamic instability.^{45,47–49}

Bertolini et al.⁴⁹ reported about a 31% higher mortality with an immune-modulating EN formula (supplemented with arginine, glutamine, nucleic acids, and Ω -3FA) compared with PN in septic patients. Patients with pneumonia receiving arginine, Ω -3FA, and antioxidant-supplemented feeding also may be at increased risk for death.⁵⁰ High plasma arginine concentrations in critically ill patients with hepatic failure have been reported and the conclusion was that supplemental arginine could be harmful in this patient population.⁵¹ Use of arginine-containing, immune-enhancing diets is not recommended by CCPG because higher-quality studies indicated no effect on mortality with these formulas and increased mortality was reported for septic patients in some studies.³² No randomized studies were available for arginine alone in critically ill patients. A consensus statement published by another group also

Table 36-5 Selected High-Protein Enteral Formulas With Altered Protein or Fat Sources^a

| Formula ^{b,c} | kcal/mL (mOsm/kg) | Free Protein Water (%) | g/L (% kcal) | NPC:N Ratio | Protein Source | ARG g/L ^d | GLN g/L ^d | Fat g/L (% kcal) | Fat Sources | Fat kcal as MCT (%) | Ratio of n-6 to n-3 FAs ^d | Fiber g/L ^d |

ARG, arginine; DHA, docosahexenoic acid; EPA, eicosapentenoic acid; FOS, fructo-oligosaccharides; GLN, glutamine; HN, high nitrogen; MCT, medium-chain triglycerides; NPC:N, nonprotein calorie to nitrogen; n-3FA, Ω-3 fatty acids; n-6FA, Ω-6 fatty acids; VHP, very high protein; VHN, very high nitrogen.

recommends against use of arginine-enriched formulas in critically ill patients.⁵² Clearly, the role of arginine-supplemented EN remains controversial. Additional studies with well-defined patient populations are necessary to determine appropriate arginine doses, the effects of arginine alone versus combinations of immune-modulating components (arginine, glutamine, nucleic acids, Ω -3FA), and to identify which patient populations would benefit from this amino acid.

Nucleic acids or nucleotides. Purines and pyrimidines, including RNA and DNA, comprise the nucleotides. Evidence for including nucleotides in the diet comes primarily from animal studies that suggest a need for preformed pyrimidines to develop and activate T cells in the immune system.⁵³ Diets lacking nucleotides may be immunosuppressive; however, little data are available on the role of nucleotides in EN formulas. Nucleotide use in EN formulas has only been in conjunction with other immune-modulating components and studies are needed to clarify their effects.

Glutamine. The proposed role of glutamine in critical illness is enhanced neutrophil function and maintenance of intestinal barrier function, thereby preventing translocation of bacteria and endotoxins from the GI tract into systemic circulation and reducing bacteremia.^{54–56} Glutamine potentially reduces the inflammatory response, lowers the risk of insulin resistance, and maintains acid-base balance. Glutamine is a nonessential amino acid synthesized in sufficient quantities for its roles in transamination, as an intermediate in numerous metabolic pathways, such as gluconeogenesis and renal ammoniogenesis, as a fuel source for rapidly dividing lymphocytes and enterocytes, and in the synthesis of glutathione. Endogenous synthesis may become inadequate during metabolic stress, however, making glutamine conditionally essential. Large, abrupt drops in plasma and muscular glutamine concentrations, which appear to correlate with increased mortality, have been reported in patients who are critically ill or septic.^{55,57} Although this observation does not necessarily indicate depletion, it is used as a hypothesis for the supplementation of glutamine in certain patient populations. Although a number of benefits have been attributed to the provision of glutamine, study results are often conflicting. Decreased methotrexate-induced enterocolitis, improved rates of GI tract recovery after radiation therapy, and a reduction in the severity or duration of mucositis have all been reported following glutamine administration.^{58,59} Although glutamine supplementation has been associated with improvements in the indicators for protein catabolic rate and immune function in critically ill patients, improvements in nitrogen balance and visceral protein status are rarely noted. The reports of less pneumonia, bacteremia, and septic events in critically ill patients receiving glutamine supplementation do not translate into reduced mortality.⁶⁰ Glutamine supplementation may however be linked to a decrease in complications and mortality rates when parenteral, high-dose glutamine is utilized. Data from a meta-analysis confirm the previous hypothesis of many investigators that the beneficial effect of glutamine in the critically ill may be very dependent on dose and route of administration.⁵⁴

Protein-bound glutamine is present in all enteral formulas. Free glutamine is unstable in ready-to-use formulas, however, and it is generally administered separately from the formula. Glutamate is stable in water and functions in many roles at-

tributed to glutamine. Additional research is needed to determine whether physiologic effects are equivalent for glutamate, protein-bound glutamine, and free glutamine. Until such questions are answered, supplementation of free glutamine separately from the formula is likely to continue despite its uncertain role in many patient populations and suggestions that it is not necessary.⁶¹ The currently recommended maximal dose of glutamine is 0.57 g/kg/day, although lower doses are used in most studies and >0.2 g/kg/day was adequate to see benefit in one meta-analysis.^{38,62} Doses of enteral glutamine used in studies reviewed for the CCPG varied from 0.16 to 0.5 g/kg/day, and the committee decided a reasonable dose would be 0.3 g/kg/day.^{32,63} Although available data do not indicate a harmful effect of glutamine, there are theoretic concerns associated with providing a large quantity of one amino acid that shares transport systems with other amino acids in the body and that has a role in ammoniogenesis. Glutamine supplementation should be avoided in patients with total bilirubin >10 mg/dL or creatinine clearance <30 mL/minute because ammonia excretion could be impaired.⁶⁴ Monitoring for potential complications with glutamine supplementation is advised given these theoretic concerns.

Alteration in the fat component of enteral formulas. Stress or critical care and immune-modulating formulas contain different sources of fat to alter the type of fatty acids provided. Fat sources commonly include MCT, along with predominantly canola oil, high oleic oils, or fish oils as long-chain fatty acids. Usual polyunsaturated vegetable oils (i.e., corn, soy, and safflower oils) are avoided or provided in relatively small quantities to limit omega-6 fatty acids (Ω -6FA), which are precursors to arachidonic acid and therefore to dienoic or “2” series prostaglandins, prostacyclins, and thromboxanes, and to “4” series leukotrienes. These compounds, taken as a whole, are potent inflammatory, vasoconstrictive, and platelet-aggregating agents.^{65,66} The source of Ω -6FA may, however, also influence the type of prostaglandins produced.⁶⁷ Dietary α -linoleic acid is converted to γ -linoleic acid (GLA), then to dihomo-GLA, and subsequently to arachidonic acid. As a dietary supplement, GLA is converted to dihomo-GLA, which effectively competes with arachidonic acid in the pathways for prostaglandin synthesis rather than being elongated to arachidonic acid. The resulting “1” series prostaglandins have lower proinflammatory effects, similar to “3” series prostaglandins. Small amounts of Ω -6FA are required in the diet to prevent deficiency of linoleic acid an essential fatty acid not provided by MCT and fish oils.

Fish oils, including menhaden oil, provide fatty acids primarily from the Ω -3 family, with the very long-chain fatty acids eicosapentenoic acid (EPA) and docosahexenoic acid (DHA) predominating. The proposed role of Ω -3FA in critical illness is to reduce infectious complications and death in selected patient populations. The Ω -3FA are precursors to the “3” series prostaglandins, prostacyclins, and thromboxanes, and “5” series leukotrienes. In total, these compounds are less inflammatory and more vasodilatory than compounds from Ω -6FA.^{65,66,68} This may be beneficial in critically ill patients, but few data are available evaluating effects of only fat modification. Combinations of immune-modulating components may produce different effects than single nutrients. For example, in vitro data demonstrate an interaction between prostaglandins and arginine metabolism. Greater arginase induction and lower

nitrate levels exist with “1” and “2” series compared to “3” series prostaglandins.⁶⁹

Improved clinical outcomes for postsurgical and critically ill patients have been associated with EN containing Ω -3FA, usually in conjunction with other immune-modulating components, although the effects remain controversial.^{19,40,42,45,68} Studies suggest a minimum of 5 to 7 days of supplementation with immune-modulating components, including Ω -3FA, is necessary to see beneficial effects on postoperative outcomes.^{70–72} Incorporation of Ω -3FA into cell membranes has been demonstrated in humans with supplementation for 5 days.⁷³ Decreased wound infections and reduced mortality have been demonstrated in burn patients with low-fat diets containing 50% of fat as fish oil.⁴¹ Other studies, however, have shown no benefit in this population.⁶⁵ Fat modification to provide high Ω -3FA content also has been studied in acute respiratory distress syndrome (ARDS) and acute lung injury, as discussed under pulmonary formulas.

Further research is needed to elucidate effects of Ω -3FA alone and to determine their safety and efficacy in various disease states. Effects of Ω -3FA on antioxidant levels, especially vitamin E, and the need for supplementation require study. Appropriate quantities of Ω -3FA and the most beneficial ratios of Ω -6FA to Ω -3FA also must be determined before routine supplementation with Ω -3FA can be recommended beyond modifying the diet to include foods rich in Ω -3FA (i.e., fish, such as salmon). Current ratios of Ω -6FA to Ω -3FA in diets range from about 4:1 in Japan to 16:1 in the United States, although a specific intake amount resulting in adverse effects has not been determined for either Ω -6FA or Ω -3FA.^{61,64} No data exist to guide the use in various illnesses.

Canola oil and high-oleic oils are other fat sources used in EN. These oils are common in standard formulas, as well as those used for stress and critical illness. Canola oil contains approximately two-thirds monounsaturated fatty acids, compared with less than half this amount in polyunsaturated vegetable oils. High-oleic safflower and sunflower oils also have a high monounsaturated fatty acid content. Monounsaturated fatty acids have been popularized by reports of low cardiovascular disease in populations using olive oil, but further research is needed to determine the role of these fatty acids in ill patients. The combination of canola oil and high-oleic oil does increase the content of linolenic acid.

Enteral formulas often contain MCT to improve fat absorption. Absorption of MCT is relatively independent of pancreatic enzymes and bile salts; thus, they can be absorbed in patients experiencing malabsorption of the long-chain triglycerides. Rapid, carnitine-independent metabolism occurs with MCT, whereas long-chain triglycerides require carnitine for metabolism. Therefore, use of long-chain triglycerides is compromised when carnitine deficiency occurs, but MCT metabolism is unaffected. Formulas containing a relatively large percentage of fat calories as MCT are frequently marketed for critically ill patients with malabsorption. Examples of formulas with higher percentages of fat calories as MCT include Nutren 1.5 and Crucial with 50% to 65%, Nutren 2.0, NutriHep, and Peptamen products with 65% to 80%, and Portagen with over 85% of fat calories as MCT.

Carnitine. An important compound in normal nutrition, carnitine is required for transport of long-chain triglycerides into the mitochondria for metabolism and export of acyl-coenzyme

A (CoA) compounds out of the mitochondria. Formulas marketed for critical care may contain higher amounts than standard formulas, but most formulas contain an adequate quantity of carnitine to prevent deficiency.

Taurine. A sulfur-containing amino acid, taurine protects cell membranes by attenuating toxic substances and acting as an osmoregulator.⁷⁴ Taurine may improve fat absorption in patients with malabsorption through effects on bile acid production and micelle formation. Taurine also is essential for normal neuronal and retinal development in infants and children; thus, pediatric formulas include taurine as an essential nutrient.⁷⁴ Dietary taurine is adequate for adults, except possibly those with catabolic illness such as cancer, chemotherapy, radiation, burns, and operative injury. Taurine is typically added to formulas marketed for stress and critical illness because these populations may be at risk of inadequate intake.

The results of clinical trials examining the effects of immune-modulating enteral formulations on mortality, hospital LOS, intensive care unit (ICU) days, incidence of nosocomial infection, duration of mechanical ventilation, and GI complications are conflicting.^{32,41–50,52,54–56,61–63,68,70–77} Differences in study design, patient population, enteral formulation (immune-modulating components and doses), time to EN commencement, and volume of formula received, make it difficult to compare study results reliably. Meta-analyses of major studies reveal particular subsets of patients who may benefit from certain immune-modulating components whereas other subgroups may exhibit increased mortality. Patients with sepsis, pneumonia, and possibly other infections appear potentially to be at risk of harm. Arginine has been identified as the component most likely responsible for poor outcomes, but no studies with arginine as a single supplemental ingredient are available. Formulas generally include some combination of arginine, glutamine, Ω -3FA, and antioxidants, making it difficult to identify the effects of any single component clearly. Elective surgical patients, especially upper GI surgery, appear to be most likely to benefit from immunonutrition, with significant reductions in infectious complications and lower hospital LOS without mortality effect. Further research is needed to examine this controversial area of nutrition. A need exists to define which patients will benefit from immunonutrition, and the optimal components, doses, and timing of immune modulators for different patient subgroups. Until such information is available, the immune-modulating formulas must be used with caution and careful evaluation of each patient. Guidelines, consensus statements, and recommendations have been developed to help the clinician provide evidence-based nutrition therapy; however, many barriers to implementation exist.^{1,28,32,52,63,72,75,78}

Pulmonary Disease

The percentage of calories from fat is relatively high (40%–55%) in formulas marketed for patients with pulmonary disease. The premise for higher fat content is that fat oxidation produces less carbon dioxide (CO₂) than carbohydrate oxidation, thereby reducing the work load of the lungs. Fats, particularly long-chain triglycerides, have a lower respiratory quotient (RQ) than carbohydrates, meaning less CO₂ is produced per volume of oxygen consumed during fat metabolism. Early studies comparing isocaloric, high-fat, low-carbohydrate diets with higher carbohydrate diets showed improved respiratory

parameters in ambulatory patients with chronic obstructive pulmonary disease (COPD) as well as reduced time on the ventilator and decreased arterial CO₂ concentrations in mechanically ventilated patients.^{19,35,36,77} Calories at 1.7 to 2.25 times measured energy expenditure in these studies were excessive by current standards and excess calories contribute to higher CO₂ production.⁷⁹ Preventing overfeeding is as important for control of CO₂ as high-fat, low-carbohydrate diets.^{19,20} In addition, improved respiratory parameters with a high-fat EN product are unlikely to be seen in patients without excess CO₂ production or retention. A more recent study in 60 malnourished, underweight patients with COPD does suggest respiratory status in this population is more likely to benefit from a high-fat, low-carbohydrate (28% of calories) formula compared with a high-carbohydrate (60%–70% of calories) formula.⁸⁰ Although the percent of calories from fat (55%) in the high-fat formula was similar to traditional pulmonary formulas, fat distribution was considerably different with 20% of fat as MCT and a predominance of monounsaturated fat. During a period of overfeeding for weight gain, pulmonary formulas may be reasonable; however, they are not warranted for routine use.

An immune-modulating pulmonary (IMP) formula has been studied in patients with ARDS and acute pulmonary injury.⁸¹ Two high-fat formulas, the IMP formula containing fish oil, borage oil, and antioxidants (vitamins C and E, beta-carotene) and a typical pulmonary formula with high Ω -6FA content were compared. The IMP formula was associated with fewer days of supplemental oxygen, fewer days of mechanical ventilation, decreased ICU days, and fewer new organ failures. However, the choice of control formula in this study has been questioned since there is some evidence of harmful effects from administration of Ω -6FA-rich fats in critically ill patients.³² Mortality was not improved. This was the only study meeting inclusion criteria for the CCPG using fish oils in critically ill adults.³² Due to the potential need for higher antioxidant intake with Ω -3FA and because of inability to separate effects of the combined components in the IMP formula, the CCPG recommendation is to consider using IMP formulas containing a combination of fish oils, borage oils, and antioxidants in patients with ARDS. Another study not available for CCPG evaluation used the same IMP formula and found lower alveolar membrane permeability and reduced leukotriene B₄ and total neutrophils in bronchoalveolar lavage (BAL) fluid of patients with ARDS.⁸² As for all immune-modulating formulas, the cost of the IMP formula is relatively high (Table 36-3).

Delayed gastric emptying is associated with high-fat diets, and must be considered when evaluating possible benefits and adverse effects of high-fat EN. Abdominal distention, increased gastric residuals, nausea, and vomiting can result from delayed gastric emptying. Delivery of a high-fat load, especially long-chain triglycerides, into the small bowel may overwhelm pancreatic lipase activity in some patients, leading to fat malabsorption. Formulas typically classified as pulmonary formulas include Nutren Pulmonary and Pulmocare. Opepa is an IMP formula.

Glucose Control

Formulas for hyperglycemic patients, known as diabetic formulas, have caloric distributions of 31% to 40% carbohydrate, 42% to 49% fat, and 16% to 20% protein. The fat content is

higher than recommended for healthy persons with diabetes, but high monounsaturated fat sources predominate.^{83–85} The source and type of carbohydrates in diabetic formulas varies, with a predominance of more complex carbohydrates (i.e., oligosaccharides, cornstarch, fiber) and insulin-independent sugars (i.e., fructose) despite total carbohydrate content probably being more important than carbohydrate type.^{19,85} For tube feeding the American Diabetes Association suggests either a standard formula with 50% carbohydrate or a formula containing 33% to 40% carbohydrate.⁸⁶ Practice guidelines for nutrition support suggest no changes in macronutrients compared with the standard diet recommendations for diabetes, including 45% to 65% of calories from carbohydrate.¹ Fiber sources associated with improved glycemic control, mainly soluble fibers but also soy polysaccharide, are included in these formulas to help minimize postprandial hyperglycemia.²⁴ Fiber content ranges from 14 to 21 g/L and formulas are 1 kcal/mL; thus, the recommended fiber intake of 25 to 38 g daily generally can be achieved with <2,000 kcal/day.^{22,23}

Results of studies with diabetic formulas have been mixed. Early studies showing improvement in glucose response were conducted in healthy volunteers, whereas patients with type 2 diabetes in a long-term care facility showed no improvement compared with a standard EN formula.^{19,28,87} Studies showing reductions in blood glucose frequently fail to achieve tight control (i.e., 80–110 mg/dL) and lack improvement in clinical outcomes, including infectious complications, hospital LOS, and mortality.^{88,89} Current evidence is insufficient to support routine use of diabetic formulas; thus, starting with a standard formula in conjunction with insulin use and changing to a diabetes formula if insulin causes difficulties with glucose control has been suggested.^{28,53,87,90,91} Problems with delayed gastric emptying or fat malabsorption must be weighed against possible benefits of improved glucose control with diabetic formulas. Clearly, treatment goals for EN in patients with diabetes mellitus should include individualization of macronutrient composition, avoidance of excess calories, and maintenance of euglycemia.¹ Formulas marketed for glucose control include Glucerna, Glucerna Select and Nutren Glytrol.

Modular Components

Modular components are individual nutrient substrates designed for addition to oral diets or enteral formulas. Glucose polymers are used to supplement calories as carbohydrate. They do not increase osmolality or alter food or formula flavor. Powdered carbohydrate modules contain 20 to 30 kcal/teaspoon, whereas liquids contain 2 kcal/mL. Protein modules are powders containing 3 to 5 g protein/teaspoon. Most protein modules are intact protein. Arginine and glutamine are available as individual packets to allow supplementation as a single amino acid. Modular components typically are mixed with water and administered through the feeding tube rather than being mixed directly into the formula.

TUBE-FEEDING ADMINISTRATION REGIMEN

The feeding route, formula selected, and anticipated duration of feeding influence the administration regimen. Patient location (e.g., hospital, nursing facility, home) and cost also are considered when developing the regimen, including delivery

schedule, formula strength or concentration for initiating and advancing feedings, and the administration method (i.e., syringe, gravity drip, pump). Limited scientific data exist regarding EN administration regimens; thus, expert opinion plays an important role and different regimens can be used in various settings, all of which appear to meet the needs of the patients and personnel. Practice guidelines or protocols for initiation and advancement of EN have been suggested to minimize variations in quality of care and facilitate optimal delivery of nutrients and appropriate monitoring.⁹² The CCPG found insufficient data to recommend the use of feeding protocols in critically ill patients.³² With or without a protocol, the administration regimen should be adjusted as necessary for feeding intolerance.

Four basic schedules for formula delivery are available to provide the daily volume of formula: continuous infusion, cyclic infusion, intermittent infusion, and bolus delivery of formula. *Continuous infusion* provides formula at a continuous rate over 24 hours/day. In contrast, *cyclic infusion* provides formula at a continuous rate for <24 hours daily. *Intermittent infusion* provides formula in a specified number of feedings daily. Each of three to eight daily feedings is administered over 20 to 60 minutes via gravity drip or infusion pump. *Bolus delivery* is similar to intermittent infusion except that each feeding is administered via a syringe or by gravity over a few minutes up to 20 minutes.

Continuous Infusion

Continuous infusion can be used with any route of feeding. Intra-gastric continuous infusion is most commonly used for hospitalized patients, although small bowel feeding may be more appropriate in certain settings (e.g., ICU).³² Risks of gastric distention and aspiration may decrease with continuous infusion compared with intermittent gastric infusion.^{18,93,94} In addition, continuous infusion may be better tolerated as judged by stool frequency and time to attain full nutrition support, especially in the elderly and in metabolically unstable patients.^{77,92,95,96} Insufficient evidence exists to include a recommendation for continuous infusion versus other administration methods for critically ill patients in the CCPG.³² Feeding into the duodenum or jejunum is best initiated with continuous infusion because rapid infusion of large formula volumes into the small bowel can result in symptoms consistent with a dumping syndrome, including sweating, lightheadedness, abdominal distention, cramping, hyperperistalsis, and watery diarrhea. With time, the jejunum may adapt to larger volumes over a shorter time allowing cyclic or longer intermittent infusions.

Cyclic Feeding

Cyclic feeding most commonly is used for patients who need supplemental nutrition because of an inability to consume adequate oral nutrients, during transition to an oral diet, and for long-term home EN patients. Infusions are typically given at night over 8 to 12 hours to minimize interference with oral intake during the day and normal activities such as work or school, although cycles can be as long as 20 hours. Formula volume and osmolality can limit tolerance to cyclic feedings, especially jejunal feedings, and transition from continuous to

cyclic infusion may require several days to weeks depending on the cycle length and patient tolerance.

Intermittent or Bolus Feedings

The stomach's reservoir capacity allows administration of relatively large-volumes on an *intermittent* or *bolus schedule*. This is more physiologic than continuous feeding and more convenient for patients in nursing facilities and ambulatory patients at home on EN. Patients are typically started on continuous infusion feedings, then transitioned to intermittent infusions, and eventually to the shorter administration time of bolus feedings. Patients may need feedings over at least 15 minutes to avoid bloating, cramping, nausea, and diarrhea. A rate of <60 mL/minute is suggested to minimize symptoms of GI intolerance with bolus feedings.^{97,98} In small studies, healthy volunteers tolerated bolus feedings of up to 750 mL at 60 mL/minute, but intolerance developed at the next higher rate of 85 mL/minute.⁹⁷

Initiation of Feedings

The rate and strength, or concentration, of formula used for initiating EN primarily depends on the site of feeding and condition of the patient's GI tract. Diluted formula and a low infusion rate were standard "starter regimens" for intragastric tube feedings in the past and still are used in some institutions based on concern for GI intolerance during the first few days of feeding when full-strength formula or a large volume of formula is administered, because adaptation to osmolality and volume has not occurred. Controlled studies do not support this theory.⁹⁵⁻⁹⁹ Dilution delays delivery of adequate nutrients without significantly affecting the incidence of GI intolerance. Hypertonic formulas are diluted rapidly in the GI tract, reaching isotonicity before or shortly beyond the ligament of Treitz.⁹⁸ Rapid infusion of formula may, however, increase the incidence of nausea, cramping, and abdominal discomfort.

For intermittent feeding, rates of 200 to 300 mL over 20 to 60 minutes every 4 to 6 hours are generally tolerated; bolus feedings are better tolerated when the rate is <60 mL/minute.^{97,99} Volumes up to 750 mL every 4 to 6 hours may be tolerated.^{92,98} Although studies have demonstrated tolerance with initiation of feedings at goal rate, starting slower is appropriate for most patients. Various recommendations for continuous infusion intra-gastric feedings include starting at 50 mL/hour for 6 to 10 hours then advancing to the goal rate in 20 to 25 mL/hour increments every 6 to 8 hours; starting at 20 to 50 mL/hour and advancing by 20 to 25 mL every 4 to 6 hours; or starting at 10 to 40 mL/hour, advancing in increments of 10 to 20 mL/hour every 8 to 12 hours.^{92,95-98,100} For critically ill patients, those with abnormal GI function, patients without use of the GI tract for a prolonged time, those at risk of refeeding syndrome, and when calorically dense or high-osmolality formulas are used, the slower start and advancement may be preferable although it is not an "evidence-based" practice.^{92,97,101,102} Feedings into the small bowel are initiated at 10 to 40 mL/hour, with rate increases of 10 to 25 mL/hour every 8 to 12 hours until goal rate is reached.^{77,96,97} Isotonic formulas can start at 30 to 40 mL/hour; hypertonic formulas may require a slower rate. A general rule for EN is to change one parameter at a time; thus,

the formula and rate or concentration should not be changed concurrently.

MONITORING ENTERAL FEEDING

Appropriate monitoring of patients receiving EN via tube is essential to recognize and prevent complications. Complications can be divided into three groups: mechanical, GI, and metabolic (Table 36-6).

Mechanical Complications

Mechanical complications often can be avoided with good nursing technique and careful observation of feeding tolerance. Frequent assessment of tube placement by auscultation, location of markings on the tube, and withdrawal of gastric contents is important to prevent pulmonary aspiration of the formula. Tube placement should be evaluated every 4 to 6 hours with continuous feeding, or before each intermittent or bolus feeding.^{97,99,103,104} Withdrawal of gastric contents through the feeding tube using a syringe allows both confirmation of tube placement and evaluation of volume in the stomach (gastric residual volume [GRV]).

Gastric residual volume varies based on the volume and timing of previous feeds, especially for intermittent or bolus feeds, feeding tube characteristics, and patient position and activity.^{97,99} Gastrostomy tubes may yield less volume than NG tubes because of their more anterior position in the stomach. Soft, small-bore feeding tubes may collapse when GRV is checked, preventing accurate measurement. GRV is not usually checked through tubes placed in the postpyloric region because of (a) problems with tube collapse and (b) the small bowel does not serve as a reservoir for residuals. If the patient has an NG tube in addition to a small bowel feeding tube, GRV can be checked through the NG tube to assess whether the formula is “backing-up” or refluxing into the stomach. Previously, methylene blue or blue food coloring was added to the formula to evaluate reflux; however, reports of mortality associated with this practice have resulted in its abandonment.^{18,105–107} The use of glucose oxidase test strips to detect the presence of enteral formula in tracheobronchial secretions lacks sensitivity and specificity, and the results have not been shown to correlate with aspiration.^{92,97}

Promotility agents (e.g., metoclopramide, erythromycin) should be considered in the systematic management of a high GRV.^{18,32,108,109} These agents may improve feeding tolerance and formula delivery and the risk of aspiration may be decreased. Postpyloric tube placement generally is recommended when the GRV is persistently high or for patients who have experienced aspiration. Elevating the head of the bed to 30 to 45 degrees, with 45 degrees preferred in critically ill patients, during and after feedings also is recommended to reduce the risk of aspiration.^{32,104}

Gastrointestinal Complications

Gastrointestinal complications are frequently associated with tube feeding. Diarrhea occurs in 2% to 70% of patients, depending on the definition used, and is one of the most difficult problems for nurses, patients, and caregivers to address.^{97–99,110} Predisposing illnesses, including diabetes

mellitus, GI infections, pancreatic insufficiency, and malabsorption syndromes, are more likely to cause diarrhea in patients receiving EN than the formula itself.^{77,92,97,111} Formula-related GI infections occur owing to contamination of an opened can or package. Sources of contamination include the water used for reconstitution or dilution, transfer to the delivery bag, formula kept in the delivery bag for a prolonged period, and poorly cleaned feeding bags or administration sets. Closed enteral feeding systems using ready-to-hang bags of formula decrease contamination by reducing manipulation of the bag and formula. Concurrent drug therapy is another major contributor to diarrhea in tube-fed patients, potentially accounting for 61% of diarrhea cases.⁹⁷

Metabolic Complications

Metabolic complications of EN include hyperglycemia, electrolyte abnormalities, and fluid imbalance. Although rigorous evaluation of monitoring frequency is lacking, regular biochemical determinations similar to those used for PN are recommended to identify metabolic abnormalities and to correct before severe abnormalities occur. Baseline values for serum glucose, creatinine, BUN, and electrolytes should be available to guide selection of the enteral formula. Fingerstick glucose measurements every 6 hours or an insulin protocol are recommended before EN starts in diabetic or hyperglycemic patients or if hyperglycemia is anticipated. After EN is initiated, serum glucose, sodium (Na), potassium (K), chloride (Cl), and bicarbonate should be determined daily until they are stable in hospitalized patients, usually 4 to 5 days. Monitoring frequency is decreased to once or twice weekly when results are stable, but typically continue daily or every other day in critically ill patients. Patients discharged to home or a nursing facility before reaching their tube feeding goal should have serum glucose and electrolytes determined two to three times during the first week of therapy, then weekly for 2 to 3 weeks in stable patients after the EN is at goal rate. Serum creatinine (SrCr) and BUN are determined daily for a few days in critically ill patients, then by the same schedule as electrolytes. These laboratory values may be needed only two to three times in the first week, then weekly in relatively stable hospitalized patients.

Monitoring schedules for SrCr, BUN, calcium, phosphorus, and magnesium for patients in a nursing facility or at home are the same as for electrolytes. For hospitalized patients, calcium, phosphorus, and magnesium are determined two to three times during the first week, then once weekly if the patient is stable. Nutrition monitoring also is recommended, including serum albumin and prealbumin or transferrin weekly while the patient is hospitalized. For patients receiving long-term EN, the frequency of laboratory monitoring gradually is decreased. Laboratory monitoring should be done once or twice yearly in stable patients without significant medical problems. Patients who have medical problems that can affect nutrient, electrolyte, or trace element requirements or tolerances should be monitored as appropriate to the medical condition.

Weight and fluid status are important parameters to monitor throughout EN therapy. For hospitalized patients, weight is primarily a reflection of fluid status, whereas in long-term patients it is an important parameter for adequacy of caloric intake. Consistent increases or decreases from the required

Table 36-6 Complications of Tube Feeding

| <i>Complication</i> | <i>Cause/Contributing Factor</i> | <i>Treatment/Prevention</i> |
|--|---|---|
| Mechanical Complications | | |
| Aspiration | Deflated tracheostomy cuff | Inflate tracheostomy cuff before feeding; keep inflated 1 hr after feeding; consider small-bore feeding tube placed past the ligament of Treitz |
| | Displaced feeding tube | Reinsert tube, check placement; consider hand restraints or feeding tube bridle |
| | Reduced gastric emptying | Check residuals every 4–6 hrs for gastric tube; raise head of bed 30–45 degrees; use lower fat formula; use prokinetic medication; use small bowel feeding tube |
| | Lack of gag reflex; coma | Place feeding tube into jejunum; keep head of bed elevated to 45 degrees; provide continuous feeding |
| Nasal or pharyngeal irritation or necrosis; esophageal erosion; otitis media | Large-bore, polyvinyl chloride tube for long periods of time | Reposition tube daily, change tape; use smaller-bore tube; position tube to avoid pressure on tissues; moisten mouth and nose several times daily |
| Tube obstruction | Poorly crushed medications | Crush medications thoroughly, dissolve in water; use liquid medications whenever possible; check compatibility of medication with tube and formula |
| | Inadequate flushing after medications or thick formula | Flush tube with 50–150 mL water after medications or thick formula and every 4–6 hr with 20 mL minimum |
| | Poorly dissolved or mixed formula | Use blender to mix powdered formula (check manufacturer's mixing guidelines); use ready-to-use formula |
| | Formula mixed with low pH substance | Avoid checking gastric residuals when safe to do so; use larger-diameter tubes when checking residuals; avoid administering acidic medications through small-diameter tubes; consider a nonacidic therapeutic alternative; flush with a minimum of 30 mL water before and immediately after medication administration |
| Metabolic Complications | | |
| Hyperglycemia, glycosuria (can lead to dehydration, coma, or death) | Stress response; diabetes mellitus | Monitor fingerstick glucose every 6 hr, use sliding scale insulin plus appropriate routine insulin (e.g., insulin drip in critically ill) |
| | High-carbohydrate formula Drug therapy (steroids) | Change formula Monitor intake and output accurately |
| Excess CO ₂ production (high RQ) | High percentage of carbohydrate calories or excess calories from any source | Reduce total calories to avoid overfeeding; consider formula with higher fat calories |
| Hyponatremia | Dilutional (fluid excess, SIADH); inadequate sodium intake; excess GI losses | Use full-strength formula or change to 1.5–2 kcal/mL formula; add salt to tube feeding (1 tsp = 2 g Na = 90 mEq); use diuretics if appropriate; replace GI losses |
| Hypernatremia | Inadequate free water intake | Use 1 kcal/mL formula; monitor intake and output accurately; temperature and weight daily; increase flush volume |
| | Excess water losses (diabetes insipidus; osmotic diuresis from hyperglycemia; fever) | Correct hyperglycemia and the cause of fever or diabetes insipidus |
| Hypokalemia | Medications (diuretics, antipseudomonal penicillins, amphotericin B) | Monitor serum potassium; give PO or IV potassium replacement PRN |
| | Intracellular or extracellular shifts (insulin therapy, acidosis) | Correct underlying problem |
| | Excess GI losses (NG suction, small bowel fistula, diarrhea) | Routinely provide potassium in replacement fluid |
| Hyperkalemia | Potassium-sparing medications (triamterene, amiloride, spironolactone, ACE inhibitors); potassium-containing medications (penicillin G potassium) | Monitor serum potassium; change to medications without potassium-sparing effect or without potassium salts |
| | Renal failure | Monitor renal function; change to formula with lower potassium content |
| Hypercoagulability | Warfarin antagonism due to formula | Use lower vitamin K formula; hold formula 1–2 hr before and after warfarin dose; monitor coagulation status |

ACE, angiotensin-converting enzyme; GI, gastrointestinal; ICU, intensive care unit; IV, intravenous; NG, nasogastric; PO, oral; PRN, as needed/ RQ, respiratory quotient; SIADH, syndrome of inappropriate antidiuretic hormone secretion.

enteral formula volume can have significant effects on weight. For example, a weight loss of 12.5 pounds over a year can be expected if the daily intake of a 1-kcal/mL formula is 120 mL less than required.

Fluid status must be monitored closely with EN therapy, especially in patients with unusual losses, an inability to recognize thirst, or voluntarily adjust their oral fluid intake. Enteral formula contains solutes, as well as water. Only free water in the formula contributes toward meeting fluid requirements. Standard caloric density formulas are approximately 80% to 85% free water and 65% to 80% is typical for calorically dense formulas. Manufacturers generally list the free water content of formulas in product labeling.

Water used to irrigate, or flush, the feeding tube can contribute a significant volume of fluid daily. Protocols for flushing feeding tubes have not been well studied, but it generally is agreed that the tube should be flushed before and after each intermittent administration of formula or medication and after each GRV evaluation. Tube patency is maintained by flushing the tube every 4 to 6 hours for continuous feedings.^{97,99,103,104} Each flush is generally 20 to 60 mL of water. For patients with signs of fluid overload, a flush volume of 20 to 30 mL can be used and the number of flushes should be kept to a minimum. Patients requiring more daily fluid may benefit from increased flush volume, number of flushes, or both.

MEDICATIONS AND ENTERAL NUTRITION BY TUBE

Patients receiving EN often receive medications through the same tube. Feeding tube occlusion, adverse effects caused by changes in pharmaceutical dosage forms, and alteration of medication pharmacokinetics and pharmacodynamics are among the potential problems. Interactions related to pharmacologic or physiologic effects of medications or enteral nutrients also may occur. For this reason, oral medication administration should be considered unless a strict “nothing by mouth” status is required.

The incidence of feeding tube occlusion is 1.6% to 66%.^{7,103,112} Pump malfunction, lack of periodic tube flushing, formula characteristics, and tube characteristics are non-medication-related factors affecting tube occlusion. Important tube characteristics include the inner diameter (bore size), tube material, and the arrangement and number of delivery holes (ports) at the distal end. The most important formula characteristic appears to be the protein source. *In vitro* studies suggest formulas with intact protein, particularly caseinates or soy, coagulate and clump when exposed to an acidic pH, whereas formulas with hydrolyzed protein do not.^{31,113}

Medication-related factors influencing feeding tube occlusion include the administration method, dosage form, pH, and viscosity. Medications admixed with formula have the greatest potential for occluding tubes owing to alteration of the texture, viscosity, or physical form of the medication or formula. Therefore, medications rarely should be admixed directly with formula. Stopping the enteral formula infusion, flushing the tube with a minimum of 10 to 20 mL water before and after medication administration and a minimum of 5 mL between each medication, limit the contact between medications and formula within the tube lumen and decrease the risk of occlusion.^{97,104,113}

Restoring Feeding Tube Patency

When a feeding tube occludes, it must be replaced unless patency can be restored. Frequent tube replacement disrupts nutrient delivery and increases patient discomfort as well as the cost of care.

The initial treatment for tube occlusion is to flush the tube with warm water using a large syringe, at least 20 mL but preferably 50 mL, to avoid generation of excessive pressure that could rupture the tube. When a specific cause for occlusion can be identified (e.g., a specific medication) and physiochemical characteristics of the responsible product are known (e.g., solubility, pH), it may be possible to select a more appropriate flush preparation than water. In most cases, however, use of an acidic or basic flush preparation could worsen the occlusion. Acidic liquids (e.g., cranberry juice, diet soda, regular soda) may perpetuate or extend the occlusion, especially when coagulated proteins are the cause.^{36,103,113,114} When water fails to restore patency, activated pancreatic enzymes prepared with one crushed Viokase tablet and one sodium bicarbonate tablet (324 mg) dissolved in 5 mL of warm water just before instillation may be useful.^{97,113} Alternatively, a commercial product containing multiple enzymes, buffers, and antibacterial agents in a powder form (Clog Zapper, Corpak Medical Systems, Wheeling, IL) can be used.

Medication Selection

Solid dosage forms are the greatest challenge to administer by feeding tube. Whenever possible, liquid dosage forms should be selected, but these are not without problems. Liquids, especially those with a high viscosity, should be diluted before administration to avoid coating the tube interior. Pharmaceutical syrups with a pH of 4 or less must be used with caution because immediate clumping and tackiness of formulas mixed with the syrups have been reported.^{113,114}

For medications not available in liquid form, a therapeutically equivalent medication in a liquid form can be considered. Extemporaneous preparation of a liquid also may be considered but can increase cost significantly. Simple compressed tablets can be crushed, then dissolved or suspended in 10 to 30 mL of water before administration through the tube. Medications in a soft gelatin capsule are best delivered by dissolving the capsule in warm water. Undissolved gelatin should not be administered, because this may occlude the tube. Powder in hard gelatin capsules can be poured into water and mixed thoroughly before administration. Failure to dissolve any of these dosage forms thoroughly in water before administration through the tube can result in occlusion. Omeprazole, potassium chloride, phenytoin, multivitamins, lansoprazole, protein supplements, sucralose, pentoxifylline, zinc salts, calcium salts, and iron salts were identified by nurses as the products most frequently contributing to feeding tube occlusion.^{110,112}

Crushing a medication and mixing the powder in water results in an altered pharmaceutical dosage form, and this may affect its efficacy or patient tolerance. The safety and efficacy of simple compressed tablets are not affected by crushing and dissolving in water immediately before use. Crushing a sustained release product, however, destroys slow release mechanisms, resulting in the immediate release of several hours worth of the medication at one time. An exaggerated therapeutic response may be seen initially, followed by a loss of response part way through the dosing interval. Therefore, sustained-release or

long-acting dosage forms should not be crushed.¹¹⁵ Instead, an immediate-release dosage form can be used with appropriate adjustment of dose and dosing interval, or an alternate administration routes (e.g., morphine suppositories rather than slow-release tablets).

Enteric-coated tablets are designed to release medication in the small bowel because the medication is either acid labile or irritates the stomach. Protection for the medication or stomach is lost when enteric-coated tablets are crushed and delivered via feeding tube into the stomach, resulting in decreased efficacy of the medication or increased gastric irritation. When an irritating medication must be given by tube into the stomach, diluting the medication in at least 60 mL of water is recommended.¹¹³ Administering buccal or sublingual dosage forms via feeding tube may result in altered absorption or destruction of the medication by stomach acid. Therefore, therapeutically equivalent medications (e.g., isosorbide dinitrate rather than sublingual nitroglycerin) or an alternate route of administration (e.g., nitroglycerin ointment or transdermal system rather than sublingual nitroglycerin) should be used.

Pharmacokinetic parameters can be altered when medications are administered by feeding tube. The medication delivery site can affect bioavailability, although few studies address this issue. Medications taken orally are delivered to the stomach, where dissolution occurs for most dosage forms and hydrolysis of some medications may occur. Delivery into the small bowel may alter these processes, thereby affecting bioavailability. For instance, recovery of digoxin from intrajejunal dosing is higher than with oral administration, primarily because of reduced intragastric hydrolysis.^{31,113} Bioavailability of medications also can be affected by the presence of enteral formula in the GI tract. Medications affected by the presence of food are expected to be affected in a similar manner by the presence of formula. For example, administration of tetracycline with formula present is expected to reduce tetracycline bioavailability because of interactions with divalent cations. A similar interaction is expected between ciprofloxacin and enteral formula, although some evidence suggests a mechanism other than binding with divalent cations is responsible for reduced ciprofloxacin concentrations with enteral feeding.³¹

Phenytoin is particularly troublesome to manage in patients receiving EN, with reduced phenytoin concentrations reported in numerous case reports and small studies. Methods suggested for management include using a meat-based formula, administering phenytoin capsules rather than the suspension, and stopping formula delivery for 1 to 2 hours before and after the phenytoin dose.^{113,116} Holding formula administration before and after phenytoin dosing is usually recommended. None of these methods, however, clearly prevents low phenytoin concentrations; thus, monitoring of serum concentrations is important whenever EN is started or altered. Large-scale, controlled trials are needed to determine the most appropriate method for managing the phenytoin–EN interaction.

Reversal of warfarin anticoagulation by the vitamin K included in enteral formulas is an important pharmacologic interaction.³¹ The vitamin K content of most enteral formulas today is unlikely to interfere with anticoagulation, but should be evaluated if adequate anticoagulation is difficult to achieve. In addition, binding of warfarin to a component of enteral formulas, likely protein, has been proposed to explain warfarin

resistance with formulas containing low vitamin K content.³¹ Stopping formula administration for an hour before and after warfarin administration appears to prevent this type of interaction.

Diarrhea is a potential problem related to physiologic effects of hypertonic medications. Diluting hypertonic medications (e.g., potassium chloride) with 30 to 60 mL of water before administration is suggested. Dividing the medication dose and separating doses by about 2 hours also decrease GI effects of hypertonic medications. In addition, selection of brands and dosage forms with minimal sorbitol can reduce the risk of diarrhea. Cumulative sorbitol doses >5 g can cause bloating and flatulence, whereas larger doses may act as a cathartic.¹¹³

PATIENT ASSESSMENT

Evaluation of Nutrition Status

1. J.K., an 81-year-old man, was hospitalized 6 days ago after collapsing at the golf course. Physical examination on admission revealed left-sided paralysis and overall muscle weakness. He was confused and disoriented, and his mucous membranes were dry. J.K. was diagnosed with mild dehydration and was thought to have had a cerebrovascular accident (CVA). His condition has changed little since admission. J.K. is estimated to be 5 ft 9 in tall; his admission weight by bed scale was 132 lb (60 kg). His maintenance IV is 5% dextrose/0.45% sodium chloride with KCl 20 mEq/L at 100 mL/hour. Laboratory evaluation today shows a serum albumin of 3.1 g/dL, down from 3.8 on admission. Other biochemical data are within normal limits: glucose, 89 mg/dL (normal, 70–110); creatinine, 0.8 mg/dL (normal, 0.6–1.2); Na, 140 mEq/L (normal, 135–145); K, 4.4 mEq/L (normal, 3.5–5.5); and Cl, 104 mEq/L (normal, 95–105). Assess J.K.'s nutrition status. Identify factors placing him nutritionally at risk. Is nutrition support indicated at this time?

J.K. has mild malnutrition based on his weight for height and serum albumin concentration. Low serum albumin in the elderly is a risk factor for malnutrition, sarcopenia, and mortality.^{117,118} He is at risk for developing more severe malnutrition during hospitalization, and possibly death. Serum albumin at the time of admission was falsely elevated because of dehydration; therefore, today's albumin should be used to evaluate his visceral protein status. Mild visceral protein depletion may have resulted from metabolic stress associated with his CVA. Weight loss to 85% of ideal body weight (IBW, 70.7 kg) most likely is owing to chronic deficiency in total energy intake but may also be associated with significant loss of lean mass, especially in older men.¹¹⁹

At 85% of IBW, J.K. should appear underweight. If not, the estimated height may be wrong. The weight of 60 kg was obtained at admission and is expected to be falsely low (by a few kilograms at most) because of J.K.'s dehydration. Records of clinic visits and hospitalizations may provide information on chronic or recent illnesses that may be contributing to his weight loss.

Socioeconomic factors contributing to nutrition risk also should be considered.¹²⁰ Low income is associated with food insecurity and inadequate nutrition. Social conditions also may influence nutrition. A nursing note states, per his friend, that

they were playing golf like they usually do two to three times weekly since J.K.'s wife died a few months ago. He says J.K. spends too much time alone staring out his window at the golf course rather than getting out to play. This indicates J.K. lives alone but also suggests he is probably not low income.

J.K. most likely has been without oral intake since admission because he is unable to feed himself; he is expected to have difficulty chewing and swallowing as a result of the CVA. The low amount of dextrose in his maintenance IV is inadequate to minimize protein breakdown for gluconeogenesis. Patients with inadequate intake for 5 to 7 days or those who are not expected to have adequate intake for 5 to 7 days are considered candidates for specialized nutrition support.¹ Malnourished patients should be considered for nutrition support sooner. Because J.K. has mild malnutrition and is not likely to take adequate nutrients by mouth within the next few days, specialized nutrition support is indicated.

Estimation of Nutrition Requirements

2. What are J.K.'s requirements for calories, protein, and fluid? Does he have any special nutrient requirements?

Because J.K. is below IBW for height, his actual weight should be used to estimate energy and protein requirements. It would be best to use a weight after J.K. was rehydrated. His chart indicates a weight of 62 kg the past 3 days, which will be used for calculations. Use of IBW to estimate requirements for malnourished patients may result in fluid and electrolyte imbalance. Once the patient is stabilized on nutrition support, calories can be increased, if necessary, to achieve weight gain.

J.K.'s level of metabolic stress is relatively low. He has no surgical wounds, no fractures or skeletal trauma, no burns, and no major infections. Therefore, caloric requirements are only slightly higher than basal needs. Although the term *calorie* is used interchangeably with kilocalorie (kcal) in nutrition literature, the large "Calorie" or kilocalorie technically is correct and energy requirements generally are listed as kcal/day or kcal/kg body weight when specific numbers are given for a patient. Requirements can be estimated using predictive equations such as Harris-Benedict or one of the many other equations.^{2,36} Indirect calorimetry (metabolic cart measurements) is an expensive procedure and probably is unnecessary in a mildly stressed patient. Metabolic cart measurements determine energy (or "metabolic") requirements from oxygen consumption and carbon dioxide production. They account for individual variations in energy expenditure not adequately accounted for by predictive equations or by the kcal/kg method of determining energy requirements, especially in highly complex patients. An estimation of 20 to 25 kcal/kg actual weight also can be used based on J.K.'s low level of metabolic stress but higher caloric intake may be needed for weight gain after he is stable. Protein requirements for healthy elderly people are estimated to be 1 g/kg/day, which is slightly higher than the DRI of 0.8 g/kg/day.¹²⁰

Mild visceral protein depletion and metabolic stress are expected to increase J.K.'s protein needs to at least 1 to 1.2 g/kg actual weight per day. Renal function appears adequate for J.K. to tolerate up to 1.2 g/kg/day without developing azotemia. SrCr, however, may provide a poor estimate of renal func-

tion in underweight patients owing to below-normal muscle mass. Daily fluid requirements for geriatric patients can be estimated at 30 to 35 mL/kg, with a minimum of 1,500 mL daily, plus replacement of excess losses from hyperthermia, vomiting, or diarrhea.^{1,120} Baseline requirements of 1,500 mL for the first 20 kg plus 20 mL per each additional kilogram of body weight also can be used to estimate fluid requirements. Based on caloric intake, fluid requirements can be estimated as 1 mL/kcal ingested.¹ J.K. does not appear to have any excess fluid losses at this time; therefore, calculation of baseline fluid requirements should provide adequate fluids.

J.K.'s estimated daily requirements are approximately 1,240 to 1,550 total calories, 62 to 74 g protein, and 1,860 to 2,168 mL of fluid. These are estimated requirements that should be adjusted based on frequent reassessment of J.K.'s response to therapy and changes in his clinical situation. Additional calories and protein may be needed for repletion of weight and protein status.

J.K.'s apparently suboptimal nutrition before hospitalization increases his risk for vitamin deficiencies. Vitamins of particular concern are antioxidants (i.e., vitamin C and beta carotene) and those that influence plasma concentrations of homocysteine (i.e., vitamin B₁₂, folic acid, and pyridoxine). Vitamins A and D also are of concern since free-living, generally healthy elderly have deficient intake of these vitamins.¹²⁰ No medical, medication, or dietary histories are available to determine nutritional risks associated with specific conditions. Factors that predispose patients to vitamin deficiencies include weight loss of >5% of usual body weight in 1 month or >10% of usual body weight in 6 months, prolonged periods of dietary restriction, high levels of physiologic stress as occurs with trauma and large areas of burn, significant alterations in biochemical tests such as serum glucose and albumin, abnormal or protracted body fluid losses, administration of medications that alter vitamin absorption or metabolism, and diagnoses associated with alteration in vitamin absorption or requirements. J.K.'s age, along with his acute illness and mild mixed protein-calorie malnutrition, increase his risk of vitamin deficiencies, and it is likely that he has at least some subclinical deficiencies. J.K. should receive 100% up to 200% of the DRI for vitamins and minerals daily. A daily multivitamin preparation providing 100% of the DRI should be considered in addition to an oral diet or EN. If actual deficiencies are identified, J.K. will require higher, therapeutic doses of the specific vitamins that are deficient.

Enteral Nutrition Route

3. The health care team decides to initiate specialized nutrition support via tube feeding. What route for tube feeding is most appropriate for J.K.?

It is likely J.K. has problems with chewing and swallowing, in addition to difficulty getting food to his mouth. Otherwise, J.K.'s GI tract is expected to be functional. Nothing indicates that J.K. has risks associated with aspiration. Some patients have a poor gag reflex after a CVA, but J.K. has no reported coughing or choking. The duration of tube feeding is uncertain because J.K. may improve with time. An NG tube is the least invasive feeding route at this time. Measures to prevent J.K. from pulling the feeding tube may be necessary.

Enteral Formula Selection

4. What type of enteral formula is most appropriate for J.K.?

J.K. has full digestive capability; therefore, a polymeric formula is most appropriate. Standard caloric density (1–1.2 kcal/mL) should be used because J.K. has no fluid restriction and no evidence of fluid overload. A high-nitrogen formula will provide protein at the upper end of the estimated requirement (1.2 g/kg/day), whereas a standard nitrogen formula will provide between 0.8 and 1 g/kg/day. A high-nitrogen formula may replete J.K.'s visceral protein status sooner but it may not provide adequate calories for weight gain. The decision to use a high- versus standard-nitrogen formula depends on the exact nutrient composition of available formulas.

Fiber can be included in the formula if desired. The benefits of fiber for short-term feeding are not clearly defined, so a fiber-free formula is an equally appropriate selection at this time. If a fiber-containing formula is selected initially, the formula should contain a low to moderate fiber content or be started at a low rate and advanced slowly to minimize gas and abdominal distention.

Fluid Provision

5. How much fluid is necessary to meet J.K.'s estimated daily fluid requirements?

The free water content of EN must be calculated to determine the volume of additional fluid that must be provided to J.K. Formulas with 1 to 1.2 kcal/mL generally contain 80% to 85% free water. Assuming a goal volume of 1,440 mL/day (six cans) of a 1 kcal/mL, 0.044 g protein/mL formula, approximately 1,150 to 1,225 mL of free water is provided daily. Using 30 mL/kg/day as J.K.'s fluid requirement, he will need 1,860 mL daily. Therefore, the volume of fluid needed in addition to the enteral formula is 635 to 710 mL/day, which can be provided with medications and tube irrigation (flushes). The feeding tube should be irrigated with a minimum of 20 mL of fluid every 4 to 6 hours, as well as before and after administration of each medication through the tube.^{97,99,103,104} Using five flushes daily with 125 mL of water each will provide 625 mL of fluid.

Selection of a 2 kcal/mL, 0.075 g protein/mL formula for J.K. would require approximately 720 mL (three cans) of formula daily to meet his caloric and protein requirements. Formulas with 2 kcal/mL contain approximately 65% to 80% free water, meaning J.K. would receive about 470 to 575 mL of free water from the formula and still need an additional 1,285 to 1,390 mL of fluid daily. Large flushes of water would be necessary. Diluting the formula to half-strength is not recommended because this increases the risk of error and contamination. Thus, a 1 kcal/mL formula is more appropriate for J.K. than a 2 kcal/mL product.

Enteral Nutrition Administration

6. Recommend a plan for initiating and advancing J.K.'s tube feeding.

J.K. receives gastric feeds; therefore, continuous infusion, intermittent infusion, or bolus feedings can be used. Continu-

ous infusion most commonly is used for hospitalized patients despite no clearly established difference in tolerance compared with intermittent infusion.

Full-strength formula should be used to initiate feedings. J.K. is assumed to have full digestive capacity and is being fed into the stomach; therefore, diluting the formula is not expected to improve tolerance to either an isotonic or hypertonic formula. Dilution or starting the feedings at a very low rate also is likely to delay reaching J.K.'s nutrition goals. The standard of practice in most institutions for patients without GI disease who are not critically ill is to start continuous infusion polymeric feedings at 40 to 50 mL/hour and advance by 20 to 25 mL/hour every 4 to 8 hour, as tolerated, until the goal rate is achieved.

The goal volume of enteral nutrition for J.K. is 1,440 mL/day of a 1 kcal/mL formula, or 60 mL/hour continuous infusion. The infusion can be started at 40 mL/hour for 4 to 6 hours, then increased to 60 mL/hour. If J.K. experiences diarrhea, abdominal distention, or a large GRV, the feeding may be held at the initial rate for 24 hours, then increased only 10 to 15 mL/hour every 12 to 24 hour as tolerated. If the formula is not advanced to goal rate within 24 hours of initiating feedings, extra care must be taken to ensure he receives an adequate fluid intake.

Continuous infusion enteral feeding can be administered by gravity drip or by enteral pump. With gravity drip, the infusion rate must be adjusted frequently to maintain a consistent flow rate and the formula flow must be checked regularly to ensure that the flow has not stopped because of kinked administration tubing or an empty delivery container. Gravity infusion has no alarms to alert nurses to these problems. Enteral pumps provide a consistent flow rate and alarms to alert nurses if there are problems with the infusion, but they are more expensive than gravity drip. Pumps often are used for hospitalized patients to help maintain delivery of the prescribed volume of enteral formula. Either gravity drip or an enteral pump could be used for J.K., depending on the hospital's protocol for enteral feeding. To prevent inadvertent IV infusion of enteral formula when an enteral pump is used, the connector at the distal (patient) end of the delivery set should not be compatible with IV devices.⁸³

Monitoring Enteral Nutrition Support

7. Recommend a plan for monitoring J.K.'s response to enteral nutrition, including clinical and biochemical parameters.

Monitoring patients on enteral nutrition is necessary to prevent complications and to assess appropriateness of therapy. Clinical parameters to monitor include tube placement, GRV, GI symptoms, respiratory status, vital signs, and weight. Tube placement should be evaluated every 4 to 6 hours, by auscultation, location of markings on the tube, and GRV. A tube displaced into the esophagus or pharynx could result in pulmonary aspiration of the formula.

High GRV has been assumed to increase the risk of esophageal reflux and pulmonary aspiration. No consensus exists, however, on the frequency for GRV assessment or the volume at which feedings should be held. GRV is typically checked every 4 to 8 hours, although this practice has been questioned because it may contribute to feeding tube

occlusion.¹⁰³ The incidence of tube occlusion was reduced from 66% to 7.6% when one institution eliminated GRV evaluation in their EN protocol.⁷ Few data are available from prospective, randomized, controlled trials to define an appropriate GRV at which to hold EN, or even to demonstrate a correlation between GRV and gastroesophageal reflux or aspiration.^{18,98,104,108,111} Endogenous secretions from saliva and gastric fluids are about 4,500 mL/day in normal adults receiving food.⁹⁸ This represents about 185 mL/hour crossing the pyloric sphincter and food or formula increases the volume. Continuing EN with a GRV <500 mL has been recommended, along with careful bedside assessment and a systematic approach to managing a GRV of 200 to 500 mL.^{18,108} Other authors suggest acceptance of GRV up to 250 or 300 mL.^{32,98} Nonetheless, many institutions hold feedings if the GRV is >200 mL, which may compromise nutrient delivery. In general, a GRV of 200 to 500 mL should prompt clinical assessment of EN tolerance and feedings should continue unless volumes are persistently high, a trend of a rising GRV is evident, or other evidence of feeding intolerance is present. Setting the residual volume too low can result in inadequate nutrition because feedings are stopped frequently. Residuals should be checked every 4 to 8 hours as long as no residual is above the volume for holding feeding. If the feeding is held because of a high GRV, hourly evaluation of the GRV is recommended until the volume is <200 to 250 mL and the feeding is restarted. The fluid withdrawn for GRV assessment should be infused through the tube back into the stomach to avoid electrolyte imbalances.

Assessment of GI symptoms is important for determining EN tolerance. Abdominal distention and bloating should be evaluated at least every 8 hours while J.K. is hospitalized. Small-bore feeding tubes may collapse during withdrawal of the gastric residual, resulting in a falsely low residual volume. Abdominal distention may be an indication of accumulating formula. Gas formation secondary to lactose intolerance or rapid increases in fiber intake, and poor gastric emptying secondary to a high-fat formula, medications, recent surgery, critical illness, or an underlying disease such as diabetes are among the conditions associated with distention. When considerable distention is present, the formula should be held temporarily, and the patient evaluated further to rule out a contraindication to EN. Gastric outlet obstruction, complete or partial small bowel obstruction, or severe ileus preclude restarting EN until the condition resolves. If no contraindication to EN is found, feeding can be restarted, preferably with the feeding tube placed into the small bowel, a formula with lower fat or fiber content, or medications to promote gastric emptying (e.g., metoclopramide or erythromycin). Feeding should be restarted at a rate of 25 to 40 mL/hour, and J.K. should be observed closely for signs of feeding intolerance. The head of the bed should be elevated 30 to 45 degrees during feeding.^{32,104}

Nausea, vomiting, abdominal cramping, diarrhea, and constipation are other GI symptoms monitored as indicators of EN tolerance. Vomiting creates the most immediate concern because tube displacement and pulmonary aspiration can occur. Nausea and vomiting commonly occur with a high GRV, severe gastric distention, poor gastric emptying during gastric feeding, GI tract obstruction, or poor GI motility. Lactose intolerance and bolus feeding into the jejunum can lead to diarrhea and abdominal cramping, as well as nausea and vomiting. Initi-

ation of EN with a hypertonic formula, a rapid rate of infusion or a large volume, and use of formula at refrigerator temperature are other factors often cited as causing GI symptoms. Although controlled studies have not supported these factors as significant contributors to GI intolerance, subjective evidence suggests they are important. Constipation is most likely to occur with long-term tube feeding in nonambulatory patients. Inadequate fluid intake and lack of fiber may be factors associated with constipation.

Respiratory status should be evaluated every 8 hours in hospitalized patients, to help recognize pulmonary aspiration and pulmonary edema. A stethoscope should be used for assessment at least two times per week, but simple observation of the patient's breathing pattern is adequate at other times unless altered respirations are noted. Coughing or respiratory distress may be indications of aspiration or other developing respiratory problems. Vital signs also may provide clues to aspiration or other problems, such as dehydration, fluid overload, or infection.

Weight and fluid input and output should be monitored daily in hospitalized patients. Day-to-day changes in weight reflect fluid status. Increasing weight for 3 or 4 consecutive days may be an indication fluid intake needs to be reduced, whereas decreasing weight may indicate a need for increased fluid. Generally, total fluid can be adjusted by the number of times the feeding tube is flushed daily and the volume of each flush. Caloric density of the formula can be changed when altering the number or volume of flushes is not adequate for fluid control. For patients with a stable fluid status, the week-to-week weight change can be used as an indicator of appropriate caloric intake. An upward trend in weight (e.g., ≥ 3 consecutive weeks with an increase) may indicate a need for fewer calories unless weight gain is a goal. A downward trend may indicate a need to increase caloric intake, unless weight loss is desired.

Regular monitoring of biochemical parameters is important for identifying metabolic abnormalities before they become critical problems. Serum glucose, sodium, potassium, chloride, and bicarbonate should be determined daily in J.K. for 4 to 5 days after feeding starts. Monitoring can then be decreased to once or twice weekly if J.K. has no evidence of tube feeding intolerance or metabolic abnormalities. Fingertstick glucose measurements should be ordered every 6 hours after tube feeding starts; then, based on the results, a decision can be made whether fingersticks are needed routinely. Because J.K. has a normal serum glucose (89 mg/dL) while receiving 5% dextrose in his IV fluid and is not highly stressed, hyperglycemia is not a major concern with EN.

During the first week of EN, SrCr, BUN, calcium, phosphorus, and magnesium should be monitored a minimum of three times. Daily monitoring of SrCr and BUN for a few days may even be considered in J.K. because of his recent dehydration. Daily phosphorus and magnesium also may be considered for a few days in J.K. because of his low body weight. Chronic malnutrition can lead to intracellular depletion of potassium, phosphorus, and magnesium, while serum concentrations are maintained. When specialized nutrition support begins, refeeding syndrome may develop as these electrolytes move from the extracellular space into the cells, causing a decrease in serum concentrations over the first few days of feeding.^{101,102} Failure to monitor the patient and replace electrolytes as necessary can

result in serious electrolyte abnormalities. If SrCr, BUN, phosphorus, and magnesium are stable after the first 4 or 5 days, the frequency of monitoring could be reduced to once or twice weekly.

Biochemical parameters used to assess response to protein provision should be monitored. For example, prealbumin (i.e., transthyretin) and transferrin are short-term indicators of visceral protein response to nutrition support and can be monitored every 3 to 4 days (transthyretin) or weekly (transferrin). Because of J.K.'s age, transferrin would not be an appropriate parameter to use, because transferrin levels are significantly reduced in the elderly as a result of increased tissue iron stores.¹²⁰ Albumin is a long-term indicator that requires 2 to 3 weeks to reflect a response to nutrition therapy; however, it may be included on a weekly monitoring schedule to allow adjustment of serum calcium for hypoalbuminemia. Nitrogen balance can be used as an alternative to prealbumin, but it requires an accurate 12- to 24-hour urine collection to be useful.

Electrolyte Abnormalities

8. J.K. has been receiving EN for 4 days. Feeding was started at 40 mL/hour for 8 hours, then increased to 60 mL/hour (goal rate). The IV fluids were stopped when the tube feeding reached the goal rate. Laboratory evaluation today shows the following: K, 2.9 mEq/L (decreased from 3.5 mEq/L yesterday, 3.9 mEq/L the previous day, and 4.6 mEq/L when tube feeding started); Cl, 95 mEq/L (normal, 95–105); calcium, 7.9 mg/dL (normal, 9–11); Mg, 2.4 mEq/L (normal, 2.5–3.5), decreased from 3.5 mEq/L 2 days ago; phosphorus, 3.5 mg/dL (normal, 3.5–4.5), decreased from 4.4 mg/dL 2 days ago; and albumin, 2.6 g/dL. Micro-K (8 mEq KCl/capsule) has been ordered as six capsules via feeding tube and calcium carbonate (260 mg elemental calcium/tablet) as two tablets twice daily (BID) via feeding tube. Is the electrolyte replacement appropriate as ordered? What changes, if any, should be considered?

Calcium carbonate, a simple compressed tablet, can be crushed, suspended in 10 to 30 mL of water, and administered through the feeding tube. Calcium salts, however, have been identified by nurses as among the products most frequently contributing to feeding tube occlusion.¹¹⁰ Risk of tube occlusion from an inadequately crushed tablet may be decreased by use of calcium carbonate suspension (500 mg Ca/5 mL), if available. Administration of either crushed and suspended tablets or commercial suspension requires flushing the tube with at least 10 to 20 mL of water before and after medication administration.^{97,104,113} Diluting the suspension 1:1 with water and flushing with 75 to 100 mL may be advisable because suspensions may otherwise coat the tube. The appropriateness of calcium supplementation should be questioned, however, because J.K.'s serum calcium concentration is within normal limits after correction for his low serum albumin concentration. Administering any medication via the feeding tube may occlude the tube. The oral route should be used for medications whenever appropriate. Many patients receiving EN are allowed some oral intake, and oral medications are frequently acceptable. J.K.'s risk for aspiration may be too high at this time to allow oral medications, however. Alternative dosage forms for electrolytes are limited to IV forms so the easiest

and most cost effective route is via feeding tube if J.K. cannot take oral medications.

Potassium is below normal today and has been decreasing since tube feeding began. Potassium supplementation should have been considered yesterday, rather than waiting until hypokalemia developed because a definite trend downward in serum potassium was evident. The selected potassium supplement is inappropriate for administration by tube because Micro-K is a slow-release product. Crushing slow-release products destroys the slow-release mechanism. Potassium chloride powder for solution (three packets with 15 mEq KCl/packet) or liquid (10% KCl 35 mL, 15% KCl 25 mL, or 20% KCl 15–20 mL) should be ordered rather than the slow-release product. Dividing the potassium dose into two or three smaller doses and diluting each dose with 60 mL of water is recommended. Giving 45 to 50 mEq of potassium as a single dose may cause nausea, vomiting, abdominal discomfort, or diarrhea. These symptoms might be mistaken as intolerance to EN, resulting in the tube feeding being stopped temporarily. The larger fluid volume for administration also may help reduce the gastric irritation associated with potassium doses.

Consideration also should be given to changes occurring in other electrolytes. J.K. appears to be developing mild refeeding syndrome.^{101,102} Magnesium and phosphorus are slightly below the normal range and have decreased significantly over the past 2 days. Supplements should be started today so that smaller daily quantities can be used before electrolytes are critically low. This may decrease the risk of diarrhea and GI upset caused by the administration of magnesium or phosphate. Magnesium supplementation could be accomplished with a magnesium oxide tablet (400 or 500 mg) administered two to four times daily. These are simple compressed tablets that can be crushed and suspended for administration via feeding tube. An alternative would be magnesium hydroxide suspension 5 mL two to four times daily. Magnesium doses are distributed through the day to avoid the cathartic action.

Phosphate supplementation could be accomplished by changing part of the potassium ordered to Neutra-Phos-K, which provides 8.1 mmol of phosphate and 14.2 mEq of potassium per 250 mg capsule. Contents of each capsule are designed to be dissolved in 75 mL of water for administration, so dissolution is not a concern. One Neutra-Phos-K twice a day plus KCl liquid to provide 20 mEq potassium is the same potassium dose as is ordered currently. The liquid KCl should be given at least 2 hours before or after the Neutra-Phos-K to minimize GI effects. The feeding tube must be flushed adequately before and after each dose of electrolyte replacement. The flush volume should be a minimum of 10 to 20 mL, although 75 to 100 mL following the magnesium dose may be better to ensure the electrolyte preparation is out of the tube. Intermittent tube flushes can be accomplished with medication administration to limit the total fluid intake to the estimated requirement of 1,860 to 2,168 mL, or 635 to 710 mL in addition to that provided by a 1 kcal/mL formula.

With the current electrolyte abnormalities, it is important to monitor potassium, magnesium, and phosphorus for the next several days. The extent of electrolyte depletion in the body is difficult to evaluate, but 1 day of electrolyte replacement is not expected to replete intracellular stores. It is difficult to provide large quantities of potassium, phosphate, and magnesium via feeding tube secondary to the GI intolerance they cause.

Therefore, IV electrolyte replacement may be necessary if intracellular depletion is extensive.

Transfer to a Nursing Facility

9. J.K. has received EN for 10 days. During this time he removed his feeding tube twice despite mittens to hinder his ability to grab the tube. Feedings were off for approximately 5 to 8 hours each time the tube was removed. J.K.'s electrolyte abnormalities have been corrected with 3 days of electrolyte replacement. He has tolerated his tube feeding without metabolic abnormalities or electrolyte replacement for the past 2 days. J.K. remains confused and disoriented. The prognosis for improvement in J.K.'s ability to feed himself is poor. Plans are made to discharge J.K. in 1 to 2 days to a nursing facility. What changes in the care plan would be appropriate relative to nutrition support goals?

J.K. should be evaluated for gastrostomy placement because he is expected to need EN for a prolonged period. Gastrostomy placement also should solve the problem of repeated tube displacement, although this alone is not an appropriate reason to place a gastrostomy. Placement of a percutaneous gastrostomy can be accomplished with local anesthesia, which may be advantageous given J.K.'s age and lack of another reason for general anesthesia. Percutaneous gastrostomy placement is less expensive and typically requires less time to perform than surgical gastrostomies, but the incidence of major complications remains essentially the same at up to 2.5%.^{4,9,12}

If fiber-free formula was selected initially, fiber-containing formula should be considered. Fiber may prevent GI tract changes associated with prolonged use of fiber-free formulas.²⁴ Constipation is frequently a problem in elderly and bedridden patients. Increased stool weight and frequency has been demonstrated in patients with constipation receiving fiber-containing formula versus fiber-free formula. Starting with a low to moderate fiber content may minimize gas and abdominal distention. To approach the recommended fiber intake of 30 g/day, however, a high-fiber formula is necessary.^{22,23} Fiber content can be gradually increased by providing half the daily formula volume as a fiber-free formula and half as a formula containing 15 g fiber/1,000 kcal for a few days, then changing completely to the fiber-containing formula. With 1,440 mL daily, the fiber provided will be slightly below recommended amounts; however, it would be reasonable to assess stooling pattern before adding another fiber source to J.K.'s regimen. Fiber can be problematic for tube occlusion.^{24,110} The fiber-free and fiber-containing formulas should not be mixed directly without prior in vitro observation of compatibility. Although the likelihood of incompatibility is low, mixing different formulas together could result in gelling or separation of formula components.

J.K. should transition to an intermittent schedule before discharge. Many nursing facilities do not routinely use enteral pumps because of increased cost. Without a pump, delivery of the prescribed volume of formula at a consistent rate may not be reliable. Transitioning from 60 mL/hour continuous infusion to intermittent delivery of formula can be accomplished by various methods. An overlapping regimen of gradually decreasing the continuous infusion rate and increasing the intermittent volume appears to be economic and efficient.⁹² For J.K., change the continuous rate to 40 mL/hour and add four intermittent

feedings of 120 mL over 60 minutes every 6 hours initially. If tolerated, decrease continuous infusion to 20 mL/hour and increase intermittent feeding to 240 mL. Finally, stop continuous feeding and increase intermittent feedings to 360 mL, or add a fifth feeding to keep the intermittent volume at 285 to 300 mL. Other methods stop the continuous feedings and progressively infuse larger intermittent volumes, starting with the equivalent volume of 2 to 4 hours of continuous infusion, over shorter time periods, starting with 2- to 3-hour infusions and ending with 20- to 60-minute infusions, with fewer daily infusions. Start with 180 mL over 2 hours for J.K., allowing an hour between each of eight feedings, then decrease infusion time to 60 minutes with 2 hours between feedings. If tolerated, the volume increases to 240 mL over 60 minutes every 4 hours, then to 360 mL every 6 hours. The time between feedings can be decreased further to allow feedings during typical meal hours and the infusion time for each feeding can be decreased down to 20 minutes, if tolerated. Ideally, the transition will be completed before he is discharged to the nursing facility.

The discharge EN prescription should state clearly the desired caloric density, protein content, fiber content per 1,000 kcal and formula volume, or the daily calories, protein, fiber, and fluid to be provided. The brand name may be included, but the nursing facility may not have the same brand of formula. Any special considerations for the feeding schedule also should be communicated (e.g., J.K. does not tolerate feeding after 9 PM; raise the head of the bed to 45 degrees for 3 hours after the last daily feeding to avoid regurgitation).

Twice-weekly monitoring of glucose, creatinine, and electrolytes should be recommended during the first week after discharge. Careful monitoring of fluid status and tolerance to the intermittent delivery schedule also is recommended. J.K. will have been on the new schedule for only a short time before discharge, so a full evaluation of tolerance to the new regimen will not have been completed.

Transfer to Home on Enteral Nutrition

10. J.K.'s overall status has improved during 3 weeks at the nursing facility, and he is now ready for discharge. J.K. has made no progress toward an oral diet; dysphagia and aspiration continue to be severe on "per swallow" studies. He is not to take solids or liquids by mouth at this time, and swallow studies are not to be repeated for 6 months. Intermittent tube feedings with a total of 1,680 mL (seven cans) daily of a 1 kcal/mL, 0.044 g protein/mL, 15 g fiber/1,000 kcal polymeric formula are to continue. His weight has increased 2 kg since hospital discharge. J.K. still needs assistance with some activities of daily living; thus, he will be staying with his sister. She is concerned about insurance coverage for the EN therapy and states J.K. has a Medicare Part D prescription plan. Will Medicare cover EN?

Strict guidelines exist for home EN coverage, Medicare Part B (not Part D) will cover 80% of the cost if criteria are met.¹²¹⁻¹²³ EN must be medically necessary to "maintain weight and strength commensurate with overall health status" and there must be a functional disability of the GI tract (e.g., dysphagia, swallowing disorder) that is expected to be "permanent."¹²⁴ The formula must be delivered by feeding tube (i.e., not oral supplements) and must provide most of the patient's nutritional requirements (i.e., not supplemental

Table 36-7 Medicare Categories for Enteral Formulas

| Category | Description | Examples (Partial Listing) |
|---------------------------|--|---|
| Category I | Semisynthetic intact protein or protein isolates | Ensure fiber w/FOS, Jevity 1 Cal, Monogen, Osmolite 1 Cal, Osmolite 1.2 Cal <i>Disease-specific formulas:</i> Glytrol |
| Category II | Intact protein or protein isolates; calorically dense | Ensure Plus, Ensure Plus HN, Jevity 1.5 Cal, Nutren 1.5, Nutren 2.0 |
| Category III ^a | Hydrolyzed protein or amino acids | Optimalen, Peptamen 1.5, Peptamen AF Documentation that <i>may</i> provide justification for use: dumping syndrome, uncontrolled diarrhea, evidence of malabsorption on appropriate semisynthetic formulas (e.g., isotonic, low long-chain fat content, lactose free) that resolves with an oligomeric formula or documentation of the disease process causing malabsorption |
| Category IV ^a | Defined formula for special metabolic need (i.e., disease-specific formulas) | Advera, Alitraq, Glucena, Glucerna Select, Modulen, NutriHep, NutriRenal, Peptamen, Peptamen VHP, Pulmocare, Renalcal, Replete Documentation that <i>may</i> provide justification for use: evidence of inability to meet nutritional goals with category I or II products without compromising patient safety and documentation of the specific diagnosis for which a formula is intended |
| Category V ^a | Modular components for protein, fat, and carbohydrate | <i>Protein:</i> Complete amino acid mix, Propac, Propass, Protifar <i>Carbohydrate:</i> Modulacal, Polycal, Polycose <i>Fat:</i> MCT oil Documentation that <i>may</i> provide justification for use: inability to meet specific nutrient requirements (i.e., protein, carbohydrate, or fat) with a commercially available formula |

^a Failure to provide adequate documentation of medical necessity for the specific formula will likely result in denial of claim or payment at the lower category I rate for Medicare Part B insurance coverage.
MCT, medium-chain triglyceride.

nutrition). Approval is on an individual basis, requires a physician's written order, and sufficient documentation must be available to support the need for EN. Calories above or below 20 to 35 kcal/kg/day require additional documentation and 90 days or more meets the test of permanence. J.K.'s therapy falls within these guidelines. In addition, the formula J.K. receives is in a category that does not require him to meet additional eligibility criteria related to the formula itself. Additional documentation would be needed to justify a pump if J.K. was receiving EN via pump.

Enteral formulas are divided into five categories for reimbursement purposes by Medicare Part B (Table 36-7). Formula manufacturers typically list the Medicare category on the product label. Medicare intermediaries may also list formula categories.¹²⁵ Most polymeric formulas containing intact (whole) protein and 1 to 1.2 kcal/mL are in category I. These products have the lowest reimbursement rate and do not require documentation of medical necessity for the specific formula itself but still require documentation of the need for EN. Clear documentation of medical need for formulas in specific categories (e.g., category III and IV) is required for their higher reimbursement rates. Appropriate forms available from the Centers for Medicare and Medicaid (CMS) must be completed for Medicare reimbursement of any EN therapy.¹²⁶

Evaluation of Nutrition Status

11. R.L., a 29-year-old woman, was admitted to the hospital 52 days ago following a motor vehicle crash. She sustained multiple rib fractures, pelvic fracture, cardiac contusion, and liver laceration. She required endotracheal intubation shortly after ad-

mission and a tracheostomy was placed 2 weeks later when prolonged intubation was expected owing to ARDS. She developed an enterocutaneous fistula about a month after admission and more recently a large perihepatic abscess was noted on a CT scan. During her hospitalization, R.L. has had several exploratory laparotomies and has been treated for multiple infections, including pneumonia, sepsis, and wound infection. She has been treated for *Clostridium difficile* diarrhea but has not had diarrhea since therapy was completed 3 weeks ago. Lysis of adhesions, closure of an enterocutaneous fistula, and placement of a feeding jejunostomy tube (J tube) were done during the last laparotomy 8 days ago.

After admission, EN was considered but ruled out based on high-dose inotropic support and abdominal distension. PN was started on hospital day 3. R.L.'s current PN regimen contains 250 g dextrose, 96 g amino acid, and 50 g fat, with a rate of 85 mL/hour. EN is to start today. R.L. is 5 ft tall and weighs 88 kg. Her weight before surgery 8 days ago was 79 kg and admission weight was 75 kg. The electronic medical record shows her weight at 64.4 kg in a clinic note 3 weeks prior to the accident. Laboratory evaluation today shows the following: Na, 133 mEq/L (normal, 135–145); Cl, 98 mEq/L (normal, 95–105); glucose, 128 mg/dL (normal, 70–110); BUN, 35 mg/dL (normal, 8–20); creatinine, 0.8 mg/dL (normal, 0.6–1.2); triglycerides, 145 mg/dL (normal, <160); C-reactive protein (CRP), 8 mg/dL (normal <0.8); albumin, 2.6 g/dL (normal, 4–6); and the prealbumin, 7 mg/dL (normal, 10–40). One week ago the CRP was 17 mg/dL and prealbumin was 15 mg/dL. A urine collection ending last night shows a volume of 2,500 mL/24-hour collection and a urine urea nitrogen (UUN) of 560 mg/dL. R.L. has been afebrile the past week, but remains on broad-spectrum antibiotics. Assess R.L.'s nutrition status and identify factors that place her at risk nutritionally.

R.L. is obviously at risk owing to her injuries, multiple surgeries, multiple complications, and duration of hospitalization. Currently, she appears to be malnourished based on low visceral protein concentrations. Her weight has increased because of fluid retention. Large urinary nitrogen losses indicate she is highly catabolic. This also is evident from the low serum prealbumin concentration despite a daily intake of 2.1 g protein/kg of IBW. Nutrition status should have been maintained with PN, but visceral protein status has declined during the past week.

R.L. has an increased risk of nutrient deficiencies because of her critical illness, long-term hospitalization, antibiotic therapy, highly catabolic condition, and complications, including a fistula.^{1,63,100,127–129} Vitamin and trace element supplementation in PN formulations generally is adequate, but highly catabolic, critically ill patients may have increased requirements for micronutrients with antioxidant properties, including vitamins C and E plus copper, selenium, zinc, and manganese.^{1,128} Niacin, thiamine, calcium, and vitamin D are other problematic micronutrients in the critically ill.^{128,129} Increased GI losses of zinc occur in patients with diarrhea and GI tract fistulas, both of which were problems for R.L. before the latest laparotomy. It is assumed excess losses of vitamins and trace elements have been managed appropriately in the PN formulation. Thus, R.L. should not have overt deficiencies. Measurement of most vitamin and trace element serum concentrations is difficult in the clinical setting in metabolically unstable patients, and interpretation of values may be equally difficult. Therefore, objective measures of marginal vitamin deficiencies rarely are available. Clinical impressions must be relied on. R.L. should receive 100% to 200% of the DRI for all vitamins and minerals.

Estimation of Nutrition Requirements

12. What are R.L.'s requirements for calories, protein, and fluid?

R.L.'s current weight is significantly above her IBW of 45.5 kg. Some of the "extra" weight most likely is water. The admission weight may not be reliable, because R.L. likely received fluid resuscitation before she was weighed. Her clinic weight is most reliable as an indicator of nutrition status. The appropriate weight, actual or adjusted, for energy calculations in obese patients remains controversial.^{130–132} R.L.'s clinic weight should be used as the "dosing" weight if no adjustment is done or to calculate an adjusted weight for dosing. Using an adjusted weight may reduce the risk of overfeeding. An adjustment of 40% of weight over IBW is based on aminoglycoside pharmacokinetics and is commonly used by pharmacists.¹³¹ Using this adjustment, the weight for calculations is 55 kg.

Calories and protein provided by the PN give an indication of R.L.'s requirements. A decline in CRP, especially <10 to 15 mg/dL, should result in a rise of 0.5 to 1 mg/dL/day in prealbumin.¹³³ Because prealbumin has declined despite a large protein intake and decreasing CRP, the nitrogen (N) balance should be calculated. (N balance = daily N intake from all sources minus N output that includes daily UUN and obligatory losses.) Intake of nitrogen is calculated from grams of protein (g protein/6.25 = g N). The UUN for nitrogen balance is based on total urine urea loss per 24 hours and must be

calculated as follows:

$$\frac{560 \text{ mg N}/100 \text{ mL urine} \times 2,500 \text{ mL urine}/24 \text{ hours}}{6.25} = 14,000 \text{ mg N/day} \quad 36-1$$

Obligatory losses generally are estimated as 2 to 4 g/day of nitrogen. Thus, the nitrogen balance for R.L. is calculated as follows:

$$\text{N balance} = \frac{96 \text{ g protein from PN}}{6.25} - (14 \text{ g N from UUN} + 3 \text{ g}) \quad 36-2$$

where N is nitrogen, PN is parenteral nutrition, and UUN is urine urea nitrogen.

R.L. is negative approximately 1.6 g N or 10 g of protein (1.6 g N × 6.25). In addition, because R.L. has wounds to heal, a positive nitrogen balance of approximately 3 to 5 g of nitrogen is desirable. Therefore, R.L. needs another 4.6 to 6.6 g N/day or 29 to 41 g protein/day more than the 96 g protein currently provided by PN. Optimal conditions for wound healing may actually require N balance results of 5 to 10 g positive when using insensible losses but not wound exudate.¹²⁷ In addition, urea accounts for only about 80% of total urine N (TUN).³⁴ Use of TUN is more reliable than UUN, when available, or an estimate of TUN can be made by adding 20% of UUN losses along with the 2 to 4 g obligatory losses. Thus, the calculated N balance for R.L. may underestimate her protein requirement. Maintaining positive nitrogen balance may not be feasible in such highly catabolic patients and some question if protein >1.5 g/kg/day promotes positive N balance or lean tissue accretion.¹²⁹ So long as R.L. does not demonstrate adverse effects, such as azotemia or hyperammonemia, from the high protein intake it is reasonable to aim for a positive N balance.

R.L. currently receives 1,734 kcal daily (31.5 kcal/kg/day); 1,350 as nonprotein calories (NPC). With R.L.'s highly catabolic state, maintaining the current NPC:N ratio of approximately 90:1 or down to 75:1 is advisable as long as R.L. can tolerate the extra protein. Estimating caloric requirements in patients such as R.L. is subject to greater error than in patients with low metabolic stress, but the most appropriate method to determine energy requirements is unclear.¹³⁴ Use of indirect calorimetry is considered the gold standard, although data were insufficient for the CCPG to recommend this method versus predictive equations in critically ill adults.³² In a study of patients in a surgical ICU, use of indirect calorimetry was no better than Harris-Benedict calculations multiplied by 1.5 or 30 kcal/kg adjusted body weight for determining energy requirements.¹³⁵ Other studies indicate unbiased and precise results in critically ill patients using adjusted body weight with Harris-Benedict equations multiplied by 1.2, or 1.6.^{136,137} Predictive equations, including Swinamer, Ireton-Jones, and Penn State, have also been developed for critically ill patients and produce varying results in different studies.^{36,134,136–138} It is reasonable to consider indirect calorimetry for R.L. If a metabolic cart is not available, the total caloric intake from the PN formulation plus calories from another 30 g of protein can be calculated as a guideline for R.L.'s caloric requirement:

$$1,734 \text{ kcal from PN} + (30 \text{ g of protein for positive balance} \times 4 \text{ kcal/g}) = 1,854 \text{ total kcal} \quad 36-3$$

Fluid requirements for younger patients (i.e., those <65 years) can be estimated at 35 to 40 mL/kg/day plus replacement of excess losses from hyperthermia, vomiting, diarrhea, fistulae, or wound drainage. Based on this method, R.L.'s fluid requirements are 1,925 to 2,200 mL/day. Estimated fluid needs also may be based on 1 mL/kcal ingested or on 1,500 mL plus 20 mL/kg over 20 kg.¹ R.L. should receive a minimum of 1 mL/kcal owing to her high-protein intake but she is likely to need at least 35 to 40 mL/kg/day.

Enteral Nutrition Therapy (Tube Feeding)

13. Enteral feeding is to start today via the J tube. What type of formula is most appropriate for R.L.?

R.L.'s hospitalization has been unusually long and complicated. She may have impaired absorptive function because of her prolonged period without GI tract stimulation. Some practice-based publications suggest consideration of an oligomeric formula for patients whose GI tract has not been used for >7 days.^{1,127,133} The CCPG recommend initiation of EN with a polymeric formula.³² Only four studies comparing oligomeric with polymeric formulas in critically ill patients were found for the CCPG, and none met the criteria for the highest level of study. Available data did not indicate a clinically important benefit for oligomeric formulas. Given the limited data and conflicting suggestions for formula selection, implementing the CCPG can be difficult.⁷⁸ Formula selection may instead be determined by physician preference and the calorie, protein, and fat content of formulas on the formulary. To obtain the necessary NPC:N ratio, a high or very high protein formula is needed, or a modular protein component must be added to the EN regimen.

One very high nitrogen polymeric formula and one oligomeric formula are available on formulary. The very high nitrogen formula has a caloric distribution of 25% protein (NPC:N = 75:1), 45% carbohydrate, and 30% fat with a 25:75 MCT:long-chain triglyceride ratio. This formula provides 1,000 kcal and 62.5 g protein/L. The hydrolyzed protein formula has a caloric distribution of 20% protein (NPC:N = 115:1), 65% carbohydrate, and 15% fat with a 50:50 MCT:long-chain triglyceride ratio. This formula provides 1,000 kcal and 50 g protein/L.

The oligomeric formula is selected based on current practice in the ICU. The osmolality is 460 mOsm/kg and the free water content is 830 mL/L (83%). The goal volume is 1,920 mL (80 mL/hour) to provide 1,920 kcal, 96 g protein, and 1,594 mL fluid. The remaining fluid requirement will be met by flushing the tube three to four times daily and by IV medications. The enteral formula provides slightly more calories than the estimated requirements (Eq. 36-3), but it is acceptable at 34.9 kcal/kg/day. The formula does not meet R.L.'s protein requirement based on nitrogen balance. At some point, the formula should be changed to a higher protein formula or 30 g of a modular protein component must be added. This is a significant amount of protein; thus, it would be preferable to transition R.L. to a very high nitrogen formula. The primary concern with the formulary product listed earlier will be whether R.L. can tolerate the more complex nutrients and higher fat content.

Additional Nutrients

14. Overall, R.L. appears to be improving despite the perihepatic abscess. She no longer requires inotropic support and ventilatory parameters have improved, although she continues to require mechanical ventilation. Should additional nutrients, such as those associated with immune modulation, be considered for R.L.?

Based on the CCPG, EN with fish oils, borage oils, and antioxidants should be considered for patients with ARDS, which R.L. was diagnosed with early in her hospitalization.³² Protein content of the pulmonary formula matching CCPG recommendations is 16.7% of calories (~42 g/1,000 kcal) and would require an exceptionally large dose of supplemental protein to meet R.L.'s requirement. This would increase the risk of tube occlusion, as well as the risk of inadequate protein provision. Soon after R.L.'s diagnosis of ARDS, the immune-modulating pulmonary formula might have received higher consideration but with her improving ventilatory status it is not warranted.

The CCPG does not recommend formulas supplemented with arginine and other selected nutrients for use in critically ill patients by owing to a potentially higher mortality rate associated with their use, especially in septic patients.^{32,48} Although R.L. does not appear septic at this time, no impetus exists to use an arginine-supplemented formula.

Glutamine should be considered based on the CCPG recommendation.³² One moderate quality study in trauma patients reported a significant reduction in infectious complications, leading CCPG to include consideration of enteral glutamine for trauma patients. It is questionable whether glutamine will provide any benefit to R.L. because she is improving overall; however, she does have a recently diagnosed intra-abdominal (perihepatic) abscess. No data indicate harm from enteral glutamine; therefore, it is reasonable to add 0.3 g/kg/day of glutamine to the EN regimen.⁶³ Glutamine powder, available in individual packets, is mixed with water and administered via the feeding tube.

Enteral Nutrition Administration

15. Recommend a plan for initiating and advancing R.L.'s tube feeding.

Enteral nutrition should be initiated slowly because R.L. has not used her GI tract for a prolonged period and may have both impaired absorption and digestion.^{92,97} Initiation at 10 to 40 mL/hour is typical in patients such as R.L., with rate increases of 10 to 25 mL/hour every 8 to 12 hours until the goal rate is reached.^{77,96,97} EN in R.L. is probably best started at 10 to 20 mL/hour for 8 to 12 hours and increased in 10- to 15-mL/hour increments every 8 to 12 hours until 80 mL/hour (goal rate) is reached, assuming tolerance with each step. An enteral infusion pump should be used to maintain consistent flow. Small-bore feeding tubes can occlude if the flow is disrupted and surgery may be required to replace the J tube if the tract has not matured adequately for nonsurgical tube replacement.

Protein in the PN formula may remain at the current level, or be increased to provide protein for a 3- to 5-g positive nitrogen balance because transition to EN is expected to be slow. The selected enteral formula is hypertonic; nonetheless, full-strength formula should be started and the formula diluted only if full strength formula causes abdominal distention, diarrhea,

or other signs of intolerance. A transition plan from the PN to EN must also be developed. Typically, the PN rate is gradually decreased as tolerance to EN is established. The sum of enteral and parenteral calories and protein should be monitored closely to avoid complications of overfeeding while ensuring adequate nutrition provision. For R.L., maintaining adequate protein intake is critical; thus, cumulative protein intake (i.e., protein from PN plus EN) should be kept at 125 g/day or higher.

Tube Feeding Intolerance

16. R.L. develops diarrhea approximately 18 hours after EN is increased to 80 mL/hour. The PN formulation is at 20 mL/hour. What is the likely cause of the diarrhea? Should the EN be stopped and the PN formulation increased to goal rate again?

Diarrhea affects 15% to 30% of patients in the ICU.¹²⁹ In patients receiving EN, diarrhea is multifactorial. Factors associated with diarrhea, but not related to EN, include medications, partial small bowel obstruction or fecal impaction, bile salt malabsorption, intestinal atrophy, hypoalbuminemia, infections such as *C. difficile*, and underlying conditions affecting the GI tract.^{97,99,104,111,113,114,129} Tube feeding-related causes of diarrhea include high fat content, lactose content, and bacterial contamination. Formula temperature, caloric density, osmolality, formula strength, lack of fiber content, and method of delivery also have been associated with diarrhea, although a cause-and-effect relationship is not clear.

R.L.'s diarrhea may be related to increasing the formula volume. The jejunum adapts slowly to changes in volume or concentration, and formula volume was increased <24 hours before diarrhea started. Changing back to the previous volume or slightly less should decrease stool output within 24 hours if the volume change was responsible. If R.L. does not respond to decreasing formula volume, the formula may be held for 24 hours to assess whether diarrhea decreases or stops. Diarrhea related directly to EN usually is an osmotic diarrhea that stops within 24 hours of stopping the formula.¹⁰⁴ The PN rate should be increased to 85 mL/hour (goal rate) if EN is stopped for more than 2 days or so. A more objective approach than stopping the formula is to measure stool osmolality. Enteral formula-induced diarrhea is associated with a large osmotic gap, whereas secretory diarrhea (e.g., infectious diarrhea) is associated with a low or negative osmotic gap.¹⁰⁴

Evaluate other potential causes of diarrhea before stopping R.L.'s EN. The current formula is lactose free and low in long-chain triglyceride content. As a ready-to-use formula, bacterial contamination from mixing technique is not of concern. Cleanliness during formula transfer to the delivery bag, the period of time formula is in the bag, and methods of cleaning the delivery bag may contribute to bacterial contamination of formula. Closed enteral systems (i.e., ready-to-hang formula-filled containers) virtually eliminate transfer-related contamination when proper technique is used. Any addition (e.g., medication, carbohydrate, fat or protein module, MCT oil) to the prefilled container before hanging can contaminate the system as well, and guidelines (e.g., hang-time, set changes) for an open enteral system should be followed.

Medications are a major contributor to diarrhea in tube-fed patients.⁹⁷ Study results implicating antibiotic therapy in diarrhea have been questioned because of failure to report stool

frequency and consistency as well as lack of a clear definition of diarrhea.¹³⁹ Treatment of antibiotic-associated diarrhea can include administration of *Lactobacillus acidophilus* preparations via the feeding tube to restore normal GI flora, administering antidiarrheal agents, changing antibiotics, or stopping therapy when appropriate to do so. Infectious causes of diarrhea require appropriate antibiotic therapy. Antidiarrheal agents decreasing motility should not be used when *C. difficile* is present, but adsorbents such as Kaolin may be beneficial.

R.L. currently receives antibiotics and has for some time. *C. difficile* may have relapsed after her previous treatment. Stool specimens should be sent for culture and *C. difficile* toxin. Evaluation of R.L.'s medications may reveal medications associated with diarrhea (e.g., sorbitol-containing products, antacids, oral magnesium, potassium chloride, phosphate supplements, H₂-receptor antagonists) for which therapeutic alternatives or different routes of administration could be considered.⁹⁷ High osmolality liquid medications should be diluted before administration to reduce GI side effects.^{113,114}

Malnutrition and hypoalbuminemia are associated with diarrhea in the ICU and might contribute to R.L.'s diarrhea given her low serum albumin and prolonged PN course without GI tract stimulation.¹²⁹ Diarrhea would be expected within 24 to 48 hours of starting feedings if this were the primary cause. Malabsorption should be limited in R.L. by use of an oligomeric formula containing only 15% of calories from fat and 50% of fat calories from MCT. Continued use of the GI tract is encouraged when malabsorption and hypoalbuminemia are the primary causes of diarrhea.

R.L.'s GI tract should continue to be used to the extent possible. EN appears to be better than PN for maintaining the GI tract barrier and host immunologic function.^{1,41,63,72,75,127,133,140} Based on 13 moderate to high level studies, the CCPG strongly recommend use of EN over PN in critically ill patients.³² The risk of sepsis increases without enteral stimulation of the GI tract. Whether this occurs through bacterial translocation, an unproved process in humans in which enteric bacteria or endotoxin cross the GI mucosa into mesenteric lymph nodes and portal circulation or through another mechanism is unclear. In addition, the GI tract serves an immune function, especially with respect to IgA secretion. Respiratory tract infections, such as pneumonia, may increase without proper stimulation of the GI tract, owing to less-effective protection from IgA. Compared with PN, EN attenuates catabolism in highly stressed patients, although initiation of feedings soon after the stressing event may be required to obtain this response. Before a decision is made to stop R.L.'s EN, possible benefits of improved fluid and electrolyte balance by stopping EN should be weighed against the potential benefits of reduced infections from continued use of the GI tract.

Medication Administration via Feeding Tube

17. It is determined that R.L. has *C. difficile* in her stool again. The tube feeding is at 30 mL/hour and the PN formulation is at 55 mL/hour. Kaolin has been ordered for administration via tube feeding. Is this an appropriate order?

It generally is better to administer medication separate from the enteral formula, because interactions are more likely to occur if the medication is admixed with the formula. Interactions

can lead to feeding tube occlusion, loss of nutrients, or loss of medication. Addition of kaolin directly into the enteral formula could result in nutrient losses because adsorption by kaolin is not selective and may include nutrients as well as bacteria, toxins, noxious materials, and drugs.¹⁴¹ Administration via a small inner-diameter jejunostomy also is likely to occlude the tube. To the extent possible, medications should be given by a route other than the feeding tube because of the risk of tube occlusion. Occlusion of the feeding tube would be more

detrimental to the overall plan of transitioning R.L. to tube feedings than stopping the tube feeding for 2 or 3 days until treatment of *C. difficile* resolves the diarrhea. PN should be increased to goal rate if EN is stopped owing to severe diarrhea. Stopping the tube feeding is not expected to resolve R.L.'s infectious diarrhea, however, and kaolin should not be administered through the jejunostomy tube even if tube feeding is stopped. Other methods of controlling diarrhea should be investigated.

Since the mid-1600s, efforts have been made to provide nutrients intravenously. Peripheral veins were cannulated and various feeding solutions, including salt water, cow's milk, and glucose, were administered. Unfortunately, peripheral venous access necessitated the administration of large volumes (up to 5 L/day) of solutions with low nutrient content to provide sufficient calories to a patient. This method of feeding often resulted in thrombophlebitis or fluid overload.

It was not until the 1960s that Dudrick et al. introduced the technique of placing an intravenous (IV) catheter into the superior vena cava, a large vessel with rapid blood flow. Hemodilution of fluids administered into this vessel allowed delivery of small volumes of solutions with high concentrations of nutrients.¹

Since then, many advances in the techniques for IV cannulation and formulation of IV nutrient solutions have been made. Today, the IV provision of complex mixtures of nutrients, known as parenteral nutrition, is an integral part of the medical management of patients, both hospitalized and at home, who cannot eat or ingest nutrients by the gastrointestinal (GI) tract.

MALNUTRITION

Adequate nutrition is important to maintain optimal health. Malnutrition occurs when there is any disorder of nutrition status, including disorders resulting from a deficiency of nutrient intake, impaired nutrient metabolism, or overnutrition. Clinically, a more useful definition of malnutrition is the state induced by alterations in dietary intake, which results in subcellular, cellular, and/or organ function changes that expose the individual to increased risks of morbidity and mortality and can be reversed by adequate nutritional support.²

The incidence of malnutrition among hospitalized patients has been reported to be as high as 55%.^{3,4} In the hospitalized patient, acute malnutrition occurs when nutrient intake is inadequate in the face of injury or stress (e.g., trauma, infection, major surgery), and nutrient stores are rapidly depleted. Acute stress or injury increases energy needs to repair tissues. When this energy is not provided exogenously, the body turns to endogenous sources of energy by breaking down skeletal muscle to release amino acids for the production of glucose. This iatrogenic malnutrition can occur rapidly even in individuals who

were well nourished prior to the stress. Once the illness or injury improves and normal nutrient intake is resumed, this acute malnutrition usually resolves.

In contrast, starvation or semistarvation states, without stress or injury, allow humans to adapt slowly to inadequate nutrient intake. This adaptation results in the use of endogenous fat stores for energy and a slow loss of muscle proteins. Nevertheless, energy and protein stores are not unlimited, and with total starvation, death occurs in normal-weight individuals in about 60 to 70 days.^{5,6} Patients with a history of chronic malnutrition who are faced with stress or injury are at the greatest risk of developing malnutrition.

Protein-calorie malnutrition, the most common type of nutrition deficiency in hospitalized patients, is manifested by depletion of both tissue energy stores and body proteins. Malnourished patients are at a higher risk of developing complications during therapy. These nutrition-associated complications, as a result of organ wasting and functional impairment, can include weakness, decreased wound healing, altered hepatic metabolism of drugs, increased respiratory failure, decreased cardiac contractility, and infections such as pneumonia and abscesses. These complications increase the length of hospital stay and costs of care.⁷⁻⁹

SPECIALIZED NUTRITION SUPPORT

Patients with inadequate intake for 7 to 14 days or those with an unintentional weight loss of 10% of their preillness weight are considered malnourished or at risk of developing malnutrition. Nutritional intervention should be considered for these patients.^{10,11} Patients who cannot meet their nutritional needs by consuming enough food by mouth should be considered for some type of specialized nutrition support. *Specialized nutrition support* is the provision of specially formulated and/or delivered parenteral or enteral nutrients to maintain or restore nutrition status.¹² For those who cannot eat by mouth but who have a functional GI tract, a method of enteral nutrition or tube feeding should be the first line of consideration (see Chapter 36).

When possible, the GI tract should be used for providing nutrients. Nutrients administered enterally may be more beneficial and less expensive than those provided by the parenteral route.¹³ Stimulation of the intestine with enteral nutrients maintains the mucosal barrier structure and function and has been associated with decreased infectious morbidity in critically ill patients compared with those receiving nutrients parenterally.¹⁴⁻¹⁸ For these reasons, parenteral nutrition (formerly referred to as total parenteral nutrition) is reserved for patients whose GI tracts are not functional or cannot be accessed and patients whose GI tracts do not absorb enough nutrients to maintain adequate nutrition status.¹⁰

PATIENT ASSESSMENT

An assessment of the nutritional status of a patient incorporates the analysis of body composition and evaluation of physiological function. Proper patient assessment should include the examination of multiple factors and should not rely on any one parameter. This evaluation is important in order to determine the presence and severity of malnutrition or the risk of developing malnutrition. The need for specialized nutrition support,

Table 37-1 Components of a Nutrition History

| Time period for weight change |
| Functional capacity |

as well as whether the goal of therapy is to maintain current nutrition status or to replete fat and lean body mass, is also determined following a complete patient assessment.

Nutrition History

A nutrition history is critical in assessing nutrition status. Information can be obtained by interviewing the patient or the patient's family and reviewing the medical record to identify factors that may contribute to malnutrition or increase the risk of developing malnutrition.

Multiple factors can contribute to the development of malnutrition, including the patient's underlying disease states, past medical history, and financial and social environment. Medications can adversely affect nutrition status by decreasing the synthesis of nutrients, minimizing food intake through alteration of appetite and taste, changing the absorption or metabolism of nutrients, or increasing nutrient requirements. A nutrition history should also include evaluation of body weight. The components of a nutrition history are summarized in Table 37-1.

Weight History

Weight and weight history are important in evaluating nutrition status. Weight loss is a sign of negative energy and negative protein balance and is associated with poor outcome in hospitalized patients.^{3,19} An unintentional weight loss of more than 10% is considered significant for malnutrition.¹²

A patient's current weight often is compared with a standard for ideal body weight (IBW). Percentage of IBW is determined as shown in Equation 37-1:

$$\% \text{ IBW} = \frac{\text{Current weight}}{\text{IBW}} (100) \quad (37-1)$$

This method of assessing weight has its shortcomings because the patient's weight is compared with a population standard rather than using the individual patient as the reference point. For example, a patient who is significantly overweight and has lost large amounts of weight may still be more than 100% of IBW and therefore not considered at risk for developing malnutrition. A more patient-specific method of evaluating weight is to compare current weight with the patient's usual

weight. This can be determined using Equation 37-2:

$$\% \text{ Usual body weight} = \frac{\text{Current weight}}{\text{Usual body weight}} (100) \quad (37-2)$$

Using this method, the obese patient who has lost weight may be determined to be less than 90% of usual weight (weight loss of more than 10%) and therefore nutritionally at risk. It is also important to assess over what time period the change has occurred. Involuntary weight loss is considered severe if loss exceeds 5% of usual weight within 1 month, or 10% of usual weight within 6 months. The pattern of weight loss must be evaluated to determine whether the loss is continuing or stabilized. Continuing weight loss is a more serious concern than if the weight loss has stabilized. Weight gain after a significant weight loss is a positive sign.

Physical Examination

A physical examination may reveal signs of nutrition deficiencies that require further evaluation. General evidence of muscle and fat wasting (commonly noticed in the temporal area), loss of subcutaneous fat and muscle in the shoulders, and loss of subcutaneous fat in the interosseous and palmar areas of the hands are readily identifiable. Other physical parameters that may be less obvious are hair for color and sparseness; skin for turgor, pigmentation, and dermatitis; mouth for glossitis, gingivitis, cheilosis, and color of the tongue; nails for friability and lines; and the abdomen for ascites or enlarged liver.

Anthropometrics

Physical examination may include anthropometrics that measure subcutaneous fat and skeletal muscle mass. Assessment of fat stores provides information about fat loss or gain and assumes fat is gained or lost proportionally over the entire body. Approximately 50% of body fat is in the subcutaneous compartment. Triceps skinfold and subscapular skinfold thickness measurements are examples of methods used to assess subcutaneous fat and therefore estimate total body fat.

The values obtained are compared with reference standards. Somatic protein mass or skeletal muscle mass can be estimated by measuring mid-arm circumference and then calculating arm muscle circumference. These values are also compared with standards, and the amount of muscle mass is estimated.

When used for the long-term study of large, nutritionally stable populations, anthropometric measurements accurately reflect total body fat and skeletal muscle mass. However, anthropometric measurements of hospitalized patients are of little value. During acute illness and stress, changes in subcutaneous fat may not be proportional to changes in weight, and peripheral edema can result in inflated values for skinfold thickness and mid-arm circumference.^{3,19}

Biochemical Assessment

Biochemical assessment of nutrition status includes measuring concentrations of serum proteins. The visceral proteins most commonly used to assess nutrition status are albumin, prealbumin, transferrin, and retinol-binding protein. These proteins are synthesized by the liver and reflect its synthetic capability. Serum concentrations decrease with hepatic insufficiency or when intake of substrates is inadequate for synthesis of

these proteins. During stress or injury, inflammatory cytokines are released and substrates are shunted away from the synthesis of these proteins to synthesize other proteins such as C-reactive protein, haptoglobin, fibrinogen, and others; these are the acute phase proteins.²⁰ Serum concentrations of proteins are altered by acute stress or inflammatory states and chronic starvation.^{19,20}

Albumin is the classic visceral protein used to evaluate nutrition status and is a prognostic indicator. Serum concentrations of <3 g/dL correlate with poor outcome and increased length of stay of hospitalized patients.²¹ Albumin serves as a carrier protein for fatty acids, hormones, minerals, and drugs, and is necessary for maintaining oncotic pressure. Albumin has a large body pool of 3 to 5 g/kg, and 30% to 40% is localized to the intravascular space. The normal hepatic rate of albumin synthesis is 150 to 250 mg/kg/day. Because albumin has a half-life of 18 to 21 days, a decrease in serum albumin concentrations is generally not observed until after several weeks of inadequate nitrogen intake. Serum albumin concentrations decrease rapidly in response to stress (which causes albumin to shift from the intravascular to the extravascular space), burns, nephrotic syndrome, protein-losing enteropathy, overhydration, and decreased synthesis with liver disease.^{19,21}

Transferrin is responsible for the transport of iron. It has a half-life of 8 to 10 days and therefore is more sensitive than albumin to acute changes in nutrition status. Normal serum concentrations for transferrin are 250 to 300 mg/dL.

Even more sensitive to changes in energy and protein intake is prealbumin (transthyretin), which has a small body pool (10 mg/kg) and a half-life of 2 to 3 days. Prealbumin transports both retinol and retinol-binding protein. Normal serum prealbumin concentrations are 15 to 40 mg/dL.

Retinol-binding protein has the shortest half-life, 12 hours; normal serum concentrations are 2.5 to 7.5 mg/dL. However, because serum concentrations of retinol-binding protein change rapidly in response to alterations in nutrient intake, monitoring it has limited use in clinical practice. The visceral proteins commonly used for nutrition assessment are summarized in Table 37-2.

Other proteins, such as fibronectin and somatomedin-C (insulinlike growth factor-1), are also used as markers of nutrition status. Fibronectin is a glycoprotein found in blood, lymph, and many cell surfaces. Somatomedin-C is important in regulating growth. Both fibronectin and somatomedin-C have half-lives of <1 day and respond to fasting and refeeding. Urinary measurement of 3-methylhistidine, a byproduct of muscle metabolism that is excreted unchanged, has been used to estimate skeletal muscle mass. Although these markers have potential use in nutrition assessment, they are used primarily as research tools and are not readily available for routine clinical use.¹⁹

Table 37-2 Visceral Proteins for Nutrition Assessment

| Visceral Protein | Half-Life (Days) | Normal Serum Concentration |
|----------------------------|------------------|----------------------------|
| Albumin | 18–21 | 3.5–5 g/dL |
| Transferrin | 8–10 | 250–300 mg/dL |
| Transthyretin (prealbumin) | 2–3 | 15–40 mg/dL |
| Retinol-binding protein | 0.5 | 2.5–7.5 mg/dL |

The interpretation of serum protein concentrations in hospitalized patients may be difficult because factors more important than hepatic synthesis rate alter serum concentrations. These factors may include renal, hepatic, or cardiac dysfunction; hydration status; and metabolic stress. Visceral proteins, as with any nutrition assessment parameter, must be used in conjunction with other parameters and comprehensive consideration of the patient's clinical status.

Nutrition assessment based on determinations of body composition using anthropometrics and biochemical parameters has many limitations. Newer techniques (e.g., bioelectrical impedance, dexta-energy x-ray absorptiometry, isotope dilution, neutron activation) are increasingly being used to determine body composition. Other parameters such as hand grip and forearm dynamometry may be used to assess skeletal muscle function, which relates changes in body composition to body function.^{3,19}

Another nutrition assessment method, subjective global assessment (SGA), combines objective parameters and physiologic function. This method is based on a history of weight change, dietary intake, presence of significant GI symptoms, functional capacity, and physical examination to assess the loss of subcutaneous fat and muscle and edema. Using the SGA system, patients are rated as well nourished, moderately malnourished, or severely malnourished. This subjective assessment is easy to use and useful in diagnosing malnutrition.²²

Classification of Malnutrition

Protein-calorie malnutrition is divided classically into three categories: marasmus, kwashiorkor, and a mixed protein-calorie. Marasmus, which means a “dying away state,” is seen in individuals who have a chronic deficiency primarily in the intake of energy (calories) over a prolonged period (i.e., partial starvation). Physical examination reveals severe cachexia through loss of both fat and muscle mass; however, visceral protein (e.g., albumin, prealbumin) production is preserved. Patients with anorexia or suffering from chronic wasting diseases such as cancer are likely to present with marasmus malnutrition.

Kwashiorkor malnutrition results from a diet adequate in calories but limited in protein or in patients extremely catabolic from their medical complication (sepsis) or injury (trauma, thermally injured). Insulin is produced to metabolize the carbohydrates; it also prevents lipolysis and promotes the movement of amino acids into muscle. To meet protein needs, protein is mobilized from internal organs and circulating visceral proteins such as albumin. Thus, an individual with kwashiorkor malnutrition has adequate fat and muscle mass but depleted serum proteins.

Hospitalized patients commonly exhibit components of both marasmus and kwashiorkor malnutrition and are classified as having mixed protein-calorie malnutrition. This often occurs when an injury or stress compounds chronic starvation or semistarvation, resulting in wasting of fat and muscle mass, as well as depletion of serum proteins.

Estimation of Energy Expenditure

An important aspect of patient evaluation is estimating energy expenditure. A common approach used to determine energy

Table 37-3 Estimation of Energy Expenditure

Basal Energy Expenditure (BEE)

Harris-Benedict Equations

$$\text{BEE}_{\text{men}} (\text{kcal/day}) = 66.47 + 13.75 W + 5.0 H - 6.76 A$$

$$\text{BEE}_{\text{women}} (\text{kcal/day}) = 655.10 + 9.56 W + 1.85 H - 4.68 A$$

or

$$20\text{--}25 \text{ kcal/kg/day}$$

Energy Requirements

| | |
|-----------------------------------|-------------------|
| Hospitalized patient, mild stress | 20–25 kcal/kg/day |
| Moderate stress, malnourished | 25–30 kcal/kg/day |
| Severe stress, critically ill | 30–35 kcal/kg/day |

A, age in years; H, height in cm; W, weight in kg.

requirements (and simplest method) is based on body weight in kilograms. The energy requirements are standardized and are determined by the metabolic condition of the patient (Table 37-3).

Many predictive equations for estimating expenditure have been described in the literature.^{23,24} The traditional method of assessing energy expenditure is the basal energy expenditure (BEE), the amount of energy (kilocalories [kcal]) needed to support basic metabolic functions in a state of complete rest, shortly after awakening, and after a 12-hour fast. BEE is most commonly calculated using the Harris-Benedict equations. Alternatively, BEE can be estimated at 20 to 25 kcal/kg/day.

Basal metabolic rate (BMR) is the energy expended in the postabsorptive state (2 hours after a meal) and is approximately 10% greater than BEE. Determination of BEE or BMR does not include additional energy needed for stress or activity. The Harris-Benedict equations can be modified to include stress and physical activity factors, or these variables can be estimated at 20 to 35 kcal/kg/day for moderate to severe stress (Table 37-3).

Energy expenditure can be determined more accurately by indirect calorimetry, which uses a machine (“metabolic cart”) to measure the patient’s breathing or respiratory gas exchange. The machine measures oxygen (O₂) consumption and carbon dioxide (CO₂) production when standard testing conditions are maintained. The amount of O₂ consumed and CO₂ produced for carbohydrate, fat, and protein is constant and known. Through a series of equations, the energy expenditure, including stress, for that point in time is calculated and then extrapolated for 24 hours.^{17,25} This is the measured energy expenditure (MEE). Because the measurement is usually conducted while the patient is at rest, activity is not included in MEE.

Indirect calorimetry is available to many clinicians and is considered the gold standard for energy expenditure determination. It is especially valuable in the energy assessment of critically ill or obese patients.

Estimation of Protein Goals

Estimation of protein needs must also be included in nutrition assessment. Protein needs are calculated based on body weight, degree of stress, and disease state. The recommended dietary allowance for the United States is 0.8 g of protein per kilogram per day. Well-nourished, hospitalized patients with minimal stress need 1 to 1.2 g of protein per kilogram per

Table 37-4 Estimation of Protein Requirements

| | |
|------------------------------------|------------------|
| U.S. recommended dietary allowance | 0.8 g/kg/day |
| Hospitalized patient, minor stress | 1–1.2 g/kg/day |
| Moderate stress | 1.2–1.5 g/kg/day |
| Severe stress | 1.5–2 g/kg/day |

day to maintain lean body mass. The requirement for protein intake may be as high as 2 g/kg/day for a patient in a hypermetabolic, hypercatabolic state secondary to trauma or burns. In addition, patients with renal or hepatic dysfunction may require decreased protein intake as a result of altered metabolism. Guidelines for protein needs are summarized in Table 37-4.

VENOUS ACCESS SITES

When parenteral nutrition is necessary, the type of venous access must be selected. Parenteral nutrient formulations may be administered via peripheral veins or central veins, depending on the anticipated duration of parenteral nutrition therapy, nutrient requirements, and availability of venous access.¹⁰

Peripheral

Peripheral administration may be considered when parenteral nutrition is expected to be necessary for more than 10 days and when the patient has fairly low energy and protein needs due to minimal stress. Candidates for peripheral parenteral nutrition must have good peripheral venous access and must be able to tolerate large volumes of fluids.²⁶

Parenteral nutrient formulations for administration via peripheral veins have traditionally contained relatively low concentrations of dextrose (5%–10%) and amino acids (3%–5%), providing <1 kcal/mL. Therefore, several liters may be needed daily to meet energy and protein needs. Although dilute with nutrients, the osmolarity of these formulations is 600 to 900 mOsm/L. These hypertonic formulations are irritating to peripheral veins and can cause thrombophlebitis. This necessitates frequent site rotations (at least every 48–72 hours), which may quickly exhaust venous access sites. Caloric density can be increased with only a modest increase in osmolarity by administering IV lipids concurrently or by adding them to the dextrose and amino acid mixtures. Lipids may also protect the vein against irritation through dilution and a buffering effect.^{27,28}

Central

Administration of parenteral nutrient formulations through a central vein is preferred for patients whose GI tracts are non-functional or should be at rest for more than 7 days, who have limited peripheral venous access, or who have energy and protein needs that cannot be met with peripheral nutrient formulations.^{10,26,29}

Traditionally, the central venous catheter is percutaneously inserted in the subclavian vein and threaded through the vein so the tip rests in the upper portion of the superior vena cava (SVC) just above the right atrium. A newer catheter technique involves the use of a peripherally inserted central catheter (PICC) that is inserted in the antecubital vein and advanced until the end of the catheter reaches the upper SVC.^{29,30} The internal and external jugular veins may also be used to thread a catheter into the

SVC. However, maintaining a sterile dressing on these sites is more difficult than with the subclavian approach or PICC. The SVC is an area of rapid blood flow, which quickly dilutes concentrated parenteral nutrient formulations, thereby minimizing phlebitis or thrombosis. Some patients are not candidates for placement of catheters in the SVC and require a femoral vein insertion with the tip of the catheter in the inferior vena cava. There may be a greater risk for infection with catheters placed using this technique.²⁹

Central venous catheters can have single or multiple lumens. Multilumen catheters permit the administration of several therapies through the same IV site. Unlike peripheral venous sites, the central venous access site does not require frequent rotation. In fact, some patients requiring parenteral nutrition for months to years may have permanently placed central venous catheters.³¹ Parenteral nutrient formulations designed for administration through central veins can contain relatively high concentrations of dextrose (20%–35%), amino acids (5%–10%), and lipids providing a caloric density of >1 kcal/mL in a solution with an osmolarity of >2,000 mOsm/L.

COMPONENTS OF PARENTERAL NUTRIENT FORMULATIONS

Parenteral nutrient formulations are very complex mixtures containing carbohydrate, protein, lipid, water, electrolytes, vitamins, and trace minerals. These admixtures must be prepared under aseptic conditions as described by the American Society of Health-System Pharmacists and U.S. Pharmacopeia standards.^{32,33} Although parenteral feeding is an important adjuvant therapy for patients with many disease states, errors have occurred in managing this complex therapy, resulting in patient harm and death. Guidelines for safe practices have been developed for the situations in which inconsistent practices have the potential to cause harm. Pharmaceutical problem areas that are addressed in the Safe Practices for Parenteral Nutrition Formulations are compounding, formulas, labeling, stability, and filtering of parenteral nutrient formulations.³⁴ These practice guidelines have become standards of practice for parenteral nutrition therapy.

The three macronutrients used in parenteral nutrient formulations, carbohydrate, fat, and protein are available from various manufacturers. Water, as sterile water for injection, is also used to dilute the macronutrients to achieve the prescribed final concentrations of dextrose, amino acids, and lipids, as well as the final volume of the parenteral nutrient formulation.

Carbohydrate

Dextrose in water is the most common carbohydrate for IV use. It is available commercially in concentrations ranging from 2.5% to 70%. These dextrose solutions are mixed with other components of the parenteral nutrient formulation and diluted to various final concentrations. From these concentrations of dextrose, all parenteral nutrient formulations can be compounded. IV dextrose is monohydrated and provides 3.4 kcal/g, in comparison with dietary carbohydrate, which has a caloric density of 4 kcal/g.

Glycerol, a sugar alcohol with a caloric density of 4.3 kcal/g, is also available (as a 3% mixture with 3% amino acids) for administration as a peripheral parenteral nutrient formulation.

Unfortunately, because of the dilute formula necessary for peripheral administration, large volume of formula may be necessary to meet the patient's caloric requirements, limiting the usefulness of the formulation. Other carbohydrates such as fructose, sorbitol, and invert sugar have been used investigational in parenteral nutrient formulations but are associated with adverse effects and are not available commercially.

Lipid

Lipid for IV use is supplied as emulsions of either soybean oil or a 50:50 physical mixture of soybean and safflower oils that provide long-chain fatty acids (>16 carbon length). The soybean oil emulsion is available in three concentrations: 10%, 20%, and 30%. The soybean/safflower oil emulsion is available as 10% and 20%. The 10% and 20% IV lipid emulsions may be administered concurrently (IV piggyback) with dextrose/amino acid solutions or admixed with dextrose and amino acids. The 30% IV lipid emulsion should not be used for IV piggyback administration. It is used exclusively for compounding formulations that combine dextrose, amino acids, and lipid in the same container.

Although lipid has a caloric density of 9 kcal/g, the caloric density of the IV lipid emulsions is increased to approximately 10 kcal/g by the addition of glycerol, which is added to adjust the osmolarity. Egg phospholipids are also added as emulsifiers. The phospholipids are derived from egg yolks; therefore, IV lipids are contraindicated in patients with severe egg allergies, especially egg yolk allergies. Phospholipids also contribute approximately 15 mmol/L of phosphorus.

Medium-chain triglycerides (MCTs) are used investigational. MCTs are 6 to 12 carbons in length and provide 8.3 kcal/g. Physical mixtures of soybean oil and MCTs are being evaluated for potential use in the United States and are already commercially available in other countries.³⁵

Research investigating the use of lipid formulations enhanced with omega-3 fatty acids is also being performed, with results showing improved patient outcomes (decreased length of hospital stay, decreased infections).³⁶ However, similar to the MCT mixtures, commercially available products are not available in the United States at this time.

Amino Acids

Protein for parenteral administration is available as synthetic amino acids and serves as the source of nitrogen. Nitrogen is the building block of cell structure and is used to produce enzymes, peptide hormones, and serum proteins. Amino acid concentrations of 3.5% to 20% are available commercially and vary slightly from one product to another in the specific amounts of each amino acid, electrolyte content, and pH. Generally, amino acid products are characterized as "standard" mixtures, which provide a balanced mix of essential, nonessential, and semiessential amino acids, or "specialty" mixtures, which are modified for specific disease states. For example, the specialty amino acid mixture for use in patients with hepatic failure contains increased amounts of the branched-chain amino acids and decreased amounts of the aromatic amino acids. Protein formulations designed for critically ill patients are supplemented with branched-chain amino acids but have normal amounts of the other amino acids. Amino acid products for patients expe-

Table 37-5 Caloric Density of Intravenous Nutrients

| Nutrient | kcal/g | kcal/mL |
|----------------------------|--------|---------|
| Amino acids | 4 | |
| Amino acids 5% | | 0.2 |
| Amino acids 10% | | 0.4 |
| Dextrose | 3.4 | |
| Dextrose 10% | | 0.34 |
| Dextrose 50% | | 1.7 |
| Dextrose 70% | | 2.38 |

| Fat emulsion 30% | | 3 |
| Glycerol | 4.3 | |
| Glycerol 3% | | 0.129 |
| Medium-chain triglycerides | 8.3 | |

riencing renal failure have increased amounts of the essential amino acids or provide only essential amino acids.³⁷ Amino acid products designed to meet the special needs of neonates also are available (see Chapter 97).

Protein or amino acids have a caloric density of 4 kcal/g. Protein calories have not always been included in the calculation of energy needs for patients receiving parenteral nutrient formulations. Ideally, protein is used to stimulate protein synthesis and tissue repair and is not oxidized for energy; however, the human body cannot compartmentalize energy metabolism this way. Today, the conventional wisdom is to include the protein calories in these total calorie calculations. Table 37-5 summarizes available nutrients and their caloric density.

Micronutrients

Micronutrients are the electrolytes, vitamins, and trace minerals needed for metabolism. These nutrients are available from various manufacturers as either single entities or in combinations. For example, the trace element zinc is available commercially as a single trace element product or as a combination product with the other trace elements: copper, chromium, manganese, and selenium. It is important to be aware of the specific products available in each institution to avoid providing inadequate or excessive amounts of various micronutrients.

PARENTERAL NUTRITION

Patient Assessment: Woman in No Acute Stress

1. S.D., a 39-year-old cachectic woman, is admitted to the hospital with shortness of breath and pleuritic chest pain. She has a history of moderate scleroderma (fibrosis of the skin, blood vessels, and visceral organs) diagnosed 3 years ago. She presents to the hospital with an increasing weight loss over the past 3 months accompanied with regurgitation, vomiting, and poor appetite. Approximately 3 months ago, S.D. weighed 130 lb. Her weight on admission is 98 lb; height is 64 in. Past medical history is also significant for hypertension. Physical examination reveals a thin woman with wasting of subcutaneous fat in the temporal area and squared-appearing shoulders. Attempts at enteral nutrition with

tube feeds have resulted in sustained gastric residual volumes of >400 mL.

Admission laboratory values are sodium (Na), 135 mEq/L (normal, 135–145); potassium (K), 4.0 mEq/L (normal, 3.5–5.0); chloride (Cl), 100 mEq/L (normal, 100–110); bicarbonate (HCO_3^-), 25 mEq/L (normal, 24–30); blood urea nitrogen (BUN), 4 mg/dL (normal, 8–20); creatinine, 0.6 mg/dL (normal, 0.8–1.2); glucose 87 mg/dL, (normal, 85–110); calcium (Ca), 8.2 mg/dL (normal, 8.5–10); magnesium (Mg), 2.0 mg/dL (normal, 1.6–2.2); phosphorus (P), 3.0 mg/dL (normal, 2.5–4.5); total protein, 6.0 g/dL (normal, 6.8–8.3); albumin, 3.5 g/dL (normal, 3.5–5.0); and prealbumin, 15 mg/dL (normal, 15–40). Her white blood cell (WBC) count is 6,800/mm³ (normal, 4,000–12,000).

Based on history and physical findings, S.D.'s working diagnosis includes aspiration pneumonia and advanced scleroderma with cutaneous, joint, and GI involvement. Assess her nutrition status.

[SI units: Na, 135 mmol/L (normal, 135–145); K, 4.0 mmol/L (normal, 3.5–5.0); Cl, 100 mmol/L (normal, 100–110); HCO_3^- , 25 mmol/L (normal, 24–30); BUN, 1.43 mmol/L (normal, 3–6.4); creatinine, 53 $\mu\text{mol/L}$ (normal, 50–110); glucose, 4.83 mmol/L (normal, 4.7–6.1); Ca, 2.04 mmol/L (normal, 2.3–2.7); Mg, 10 mmol/L (normal, 8–11); P 0.97 mmol/L (normal, 0.81–1.45); albumin, 35 g/L (normal, 35–50); WBC count, $6.8 \times 10^9/\text{L}$ (normal, 4–12)]

Assessment of nutrition status requires evaluation of multiple factors. S.D.'s nutrition history indicates that she is unable to eat because of the gastroparesis, and the scleroderma diagnosis raises the question of nutrient malabsorption. Most striking about S.D.'s history is her weight loss of 30 lb in 3 months, or about 2.5 lb/week. S.D. is now 75% of her usual weight (Eq. 37-2). Another way of analyzing this is that she has lost 25% of her original weight, which is a severe weight loss. S.D.'s physical findings of cachectic appearance, temporal wasting, and loss of subcutaneous fat and muscle in her shoulders are significant. No anthropometric measurements are available. S.D.'s visceral proteins are also in low-normal ranges, indicating both short-term (prealbumin) and longer-term (albumin) malnutrition.

Consideration of these factors leads one to conclude that S.D. is severely malnourished. Her cachectic appearance with loss of subcutaneous fat and muscle, but normal visceral proteins, would be best classified as marasmus malnutrition. If S.D. were to be faced with stress or injury (e.g., major surgery, infection) necessitating use of visceral proteins for energy production, she would likely exhibit characteristics of both marasmus and kwashiorkor, or mixed protein-calorie malnutrition in which fat, muscle, and visceral proteins are all depleted.

2. Why is S.D. a candidate for parenteral nutrition therapy?

S.D. is admitted to the hospital for tests to evaluate her scleroderma, weight loss, and aspiration pneumonia. Many of the expected diagnostic tests will require that S.D. remain NPO. The subjective and objective evidence points to a nonfunctioning GI tract. If the diagnosis of advanced GI scleroderma is accurate, S.D. may require long-term parenteral nutrition therapy. In addition, attempts at enteral nutrition were unsuccessful with continued increased gastric residual volumes indicating decreased GI motility. With her malnourished state, continued inadequate nutrition in the hospital will result in further dete-

rioration of her nutrition status. Parenteral nutrition should be implemented.

Goals of Therapy

CALORIE AND PROTEIN GOALS

3. Calculate calorie and protein goals for S.D.

S.D.'s initial calorie goals are to meet her current energy expenditure needed for basal metabolism and activity of ambulating. S.D. would fall into the category of "moderate stress, malnourished" requiring 25 to 30 kcal/kg/day (Table 37-3). For this calculation, S.D.'s actual weight of 98 lb (44.5 kg) should be used because her metabolism and current energy expenditure react this decrease in body mass. Using usual weight or ideal body weight in patients who have severe weight loss may result in overfeeding. For S.D., her caloric goal should be 1,112 to 1,335 kcal/day.

Protein goals are estimated based on weight, degree of stress, and disease state. Because S.D. has not had surgery and her stress is minimal, her protein goal should be based on the desire to maintain her current protein status. Using the guidelines provided in Table 37-4, S.D.'s protein dose is 1.2 to 1.5 g/kg/day, or 53.4 to 66.7 g/day. As with energy expenditure, calculations of protein needs are only estimates; the patient's clinical course should be monitored, and the protein dose adjusted accordingly. The protein source for parenteral nutrition is synthetic amino acids. Generally, 1 g of protein is equivalent to 1 g of amino acids. S.D. will need 53.4 to 66.7 g/day of amino acids. If S.D. requires parenteral nutrition following a surgery, her energy or calorie goals should be reassessed to include a stress factor.

ACCESS

4. S.D. has a peripheral IV, and her peripheral access appears to be adequate. Is she a candidate for using a peripheral parenteral nutrition formulation?

With good peripheral access, S.D. meets one of the criteria for peripheral parenteral nutrition. Furthermore, she should be able to tolerate the volume of a peripheral parenteral nutrition formulation necessary to meet her goals. A common complication (up to 70%) of peripheral parenteral nutrition is phlebitis, which occurs within 72 hours.^{27,38} Phlebitis is usually attributed to the acidic pH or hyperosmolarity of the nutrient formulation. The osmolarity of typical peripheral parenteral feedings ranges from 600 to 900 mOsm/L. Osmolarity of a dextrose/amino acid formulation can be approximated quickly by multiplying the % dextrose concentration by 50 and the % amino acid concentration by 100. Alternatively, the osmolarity can be estimated by multiplying the number of grams of dextrose by 5 and the number of grams of amino acids by 10, then dividing by the total volume in liters. Approximately 150 mOsm/L should be added for contribution of electrolytes, vitamins, and trace elements. Although the concurrent administration of fat emulsions (up to 60% of non-protein calories) decreases osmolarity, buffers the pH, and improves peripheral vein tolerance, it does not eliminate the risk of thrombophlebitis.³⁹

Because parenteral nutrition is anticipated to be a long-term therapy for S.D., it would be most appropriate to obtain central venous access. Central access allows for longer-term

access, more concentrated solutions, and has no osmolarity restrictions.

FORMULATION DESIGN

Macronutrients and Micronutrients

5. Design a parenteral nutrient base formulation for S.D. based on the caloric and protein goals determined previously.

S.D.'s caloric goal was determined to be approximately 1,300 kcal/day and 60 g protein/day. Giving 60 g of protein per day would provide 240 kcal/day (1 g protein = 4 kcal). Subtracting these protein calories from total desired calories results in the amount of nonprotein calories (to be provided by carbohydrates and fat) needed. For S.D., this would be 1,300 total calories – 240 protein calories = 1,060 nonprotein calories needed. Typically, dextrose should account for 60% to 70% of nonprotein calories, and lipids would account for the remaining 30% to 40% of nonprotein calories. Providing S.D. with 742 kcal of dextrose (approximately 218 g of dextrose; 1 g dextrose = 3.4 kcal) would supply 70% of nonprotein calories as dextrose. The remaining 30% of nonprotein calories would be provided by lipids at 318 kcal (31.8 g of lipids; 1 g of IV lipids = 10 kcal).

As with any medical therapy, the parenteral nutrition formula should be adjusted based on patient response and tolerance. If S.D. had complications of hyperglycemia, the dextrose component could be reduced with a subsequent increase in the lipid proportion of nonprotein calories. If hypertriglyceridemia resulted, the lipid component may be reduced with a subsequent increase in dextrose.

S.D.'s nutrient formulation should also contain standard amounts of electrolytes, as well as a daily dose of IV multivitamins and trace elements.

6. The pharmacy has the following stock solutions available for compounding the parenteral nutrition formula: dextrose 70%, amino acids 10%, and IV lipids 20%. How much of each stock solution is needed to compound the parenteral nutrition formula determined previously?

For dextrose, a 70% stock solution provides 70 g of dextrose/100 mL. To obtain 218 g of dextrose, 311 mL of the stock solution are needed:

$$\begin{aligned} \text{mL} &= \frac{218 \text{ g dextrose} \times 100 \text{ mL}}{70 \text{ g dextrose}} & (37\text{-A}) \\ &= 311.4 \text{ mL} \end{aligned}$$

Similarly, the volume necessary to provide 60 g of amino acids is 600 mL. IV lipids at 20% provide 20 kcal/mL or 20 g/100 mL. Using this stock solution, 159 mL would provide 31.8 g of lipids. The total volume of the compounded solution would be 1,070 mL/day.

Fluids

7. The institution uses a total nutrient admixture (TNA) system, and S.D.'s parenteral nutrient formulation is provided in 1,070 mL/day. Will this meet S.D.'s maintenance fluid requirements?

Maintenance fluid needs can be estimated using several methods. The simplest method uses 30 to 35 mL/kg/day as the basis. Another method is to provide 1,500 mL for the first 20 kg body weight plus an additional 20 mL/kg for actual weight

beyond the initial 20 kg. Both methods provide estimates of fluid needs for basic maintenance, and additional fluid must be provided for increased losses such as vomiting, nasogastric (NG) tube output, diarrhea, or large open wounds. S.D.'s fluid needs are estimated as follows:

$$\begin{aligned} \text{mL/day} &= 1,500 \text{ mL} + [(20 \text{ mL/kg})(44.5 \text{ kg} - 20 \text{ kg})] \\ &= 1,500 \text{ mL} + (20 \text{ mL/kg})(24.5 \text{ kg}) & (37\text{-B}) \\ &= 1,500 \text{ mL} + 490 \text{ mL} \\ &= 1,990 \text{ mL} \end{aligned}$$

The peripheral parenteral nutrient formulation will not meet S.D.'s needs of 1,990 mL/day. The parenteral nutrition formula may be supplemented with sterile water to make the final formula 1,990 mL. Another option would be to provide the additional fluids via a separate IV line. It is important to not supply fluids in excess. The extra fluid intake may put patients at risk for becoming fluid overloaded, manifesting as hypervolemic, hypotonic hyponatremia. Therefore, S.D. should be monitored for signs of fluid overload, including peripheral edema, shortness of breath, daily intake exceeding daily output, hyponatremia, and rapidly increasing weight.

Monitoring and Management of Complications

8. What metabolic complication is a potential concern due to S.D.'s malnutrition?

Refeeding syndrome is the term used to define the severe hypophosphatemia and associated metabolic complications that occur when malnourished patients receive a concentrated source of calories via parenteral or enteral nutrition. This phenomenon was first reported when the Holocaust victims and prisoners of war in World War II were rescued and given normal food and liquid intake. Complications coinciding with refeeding these individuals included hypertension, cardiac insufficiency, seizures, coma, and death. These complications were reported later in the 1970s and 1980s, with the introduction of parenteral nutrition in chronically ill, essentially starved hospitalized patients.

Metabolic complications from refeeding are associated primarily with severe hypophosphatemia, but hypokalemia, hypomagnesemia, vitamin deficiencies, fluid intolerance, and glucose alterations may occur. In the starved, depleted individual, there is a loss of lean body mass, water, and minerals. Individuals may preserve some intracellular electrolytes, including phosphorus. When these individuals are given a concentrated source of calories, the carbohydrates are converted to glucose. Glucose, in turn, results in the secretion of insulin. The release of insulin enhances the uptake of glucose, water, phosphorus, and other intracellular electrolytes. The combination of phosphorus depletion and intracellular uptake causes severe hypophosphatemia.

To minimize the risk of refeeding syndrome in S.D., all electrolyte abnormalities must be corrected before any nutrition is initiated. Because S.D.'s electrolytes are within normal range, no adjustments are necessary. Nutrition should then be implemented slowly and vitamins administered routinely. Electrolytes, including phosphorus, potassium, magnesium, and glucose, should be monitored at least daily over the first week. Although electrolyte and mineral abnormalities may not be avoided, careful recognition of and close monitoring for refeeding syndrome will prevent serious complications.^{40,41}

9. Members of the medical team are anxious to have S.D. gain weight and are concerned by her malnourished appearance. Therefore, there is a desire to increase the calories provided to S.D. What potential complications could result from overfeeding S.D.?

Overfeeding should be avoided in all patients, especially those with respiratory concerns (i.e., mechanically ventilated, chronic obstructive airway disease). Overfeeding with carbohydrates is particularly detrimental because of the amount of CO₂ produced relative to the amount of O₂ consumed. This results in CO₂ retention that may lead to acid–base disturbances. Complete oxidation of carbohydrate is demonstrated at dextrose infusions of 4 to 5 mg/kg/minute. Infusions exceeding this rate increase CO₂ production and may cause respiratory distress. In designing a parenteral nutrient formulation for S.D., it is important to provide a moderate calorie dose and to limit her dextrose dose to <4 mg/kg/minute.^{42,43} S.D.'s current parenteral nutrition formulation provides 3.4 mg/kg/minute of dextrose.

For adults, the daily lipid intake should not exceed 2.5 g/kg/day. However, current literature supports a maximum of 1 g/kg/day. S.D.'s formulation provides approximately 32 g of lipid daily, or 0.72 g/kg/day. It is also important to monitor serum triglyceride levels to assess tolerance to this dose of IV lipid. If the blood sample is obtained while the triglycerides are infusing, as with the TNA formulation, a serum triglyceride concentration of 400 mg/dL, although elevated, is acceptable.⁴⁴ Hypertriglyceridemia can sometimes be noted quickly by gross observation of the blood sample.

Patient Assessment: Man in Moderate Stress

10. D.C., a 38-year-old man with a 12-year history of Crohn's disease, is admitted to the hospital after being evaluated in the clinic for a complaint of increasing abdominal pain, nausea, and vomiting for 9 days, and no stool output for 5 days. Questioning reveals that over the past week he has been drinking only liquids secondary to nausea and vomiting, and his weight has decreased 10 lb during that time. D.C.'s medical history is significant for frequent exacerbations of his Crohn's disease during the past 2 years. His surgical history includes an exploratory laparotomy 6 months ago for resection of 10 cm of ileum. Family and social histories are noncontributory. His current medications include mesalamine 1,000 mg orally (PO) four times a day (QID) and prednisone 10 mg PO every day. Review of systems is positive for severe abdominal pain. On physical examination, D.C. appears thin, and his abdomen is distended. Vital signs are notable for a temperature of 38.3°C, heart rate of 98 beats/minute, and a blood pressure (BP) of 108/71 mmHg. He is 6 feet tall and weighs 60.5 kg. His medical record indicates that 1 month ago he weighed 64 kg, and 6 months ago, his weight was 70 kg. Abdominal radiographs are consistent with a small bowel obstruction.

Admission laboratory values are Na, 131 mEq/L (normal, 135–145); K, 3.2 mEq/L (normal, 3.5–5.0); Cl, 98 mEq/L (normal, 100–110); HCO₃⁻, 28 mEq/L (normal, 24–30); BUN, 19 mg/dL (normal, 8–20); creatinine, 0.9 mg/dL (normal, 0.8–1.2); glucose, 105 mg/dL (normal, 85–110); albumin, 3.2 g/dL (normal, 3.5–5.0); WBC count, 10,900/mm³ (normal, 4,000–12,000); hematocrit (Hct), 46% (normal, 34%–50%); alanine aminotransferase (ALT), 29 U/L (normal, 20–70); aspartate aminotransferase (AST), 25 U/L (normal, 20–55); alkaline phosphatase, 45

U/L (normal, 40–125); and total bilirubin, 0.5 mg/dL (normal, 0–1.2).

D.C. is admitted with a diagnosis of a small bowel obstruction secondary to a stricture or narrowed area in his small intestine. The plan is to manage him with IV fluids, bowel rest, decompression, and possible surgery. Why is D.C. a candidate for parenteral nutrition?

[SI units: Na, 131 mmol/L (normal, 135–145); K, 3.2 mmol/L (normal, 3.5–5.0); Cl, 96 mmol/L (normal, 100–110); HCO₃⁻, 28 mmol/L (normal, 24–30); BUN, 6.78 mmol/L (normal, 3–6.4); creatinine, 54 μmol/L (normal, 50–110); glucose, 6.5 mmol/L (normal, 4.7–6.1); albumin, 32 g/L (normal, 35–50); WBC count, 10.9 × 10⁹/L (normal, 4–12); Hct, 0.46 (normal, 0.34–0.50); ALT, 0.334 μkat/L (normal, 0.03–0.4); AST, 0.25 μkat/L (normal, 0.1–0.28); alkaline phosphatase, 0.75 μkat/L (normal, 0.48–1.5); total bilirubin, 8.5 μmol/L (normal, 0–20)]

Parenteral nutrition should be considered when the patient's nutrient intake has been inadequate for 7 days or longer and the GI tract is not functioning. D.C. has eaten little in the past week, and his 5% decrease in weight is of concern. Furthermore, his weight has decreased by more than 10% over the past 6 months, which is considered a severe weight loss. D.C. is not expected to resume oral intake because his small bowel obstruction is being managed conservatively with bowel rest and decompression.

Assessment of weight loss should include evaluation of hydration status, especially because D.C.'s vomiting and minimal oral intake for the past week place him at risk of dehydration. Loss of lean body mass is probably less than that reflected by the decrease in weight. Although D.C. may be dehydrated, he also may have significant loss of muscle resulting from his chronic intake of prednisone, which stimulates gluconeogenesis and muscle breakdown for amino acids. In addition, D.C.'s admission serum albumin concentration is low at 3.2 g/dL. His hydration status should be considered when evaluating this visceral protein, since D.C.'s serum albumin concentration will probably decrease further after he is rehydrated.

One factor contributing to his low serum albumin is the loss of proteins from the GI tract (protein-losing enteropathy) during exacerbations of his Crohn's disease. Continued inadequate nutrient intake increases his risk of malnutrition. Some type of specialized nutrition support should be initiated, and because D.C.'s GI tract is not functioning, parenteral nutrition is indicated.

11. What type of malnutrition does D.C. have?

At this point, D.C. exhibits some loss of fat and muscle, as well as depletion of visceral proteins. He has components of both marasmus and kwashiorkor malnutrition; therefore, he would be considered to have mixed protein-calorie malnutrition.

Calorie and Protein Goals

12. After hydration with IV fluids, D.C.'s weight is 62.5 kg. Parenteral nutrition therapy was delayed because, within 24 hours after admission, D.C. developed severe abdominal pain and distention and required surgery. An exploratory laparotomy was performed, and 25 cm of ileum was resected to remove the area of bowel with severe disease and a stricture that was causing the obstruction. A small abscess near his colon was also drained. His postoperative medications include hydrocortisone 100 mg IV Q 8 hr and piperacillin-tazobactam 4.5 g IV Q 6 hr. Bowel sounds

are absent. He has a right subclavian triple-lumen central venous catheter and a nasogastric (NG) tube output of 1,800 mL/day. His urine output is 1,400 mL/day. Parenteral nutrition is to begin on postoperative day 1. Calculate energy and protein goals for D.C.

Using the Harris-Benedict equation for men, his current weight of 62.5 kg, height of 182.9 cm, and age of 38 years, D.C.'s BEE is 1,583 kcal/day (Table 37-3). To estimate his total energy expenditure, the BEE should be modified with an activity factor for being confined to bed of 1.2 and a stress factor of 1.2 for surgery. These modifications result in an estimated energy expenditure of 40% greater than his BEE, or 2,216 kcal/day. Using the simpler method for moderate stress (27 kcal/kg/day) results in an estimated energy expenditure of 1,875 kcal/day. Therefore, an energy goal of 2,000 kcal/day is reasonable. In a similar manner, his protein goal (Table 37-4) for moderate stress is 75 to 94 g/day of protein (1.2–1.5 g/kg/day).

Formulation Design

13. Design a single daily bag, TNA parenteral nutrient formulation for D.C. that provides 2,200 kcal and 90 g of amino acids with a nonprotein calorie distribution of 75% carbohydrate and 25% lipid. The macronutrients available on the formulary for compounding the parenteral nutrient formulations are 70% dextrose, 30% lipid emulsion, and 10% amino acids.

1. Amino acids calculation

$$\begin{aligned} \text{Calories from amino acids (protein)} &= 90 \text{ g} \times 4.0 \text{ kcal/g} \\ &= 360 \text{ kcal} \end{aligned}$$

$$\begin{aligned} \text{mL of 10\% amino acids} &= \frac{90 \text{ g}}{0.1 \text{ g/mL}} \quad (37\text{-C}) \\ &= 900 \text{ mL} \end{aligned}$$

2. Dextrose calculation

$$\begin{aligned} \text{Calories from dextrose} &= (2,200 - 360)(0.75) \\ &= 1,380 \text{ kcal} \end{aligned}$$

$$\begin{aligned} \text{g of dextrose} &= \frac{1,380 \text{ kcal}}{3.4 \text{ kcal/g}} \quad (37\text{-D}) \\ &= 406 \text{ g} \end{aligned}$$

$$\begin{aligned} \text{mL of 70\% dextrose} &= \frac{406 \text{ g}}{0.7 \text{ g/mL}} \\ &= 580 \text{ mL} \end{aligned}$$

3. Lipid emulsion calculation

$$\begin{aligned} \text{Calories from lipid} &= (2,200 - 360)(0.25) \text{ or} \\ &\quad (1,840 - 1,380) \\ &= 460 \text{ kcal} \end{aligned}$$

$$\begin{aligned} \text{mL 30\% lipid emulsion} &= \frac{460 \text{ kcal}}{3.0 \text{ kcal/mL}} \quad (37\text{-E}) \\ &= 153 \text{ mL} \end{aligned}$$

4. Calculation of final volume

$$\begin{array}{r} 900 \text{ mL amino acids } 10\% \\ 580 \text{ mL dextrose } 70\% \\ 153 \text{ mL lipid emulsion } 30\% \\ \hline 1,633 \text{ mL total volume} \end{array} \quad (37\text{-F})$$

Other additives such as electrolytes, vitamins, and trace elements are included in the parenteral nutrient formulation and slightly increase the final volume to 1,800 mL/day. The infusion rate for this formulation can be calculated as follows:

$$\begin{aligned} \text{Hourly infusion rate (mL/hr)} &= \frac{1,800 \text{ mL/day}}{24 \text{ hr/day}} \\ &= 75 \text{ mL/hr} \quad (37\text{-G}) \end{aligned}$$

D.C.'s parenteral nutrient formulation of 1,800 mL/day will not meet his maintenance fluid needs of 2,350 mL/day (see question 7). He will require extra fluid to meet the remainder of his basic fluid needs plus additional fluid to replace the fluid loss from his NG tube. These additional fluids should be provided through another IV.

Monitoring and Management of Complications

METABOLIC COMPLICATIONS: ESSENTIAL FATTY ACID DEFICIENCY

14. What consequences are associated with providing only dextrose and amino acids to meet D.C.'s nutrient needs?

A small amount of lipid is necessary to prevent essential fatty acid deficiency (EFAD). The essential fatty acids, linoleic and alpha-linolenic, are those that cannot be synthesized by humans. Of these, linoleic acid appears to be the only one required by adults. The continuous infusion of hypertonic dextrose from the parenteral nutrition is associated with high circulating concentrations of insulin. Because insulin promotes lipogenesis rather than lipolysis, linoleic acid cannot be released from adipose tissue.⁴⁵

Clinical symptoms of EFAD are dry, thickened, scaly skin, hair loss, poor wound healing, and thrombocytopenia, which may be observed after a few weeks to months of lipid-free parenteral feedings.⁴⁶ Biochemical evidence of EFAD, determined by a triene:tetraene ratio of >0.4, may be seen after 1 week of lipidfree parenteral feedings and is characterized by a decrease in the serum concentrations of linoleic and arachidonic acids and an increase in the concentration of 5,8,11-eicosatrienoic acid.⁴⁵ The requirement for essential fatty acids is 1% to 4% of total caloric intake and can usually be met by the administration of 500 mL of a 10% lipid emulsion twice weekly or 500 mL of a 20% lipid emulsion once a week to patients receiving a dextrose/amino acid parenteral nutrient formulation.^{10,45} The lipid emulsions should be infused at a rate of <0.11 g/kg/hour to prevent adverse effects, which include impaired hepatic, pulmonary, immune, and platelet function.³⁵

METABOLIC CONSEQUENCES OF EXCESSIVE DEXTROSE ADMINISTRATION

15. What are the benefits of using a mixed-fuel system, combining dextrose and fat to meet energy needs?

Providing a portion of nonprotein calories as fat may reduce the metabolic consequences of excessive dextrose administration. The maximum rate of dextrose metabolism in humans is 5 to 7 mg/kg/minute, or approximately 7 g/kg/day. In doses of

>7 g/kg/day, dextrose is used inefficiently and is converted to fat.⁴⁶ The conversion to fat may be associated with respiratory compromise and hepatic dysfunction.⁴⁷⁻⁴⁹ Hyperglycemia, another complication of excessive dextrose infusion, is associated with electrolyte and acid-base disturbances, osmotic diuresis, increased risk of infections (especially *Candida albicans*), and altered phagocyte and complement function. Furthermore, using a mixed-fuel system allows the administration of a small amount of IV lipid daily and avoids the need for larger boluses of lipid twice weekly to prevent EFAD. Rapid administration of IV lipids has been associated with alterations in the reticuloendothelial system that are not observed with continuous administration of small doses.⁵⁰ Typically, a mixed-fuel system provides 15% to 30% of nonprotein calories as fat, 70% to 85% as carbohydrate.

Total Nutrient Admixtures

16. What are the advantages to combining the dextrose, fat, and amino acids in one container?

The system of providing one container per day offers the advantage of convenience to pharmacy staff, nursing personnel, and the patient. The pharmacy department usually prepares TNA only once per day and therefore requires fewer supplies and inventory; waste of unused feeding formulations is minimized as well. Nursing time to administer TNAs is decreased because only one bag is hung per day, minimizing venous catheter interruptions and avoiding the need to manipulate a secondary infusion of lipid emulsions, as well as additional IV tubing and an infusion pump.⁵¹

Although there are many practical benefits to using TNA parenteral feeding formulations, this system is not without concerns. These formulations must be mixed in plastic containers constructed with ethylvinylacetate. Containers with diethylhexylphthalate (DEHP) should be avoided because this toxic material may be extracted by the lipid and may harm patients. The addition of lipid to the traditional mixture of dextrose and amino acids converts this solution to a complex emulsion formulation with physiologic differences that alter the stability of the product.⁵² These differences must be considered in the compounding of TNA parenteral feeding formulations.

STABILITY

17. How stable are the TNA parenteral feeding formulations?

IV lipid emulsions alone gradually deteriorate over time because of increased formation of free fatty acids and a resultant decrease in pH. When lipids are mixed with dextrose and amino acids, this process is accelerated. IV lipid products commercially available in the United States use an anionic egg yolk phosphatide emulsifier, which stabilizes the lipid droplets of the dispersed phase with the aqueous external phase and maintains the integrity of the dispersion. Because the emulsifier is anionic, the addition of any substance with cationic properties can neutralize the negative charge of the emulsifier and alter the emulsion's stability. When the emulsion becomes unstable or breaks down, the fat particles begin to aggregate and the particle size increases.

Destabilization of the emulsion occurs in steps that begin with creaming and end with the coalescence of the lipid particles, or "cracking" of the emulsion. A decrease in pH and the

addition of divalent cations (Mg^{2+} , Ca^{2+}) increase fat particle size. Although dextrose decreases the pH, the addition of amino acids provides an adequate buffer for this variable. The amount of divalent cations added to TNAs should be limited to minimize the risk of emulsion instability. Trivalent cations such as iron should never be added to a TNA parenteral nutrient formulation. Nutrient formulations containing lipid must be assessed visually for signs of phase separation, in which the instability of the emulsion is manifested by "oiling out," indicated by a continuous layer of oil or individual fat droplets. Fat emulsion particles have an average size of 0.5 μm . A destabilized emulsion is not visibly apparent until the lipid particles are 40 to 50 μm . Fat particles as small as 5 μm may occlude pulmonary capillaries.^{51,52} Therefore, the use of a 1.2- μm filter is recommended to protect against the infusion of enlarged lipid particles.^{34,51}

Using dual-chamber bags may extend the shelf life of TNAs because they allow the lipid to be physically separated from the dextrose, amino acids, and other additives until it is time to administer the feeding. The use of dual-chamber bags has the greatest advantage for the home care setting, where up to a week's supply of parenteral feedings are prepared at one time.⁵¹

After preparation, TNAs should be refrigerated (4°C) to preserve stability. Once the bag is removed from the refrigerator, it may be warmed to room temperature and the contents mixed well before administration. Mixing is best accomplished by gently inverting the container up and down to ensure top-to-bottom transfer of the fluid. Vigorous shaking should be avoided because it introduces air, which can destabilize the emulsion.^{51,52}

MICROBIAL GROWTH

18. How does the microbial growth in TNAs compare with that of dextrose/amino acid formulations?

Dextrose/amino acid parenteral nutrient formulations are not conducive to growth of most organisms because of their high osmolarity (>2,000 mOsm/L) and acidic pH. Lipid emulsions alone, however, are isotonic and have a physiologic pH, providing an optimal growth medium. Combining these three substrates in a TNA provides a formulation with a microbial growth potential that is intermediate between these two.^{51,52} The number of central venous catheter violations or manipulations correlates strongly with the incidence of catheter-related infections. From an infection control perspective, the use of a single daily bag TNA system limits the number of manipulations of the central venous catheter to one per day, thereby minimizing touch contamination. The Centers for Disease Control and Prevention guidelines allow TNA or dextrose/amino acid formulations to hang for up to 24 hours. However, because of concerns about the potential of lipid emulsions to support microbial growth, the hang time for lipids when administered alone is 12 hours.⁵¹

MICRONUTRIENTS

Electrolytes

19. D.C.'s current laboratory values are Na, 137 mEq/L; K, 4.5 mEq/L; Cl, 102 mEq/L; HCO_3^- , 26 mEq/L; BUN, 9 mg/dL; creatinine, 0.8 mg/dL; glucose, 148 mg/dL; Ca, 8.9 mg/dL (normal, 8.5-10.0); Mg, 1.9 mg/dL (normal, 1.6-2.2); P, 2.8 mg/dL (normal,

Table 37-6 Guidelines for Daily Electrolyte Requirements

| Electrolyte | Amount |
|------------------------|-------------------------|
| Sodium | 80–100 mEq |
| Potassium | 60–80 mEq |
| Chloride | 50–100 mEq ^a |
| Acetate | 50–100 mEq ^a |
| Magnesium | 8–20 mEq |
| Calcium | 10–15 mEq |
| Phosphorus (phosphate) | 20–40 mmol |

^aAs needed to maintain acid–base balance.

2.4–4.5); and albumin, 3.0 mg/dL. Which electrolytes should be included in D.C.’s parenteral nutrient formulation?

[SI units: Na, 137 mmol/L; K, 4.5 mmol/L; Cl, 102 mmol/L; HCO₃⁻, 26 mmol/L; BUN, 3.2 mmol/L; creatinine, 48 μmol/L; glucose, 8.2 mmol/L; Ca, 2.22 mmol/L; Mg, 9.5 mmol/L; P, 0.9 mmol/L; albumin, 30 g/L]

Electrolytes added are sodium, potassium, chloride, acetate (which is metabolized to bicarbonate), magnesium, calcium, and phosphate. Electrolytes should be added to the parenteral nutrient formulation based on the individual patient’s needs. However, patients without significant fluid and electrolyte losses, hepatic or renal dysfunction, or acid–base disturbances do well with maintenance doses of electrolytes. Electrolytes may be added individually or as commercially available combination products of maintenance doses, but the electrolyte content of the amino acid solution should be considered. General guidelines for electrolyte requirements for parenteral feedings are included in Table 37-6.

Vitamins and Trace Elements

20. What doses of multiple vitamins and trace elements should D.C. receive in his parenteral nutrient formulation?

Vitamins and trace elements are essential for normal metabolism and should be included in a patient’s daily parenteral nutrition regimen. Guidelines for the 13 essential vitamins have been established by the Nutrition Advisory Group of the American Medical Association⁵³ (Table 37-7).

Guidelines for daily doses of the trace elements zinc, copper, chromium, and manganese have also been developed.⁵⁴ In addition to these trace elements, many practitioners provide selenium on a daily basis. Recommended doses of the trace elements are listed in Table 37-8. As with vitamins, trace elements are available as single entities or combination products. Molybdenum and iodine are also available commercially.

21. D.C.’s daily parenteral nutrient formulation of 1,800 mL provides 2,200 calories (75% nonprotein calories as carbohydrate, 25% as fat) and 90 g of amino acids with the following additives per daily volume: NaCl, 75 mEq; K acetate, 70 mEq; phosphate as Na, 27 mmol; MgSO₄, 16 mEq; calcium gluconate, 10 mEq; and standard doses of adult multivitamins and multiple trace elements providing copper, chromium, manganese, selenium, and zinc. The infusion is initiated at a rate of 40 mL/hour. Why is this slow infusion rate selected?

Standard practice for administering parenteral nutrient formulations containing hypertonic dextrose is to begin at a slow

Table 37-7 Recommended Adult Daily Doses of Parenteral Vitamins

| Vitamins | Dose |
|-----------------------------------|---|
| Fat-Soluble Vitamins | |
| A | 3,300 IU (990 retinol equivalents) |
| D | 200 IU (5 mg cholecalciferol) |
| E | 10 IU (6.7 mg/dL- α -tocopherol) |
| K | 150 mcg |
| Water-Soluble Vitamins | |
| Thiamine (B ₁) | 6 mg |
| Riboflavin (B ₂) | 3.6 mg |
| Niacin (B ₃) | 40 mg |
| Pyridoxine (B ₆) | 6 mg |
| Cyanocobalamin (B ₁₂) | 5 mcg |
| Folic acid | 600 mg |
| Pantothenic acid | 15 mg |
| Biotin | 60 mcg |
| Ascorbic acid (C) | 200 mg |

infusion rate of <250 g during the first 24 hours for most patients and <150 g for patients with known diabetes mellitus or hyperglycemia. The infusion is increased slowly over the next 24 to 48 hours to the goal infusion rate. This initial period allows the clinician to assess the patient’s ability to tolerate the nutrient formulation components and to avoid metabolic complications, primarily hyperglycemia.⁴⁵ If D.C.’s serum glucose level remains <150 mg/dL, the parenteral nutrient formulation infusion rate can be increased to his goal rate of 75 mL/hour.

Monitoring and Management of Complications

METABOLIC COMPLICATIONS

Parenteral nutrition therapy may be associated with multiple metabolic complications. The most common abnormalities are hypokalemia, hypomagnesemia, hypophosphatemia, and hyperglycemia. The plan for parenteral nutrition therapy should include routine monitoring of these serum chemistries to identify complications early and institute methods to manage or prevent complications.

22. Over the next 24 hours, D.C.’s infusion rate is increased to the goal rate of 75 mL/hour. A comparison of his intake and output reveals an overall negative fluid balance because a high volume of gastric fluid is being removed via the NG tube. Laboratory values at this time are Na, 138 mEq/L; K, 3.1 mEq/L; Cl, 91 mEq/L; HCO₃⁻, 33 mEq/L; BUN, 28 mg/dL; creatinine, 0.9 mg/dL; glucose, 279 mg/dL; Ca, 7.8 mg/dL; Mg, 1.4 mg/dL; P, 1.8 mg/dL;

Table 37-8 Recommended Daily Adult Doses of Parenteral Trace Elements

| Trace Element | Dose |
|---------------|------------|
| Zinc | 2.5–5 mg |
| Copper | 0.3–0.5 mg |
| Chromium | 10–15 mcg |
| Manganese | 60–100 mcg |
| Selenium | 20–60 mcg |

and albumin, 2.8 g/dL. Arterial blood gas (ABG) results are pH, 7.46 (normal, 7.37–7.44); PO₂, 98 (normal, 85–100); PCO₂, 47 (normal, 35–45); and HCO₃⁻, 31 (normal, 24–30). What factors contribute to these metabolic abnormalities?

[SI units: Na, 130 mmol/L; K, 3.1 mmol/L; Cl, 91 mmol/L; HCO₃⁻, 33 mmol/L; BUN, 8.96 mmol/L; creatinine, 75 μmol/L; glucose, 15.5 mmol/L; Ca, 1.92 mmol/L; Mg, 0.8 mmol/L; P, 0.58 mmol/L; albumin, 28 g/L]

Hypokalemia

Hypokalemia, a common metabolic abnormality associated with the initiation of parenteral nutrition, usually occurs within 24 to 48 hours. Potassium moves, along with dextrose, from the extracellular to the intracellular space. Furthermore, building lean body mass (i.e., anabolism) requires approximately 3 mEq of potassium per gram of nitrogen provided by the amino acids. Administering dextrose promotes repletion of glycogen stores, which also requires potassium.^{41,45,55}

D.C.'s decreased serum potassium concentration is compounded by metabolic alkalosis caused by his loss of gastric secretions through the NG tube and the administration of hydrocortisone. With this type of metabolic alkalosis, the renal excretion of potassium is increased. Additional potassium should be administered and can be provided in D.C.'s parenteral feeding or through another IV.

Hypomagnesemia

Magnesium, like potassium, is primarily an intracellular cation and is considered an anabolic electrolyte. It is common to observe decreases in magnesium serum concentrations during the administration of parenteral nutrient formulations. Synthesis of lean tissue requires 0.5 mEq magnesium per gram of nitrogen.^{41,45,55} Additional magnesium can be added to the parenteral nutrient formulation. However, when a TNA formulation is used, the amount of magnesium must stay within the guidelines for the cation content to maintain the stability of the lipid emulsion.

Hypophosphatemia

Hypophosphatemia occurs when phosphorus moves into the cells for the synthesis of adenosine triphosphate (ATP), an important energy carrier. Phosphorus is depleted quickly with the administration of hypertonic dextrose, especially in malnourished patients (see question 8 for discussion of refeeding syndrome). The phosphorus is used for ATP synthesis, primarily in the liver and skeletal muscle. Alkalosis also decreases phosphate stores by stimulating the phosphorylation of carbohydrates. As a component of 2,3-diphosphoglycerate (2,3-DPG), found in red blood cells (RBCs), phosphorus is necessary for the disassociation of oxygen from hemoglobin.⁵⁵

Clinical signs and symptoms of hypophosphatemia usually occur when serum concentrations fall below 1.0 mg/dL; they include lethargy, muscle weakness, impaired WBC function, glucose intolerance, rhabdomyolysis, seizures, hemolytic anemia, reduced diaphragmatic contractility, and death. Moderate to severe, complicated hypophosphatemia can be managed by administering up to 0.625 mmol/kg of phosphate IV.^{41,55–57} Although D.C.'s serum phosphorus is not <1.0 mg/dL, it is low (1.8 mg/dL), and he should receive 15 to 30 mmol phosphate in the parenteral nutrient formulation per day. Additional supplements may be necessary to replete his phosphorus stores.⁵⁶

Metabolic Alkalosis

D.C. has evidence of a metabolic alkalosis based on his ABG results, hypochloremia, and elevated bicarbonate level. The continued loss of fluid and HCl from the NG tube is the most probable cause of his metabolic alkalosis. Management of this type of metabolic alkalosis is to replace the fluid and chloride through another IV. Because acetate is converted to bicarbonate and can further contribute to the alkalosis, the acetate salts in the parenteral nutrient formulation can be changed to chloride salts.⁵⁵ Nevertheless, the parenteral nutrient formulation is not the primary vehicle for adjusting and supplementing electrolytes and fluids. Instead, the fluid and electrolyte balance should be adjusted with maintenance IV fluid and electrolyte supplements.

Hyperglycemia

Hyperglycemia is a common metabolic complication of parenteral nutrition therapy, especially in stressed patients. Stress alone increases gluconeogenesis, and the administration of hypertonic dextrose compounds the potential for hyperglycemia.⁵⁸ D.C. is at particular risk for hyperglycemia because he is recovering from surgery and is receiving steroids, which increase gluconeogenesis.

Persistent hyperglycemia leads to glucosuria and an osmotic diuresis, resulting in dehydration and concomitant electrolyte abnormalities. It also compromises the immune response by causing abnormalities in chemotaxis and phagocytosis and by impairing complement function. Hyperglycemia is associated with an increased risk of infections, especially *C. albicans*. In extreme cases, hyperglycemia progresses to hyperosmolar, nonketotic acidosis and coma, a condition associated with 40% mortality.

Hyperglycemia can be minimized by limiting the dextrose infusion rate to <4 mg/kg/minute.⁵⁹ (D.C.'s parenteral nutrient formulation provides 4 mg/kg/minute.) Other measures that will minimize the risk of hyperglycemia include gradually increasing the parenteral nutrient formulation infusion rate, frequently monitoring capillary blood glucose concentrations, and advancing therapy only when the serum glucose is consistently <150 mg/dL for stable patients and <120 mg/dL for critically ill patients. Insulin therapy should be considered if serum glucose concentrations exceed these parameters and can be administered subcutaneously according to a sliding scale, IV by continuous infusion, or by adding insulin to the parenteral nutrient formulation.^{60,61} Only regular insulin can be added to a parenteral nutrient formulation. A reasonable strategy for adding insulin to the parenteral nutrient formulation is to begin with 0.1 U of regular insulin per gram of dextrose. This dosage is adjusted depending on serum glucose concentrations.⁶⁰ Clinical evidence suggests that treatment of hyperglycemia and maintenance of euglycemia may reduce morbidity and mortality, length of stay, and hospital costs.^{61–65}

Formulation Design

Compatibility

23. In response to these serum chemistries, the electrolytes in D.C.'s parenteral nutrient formulation are changed to the following per liter: NaCl, 160 mEq; KCl, 140 mEq; phosphate as K, 60 mmol; MgSO₄, 54 mEq; and calcium gluconate, 30 mEq. How

do the doses of calcium and phosphate compare to maintenance doses? What calcium and phosphate incompatibilities should be anticipated? Will the calcium and magnesium content alter the lipid stability?

The dose of calcium ordered for D.C. is more than three times the usual maintenance dose (Table 37-7). This amount of calcium is not necessary because the observed hypocalcemia merely reflects D.C.'s low serum albumin concentration; therefore, less calcium is bound to albumin. D.C. probably does not have true hypocalcemia because his free (or ionized) calcium, which is critical for physiological function, has not changed. If available, obtaining an ionized calcium concentration is advised. However, some laboratories do not have this test available. In this situation, a "corrected" calcium formulation may be used. For every 1-g/dL decrease in serum albumin concentration, there will be about a 0.8-mg/dL reduction in the serum calcium concentration.⁶⁶ For D.C., a serum calcium of 7.8 mg/dL will correct to a serum concentration of 8.8 mg/dL ($[4.0-2.8 \text{ g/dL albumin}][0.8] + 7.8 \text{ mg/dL calcium}$).

The amount of phosphate prescribed for D.C. at this time exceeds the usual recommended dose of 15 to 30 mmol/day (Table 37-6). Although D.C. has a low serum phosphorus concentration and needs additional phosphate, increasing the dosage in the parenteral nutrient formulation to 60 mmol/day may be incompatible with the calcium content, resulting in calcium phosphate precipitation. Administering a parenteral nutrient formulation containing calcium phosphate crystals may occlude blood flow, especially in the lungs, and has been associated with adverse events, such as respiratory distress and death.^{34,67}

It is important to consider the factors that affect calcium phosphate solubility and to take measures that ensure the solubility limits are not exceeded when preparing parenteral nutrient formulations. The *in vitro* precipitation of calcium phosphate depends on multiple factors, including the calcium salt, concentrations of calcium and phosphate, amino acid concentration, temperature, pH of the formulation, and infusion time. Using calcium gluconate rather than the chloride salt can enhance calcium phosphate solubility. In solution at equimolar concentrations, calcium chloride dissociates more than calcium gluconate, thereby increasing the yield of free calcium available for binding with phosphate.

The amounts of calcium and phosphorus in the formulation are critical. Multiple investigators have varied the calcium and phosphate concentrations in parenteral nutrient formulations and have developed precipitation curves to assist practitioners in determining the amounts of calcium and phosphate that can be added safely to nutrient formulations. These guidelines help predict the points at which calcium phosphate precipitation is likely to occur. However, extrapolating these data to parenteral nutrient formulations different from those described is difficult because these mixtures are extremely complex, and numerous variables affect the interrelationship between calcium and phosphate.

The solubility of calcium and phosphate must be determined based on the volume of the formulation at the time the calcium and phosphate are mixed together, not the final volume. For example, if the electrolytes including calcium and phosphate are added to 1,000 mL of a dextrose/amino acid mixture and then 300 mL of IV fat is added, the calcium phosphate solubility is based on the 1,000 mL, not the final 1,300 mL volume. In ad-

dition, some amino acid products contain phosphate ions, and these should be considered when determining calcium phosphate solubility.³⁴

Last, calcium and phosphate should not be added to the parenteral nutrient formulation in close sequence. It is recommended to add phosphate first and calcium last, thereby taking advantage of the maximum parenteral volume. Also, during preparation, the parenteral nutrient formulation should be agitated periodically and inspected for precipitates.⁶⁸ Other guidelines for improving the solubility of calcium are a final amino acid concentration of >2.5% and a pH <6. Temperature is a critical variable, and an increase in the ambient temperature can facilitate the precipitation of calcium phosphate. Formulations should be infused within 24 hours after compounding if stored at room temperature; if refrigerated, they should be infused within 24 hours after rewarming. Furthermore, slow infusions may decrease solubility. Increasing temperature and slow infusions may result in precipitation in the IV catheter, even if precipitation has not occurred in the infusion container.³⁴

The amount of divalent cations, calcium (20 mEq) and magnesium (30 mEq), exceeds the general guidelines for maximum amounts that can be added safely to a TNA without disrupting the stability of the lipid emulsion. A limit of 20 divalent cations per liter is a general guideline. The amount prescribed for D.C.'s regimen is excessive because it provides 50 divalent cations in 1.8 L (28 divalent cations/L) and may result in a potentially unstable admixture.

Last, a 1.2- μm air-eliminating filter should be used when infusing TNA parenteral nutrient formulations, and a 0.22- μm air-eliminating filter should be used for non-lipid-containing admixtures.³⁴

Medication Additives

24. In addition to his parenteral nutrient formulation, D.C. is receiving ranitidine 50 mg IV Q 8 hr and hydrocortisone 100 mg IV Q 8 hr, and now he needs insulin. Can these medications be mixed with his parenteral nutrient formulation to simplify his medication regimen?

Patients receiving parenteral nutrition therapy often require concomitant drug therapy. Most patients have adequate venous access or have multiple-lumen central venous catheters, so that mixing medications with the parenteral nutrient formulation is not an issue. However, for some patients with limited venous access, directly added medications or piggybacking medications via a secondary infusion must be considered.

The stability of medications when mixed with parenteral nutrient formulations is a complex issue. Some medications may be added directly to the parenteral nutrient formulation, whereas others should be administered via a secondary infusion set (piggybacked). Many medications have been studied for physical compatibility, but few have been evaluated for pharmacologic activity. Furthermore, the study conditions vary, and different nutrient formulations have been used; therefore, interpretation and application of data from a particular scientific study to a specific nutrient formulation may be difficult. This area of knowledge is growing rapidly, and current information regarding compatibility and stability is available in standard references such as Trissel's *Handbook of Injectable Drugs*.⁶⁹

Although insulin, antibiotics, chemotherapeutic agents, H₂-receptor antagonists, and heparin have been considered for

addition to parenteral nutrient formulations in some specific circumstances, the routine addition of medications to parenteral nutrient formulations is discouraged. The addition of insulin to parenteral nutrient formulations may be an option, as described in question 23.

MONITORING PARAMETERS

25. Design a plan to monitor the adequacy of D.C.'s specialized nutrition support and to identify and prevent adverse complications.

Routine evaluation of patients receiving nutrition support should include an assessment of nutrition and the metabolic effects of therapy. Goals for nutrition therapy are estimates of a patient's needs; therefore, the adequacy of therapy to meet these needs must be evaluated. Daily monitoring parameters must include vital signs, body weight, temperature, serum chemistries, hematologic indices, nutrition intake, and fluid intake and output.

The adequacy of nutrition therapy should be assessed weekly. This may include measuring serum concentrations of visceral proteins (Table 37-2). Because prealbumin has a half-life of only 2 to 3 days, serum concentrations of this protein should increase with adequate nutrition and improving clinical status. Albumin, with a much longer half-life, may not change for several weeks to months despite provision of adequate nutrients. In addition, it is reasonable to perform indirect calorimetry to reassess energy expenditure.

Another method to assess the adequacy of protein intake is to evaluate nitrogen balance. This test is designed to estimate the amount of nitrogen retained by comparing the amount of nitrogen administered to the amount of nitrogen excreted (amount "in" vs. amount "out"). The nitrogen "in" is provided by the amino acid component of the parenteral nutrient formulation and other sources from tube feeding or an oral diet. Each commercially available amino acid formulation has a slightly different amount of nitrogen per gram of amino acids, and the manufacturer's product information should be consulted to obtain this value. An average value is 6.2 g of nitrogen per gram of amino acids.

Most of the nitrogen is excreted as byproducts of protein breakdown for energy. This nitrogen is excreted in the urine as urea nitrogen, which increases with increasing stress. To determine this value, urine must be collected for 24 hours and the amount of urea nitrogen (UUN) measured. Some laboratories have the capability of measuring total urine nitrogen, which measures all nitrogen entities in the urine. In addition, some nitrogen lost via skin, respiration, and stool is not measurable but is estimated to be 2 to 4 g/day.

$$\begin{aligned} \text{Nitrogen balance} &= \text{Nitrogen in} - \text{Nitrogen out} \\ &= \frac{\text{AA(g)}}{6.2} - (\text{UUN(g)} + 3 \text{ g}) \quad (37-3) \\ &= \text{g} \end{aligned}$$

Achieving a positive nitrogen balance is difficult, if not impossible, in critically ill patients; therefore, the calculation may result in a negative number or zero. For convalescing patients, a nitrogen balance of plus 2 to 4 g is acceptable. A negative nitrogen balance prompts a re-evaluation of the amount of protein and energy a patient is receiving. For patients with a negative

Table 37-9 Routine Monitoring Parameters for Parenteral Nutrition

Before Initiating Therapy

Body weight
Serum electrolytes (Na, K, Cl, HCO₃⁻, BUN, creatinine)
Glucose
Ca, Mg, P
Albumin, transthyretin
Triglycerides
Complete blood count
Liver-associated tests (AST, ALT, alkaline phosphatase, bilirubin)
INR, Prothrombin time

Daily

Body weight
Vital signs (pulse, respirations, temperature)
Fluid intake
Nutritional intake
Output (urine, other losses)
Serum electrolytes (Na, K, Cl, HCO₃⁻, BUN, creatinine)
Glucose

Two or Three Times a Week

CBC
Ca, Mg, P

Weekly

Albumin, transthyretin
Liver-associated tests (AST, ALT, alkaline phosphatase, bilirubin)
INR, prothrombin time
Nitrogen balance

ALT, alanine aminotransferase; AST, aspartate aminotransferase; BUN, blood urea nitrogen; Ca, calcium; CBC, complete blood count; Cl, chloride; HCO₃⁻, bicarbonate; INR, international normalized ratio; K, potassium; Mg, magnesium; Na, sodium; P, phosphorus.

nitrogen balance, it may be helpful to increase intake of both calories and protein.

As with all tests, assessment should include monitoring several parameters, including the patient's clinical status. Most important is the identification of trends that may alert one to impending complications. A suggested schedule for monitoring is provided in Table 37-9.

Home Therapy

Enterocutaneous Fistulas

26. S.A. is a 24-year-old female hospitalized following an abdominal trauma injury. Her hospital course includes abdominal surgery to repair a small bowel perforation. On hospital day 10, she presents with a fever and green, purulent fluid draining from a small hole in her previous abdominal incision site. She is diagnosed with an enterocutaneous fistula, which is a communication between her intestine and the skin. The fluid loss from S.A.'s fistula is about 1,300 mL/day. Management will include nothing by mouth (NPO) and parenteral nutrition for 4 to 6 weeks in anticipation that the fistula will heal and further surgery can be avoided. The physician would like to begin parenteral nutrition therapy in the hospital with the plan to discharge S.A. home in a few days. S.A. is 5 feet 4 inch and weighs 54 kg.

Parenteral nutrition therapy in the home has allowed patients such as S.A. to be discharged after a much-shortened hospital stay. Candidates for home therapy must be physically and medically stable, have a strong support network in the home setting to assist with care, and have an appropriate home environment; they must be educated regarding the prescribed therapy.⁷⁰

The first step in designing a parenteral nutrition regimen is to estimate energy and protein needs. S.A. is 10 days post injury, and her estimated requirements would be 25 to 30 kcal/kg/day or 1,550 to 1,620 kcal/day. Protein goals must include adequate nitrogen (protein) for wound healing and replacement for losses from the enterocutaneous fistula. A goal of 1.5 to 1.8 g/kg/day (81–97 g) is reasonable.

To simplify her nutrition and fluid regimen, all of S.A.'s fluids, including parenteral nutrients, electrolytes, vitamins, trace minerals, and water, should be provided in one container per day. S.A.'s home parenteral nutrient formulation can be provided in 3,000 mL/day to meet maintenance requirements (30–35 mL/kg/day) and to replace losses from her enterocutaneous fistula (1,300 mL/day). Nutrients provided include 95 g amino acids (390 kcal); 217 g dextrose (750 kcal); 38 g lipid (375 kcal); and electrolytes, vitamins, and minerals to maintain normal serum chemistries. Initially, daily intake and output must be monitored; therapy should be adjusted based on this information and S.A.'s clinical status.

Adjustments in fluids and electrolytes may be needed. The fluids secreted by the GI tract are rich in electrolytes, including sodium, potassium, chloride, and bicarbonate. Measurement of the electrolyte content of the fistula fluid will determine those that must be replaced, and in what quantities. Both fluid and electrolytes should be replaced to prevent dehydration and electrolyte and acid–base imbalances.

In addition to losses of fluids and electrolytes, the trace element zinc is lost in fluid from the small intestine. Approximately 12 mg of zinc is lost in each liter of small bowel fluid, and this should be replaced to prevent zinc deficiency. Furthermore, zinc may play a role in wound healing.⁷⁰ Management of enterocutaneous fistulas may include octreotide 50 to 100 mg given subcutaneously two or three times daily or added to the parenteral nutrient formulation to decrease fistula output.⁷¹

A home infusion pharmacy will be responsible for preparing S.A.'s parenteral nutrient formulations. Typically, nutrient formulations for 7 days are prepared and delivered to the patient's home. These formulations must be refrigerated until administration; however, formulations should be warmed to room temperature and visually inspected for particulate matter before being administered. Because some additives such as multivitamins are not stable for long periods, the patient or caregiver must add these to the parenteral nutrient formulation just before administration.

Patients and caregivers preparing for home parenteral nutrition therapy must be taught how to manage home therapy. This includes assessment of fluid status, care of a central venous catheter, infection, and the technical aspects of administering parenteral feeding formulations.⁷²

Preparation for home parenteral nutrition will include placement of a central venous access device. Various devices are available for long-term therapy.^{29,31} However, because the duration of S.A.'s therapy is expected to be 4 to 6 weeks, she may be a good candidate for a PICC.

Cyclic Therapy

27. What other measures can be used to simplify S.A.'s parenteral feeding regimen and encourage ambulation?

After S.A.'s daily nutrient and fluid needs are consolidated and she is stable on that regimen, her parenteral nutrient regimen can be cycled. *Cycling* means infusing the parenteral nutrient formulation over <24 hours so there is some time free from therapy. Cycling is usually done gradually and depends on the patient's ability to tolerate the changes in fluid and dextrose intake. Initially, the infusion period is decreased by 2 to 6 hours, and the infusion rate is increased to compensate for the shorter infusion period. For example, a 24-hour infusion at 100 mL/hour would be changed to a 20-hour infusion at 120 mL/hour. This gradual adjustment is more likely to ensure that all nutrients are infused and well tolerated. With each incremental decrease in time, the infusion rate should be increased.

Vital signs, fluid intake and output, and serum electrolytes and glucose concentrations should be monitored during this period. The serum glucose concentration should be evaluated 30 minutes after the infusion is completed to be sure that hypoglycemia does not occur as the result of the rapid cessation of the nutrient formulation. If hypoglycemia occurs, the infusion rate can be tapered at the end of the infusion because a gradual decrease in glucose intake should minimize the potential for hypoglycemia. Furthermore, the infusion can be gradually increased to minimize sudden hyperglycemia at the beginning of the infusion. Infusion management devices used at home can automatically make these adjustments in the infusion rate. Eventually, the nutrient formulation can be infused over 10 to 12 hours during the night, leaving S.A. free from her infusion bag during the day.

METABOLIC COMPLICATIONS: ELEVATED LIVER-ASSOCIATED ENZYMES

28. After receiving home parenteral nutrition for 3 weeks, S.A.'s liver function tests are found to be elevated. Current values are bilirubin, 0.8 mg/dL (normal, 0–1.2); AST, 70 U/L (normal, 19–25); ALT, 90 U/L (normal, 19–72); and alkaline phosphatase, 100 U/L (normal, 38–126). Could her parenteral nutrition be contributing to these abnormalities?

Elevations in liver function tests are common in adults receiving long-term parenteral nutrition therapy and may be noted as early as 2 to 3 weeks after beginning therapy. The abnormalities are usually mild and transient and do not progress to significant liver dysfunction in adults. The predominant type of hepatobiliary dysfunction is steatosis, whereas other patients develop cholestasis or cholelithiasis. Liver-associated enzyme elevations usually resolve when parenteral nutrition therapy is discontinued. Rarely does this dysfunction proceed to hepatic failure.^{73,74}

Although parenteral nutrition-associated liver abnormalities were first noted more than 30 years ago, a cause-and-effect relationship has been difficult to establish because patients have many confounding factors that can also cause liver dysfunction, including medications, inflammatory bowel disease, and sepsis. Other contributing factors are overfeeding with parenteral nutrient formulations containing high amounts of carbohydrate, amino acid deficiencies, excess fat, EFAD, carnitine deficiency, choline deficiency, toxic effects of the amino

acid degradation products, bacterial overgrowth in the small intestine, and lack of stimulation of the GI tract.^{73,74} Other than avoiding overfeeding with carbohydrate and lipid, there are few options to prevent or manage parenteral nutrition–associated liver abnormalities. Potential treatments include metronidazole and supplements of ursodeoxycholic acid, choline, and carnitine. Patients with progressive liver disease may be candidates for liver and small bowel transplantation.⁷⁴

The elevations in S.A.'s liver enzymes should be monitored weekly for continued increases. Because she may not need lifelong parenteral nutrition therapy, the mild elevations are likely to resolve.

USE OF PARENTERAL NUTRITION IN SPECIAL DISEASE STATES

Hepatic Failure

29. V.G. is a 42-year-old woman with a 15-year history of alcohol abuse, cirrhosis, ascites, and esophageal varices who was admitted to the hospital 5 days ago with an upper GI bleed after a weekend drinking binge. She was supported initially with IV fluids, packed RBCs, and fresh frozen plasma. Endoscopic examination showed bleeding esophageal varices, which were banded. V.G.'s hospital course is now complicated by primary bacterial peritonitis causing a paralytic ileus. On physical examination, V.G. is cachectic, with a large protuberant abdomen and ascites; bowel sounds are absent. She is alert, oriented, and without evidence of encephalopathy. V.G. has a central venous catheter. The plan is to begin parenteral nutrition because she has not eaten in 8 days and is not expected to eat for several more days when her peritonitis resolves. Is V.G. a candidate for a specialty amino acid product specifically designed for use in hepatic failure?

Aromatic Amino Acids and Branched-Chain Amino Acids

Patients with chronic hepatic failure, especially those with alcohol-induced disease, are malnourished and prone to complications such as GI bleeding and infection. The metabolism of glucose, fat, and protein is altered in liver disease. Amino acid metabolism is particularly affected because blood is shunted around the liver.

In patients with hepatic insufficiency, adequate protein must be provided to support regeneration of the liver and other vital functions such as the immune system. However, administration of protein may result in hepatic encephalopathy, a severe complication of hepatic failure. Encephalopathy is characterized by progressive depression and impaired neurologic function. The pathogenesis of encephalopathy is controversial, although several theories have been proposed. It is probably caused by the inability of the diseased liver to remove neurotoxins, which accumulate in the brain, resulting in abnormal neurotransmitters. Substances implicated as neurotoxins include ammonia, benzodiazepines, and aromatic amino acids.

Cirrhosis and chronic hepatic failure are associated with significant protein breakdown. The branched-chain amino acids (BCAAs) (e.g., leucine, isoleucine, valine) are used in the muscle as an energy source rather than being released into the circulation. Although the BCAAs are used for energy, the aromatic amino acids (AAAs; phenylalanine, tyrosine, and free tryptophan) are released, increasing circulating concentrations

of these amino acids. This results in increased plasma concentrations of the AAAs and methionine and subnormal concentrations of the BCAAs. Both AAAs and BCAAs share a common pathway across the blood–brain barrier and compete for entry into the cerebrospinal fluid (CSF). The “false neurotransmitter” theory proposes that because the concentration of AAAs is greater, more are transported across the blood–brain barrier, where they accumulate and form “false neurotransmitters” such as octopamine and serotonin, an inhibitory neurotransmitter. These compete with normal neurotransmitters for binding sites and impair normal neurotransmission and brain activity.⁷⁵

Based on these theories, an amino acid mixture was designed to provide adequate protein for anabolism while also treating hepatic encephalopathy. To normalize the amino acid profile in the brain, specially designed products with increased amounts of BCAAs and decreased amounts of both AAAs and methionine are available (Table 37-10). Controversy exists with regard to the ability of this special amino acid mixture to improve encephalopathy by altering the amino acid profile of the CSF.^{75–77} Generally, this amino acid mixture is reserved for patients with significant hepatic encephalopathy.

Because V.G. is alert, oriented, and without signs of encephalopathy, use of this product is not warranted at this time. Furthermore, protein restriction is not necessary. She should receive 1 to 1.2 g/kg/day of a standard amino acid product, and she should be monitored for signs of encephalopathy. Should she develop hepatic encephalopathy while receiving the standard amino acids, temporary protein restriction of 0.6 to 0.8 g/kg/day is reasonable while the etiology of the encephalopathy is determined and treated. The use of the increased BCAA–decreased AAA mixture may be appropriate for patients with chronic encephalopathy who are unresponsive to pharmacotherapy.¹⁰

30. What other amino acid mixtures are enriched with BCAAs?

BCAAs have metabolic properties that are considered beneficial during physiological stress (multiple trauma, sepsis, and major surgery). BCAAs can be used as an alternative energy source by the heart, brain, and skeletal muscle. These BCAAs can increase protein synthesis in muscle and liver, decrease excessive proteolysis in muscle, and normalize abnormal plasma amino acid profiles. These unique properties led to the design of commercially available amino acid mixtures that provide about 45% of the amino acids as BCAAs. In comparison, most standard amino acid mixtures contain 19% to 25% BCAAs.

Multiple trials have evaluated the effects of BCAA-enriched amino acid formulations in critically ill patients. Although most evidence suggests that these formulations may improve nitrogen retention, they do not appear to improve clinical outcome.^{78,79} It is important to appreciate the differences between the amino acid composition of the mixtures for hepatic failure and those designed for stress. They are not therapeutically equivalent, and one should not be substituted for the other.

Renal Failure

31. O.M. is a 75-year-old man with a long history of hypertension, coronary artery disease, and peripheral vascular disease. Four days ago, he was admitted to the hospital complaining of

Table 37-10 Amino Acid Product Comparison

| Description | Product Name | Supplier | Available Concentrations (%) |
|--|-----------------------|----------|--|
| Standard Formulations | | | |
| Contain essential ^a and nonessential ^b amino acids, some available with electrolytes ^c | Aminosyn, Aminosyn II | Abbott | 3.5, ^c 5, 7, ^c 8.5, ^c 10, ^c 15 |
| | FreAmine III | B. Braun | 3, 8.5, 10 |
| | Novamine | Baxter | 15 |
| | ProSol | Baxter | 20 |
| | Travasol | Baxter | 3.5, ^c 5.5, ^c 8.5, ^c 10 |
| Hepatic Failure Formulations | | | |
| Contain essential and nonessential amino acids with a proportion of branched-chain amino acids (leucine, isoleucine, valine) | HepatAmine | B. Braun | 8 |
| | HepAtasol | Baxter | 8 |
| Renal Failure Formulations | | | |
| Contain primarily essential amino acids; RenAmin also contains a complement of nonessential amino acids | Aminess | Baxter | 5.2 |
| | Aminosyn-RF | Abbott | 5.2 |
| | NephrAmine | B. Braun | 5.4 |
| | RenAmin | Baxter | 6.5 |
| Stress Formulations | | | |
| Contain percentages of leucine, isoleucine, and valine, as well as all essential and nonessential amino acids | Aminosyn HBC | Abbott | 7 |
| | FreAmine HBC | B. Braun | 6.9 |
| Supplements | | | |
| Contain only branched-chain amino acids (isoleucine, leucine, valine); must be used with a general formulation | BranchAmin | Baxter | 4 |

^aEssential amino acids: isoleucine, leucine, lysine, methionine, phenylalanine, thionine, tryptophan, valine, histidine.
^bNonessential amino acids: cysteine, arginine, alanine, proline, glycine, glutamine, aspartate serine, tyrosine.
^cThese concentrations are available with or without electrolytes.
Adapted from references 42 and 43.

severe abdominal pain and was diagnosed with a ruptured abdominal aortic aneurysm, which was repaired surgically. Hypotension and hemodynamic instability requiring pressors, respiratory distress necessitating endotracheal intubation and mechanical ventilation, and renal failure with oliguria have complicated his post-operative course. Furthermore, there is concern that O.M. has an ischemic bowel, which precludes using his GI tract for enteral feeding. Serum chemistries are Na, 130 mEq/L; K, 5.2 mEq/L; Cl, 99 mEq/L; HCO₃⁻, 15 mEq/L; BUN, 79 mg/dL; creatinine, 4.0 mg/dL; glucose, 143 mg/dL; Ca, 7.9 mg/dL; Mg, 2.4 mg/dL; P, 5.8 mg/dL; and albumin, 2.7 g/dL. The decision is made to initiate parenteral nutrition therapy via a central venous catheter. In view of O.M.'s acute renal failure, what adjustments should be made in the amount and type of protein (amino acid) provided in the parenteral feeding formulation?

[SI units: Na, 130 mmol/L; K, 5.2 mmol/L; Cl, 99 mmol/L; HCO₃⁻, 15 mmol/L; BUN, 28 mmol/L; creatinine, 240 μmol/L; glucose, 9.6 mmol/L; Ca, 1.96 mmol/L; Mg, 12 mmol/L; P, 1.9 mmol/L; albumin, 27 g/L]

The protein dose in acute renal failure should be reduced to 0.6 to 1 g/kg/day because the kidneys have a limited ability to excrete nitrogenous byproducts of protein metabolism.⁸⁰ The use of essential amino acids (EAAs) orally has been demonstrated to improve uremic symptoms. Based on this experience, parenteral amino acid mixtures containing only EAAs were investigated. These studies compared parenteral feedings containing dextrose and EAAs to the administration of only dextrose; there was an improved rate of recovery in the group

that received the EAA and dextrose. Subsequent studies comparing parenteral nutrient formulations containing a standard mix of both EAAs and nonessential amino acids to EAAs alone have not demonstrated any difference in urea appearance or nitrogen balance.^{80,81} The use of EAAs alone in parenteral nutrient formulations for patients with acute renal failure offers no clinical advantage over formulations providing a balanced mixture of EAAs and nonessential amino acids.

32. What other adjustments should be made in formulating a parenteral nutrient formulation for O.M.?

O.M.'s nutrient needs should be provided in the least amount of fluid possible. This can be accomplished by using the most concentrated macronutrients of 70% dextrose, 20% amino acids, and 30% lipid. Using these substrates, a patient's entire needs can often be provided in <1,200 mL/day. Electrolytes should also be adjusted. Initially, patients with acute renal failure may not require potassium, magnesium, and phosphorus because they cannot excrete them. However, once parenteral feedings begin and an anabolic state occurs, these patients commonly experience decreases in the serum concentrations of these minerals and will require small daily doses to maintain normal serum concentrations.

Renal Replacement Therapies

33. O.M.'s renal failure progresses, and he requires renal replacement therapy. Because of his hemodynamic instability,

continuous venovenous hemodialysis (CVVHD) is initiated. How should his nutrition therapy be altered?

Continuous renal replacement therapies (CRRTs), including CVVHD, continuous arteriovenous hemodialysis, continuous venovenous hemofiltration, continuous venovenous hemodiafiltration, and slow continuous ultrafiltration delivery provide a means to remove large volumes of water, nitrogenous byproducts, and electrolytes. Consequently, the delivery of unlimited quantities of fluids, nutrients, and electrolytes is possible. Several factors must be considered in the nutritional management of a patient requiring these therapies. First, a dialysate solution of 1.5% to 2.5% dextrose may be used. If so, some dextrose is absorbed during the process and contributes to the caloric intake. A solution with a 1.5% dextrose concentration at a rate of 1 L/hour delivers approximately 5.8 g of glucose per hour. Increasing the dextrose concentration of the dialysate solution to 2.5% increases the glucose delivery to 11.5 g/hour. The amount of glucose absorbed (550–700 kcal/day) must be considered when designing the amount of calories that will be provided in the parenteral nutrient formulation.^{80–85}

The second nutritional consideration is the loss of amino acids across the dialysis filter, which can range from 20 to 28 g of nitrogen per day. Sufficient amino acids should be provided to compensate for this daily loss of 120 to 175 g of amino acids (approximately 6.25 g of amino acids per gram of nitrogen).^{80,82,84,85} Protein requirements for patients on CRRT may be as high as 2.5 g/kg/day to promote positive nitrogen balance.⁸⁶

Last, the rapid loss of electrolytes must be considered. Patients may experience dramatic decreases in potassium, magnesium, and phosphorus once CRRT is initiated. This requires frequent monitoring and replacement of these electrolytes, usually as IV supplements rather than as additions to the parenteral feeding formulation.

34. After several days of CVVHD, O.M. is changed to intermittent (three times a week) hemodialysis. What alterations in his parenteral nutrition are necessary?

Hemodialysis also allows the passage of amino acids through a semipermeable membrane. The loss is approximately 1 g of amino acids for each hour of hemodialysis with a glucose-free dialysate. This loss is reduced by 50% when a glucose-containing dialysate solution is used. These losses should be considered when determining the dosage of protein that will be provided by the parenteral nutrient formulation. The recommended protein dosage for patients requiring hemodialysis is 1.2 to 1.3 g/kg/day,^{80,84,85} but dosages up to 1.8 g/kg/day have been reported.^{80,87} In addition, hemodialysis can increase energy expenditure by increasing oxygen consumption and gluconeogenesis; therefore, energy goals should range between 25 to 35 kcal/kg/day.⁸⁰ Patients requiring chronic hemodialysis may require protein doses of 1.2 to 1.4 g/kg/day to maintain a positive nitrogen balance and prevent protein malnutrition. Patients requiring peritoneal dialysis have higher losses of protein through the peritoneal cavity and may need 1.2 to 1.5 g/kg/day of protein. In contrast to patients on hemodialysis, those on peritoneal dialysis require fewer calories provided by parenteral feedings because 600 to 800 cal/day may be absorbed

through the peritoneal membrane from the glucose-containing dialysate.^{80,84,85}

Diabetes, Obesity, and Short Bowel Syndrome

35. F.L., a 51-year-old man with a history of diabetes mellitus, is hospitalized after receiving a gunshot wound to the abdomen. His injuries included a lacerated spleen, requiring a splenectomy, and several tears in his small and large intestine, necessitating resection of these areas. A feeding jejunostomy tube is placed at the time of surgery, and enteral tube feedings are begun on postoperative day 2. Five days later, F.L. is noted to have a temperature of 39.6°C; a WBC count of 18,900/mm³; and a distended, tender abdomen. He requires surgery for a small bowel perforation at the site of the feeding jejunostomy and peritonitis. The jejunostomy tube is removed, but F.L. is not expected to have return of bowel function for 7 to 10 days. Parenteral nutrition is to be initiated. F.L. is 5 feet 8 inches tall, and his usual weight is 215 lb. What adjustments should be made in determining F.L.'s energy goals?

First, F.L. is considered obese, and an adjusted body weight should be calculated and used in nutrition calculations. Obesity is defined as weight exceeding 120% of IBW or a body mass index (BMI) of >27 kg/m². F.L. weighs 215 lb, or 98 kg, which is 142% of his IBW of 69 kg –10%. BMI is determined as shown by Equation 37-4.

$$\begin{aligned} \text{BMI} &= \frac{\text{Weight (kg)}}{\text{Height (m)}^2} \\ &= \frac{98 \text{ kg}}{(1.73 \text{ m})^2} \\ &= 32.7 \text{ kg/m}^2 \end{aligned} \quad (37-4)$$

Obese patients should have their weight adjusted because adipose tissue is not metabolically active. However, about one-fourth of the adipose tissue is composed of some supporting tissue that is metabolically active. Adjusted weight for obesity is calculated using Equation 37-5.⁸⁸

$$\begin{aligned} \text{Adjusted weight} &= (0.25)(\text{Actual Weight} - \text{IBW}) + \text{IBW} \\ &= (0.25)(98 - 69) + 69 \\ &= 76 \text{ kg} \end{aligned} \quad (37-5)$$

Using an adjusted weight will decrease the risk of overfeeding, which can further increase adipose tissue and complicate glucose management, especially in a patient with a history of diabetes mellitus. Another approach is to use the Ireton-Jones predictive equation that includes a factor for obesity. Using indirect calorimetry to obtain an MEE may more accurately assess energy expenditure and avoid overfeeding.

36. What special considerations should be addressed in designing a parenteral nutrient regimen for F.L.?

Patients without a history of diabetes mellitus may develop hyperglycemia under conditions of stress. Even greater derangements in glucose metabolism may be observed in patients with diabetes mellitus during a critical illness. Dextrose should be limited to 150 g during the first 24 hours of therapy, and the amount of dextrose should not be increased until serum glucose concentrations are consistently <150 mg/dL. It can be

anticipated that F.L. will need supplemental insulin when his parenteral nutrient regimen is infused. Insulin may be added to the parenteral nutrient formulation. Initial insulin therapy of 0.1 U of regular insulin per gram of dextrose is a good starting point and should be adjusted to achieve serum glucose levels between 80 to 120 mg/dL. Alternatively, a separate insulin infusion may be used. Frequent capillary glucose monitoring is required in these patients, and it may be necessary to provide additional subcutaneous insulin.^{62,63,89} (See question 22 for additional discussion on management of hyperglycemia.)

37. F.L. has a prolonged hospital course complicated by multiple intra-abdominal abscesses, poor wound healing, and necrotic bowel, requiring removal of all but 55 cm of his small intestine but leaving his colon intact. F.L. is given a diagnosis of short bowel syndrome (SBS). What issues should be addressed in the nutrition and metabolic management of this patient?

SBS is characterized by maldigestion, malabsorption, dehydration, and both macronutrient and micronutrient abnormalities. Severe malnutrition will develop without adequate nutrition support. To maintain adequate nutrition status, F.L. will require parenteral nutrition until his remaining intestine begins to adapt. This adaptive period may take several weeks to months to years. Adaptation is enhanced by stimulation of the enterocytes with nutrients, which is best provided by small, frequent oral meals or tube feeding.^{10,90,91}

First, F.L. should be continued on parenteral nutrition support, including therapy at home, to meet his nutrient and fluid requirements. After extensive small bowel resection, F.L. may experience severe diarrhea. This increase in GI losses may lead to dehydration and electrolyte abnormalities, including hyponatremia, hypokalemia, hypomagnesemia, hypocalcemia, and metabolic acidosis.⁹¹ F.L.'s fluid status must be monitored and evaluated daily for clinical signs of dehydration or fluid overload.

Medication therapy plays an important role in managing fluid and electrolyte imbalances secondary to excessive GI fluid losses. H₂-receptor antagonists are useful in decreasing gastric secretion, thereby reducing fluid and electrolyte losses and enhancing absorption. Antimotility agents should be used to decrease diarrhea. Octreotide also may have a role in decreasing diarrhea in patients with SBS. Patients with extensive small bowel resections and an intact colon, such as F.L., may develop diarrhea as a result of bile salt depletion.^{10,90,91}

Patients with SBS are at risk for developing vitamin deficiencies, especially folate and B₁₂. These patients should receive supplemental B₁₂ and IV parenteral or oral liquid multivitamin supplements. GI losses of trace minerals, particularly zinc and selenium, are increased in SBS, and these minerals should be supplemented.^{90,91}

Pancreatitis, Respiratory Failure

38. K.R., a 59-year-old woman, is admitted to the hospital complaining of increasing abdominal pain and vomiting. She is diagnosed with pancreatitis. This is her third admission for acute pancreatitis during the past year. Her past medical history is significant for ethanol abuse and chronic obstructive airway disease. An NG tube is inserted, and she is to be NPO. IV fluids are begun for hydration. Over the next 5 days, K.R.'s abdominal pain sub-

sides, her pancreatitis resolves, and she is started on an oral diet. Two days after beginning an oral diet, K.R. complains of severe abdominal pain and is vomiting. She is febrile, her WBC count has increased to 21,000/mm³, and she is hypotensive, requiring large volumes of IV fluids. Furthermore, she develops respiratory distress and requires endotracheal intubation and mechanical ventilation. Her most recent ABG is notable for pH, 7.36 (normal, 7.37–7.44); PCO₂, 51 mmHg (normal, 35–45); PO₂, 88 mmHg (normal, 85–100); and HCO₃⁻, 28 mEq/L (normal, 24–30). This clinical presentation is consistent with severe pancreatic necrosis. A small-bore nasojejunal feeding tube is placed and enteral nutrition therapy is begun. However, K.R. develops severe abdominal pain and distention and bowel sounds are absent, so the enteral feeding is discontinued. The decision is made to begin parenteral nutrition because K.R. is not expected to have a functional GI tract in the near future and her nutrient intake has been inadequate during her hospitalization. What special considerations should be addressed in designing a parenteral feeding formulation for K.R.? Is the use of fat contraindicated in patients with pancreatitis?

Several observations have caused concern over the use of IV lipid emulsions in patients with pancreatitis. The oral ingestion of fats may stimulate pancreatic exocrine function and should be restricted in patients with pancreatitis. Although hyperlipidemia has been well described in patients with alcohol-induced pancreatitis, it is unlikely that it is primarily responsible for initiating the pancreatitis. Hypertriglyceridemia associated with acute pancreatitis is most often seen in patients with hereditary or acquired defects in lipid metabolism. Furthermore, pancreatitis alone may be associated with hypertriglyceridemia.⁹²

Several investigators have evaluated the effects of parenteral nutrient formulations containing fat emulsions in patients with acute pancreatitis and have found no stimulation of pancreatic exocrine function. Furthermore, IV lipids did not result in abdominal pain or relapse in patients with a history of pancreatitis. Available data suggest that IV lipid emulsions are a safe and efficacious form of calories for patients with pancreatitis.⁹²

Monitoring serum triglyceride concentrations should be part of routine management for patients with pancreatitis and those receiving parenteral nutrient formulations containing lipids. Serum triglyceride concentrations should be maintained at <400 mg/dL with a continuous infusion of lipids and <250 mg/dL when checked 4 hours after the infusion for patients receiving intermittent lipid infusions.^{10,44,92} If serum concentrations exceed these parameters, consideration must be given to decreasing or eliminating the IV lipid from the parenteral nutrient regimen.

39. K.R. is recovering from her pancreatitis, and the small-bore nasojejunal enteral feeding tube is reinserted. Tube feeding is considered because she cannot eat by mouth secondary to the endotracheal tube and mechanical ventilation. How should she be transitioned from parenteral to enteral feedings?

Tube feedings can begin with a full-strength isotonic enteral feeding formulation at a slow infusion rate (25 mL/hour). Concurrently, the parenteral nutrient formulation should be decreased to avoid fluid overload and to keep the calorie and protein intake constant. It can be anticipated that K.R. can transition from parenteral to enteral feedings in 24 to 48 hours (see Chapter 36).

ANATOMY AND PHYSIOLOGY OF THE SKIN

The skin is the largest organ in the body and constitutes, on average, 17% of a person's body weight. The skin's thickness ranges from 3 to 5 mm. Figure 38-1 shows a cross-section of the anatomy of human skin. The major function of the skin is to protect underlying structures from trauma, temperature variations, harmful penetrations, moisture, humidity, radiation, and invasion of micro-organisms. There are three layers of skin: the epidermis, the dermis, and subcutaneous tissue.^{1–6}

Epidermis

The epidermis consists of four distinct layers: stratum corneum, stratum lucidum, stratum spinosum, and stratum germinativum. The major function of the epidermis is to serve as a barrier. This layer keeps chemicals and other substances from penetrating into the body and prevents the loss of water from the skin and underlying tissues. The maturation of keratinocytes from the stratum germinativum to the stratum corneum is critical for this barrier function. As keratinocytes

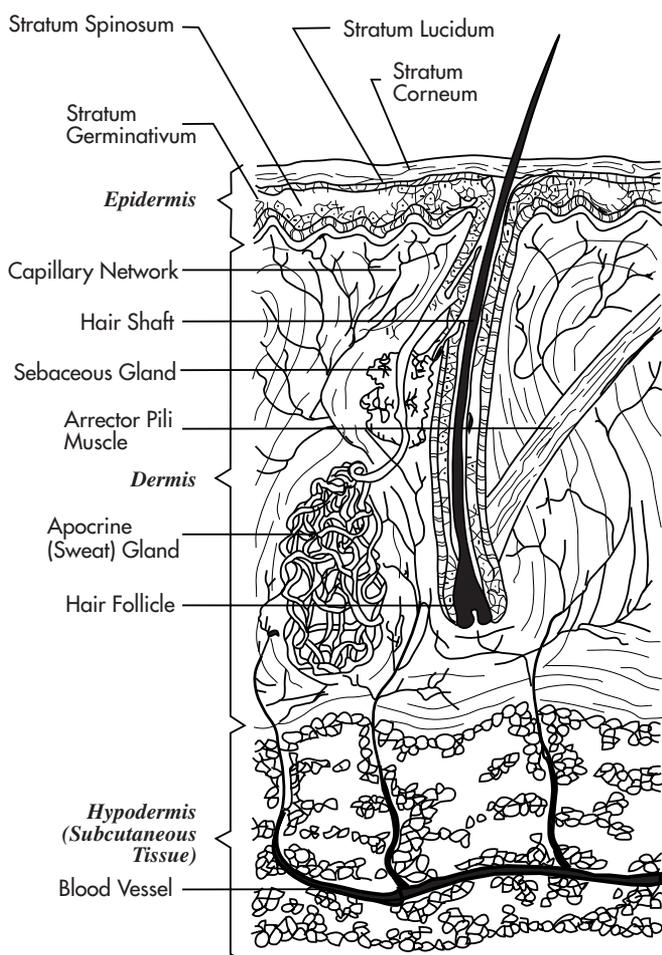

FIGURE 38-1 Cross-section of the anatomy of human skin.

migrate to the skin surface, they change from living cells to dead, thick-walled, nonnucleated cells containing keratin, a hard fibrous protein. It normally takes 26 to 28 days for a keratinocyte to divide, differentiate, move up to the stratum corneum, and be sloughed off.

The *stratum corneum*, which is composed of the dead cells, provides the greatest resistance to the percutaneous absorption of chemicals and drugs. It behaves as a semipermeable membrane through which drugs are absorbed by passive diffusion. Factors that can affect drug absorption are hydration of the skin and damage to the stratum corneum. In general, the greater the damage to the stratum corneum, the greater is the absorption of topically applied drugs. Skin diseases affecting only the epidermis heal without scarring.¹⁻⁶

Dermis

The dermis, which ranges in thickness from 1 to 4 mm, is composed of collagen fibers, elastic fibers, and an extrafibrillar gel of mucopolysaccharides called *glycosaminoglycans* (formally called *ground substances*). The major function of the dermis is to protect the body from mechanical injury and to support the dermal appendages (i.e., apocrine and eccrine sweat glands, sebaceous glands, hair follicles) and the epidermis. It also provides capillary, lymphatic, and nerve supply to the skin and

its appendages. The capillary network plays a major role in temperature regulation and provides nutrition to the epidermis. The nerves transmit sensations of touch and pain. Finally, the dermis contains large amounts of water, thus serving as a water storage organ. All but the most superficial injuries to the dermis generally result in scarring as the wound heals.¹⁻⁶

Drugs passing through the epidermis penetrate directly into the dermis and may be absorbed into the general circulation through the capillary network. Generally, only small amounts of topically applied drugs enter the dermis via the sweat glands or the pilosebaceous units.

Subcutaneous Layer

The subcutaneous layer supports the dermis and epidermis, and serves as a fat storage area. This layer helps regulate temperature, provide nutritional support, and cushion the outer skin layers.¹⁻⁶

INFLAMMATORY LESIONS

One of the dermatologic axioms regarding therapy is particularly useful in selecting dosage forms. “If it’s wet, dry it; if it’s dry, wet it.” Paradoxically, wet dressings are most useful in drying acute, inflamed lesions, because they draw out fluid as they evaporate. Ointment types bases are most useful for chronic, lichenified, scaling lesions. The choice of vehicle for chronic lesions is often based on what the patient has found to work best or is willing to use. Frequently, patients with chronic dermatologic conditions use multiple types of vehicles concomitantly (e.g., cream bases [which are drying]) during the day, as they are cosmetically acceptable, and ointment bases at night (greasy, but better emollients).

Acute Lesions

Acute inflammatory lesions are characterized by vesiculation, erythema, swelling, warmth, pruritus, oozing, and/or weeping. Generally, the more severe the dermatitis, the milder is the initial topical therapy. For instance, cool water in the form of an aqueous vehicle, preferably a wet dressing, soak, or bath, is more effective as the initial therapeutic agent than a potent topical corticosteroid applied to a warm, erythematous, weeping dermatitis. The specific approach depends on the part(s) of the body involved.

Subacute and Chronic Lesions

Subacute lesions are characterized by decreasing vesiculation and oozing, and are often covered with crusts. They still require cleaning and drying with aqueous preparations, but for a shorter duration than with acute lesions. Chronic inflammatory lesions are characterized by erythema, scaling, lichenification, dryness, and pruritus. There are no absolute rules for treating chronic lesions. If the lesion is dry, an oleaginous or occlusive base should be used, perhaps with a keratolytic agent.

DERMATOLOGIC DRUG DELIVERY SYSTEMS

A range of dermatologic formulations are available: solutions, suspensions or shake lotions, powders, lotions, emulsions, gels,

creams, ointments, and aerosols. Each dermatologic delivery vehicle has specific characteristics and uses based on the type, relative acuteness, and location of the lesion.

Solutions

Solutions provide evaporative cooling, vasoconstriction, and resultant mild antipruritic effects. They soothe and cool inflamed skin, dry oozing lesions, soften crusts, aid in cleaning wounds, and assist in the drainage of purulent wounds. Aqueous solutions are most useful for acutely inflamed, oozing lesions; erosions; and ulcers. In most instances, solutions should be the sole therapy until the oozing or weeping subsides. If other topical medications are applied to oozing or weeping lesions, they will be washed away and will not provide the desired effect. The most commonly used solutions are normal (0.9%) saline and aluminum acetate 5% solution (Burow's solution) diluted 1:10 to 1:40. Solutions are often applied as wet dressings.

The most important component of a solution is water. Although active or inert substances may be added to solutions, the cleansing, drying and cooling effect of water provides the major therapeutic benefit. Some of the products (e.g., Burow's solution) also have *astringent* properties that alter the skin surface and interstitial spaces to cause contraction and wrinkling. Water penetration is reduced to minimize edema, inflammation, and exudation. Table 38-1 lists the most commonly used solutions. Boric acid should not be used as a topical agent because it can be absorbed through the skin, causing systemic toxicity.⁷

Depending on the affected area and its size, a patient may soak the affected area directly in the solution for 15 to 30 minutes three to six times per day. If larger areas are involved or if the affected area cannot be easily soaked (e.g., a shoulder), a clean towel or cloth soaked in the solution (lightly wrung out) is directly applied to the lesion(s) as a wet dressing. The soaked cloth should be left in place for 5 to 10 minutes, then resoaked in the solution and reapplied. The patient may repeat

this procedure for 15 to 30 minutes three times daily. Solutions applied with a cloth should have the cloth material wrapped around the lesions several times, if possible. If large areas are involved, the patient may draw a bath, add appropriate amounts of medications, and soak for 15 to 30 minutes three to six times per day. It is impractical to prepare a Burow's solution bath at the 1:10 to 1:40 concentration. Again, the concentration of the Burow's solution is probably insignificant because the major effect of the solution is produced by the water. In general, no more than one-third of the body should be soaked in this manner at any time. One should be aware that evaporation can concentrate solutions, potentially making them too irritating to use. Small volumes of a 1:40 concentration of Burow's solution left standing open at room temperature after 30 to 60 minutes may yield a 1:10 solution. This problem is not as significant with larger volumes or if the solution is stored in a closed container. For this reason, wet dressings should always be freshly prepared (i.e., within 24 hours), kept in closed containers, and never reused. Wet dressings are most comfortable if they are slightly cool or warm, depending on the patient's preference. When drying the affected area after a wet dressing has been used, care must be taken not to irritate the inflamed skin by rubbing it with a towel. The proper technique for drying the skin is to pat the area gently with a soft, clean towel.⁷

Baths

In addition to wet dressings and soaks, topical solutions can be applied to large areas of the body through bathing. In using this type of treatment, the bath should be about half full. Soothing and antipruritic colloidal bath additives may be used to treat widespread eruptions such as lichen planus, pityriasis rosea, urticaria, and other weeping or crusting dermatoses. Colloidal oatmeal (1 cup of oatmeal [Aveeno] mixed with 2 cups of cold tap water and poured into 6 inches of a lukewarm bath) produces a pleasing and soothing bath. Alternatively, a starch bath using 2 cups of hydrolyzed starch (Linit) or cornstarch mixed with 4 cups of tap water and added to a bath may

Table 38-1 Solutions for Wet Dressings or Drying Weeping Lesions

| Agent ^a | Strength | Preparation (H ₂ O) | Germicidal Activity | Astringent Activity | Comments |
|--|------------------------|--|---------------------|---------------------|------------------------------------|
| Normal saline | 0.9% NaCl | 1 tsp NaCl per pint H ₂ O | None | None | Inexpensive; easy to prepare |
| Aluminum acetate (Burow's solution) (Domeboro packets/tablets) | 5% | Dilute to 1:10–1:40 (0.5%–0.125%) One packet/tablet to a pint of water yields a 1:40 solution; two packets/tablets yields a 1:20 solution | Mild | + | |
| Potassium permanganate | 65- and 330-mg tablets | Dilute to 1:4,000–1:16,000; 65-mg tablet to 250–1,000 mL; 330-mg tablet to 1,500–5,000 mL | Moderate | None | Stains skin, clothing |
| Silver nitrate | 0.1%–0.5% | 1 tsp of 50% stock solution to 1,000 mL will yield a 0.25% solution | Good | + | Stains; can cause pain |
| Acetic acid ^b | 1% | Dilute 1 pint of standard 5% household vinegar with 5 parts H ₂ O | Good | + | Unpleasant odor; can be irritating |

^a Although many substances are added to wet dressings, the cleansing and drying effect of the water is the major benefit.

^b Used primarily for *Pseudomonas aeruginosa* infections.

Adapted from reference 7.

be used. A mixture of equal parts baking soda and starch may also be used. Epsom salt baths, made by dissolving 3 cups of magnesium sulfate in 6 inches of lukewarm water in a tub, are useful in treating pyodermas, furuncles, and necrotic acne (especially when the back, shoulders, and buttocks are affected). Water-soluble coal tar preparations applied via a bath for the treatment of psoriasis may be the most acceptable way to apply this medication. Ointments or creams containing coal tar are malodorous and have a tendency to stain materials on contact.

A variety of bath oils are available: Alpha-Keri, Domol, Lubriderm, and Nutraderm. Adding bath oil directly to the bath is not recommended because it makes the tub slippery and potentially dangerous. The concentration of the oil in the water becomes almost insignificant anyway (5–10 mL in 20–40 gal). Five to 10 mL of bath oil may be applied directly to wet skin on leaving a bath and patted dry with a towel for a more significant effect. This is most useful in preventing and treating mild cases of xerosis (dry skin). With moderate to severe cases of xerosis, additional topical oleaginous products are generally required to improve the condition. Patients may make their own bath oil by adding 2 oz of olive oil or Nivea oil to a cup of milk and applying it following a bath.⁷

Powders

Powders are drying and cooling; they absorb moisture and create more surface area for evaporation. They are used mainly in intertriginous areas (e.g., groin, under the breasts or in skin folds) to decrease friction, which can cause mechanical irritation. They also are useful in the treatment of chafing, tinea pedis (athlete's foot), tinea cruris (jock itch), and diaper dermatitis (diaper rash). Occasionally, powders are applied on top of ointments to protect clothing from the ointment. The liberal use of powders on bedridden patients helps prevent pressure ulcers (bed sores).

Powders can be applied with a cotton puff or shaker. Care should be taken to minimize breathing the powder because this can lead to respiratory tract irritation, particularly in infants. Powders that contain starch or cellulose should be washed off before reapplication, as continued buildup can produce mechanical irritation. Corn starch-containing powders should not be used for intertrigo (inflammation of body folds—thighs, armpits, under breasts or enlarged abdomen; aggravated by heat, moisture, and maceration) because starch can serve as a substrate for *Candida albicans*. Powders should not be applied to oozing lesions because they tend to cake into hard granules, making them difficult and painful to remove and promoting maceration. Concerns regarding the association of routine cosmetic talc use and ovarian cancer and granulomatous lung changes are without convincing evidence.⁸ The most commonly used powders are talc and the antifungal, nystatin.

Lotions

Lotions are suspensions or solutions of powder in a water vehicle. They are usually cooling and drying, but may provide some lubrication, depending on the formulation. Lotions are used to treat superficial dermatoses, especially if there is slight oozing. They are useful if large or intertriginous (see previous definition) areas are affected, and they are especially advanta-

geous in the treatment of conditions characterized by significant inflammation and tenderness. In these situations, creams or ointments may cause pain on application. Sunburn, acute contact dermatitis, and poison ivy/oak are examples of conditions in which this principle may apply. Generally, lotions are applied three or four times daily, with each fresh application placed over previous application, unless there is significant oozing present, which could promote caking of dried solid ingredients. If this is the case, the area should be cleansed before repeat application. Because many lotions are suspensions, it is advisable to shake the lotion well before application. Generally, 6 oz of lotion covers the entire body of an average adult.⁷

Emulsions

Emulsions are solid or liquid and can be divided into two classes: *oil-in-water* and *water-in-oil* emulsions. Cream preparations are generally oil-in-water emulsions, whereas ointment preparations are water-in-oil emulsions. As the amount of oil increases, the viscosity of the emulsion will also increase.

The indications for liquid oil-in-water emulsions are similar to those for lotions, except that this dosage form provides greater occlusion and is more useful in conditions where dry skin predominates. Liquid water-in-oil emulsions have similar indications to ointments, except they can be applied more easily than ointments. Water-in-oil emulsions are most useful in conditions where dry skin predominates; application to hairy or intertriginous areas should be avoided. As with lotions, 6 oz of a liquid emulsion will cover all exposed skin on an average adult.⁷

Table 38-2 lists some commercially available oil-in-water and water-in-oil emulsion bases.

Gels

Gels are a form of ointment (semisolid emulsion) that contain propylene glycol and carboxypolymethylene. They are clear, nongreasy, nonstaining, nonocclusive, and quick drying. They are thixotropic (i.e., become thinner with rubbing and may sting on application). Gels are most useful when applied to hairy areas or other areas such as the face or scalp, where it is considered cosmetically unacceptable to have the residue of a vehicle remain on the skin. Because of their ingredients, gels tend to be more drying.

Table 38-2 Commercially Available Emulsion Bases

| <i>Oil-in-Water</i> | <i>Water-in-Oil</i> |
|--------------------------|---------------------|
| Acid mantle cream | Aquaphor |
| Aquaphilic | Eucerin |
| Cetaphil | Lubriderm |
| Dermabase | Nivea Cream |
| Dermovan | Nutraderm |
| Hydrophilic ointment USP | Polysorb |
| Keri Lotion | Vanicream |
| Lanaphilic | Velvachol |
| Unibase | |

Table 38-3 Amount of Topical Medication Needed for Various Dosage Regimens

| Area Treated | Single Application (g) | BID for 1 week (g) | BID for 1 month (g) |
|-------------------------------------|------------------------|--------------------------|---------------------------|
| Hands, head, face, anogenital area | 2 | 28 | 120 |
| On arm, anterior or posterior trunk | 3 | 42 | 180 |
| One leg | 4 | 56 | 240 |
| Entire body | 30–60 | 420–840 kg (14–28 oz) | 1.8–3.6 kg (60–120 oz) |

Adapted from reference 7.

Creams

Creams are the most commonly used vehicle in dermatology. Most are oil-in-water emulsions and are intended to be rubbed in well until they vanish (vanishing creams). Because creams do not provide much occlusiveness, they are most often recommended for subacute lesions and occasionally for chronic lesions without significant lichenification. The most common mistake made by patients when applying creams is that they use too much and/or do not rub them in fully. Generally, if the cream can be seen on the skin after application, the patient has made one or both of these application mistakes. Ultimately, they are wasting the preparation or are not getting the full therapeutic benefits. One gram of cream should cover 100 cm² of surface area. Table 38-3 lists the approximate amount of cream required for application to various parts of the body.⁷

Ointments

Ointments are made of inert bases such as petrolatum or may consist of droplets of water suspended in a continuous phase of oleaginous material (water-in-oil emulsions). Ointments are most useful on chronic lesions, relieving dryness, brittleness, and protecting fissures due to their occlusive properties. They should not be used on acutely inflamed lesions. Ointments should not be applied to intertriginous or hairy areas because they tend to trap heat and promote maceration. Ointments are greasy and may be cosmetically unacceptable.

Aerosols

Aerosols are the most expensive and inefficient way to apply dermatologic medications. Their only advantage over other dosage forms is that they do not require direct mechanical contact with the skin and may be useful if application causes intolerable pain for the patient. If an aerosol is used, it should be shaken well before use, and the patient should be cautioned not to spray the product around the face where it could get into the eyes or nose, or could be inhaled. Generally, aerosols should be sprayed from approximately 6 inches above the skin in bursts of 1 to 3 seconds. Aerosols are also useful for application to hairy areas if a special application nozzle is used. Aerosols have a drying effect and should not be used for a long period of time.

Table 38-4 Appropriate Dermatologic Vehicle Selection Across the Range of Dermatologic Lesions

| Range of Lesions | Range of Vehicles |
|---|---|
| Acute inflammation: Oozing, weeping, vesication, edema, pruritus | Aqueous vehicles and water, and then powders solutions, lotions, sprays, and aerosols |
| ↓ | ↓ |
| Subacute inflammation: Crusting, less oozing, pruritus | Creams, gels |
| ↓ | ↓ |
| Chronic inflammation: Lichenification, dryness, erythema, pruritus, scaling | Ointments |

Other Delivery Systems

The addition of solvents, such as dimethyl sulfoxide, may enhance dermal absorption, allowing the delivery of many drugs directly through the skin. Skin patch delivery systems have also been designed to deliver drugs directly through the skin. Examples include scopolamine, nitroglycerin, clonidine, nicotine, opioids, and various hormones. These dermatologic drug delivery systems, or similar ones, offer great potential for the sustained delivery of pharmaceuticals over extended periods of time.

Selection of a Delivery System

Dermatologic vehicles should be matched to the type of lesion for which they will be used. Acute lesions require aqueous vehicles until the lesions become dry. Subacute lesions also benefit from aqueous vehicles, but for shorter periods of time before switching to creams or gels. Chronic lesions usually require ointments because of their dry, lichenified characteristics. Although there are exceptions, these principles are depicted on Table 38-4.

ASSESSING THE DERMATOLOGIC PATIENT

1. C.B., a 23-year-old, 66-kg woman, complains of a rash. What types of questions should C.B. be asked to help determine the appropriate diagnosis and treatment?

The diagnosis of dermatologic conditions can be simplified by considering six primary factors: morphology (what the lesions look like, pattern of the lesions); location or distribution of the lesions on the body; symptoms, both local and systemic; history of the present condition as well as related conditions; age of the patient; and patient gender. These six factors are discussed in the following sections, along with their significant qualifying characteristics.

Morphology

Table 38-5 provides a listing of common dermatologic lesions, their respective definitions, and some well-known clinical examples. Lesions may also be classified as either primary or secondary. Primary lesions are lesions as they first appear on the skin, whereas secondary lesions develop from primary lesions. A papule (primary lesion) might progress to a pustule (secondary lesion). A pustule may also be a primary lesion if it

Table 38-5 Dermatologic Lesions, Definitions, and Clinical Examples

| Name | Definition | Examples |
|--------------------------------|--|---|
| Primary Lesions | | |
| Macule | Nonpalpable, flat, change in color, <1 cm | Freckles, flat moles |
| Patch | Nonpalpable, flat, change in color, >1 cm | Vitiligo, cafe au lait spots, chloasma |
| Papule | Palpable, solid mass, may have change in color, <1 cm | Verrucae, noninflammatory acne (comedone), raised nevus |
| Nodule | Palpable, solid mass, most often below the plane of the skin, 1–2 cm | Erythema nodosum, severe acne |
| Tumor | Palpable, solid mass, >2 cm, most often above and below the plane of the skin | Neoplasms |
| Plaque | Flat, elevated, superficial papule with surface area greater than height, >1 cm | Psoriasis, seborrheic keratosis |
| Wheal | Superficial area of cutaneous edema, fluid not confined to cavity | Urticaria (hives), insect bite |
| Vesicle | Palpable, fluid-filled cavity, <1 cm, filled with serous fluid (blister) | Herpes simplex, herpes zoster, contact dermatitis |
| Bulla | Palpable, fluid-filled cavity, >1 cm, filled with serous fluid (blister) | Pemphigus vulgaris, second-degree burn |
| Pustule | Similar to vesicle, but filled with purulent fluid | Acne, impetigo, folliculitis |
| Special Primary Lesions | | |
| Comedone | Plugged opening of sebaceous gland | Acne, blackhead, whitehead |
| Cyst | Palpable lesion filled with semiliquid material or fluid | Sebaceous cyst |
| Abscess | Accumulation of purulent material in dermis or subcutaneous layers of skin; purulent material not visible on surface of skin | |
| Furuncle | Inflammatory nodule involving a hair follicle, following an episode of folliculitis | Small boil |
| Carbuncle | A coalescence of several furuncles | Large boil |
| Secondary Lesions | | |
| Erosion | Loss of part or all the epidermis | Ecthyma |
| Ulcer | Loss of epidermis and dermis | Stasis ulcer |
| Fissure | Linear crack from epidermis into dermis | Tinea pedis |
| Excoriation | Self-induced linear, traumatized area caused by intense scratching | Atopic dermatitis, extreme pruritus |
| Atrophy | Thinning of skin with loss of dermal tissue | Striae |
| Crusts | Dried residue of pus, serum, or blood from a wound, pustule, or vesicle | Impetigo, scabs |
| Lichenification | Thickening of epidermis, accentuated skin markings, usually induced by scratching or chronic inflammation | Atopic dermatitis, allergic contact dermatitis |

originally developed as a pustule. The ability to recognize and describe specific lesions is critical to a successful diagnosis and communication regarding response to therapy.

In addition, many lesions present in a particular distribution or pattern. Poison ivy lesions are commonly distributed linearly. Herpetic lesions are so typical that the term herpetiform is used for lesions due to other conditions that have a herpes-like distribution. The specific size of the lesion is also important in assessing a patient's condition. Dermatologic terms related to lesion distribution or pattern are shown in Table 38-6. The lesion's consistency (firm vs. soft), borders, and color are also important diagnostic considerations.

Location

“Location, location, location” is another axiom of dermatology. Simply put, certain lesions or conditions almost always occur in certain body locations. Table 38-7 provides a list of anatomic sites with common dermatoses occurring in those locations. For example, diseases of the sebaceous glands (e.g., acne, seborrheic dermatitis, rosacea) occur only in sites with high concentrations of sebaceous glands, such as the scalp, head, neck, chest, and umbilicus. Atopic dermatitis shows a predilection for the flexor surfaces of the body (i.e., antecubital and popliteal fossae).

Symptoms

Most skin conditions have only localized symptoms with the most common symptom being pruritus. Occasionally, localized burning or pain is the predominant symptom.

History

Although a diagnosis may often be made from morphology, location, and symptoms, the patient history provides useful diagnostic and therapeutic information. Similar to the historical information obtained for any acute medical problem, the following questions should always be asked:

1. When and how did the problem start?
2. How has it progressed or changed since its onset? How have the lesions changed in size, color, appearance, or severity?
3. What is the patient's past and current medical history? What other symptoms might indicate that this is a dermatologic manifestation of a systemic disease?
4. What are the patient's symptoms?
5. What kind of allergies does the patient have?
6. What makes the condition worse or better?
7. What events or happenings have occurred with the onset or worsening of the condition (e.g., increased stress, exposure to new products, recent travel, changes in climate)?

Table 38-6 Descriptive Dermatologic Terms

| Term | Characteristics | Examples |
|----------------|--|---------------------------------------|
| Annular | Ring shaped | Tinea |
| Arcuate | Shaped like an arc | Syphilis |
| Circinate | Circular | Tinea |
| Confluent | Lesions run together | Psoriasis, tinea |
| Discrete | Lesions remain separate | Psoriasis, tinea |
| Eczematous | General term for vesiculation, crusting, and lichenification | Contact dermatitis, atopic dermatitis |
| Geographic | Shaped like islands or continents; maplike | Generalized psoriasis |
| Grouped | Lesions clustered together | Herpes |
| Herpetiform | Appears like herpes simplex | Herpes simplex |
| Intertrigo | Irritant dermatitis in skin folds | Diaper dermatitis |
| Iris | Looks like a bull's eye, lesion within a lesion, target lesion | Erythema multiforme |
| Keratotic | Horny thickening | Psoriasis, corn, callus |
| Linear | Shaped in lines | Poison ivy |
| Multiform | More than one type or shape of lesion | Erythema multiforme |
| Papulosquamous | Papules with desquamation | Psoriasis |
| Serpiginous | Snakelike lesions | Cutaneous larva migrans |
| Zosteriform | Appears like herpes zoster | Herpes zoster |

- What have you used to treat the condition, and how have the treatments worked?
- How did the patient use any previous therapy, and for how long did they use it?

Age

Many conditions occur predominantly in certain age groups, such as acne in neonates and those ages 11 to 20 years, seborrheic dermatitis in neonates and those ages 11 to 12 years, rosacea in those older than 30 years, and atopic dermatitis primarily in children younger than 6 years. In fact, atopic dermatitis begins and ends prior to age 6 years in 95% of patients. It is equally important to realize that many conditions, such as primary irritant and allergic contact dermatitis, occur independent of age. In addition, the skin of children and patients older than 65 years is more penetrable, thus more responsive and more susceptible to adverse effects from therapy with topical agents. Topical therapeutic agent potency and delivery systems must be carefully evaluated before usage.

Table 38-7 Common Skin Diseases by Body Location

| Location | Skin Diseases |
|--------------------------|---|
| Scalp | Seborrheic dermatitis, dandruff |
| Face | Acne, rosacea, seborrheic dermatitis, perioral dermatitis, impetigo, herpes simplex |
| Ears | Seborrheic dermatitis |
| Chest/abdomen | Tinea versicolor, tinea corporis, pityriasis rosea, acne, herpes zoster |
| Back | Tinea versicolor, tinea corporis, pityriasis rosea |
| Genital area | Tinea cruris, scabies, pediculosis, condyloma acuminata (venereal warts) |
| Extremities | Atopic dermatitis |
| Hands | Tinea manuum, scabies, primary irritant contact dermatitis, warts |
| Feet | Tinea pedis, contact dermatitis, onychomycosis |
| Generalized or localized | Primary irritant or contact dermatitis, photodermatitis |

Gender

Although most dermatologic conditions occur in both genders, sometimes frequency and severity are gender dependent. Rosacea occurs more frequently in females, but is often more serious in males.

TOPICAL CORTICOSTEROIDS

General Principles of Therapy

Table 38-8 lists the most common topical corticosteroid preparations by their degree of potency. The following principles are used to guide the choice of agent and application technique.

- Topical corticosteroids should be applied twice daily. Increasing the application from twice daily to four times daily does not produce superior responses and is more expensive.⁹
- Preparations should be rubbed in thoroughly and, when possible, applied while the skin is moist (e.g., after bathing).⁷ Hydration of the skin increases percutaneous absorption and the resultant therapeutic effect of topical steroids.
- Appropriate-strength preparations should be used to control the condition. For maintenance, most dermatologic conditions requiring topical corticosteroids can be managed with medium- or low-strength corticosteroid preparations (i.e., 1% hydrocortisone or a low-strength fluorinated corticosteroid such as triamcinolone acetonide 0.025%).^{9,10}
- Occluded areas and certain, thin-skinned areas of the body, such as the face and flexures, are more prone to the development of side effects.^{9,11} If corticosteroids must be used on the face or flexures, hydrocortisone or other nonfluorinated topical steroids should be used to reduce the probability of side effects.
- Children, elderly patients, and patients with liver failure are at risk for systemic corticosteroid toxicities. In addition, patients who use the highest-potency preparations for longer than 2 weeks are susceptible to percutaneous absorption and systemic toxicity.^{9–11}

Table 38-8 Topical Corticosteroid Preparations

| <i>Corticosteroid</i> | <i>Brand Name(s)</i> | <i>Vehicle</i> |
|--------------------------------------|--------------------------|------------------------------------|
| 1 (Most Potent) | | |
| Betamethasone dipropionate | Diprolene 0.05% | Ointment, optimized vehicle |
| Clobetasol propionate | Temovate 0.05% | Cream, ointment, optimized vehicle |
| Difflorasone diacetate | Psorcon 0.05% | Ointment |
| Halobetasol propionate | Ultravate 0.05% | Cream, ointment |
| 2 | | |
| Amcinonide | Cyclocort 0.1% | Cream, lotion, ointment |
| Betamethasone dipropionate | Diprolene AF 0.05% | Cream |
| Betamethasone dipropionate | Diprosone 0.05% | Ointment |
| Desoximetasone | Topicort 0.25% | Cream, ointment |
| Desoximetasone | Topicort 0.05% | Gel |
| Difflorasone diacetate | Florone, Maxiflor 0.05% | Ointment |
| Fluocinonide | Lidex 0.05% | Cream, ointment, gel |
| Halcinonide | Halog 0.1% | Cream |
| Mometasone furoate ^a | Elocon 0.1% | Ointment |
| Triamcinolone acetonide | Kenalog 0.5% | Cream, ointment |
| 3 | | |
| Amcinonide | Cyclocort 0.1% | Cream, lotion |
| Betamethasone | Benisone, Uticort 0.025% | Gel |
| Betamethasone benzoate | Topicort LP 0.05% | Cream (emollient) |
| Betamethasone dipropionate | Diprosone 0.05% | Cream |
| Betamethasone valerate | Valisone 0.1% | Ointment |
| Difflorasone diacetate | Florone, Maxiflor 0.05% | Cream |
| Fluocinonide | Cutivate 0.005% | Ointment |
| Fluticasone propionate | Lidex E 0.05% | Cream |
| Halcinonide | Halog 0.1% | Ointment |
| Triamcinolone acetate | Aristocort A 0.1% | Ointment |
| Triamcinolone acetate | Aristocort HP 0.5% | Cream |
| 4 | | |
| Betamethasone benzoate | Benisone, Uticort 0.025% | Ointment |
| Betamethasone valerate | Valisone 0.1% | Lotion |
| Desoximetasone | Topicort-LP 0.05% | Cream |
| Fluocinolone acetonide | Synalar-HP 0.2% | Cream |
| Fluocinolone acetonide | Synalar 0.025% | Ointment |
| Flurandrenolide | Cordran 0.05% | Ointment |
| Halcinonide | Halog 0.25% | Cream |
| Hydrocortisone valerate ^a | Westcort 0.2% | Ointment |
| Mometasone furoate ^a | Elocon 0.1% | Cream |
| Triamcinolone acetonide | Aristocort, Kenalog 0.1% | Ointment |
| 5 | | |
| Betamethasone benzoate | Benisone, Uticort 0.025% | Cream |
| Betamethasone dipropionate | Diprosone 0.02% | Lotion |
| Betamethasone valerate | Valisone 0.1% | Cream |
| Clocortolone | Cloderm 0.1% | Cream |
| Fluocinolone acetonide | Synalar 0.025% | Cream |
| Flurandrenolide | Cordran 0.05% | Cream |
| Fluticasone propionate | Cutivate 0.05% | Cream |
| Hydrocortisone butyrate ^a | Locoid 0.1% | Cream |
| Hydrocortisone valerate ^a | Westcort 0.2% | Cream |
| Prednicarbate | Dermatop 0.1% | Cream |
| Triamcinolone acetonide | Aristocort 0.25% | Cream |
| 6 | | |
| Alclometasone dipropionate | Aclovate 0.05% | Ointment |
| Betamethasone valerate | Valisone 0.1% | Lotion |
| Desonide ^a | Tridesilon 0.05% | Cream |
| Fluocinolone acetonide | Synalar 0.01% | Solution |
| Triamcinolone acetonide | Kenalog 0.1% | Cream, lotion |
| 7 (Least Potent) | | |
| Hydrocortisone ^a | Generic 0.5, 1.0, 2.5% | Cream, ointment |
| Dexamethasone | Decadron 0.1% | Cream |

^aNonfluorinated corticosteroid.

- With chronic conditions such as atopic eczema, it is best to discontinue therapy gradually. This reduces the potential for rebound flares of topical lesions.⁷

Indications

A topical corticosteroid is often the drug of choice for inflammatory and pruritic eruptions. In addition, topical corticosteroids are useful with hyperplastic and infiltrative disorders. The following conditions generally respond well to topical corticosteroids: primary irritant and allergic contact dermatitis, alopecia areata, atopic eczema, discoid lupus erythematosus, granuloma annulare, hypertrophic scars and keloids, lichen planus, lichen simplex, lichen striatus, various nail disorders, pretibial myxedema, psoriasis, sarcoidosis, and seborrheic dermatitis.

Contraindications

The following conditions (predominantly infectious etiologies) are worsened by topical corticosteroids: acne vulgaris, ulcers, scabies, warts, molluscum contagiosum, fungal infections, and balanitis. However, during the acute phase, topical corticosteroids are sometimes combined with other active ingredients (e.g., antifungal agents) for a few days if marked inflammation is present.

Side Effects

Although relatively infrequent, both localized (i.e., at the application site) and systemic side effects (from percutaneous absorption) can be caused by topical corticosteroids. The risks for adverse reactions are influenced by the potency of preparation used, frequency of application, duration of use, anatomical site of application, and individual patient factors. Any of the previously discussed factors that increase potency, such as inflammation and occlusion, increase the chances of side effects.⁹

Epidermal and dermal atrophy (thinning of the skin), telangiectasia, localized fine hair growth, bruising, hypopigmentation, and striae can result from repeated application of topical corticosteroids.¹¹ Epidermal changes consisting of a reduction in cell size may begin within several days of therapy and are generally reversible after therapy is stopped.⁹ Exposed areas are most vulnerable to epidermal atrophy.

Dermal atrophy generally takes several weeks to occur and is usually reversible, depending on how long the patient has used the corticosteroid and on individual host factors such as skin age. Inguinal, genital, and perianal areas are most vulnerable to dermal atrophy. Most cases of dermal atrophy are reversible within 2 months after stopping the corticosteroid.¹¹

Telangiectasia, which occurs most often on the face, neck, groin, and upper chest, may not be reversible after stopping corticosteroid therapy. Striae, which occur most commonly in the groin, axillary, and inner thigh areas, are usually permanent.¹¹ Fine hair growth may be particularly bothersome to female patients using corticosteroid preparations on the face. This problem is generally reversible after stopping therapy. Hypopigmentation, predominantly a problem of dark-skinned patients, is generally reversible after therapy is discontinued.¹¹

Prolonged (several weeks or months) of application of high-potency steroids to large areas of the body, especially if occlusion is used, can lead to systemic absorption and subsequent adrenal suppression. Rarely, typical cushingoid features are observed.

Atopic Dermatitis

2. P.K., a 17-year-old boy, presents to a dermatology clinic with 30% of his body covered with a pruritic, eczematous rash. There is extensive involvement of popliteal and cubital fossae bilaterally. There is evidence of excoriation with cosmetic disfigurement in the antecubital fossae, around the neck, and on his forehead.

Family History: P.K.'s mother and aunt have asthma. One sister (L.K.), age 15, has seasonal allergic rhinitis and atopic eczema. His father and younger brother, age 11, appear to have no atopic manifestations.

Past Medical History: A rash was first noted 1 month after birth. The scalp, face, and neck were the only areas affected, and the rash continued with varying degrees of severity until age 2 years, when it spontaneously resolved. A similar rash reappeared at age 12, was diagnosed as atopic eczema, and has not disappeared since that time. P.K. developed seasonal allergic rhinitis at age 6 years and has had occasional attacks of asthma (last attack, age 15). He has had a difficult time trying to follow provided nondrug recommendations for eczema. He has used over-the-counter topical hydrocortisone cream to cool down flare-ups over the years. He reports a variable course; clearing in the summer and during periods of little stress, and worsening during the winter and periods of stress.

Physical Examination: P.K. is a well-nourished, well-developed, adolescent male with no abnormal physical findings other than marked allergic shiners, pale boggy nasal mucosa, and Dennie's lines noted near the eyes, plus extensive skin lesions. Oozing, crusted, erythematous, eczematous, lichenified, maculopapular, and fine vesicular eruptions are on his face, neck, flexor aspects of both arms and legs, hands, and chest. There is some evidence of secondary bacterial infection in both cubital fossae and on portions of the left leg. Identify the presenting history, symptoms, and signs characteristic of eczema.

Atopic dermatitis, a form of eczema, can be acute or subacute, but is more commonly a chronic pruritic inflammation of the epidermis and dermis. Roughly two-thirds of the patients have a personal or family history of allergic rhinitis, eczema, or asthma. Atopic dermatitis in infants may be a prelude to the development of other atopic disorders later in life (i.e., allergic rhinitis or asthma). Presence of these disorders many times is the key to differential diagnosis. About 80% of patients with atopic dermatitis have a type I (IgE-mediated) hypersensitivity reaction occurring as a result of the release of vasoactive substances from both mast cells and basophils that have been sensitized by the interaction of the antigen with IgE. An allergy workup is rarely helpful in determining the allergen. The disorder affects 0.5% to 1.0% of the general population, although its prevalence in children is 5% to 10%. In infants and young children, the dermatitis often occurs on the scalp, face, and extensor surfaces. In older children and adults, it tends to localize to the flexural areas, especially the cubital and popliteal fossae and the neck. In addition, the rash may affect the hands and feet, sometimes in the absence of eczema elsewhere. Most

patients become afflicted between infancy and age 12, with 60% being affected by the first year; another 30% are seen for the first time by age 5, with the final 10% developing atopic dermatitis between 6 and 20 years of age.

Pruritus is the hallmark of atopic dermatitis. The constant scratching leads to a vicious cycle of itch-scratch-rash-itch, with the rash consisting primarily of lichenification of the skin. Atopic dermatitis has been described as “the itch that rashes, rather than the rash that itches.” In other words, the itching precedes the rash. Wool, detergents, soaps, a change in room temperature, and mental and/or physical stress precipitate itching. Patients tend to have dry skin (xerosis). This is due to a reduced water-binding capacity and a higher transdermal water loss. Xerosis is worsened during periods of low humidity, such as winter in northern latitudes.

P.K.’s family and medical history are classic for atopic dermatitis. His family history is significant for asthma, allergic rhinitis, and atopic dermatitis. He had his initial outbreak at age 1 month and then developed seasonal allergic rhinitis and asthma. His skin examination reveals findings of both acute and chronic atopic eczema, with typical lesion location and description.

3. What are the relevant biopharmaceutic considerations for selecting a topical corticosteroid for P.K.?

Topical corticosteroids are classified into potency categories (Table 38-8). The relative potency assigned to a topical corticosteroid is determined by the ability of the preparation to penetrate the skin after release from the vehicle, the intrinsic activity of the corticosteroid at the receptor, and the rate of clearance from the receptor. Activity of corticosteroids may be enhanced by the use of a more occlusive vehicle, the addition of penetration-enhancing substances (i.e., urea, salicylic acid, propylene glycol), and modifications of the steroid molecule. Hydrocortisone was the initial local corticosteroid discovered, and since then, the molecule has been modified in several ways. The addition of a fluorine atom protects the steroid ring from metabolic conversion, resulting in more potent activity. The introduction of an acetonide bond and/or lipophilic ester groups increases skin penetration. Many newer topical corticosteroids have incorporated one or more of these molecular changes, resulting in increased-potency agents and a growing armamentarium of agents.

It is believed that topical corticosteroids penetrate into the stratum corneum by passive diffusion, which varies considerably, depending on the part of the body to which the preparation is applied. When a standard hydrocortisone preparation was applied to various parts of the body, absorption was found to be 0.14% on the plantar surface of the foot, 1% on the forearm, 4% on the scalp, 7% on the forehead, 13% on the cheeks, and 36% on the scrotum. Because penetration is high in the groin, axillae, and face, lower-potency nonfluorinated topical preparations such as hydrocortisone 0.5% to 1% should be used on these areas.^{9,10} In areas where penetration is poor, owing to thickening of the stratum corneum, such as the elbows, knees, palms, or soles, higher-strength preparations should be used.⁹

For P.K., a 1% hydrocortisone cream should be used on his face and other areas of high penetrability to reduce the possibility of complications.⁹ A high-potency cream (intermediate- or

higher-potency classification from Table 38-8) should be used initially on acutely inflamed areas or where high penetration is not a problem. This will “cool down” these lesions quickly.

If equal amounts of a corticosteroid are incorporated into ointments, gels, creams, and lotion bases, the gel and ointment preparations are generally more active than creams and lotions.^{9,10} However, with the increased use of optimized vehicles, that rule is not as true as in the past. The addition of certain substances enhances penetration and potency. Using these principles, pharmaceutical manufacturers have increasingly developed optimized vehicles that maximize diffusion of individual corticosteroids into the stratum corneum. Therefore, for new products, the only reliable way to ascertain potency is to consult the manufacturer’s literature for its Stoughton classification. Increasing the concentration of a corticosteroid in a preparation also increases its potency, but not in a linear fashion. Because P.K. has a fine vesicular eruption, a cream should be used initially, to facilitate drying. However, patients often express a preference (e.g., cream or gel), and this should be considered.

Occlusion

4. It has been some time since P.K.’s atopic eczema has been aggressively treated. He has many acute, inflamed lesions. Should occlusive therapy be used? What complications could develop from occlusion? How would you describe the use of occlusion to P.K.?

As discussed previously (see Dermatologic Delivery Systems section), occlusion traps heat and promotes maceration. This same mechanism increases the hydration of the skin and resultant absorption of corticosteroid preparations, thus producing a heightened therapeutic effect. As a general rule, occlusion enhances the potency of corticosteroids by a factor of 10. Occlusion can be accomplished by selecting an ointment-based corticosteroid, applying a nonmedicated ointment base over another corticosteroid preparation (gel, cream, lotion, or aerosol), or by enveloping the medicated area with plastic (e.g., plastic wrap, gloves, or plastic suit [space suit]).^{5,7,9,11} Several hours of occlusion are all that is necessary to increase potency; thus, relatively short periods of occlusion are clinically useful. Occlusion can be uncomfortable, and can lead to sweat retention and an increased risk of bacterial and candidal infections. To reduce these problems and the chances of systemic side effects, occlusion should not be maintained for more than 12 hours in a 24-hour period. Occlusion should not be used for acute lesions, which already have increased absorptive capability and need the vasoconstrictive effects of cooling first. Occlusion is best used for chronic lesions that are thick and scaly, where drug absorption is impaired. Most patients with atopic dermatitis do not tolerate occlusion because their itch threshold is low, and heat, sweat retention, and maceration increase pruritus. The long-term benefit of occlusion in a patient with atopic dermatitis is reduced by the increased pruritus, which may lead to noncompliance. When using occlusion in patients with eczema, care should be taken not to occlude unaffected skin (because of the low itch threshold). For other chronic dermatologic conditions (e.g., psoriasis) that are not associated with severe pruritus, occlusion could be used for prolonged periods if necessary. Increasing the hydration of the skin (after a shower or bath) also increases the effects of

medications immediately applied after the bath or shower, which would be an appropriate recommendation for P.K.

Product Selection

Pharmacokinetic Considerations

5. P.K. received a prescription for halcinonide (Halog) 0.1% cream, 80 g, to be applied at bedtime, with five refills. Comment on the appropriateness of this prescription based on pertinent biopharmaceutical considerations.

Corticosteroids tend to penetrate human skin very slowly, leading to a reservoir effect. With low-potency preparations, this reservoir effect persists for several days, and with the most potent preparations under occlusion, the effects may persist for up to 14 days.^{9,10} The clinical implication of this reservoir effect on chronic conditions is a cumulative effect with repeated application of topical corticosteroids. As a result, the number of applications per day can be reduced, and less potent preparations can be used after the acute inflammatory process has been brought under control. Results from P.K.'s treatment regimen might be improved by providing more frequent (twice-daily) application or a more potent preparation for twice-daily administration to control inflamed lesions. Once control is achieved, a less-potent preparation could be used for maintenance and the number of applications may be reduced. Due to the reservoir effect, control can be maintained in many cases with intermittent regimens such as once daily, every other day, or every third day use of topical corticosteroids. In addition, intermittent regimens can involve alternating corticosteroids and agents such as pimecrolimus.

Side Effects

Acne

6. After several months of continuous corticosteroid therapy in a maintenance format, P.K. presents with four pustules and two closed comedones on his forehead and multiple pustules on both cheeks. What problems from the use of topical corticosteroid therapy on the face does this represent?

The face is particularly vulnerable to corticosteroid side effects because of enhanced penetration.¹¹ Acne, acne rosacea, and perioral dermatitis can develop after several weeks to months of application. Corticosteroid-induced conditions can generally be distinguished from naturally occurring disorders. Corticosteroid-induced acne lesions are uniformly at the same level of development throughout the affected area and are present only in areas treated with the corticosteroid. Generally, steroid acne, acne rosacea, and perioral dermatitis resolve after discontinuing the drug. Application of corticosteroid preparations (particularly the potent preparations) to areas around the eye can lead to increased intraocular pressure, glaucoma, cataracts, increased risk of ocular mycotic infections, and exacerbation of pre-existing herpes simplex infections.¹¹ Hydrocortisone or nonfluorinated topical corticosteroids are often the agents of choice for facial lesions.

P.K.'s acneiform lesions may get worse after the application of topical corticosteroids. He should be instructed to apply the corticosteroid preparation only to the atopic eczema and to avoid areas where acne exists. If the atopic eczema and acne

lesions are in the same area and his acne gets worse after using the topical corticosteroid, P.K. must make a decision as to which of these two dermatologic conditions bothers him more and treat the condition that is most disturbing. Some improvement in corticosteroid-exacerbated acne may be achieved by decreasing the strength of the topical product applied to the face and reducing the frequency of application. An alternative to this approach, if P.K.'s acne is severe, would be to continue topical corticosteroid therapy, but treat the acne systemically.^{5,6} (See Chapter 39 for a more extensive discussion.)

Idiosyncratic/Allergic Reactions

7. P.K.'s sister, L.K., who also has atopic eczema, started using a new topical corticosteroid preparation (halcinonide) 10 days ago. She has been complaining of a burning sensation lasting for 1 hour after every application of this product. She stopped using the product 2 days ago because of this. Is it possible that she has developed an allergy to a corticosteroid-containing medication?

Cortisol is endogenously secreted by the adrenal gland and is essential to life. As a result, allergic reactions to topical corticosteroid preparations are rare. When allergic symptoms do occur, they are generally not due to the corticosteroid, but to the preservatives (e.g., paraben) or other ingredients in the formulation or the base (e.g., lanolin). Allergic sensitization can occur within 2 weeks of therapy, but may be difficult to diagnose because the corticosteroid can modify the allergic reaction.¹² One should suspect an allergic reaction if lesions change appearance after starting therapy, if healing does not occur within the expected period of time, or if the condition improves and then abruptly gets worse. Most case reports of allergic reactions (dryness, itching, burning, or irritation) to topical corticosteroids are nonspecific and have been in patients with atopic eczema.¹² Atopic individuals are more likely to react to the vehicle base than the active corticosteroid ingredient.

Because of the time course of the burning sensation in L.K. (starting the first day and lasting only 1 hour), it is doubtful that she is actually allergic to this product. However, atopic eczema patients often have "sensitive" skin that reacts idiosyncratically to a variety of topical preparations.¹² To remedy this situation, L.K. should be given another topical corticosteroid preparation with a different formulation (base and preservatives). If the reaction continues with a new product, an allergy workup may be necessary and patch testing could be considered.

Adrenal Axis Suppression/Risk of Infection

8. P.K. recently sustained a knee injury and corrective surgery is being considered. Should he receive a systemic corticosteroid during the perioperative period as a precaution against adrenal insufficiency? Should he wear a Medic-Alert tag while using long-term topical corticosteroids? Is he at risk for developing an infection after surgery?

Systemic adrenal axis suppression from topically applied corticosteroids appears to be more of a theoretic risk than a clinical entity in adults, except when the highest-potency preparations are used¹³ or other risk factors are present (Table 38-9). Although suppression has been reported with use of mild to moderately potent agents, these cases can be attributed to excessive use or to application of corticosteroids over large areas of the body for prolonged periods under

Table 38-9 Risk Factors for Systemic Side Effects From Topical Corticosteroids

| |
|--|
| Duration of application |
| Prolonged application (>3–4 wk) |
| Potency of corticosteroid |
| Weak or moderately strong, 100 g/wk without occlusion |
| Very potent, >45 g/wk without occlusion |
| Application location |
| Thin stratum corneum results in easier penetration (eyelids, forehead, cheeks, armpits, groin, and genitals) |
| Age of patient |
| Very young children and elderly people have very thin epidermis |
| Manner of application |
| Occlusion |
| Presence of penetration-enhancing substances |
| Propylene glycol |
| Salicylic acid |
| Urea |
| Condition of the skin |
| General factors |
| Compromised liver function |

occlusion. If suppression does occur, it reverses within 2 to 4 weeks after application is stopped. Patients using more than 45 g/week of a high-potency corticosteroid are at risk for adrenal axis suppression.¹³ Therefore, the use of preparations such as clobetasol (Temovate) should be limited to no more than 45 g/week for 2 weeks or less. In addition, these preparations should not be used under occlusion and should be reserved for dermatoses that are unresponsive to less potent preparations.

Because young children absorb corticosteroids to a greater extent, they have a greater risk of developing adrenal axis suppression and other systemic side effects.¹³ To reduce this risk, hydrocortisone topical preparations should be used in children, and their use should be limited to short periods of time. Patients whose corticosteroid clearance is impaired (e.g., liver failure) should also use hydrocortisone and be monitored closely for signs of systemic toxicity.¹¹

The risk of developing an Addisonian crisis during surgery or at other times of stress secondary to adrenal suppression from topical steroids is extremely low. Patients who have used potent topical corticosteroids over large areas of their bodies (>30%) or those who have used occlusion are at greater risk (see previous discussion) and are often given systemic hydrocortisone prophylactically before surgery. Because P.K. is not likely to require such supplementation, a MedicAlert tag is unnecessary.

Infection secondary to topically administered corticosteroids is also a theoretic risk, but is uncommon. Although anecdotal reports of secondary bacterial infections appear in the literature, there is scant evidence to suggest that they occur with any frequency. Topical corticosteroids do not alter normal skin flora.¹⁴

Topical Antibiotics with Corticosteroids

9. P.K.'s atopic eczema presentation is complicated with areas of erythematous, honey-colored, crusted lesions on his forehead, arm, and leg. Can a corticosteroid and an antibiotic preparation

be used together? What are the risks associated with topical antibiotics?

It is determined that P.K. has impetigo superimposed on his atopic dermatitis. Because impetigo can be treated with topical antibiotics such as mupirocin, combination therapy with a corticosteroid-antibiotic preparation appears to be a logical choice. The corticosteroid suppresses the clinical signs of infection and helps re-establish the normal skin barrier function. This, in combination with an appropriate antibiotic, allows the skin's normal defense mechanisms to ward off the infection. However, because staphylococci toxins act as superantigens, eliciting the production of IgE, thus worsening the atopic dermatitis, almost all clinicians treat impetiginized atopic dermatitis with oral antibiotics such as penicillin, dicloxacillin, erythromycin, or cephalexin, in combination with topical corticosteroids for the eczema.^{15–17} Oral antibiotics reduce the bacterial counts faster and have a lower incidence of recurrent impetigo compared with topical agents. In areas where community methicillin-resistant *Staphylococcus aureus* rates are high, other more effective antibiotic therapy might be indicated.

Otitis externa, certain intertriginous eruptions, and possibly seborrheic dermatitis may respond favorably to combination antibiotic-corticosteroid preparations. Table 38-10 describes the spectrum of activity of common topical antibiotics. Although mupirocin may be an appropriate alternative for topical dermatologic infections, the current over-the-counter topical antibiotics (bacitracin, neomycin, and polymyxin) are ineffective for most dermatologic infections and are indicated only for the prophylaxis of skin infections. Mupirocin resistance occurs with overuse.¹⁸

P.K. would most likely benefit from a treatment course of an oral antibiotic plus a topical corticosteroid preparation.

Table 38-10 Spectrum of Activity of Antibiotics Available for Topical Use

| |
|---|
| Bacitracin |
| Effective against all anaerobic cocci, most strains of streptococci, staphylococci, and pneumococci. Not effective against most gram-negative organisms. |
| Gentamicin |
| Effective against most gram-negative organisms (similar to neomycin), including <i>Pseudomonas</i> and many strains of <i>Staphylococcus aureus</i> . |
| Mupirocin |
| Very effective against <i>S. aureus</i> and does not interfere with wound healing. Currently, the only topical antibiotic that has been proved to be more effective than the vehicle based on U.S. Food and Drug Administration guidelines. |
| Gramicidin |
| Effective against most gram-positive organisms. Not effective against most gram-negative organisms. |
| Neomycin |
| Effective against most gram-negative organisms (except <i>Pseudomonas</i>) and some gram-positive organisms. Group A streptococci are resistant. |
| Polymyxin B |
| Effective against most gram-negative organisms (including <i>Pseudomonas</i>). Most strains of <i>Proteus</i> , <i>Serratia</i> , and gram-positive organisms are resistant. |

Table 38-11 Systemic Diseases Associated With Pruritus

| | |
|---|--|
| Brain abscesses | Iron-deficiency anemia |
| Carcinoid syndrome | Multiple myeloma |
| Carcinoma of the breast, lung, or stomach | Multiple sclerosis |
| Central nervous system infarct | Mycosis fungoides |
| Diabetes mellitus | Obstructive biliary disease |
| Gout | Polycythemia vera |
| Hodgkin disease and other lymphomas | Pregnancy (first trimester) |
| Hypertension | Thyroid disease (both hyper- and hypothyroidism) |
| | Uremia |

Side Effects

There have been many reports of contact dermatitis caused by topical antimicrobials, particularly neomycin.¹⁹ Neomycin sensitivity has been reported in 4% of the general population by patch testing and in 40% of patients with a history of allergic contact dermatitis or a history of recurrent use of topical antibiotics.^{19,20} The corticosteroid contained in many neomycin preparations does not prevent these allergic reactions, although it may decrease the severity of the reaction.

Pruritus

10. As stated in Question 2, one of P.K.'s complaints is pruritus. What could you recommend for relief of pruritus?

Pruritus (itching) is the most common cutaneous symptom. It has many different causes and has been associated with a variety of systemic diseases, several of which are listed in Table 38-11.^{5,7,21} In the absence of a cutaneous manifestation, a careful history and physical examination should be performed to rule out one of the systemic causes of pruritus. In addition, a chest radiograph, stool examination for occult blood, complete blood count with differential, thyroid panel, blood urea nitrogen, creatinine, liver function panel, glucose, and urinalysis may be necessary to help screen for the aforementioned systemic diseases.²¹

Scratching, which can damage or fatigue receptor nerve endings, is the most common method of relieving pruritus. One would, therefore, expect topically applied local anesthetics or antihistamines to be effective in dulling the sensation. However, this approach is often disappointing, probably because the intact epidermis poorly absorbs the salt forms of these drugs. Also, low concentrations are used in many over-the-counter preparations. If adequate concentrations of local anesthetics are used (benzocaine 20% or lidocaine 3%–4%), pruritus or pain may be reduced for up to 45 minutes. These agents are most useful for relieving pruritus or pain for short periods of time (e.g., when trying to go to sleep at night).²¹ A drawback to the use of benzocaine and topical antihistamine preparations are their propensity to induce allergic contact dermatitis.^{22–24}

P.K. could also try cold water or ice cubes, which effectively relieve pruritus via vasoconstriction, as do products containing aluminum acetate (Burow's solution), tannic acid, or calamine. A cool bath may be useful for the relief of pruritus from dermatologic lesions if they are widespread.

Moisturizing mixtures such as Keri Lotion, Lubriderm, or, simply, mineral or baby oil are useful in the treatment of pruritus caused by dry skin.

This problem is often encountered in the elderly and others during the winter months. Bathing should be restricted to avoid washing away normal body oils, the drying effect of water, the irritant effect of alkaline soaps, and the trauma of toweling.⁷

Topical corticosteroid applications can be very effective. They reduce inflammation and are often contained in a cream base, which helps soothe the affected area.

Systemic antihistamines are effective antipruritics, although their major beneficial effect may be due to sedation. The newer, nonsedating antihistamines are notably ineffective at relieving itch, with the exception of cetirizine.²⁵ There is disagreement over which antihistamine or antiserotonin agents are most effective for treatment of pruritus.^{21,25,26} Many practitioners consider hydroxyzine to be the antihistamine of choice; doses of 10 to 25 mg three to four times a day are commonly used. Other practitioners favor cyproheptadine. There is little evidence that antihistamines are effective in treating non-histamine-mediated pruritus, except that their inherent sedative effect may be somewhat beneficial in all pruritic conditions. Doxepin, a tricyclic antidepressant with potent H₁-blocking properties, is valuable as a second-line antihistamine topically or systemically if others fail.²⁷ Because P.K.'s pruritus is worse at night as is typical with atopic dermatitis, the use of any of the four H₁-blockers mentioned at bedtime would be appropriate.²⁸

Nondrug Recommendations for Atopic Dermatitis

11. In addition to prescriptions for topical corticosteroids (triamcinolone acetonide cream 0.1%/augmented betamethasone dipropionate 0.05%) for flare-ups, a systemic antibiotic (erythromycin 250 mg QID × 10 days), and an oral antihistamine (hydroxyzine 25 mg, 1–2 tablets HS as needed), what nondrug interventions should be suggested for P.K.?

The general goals of therapy for atopic dermatitis are to decrease pruritus, suppress inflammation, lubricate the skin, and reduce anxiety. The nondrug recommendations shown in Table 38-12 are useful adjuncts and mainstays between disease flares, for patients such as P.K. with eczema or any other irritant dermatitis. Often careful attention to nonpharmacologic measures can reduce the incidence of disease flare. Because

Table 38-12 Nondrug Recommendations for Patients With Atopic Eczema or Other Irritant Dermatitis

- Clothing should be soft and light. Cotton or corduroy is preferred. Wools and coarse, heavy synthetics should be avoided.
- Heat should be avoided because it often makes eczema worse. The environment should be well ventilated, cool, and low in humidity (30%–50%). Rapid changes in ambient temperature should be avoided.
- Bathing should be kept to a minimum (no longer than 5 minutes), and the patient should use a nonirritating soap (e.g., Basis soap). A colloid bath or the use of appropriate amounts of bath oil may be useful.
- The skin should be kept moist with frequent applications of emollients (e.g., Keri, Lubriderm, Nivea, Aquaphor, Eucerin, or petrolatum).
- Primary irritants such as paints, cleansers, solvents, and chemical sprays should be avoided.

even nonlesional skin in patients with atopic dermatitis has reduced moisture, the use of emollients should include all skin surfaces.

P.K. should be warned to avoid people with active herpes simplex infections because severe disseminated infections can occur. Similarly, based on the anthrax bioterrorism attack in October 2001, debate has emerged on the advisability of reinitiating routine vaccination against smallpox. Vaccinia virus was the live poxvirus used throughout the world as the vaccine against smallpox. Because of the increased risk for eczema vaccinatum, vaccinia vaccine should not be administered to persons with eczema of any degree, those with a past history of eczema, household contacts who have active eczema, or household contacts who have a history of eczema.^{26,29}

Tachyphylaxis/Specialized Corticosteroid Dosage Forms/Antihistamines

12. P.K. responded well to the previous treatment plan and now requests a refill of his topical corticosteroid prescriptions. The bacterial superinfected areas have cleared. He continues to have problems with his fingers. He has applied betamethasone dipropionate to his hands five to six times daily for the past 3 weeks without any noticeable improvement. Triamcinolone cream resolved the rash on other areas of his body. Other than occasional sedation early on from the hydroxyzine and when he uses it intermittently, he has not had any other adverse effects. As P.K. continues to follow other nondrug recommendations, he inquires if anything else could be done for his hands. Assess P.K.'s use and response to the corticosteroids.

P.K. is overusing the potent topical corticosteroid and may have developed tachyphylaxis. Tachyphylaxis can occur within 1 week of therapy, but generally takes several weeks to a month to occur.³⁰ To treat this problem, P.K. should stop applying the betamethasone preparation for 4 to 7 days and then restart therapy in a more appropriate manner (i.e., twice daily). Limited courses of treatment separated by short periods of rest may be more effective than continuous treatment. However, clinicians commonly misdiagnose tachyphylaxis. Failure of topical corticosteroids to clear difficult atopic dermatitis after an initial improvement may give the false impression of tachyphylaxis when the actual problem is a primary failure of the treatment.³¹ This could be caused by either inappropriate application technique by the patient or the choice of a product with inadequate potency.

Flurandrenolide 4 mg/cm² tape (Cordran) may be useful after P.K. stops his other corticosteroids for 4 to 7 days. Although this product is expensive, it is effective for small areas because the tape serves as a protectant and provides occlusion. It is a good choice for use on the hands, particularly the fingers, where P.K. is having problems, because other vehicles are often quite messy when applied to the hands. When using Cordran tape, the general principles previously outlined for occlusion should be followed.

Topical tacrolimus (Protopic) is an effective alternative to topical corticosteroids and is safe for use in children.^{32,33} In addition to its inhibitory effect on cytokine production, topical tacrolimus has been shown to cause alterations in epidermal antigen-presenting dendritic cells that may result in decreased immunologic response to antigens. Transient burning, erythema, and pruritus are the most common adverse ef-

fects. Pimecrolimus cream (Elidel) 1% is an immunomodulatory agent with properties similar to those of cyclosporine and tacrolimus, but it does not appear to affect the systemic immune response and might, therefore, be better tolerated for long-term therapy.³⁴ Neither pimecrolimus nor tacrolimus causes skin atrophy, making them attractive alternatives for patients with lesions on the face and neck. Recently, issues regarding the long-term safety of these products has led the U.S. Food and Drug Administration to place a temporary black box warning in the manufacturer's literature regarding a potential increased cancer risk.

XEROSIS

13. C.R., a 64-year-old woman, requests something for dry skin on her arms and back. She has had this problem for a number of years. It is generally not a problem in the summer, with most symptoms troubling her in the winter. She has no other medical conditions and only takes an occasional aspirin for "arthritis." How would you advise C.R. to manage this condition?

C.R.'s complaints represent a common problem of the elderly, xerosis (dry skin). The seasonal cycle described is frequently called "winter itch." Most cases of dry skin are caused by dehydration of the stratum corneum.³⁵ Table 38-13 gives general recommendations for the treatment of dry skin.

Table 38-13 General Recommendations for Treatment of Dry Skin

1. Use room humidifiers.
2. Keep room temperature as low as comfortable to prevent sweating and water loss from the skin.
3. Keep bathing to a minimum (every 1–2 days) with warm, but not hot, water. After bathing, the patient should immediately apply an emollient (Table 38-2). When the skin is soaked for 5 to 10 minutes, the stratum corneum can absorb as much as six times its weight in water. Application of an emollient immediately after bathing will trap the water in the skin and reduce dryness.
4. Eliminate exposure to solvents, drying chemicals, harsh soaps, and cleaners. These substances remove oils from the skin and reduce its barrier function. As the barrier function is lost, water loss from the skin is increased up to 75 times higher than normal. Exposure to cold, dry winds will also enhance water loss.
5. Apply emollients (Table 38-2) three to six times a day, especially after bathing to help retain moisture in the skin from bathing.
6. The selection of emollients depends on the atmospheric moisture content of the region. In dry parts of the western United States where humidity is very low, water-in-oil emollients such as Lubriderm, Eucerin, or Nivea are preferred because the high oil content prevents the loss of moisture from the skin. In those areas, a general rule is to avoid products where glycerin is one of the top four ingredients on the label because glycerin is hygroscopic and in low humidity will pull moisture out of the dermis leading to drier, cracked skin. In areas with higher humidity such as the eastern United States, glycerin in both types of emollients pulls moisture from the atmosphere into the skin. Regardless of region, if application of an emollient appears to be ineffective, switching to a product with less glycerin and more oil may resolve the dryness.
7. If scaling is a problem, a keratolytic (Lac-Hydrin, AmLactin) or a higher-strength, urea-containing preparation (20%) may be useful.
8. If inflammation is present, a mild to moderately potent topical corticosteroid may be useful (Table 38-8). An ointment vehicle is more effective than others.

However, before recommending therapy, the following differential should be considered: ichthyosis vulgaris (familial history usually present), atopic eczema, psoriasis, contact dermatitis, and hypothyroidism. Usually, simple questioning can rule out these conditions.

DRUG ERUPTIONS

Clinically recognizable adverse drug reactions are manifested on the skin more often than any other organ or organ system.^{36,37} An estimated 1% to 5% of hospitalized patients develop a drug eruption.³⁷ Outpatient statistics are more difficult to obtain, but are probably within the same range. There is no correlation between age, diagnosis, or severity of illness and the likelihood of developing a drug eruption. Women appear to be twice as likely as men to develop a drug eruption.

The most common type of eruption encountered in clinical practice, and probably the one most often overlooked, is the exanthematic (bursting out) eruption. This type of reaction comprises both morbilliform (measles-like) and scarlatiniform (scarlet fever-like) eruptions. Stevens-Johnson syndrome (SJS), toxic epidermal necrolysis, drug hypersensitivity syndrome, vasculitis, serum sickness, coagulant-induced skin necrosis, and angioedema are the most important severe reactions and require immediate attention and management. Many of the common dermatologic reactions that can be induced by drugs have other causes as well, so a complete workup must include other nondrug etiologies. Viral, fungal, and bacterial infections, as well as certain systemic diseases and foods, have been identified as causes for common reactions such as urticaria, erythema multiforme, and erythema nodosum. The diagnosis of drug eruptions is best made by identifying the type of lesions observed and associating the lesions with specific drug therapy. The most important diagnostic criterion is an accurate assessment of the skin lesions. With this critical information, the clinician can then refer to a drug information source to associate any current or past drug therapy with the specific lesions observed.

Acneiform Eruptions

Acneiform eruptions appear very much like common acne. They may be distinguished from acne by their sudden occurrence, the absence of comedones, uniform appearance (i.e., all at the same stage of development), and the fact that they may occur on any part of the body. Cysts and scarring are rarely associated with drug-induced acne. Eruptions can also occur during any period of the patient's life; thus, drug-induced acne should be suspected when the lesions appear in persons outside the typical age bracket for acne. Drugs implicated include adrenocorticotrophic hormone, anabolic steroids, azathioprine, danazol, glucocorticoids, halogens (iodides, bromides), isoniazid, lithium, and oral contraceptives. For patients with acne vulgaris, these drugs may worsen existing lesions (see Chapter 40).

Photosensitive Eruptions

Photosensitivity eruptions require the presence of both a drug (or chemical) and a light source of appropriate wavelength. These eruptions are divided into two subtypes: phototoxic and photoallergic. *Phototoxic* reactions, the most common drug-

induced photodermatitis, manifest themselves as an exaggerated sunburn or increased sensitivity to sunburn. The ultraviolet A (UVA) light source alters the drug to a toxic form, resulting in tissue damage independent of any allergic response and occurs in everyone who gets high enough skin levels of the offending drug. This eruption can occur on first exposure to a drug, is dose related, usually has no cross-sensitivity, and will continue as long as the skin concentration of the drug exceeds the threshold level for the reaction to occur. *Photoallergic* reactions, which are very uncommon, may appear as a variety of lesions, including urticaria, bullae, and sunburn. UVA light alters the drug so it becomes an antigen or acts as a hapten. Photoallergic eruptions require previous contact with the offending drug, are not dose related, exhibit cross-sensitivity with chemically related compounds, and are secondary to the use of topical agents. Unfortunately, outside light through a window and fluorescent lighting permits passage of or can emit UVA light. In addition, until recently, there were inadequate topical preparations that provide protection against UVA light. Avobenzone, while covering much of the UVA spectrum, is photolabile, losing 60% of its effectiveness in <1 hour. New products containing ecamsule appear to offer an advance in protection against UVA rays. In some instances, a drug may produce both photoallergic and phototoxic reactions. Most phototoxic and photoallergic reactions occur fairly soon after exposure to light. Implicated drugs are numerous, including, among others, antibiotics (tetracyclines, fluoroquinolones), antidepressants (tricyclics), antihypertensives (hydrochlorothiazide, β -blockers), hypoglycemics (sulfonylureas), nonsteroidal anti-inflammatory drugs, sunscreens (PABA), oral contraceptives, and antipsychotics (phenothiazine) (see Chapter 42).

Lichen Planus–Like Eruptions

Lichen planus–like lesions appear as flat-topped papules that have a distinctive sheen. Pruritus is usually quite pronounced. Any part of the body can be affected (most commonly the arms and legs), including mucous membranes. The lesions are sometimes confused with fixed eruptions, but can easily be differentiated histologically. Implicated drugs include angiotensin-converting enzyme inhibitors, antimalarials, phenothiazine derivatives, thiazide diuretics, and sulfonylurea hypoglycemic agents among others.

Alopecia

Alopecia (hair loss) is not a true drug eruption, but hair may occasionally be lost when other drug reactions such as exfoliative dermatitis and erythema multiforme occur. Hair loss can be caused by a direct toxic action of a drug (e.g., a cancer chemotherapeutic agent) or from interference with the normal growth phases of hair (e.g., warfarin).

Bullous Eruptions

Bullous (blister-like) lesions can occur in combination with other drug eruptions, such as erythema multiforme and toxic epidermal necrolysis or by themselves. The lesions may be round or irregular and contain a clear, serous fluid. The fluid-filled sacs may be tense or flaccid and can occur on both mucous membranes and skin. These lesions are similar to those associated with pemphigus and pemphigoid reactions. Lesions

Table 38-14 Frequent Contact Sensitizers

| Substance | Found In |
|----------------------|--|
| Ammonia | Soaps, chemicals, hair dyes |
| Balsam of Peru | Cosmetics |
| Benzyl alcohol | Medications, cosmetics |
| “Caine” anesthetics | Medications (e.g., over-the-counter benzocaine products) |
| Carba | Rubber |
| Chromium | Jewelry |
| Epoxy resin | Glue |
| Ethylenediamine | Stabilizer in topical products (e.g., aminophylline) |
| Formaldehyde | Shoes, clothing, soaps, insulations |
| Mercaptobenzothiazol | Rubber |
| Naphthyl | Rubber |
| Neomycin | Topical medications (e.g., Neosporin) |
| Nickel sulfate | Jewelry, fasteners |
| Paraben | Preservative in many topical products |
| Paraphenylenediamine | Hair dyes, leather |
| Potassium dichromate | Shoes, leather |
| Thiomersal | Preservatives, contact lens products |
| Thiram | Rubber products |
| Turpentine | Paint products |
| Wool alcohols | Lanolin-containing products, clothes |

usually resolve after discontinuation of the drug, but occasionally become chronic. Implicated drugs include amiodarone, barbiturates, coumarin, gold, penicillins, and sulfonamides.

Allergic Contact Dermatitis

Topical administration of a sensitizing agent produces localized lesions limited to areas of contact with the topical product. Neomycin, benzocaine, and diphenhydramine are well-known topical sensitizers (Table 38-14). Systemic administration of a drug to a patient previously sensitized to the drug by topical application can provoke widespread eczematous dermatitis. Implicated systemically or topically administered drugs that reactivate allergic contact dermatitis include procaine/benzocaine, radiographic contrast media/iodine, and streptomycin and gentamicin/neomycin among others.

Erythema Multiforme

As the name implies, erythema multiforme (EM) eruptions take on a varied spectrum of morphologic forms, ranging from the mildest with tiny maculovesicular lesions to more severe forms such as SJS and toxic epidermal necrolysis syndrome (TENS) with extensive bullous lesions and routine involvement of mucous membranes. Although all forms have been reported to have oral lesions, they are much more severe in SJS and TENS, where genital, nasal, and ocular mucosae are also involved. Target lesions are usually present in all forms of the disorder, which characteristically are erythematous, iris-shaped papules and vesiculobullous lesions typically involving the extremities (especially the palms and soles) in EM and the torso in SJS/TENS. The lesions take on the appearance of a circular target with a bulls-eye in the middle, thus the term target lesion. However, questions have recently been raised about the shared pathological nature of these forms of

erythema multiforme.³⁸ EM in its mildest forms, EM minor and EM major, is more common in children and young adults, and is self-limited in nature with only transient hypo- or hyperpigmentation as complications. Sometimes malaise, a low-grade fever, and itching or burning may accompany this type of eruption. Etiologic factors associated with EM include drugs, mycoplasma and herpes infections, radiation therapy, foods, and sometimes neoplasms. Allopurinol, barbiturates, phenothiazine, and sulfonamides are the drugs most often implicated in EM eruptions.

Stevens-Johnson Syndrome

SJS is probably the most common type of severe drug eruption. The syndrome is usually a moderate mucocutaneous and systemic reaction. Blisters and atypical target lesions involve less than 10% of body surface area, with some epidermal detachment, which can cause scarring in some cases. With more extensive involvement, clinical findings are almost indistinguishable from toxic epidermal necrolysis. The skin can become hemorrhagic, and pneumonia and joint pains may occur. Serious ocular involvement is common and can culminate in partial or complete blindness. Besides drugs, this syndrome has been associated with infections, pregnancy, foods, deep radiographic therapy, and neoplasms. Mortality is estimated to be in the range of 5% to 18%. The duration of the syndrome is usually 4 to 6 weeks. The long-acting sulfonamides are most often implicated. Allopurinol, carbamazepine, fluoroquinolones, hydantoin, phenylbutazone, and piroxicam are also possible causative agents.

Toxic Epidermal Necrolysis Syndrome

Epidermal necrolysis, a severe, life-threatening mucocutaneous and systemic reaction, may be preceded by a prodrome characterized by malaise, lethargy, fever, and occasionally throat or mucous membrane soreness. Epidermal changes follow and consist of erythema and massive bullae formations that easily rupture and peel, giving the skin a scalded appearance. Hairy parts of the body are usually not affected, but mucous membrane involvement is common. Blisters cover >30% of body surface area, with extensive epidermal detachment that can result in scarring. Approximately 30% of patients with toxic epidermal necrolysis succumb, often within 8 days after bullae appear. The usual cause of death is infection complicated by massive fluid and electrolyte loss, similar to patients with extensive burns. Although the skin takes on a grave appearance, healing occurs within 2 weeks in approximately 70% of patients, with some potential for scarring. In addition to drugs, certain bacterial infections and foods are believed to cause this type of eruption. Most causes of toxic epidermal necrolysis in children are due to infection (e.g., *Staphylococcus aureus*). There appears to be a higher incidence of this type of drug eruption in HIV-positive patients. Drugs most frequently implicated include allopurinol, aminopenicillins, carbamazepine, hydantoin, phenylbutazone, piroxicam, and sulfa drugs.

Erythema Nodosum

Erythema nodosum eruptions appear as red, indurated, inflammatory nodules on the shins and knees. In addition to the

unusual distribution, the lesions are tender when palpated. Occasionally, these lesions are accompanied by mild constitutional symptoms, but there is usually no mucous membrane involvement. Etiologic factors associated with the development of erythema nodosum include drugs, female gender, rheumatic fever, sarcoidosis, leprosy, certain bacterial infections (e.g., tuberculosis), and systemic fungal infections such as coccidioidomycosis. Usually, the lesions heal slowly over several weeks after the offending agent is removed. Oral contraceptives are the most frequently implicated drug with this type of eruption. Other implicated drugs include sulfonamides and analgesics.

Drug Hypersensitivity Syndrome

This severe systemic reaction is also known as anticonvulsant hypersensitivity syndrome and as drug reaction with eosinophilia and systemic symptoms (DRESS). Symptoms begin with a high fever followed by widespread maculopapular-pustular rash on the trunk, arms, and legs that may lead to exfoliative dermatitis with large areas of skin sloughing. Hair and nails are sometimes lost. Eosinophilia occurs in >50% of cases, 30% have abnormal lymphocytosis, and 20% have lymphadenopathy. Internal organ damage appears late in the syndrome with elevations of liver function and/or renal function laboratory values. These may be accompanied by other general systemic symptoms such as headache and malaise. Secondary bacterial infections can occur. Approximately 10% of patients die, many due to infection. If exfoliative dermatitis occurs, it can take weeks or months to resolve, even after withdrawal of the offending agent. The most commonly implicated drugs are sulfonamides, antimalarials, anticonvulsants, and penicillin. Although rarely reported in the literature, its broad range of symptoms, confusing nomenclature, and symptom overlap with other drug-related adverse effects may lead to underdiagnosis and reporting.

Fixed Drug Eruptions

Fixed drug eruptions, unlike the previously mentioned reactions, are caused exclusively by drugs. The lesions are erythematous and sharply bordered, and have a tendency to be darker than the surrounding, unaffected skin. Eruptions can be eczematous, urticarial, vesicular, bullous, or nodular. Lesions appear 30 minutes to 8 hours after readministration in sensitized individuals. Because these lesions have a marked propensity to recur at the same location with each drug exposure, the word *fixed* is applied. The face and genitalia are common sites for this type of drug eruption. Although the eruptions heal after withdrawal of the causative drug, there is usually a marked hyperpigmentation of the area that may take months to resolve. The mechanism by which fixed drug eruptions occur has not been elucidated, but is believed to be allergic in nature. It can be described figuratively as islands of hypersensitivity; one area of the skin having the ability to evoke an allergic response and other areas lacking this ability. Commonly implicated drugs include antimicrobial agents (tetracycline, sulfonamides, metronidazole, nystatin), anti-inflammatory drugs (salicylates, nonsteroidal anti-inflammatory drugs), barbiturates, oral contraceptives, and phenolphthalein-containing laxatives.

Maculopapular Eruptions

Maculopapular eruptions are subdivided into two groups: scarlatiniform and morbilliform. Most drug eruptions fall within one of these two groups. *Scarlatiniform* eruptions are erythematous and usually involve extensive areas of the body. They are differentiated from streptococcal-induced scarlet fever by the lack of other diagnostic signs and laboratory studies. *Morbilliform* eruptions usually begin as discrete, reddish-brown maculae that may coalesce to form a diffuse rash. These eruptions are differentiated from measles by the lack of fever and other typical clinical signs. In either type of maculopapular eruption, pruritus may or may not be present. Generally, this type of eruption appears within 1 week after the causative drug (with penicillins, 2 or more weeks) has been started and completely clears within 7 to 14 days after stopping it. Morbilliform eruptions commonly are caused by ampicillin, amoxicillin, and allopurinol.

Purpura

Purpuric lesions are characterized as hemorrhages into the skin. They are purplish and sharply bordered, and have a tendency to become brownish as they get older. These lesions may or may not be associated with thrombocytopenia. Etiologic factors other than drugs that are associated with purpura are vitamin C deficiency, snake bites, and infections. The mechanism by which these lesions are produced is not known, but they have a tendency to recur with re-exposure to the causative agent. Sometimes purpura may develop concurrent with other types of eruptions, such as erythema multiforme.

Urticaria

Urticarial eruptions are immediate hypersensitivity reactions (IgE mediated) and usually appear as sharply circumscribed (raised), edematous, and erythematous lesions (wheals) with an abrupt onset. In most cases, the lesions disappear within a few hours, rarely last longer than 24 hours, and are associated with an intense itching, stinging, or prickling sensation. Commonly called *hives*, urticarial eruptions are frequently associated with certain drugs, foods, psychic upsets, and serum sickness. Rarely, parasites or neoplasms can precipitate hives. The most frequently implicated drugs with this type of reaction are aspirin, penicillin, and blood products. Patients who develop urticaria due to a drug are at increased risk of anaphylaxis if re-exposed to the same medication in the future.

Angioneurotic Edema

Angioneurotic edema (also called angioedema) is a more severe form of urticaria in which giant hives penetrate more deeply into surrounding tissues. Lips, mouth, tongue, and eyelids are common locations. Extensive involvement of the tongue, throat, or larynx can be fatal. Angiotensin converting enzyme inhibitors (ACEIs) are the most common drug cause of angioedema. Patients taking ACEIs should be warned to look out for any unusual swelling in the facial/oral area and, if present, should go immediately to the nearest emergency room for treatment. Although it usually occurs within the first several months of treatment, cases have been reported up to as long as 3 years after initiation of ACEI therapy (see Chapter 18, Heart Failure).

14. D.Z., a 42-year-old man with a chronic seizure disorder and long-standing anxiety was recently given a prescription for penicillin V 250 mg QID for a group A, α -hemolytic streptococcal-positive pharyngitis. Chronic medications include carbamazepine 200 mg TID and clonazepam 2 mg BID. One week later, D.Z. presents with urticarial lesions on his chest and arms. Is this a typical time of onset for a drug-induced dermatologic reaction? How should the drug eruption in D.Z. be managed?

Although most drug eruptions occur within 1 to 2 weeks after starting therapy, it may take 3 to 4 weeks after an initial exposure to a medication for the reaction to occur. Repeated exposure to the same offending agent can reduce the time of onset of the reaction to a few days or even within hours of ingestion. Because D.Z. has been taking clonazepam and carbamazepine chronically and penicillin for only 8 days, the temporal relationship would logically lead to the conclusion that penicillin is a highly probable cause. However, before labeling penicillin as the cause of his drug eruption, a thorough history to rule out other common causes should be done.

For D.Z., a different antibiotic should be substituted for penicillin (to complete the 10-day course of therapy). The lesion should begin to clear in 24 hours (if the penicillin is the cause of the urticaria). If the urticaria does not begin to clear in a few days, another cause should be investigated.

Treatment is primarily supportive, and use of an oral antihistamine (e.g., diphenhydramine 25–50 mg BID-QID) for several days would be recommended. If the reaction is severe, a 1- to 2-week course of prednisone 40 to 60 mg/day will control most symptoms within 48 hours.

ALLERGIC CONTACT DERMATITIS: POISON IVY/OAK/SUMAC

Poison ivy (*Rhus*) dermatitis is the major cause of allergic contact dermatitis in the United States, exceeding all other causes combined. It is estimated that 50% to 95% of the population is sensitive to the plant to some degree. The severity of the condition varies from mild discomfort to an extremely painful, debilitating condition. *Rhus* dermatitis is caused by sensitization to an allergic substance in the leaves, stems, and roots of poison ivy, poison oak, and poison sumac plants. All three plants contain the same sensitizing oleoresin, urushiol oil, which contains pentadecacatechol, the actual sensitizing agent. Therefore, the dermatitis caused by the three different plants is identical.

Direct contact with the plant is unnecessary for the rash to occur. Highly sensitive persons may develop severe dermatitis merely from exposure to *Rhus* oleoresin carried by pollen or by smoke from burning leaves. The oleoresin may remain active for months on clothing, shoes, tools, and sporting equipment. Once the toxic substance comes in contact with the skin, it can be spread by the hands to other areas of the body (e.g., genitals or eyes) or to people who may come into close contact with the exposed person. Although washing with soap and water will not prevent the dermatitis, even if it is done within 15 minutes of exposure, it will prevent spread of the oleoresin to other parts of the body.

Rhus dermatitis can be contracted throughout the year, even in winter, by contact with the roots of the plant. The virulence of the leaf sap varies little during the foliage period. The incidence of poison ivy is higher during the spring because the leaves are

tender and bruise easily, and people spend more time outdoors. Sensitive individuals should be instructed to avoid contact with the offending plant. If contact is inevitable, every effort should be made to shield exposed areas of the skin with appropriate clothing, and bentoquatam (Ivy Block), a topical organoclay compound, should be considered. A 5% lotion applied to the skin 15 minutes before exposure and reapplied every 4 hours has reduced or prevented contact dermatitis induced by experimental challenge with urushiol in sensitive individuals. Cost may limit its routine use.

Exposed individuals should bathe or shower as soon as they come in from outdoors and should wash their clothes. A non-prescription topical cleanser called Tecnu Extreme claims to remove urushiol oil embedded in the skin through the action of microfine scrubbing beads and surfactants, thus possibly preventing the rash or limiting spread. It also contains the homeopathic agent Grindelia as an antipruritic. It is formulated as a thick, creamy gel that is applied to exposed areas of the skin, followed by vigorous scrubbing, and rinsed off after application.

After an initial incubation period of 5 to 21 days, a patient would be expected to react to the oleoresin in 12 to 48 hours after re-exposure. A mild exposure to these plants in a sensitized person results in a typical erythematous, vesicular, linear, and sometimes, oozing rash after 2 to 3 days; complete clearing occurs in 1 to 3 weeks. If a large area is exposed, lesions appear within 6 to 12 hours and may appear blistered and eroded; in some cases, ulcers may appear. Healing occurs more slowly, often requiring 2 to 3 weeks for complete resolution. The following factors contribute to the development of poison ivy/oak/sumac: the concentration of the oleoresin to which the skin is exposed, area of exposure (i.e., the thickness of the stratum corneum), duration of exposure, site of exposure, genetic factors, and immune tolerance. It is important to determine the areas of the body that are affected. If the eyes, genital areas, mouth, respiratory tract, or >15% of the body is affected, the patient should receive a course of systemic corticosteroids.

Because different sites of the body differ in their sensitivity to the oleoresin and because patients spread the *Rhus* oleoresin to different parts of their bodies over a period of time, lesions often erupt over a period of several days. A common misconception many people have is that the fluid from the *Rhus*-induced vesicles will spread the disease to unaffected areas. A more likely explanation is the presence of residual resin underneath poorly washed fingernails, soiled clothes (including gloves used in yard work), and pet fur.

Treatment

15. K.P., a 27-year-old woman, has recently returned from an outing in the woods. She now has vesicular eruptions that appear in a linear pattern on one arm and hand. She believes that she has had a poison oak reaction and requests therapy. What should be recommended at this point? What should be recommended if the condition becomes more severe?

Weeping lesions should be treated with aqueous vehicles (e.g., Burow's solution or saline) as outlined in the beginning of this chapter. Lesions that are not wet or weeping should be treated with calamine lotion applied two to four times daily. The zinc oxide in calamine lotion may act as a mild astringent, although some people find this preparation to be unacceptable

because of its pink color, which can stain clothes. Alternatively, a topical corticosteroid appropriate for the body part affected could be used. If K.P.'s poison oak reaction becomes more severe, additional treatment with prednisone 1 mg/kg/day for at least 2 or 3 weeks will be required; such therapy should be withdrawn slowly (over 1–2 weeks) to prevent recurrence of the lesions.

Systemic Therapy

16. Z.T., a 19-year-old man, has just returned from a fishing trip and now has an erythematous, linear, dry eruption on his leg and arm, and a generalized eruption on his hands and face. He has been in areas that have dense poison ivy growth, and he may have burned some in the campfire. Z.T. has washed himself and his clothes thoroughly. How should he be treated?

The fact that Z.T.'s facial rash is not linear (as one would expect if he had just contacted the plant) suggests that he may have contacted the smoke of a burning poison ivy plant. This can be quite serious because the oleoresin can be carried in smoke and, if inhaled, can cause severe respiratory problems. Z.T. should be observed for signs of respiratory difficulties and should be treated with a course of systemic corticosteroids.

Relapse

17. Z.T.'s physician prescribed prednisone for his rash. He was instructed to take 80 mg/day for 14 days and to decrease the dose

by 5 mg/day each day thereafter. Calamine lotion (TID to affected areas) also was prescribed. After 12 days, Z.T. complains that the lesions seem to be getting worse. The lesions had cleared after 8 days of treatment, and he began rapidly tapering the prednisone at that time. Why is he experiencing a relapse?

Two weeks is the absolute minimum course of treatment when systemic corticosteroids are used for severe cases of poison ivy/oak/sumac. The oleoresin remains fixed in the skin, and if the systemic corticosteroid is withdrawn too soon, the lesions return. This is probably the most common reason for treatment failure with systemic corticosteroids.

Allergic Contact Dermatitis

18. Z.T.'s corticosteroid therapy was reinstated. After 3 weeks, most of the lesions had disappeared, and the prednisone therapy was discontinued. However, Z.T. continued to complain of a rash on his hands. Further questioning revealed that he was continuing to apply an over-the-counter topical calamine lotion containing diphenhydramine. What is a potential drug-related cause of this persistent rash?

Topical application of diphenhydramine and other antihistamines may cause allergic contact dermatitis.²⁴ Z.T. should stop using this product to see if his rash clears. A list of common contact sensitizers is found in Table 38-14.

The treatment for sensitivity reactions is basically the same as that outlined for poison ivy/oak/sumac.

Definition, Clinical Signs, and Symptoms

The term *acne* usually refers to acne vulgaris, a common disease in which the pilosebaceous units of the skin become plugged and distended (see Fig. 38-1 in Chapter 38). It differs from rosacea (formerly called *acne rosacea*), which causes facial erythema, telangiectasia, and papules, and occurs later in life. *Acne cosmetica* and *acne mechanica* are terms describing aggravation of the condition by cosmetics or by mechanical irritation such as that from helmet straps.

Acne lesions generally appear on the face, but the chest, back, or upper arms may also be affected. Comedones, plugged follicular openings, are noninflammatory lesions that may be closed (“whiteheads”) or open (“blackheads”). The dark pigmentation in open comedones is caused by oxidation of sebaceous material or melanin rather than by dirt, a common misperception.¹ Inflammatory lesions are typically erythematous and can include pustules (raised, superficial, pus-filled lesions), papules (raised, solid lesions up to several millimeters in diameter), and nodules (like papules but larger and deeper in the skin); in severe cases (*acne conglobata*), multiple lesions coalesce into abscesses with draining sinus tracts.² Although no single severity scale has emerged as standard, clinicians must use some acne grading scale consistently to evaluate treatment options and clinical response. Often, clinicians describe acne as mild (few lesions, little or no inflammation), moderate (many lesions, significant inflammation), or severe (numerous lesions, extreme inflammation and/or nodules, significant scarring).³ The Combined Acne Severity Classification is one recommended codification system (Table 39-1).⁴ Lesion counts per se are not practical for clinicians, but are used by researchers.

Acne can cause psychological distress, low self-esteem, and social withdrawal, affecting quality of life as much as more

physically disabling diseases such as asthma and diabetes.⁵ Considerable psychological morbidity can result from even mild to moderate acne.⁶ Questionnaires have been developed to identify the psychosocial impact of acne.⁷ The major long-term complication of acne is scarring, usually “ice pick” pitting with significant disfigurement. Scarring can be exacerbated by tissue excoriation caused by picking at or squeezing the lesions. Early initiation of effective therapy is critical to prevent scarring.⁸

Acne occurs in people of all ages, but acne vulgaris primarily afflicts teenagers and young adults. Acne is also associated with systemic diseases such as SAPHO (synovitis, acne, pustulosis, hyperostosis, osteitis) and Apert syndromes.^{9,10} The differential diagnosis of acneiform eruptions includes acne vulgaris; rosacea; folliculitis caused by gram-negative bacteria, *Pityrosporum*, or mechanical irritation; drug-induced acne such as that caused by topical or systemic corticosteroids, or by anabolic steroids, including those abused by athletes; and perioral dermatitis.^{11–14} Detailed discussions of severe acne variants, such as acne conglobata and acne fulminans, are beyond the scope of this chapter.^{11,15}

Incidence and Prevalence

Acne vulgaris affects more than 50 million people in the United States¹⁶ and about 90% of all adolescents.¹⁷ Studies suggest that it is primarily an inherited disorder with environmental factors playing a secondary role.⁸ Although no gender preference exists, females typically develop acne at a younger age and have milder cases than males.¹⁵ Acne can occur in children as young as 8 years; however, it is most prevalent in adolescents between 14 and 19 years of age.¹⁸ Although most cases resolve by the time patients reach their mid-20s, acne persists into later life in

Table 39-1 Combined Acne Severity Classification

| Acne Severity Grade | Description ^a |
|---------------------|--|
| Mild | <20 comedones; or <15 papules; or <30 lesions total; no nodules |
| Moderate | 20–100 comedones; or 15–50 inflammatory lesions; or 30–125 lesions total; nodules may be present |
| Severe | >5 nodules; or >100 comedones; or >50 inflammatory lesions; or >125 lesions total |

^aStage acne in the most severe applicable grade.
Adapted from reference 4.

7% to 17% of patients, more often in women than men.¹⁵ Acne may be slightly less common in patients with darker skin, but some believe research in prevalence is confounded by poorer access to health care among patients of color; most studies find that acne is the top dermatologic complaint in patients of all skin tones.¹⁹ Severe nodular acne is more common in light-skinned patients, but dark-skinned patients show more inflammation at the histologic level than in light-skinned patients with similar clinical lesion severity. Dark-skinned individuals are also more likely to contend with postinflammatory hyperpigmentation (PIH) and keloid scar formation in the wake of acne lesions.^{19,20} Females treated with antiepileptic drugs such as phenytoin or phenobarbital experience acne more commonly than age-matched controls (80% vs. 30%).²¹

Etiology and Risk Factors

The development of acne is related to increased sebum production, abnormal keratinization within the pilosebaceous canal (hypercornification), bacterial colonization, and immune-mediated inflammation. Multiple exogenous and endogenous factors can affect the development of acne vulgaris. Diet (with rare individual exceptions), cleanliness, and sexual activity do not contribute to the severity of acne or the frequency of its exacerbations, but some evidence does support the popular belief that psychological stress may promote exacerbations in predisposed patients.¹ Premenstrual exacerbations of acne are common.¹⁵ Oil-based cosmetics, pomades, and moisturizers may also encourage the development of acne.²² Hot and humid conditions that stimulate sweating often worsen acne.¹

Studies of sunlight exposure have found contradictory results; ultraviolet light may make sebum more comedogenic, but some of the visible wavelengths may reduce the follicular bacterial population.^{1,23} Occupational or environmental exposure to halogenated compounds, ultraviolet light, animal fats, dioxin, or petroleum derivatives may cause “chloracne” or other acneiform lesions.^{24,25} It is important to identify drug-induced acne (see Chapter 38) because treatment success likely depends on drug therapy modification. Mechanical skin irritation caused by headbands, hats, chin straps, backpacks, or shoulder pads may also induce acne mechanically.³

Pathogenesis

The key pathophysiologic change leading to acne occurs when keratinocytes in the follicular epithelial lining proliferate and

undergo changes in cellular differentiation. Keratinization increases and the cells adhere more to each other, interfering with normal desquamation. Cellular debris and sebum accumulate to plug sebaceous follicles and form clinically undetectable microcomedones.² If the superficial portion of the follicular opening dilates from the pressure of the impaction, an open comedo forms. Such lesions rarely become inflamed because as pressure builds from further sebum production and cellular accumulation, follicular contents can escape to the skin surface.²² If the follicular opening remains narrow and a closed comedo forms, increased pressure ruptures the follicular wall and infiltration of foreign matter into the dermis incites an inflammatory response. The depth and extent of this occurrence determine whether a pustule, papule, or nodule results.¹¹

Androgen-enhanced sebocyte activity and bacterial colonization mediate lesion development. Testosterone, of testicular origin in males or ovarian and adrenal origin in females, is metabolized in the skin by 5- α -reductase to dihydrotestosterone (DHT), which in turn stimulates sebum biosynthesis.² Increased sebum production dilutes the availability of linoleic acid and increases the production of interleukin-1- α , triggering hypercornification and thus comedogenesis.^{2,22} Increased sebum production also creates a lipid-rich, microaerophilic environment favorable to the growth of *Propionibacterium acnes*. This gram-positive rod releases proteases, hyaluronidases, lipases, and chemotactic factors that attract neutrophils, T cells, and macrophages.²⁶ Even after being engulfed by macrophages, this organism can persist intracellularly.²⁷ Hydrolytic enzymes released by macrophages may contribute to weakening the follicular wall, hastening rupture and the resulting progression of comedo to inflammatory lesion.²² Inflammatory mediators traverse the follicular wall into the dermis and initiate the inflammatory process even prior to wall rupture.¹⁵ Interleukins and tumor necrosis factor- α released by macrophages and lymphocytes complement activation by *P. acnes*, and antibody- and cell-mediated immunologic mechanisms activated by *P. acnes* all participate in the inflammatory response.² Finally, a genetic predisposition may exist in which patients with acne have enhanced cytochrome P450 1A1 activity, which reduces levels of protective endogenous retinoids.²⁸

Therapy

No known cure exists for acne, but treatment can reduce its severity and minimize complications of scarring. In most cases, especially in severe forms, treatment is more an “art” than a science and must be individualized, depending on the particular clinical presentation of the patient. The goals of treatment are to relieve discomfort, improve skin appearance, prevent scarring, and minimize the psychosocial impact of the condition.

Treatment is largely preventive because little can be done for existing lesions. Slow improvement over weeks to months is the rule for all treatments. Patients can generally expect 20%, 60%, and 80% resolution of lesions within 2, 6, and 8 months, respectively, after effective therapy is begun (slower resolution with hormonal therapies, faster resolution with oral isotretinoin).¹⁵ Therefore, treatment regimens should not be modified more often than every 6 to 8 weeks. Patients should be counseled on the basic pathophysiology of acne, proper drug administration or application technique, delay in onset of therapeutic effect, potential adverse effects, and steps to take if adverse effects

- Areas of skin friction or irritation

occur. Clinical practice guidelines are available.^{4,29,30} Therapy is tailored to patient-specific data (Table 39-2).

Nondrug Therapy

Nondrug therapy plays a minimal role in the management of acne. In general, patient education regarding nondrug therapy boils down to “first, do no harm.” Twice-daily washing with warm water and a mild facial cleanser is sufficient; acne is not a disorder of poor hygiene, and aggressive skin washing and abrasive cleansers needlessly traumatize the skin.¹⁵ Manipulation (e.g., squeezing, picking) of acne lesions should be strongly discouraged because it can lead to scarring. Drugs known to cause acne, oil-based cosmetics, and other known precipitants should also obviously be avoided. However, oil-free, noncomedogenic moisturizers formulated for facial skin can improve the penetration and tolerability of many topical acne drugs by improving the skin’s hydration, especially in patients with sensitive skin. Many such moisturizers also contain sunscreen, which is recommended for use with many of the available acne therapies.¹⁶

Dermatologists may use physical modalities to treat acne, especially as adjuncts to medication in severe cases. Options include surgical comedo extraction, dermabrasion, cryotherapy, and experimental light and laser therapies.^{11,31,32} No prospective, controlled trials comparing medical and physical measures for managing severe acne exist. Acne scarring is treated with dermabrasion, laser therapy, chemical peels, and recollagenation, but systematic randomized trials are needed to fully assess safety and comparative efficacy.^{11,33,34}

Drug Therapy

Although many drugs either alone or in combination may ultimately be used in acne treatment, all therapies are based on treating one or more of the primary pathogenic factors.^{35,36} Effective drugs work by (a) normalizing follicular keratinization (e.g., retinoids, benzoyl peroxide, azelaic acid); (b) decreasing sebum production (e.g., isotretinoin, hormonal therapies); (c) suppressing *P. acnes* (e.g., antibiotics, benzoyl peroxide, azelaic acid, systemic isotretinoin); and (d) reducing inflammation (e.g., antibiotics, retinoids).

Topical therapy is generally preferable for mild to moderate acne. Common choices include a retinoid for mild comedonal

acne or benzoyl peroxide for mild inflammatory acne, initially augmented in moderate acne with a course of topical antibiotics. Treatments are applied to the entire acne-prone area, not just to existing lesions, because the mechanisms of action more effectively prevent than resolve lesions. With topical therapy, choice of vehicle is as important to treatment success as choice of drug. Gels and solutions are highly drying and suitable for oily skin, whereas less drying creams and moderately drying lotions are preferred in dry and/or sensitive skin; ointments are generally too comedogenic to be useful in acne. Comedolytic therapies such as retinoids and benzoyl peroxide are often initiated at low concentrations and application frequencies using a vehicle appropriate to the patient’s skin type, and titrated up in strength, frequency, and drying effect as tolerated to achieve desired outcomes.

Moderate to severe acne often requires combination therapy using agents with different mechanisms of action, such as topical benzoyl peroxide and/or a topical retinoid plus a systemic antibiotic. Hormonal therapies (e.g., oral contraceptives) are an option in female patients who are not pregnant and not planning to become pregnant. Severe acne requires oral isotretinoin. Because oral isotretinoin addresses every known pathophysiologic mechanism of acne, combining it with other medications is unnecessary.

RETINOIDS

Vitamin A and its analogs have been used to treat acne for more than 50 years.^{37,38} Retinoids normalize keratinization by decreasing horny cell cohesiveness and stimulating epidermal cell turnover. These actions combine to unplug follicles and prevent microcomedo formation.³⁹ Retinoids also reduce inflammation by inhibiting the production of inflammatory mediators.⁴⁰ Topical retinoids have no antibacterial properties, but systemic (oral) isotretinoin indirectly reduces *P. acnes* colonization by reducing the production of sebum, which *P. acnes* requires for survival.² Systemic isotretinoin therefore exhibits all four of the mechanisms of action outlined previously, making it uniquely effective monotherapy.

As the most potent comedolytic agents, topical retinoids are preferred therapy in mild acne cases with mostly noninflammatory lesions.⁴¹ They may also be used in combination with antibiotics and/or other therapies to manage moderate to severe acne. They are usually applied once daily at bedtime. Common side effects include skin irritation, peeling, erythema, and dryness; patients should be advised to use sunscreen because the newly exfoliated skin is prone to burn. Patients should also be warned that acne may initially worsen before improvement is noted,⁴² although this rarely occurs if topical antibiotics are also being used.⁴³ Tretinoin (Retin-A[®]), also called all-*trans*-retinoic acid, is the naturally occurring form of vitamin A acid and is available for topical application as a cream (0.025%, 0.05%, 0.1%) and gel (0.01%, 0.025%). Newer dosage forms are less irritating (and more expensive): delayed-release cream and gel (0.025%; Avita[®]) and microsphere gel (0.04%, 0.1%; Retin-A[®] Micro). Another topical retinoid, adapalene (Differin[®]), is available as a 0.1% cream and gel. It binds to different receptors than tretinoin⁴⁴ and has more anti-inflammatory activity.⁴⁰ Adapalene is at least as effective as tretinoin and may cause less skin irritation than other topical retinoids.⁴⁵ Irritation from topical tretinoin can darken skin if used too aggressively in dark-skinned patients, but adapalene

may reduce hyperpigmentation in such patients.⁴⁰ The newest agent in the class, tazarotene (Tazorac[®]), is available in cream and gel formulations (0.05% and 0.1%). It may not only be the most effective, but also the least well tolerated, of the topical retinoids.⁴² Among the topical retinoids, only the older dosage forms of tretinoin are available generically. Topical isotretinoin is not yet available in the United States. Because benzoyl peroxide inactivates tretinoin, combination therapy with these two agents should be avoided. However, benzoyl peroxide can be used in combination with either adapalene or tazarotene to provide potential additive benefit.⁴⁶

Isotretinoin (Accutane[®], Amnesteem[™], Claravis[™], Sotret[®]), a synthetic 13-*cis*-isomer of tretinoin, has greater pharmacologic activity than tretinoin. It is administered orally as 10-, 20-, 30-, and 40-mg capsules and is the only effective agent for severe nodular acne. Essentially all patients will respond to systemic isotretinoin; in most cases, one or two 5-month-long courses of therapy induce a remission lasting for several months or even years after the drug is stopped. Use of oral isotretinoin is perhaps more cost effective than use of long-term oral antibiotics in patients with severe acne, due to its superior efficacy and the long-term cost savings realized by a shorter total duration of therapy.⁴⁷ The common adverse effects of systemic isotretinoin, invariably including drying of skin and mucous membranes, can usually be managed without having to stop the drug. However, the risk of serious adverse effects from oral isotretinoin, the high cost of the drug, and its potential for overuse necessitate strict guidelines for its rational use (Table 39-3).^{29,48} Table 39-4 summarizes common and significant adverse effects of isotretinoin. Patients should also be warned that acne may worsen initially because flares occur in about half of patients.⁴⁹

Retinoids, even for topical use, must be avoided during pregnancy because the drug class is notoriously teratogenic.

Table 39-3 Guidelines for Isotretinoin Use in Acne

Patient Selection

Severe nodular acne
Moderate acne, but resistant to combination conventional therapies or inducing significant scarring
Unusually severe acne variants (conglobata, fulminans)

Dosage and Duration of Therapy

0.5–1 mg/kg/day in two divided doses with food; use lower initial dose to minimize flaring
Usual course about 20 weeks (best results if cumulative dose reaches 120–150 mg/kg)
Use higher dosage in young patients, males, those with severe acne, patients with acne involving the trunk (up to 2 mg/kg/day)
Consider pretreatment or concomitant oral corticosteroids for severely inflamed acne

Relapse Rate

Repeat courses required in 10%–20% of patients, often younger patients or patients who received lower doses
Allow 2–3 months between courses
Very rarely, patients may require three to five courses

Adapted from references 11, 29, and 58.

A strict risk management program called iPLEDGE regulates the prescription and distribution of isotretinoin in the United States.⁵⁰ The program requires all patients, prescribers, pharmacies, and even drug wholesalers involved in distribution and use of the drug to register with a national database. Proper patient monitoring and education, including negative pregnancy tests in female patients of child-bearing potential, must be documented in the database each month before initial or refill medication can be dispensed to a patient. Female patients of child-bearing potential must use two forms of contraception for at least a month before, all during, and for at least a month following isotretinoin therapy. All isotretinoin patients, male and female, must refrain from donating blood during or for a month after therapy to ensure no isotretinoin-contaminated blood products are unknowingly administered to a pregnant woman.

BENZOYL PEROXIDE

Topical benzoyl peroxide primarily works as an antibacterial agent, but also has comedolytic properties. Lipophilic, it penetrates to the site of *P. acnes* growth and releases oxygen free radicals that damage bacterial cell walls.⁵¹ Because resistance cannot develop to this bactericidal mechanism, benzoyl peroxide is often paired with oral antibiotics to prevent the development of antibiotic resistance. The irritant effects of benzoyl peroxide also cause vasodilation and increase blood flow, which may hasten resolution of inflammatory lesions. Benzoyl peroxide improves both inflammatory and noninflammatory lesions; it is similar to topical retinoids in improving comedonal acne and preferred for inflammatory acne.^{52,53}

Benzoyl peroxide is available over the counter (OTC) and by prescription in a variety of dosage forms (cleansers, lotions, creams, and gels) and concentrations (2.5%–10%). It is usually applied to the affected area once or twice daily. Cleansers allow little contact time compared to other dosage forms, but they can enhance adherence to therapy when patients must apply medication to the trunk because the cleanser can be conveniently applied and left on for a few minutes in the shower. Patients should be instructed to use sunscreen while using benzoyl peroxide because the skin is more prone to burn. Patients must also be advised that benzoyl peroxide can bleach or discolor towels, pillowcases, rugs, or other fabrics on which it is wiped or spilled.

Benzoyl peroxide has been associated with tumors in mice, but long-term use has not been associated with skin cancer.⁵⁴ The World Health Organization International Agency for Research on Cancer concluded that there is inadequate evidence to determine the human carcinogenicity risk with benzoyl peroxide.⁵⁵

AZELAIC ACID

Azelaic acid 20% cream (Azelex[®]) carries an indication for acne vulgaris, while the 15% gel (Finacea[®]) formulation is indicated for rosacea. This dicarboxylic acid normalizes keratinization and also reduces inflammation by suppressing *P. acnes*.^{56,57} *P. acnes* resistance has not been reported.⁴¹

Azelaic acid causes less skin irritation than other topical therapies (except for antibiotics), but may not be as effective.^{2,29,58} In addition to being less irritating than other comedolytic therapies, azelaic acid inhibits tyrosinase and thereby melanin production, giving it a useful niche in treating

Table 39-4 Adverse Effects of Systemic Retinoids

| <i>Body System</i> | <i>Adverse Effect</i> | <i>Management</i> |
|------------------------------|--|---|
| Common, Pharmacologic | | |
| Reproductive | Teratogenicity (birth defects, premature birth, neonatal death) | Avoid pregnancy; patients should not donate blood during therapy |
| Skin | Dryness, peeling, pruritus, photosensitivity | Use moisturizers, sunscreens, protective clothing; avoid skin waxing, dermabrasion, and other dermatologic procedures during and 6 months following therapy |
| Hair, nails | Hair dryness, hair thinning, nail fragility | None; discontinue drug if severe |
| Mucous membranes | Cheilitis, dry mouth, dry nose, nosebleeds, dry eyes, blepharconjunctivitis | Use lip balms, sugarless gum/candy, saline nasal spray, artificial tears or ophthalmic ointment; avoid contact lenses; lower dosage if severe or bothersome |
| Metabolic | Elevated triglycerides, cholesterol; lowered HDL (rare reports of pancreatitis) | Reduce/eliminate alcohol; consume low-fat diet; consider dosage reduction or drug discontinuation |
| Uncommon, Toxic | | |
| CNS | Pseudotumor cerebri, hearing loss, tinnitus | Discontinue drug if patient develops severe headache, nausea, vomiting, papilledema, visual changes (suggest pseudotumor cerebri) or hearing changes |
| Bones | Pain Bone mineral density loss (osteopenia), premature epiphyseal closure, hyperostosis | Monitor at each visit Routine monitoring is not recommended for usual durations of therapy |
| Muscle, ligaments | Pain, calcifications | Monitor; more likely in physically active patients; discontinue if severe |
| Eyes | Impaired night vision, corneal opacities | Patients should use caution when driving |
| Liver | Elevated transaminases; hepatitis | Monitor if transaminase elevation is mild; avoid in patients with previous liver dysfunction; discontinue drug if hepatitis occurs |
| Hematologic | Anemia, neutropenia, thrombocytopenia | Monitor CBC |
| Psychiatric | Depression, suicide | Monitor for depressed mood and suicidal thoughts |

CBC, complete blood count; CNS, central nervous system; HDL, high-density lipoprotein.
Adapted from reference 49.

patients of color with postinflammatory hyperpigmentation.⁵⁹ A small amount of azelaic acid cream is applied twice daily. Patients should protect their skin with sunscreen. Due to its cost and possibly lower efficacy, it is usually reserved for patients who cannot tolerate benzoyl peroxide or topical retinoids.

MISCELLANEOUS TOPICAL AGENTS

Salicylic acid, sulfur, and resorcinol have been used for many years in acne, but are not well studied. Topical salicylic acid, a concentration-dependent keratolytic, is more effective than placebo, but less effective than topical benzoyl peroxide or tretinoin.²⁹ It may be useful in patients with mild acne who cannot tolerate other comedolytics and may augment the effectiveness of other agents when used in combination. It is available in nonprescription creams, lotions, and gels in strengths ranging from 0.5% to 2%. Chronic use over large body surfaces should be avoided because of the risk of percutaneous absorption that could cause systemic salicylate toxicity.⁴⁶ Sulfur preparations have mild comedolytic properties, but can produce skin discoloration and odor, and may be comedogenic with continued use.⁶⁰ Anecdotal, however, sulfur products succeed for some patients who have failed first-line therapies. They are available in strengths of 2% to 10%, in a variety of vehicles, often in nonprescription combination products. Resorcinol alone is ineffective,¹⁵ but is combined in a 2% concentration with sulfur preparations to enhance the kera-

tolytic effect. It can cause dark scaling on some patients.⁶⁰ Topical nicotinamide, a form of vitamin B₃, appears as effective as 1% clindamycin gel monotherapy in treating inflammatory acne.¹⁵

ANTIBIOTICS

Acne is not an “infectious” disease per se and is certainly not contagious. Rather, *P. acnes* helps transform comedones into inflammatory pustules or papules. Antibiotics do not resolve existing lesions, but they can prevent future lesions by decreasing *P. acnes* colonization. Antibiotic courses used in acne are months long, unlike the short courses used in most infectious diseases. One reason for this may be that *P. acnes* colonies encase themselves within a polysaccharide biofilm that shields them from antibiotics.²⁶ Another is that antibiotics can exert anti-inflammatory effects independent of their antibacterial activity. Tetracyclines and macrolides can reduce neutrophil chemotaxis and inhibit cytokines, even at subminimal inhibitory concentrations.^{61,62} As a result, clinical efficacy does not correlate perfectly to reductions in bacterial load; unlike in standard antibiotic treatment, successful antibiotic courses do not necessarily eradicate *P. acnes*.⁶³ Just 20 mg orally twice daily of doxycycline, far lower than usual doses, was shown to reduce acne lesion counts despite causing no changes in the numbers or resistance patterns of bacteria on the skin surface.⁶⁴ However, the efficacy of this

regimen has not been compared to that of traditional regimens.

Topical Antibiotics

Topically applied antibiotics avoid systemic exposure and achieve high follicular concentrations. They can augment topical retinoids when initiating therapy in mild to moderate acne cases involving inflammatory lesions, or they can be added to patients failing benzoyl peroxide monotherapy.⁶⁵ Topical antibiotic monotherapies are more effective than placebo, but they are not superior to benzoyl peroxide monotherapy.^{46,66} Topical antibiotic and benzoyl peroxide combinations outperform either ingredient alone.^{46,65}

Clindamycin and erythromycin are most commonly used. Clindamycin (e.g., Cleocin T[®]) is available as a 1% gel, lotion, solution, and foam; 1% gel in combination with 5% benzoyl peroxide (BenzaClin[®], Duac[™]); and 1.2% gel in combination with 0.025% tretinoin (Ziana[™]). Erythromycin (e.g., Erygel[®]) is available as 2% solution, gel, ointment, and pledgets, and as 3% gel in combination with 5% benzoyl peroxide (Benzamycin[®]). Sodium sulfacetamide is not as well studied, but offers an option in patients who have failed first-line agents.³ It is available at 10% strength, often with 5% sulfur, in a variety of vehicles.

Topical antibiotics are usually applied once or twice a day for 2 to 3 months. Although rare reports of systemic side effects exist, topical effects such as stinging and tingling are the most common adverse effects, and even these occur more rarely with topical antibiotics than with other topical therapies.

Oral Antibiotics

Oral antibiotics should be paired with topical retinoids and/or benzoyl peroxide in patients with moderate to severe acne, especially if lesions are in widespread or difficult-to-reach areas. Oral antibiotics can also replace topical antibiotics when other topical combination regimens fail.

Tetracycline and doxycycline are effective.⁶⁷ Minocycline is sometimes tried if other antibiotics fail, but is significantly more expensive and not clearly better in efficacy, even in resistant acne.⁶⁸ It is also associated with a higher rate of serious adverse effects than other tetracycline antibiotics (Table 39-5). Tetracyclines cannot be prescribed in children due to potential impairment of bone growth and discoloration of forming teeth. Pregnant women must avoid tetracyclines due to similar effects

Table 39-5 Potentially Serious Adverse Effects Associated With Minocycline

- Lupuslike syndrome
- Necrotizing vasculitis of uterine cervix
- Hepatotoxicity
- Eosinophilic pneumonitis
- Polyarteritis nodosa
- Arthralgia, arthritis, or other autoimmune phenomena
- Intracranial hypertension or pseudotumor cerebri
- Discoloration or hyperpigmentation of the skin or gums
- Hypersensitivity (e.g., fever, rash, neutropenia, eosinophilia)

Adapted from references 68 and 95.

Table 39-6 Frequently Used Oral Antibiotics

| Drug | Initial Dose | Maintenance Dose |
|-----------------------------------|-------------------|------------------------|
| Doxycycline | 100 mg PO BID | 100 mg PO daily |
| Tetracycline | 500 mg PO BID | 250–500 mg PO daily |
| Minocycline | 50–100 mg PO BID | 50–100 mg PO daily |
| Erythromycin | 250–500 mg PO BID | 250–500 mg PO daily |
| Trimethoprim/ sulfamethoxazole | 160/800 mg PO BID | 160 mg/800 mg PO daily |

Adapted from reference 77.

on the fetus. Trimethoprim-sulfamethoxazole is effective, but has a less favorable side effect profile than tetracyclines.¹¹ Erythromycin is associated with higher rates of resistance, but can be useful in patients who cannot use the drugs previously mentioned, such as pregnant women. Azithromycin has also been studied.^{69,70} Clindamycin is not used systemically to treat acne due to the risk of pseudomembranous colitis.

Oral antibiotics are initiated with twice daily dosing for 6 to 8 weeks; if a good clinical response is noted, dose frequency may be reduced to once daily for maintenance (Table 39-6). To minimize the emergence of bacterial resistance, the patient should attempt to discontinue antibiotic therapy after achieving treatment success for a few months.

Antibiotic Resistance

Resistance of *P. acnes* to antibiotics frequently used for acne is increasing and correlates to prescribing patterns. Erythromycin resistance is highest; clindamycin resistance follows similar patterns, and cross-resistance between these two agents is high.⁷¹ More than half of European patients harbor resistant bacteria.⁷² At one British site, resistance rates almost doubled over a span of 6 years.⁷¹ Resistance to tetracyclines is less common and is increasing at a slower rate than resistance to other antibiotics. Nonetheless, up to 20% of European patients and nearly one-third of patients in the United States are colonized with tetracycline-resistant strains (reflecting higher historical use of tetracyclines to treat acne in the United States than in Europe).^{63,71} One reason tetracycline resistance may lag behind erythromycin and clindamycin resistance is that, in environments free of tetracycline, tetracycline-resistant bacteria do not grow as well as susceptible bacteria. Because the genetic material that allows survival in tetracycline-containing environments is a liability in normal environments, selection pressure reduces resistance levels once tetracycline use is discontinued. However, erythromycin/clindamycin-resistant bacteria grow about as well as susceptible strains in antibiotic-free environments, so resistance to these antibiotics fades less quickly after antibiotic use stops.⁷¹ Tetracycline resistance is often accompanied by erythromycin and clindamycin resistance.⁶³

The increasing rates of antibiotic resistance have had limited impact on prescribing patterns because resistance is not consistently linked to treatment failure in prescribers' everyday clinical experience, and research on the significance of resistance has been conflicting and sparse. However, notwithstanding the extra-antimicrobial mechanisms of action of antibiotics, bacterial resistance to erythromycin and tetracyclines has

appeared to cause higher rates of treatment failure in the few trials that have specifically examined this issue.^{73–75} Increasing bacterial resistance is also postulated to explain why recent clinical trials of erythromycin obtain far lower efficacy rates than trials from earlier decades.⁷⁶ Although acne treatment failure may not be clearly linked to antibiotic resistance, it is also not the only possible consequence. Acne patients are likelier to carry not only resistant *P. acnes*, but also resistant strains of more clinically significant pathogens such as *Streptococci* and *Staphylococci*.^{63,65} As a result, guidelines increasingly emphasize that antibiotics should be reserved for acne of at least moderate severity; should be used for courses of no more than 3 to 6 months' duration; and should not be used as monotherapy, but rather should be teamed with drugs exerting additional mechanisms of action. Furthermore, combinations of two antibiotics should be avoided.^{29,30,63,65,66,77} Many prescribers habitually extend patients' antibiotic therapy almost indefinitely to prevent relapse, but studies show that topical retinoids can be as effective as antibiotics for maintenance therapy after successful courses of antibiotics.⁷⁸

HORMONAL THERAPIES

Hormonal therapies with antiandrogenic effects, such as androgen receptor antagonists and combination oral contraceptives, are the only treatments besides oral isotretinoin to attack acne by reducing sebum production. Hormonal therapies may be helpful in patients with normal serum androgen levels, as well as in patients with elevated serum androgen levels, because hypersensitivity to androgens sometimes occurs at the follicular level despite normal circulating androgen levels.⁷⁹ Well-conducted comparative studies are needed to clarify the place of these therapies relative to other treatments suitable for moderate to severe acne, such as antibiotics, but they are good options for women with acne who are not pregnant and not planning to get pregnant.⁸⁰ However, their systemic effects limit the use of hormonal therapies to female patients, and because of their “upstream” mechanism of action, response to hormonal therapies can be delayed 3 to 6 months.⁵⁸

Androgen Receptor Antagonists

Cyproterone (Androcur[®]), an antiandrogen with orphan drug status in the United States, and the antiandrogenic progestins chlormadinone and dienogest are each available abroad in combination with ethinyl estradiol in contraceptive products that have been shown to improve acne.⁸¹ More accessible to U.S. patients, spironolactone (Aldactone[®]) is an androgen receptor antagonist and inhibits 5- α -reductase.⁸² Doses of 50 to 200 mg/day have been used successfully in acne due to its antiandrogenic effects,⁸³ although higher-quality data are needed.⁸⁴ Flutamide (Eulexin[®]), an antiandrogen licensed for metastatic prostate cancer, is effective but potentially hepatotoxic.⁸² Antiandrogens are avoided in males because gynecomastia is likely to develop. Female patients not taking concomitant estrogens often develop menstrual irregularities when taking these drugs. Patients must use contraception because antiandrogen exposure impairs the sexual development of male fetuses.⁸³

Combination Oral Contraceptives

Estrogen, usually administered as ethinyl estradiol in a cyclic combination oral contraceptive (OC), improves acne in females by reducing ovarian androgen production and by increasing sex hormone binding globulin concentrations in the serum, thereby lowering free testosterone levels.⁷⁹ The manufacturers of Ortho Tri-Cyclen[®] (ethinyl estradiol, norgestimate), Estrostep[®] Fe (ethinyl estradiol, norethindrone acetate), and Yaz[®] (ethinyl estradiol, drospirenone) specifically sought and obtained U.S. Food and Drug Administration approvals for acne indications, but acne improvement may be seen with any combination OC relative to baseline. Studies of ethinyl estradiol in combination with levonorgestrel, desogestrel, or gestodene (not available in the United States) demonstrate efficacy in acne for those products as well.⁸⁰ Comparative trials have not yet clearly established clinically significant superiority of one product over another.^{79,80,85} In individual patients, products containing progestins with androgenic effects (e.g., norgestrel, levonorgestrel) may override the effect of ethinyl estradiol and worsen acne. Conversely, patients already on a combined OC may improve when switched to a formulation with a less androgenic progestin.⁸¹ Other estrogen-containing contraceptives (transdermal patches, vaginal rings) may have similar beneficial effects to OCs, but studies have not been conducted.

CORTICOSTEROIDS

Although corticosteroids sometimes cause acne, under some circumstances they can be used to treat severe acne. To avoid potentially severe flaring when oral isotretinoin is begun, patients may pretreat 1 to 2 weeks with prednisone 40 to 60 mg/day and continue concomitant prednisone for the first 2 weeks of isotretinoin therapy.¹¹ Corticosteroids are used concomitantly with isotretinoin when treating acne fulminans to decrease the inflammatory response.¹⁵ In acne patients with diagnosed adrenal hyperplasia, prednisone 5 to 10 mg/day may be given in the evening to suppress diurnal corticotropin release and thus adrenal hypersecretion of endogenous steroids.⁸⁶ Intralesional triamcinolone injections markedly improve severe nodules, but repeated or careless use of the technique can lead to atrophic scarring.⁴ Topical application of corticosteroids is not effective.

CLINICAL ASSESSMENT

1. L.Y., a fair-skinned, 15-year-old, Caucasian girl presents to her physician complaining of worsening “zits.” Several of her classmates are taking antibiotics for acne, and she wants to move up from nonprescription treatments to “strong medicine.” The problem began when she was 13 and has progressively worsened. At first, lesions occasionally appeared on her chin and forehead; now she consistently has four to eight lesions, which have spread to her cheeks and nose. She uses a nonprescription 10% benzoyl peroxide gel as needed on lesions when her acne “gets really bad,” but it is too drying for everyday use. She tried a “medicated” soap in the past, but stopped because it caused excessively dry skin. She has no other medical problems and takes no chronic prescription medications. She has had normal menstrual periods since menarche at age 12. Both her older brothers have acne,

one mild and one severe. L.Y. denies alcohol, tobacco, or illicit drug use. She has a boyfriend but denies sexual intercourse. After school, she works part time at a fast food restaurant, plays varsity tennis, and practices violin. She wears a sweatband around her head while playing tennis and uses a hair styling gel.

Examination reveals three pustules and two closed comedones on her forehead, three papules on her cheeks and chin (which are covered with makeup), two well-healing areas on her nose, and no open comedones or nodules. Her skin is only slightly oily. Her chest, back, and arms are clear. She has no facial hair, and her voice is normal in pitch. What are the key components in the clinical assessment of L.Y.'s acne?

The clinical assessment of L.Y.'s acne should include evaluating each of the following factors:

- Type, number, and distribution of lesions. This patient has relatively few lesions that are mostly inflammatory (pustules) and located on the face.
- Contributing factors such as family history of acne (noted in brothers), work-related exposures (oils from fast food restaurant), systemic or topical medications, cosmetic or hair care products (makeup and hair gel), or mechanical pressure on the skin (sweatband and violin chin rest).
- Hormonal influences that indicate androgen excess or atypical menstrual cycles. This patient has no signs of virilization (normal voice and lack of facial hair), and her menstrual periods are normal.
- A detailed medical history. This patient is healthy and does not have epilepsy, liver disease, alcohol abuse, or dyslipidemia.
- Effectiveness of current or past treatments. This patient's response to two therapies was suboptimal, but because she used them erratically, effectiveness is difficult to assess.
- Psychosocial impact of acne on her quality of life. This appears to be very important to her based on her plea for effective therapy.

2. What subjective and objective data support a diagnosis of acne vulgaris?

This patient's age (teenager) puts her in the highest prevalence category. The facial distribution of lesions, while sparing most other areas, further supports acne, as does a positive family history. The fact that her condition has waxed and waned but progressively worsened is consistent with acne. Her condition also worsened because of mechanical irritation caused by sweatband use and violin playing. The lesion type and severity rule out more severe variants such as gram-negative folliculitis or acne fulminans.

MILD ACNE

Benzoyl Peroxide

3. Evaluate L.Y.'s current acne medication regimen.

L.Y.'s current antiacne regimen is suboptimal, which explains her progressively worsening course. Benzoyl peroxide is excellent for mild to moderate inflammatory acne, but 2.5% and 5% concentrations are less irritating than 10% concentrations and equally effective overall.⁸⁷ The product is failing to

control L.Y.'s acne because she applies it infrequently to existing lesions only. Routine use over the entire susceptible area is required for long-term acne control.

4. Why should other treatment options be avoided at this time?

Topical retinoids are more expensive and may not be as effective for inflammatory lesions as benzoyl peroxide. Azelaic acid is more expensive and should be reserved for patients who cannot tolerate other comedolytic topical therapies. A course of topical antibiotics may be added if appropriate benzoyl peroxide therapy is ineffective. Oral antibiotics should not be added because her acne is mild and distributed in a small area. Although oral isotretinoin would be very effective, it is not warranted at this time because of high cost, significant bothersome adverse effects, need for close monitoring, and potential teratogenicity. Combination oral contraceptives would have been a reasonable choice if L.Y. were sexually active or had menstrual abnormalities.

Skin Irritation

5. How can L.Y. reduce the risk of developing skin irritation and dryness while using benzoyl peroxide?

Topical application of benzoyl peroxide may cause transient warmth or stinging, significant drying, or skin irritation. Mild skin redness or drying is acceptable and indicates proper dosage and optimal therapeutic response. Factors that worsen skin irritation include increased benzoyl peroxide concentration and contact time, gels or lipophilic vehicles, thin and sensitive skin, low environmental humidity, use of irritating adjunctive therapies, and increased application frequency.⁸⁸ Initiating regular benzoyl peroxide use in a less drying vehicle (cream) and at lower strength (2.5%) would minimize the risk of intolerable skin irritation while still achieving the desired therapeutic effect. L.Y. could apply the product every other day for the first week or two, and then advance to daily application as tolerated. The cream should be applied at bedtime, ideally half an hour after washing the face with a mild cleanser, and washed off in the morning (or after several hours, if excessive skin dryness or peeling occurs). In a few weeks, she may be able to tolerate a second daily application half an hour after washing the face in the morning. L.Y. should be reminded of the product's potential to bleach fabrics.

To minimize skin irritation, L.Y. should also discontinue use of medicated cleansers. Oilfree moisturizer increases skin hydration and comfort, and can perform double duty if it also contains sunscreen. Patients using benzoyl peroxide should use a sunscreen every day that blocks ultraviolet (UV) light in both A and B wavelengths and that provides a sun protection factor (SPF) of at least 15. (See Chapter 41 for a more detailed discussion of sunscreens.) If L.Y. is applying benzoyl peroxide in the morning, she should apply it before applying the moisturizer with sunscreen.

Topical Antibiotics

6. How should L.Y.'s benzoyl peroxide therapy be modified if the desired effect is not achieved?

If L.Y. notices no improvement after 6 to 8 weeks of consistent twice-daily use and feels like the product is not having any effect on her skin, she should switch to gel and/or increase the strength of her benzoyl peroxide. Titration should continue to the point of mild, tolerable skin irritation. Alternatively, if she experiences inadequate improvement despite 6 to 8 weeks of benzoyl peroxide therapy strong enough to cause mild redness and drying, she should be given a course of topical antibiotics, applying the antibiotic in the morning while benzoyl peroxide is applied at bedtime. Combination products are convenient but often expensive; a recent community-based trial found no advantage, in efficacy or in preventing antibiotic resistance, to using Benzamycin® (3% erythromycin, 5% benzoyl peroxide gel) twice daily over 2% erythromycin gel in the morning and benzoyl peroxide 5% gel in the evening.⁷⁵ If a 2- to 3-month antibiotic course is successful, L.Y. should continue maintenance therapy with just benzoyl peroxide.

Adverse Effects to Topical Medications

7. R.P., a fair-skinned, 17-year-old Hispanic male, has been using a benzoyl peroxide 5% gel (Benzac®-W) for 2 months. Since he began using this treatment, his acne has slightly improved. The treatment caused some peeling at first, but soon only barely noticeable redness and dryness. About 1 week ago, he began noticing significant redness and itching in the areas where he had applied the gel. He denies any changes in sun exposure or skin care routine. He stopped using the medication until last night, when the irritation had almost resolved. Last night, he attempted to resume benzoyl peroxide therapy. Within 10 minutes after applying a small amount of gel, his skin became reddened, and began to burn and itch. He immediately washed the area well with cool, soapy water, but the skin irritation prevented him from getting a good night's sleep. The area is better this morning, but remains red and itchy. Currently, his acne consists of several noninflammatory and about 10 inflammatory lesions located primarily in the T-zone (forehead and nose). Is this a typical adverse reaction to benzoyl peroxide?

No. Because sun exposure or dryness from a change in skin cleanser did not appear to provoke the skin reaction, it is unlikely due to benzoyl peroxide's direct irritating effects. The intense itching and burning following rechallenge is more consistent with an allergic-type contact dermatitis, which occurs in up to 2.5% of patients.⁴⁶ Those who develop such contact dermatitis should discontinue benzoyl peroxide use.

8. R.P.'s treatment with benzoyl peroxide was discontinued. What alternative therapy is indicated at this time?

After the allergic reaction has resolved, R.P. should resume comedolytic therapy with a more tolerable formulation of tretinoin, or with adapalene or azelaic acid. Because benzoyl peroxide monotherapy was not achieving optimal results, therapy can be intensified by adding a course of topical clindamycin. Erythromycin is more associated with the development of resistance than clindamycin, and benzoyl peroxide cannot be used concomitantly to prevent resistance. The entire face, not just the lesions, should be treated for optimal results. An oral antibiotic is not indicated at this time because only a small area is affected.

MODERATE ACNE

9. R.P. moved away to go to college and returns for follow-up care after 2 months. He has been applying Ziana® gel (1.2% clindamycin and 0.025% tretinoin) regularly. Nevertheless, his inflammatory lesions have increased in number and have spread to his chest and back. He has one painful nodule on his cheek and another on his back. R.P. is embarrassed by the appearance of his skin, especially on his trunk, which is exposed when he wears his basketball jersey while playing on the school team. How would you assess his acne now? Why might his acne be worsening?

R.P.'s acne is now moderate in severity, as defined by the extensive distribution of lesions. For unknown reasons, perhaps hormonal changes that are increasing keratinization of the pilosebaceous unit, the acne has clearly progressed. The hot and humid conditions associated with playing basketball and potentially colonization with clindamycin-resistant *P. acnes*, or the stress of college, may also be contributing to his acne flare.

Systemic Antibiotics

10. Suggest modifications to R.P.'s treatment regimen to help him achieve better control of his acne. Provide a rationale for your choice.

Because R.P.'s lesions are primarily inflammatory in nature, antibiotics remain a good choice. However, the area affected is more widespread, so oral antibiotics should now be used in addition to a topical retinoid. Topical clindamycin should be discontinued, a retinoid-only topical product initiated (perhaps adapalene, or the higher concentration of tretinoin available as microsphere gel, if the patient can afford it), and doxycycline initiated at 100 mg PO BID with food. Doxycycline may cause gastrointestinal effects such as heartburn, nausea, and diarrhea, and dermatologic effects, such as rash and photosensitivity. Patients should be advised to take the drug with a full glass of water to avoid esophageal erosions from prolonged esophageal contact, and to wear protective clothing and use UV-A/UV-B sunscreen with an SPF of at least 15 on a daily basis. Because tetracycline may cause less photosensitivity, it may be an alternative to doxycycline if the patient spends a lot of time outdoors (although a sunscreen should still be used).⁷⁷ However, tetracycline must be taken at least 1 hour before or 2 hours after eating because food, particularly dairy, impairs its absorption.

If gram-negative folliculitis is suspected, oral trimethoprim/sulfamethoxazole should be considered. However, this is probably not the case in this patient. Rather than continued gradual deterioration, gram-negative folliculitis usually presents as worsening of acne in long-term antibiotic patients whose control had improved. Gram-negative organisms overgrow in the anterior nares and cause pustules on the central and lower face, often in the nasolabial folds. With their usual history of multiple antibiotic courses, gram-negative folliculitis patients often require isotretinoin therapy.⁵⁸

11. How should R.P.'s doxycycline regimen be monitored and the dosage adjusted?

If tolerated, doxycycline should be continued for 6 to 8 weeks, at which point changes can be made if there is no improvement.^{75,77} If therapy is effective at that point, the frequency can be lowered from BID to daily to minimize the risk of adverse effects (the same could be done for any of the other frequently used antibiotics; Table 39-6).⁷⁷ Routine laboratory monitoring is not necessary for most young, healthy patients receiving long-term oral tetracyclines or erythromycin because the incidence of serious adverse effects is low.⁸⁹ Antibiotics should be discontinued after the acne has been controlled for about 2 months in order to limit antibiotic exposure; courses are generally 3 to 6 months long. Longer courses are associated with little additional clinical improvement, but with the development of antibiotic resistance.⁶⁵ Topical retinoid therapy should continue during doxycycline therapy and then after the antibiotic course to maintain treatment benefit. If R.P. relapses again in the future after successful use of an oral antibiotic, another course of the same antibiotic should be used.⁷⁷

Retinoids in Postinflammatory Hyperpigmentation

12. J.H., a 23-year-old African American woman with medium brown skin tone, has had acne vulgaris for the past 10 years. During this time, she has tried several medications. Benzoyl peroxide was somewhat helpful, but even low concentrations caused excessive irritation. She also tried extended courses of topical erythromycin and clindamycin, with little clinical improvement. Oral tetracycline was moderately effective, but caused her to get frequent yeast infections. A year ago, she began using Yaz[®] for contraception and has noticed improvement in her acne as well. However, she still has about 20 open and closed comedones on her forehead, cheeks, and chin. She has 2 papules on her nose and 1 papule along the jawline. J.H.'s biggest concern about her skin is that lesions "take forever to clear completely." She shows you 8 hyperpigmented macules on her cheeks and forehead at the sites of lesions that healed over the past 6 months. Recommend a new treatment strategy for J.H.

Because J.H.'s acne is mostly comedonal, a topical retinoid would likely be an effective addition to the hormonal therapy provided by her contraceptive. However, given her history of sensitive skin and propensity toward postinflammatory hyperpigmentation (PIH), it is important that therapy not be so irritating as to prompt severe inflammation. Adapalene would be a good option because it has less irritation potential than tretinoin and can reduce PIH as well. Cream is a less irritating vehicle than gel. She should apply the cream to her entire face every night. Some acne might appear worsened within the first 1 to 2 weeks because preclinical lesions may become visible. Sun exposure significantly intensifies skin irritation, so all patients regardless of skin color (and especially those prone to PIH) should be instructed to apply sunscreen to sun-exposed areas when using comedolytic therapies.⁹⁰ It is also important to ask J.H. about her skin care regimen and use of hair products to identify the use of any counterproductive cleansing strategies or comedogenic hair pomades.

Like many patients with PIH, J.H. is more distressed by the splotchy aftermath of her acne than by the acne itself.²⁰ She should be assured that the adapalene cream will likely aid the resolution of her current hyperpigmentation in addition to

interrupting the comedogenic process behind future lesions. If the hyperpigmentation shows no signs of improvement when J.H. returns for follow-up in 6 weeks, once- or twice-daily application of nonprescription skin-lightening hydroquinone 2% cream can be added to speed resolution.¹⁹ Hydroquinone is applied only to the areas of hyperpigmentation and only until they fade, typically 1 to 3 months. If it is being applied at the same time of day as acne medication, it should be applied following the acne medication.

SEVERE ACNE

Isotretinoin

Dose

13. Four years ago, K.S., an olive-skinned, 24-year-old, Hispanic woman, was diagnosed with moderate noninflammatory and inflammatory acne that was primarily located on her face and back. She tried topical benzoyl peroxide and systemic erythromycin with limited success. Two years ago, she was diagnosed with polycystic ovary syndrome and began taking Ortho Tri-Cyclen[®], after which her acne improved but remained inadequately treated. Five months ago, she also began taking minocycline 100 mg PO BID. After a few months, she experienced significant improvement, but she has not been able to reduce her dosage to 100 mg daily because of predictable flare-ups. In fact, her acne has worsened over the past 2 months, and she now has at least a dozen nodules widely distributed among multiple papules and pustules on her face and back.

K.S. is 5'6" and weighs 180 lb (81.8 kg). She has no other health problems. She does not smoke, but she occasionally drinks three to four alcoholic beverages on weekends. She is sexually active with one partner, her husband. A month ago, a comprehensive metabolic panel, thyroid-stimulating hormone level, complete blood count with platelets, and lipid panel were normal. Suggest a therapeutic plan for K.S.'s acne.

K.S. has severe acne based on the large number of lesions, wide distribution on multiple body sites, and presence of multiple inflammatory lesions, including nodules. The most effective medication for K.S. will be oral isotretinoin at an initial dose of 20 mg twice daily (approximately 0.5 mg/kg). The dosage should be increased to 40 mg twice daily (1 mg/kg) as tolerated after 1 month. A single treatment course is most effective if a cumulative dose of approximately 120 mg/kg, which should take almost 5 months to complete, is attained. Higher dosages are associated with an increased risk of adverse effects. K.S. should stop taking minocycline when isotretinoin therapy begins because isotretinoin is effective monotherapy, and coadministration of isotretinoin and tetracyclines increases the risk of intracranial hypertension.⁷⁷ Her acne should significantly improve within the first month of therapy and gradually resolve by the third or fourth month. A second course of therapy is usually not necessary.

Teratogenicity

14. What should K.S. be told about avoiding pregnancy while taking isotretinoin?

Because of isotretinoin's teratogenic effects (e.g., severe birth defects, premature birth, neonatal death), the iPLEDGE

program emphasizes repeated patient education regarding contraception.⁹¹ The program requires that all female patients of child-bearing potential use two forms of contraception, of which at least one must be a “primary” method, for a month before, all during, and for a month after therapy. K.S. is already using an approved primary method with Ortho Tri-Cyclen®; approved primary methods include bilateral tubal ligation, partner’s vasectomy, some intrauterine devices, or hormonal methods (other than progestin-only minipills). However, she must also begin using a backup method, such as condoms. The program requires that all female patients of child-bearing potential must have two negative pregnancy tests before beginning isotretinoin therapy, one at the time of screening and then another, from an appropriately certified laboratory, after a month on their chosen contraception regimen. The program also requires a negative pregnancy test before each monthly refill is prescribed, immediately after therapy, and a month following therapy. K.S. and her prescriber will both have to verify with the program on a monthly basis that she has been counseled again regarding contraception. K.S. must also be reminded to avoid donating blood during therapy and for a month following therapy because blood products created from her donation could potentially be used in pregnant patients.

Laboratory Monitoring Parameters

15. In addition to the pregnancy testing discussed, which baseline and periodic laboratory monitoring parameters should be followed in this patient?

Before beginning isotretinoin therapy, baseline values for the following laboratories should be obtained for all patients, male and female: a fractionated lipid panel; a liver function panel, including both serum transaminases and bilirubin; and a complete blood count, including platelets.^{11,29}

If a particular patient’s other medical history suggests potential risk, providers might order baseline serum glucose levels, erythrocyte sedimentation rate, and creatine phosphokinase.⁹² For accurate triglyceride results, the blood sample should be collected at least 36 hours after alcohol consumption and 10 hours after eating food. The laboratory results measured a month ago will suffice for K.S. because they likely would not be significantly different now.

A fractionated lipid panel should be redrawn 4 weeks and 8 weeks into isotretinoin therapy to document the effect of the drug.¹¹ About 20% of patients develop significant triglyceride elevations.⁴⁹ Triglyceride levels >400 mg/dL should be treated with diet and reduced alcohol intake; monthly monitoring should continue throughout isotretinoin therapy. In the unusual event that triglyceride levels exceed 800 mg/dL, isotretinoin should be discontinued, or continued at a reduced dosage with concomitant gemfibrozil therapy to reduce the risk of pancreatitis.¹¹ If pancreatitis develops, isotretinoin must be discontinued. High-density lipoprotein concentrations may decrease slightly, and total cholesterol concentrations may increase during isotretinoin therapy; however, the clinical significance is unknown. These lipid abnormalities usually resolve within several weeks of completion of therapy.⁴⁹

Liver function tests and blood counts only need to be redrawn during therapy if symptoms suggestive of hepatitis or blood dyscrasias appear,¹¹ although some guidelines suggest periodic monitoring.²⁹ Mild elevations in serum transaminases

may simply be monitored if they occur. However, isotretinoin dosage reduction or drug discontinuation should be considered in asymptomatic patients with persistent enzyme elevations greater than twice the upper limit of normal. Clinical hepatitis occurs rarely, but requires drug discontinuation if suspected.

Adverse effects on bone such as hyperostosis, premature epiphyseal closure, and reduced bone mineral density have not been observed when isotretinoin is used at the doses and durations typical in acne treatment, so monitoring for this toxicity is not required unless a patient is undergoing multiple isotretinoin courses or has pertinent medical history.^{29,48}

Adverse Effects

16. How should K.S. be counseled with regard to adverse effects of isotretinoin?

Severe photosensitivity can occur in any patient taking isotretinoin; K.S. should be advised to wear protective clothing and to use UV-A and UV-B blocking, high-SPF sunscreen daily, even if she does not anticipate sun exposure. She should also be cautioned about limiting alcohol consumption, which can enhance isotretinoin-induced hypertriglyceridemia and hepatotoxicity. She should expect significant skin and mucous membrane dryness, which is reported by virtually all patients taking isotretinoin. Another possible adverse effect is muscle or joint pain, especially if she exercises more than usual. She should avoid waxing, dermabrasion, and other skin procedures during and for 6 months after therapy because her skin would be likelier than usual to scar. She should drive with caution, paying attention to any potential vision changes, particularly at night. Bone growth is not impaired when isotretinoin is used in recommended dosages. Refer to Table 39-4 for a list of other noteworthy potential adverse effects caused by isotretinoin.

17. The package insert for isotretinoin warns against possible drug-induced depression. How significant is this risk?

Isotretinoin product labeling includes a warning that isotretinoin may cause depression, including suicide attempts, psychosis, and violent behavior. Case reports suggest that isotretinoin causes psychiatric symptoms in some patients. However, severe acne is itself associated with depression, and prospective trials and literature reviews have not established a causal relationship between isotretinoin and depressive symptoms.⁹³ Although the absolute risk is low, drug-induced depression is a possible idiosyncratic reaction to isotretinoin in individual patients. In any case, all patients with severe acne, whether receiving isotretinoin or not, should be monitored for the development or worsening of depression.²⁹

18. After 3 weeks of therapy, K.S. complains of dry eyes, dry skin, and cracks with bleeding at the corners of her mouth. How might these bothersome mucocutaneous side effects be managed?

K.S. should use artificial tears to relieve the discomfort of her dry eyes; if she is still uncomfortable after several days, she can also apply lubricating ophthalmic ointment at bedtime. Dry skin may be treated with frequent application of moisturizer, particularly after bathing (see Chapter 38). Frequent application of a lip balm or emollient, ideally one containing sunscreen, is recommended to treat cheilitis. If the symptoms become intolerable, a small reduction in the isotretinoin dose

(e.g., reduction of 10–20 mg/day) usually decreases the intensity of skin and mucous membrane reactions. Drug discontinuation is rarely necessary.⁴⁹

ACKNOWLEDGEMENT

Epidemiology

Psoriasis, a chronic, proliferative skin disease is one of the most common immune-mediated disorders occurring in 1.5% to 3% of the population worldwide, with northern Europeans and Scandinavians affected most.^{1,2} It is characterized by well-delineated, thickened erythematous epidermis or dermal plaques covered with a distinctive silvery scale. Of patients, 75% present with symptoms of psoriasis before the age of 46 years.² A family history of psoriasis is found in nearly half of patients. At least nine chromosomal loci have been identified that increase psoriasis susceptibility.^{3,4} The primary genetic determinant is PSORS1, a region of the major histocompatibility complex on chromosome 6p2, which accounts for 35% to 50% of the heritability of the disease.^{2,3} Environmental triggers also play a major role in disease expression.

Pathogenesis

Innate and adaptive immunity are both involved in the initiation and maintenance of psoriatic plaques. Indeed, because the epidermis is the body's main barrier to environmental insult, epidermal hyperplasia forms a key component of the innate immune response. Natural killer cells and natural killer T cells are part of the cutaneous inflammation in psoriasis.⁵

As CD4+ and CD8+ T-lymphocytic cells constitute most of the leukocyte infiltrate found in plaques early in the development of lesions, current evidence supports an autoimmune mechanism for psoriasis. Cytokines such as interferon- α_2 or interleukin 2 are also found in psoriatic plaques.⁶ T cells in the cutaneous infiltrate are positive for cutaneous lymphocyte-associated antigen (CLA), a marker for skin-homing leukocytes. Pathogenesis also involves vascular and inflammatory

changes, which precede epidermal changes.⁷ The alterations in the dermal vasculature also appear to be a result of angiogenesis, the development of new blood vessels, similar to a number of other disease processes, including tumor growth. Many commonly used therapeutic agents for psoriasis have antiangiogenic activity.¹

The epidermal changes of psoriasis are based on the time required for affected epidermal cells to travel to the surface and be cast off, which is markedly reduced (3–4 days, vs. 26–28 days in normal cells).⁸ This sixfold to ninefold transit time decrease does not allow the normal events of cell maturation and keratinization to take place and is reflected clinically as diffuse scaling. T cells contribute to this keratinocyte hyperproliferation through the secretion of various growth factors.^{9,10} Memory T lymphocytes marked with CLA, to remember the anatomic site where they first encountered antigen, migrate to the (epi)dermis by a number of immunologic and inflammatory triggering mechanisms released from keratinocytes after minor trauma. On entry into the skin, these T cells complex with epidermal self-antigens presented by major histocompatibility complex molecules that confer the risk of psoriasis. The subsequent release of T-cell cytokines results in further inflammation, the recruitment of additional marked (i.e., with CLA) T cells, and ultimately the development of psoriatic lesions in susceptible persons.^{9,10}

Signs and Symptoms

Most psoriatic lesions are asymptomatic, but not always. Pruritus, for example, is noted in 50% of patients, and it can be severe.¹¹ The primary psoriatic lesion is a relapsing eruption of scaling papules that rapidly coalesce or enlarge to form

circumscribed, erythematous, scaly, plaques. The scale is adherent and silvery white, and may reveal bleeding points when removed (*Auspitz sign*). Scales can become extremely dense on the scalp or macerated and dispersed in intertriginous areas. (Web sites, such as www.dermnet.com or www.psoriasiscafe.org/psoriasis-pictures, provide representative pictures of psoriatic lesions.)

Lesions of active psoriasis can develop at the site of epidermal trauma (*Koebner phenomenon*). Scratch marks, sunburn, or surgical wounds may heal, leaving psoriatic lesions in their place. The elbows, knees, scalp, gluteal cleft, fingernails, and toenails are favored areas of involvement. Extensor surfaces are affected more than the flexor surfaces, but the disease usually spares the palms, soles, and face. Nail beds may show punctate pitting, profuse collections of keratotic material, yellow-brown subungual discoloration (“oil spot”), or onycholysis (nail plate separation) in approximately 50% of patients.¹² Psoriatic arthritis is a seronegative inflammatory arthritis that occurs in approximately 25% of all patients with psoriasis, with combined features of both rheumatoid arthritis and the seronegative spondyloarthropathies.^{2,11}

Most patients (90%) have chronic localized disease (plaque-type or *psoriasis vulgaris*), but there are several other presentations. The most severe form of the disease is *erythrodermic psoriasis*, which describes a condition of acute inflammatory erythema and scales involving >90% of body surface area. *Pustular psoriasis* is generally localized to palms and soles, but there is also a generalized version. Both generalized *pustular psoriasis* and *erythrodermic psoriasis* can be accompanied by systemic symptoms (hyperthermia, tachycardia, edema, dehydration, shortness of breath) and can have life-threatening consequences (hypovolemia, electrolyte imbalance, septicemia) if not promptly treated.¹³ Lesions of *Guttate psoriasis* are small, fine, erythematous scales, usually found on the trunk, arms, or legs, classically following β -hemolytic streptococcal pharyngitis. *Flexural or inverse psoriasis* is shiny, red, and typically lacks scales and looks more like intertrigo.² Interestingly, psoriatic skin is rarely secondarily infected, because of the overexpression of endogenous peptides (cathelicidins and beta-defensins).¹⁴

Systemic disorders that can have a causative association with psoriasis include type 2 diabetes mellitus, Crohn's disease, metabolic syndrome, depression, and cardiovascular disease.^{2,15,16} This increased risk is thought to be caused by the presence of endothelial activation, proinflammatory cytokines and hyperlipidemia.^{2,13,15} In a prospective cohort study, the relative risk of myocardial infarction was significantly increased with a greater risk in younger patients with more severe disease.¹⁵

Prognosis

Similar to those with diabetes, cancer, and heart disease, patients with psoriasis experience a decreased quality of life related to social, psychological, and physical functioning.^{16,17} It is important to emphasize that psoriasis is a treatable disease, but with no known cure. Optimism and encouragement are justified and make it easier for patients to conscientiously apply sometimes awkward and messy topical treatments or take medications that have significant adverse effects. The goal of therapy should be to achieve complete clearing of psoriatic le-

sions, particularly during emotionally critical times, such as the commencement of school, puberty, and the summer months.

The Self-Administered Psoriasis Area and Severity Index (SAPASI) is a validated, structured instrument that can be used for patient assessment of psoriasis severity and response to therapy. It closely correlates with the standard clinician assessment instrument, Psoriasis Area and Severity Index (PASI), which includes quantification of the percentage of body involvement and severity of lesions.¹⁸ PASI 75 (a $\geq 75\%$ decrease in PASI score) at 3 months from baseline has become the most prominent marker to assess systemic agent efficacy.¹⁹

The National Psoriasis Foundation recently released a clinical consensus statement on the classification of severity of disease. Rather than using a mild, moderate, or severe classification system, the statement recommends two categories for patients, those who are candidates for localized (i.e., topical) therapy, and those who are candidates for systemic or phototherapy (e.g., methotrexate or immunomodulators). The National Psoriasis Foundation (<http://www.psoriasis.org>) is a good resource for both patients and providers for information on treatment options as well as psychosocial support.^{20,21}

TOPICAL PHARMACOTHERAPY

Many topical and systemic therapeutic agents are available, varying from simple topical emollients to systemic, highly potent immunosuppressant drugs for more recalcitrant conditions. Treatment modalities are chosen on the basis of disease severity, patient preference (including cost and convenience), and response. Patients with mild disease can generally be treated with topical therapy (Table 40-1). Patients with psoriasis covering >20% of the body need more specialized systemic treatment programs (Table 40-2).

Topical Corticosteroids

Topical corticosteroids, the most widely prescribed treatment for psoriasis, are effective in the treatment of psoriasis because of their anti-inflammatory, antimitotic, immunosuppressant, and antipruritic properties.^{22,23} These properties are explained by a reduction in phospholipase A₂, DNA synthesis, and epidermal mitotic activity, as well as their vasoconstrictive actions. They provide prompt relief, and patients find them convenient and acceptable, but some are expensive. Tachyphylaxis occurs, and long-term use after skin has returned to a normalized state leads to typical corticosteroid adverse effects (atrophy, telangiectasia, and striae). Thin-skinned areas (facial and intertriginous) are particularly susceptible. Psoriasis is generally a relatively corticosteroid-resistant disease; therefore, the more potent corticosteroids are frequently necessary, often with occlusion, for best results. (See Table 38-8 in Chapter 38, Dermatotherapy and Drug Induced Skin Disorders, for a listing of topical corticosteroids by potency.) Less potent agents are more appropriate in intertriginous areas, on the face, and for maintenance. Potent corticosteroids clear psoriasis in 25% of patients in 3 to 4 weeks, with 75% clearing in 50% of treated patients.²⁴

Intermittent dosing or “pulse therapy” seems to yield the best long-term results and minimizes tachyphylaxis and adverse effects. An additional drawback of chronic corticosteroid

Table 40-1 Topical Agents for the Treatment of Psoriasis (Mild to Moderate; <20% Body Involvement)

| <i>Treatment Modality</i> | <i>Advantages</i> | <i>Disadvantages</i> |
|--|--|---|
| Emollients | Basic adjunct for all treatments; safe, inexpensive, reduces scaling, itching, and related discomfort | Provide minimal relief alone |
| Keratolytics (salicylic acid, urea, α -hydroxy acids [i.e., glycolic and lactic acids]) | Reduce hyperkeratosis; enable other topical modalities to better penetrate; inexpensive | Provide minimal relief individually; nonspecific; salicylism (tinnitus, nausea, vomiting) with salicylic acid if applied extensively |
| Topical corticosteroids | Rapid response; control inflammation and itching; best for intertriginous areas and face; convenient, not messy; mainstay topical treatment modality for psoriasis | Temporary relief; less effective with continued use (tachyphylaxis occurs); withdrawal can produce flares; atrophy, telangiectasia, and striae with continued use after skin returns to normalized state; expensive; adrenal suppression possible |
| Coal tar | Particularly effective for “flaky” scalp lesions; new preparations “pleasant”; efficacy enhanced in combination with UVB (i.e., Goeckerman regimen) | Effective only for mild psoriasis or scalp psoriasis; inconvenient—difficult to apply; stains clothing and bedding, not skin; strong smelling; folliculitis and contact allergy (bronchospasm in atopic patient with asthma after inhalation of vapor); carcinogenic in animals |
| Anthralin | Effective for widespread, refractory plaques; produces long remissions; short, concentrated programs preferred; enhanced efficacy in combination with UVB (i.e., Ingram regimen) | Purple-brown staining (skin, clothing, and bath fixtures); irritating to normal skin and flexures; careful application required (inpatient?); can precipitate generalized psoriasis |
| Calcipotriene (Dovonex) | As effective as topical corticosteroids, although slower onset, without long-term corticosteroid adverse effects; convenient, well tolerated | Slow onset; expensive; potential effects on bone metabolism (hypercalcemia); irritant dermatitis on face and intertriginous areas; contraindicated during pregnancy |
| Tazarotene (Tazorac) | Extended response; convenient (applied daily, in gel formulation); maintenance therapy; effective on scalp and face; used in combination with topical corticosteroids | Slow onset; local irritation and pruritus; teratogenic (adequate contraception is required) |
| Ultraviolet B (UVB) | Effective as maintenance therapy; eliminates problems of topical steroids | Expensive (insurance reimburses); office-based therapy; sunburn (exacerbates psoriasis); photoaging; skin cancer |

Table 40-2 Agents for the Treatment of Severe Psoriasis (>20% Body Involvement)

| <i>Treatment Modality</i> | <i>Advantages</i> | <i>Disadvantages</i> |
|--|---|--|
| UVA and psoralen (PUVA) | 80% efficacy; “suntan” cosmetically desirable | Time-consuming; expensive, office-based therapy (restrictive); sunburn (exacerbates psoriasis); photoaging; both nonmelanoma skin cancer and melanoma; contraindicated during pregnancy and lactation |
| Acitretin (Soriatane) | Not as effective as other systemic agents; efficacy enhanced if given with PUVA or UVB (i.e., RePUVA or ReUVB); less hepatotoxic than methotrexate | Teratogenic (contraception required); contraindicated with liver or renal dysfunction, drug or alcohol abuse, hypertriglyceridemia, hypervitaminosis A |
| Methotrexate | Effective for both skin lesions and arthritis as well as psoriatic nail disease | Hepatotoxicity (periodic liver biopsy?); bone marrow toxicity; folic acid protects against stomatitis (not against hepatic or pulmonary toxicity); drug interactions; contraindicated during pregnancy and lactation, drug or alcohol abuse; caution during acute infections |
| Cyclosporine | Toxicities and short-lived remissions; used in patients with extensive disease—not responsive to other agents; however, given changing pathophysiology and increasing experience at lower dosages, increasing role in rotational therapy to induce remissions | Renal impairment; suppressive therapy (relapse occurs when discontinued); increased risk of skin cancer, lymphomas, and solid tumors; phototoxic; contraindicated during pregnancy and lactation, and with hypertension, hyperuricemia, hyperkalemia, acute infections |
| Immunomodulators (alefacept, efalizumab, etanercept, infliximab) | Specific, targeted therapy; effective for moderate to severe both skin lesions and arthritis; maintains remission | Expensive; parenteral (often office-based) therapy; long-term safety unknown; increased risk of serious infections |

PUVA, psoralens plus ultraviolet A light; RePUVA, retinoid-PUVA; UVA, ultraviolet A; UVB, ultraviolet B.

therapy is an associated acute flare-up of psoriasis when corticosteroid therapy is terminated.²⁵ Continuous application for >3 to 4 weeks should be discouraged in patients with psoriasis, and systemic corticosteroids have no place in therapy.^{24,26} Topical corticosteroids occasionally can cause a reversible suppression of the hypothalamic-pituitary-adrenal (HPA) axis, as indicated by a decrease in the morning plasma cortisol level.²⁶ For anything more extensive than mild disease, topical corticosteroids are best used in an adjunctive role. During a flare, corticosteroids help reduce inflammation, redness, and irritation and prepare the involved area for initiation of other potentially irritating, but more appropriate, maintenance topical treatments (e.g., coal tar, anthralin, calcipotriene, or tazarotene).

Coal Tar

Crude coal tar is a complex mixture of thousands of hydrocarbon compounds.²⁷ It is a time-honored modality for treating psoriasis. It affects psoriasis by enzyme inhibition and antimetabolic action (antiproliferative and anti-inflammatory).²⁷ The efficacy of the combination of tar and ultraviolet B (UVB) light (i.e., Goeckerman regimen) led to its increased popularity beginning in the 1920s. Tar preparations of 2% to 10% are processed as creams, ointments, lotions, gels, oils, shampoos, and coal tar solution (liquor carbonis detergens). Newer purified preparations, using refined coal tar, are less messy and more cosmetically acceptable, but perhaps not as effective.²⁷ Tar may be helpful for patients with mild to moderate disease, and tar shampoos are useful for psoriasis of the scalp. The potential severity of adverse drug effects from topical tar products is less than that from anthralin, and much less than that from topical corticosteroids. Because tar, in every form, is messy, stains the skin, and has an odor, it has been relegated to second-line therapy for most patients, despite its moderate price.²⁸

Tar preparations generally are used once or twice daily, and bedtime application (as a shampoo or cream overnight) is particularly useful in psoriasis of the scalp and overcomes some of the negative cosmetic bias. Patients should be warned about the staining properties of tar on clothing and bedding. Other adverse effects include photosensitivity, acneiform eruptions, folliculitis, and irritation dermatitis. Care should be taken to avoid use of tar on the face, flexures, and genitalia and with inflammatory psoriasis because of tar's irritant properties.

The polyaromatic hydrocarbons contained in coal tar may be metabolized to active carcinogens by epidermal microsomal enzymes. The incidence of hyperkeratotic lesions, including squamous-cell carcinomas, is increased after prolonged industrial exposure to tar; however, extensive reviews of patients who have used tar preparations in psoriasis have not revealed an increased risk of carcinoma.²⁹

Anthralin

Anthralin (dithranol in the United Kingdom) is a hydroxyanthrone derivative that inhibits DNA synthesis, mitotic activity, and a variety of enzymes crucial to reducing cell proliferation.²⁴ It is effective for treatment of widespread, discrete psoriatic plaques. It is applied as a stiff paste (anthralin in Lassar's paste) overnight and used in conjunction with coal tar baths and UVB light (i.e., Ingram regimen). Most cases of chronic plaque psoriasis clear in 3 weeks. The primary disad-

vantages of anthralin are its irritant and staining properties to skin and clothing. Anthralin also can precipitate generalized psoriasis if applied to unstable psoriasis (i.e., plaque transformation to pustular form).

The standard anthralin regimen involves liberal application of gradually increasing concentrations (0.1%–0.2% up to no more than 3%–5%) for 8 to 12 hours (often overnight), depending on degree of irritation and clinical response. To minimize brownish to purplish staining (of hair, skin, clothing, furniture, and bedding), plastic gloves should be used, as well as old bed linens and clothing for sleep. Contact with the face, eyes, mucous membranes, and nonpsoriatic skin should be avoided because of irritant properties. Application of petrolatum ointment around the psoriatic lesion prevents perilesional irritation. Removal of the anthralin application is facilitated with a bath (often containing coal tar) or mineral oil in the morning. A corticosteroid cream may be used during the day.

Alternative, shorter contact (10–60 minutes twice daily) regimens (e.g., short-contact anthralin therapy [SCAT]) have been developed to minimize application time and staining. These SCAT regimens are most appropriate for the outpatient setting.^{24,30} Higher concentrations of anthralin are used in the shorter-contact regimens and irritation is more of a problem. Both methods are used daily for clearing of psoriasis, then once or twice weekly for maintenance therapy, which is instituted after a response is seen at 2 to 3 weeks. Short-course regimens clear 32% of lesions and produce >75% improvement in 50% of patients after 5 weeks. These regimens are comparable in effectiveness to the Ingram regimen and topical corticosteroids are associated with fewer adverse drug events.^{24,30}

Calcipotriene (Dovonex)

Calcipotriene (calcipotriol in Europe), a topical vitamin D₃ analog that suppresses keratinocyte proliferation and that has anti-inflammatory effects,³¹ can be applied twice daily as a cream, ointment, or solution. Although systemic absorption is slight and the vitamin D effects of calcipotriene on calcium and bone metabolism are about 100 to 200 times less than that of 1,25-dihydroxyvitamin D₃, serum calcium levels and urinary calcium excretion should be monitored to prevent serious effects on calcium and bone metabolism. Other adverse effects of calcipotriene include lesional and perilesional irritation, burning, stinging, pruritus, erythema, and scaling, especially in facial and intertriginous areas.²² About 30% of patients using calcipotriene develop skin irritation.³²

Most patients see improvement, although not clearing, of psoriatic plaques at 2 weeks when treated with calcipotriene, often in combination with potent topical corticosteroids. A maximal response is usually seen at 6 to 8 weeks. Of treated patients, 57% experience >75% clearance of psoriatic plaques, which is comparable to that achieved with corticosteroids, albeit slower in onset and associated with more dermal irritation.^{24,32} Tachyphylaxis has not been a problem.³³ A formulation of calcipotriene and betamethasone (Taclonex) is available.

Tazarotene (Tazorac)

Tazarotene is a topical synthetic retinoid that is rapidly converted to its biologically active metabolite, tazarotenic acid.³⁴ By interacting with the predominant retinoid receptors on

the skin surface regulating gene transcription, retinoic acids normalize abnormal keratinocyte differentiation, reduce hyperproliferation, and decrease inflammation associated with psoriasis.³⁴ Treatment success rates compare favorably with corticosteroids (52% clearing of all lesions; 70% clearing of trunk and limb lesions). The antipsoriatic effects of tazarotene are sustained for a longer period after treatment compared with corticosteroids.^{24,35} Because local skin irritation and pruritus are common adverse effects of tazarotene use, combination therapy with corticosteroids not only provides additive antipsoriatic effects, but also reduces retinoid-induced irritation.³⁶ Oral retinoids are known *teratogens*, and tazarotene is not recommended for use during pregnancy. Women should be warned of potential risk and the need to use adequate contraception while using these preparations.^{34,35}

PHOTOTHERAPY

Ultraviolet B

Ultraviolet B light (sunburn spectrum, 290–320 nm) induces pyrimidine dimers, inhibits DNA synthesis, and depletes intraepidermal T cells found in psoriatic epidermis (i.e., UVB has antiproliferative and local immunologic effects).²² UVB light, unlike ultraviolet A (UVA) light, is effective without additional sensitizers (i.e., psoralens). UVB therapy is generally considered pleasant to use and relatively nontoxic. Typically, 60% of patients with chronic plaque psoriasis experience clearing, and an additional 34% achieve a 75% clearance with UVB treatment for 7 to 8 weeks.²⁴ Heat and humidity from sunlight provide additional positive effects. Narrow-band UVB (NBUVB) phototherapy, 311 nm, has been found to be more effective than broad-band UVB (BBUVB)¹⁹; however, it is not as effective as psoralens plus ultraviolet A light (PUVA) therapy in terms of clearing psoriatic lesions.³⁷ The greater efficacy of PUVA, however, may be offset by the short-term adverse effects of psoralens (e.g., nausea, headaches), the greater incidence of phototoxic reactions (erythema), the inconvenience of wearing photoprotective eyewear after treatments, and the extra cost. Although not currently proved, it is hypothesized that NBUVB will produce less long-term photodamage and fewer skin cancers than PUVA.

Ultraviolet B treatments are administered three times weekly. The use of pretreatment emollients (e.g., petrolatum, mineral or “baby” oil, Eucerin) applied before UVB exposure, long thought to improve results, actually inhibits the penetration of UVB and should not be used.³⁸ After the skin clears, therapy is discontinued gradually over 2 to 4 months to prolong remissions. The risks of UVB radiation and sunlight are similar: sunburn, photoaging, and skin cancer.

Regimens combining UVB with anthralin (Ingram regimen) or tar (Goeckerman regimen) have been used for years, theoretically, taking advantage of the photosensitizing properties of tar and anthralin. The Goeckerman regimen involves daily application of coal tar for at least 4 hours along with exposure to UVB light. The Ingram regimen combines daily application of anthralin plus tar baths with exposure to UVB light.²⁴ Both the Goeckerman and Ingram regimens can clear widespread psoriasis in 3 to 4 weeks, induce remissions that last for weeks to months, and may reduce the long-term adverse effects of UVB exposure.²⁴

A recent development in UVB therapy involves use of a high-energy, 308-nm excimer laser. Laser treatment allows exposure of only involved skin, thus higher doses of UVB can be administered during a given treatment. After only 10 twice-weekly treatments, 84% and 50% of patients achieved 75% or better and 90% or better clearing of plaques, respectively. Adverse drug effects include erythema and blistering, but are generally well tolerated.³⁹

Photochemotherapy

Photochemotherapy combines psoralens with UVA light in the 320 to 400 nm spectrum. The psoralens (methoxsalen, 8-methoxypsoralen, and trioxsalen) are a group of photoactive compounds that on absorption of UV light, are both antiproliferative and immunomodulatory. When photoactivated by UVA, psoralens form monofunctional adducts and cross-links with pyrimidine bases. PUVA also inhibits cytokine release and depletes both epidermal and dermal T cells. As measured by extent of T-cell depletion and decreases in delayed hypersensitivity, PUVA has greater immunomodulatory effects in the skin than UVB. Use of PUVA for scalp or nail involvement is limited, however, because of lower exposure.^{22,40} Remissions are longer in duration than with UVB. Psoralens are not active without UVA.

Photochemotherapy is used to control severe, recalcitrant, disabling plaque psoriasis. After 10 to 20 treatments over 4 to 8 weeks, >80% of patients experience clearing of symptoms, which can be maintained with periodic (twice monthly) treatments.²⁴ UVA penetrates the skin more deeply than UVB and may have marked effects on the dermis. The use of PUVA requires careful consideration and adherence to strict photoprotective measures. Patients unwilling to adhere to PUVA-related precautions may prefer UVB treatment because it is much less restrictive.

The peak range for UVA light's therapeutic action is between 320 and 335 nm. 8-Methoxypsoralen (8-MOP) is the most widely used agent, taken at an oral dosage of 0.6 to 0.8 mg/kg of body weight rounded to the nearest 10 mg, 1.25 to 1.5 hours before exposure to UVA light.³⁷ The initial dose is selected based on the patient's skin type (i.e., ease of sunburn and inherent skin color). Other options for combination therapy with UVA include calcipotriol-PUVA (D-PUVA) and retinoid-PUVA (RePUVA). Both of these modalities have shown to have greater efficacy as compared to PUVA alone.¹⁹

Acute adverse phototoxic effects, such as erythema and blistering, are dose related and, therefore, controllable. Other acute adverse drug effects include nausea, lethargy, headaches, pruritus, and hyperpigmentation. Topical steroid therapy should be continued until the psoriasis is brought under control. If topical steroids are discontinued at the start of PUVA, an exacerbation of psoriasis usually occurs. Patients should wear protective clothing (with long sleeves and high necklines), use sunscreens that filter out both UVA and UVB, and wear sunglasses that block UVA after PUVA (see Chapter 41, Photosensitivity and Burns). Because methoxsalen has a short half-life and 80% is eliminated within 6 to 8 hours, physical barriers are most important during the 8 hours immediately following PUVA therapy.

Of greater concern are the potential long-term adverse effects: mutagenicity, carcinogenicity, and cataract formation. Squamous cell carcinoma has been associated with

cumulative PUVA treatments (11-fold increase in patients who receive >260 treatments compared with patients who received <160 treatments).²⁴ Male patients have an increased risk of developing genital squamous cell carcinoma.²⁴ More controversial is the relationship of exposure to PUVA and the risk of malignant melanoma. At present, there appears to be a dose-dependent increase in the risk of melanoma associated with high-dose exposure to PUVA. The risk is first manifested ≥ 15 years after initial exposure to PUVA.^{41–43} Long-term maintenance and high cumulative dosages should be avoided. Shielding the face and genitalia during treatment and performing annual examinations to detect skin cancer at an early stage may lessen the risk of long-term adverse effects of photochemotherapy.

Topical psoralens are extremely photosensitizing, hence difficult to administer. Application of methoxsalen 0.1% followed by small UVA doses (i.e., $\leq 20\%$ of the level of usual doses for oral PUVA) has been used, however, to treat localized areas and to prevent adverse gastrointestinal effects.²⁴

SYSTEMIC PHARMACOTHERAPY

Acitretin (Soriatane)

Second-generation systemic retinoids are effective for treatment of recalcitrant psoriatic disease. Antipsoriatic effects stem from the drug's ability to modulate epidermal differentiation and immunologic function in addition to an anti-inflammatory action.⁴⁴ This latter effect may alleviate the arthritis that accompanies psoriasis.^{22,44} Acitretin is the principal metabolite of etretinate. It is less lipophilic, has a considerably shorter half-life (50 hours vs. 120 days),⁴⁴ and has a favorable adverse drug effect profile; however, patients taking any retinoid product should still be monitored closely.

Systemic retinoids are not as effective in psoriasis as are other systemic agents. Acitretin 50 mg/day completely cleared psoriatic plaques in 11% of patients and provided >75% clearance in 40% of patients treated for 8 to 12 weeks.²⁴ When the combination RePUVA or ReUVB phototherapy (about 50% of usual phototherapy dose) was used, however, the oral retinoids were highly effective, resulting in superior clinical efficacy. Acitretin 30 to 35 mg/day with UVB cleared psoriatic plaques in 55% of patients and provided >75% improvement in an additional 20% of patients treated for 6 to 8 weeks.^{24,45} Acitretin is indicated for patients who have received extensive radiation with PUVA, pretreatment for PUVA (1–3 weeks) to accelerate the response rate, for patients who fail to respond to UVB with anthralin or tar, or for patients who are not candidates for methotrexate. Most patients require maintenance or intermittent therapy to prevent relapses.⁴⁶

Numerous other adverse effects are associated with acitretin use, including hypervitaminosis A syndrome (i.e., dry skin, skin thinning and fragility, chapped lips, dry nasal mucosa, skin peeling, alopecia, and nail dystrophy), retinoid rash, extraspinal tendon and ligament calcification and bone changes in children, hyperlipidemia with elevated levels of serum triglycerides and cholesterol, and liver enzyme alteration and hepatitis.⁴⁷

Many patients find the adverse effects of the retinoids intolerable and discontinue treatment. Topical corticosteroids can reduce some of the cutaneous retinoid adverse effects. With

continued therapy, retinoids accumulate in adipose tissue and the liver and may be detectable in serum for >2 years after discontinuation of therapy. Appropriately, pregnancy should be avoided after treatment with acitretin for 3 years, because of its teratogenicity.⁴⁷

Immunosuppressive Agents

Methotrexate

Methotrexate (MTX), a folic acid analog, inhibits dihydrofolate reductase needed for synthesis of several amino acids, pyrimidines, purines, and subsequently DNA, RNA, and protein synthesis. MTX therapy greatly suppresses rapidly proliferating cells, such as those in psoriatic skin. Antipsoriatic mechanisms of MTX action include inhibition of keratinocyte differentiation and immunomodulation by destruction of lymphoid cells.^{22,24}

Unlike other cytotoxic drugs, MTX produces antipsoriatic effects at dosages that are much lower than those used in cancer chemotherapy. Methotrexate in 10- to 25-mg weekly doses cleared psoriatic plaques in 50% of patients treated for 3 to 4 weeks and resulted in >75% improvement in an additional 40% of patients. Prolonged remissions are expected with continued therapy.²⁴ MTX is relatively safe and well tolerated, but the long-term concerns for hepatotoxicity (fibrosis and cirrhosis) and the need for periodic liver biopsies can discourage many patients and physicians from using it.⁴⁸ Alcohol and methotrexate are a particularly potent hepatotoxic combination. Patients with psoriasis receiving MTX have a 2.5- to 5-fold higher incidence of advanced liver changes than patients with rheumatoid arthritis receiving comparable regimens.⁴⁹ Methotrexate hepatotoxicity may be related to both cumulative doses and constant blood levels. Daily administration has been replaced by weekly dosage schedules for this reason. Liver chemistry tests (i.e., serum alanine aminotransferase [ALT], serum aspartate aminotransferase [AST], serum albumin, bilirubin) can be within normal limits, even in the presence of methotrexate-induced liver disease.^{48,49} Therefore, consensus guidelines call for a liver biopsy in all patients with psoriasis at baseline and then at intervals of approximately 1- to 1.5-g cumulative MTX dose. Liver chemistry, including AST, ALT, bilirubin, and albumin, should be monitored every 3 months.⁵⁰ A high degree of vigilance is necessary in methotrexate-treated psoriatic patients.

Bone marrow depression, nausea, diarrhea, and stomatitis are other adverse effects associated with MTX. Pneumonitis can occur early in the course of treatment, particularly when MTX is given at higher dosages similar to those used in cancer chemotherapy regimens. Folic acid, 1 mg daily, may prevent some of these adverse events, but not hepatitis or pulmonary toxicities. Teratogenesis and miscarriage have occurred, and MTX may cause reversible oligospermia. A number of clinically significant drug interactions may enhance the toxicity of methotrexate. Drug interactions are most likely to be clinically relevant problems in patients with decreased renal function.⁵⁰

Relative contraindications to treatment with MTX include decreased renal function, significant abnormalities in liver function (i.e., fibrosis, cirrhosis, hepatitis), pregnancy or breastfeeding, anemia, leukopenia, thrombocytopenia, active peptic ulcer disease or infectious disease (tuberculosis, pyelonephritis), alcohol abuse, and patient unreliability.⁵⁰

Conception must be avoided during MTX therapy and for at least 3 months after cessation of MTX in men or one full ovulatory cycle in women.⁵⁰ Monthly monitoring of complete blood count with differential should be performed as well as renal function tests (specifically serum creatinine) every 3 months.

Hydroxyurea, thioguanine, and azothioprine are additional antineoplastic agents that have antipsoriatic activity. Their effects are not as potent as methotrexate, but they cause less hepatotoxicity with continuous use.^{51,52} Dose-dependent myelosuppression is a bigger concern with these agents compared with MTX.^{24,52}

Cyclosporine

The positive dermatologic effects of cyclosporine, an immunosuppressive agent, highlight the importance of immune alterations in the pathogenesis of psoriasis. The toxicity and the short duration of remissions induced by the immunosuppressant agents cyclosporine and tacrolimus limit their usefulness, however. Cyclosporine is generally reserved for patients with extensive psoriasis who have not responded adequately to topical agents, UVB, PUVA, and other systemic agents.

In psoriasis, cyclosporine most likely acts via its effect on lymphocytes. Cyclosporine inhibits calcineurin, which is necessary for production of interleukin (IL)-2. IL-2 amplifies helper T cells and cytotoxic lymphocytes. Decreased IL-2 production leads to a decline in activated CD4 and CD8 cells in the epidermis. Cyclosporine also inhibits tumor necrosis factor- α (TNF- α) and interferon- α_2 , both of which are involved in the chemotaxis of inflammatory cells; it inhibits release of cytokines and the growth of keratinocytes.⁵³

Cyclosporine is used at lower dosages for the treatment of psoriasis than for prevention of organ transplant rejection. In general, 3 to 5 mg/kg of cyclosporine is recommended for the treatment of psoriasis. Rapid improvement of plaque psoriasis is expected, with 30% of patients experiencing clearing of psoriatic plaques and 50% achieving >75% clearing of lesions within 10 weeks at 2 to 3 mg/kg/day. Increasing the dosage to 5 mg/kg/day cleared psoriatic lesions in 97% of those treated for 10 weeks.²⁴ Most people relapse 2 to 4 months after the discontinuation of cyclosporine therapy.²⁴ Cyclosporine showed comparable efficacy to methotrexate in patients with psoriasis with average doses of 4.5 mg/kg/day and 20.6 mg/wk, respectively.⁵⁴

Drug-induced renal impairment is common with cyclosporine use, but usually reversible. Hypertension, secondary to vasoconstrictive effects on the smooth muscle of renal blood vessels or drug-induced arteriolar hyalinosis, is dose dependent and insidious in onset. Blood pressure and serum concentrations of creatinine should be monitored closely in patients receiving cyclosporine.⁵⁵ Hypokalemia, hypomagnesemia, hyperuricemia, gingival hyperplasia, hypercholesterolemia, hypertriglyceridemia, adverse gastrointestinal effects, hypertrichosis, fatigue, myalgia, and arthralgia also have been attributed to cyclosporine therapy.⁵⁶ The risk of skin cancer, lymphomas, and solid tumors also can increase.^{57,58} Patients should be cautioned about excessive sun exposure and should not receive concurrent UVB or PUVA treatment during cyclosporine therapy.⁵⁶ Both systemic tacrolimus and mycophenolate mofetil are also reported to be highly effective and well tolerated in the treatment of severe recalcitrant psoriasis. More clinical experience with these agents is needed.^{59,60}

Immunomodulatory Drugs

Advances in biotechnology immunomodulatory therapy, specifically the use of anticytokines, are becoming important treatment alternatives for moderate to severe plaque and arthritis type psoriasis that is resistant to other systemic therapies. These agents are thought to work owing to the immune-mediated and elevated levels of TNF found in psoriasis. These biotechnology agents are expensive, estimated to cost \$13,000 to \$20,000/year.

Alefacept and Efalizumab

The agents, alefacept and efalizumab, act as immunosuppressants mainly by inhibiting activation of T lymphocytes in plaques. The mechanism is by binding to CD2 on memory effector T lymphocytes (alefacept) or binding to a subunit of leukocyte function antigen-1 (LFA-1). They are U.S. Food and Drug Administration (FDA) approved for the treatment of plaque psoriasis. Administered subcutaneously or intramuscularly on a weekly regimen, benefit includes approximately 25% obtaining PASI 75 after 12 weeks of alefacept and 30% obtaining PASI 75 after 12 weeks of efalizumab compared with placebo. Some patients have sustained clinical response even after cessation of therapy.^{61,62} Alefacept is also effective in combination with NB-UVB phototherapy.⁶³ Because of immunosuppression, these agents are contraindicated in pregnancy or in patients already immunocompromised because of malignancy, infection, or medications. Monitoring includes complete blood counts monthly for the first 9 months and liver function tests every 3 months for the first 3 months.⁶⁴

Infliximab, Etanercept, and Adalimumab

The TNF- α inhibitors, infliximab, etanercept, and adalimumab, are FDA approved for the treatment of both plaque and arthritic psoriasis, except for adalimumab, which is only approved for arthritic psoriasis. Their mechanism of action is through blocking the interaction of TNF- α with cell-surface TNF receptors. Dosing is either subcutaneous injection (etanercept and adalimumab) or intravenous infusion (infliximab) on a weekly or every other weekly schedule for initiation. These agents have been proved to produce rapid, well-tolerated, beneficial responses compared with placebo, with infliximab showing the greatest benefit. Benefit is seen anywhere from 2 weeks to 12 weeks with $\geq 80\%$ of patients obtaining PASI 75 after 10 weeks of infliximab, $\geq 50\%$ obtaining PASI 75 after 12 weeks of etanercept, and $\geq 50\%$ obtaining PASI 75 after 48 weeks of adalimumab treatment.⁶⁵⁻⁶⁷ Contraindications to therapy include active infection, including tuberculosis, and New York Heart Association (NYHA) III-IV heart failure. All three are a pregnancy category B. However, during pregnancy, they should be used only if clearly necessary.^{64,66} An association of increased rate of lymphoma has been seen in patients with psoriasis and treatment with TNF- α inhibitor.⁶⁸

ALTERNATIVE THERAPY

Balneology (bathing in the sea) and spa therapy are not accepted as mainline dermatologic treatment modalities for psoriasis; however, these approaches are used throughout the

world. The antipsoriatic properties of the Dead Sea area may be attributed to its unique climatic characteristics and natural resources. Mechanisms may involve mechanical, thermal, and chemical effects.⁶⁹ Favorable results of climatotherapy have been reported from specialized treatment centers along the Dead Sea, the German North Sea coast, and the Mediterranean Sea.⁶⁹ Climatotherapy is the combination of bathing in the sea (thalassotherapy or balneotherapy) and exposure to sunlight (heliotherapy). A major aspect of climatotherapy, in addition to daily sunbathing, is bathing in salt (sea) water. Relaxation, rest, and simple topical remedies (e.g., petrolatum) are also important. When rigorously studied, little difference is found in therapeutic outcomes of bathing in salt water or tap water, or the application of various topical ointments (e.g., 2% salicylic acid in white petrolatum, Eucerin, or mineral oil) when used in the current UVB phototherapy protocols.⁷⁰ Psychological factors (especially relaxation), however, may contribute substantially to the favorable results of natural heliobalneotheapy. If UV phototherapy is administered via artificial UV sources on an outpatient basis, the psychological effect will certainly be much less than when the patient receives this treatment far from home, when cares and social problems are left behind.⁷⁰

Traditional Chinese medicine provides an alternative method of therapy that emphasizes the importance of using many herbs that are combined in different formulations for each patient. This has become popular among some segments of the population. Both topical and systemic use of herbs has been administered to treat psoriasis, as well as a combination of herbal medications with UVA. For example, *Radix angelicae dahuricae*, combined with UVA, was not significantly different from 8-MOP and UVA.⁷¹

Amphiregulin is an autocrine growth factor that is overexpressed in psoriatic lesions. Keratinocytes produce protein-bound and free heparin sulfate, which function physiologically as an amphiregulin antagonist. Because glucosamine promotes keratinocyte synthesis of heparin sulfate, it may provide a therapeutic benefit in psoriasis. Clinical trials evaluating the efficacy of amphiregulin are unavailable.⁷²

MILD TO MODERATE (<20% BODY) PSORIASIS

Classic Presentation

1. M.M., a 35-year-old man, presents with worsening psoriasis. Approximately 1 year before presentation, he was given triamcinolone 0.025% cream to apply to several thick, well-defined erythematous plaques on his elbows and knees that were covered with silvery scales. He recently returned from a trip to the Dominican Republic, where he noted gradual worsening of redness and scaling, despite adherence to a twice-daily triamcinolone regimen. He is emotionally distraught because of this “flare-up,” which disrupted his vacation. On examination, besides erythematous, scale-covered plaques on his elbows and knees, several scattered, circumscribed, erythematous, scaly plaques are noted on the flexural surfaces of both arms and legs. A dense scale was evident on his scalp (forehead). These and other areas, demonstrating typical psoriatic involvement, including the gluteal fold and fingernails, now total approximately 20% of his body area. His medical history is noncontributory. His only medication besides the topical corticosteroid product is a recently completed course of chloro-

quine for malaria prophylaxis during recent travel. Characterize the classic psoriatic lesions demonstrated by M.M.

The classic plaques of psoriasis appear symmetrically on the extensor surfaces of the elbows and knees as distinctive, chronic, erythematous plaques covered with silvery scales, as typified by M.M.’s presentation. Patients can present a broad clinical spectrum, ranging from only scalp involvement to scattered plaques on the trunk and extremities to, in the most serious cases, a generalized erythroderma accompanied by a rheumatoid factor-negative symmetric arthritis. In addition, the finding of very small pits in the nail plates of the hands and feet (“oil spots”), the presence of gluteal “pinkings” (erythema and slight scaling of the intergluteal cleft), and the occurrence of lesions conforming to specific sites of skin trauma (Koebner phenomenon) help characterize psoriatic plaques from seboremic dermatitis and eczema. Most psoriatic lesions are asymptomatic, but pruritus is noted in 50% of patients.

2. What part does emotional support play in the total management of M.M.’s psoriasis?

Psoriasis is often more emotionally or psychologically disturbing than is recognized, and it may cause a reluctance of the patient to participate in sports, which may expose their skin. Although exposure to sunlight helps most patients with psoriasis, there is an unwillingness to sunbathe if the lesions can be seen. Furthermore, if the psoriatic lesions become pruritic and are scratched, there can be further deterioration at the site. Many patients alter their lifestyles or use nontraditional medicine (perhaps irrationally) in desperation.

Emotional support should begin with explanation of the psoriatic condition. M.M. needs to be reassured that many other people have the same affliction, that the disorder is not contagious or fatal, and that it can be controlled although, as yet, no cure exists. The National Psoriasis Foundation website (<http://www.psoriasis.org>) contains much useful information for patients afflicted with psoriasis.²⁰ Patients usually are comforted in the knowledge that a wide range of treatments are available. Clinical optimism and psychological encouragement and support are justified and make it easier for the patient to conscientiously apply sometimes awkward and messy topical treatments or to take toxic medications.

3. What are the potential causes of M.M.’s psoriatic exacerbation? List other factors that can precipitate or aggravate psoriasis.

A thorough medical history may reveal a cause for exacerbations of psoriatic lesions. Most patients report that hot weather, sunlight, and humidity help clear psoriasis, whereas cold weather has an adverse effect on its course. Anxiety or psychological stress is believed to contribute adversely. Viral or bacterial infections, especially streptococcal pharyngitis may precipitate the onset or flare-up of psoriasis. Trauma to the uninvolved skin can cause a lesion to appear at the site of injury (Koebner phenomenon). Cuts, burns, abrasions, injections, and other trauma can elicit this reaction. Any drug that causes a skin eruption to develop can exacerbate psoriasis via this response.

Drug-Induced Psoriasis

A number of drugs have been reported to exacerbate pre-existing psoriasis, induce psoriatic lesions on apparently

Table 40-3 Drugs Reported to Induce Psoriasis

| | |
|-----------------------------|---|
| Anesthetics | Procaine |
| Antimicrobials | Amoxicillin, ampicillin, imiquimod, penicillin, sulfonamides, vancomycin, terbinafine, tetracycline |
| Anti-inflammatory drugs | Corticosteroids (following withdrawal), NSAID (indomethacin, salicylates) |
| Antimalarials | Chloroquine, hydroxychloroquine |
| Cardiovascular drugs | Acetazolamide, amiodarone, angiotensin-converting enzyme inhibitors (captopril, enalapril), β -blockers (atenolol, propranolol, timolol [topical]), calcium channel blockers (dihydropyridines, diltiazem, verapamil), clonidine, digoxin, gemfibrozil, quinidine |
| H ₂ -antagonists | Cimetidine, ranitidine |
| Hormones | Oxandrolone, progesterone |
| Opioid analgesics | Morphine |
| Psychotropics | Lithium carbonate, valproic acid, fluoxetine |
| Miscellaneous | Potassium iodide, mercury |

NSAID, nonsteroidal anti-inflammatory drugs.

Adapted from Dika E et al. Drug-induced psoriasis: an evidence-based overview and the introduction of psoriatic drug eruption probability score. *Cutan Ocul Toxicol* 2006;25:1, with permission.

normal skin in patients with psoriasis, or precipitate psoriasis in persons with or without a family history of psoriasis (Table 40-3).⁷³ Antimalarial agents, such as chloroquine (taken by M.M.), may have an adverse effect on the course of psoriasis and can cause exfoliative erythroderma.⁷⁴ Hydroxychloroquine, however, has not shared this association (except for one recent case report) and usually induces a beneficial response in 75% of patients with psoriatic arthritis.⁷⁴ It is preferred over chloroquine in patients with psoriasis who need prophylactic treatment for malaria when both are effective against the particular plasmodium species in the area (see Chapter 74, Parasitic Infections).⁷⁴

Lithium also can precipitate psoriasis and contribute to resistance to treatment through its effects on cell kinetics (increase in circulating neutrophils, accelerated neutrophil turnover, increased epidermal cell proliferation).⁷³ Psoriasis is not a general contraindication, however, to lithium therapy. More intensive psoriasis treatment can be used if these reactions occur and lithium must be continued.⁷³

β -Blockers and some nonsteroidal anti-inflammatory drugs (NSAIDs) also can precipitate a psoriasiform state.⁷³ As both lithium and propranolol inhibit cyclic adenosine monophosphate (cAMP), cyclic nucleosides may play a role in the onset and clinical course of psoriasis. Chemotactic substances, including 12-HETE and leukotrienes, may accumulate in the epidermis of some patients taking indomethacin, thereby precipitating psoriasis. When compared with other NSAIDs, indomethacin may selectively inhibit cyclooxygenase more than lipoxygenase pathways of arachidonic acid metabolism. As a result, indomethacin may have a more significant adverse psoriatic effect than other NSAIDs that have been reported to ameliorate psoriasis.⁷³

Flare-ups of pustular psoriasis also can be precipitated by withdrawal from systemic corticosteroids or withdrawal from high-potency topical corticosteroids that are applied under oc-

clusion to large areas.²² Systemic corticosteroids are not routinely used to treat psoriasis because of this problem, and because fatalities have been associated with systemic corticosteroid use and withdrawal.

Chloroquine prophylaxis, a Caribbean sunburn, and triamcinolone tachyphylaxis probably all contributed to the exacerbation of M.M.'s psoriasis.^{22,74}

Topical Corticosteroids

4. Are additional potent topical corticosteroids appropriate for treatment of M.M.'s psoriasis? Outline the place of steroids in the pharmacotherapy of psoriasis.

For isolated hyperkeratotic plaques, potent topical corticosteroids are the most widely used initial treatment for psoriasis. They give fast relief, especially in reducing inflammation and in controlling itching. Patients find them convenient and acceptable, however, their relief is temporary because they become less effective with continued use (tachyphylaxis).²⁶ In addition, psoriasis is a relatively steroid-resistant disease that responds only to potent or superpotent agents.²⁶ Long-term use of potent agents also leads to predictable adverse effects (i.e., atrophy, telangiectasia, and striae). For these reasons, topical corticosteroids are best used in an adjunctive role unless used to treat mild disease for short periods. Continuous application of topical corticosteroids for >3 weeks, particularly after skin normalization, should be discouraged. An interval of several weeks between successive courses of therapy is recommended. High-potency corticosteroids produce better clinical results than low-potency corticosteroids, but the potential for adverse drug effects is greater. Potent topical steroids can suppress the HPA axis as a result of cutaneous absorption, especially when large areas of the body are involved.²⁶

A short course of a potent topical corticosteroid is appropriate for this “flare-up” of erythematous plaque psoriasis in M.M. With plastic occlusion (e.g., plastic food wrap on top of the steroid-treated area), topical corticosteroids help reduce inflammation, redness, and irritation before initiation of more appropriate chronic topical treatments, such as calcipotriene, coal tar, or anthralin with UVB, all of which are potentially irritating. Topical corticosteroids also may continue to be useful on the face and flexures, where the alternative topical agents are poorly tolerated. Potent fluorinated corticosteroid preparations should be used cautiously and only for short periods on the face and flexures, if at all. Scalp psoriasis can be treated with steroid preparations in gels, lotions, or aerosol sprays, but a coal tar shampoo lathered into the scalp for 5 to 10 minutes, then rinsed out, generally is more effective for scaling and pruritus.

The response to once- or twice-daily corticosteroid application is as effective or better than that observed with more frequent regimens (due to a steroid reservoir effect) and is much less expensive. Patients should apply steroids after a bath, at bedtime with occlusion, and possibly again during the day without occlusion. As the lesions subside, occlusion should be decreased or omitted, emollient use should increase, and steroid potency should decrease. After lesions have flattened, steroids can be continued intermittently (e.g., 1–2 weeks on, 1–2 weeks off; or on alternate days [e.g., days 1, 3, 5, 7]).

Alternative Topical Treatments

5. Assuming that a short course of a potent topical corticosteroid is effective in reducing the acute flare-up, what alternative topical therapeutic regimens are available for patients such as M.M. who have localized disease (involving <20% of the body)?

Four effective alternative topical therapies are available for patients with localized, mild to moderate psoriasis. Older, well-known agents are crude coal tar and anthralin, with more recent additions of calcipotriene and tazarotene. Although anthralin has irritating properties and both coal tar and anthralin generally stain clothing and skin, and are somewhat inconvenient to apply, their efficacy is well established, and may be an option to consider for initial management. Tachyphylaxis does not occur with chronic use of any of these alternative agents. Once corticosteroids have flattened acute psoriatic lesions and diminished erythema significantly, daily application of one of these alternative agents can be used until the lesions are totally clear.

Ointment vehicles are favored for patients with psoriasis because ointments help moisturize the plaques (in contrast to creams, which dry the plaques further). Moisturizers or emollients alone are often helpful for psoriasis.

Coal tar, although effective, is of low potency when compared with anthralin. Topical tar products (e.g., Tegrin, T/Gel), or 1% to 5% crude coal tar ointment (messy, but more effective), are commonly applied to lesions at night, even during the initial corticosteroid phase. Short-contact tar therapy, unlike anthralin, generally is ineffective. A number of tar shampoos (e.g., T/Gel, Zetar) and bath additives (Balnetar Therapeutic Tar Bath) are available. The combination of coal tar with salicylic acid, in concentrations from 2% to 6%, (e.g., Coco-Scalp) is useful in reducing scaling. Both tar (Goeckerman regimen) and anthralin (Ingram regimen) can be used in combination with UVB, with results superior to UVB monotherapy. These two regimens are reported to clear plaques in 75% of patients treated for 6 weeks for chronic plaque psoriasis (vs. 56% with UVB alone). The total number of treatments and the total UVB dose required for clearing are less in the combination groups.²⁴

Once the inflammation and erythema have lessened with corticosteroid use or when a twice-daily, high-potency corticosteroid regimen along with bedtime application of tar is ineffective, calcipotriene ointment applied twice daily or tazarotene gel applied once daily is effective in treating flare-ups and maintaining remission.

Calcipotriene may be the topical maintenance treatment of choice in patients with generalized mild to moderate psoriasis. The drug is usually effective, relatively easy to apply, odorless, and nonstaining (cream, ointment, or scalp solution). It is generally considered to be about as effective as moderate- to high-potency topical corticosteroid products. It has a slower onset of action than corticosteroids, and about 10% of patients develop irritation. This irritation precludes use on the face or in intertriginous areas. Sequential or simultaneous use of topical corticosteroids and vitamin D derivatives may provide synergy and reduce irritation. Tachyphylaxis does not occur. Patient use must be monitored to ensure that a 100-g/week limit is not exceeded; exceeding this limit results in negative effects on calcium and bone metabolism. When used concurrently with

topical salicylic acid, calcipotriene will be chemically inactivated.

Similar to calcipotriene, tazarotene works slowly and can be irritating. It is formulated as a gel, which many patients find more cosmetically appealing than an ointment. It is also effective in a once-daily regimen, which might help to improve compliance. The ointment should be used in combination with a high-potency topical corticosteroid to increase efficacy and to reduce irritation. Because of a potential for retinoids to be teratogenic, tazarotene should not be used in women who are pregnant or who are contemplating becoming pregnant.

Topical anthralin, generally reserved for resistant cases, clears lesions in some patients within 2 to 3 weeks. Although overnight regimens are available, short-contact therapy, which is more appealing, starts with 0.1% anthralin applied for 20 to 30 minutes and then washed off. Irritation should be checked for at least 48 hours. According to tolerance, potency can be increased (up to 1%) and the contact time shortened, or for resistant plaques, increased. This regimen is used daily for clearing, then once or twice weekly for maintenance therapy.

Phototherapy also is an option. If available locally, UV light can be used as an outpatient modality; it produces comparatively long-lasting remissions, is pleasant to use, and is relatively nontoxic. Different protocols require exposure daily or multiple times per week for varied lengths of time, depending on patient variables. The optimal effect of UVB on psoriasis is a dose that produces minimal erythema at 24 hours. The usual time to induce clearing of psoriasis is approximately 4 to 6 weeks.

In summary, the first step in the treatment of mild localized disease is to start with a high-potency corticosteroid ointment twice daily along with tar ointment at night. If this is ineffective, either calcipotriene ointment can be added twice daily, or tazarotene gel can be used once a day for 8 weeks. Once control is achieved, patients may use calcipotriene or tazarotene without topical corticosteroids; these products do not cause corticosteroid atrophy and they do not have the potential for systemic adverse effects associated with topical corticosteroids. Topical anthralin, with or without UVB, can be used for resistant cases.

SEVERE (>20% BODY) PSORIASIS

Psoralens and Ultraviolet A Light

6. G.L., a 35-year-old man with a several-year history of psoriasis (generally fairly localized) presents with diffuse, erythematous plaquelike lesions now extending over 80% of his body surface area. The areas have become inflamed, and application of his maintenance topical medication (anthralin) causes pain and irritation. He expresses frustration with the messiness of the current topical regimen. He has reinstated topical steroids, which helped the redness and itching but are too expensive to use long term. He is free of cardiovascular, renal, or hepatic disease and takes no systemic medications. He is self-employed as a business consultant. Which “systemic” therapy would be most appropriate for G.L. at this point?

Systemic therapies for psoriasis include PUVA; the systemic retinoid, acitretin; methotrexate; and cyclosporine. Newer biologics, including the TNF inhibitors infliximab,

etanercept, and adalimumab and the immunosuppressants alefacept and efalizumab, have also been used for skin lesions. These agents prevent the activation and reduce the number of memory T lymphocytes.

Although PUVA and methotrexate are used most often, cyclosporine and the newer immunomodulatory agents are being used increasingly as more experience is gained with them for treatment of severe psoriasis.^{22,68} The choice of agents depends on patient and drug characteristics. Because patients with psoriasis generally have the disease for the rest of their lives, the goal of treatment is not just safe and effective resolution of disease at a specific point in time, but also safe and effective maintenance therapy for long periods. Anecdotal experience suggests that long-term maintenance therapy for psoriasis can generally be achieved even with weaning or discontinuation of UVB, PUVA, and methotrexate. From a histologic perspective, these drugs have been shown to induce remittive cellular changes. In contrast, partial to full doses of acetretin or cyclosporine are necessary to maintain the therapeutic effects of these two drugs, because they induce suppressive rather than remittive histopathologic changes. For example, relapse will occur in most patients in a predictable manner 2 to 4 months after cyclosporine is discontinued.⁷⁵

Rotational Therapy

No form of therapy used in psoriasis today is without toxicity. Rotational therapy involves the use of alternating monotherapies, which allows the patient to experience extended intervals off a particular treatment. When used in long-term maintenance, rotational therapy limits adverse effects associated with either long-term use of one specific agent or the additive or synergistic interactions when multiple therapies are used concurrently. As discussed, the relative risk of skin cancer associated with PUVA increases after 160 treatments. If a patient in remission is rotated off PUVA to another treatment after 100 exposures, the skin has time to recuperate from the light therapy, and PUVA can eventually be reinstated presumably with lesser risk. Rotational therapy assumes that the patient can tolerate three to four alternative treatments with unrelated toxicity profiles.⁷⁵ By rotating each treatment after 12 to 18 months of cumulative use, the potential for long-term toxicity associated with any single treatment is minimized. With this theoretic rationale, cyclosporine could be used for a limit of possibly 3 to 6 months, thus inducing a remission. The patient could then be rotated to another treatment (e.g., methotrexate or PUVA) for maintenance.

Psoralens and UVA irradiation become noticeably effective in 80% to 90% of patients in 6 to 8 weeks.²⁴ The regimen is time-consuming because UV radiation treatments must be administered at least three times a week. Adverse long-term effects (premature photoaging, dyskaryotic or precancerous dermal changes, skin cancer [including melanoma], immunologic changes, and cataracts) can be minimized with appropriate patient selection and monitoring. More immediate adverse effects (e.g., itching, nausea, headache, lethargy, erythematous phototoxic reactions with overexposure, skin pain, and hyperpigmentation) are common. Male patients have increased risk of developing genital squamous-cell cancer (the groin should be shielded during therapy), wrinkling, lentigines (brown macule resembling a freckle), irregular pigmentation, and cataracts

(if protective eye wear is not used). Generally, 8-MOP is administered (0.6–0.8 mg/kg of body weight), followed by UVA (dose selected based on skin type, ease of sunburn, and inherent skin color) about 75 to 90 minutes later when psoralen blood levels peak. PUVA-induced erythema generally appears later than with UVB therapy, reaching a peak by 48 hours. Consequently, treatment should not be administered more frequently than every second day. The time to produce clearing of psoriatic plaques with PUVA takes longer than with UVB therapy (average 10 weeks compared with ≤ 3 weeks for UVB).⁴⁰ PUVA treatment must be decreased slowly once plaques have been cleared (frequency of treatment is reduced over 2–3 months) to prevent recurrence of psoriatic plaques. In contrast, UVB therapy can be ceased abruptly. Taking time off from work three times weekly for photochemotherapy can be disruptive to some patients' work or school schedules.

Psoralens and UVA should be avoided in patients with a history of skin cancer, in children, during pregnancy, in patients who are immunosuppressed, and in those who have light-colored skin that burns rather than tans. Absolute contraindications to treatment with PUVA include a history of photosensitivity diseases (i.e., lupus erythematosus, porphyria), idiosyncratic or allergic reactions to psoralens, arsenic intake, exposure to ionizing radiation, skin cancer (relative contraindication), pregnancy, and lactation. Techniques to minimize cumulative dosage of radiation and reduce the risk of long-term adverse effects of photochemotherapy include use of sunscreen, protective clothing, and sunglasses; and use of combination therapy (RePUVA). Other photosensitizing drugs (e.g., fluoroquinolones, phenothiazines, sulfonamides, sulfonyleureas, tetracyclines, thiazides) should be avoided in patients receiving PUVA.

In summary, PUVA is effective in 80% to 90% of patients, and G.L.'s severe, extensive, plaque psoriasis should be expected to respond accordingly. The systemic drugs (e.g., methotrexate, cyclosporine) may be preferred if G.L. had systemic symptoms (e.g., psoriatic arthritis). Although thrice-weekly PUVA treatments can be disruptive to work schedules, G.L. is self-employed and presumably has some flexibility in his working hours. Rotational therapy could be considered at a later time depending on G.L.'s response and tolerance of PUVA.

Psoriatic Arthritis

7. R.T. is a 38-year-old male aerospace machinist with psoriasis and increasing joint complaints. He describes a flare-up over the last month involving predominantly the middle finger of the right hand. He also has arthralgias of the shoulders, knees, and the rest of his hands. Concomitantly, his skin disease has once again become active, despite nightly betamethasone dipropionate (Diprolene) administration. He has a history of chronic depression and alcoholism, although he is currently sober and not being treated with antidepressant medications. Physical examination reveals a significant amount of tenderness of the right third metacarpophalangeal joint, without a great deal of active synovitis. He also has a moderate effusion of his right knee, but the rest of the joint examination is otherwise benign. Active psoriatic lesions are noted on his feet, knees, and elbows, and he has characteristic psoriatic nail changes. An erythrocyte sedimentation

rate is mildly elevated. Which systemic therapy would be most appropriate for both R.T.'s skin and joint complaints?

Psoriatic arthritis is a distinct form of inflammatory arthritis that is usually seronegative for rheumatoid factor. In various reports, 6% to 42% of patients with psoriasis experience arthritis, and the prevalence is increased among patients with severe cutaneous disease.⁷⁶ Nail involvement occurs in >80% of patients with psoriatic arthritis, as compared with 30% of patients with only cutaneous psoriasis.⁷⁶ Five clinical subsets of psoriatic arthritis have been identified: distal interphalangeal arthritis (classic, 5%–10%, often accompanied by nail changes), arthritis mutilans (5%, starts in early age, accompanied by osteolysis with severe deformities of fingers and toes), symmetric polyarthritis (rheumatoidlike, <25% incidence, milder course), asymmetric oligoarthritis (most prevalent, 70%, proximal and distal interphalangeal joints, metacarpophalangeal joints, knee and hip), and spondylitis (5%–40%, often asymptomatic).

The presentation of R.T. is representative of asymmetric oligoarthritis. Treatment of this form of psoriatic arthritis consists of an NSAID, local corticosteroid injections, and immunosuppressive agents, including TNF inhibitors. NSAIDs suppress symptoms, but do not induce remissions and can exacerbate cutaneous symptoms.⁷³ Systemic corticosteroids are avoided because they destabilize psoriasis (transformation to pustular forms), induce resistance to other effective therapies, and re-exacerbate the skin disease during withdrawal.^{26,77} PUVA and acitretin have negligible antiarthritic efficacy.

Methotrexate

Methotrexate has traditionally been the drug claimed to produce benefit in both the cutaneous and the articular manifestations of psoriatic arthritis.⁷⁶ Despite its widespread use in psoriatic arthritis, data on its effectiveness are sparse. In a meta-analysis of the published randomized trials of second-line drugs for psoriatic arthritis, only sulfasalazine (no activity against skin disease) and methotrexate were proved to be effective.⁷⁷ Cyclosporine was not considered because no controlled study met the inclusion criteria for this particular meta-analysis. Another study compared low-dose methotrexate (up to 15 mg/week) with cyclosporine. Both were found to be effective, but methotrexate was better tolerated (28% vs. 41% withdrawal rate).⁷⁸ After a sufficient trial of an NSAID, initiation of methotrexate therapy is a reasonable second-line agent for R.T.'s arthralgias in his shoulders, knees, and hands and his active skin disease.

Therapy with methotrexate usually is initiated with a 2.5-mg test dose. If no idiosyncratic reaction occurs, doses are gradually increased to a maintenance dose of 10 to 25 mg/week. Methotrexate is best given in a single weekly oral dose or in three 2.5- to 7.5-mg doses at 12-hour intervals during a 24-hour period (e.g., 8 AM, 8 PM, and again at 8 AM). Folic acid 1 mg daily should be prescribed concomitantly to protect against common adverse effects, such as stomatitis. Folate does not protect against hepatic or pulmonary toxicity, and monitoring for these complications is necessary during therapy. Regular blood counts, urinalysis, and renal and liver function tests should be evaluated. An aspiration needle biopsy of the liver should be performed at or near the initiation of treatment.⁵⁰

More practically, if no risk factors for hepatotoxicity exist, the liver biopsy can be postponed for 2 to 4 months until the drug's efficacy and lack of toxicity have been established for the patient and long-term therapy is about to be initiated. Delaying the biopsy for this period does not pose a risk because it is rare for life-threatening liver disease to develop with the first 1.0 to 1.5 g of methotrexate.^{49,50}

Hepatotoxicity, however, may not be apparent on routine laboratory evaluation. When liver chemistry tests are obtained, there should be at least a 1-week interval after the last methotrexate dose because liver chemistry values are often elevated 1 to 2 days after methotrexate therapy. If a significant abnormality in liver chemistry is noted, methotrexate therapy should be withheld for 1 to 2 weeks and the battery of liver chemistry tests repeated. Liver chemistry values should return to normal in 1 to 2 weeks. If significantly abnormal liver chemistry values persist for 2 to 3 months, a liver biopsy should be considered. Liver biopsy is recommended when the cumulative dosage level reaches 1.5 g and after each subsequent 1.5-g increase in the cumulative dose. Risk factors for hepatotoxicity include daily methotrexate administration, heavy alcohol intake, diabetes, obesity, intravenous drug abuse, previous exposure to hepatotoxic drugs, and pretreatment of liver dysfunction. Liver function abnormalities may improve after cessation of MTX therapy for 6 months.

8. During a follow-up visit to his family doctor several months later, R. T. had several somatic complaints that led to a diagnosis of recurrent depression. Subsequent history reveals that he also has resumed use of alcohol. He tends to drink four to five beers a night on weekends or when he is feeling low, although he does admit that his level of alcohol use is sometimes higher. His skin disease is relatively well controlled, but joint complaints have persisted. What additional options now exist for R. T.?

Methotrexate should be discontinued because the risks probably now exceed the benefits, particularly because rheumatic complaints have not been controlled and alcohol consumption has resumed. RT should be referred for physical and occupational therapy, encouraged to exercise, and (if needed) referred for orthotics. An NSAID can be given symptomatically. Sulfasalazine and hydroxychloroquine might be beneficial for joint symptoms alone, and cutaneous manifestations may be controlled with topical agents. Alternative second-line agents include immunomodulatory agents, cyclosporine, anti-cytokines, TNF inhibitors, infliximab, and etanercept.

Immunomodulatory Agents

Oral cyclosporine is given in divided daily doses in the range of 2.5 to 5 mg/kg, lower than for organ transplantation. Improvement is generally observed within 4 weeks. In one study, pain, number of painful and swollen joints, and duration of morning stiffness all decreased by 30% to 50%, along with 52% improvement in skin scores and serum C-reactive protein.⁷⁹ Another open-label study of 99 patients randomized to cyclosporine, sulfasalazine, or placebo reported beneficial effects from cyclosporine compared with placebo, but not sulfasalazine over 6 months, in terms of pain and tender, swollen joints counts.⁸⁰ Hypertension (13.9%), declining renal function (27.8%), and a variety of neurologic complaints (19.4%) were common in the cyclosporine-treated group. Skin disease

also abated more in the cyclosporine group. Close monitoring is required because these toxicities often limit the long-term use of cyclosporine.

Both methotrexate and cyclosporine reduce inflammatory joint activity in the short term, but it remains to be seen whether they actually modify the long-term disease process. It is clear that better therapies for psoriatic arthritis are necessary.

Tumor necrosis factor- α is a potent cytokine involved in inflammation and joint damage. Inhibition of this cytokine reduces direct actions as well as the action of other proinflammatory cytokines. Etanercept is a TNF- α receptor blocker. In a 3-month, double-blind, placebo-controlled study of 60 patients with psoriatic arthritis, an etanercept response was observed in 73% of patients (vs. 13% with placebo) and skin condition improved in 50% (vs. 0% with placebo).⁸¹ Infliximab is a human/mouse chimeric anti-TNF- α antibody. Patients given infliximab intravenously 10 mg/kg at 0, 2, and 6 weeks, reported 91% clinical response (vs. 18%, placebo) at 10 weeks

and 82% (vs. 18%, placebo) had at least 75% improvement in PASI. The median time to response was 4 weeks. No serious adverse events occurred during this short trial.⁶⁵ In two other 1-year, open-label trials, infliximab at 5 mg/kg every 4 to 8 weeks produced significant reduction in both psoriatic skin lesions and joint symptoms, which was maintained with continued 5 mg/kg doses every 14 weeks.^{82,83}

For patients such as R.T., whose disease cannot be treated successfully or safely with methotrexate, proceed with an anti-TNF- α agent. If available, etanercept (25–50 mg subcutaneously twice weekly) is preferred for convenience. Screening for tuberculosis before beginning therapy with anti-TNF agents is prudent, and those with evidence of prior tuberculous chest infection or with a positive skin test for tuberculosis should be offered prophylactic antitubercular therapy. If further studies confirm long-term effectiveness and safety of the anti-TNF treatments, these may become the preferred treatments for patients with moderate to severe disease.

PHOTOSENSITIVITY

Effects of Ultraviolet Radiation

Changing lifestyles have considerably increased human exposure to sunlight: more outdoor recreational activities, more emphasis on tanning, longer life spans, and seasonal population shifts to the Sunbelt. Public attitudes toward tanning and sun exposure have not changed although epidemiologic evidence clearly implicates sunlight as a causative factor in many skin diseases. Squamous cell carcinoma (SCC) and basal cell carcinoma (BCC), which together account for more than half of all malignancies in the United States, are linked closely to exposure to ultraviolet radiation (UVR).¹ Malignant melanoma, the incidence of which has increased >100% in the last decade,

most likely is linked to UVR exposure.² Sunburn, photoaging, immunologic changes in the skin, cataracts, photodermatoses, phototoxicity, and photoallergy are other commonly encountered photosensitivity reactions. The appropriate use of sunscreens or other photoprotective behaviors can help mitigate the incidence of the adverse effects of UVR.

Ultraviolet Radiation Spectrum

Ultraviolet radiation, the primary inducer of photosensitivity reactions in humans, is divided into ranges according to the effects of the four primary wavelengths: UVA1 (340–400 nm), UVA2 (320–340 nm), UVB (290–320 nm), and UVC (200 to 290 nm) (Fig. 41-1). UVA, with a wavelength of 320 to 400 nm, is closest in wavelength to visible light.³ Unlike UVB rays,

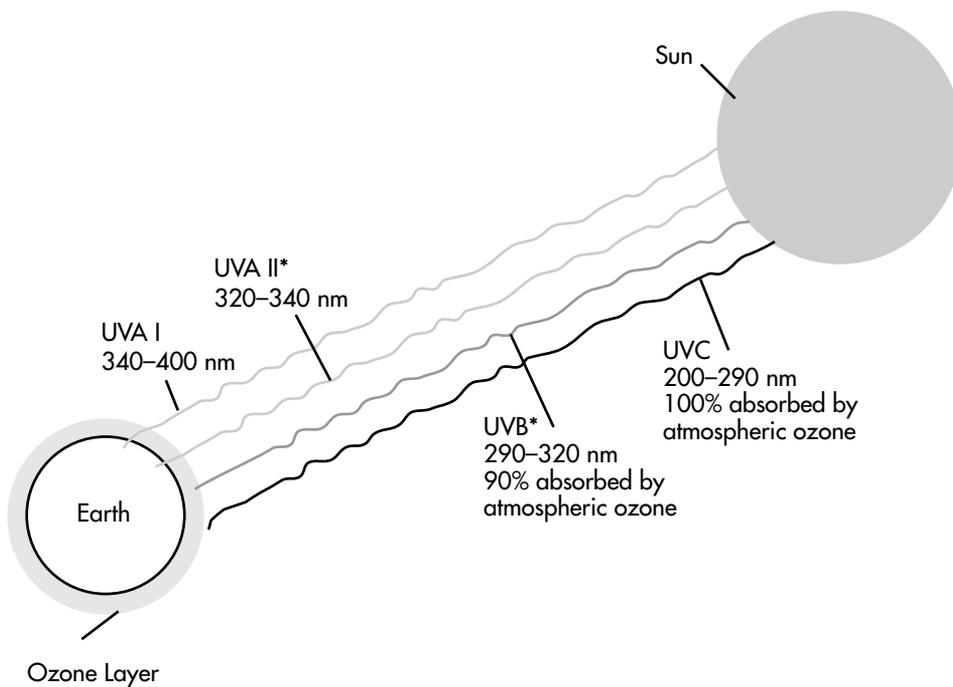

FIGURE 41-1 Ultraviolet radiation (UVR) spectrum. *Erythro-genic and melanogenic bands of UVR.

UVA radiation levels have small fluctuations during the day, and are present from sunrise to sunset every day, all year round, even in the winter and on cloudy days. It is considerably less likely than a comparable dose of UVB to cause a similar degree of erythema.^{4,5} Unlike UVB, however, UVA penetrates to the dermal layer and may cause harmful effects not caused by UVB.³ About 10 to 100 times more UVA reaches the earth's surface than UVB. Consequently, UVA may contribute up to 15% of the erythemal response at midday.^{3,6} UVB is the most erythemogenic and melanogenic of the three UVR bands.^{3,7} Up to 90% of UVB is blocked by the earth's stratospheric ozone layer, and it is absorbed completely by the epidermal layer of the skin.^{8,9} The only known beneficial effect of UVR in humans is exposure to small amounts of UVB, most commonly through sunlight, which converts 7-dehydrocholesterol to cholecalciferol (vitamin D₃). Vitamin D enhances calcium homeostasis and has direct and indirect effects on cells involved with bone remodeling. As a result, vitamin D can decrease the risk of rickets in childhood and fractures and osteomalacia in adults.¹⁰

The UVC wavelengths are absorbed completely by the earth's stratospheric ozone layer. Artificial sources of UVC have been used in the sterilization and preservation of food and in minimizing bacterial growth in laboratories and hospital operating rooms by germicidal lamps, which can cause erythema or cataracts if mishandled.^{3,7}

Environmental Effects on UVR

OZONE AND CHLOROFLUOROCARBONS

The amount of UVR that reaches the earth's surface is influenced by many factors. Concern has been focused on the implications of depletion of the ozone layer.^{6,9,11} In the decade after it was first detected in 1983, ozone levels above the Antarctic had fallen to 50% of normal.¹¹ In the early 1990s, worldwide estimates from the Environmental Protection Agency (EPA)

predicted an additional 40% depletion of ozone by the year 2075 if controls on chlorofluorocarbons (CFC) were not enacted. The EPA also concluded that for every 1% decrease in ozone, UVB radiation reaching the earth's surface would increase by 2% per year, possibly resulting in a 1% to 3% increase per year in nonmelanoma skin cancer.¹² In addition, UVB radiation can alter the immune system. As demonstrated by the worldwide meteorologic phenomena known as *El Nino* and *La Nina*, an impaired immune system can increase the incidence of certain cancers, including skin cancers.⁹ These losses in the ozone layer are thought to be caused by man-made pollutants (e.g., nitrous oxides from jet airliners in stratospheric aviation and CFC as propellants and refrigerants). The effect of the ban on the commercial use of CFC by many of the industrialized nations has begun to be seen, as evidenced by a slow decline in these ozone-depleting compounds. Because ozone depletion takes place approximately a decade after CFC expression in the stratosphere, this recovery may take place later than expected.¹³ Because UVA is only slightly filtered by the ozone layer, any decrease in the ozone layer would result in a disproportionate increase in UVB reaching the earth.

TIME OF DAY, CLOUD COVER, AND SURFACE REFLECTION

The time of day influences the amount of UVR reaching the earth's surface; 20% to 30% of the total daily UVR is received from 11 AM to 1 PM, with 75% between 9 AM and 3 PM. Cloud cover can decrease UV intensity by 10% to 80% and decreases infrared radiation to an even greater extent. This greater attenuation of infrared radiation by cloud cover can lead to an increased risk of UVR overexposure because less infrared radiation will be absorbed by the body and transformed into heat, resulting in less warning of overexposure to UVR. Reflection of UVR by substances (e.g., sand, water, snow) also may be important. For example, sand reflects about 25% of incident UVB radiation; therefore, sitting under an umbrella at the beach may

not offer adequate protection. In general, whenever someone's shadow is shorter than his or her height, care should be taken; the shorter the shadow, the more likely a sunburn will occur. Fresh snow can reflect 50% to 95% of incident sunlight. Water reflects approximately 5% of erythemal UVR, whereas 75% of the radiation is transmitted through 2 m of water, offering swimmers little protection.³ Seasonal changes, geographic latitude, and altitude also influence the amount of UVR reaching the earth's surface.

UV INDEX

The UV Index, offered by the EPA, the National Weather Service, and the Centers for Disease Control and Prevention, is a public health education service that is available in 58 U.S. cities.¹⁴ This Index, with a scale from 1 (minimal exposure) to 10 (very high exposure), forecasts the probable intensity of skin-damaging UVR expected to reach the surface during the noon hour when the sun is highest in the sky. Theoretically, the UV Index can range from 0 (e.g., during the night) to 15 or 16 (in the tropics at high elevations under clear skies). The higher the UV Index, the greater the dose received of skin- and eye-damaging UVR, and the less time it takes before skin damage occurs.

The amount of UVR exposure needed to damage an individual's skin is affected by the elevation of the sun in the sky, the amount of ozone in the stratosphere, and the amount of clouds present. Clear skies transmit 100% of UVR to the earth's surface, with scattered clouds 89%, broken clouds 73%, and overcast clouds 32%. The darker an individual's skin tone, the longer (or the more UVR) it takes to cause erythema.

Erythema, Sunburn, and Tanning

ERYTHEMA AND OXYGEN-FREE RADICALS

Excessive exposure of the epidermal and dermal layers of the skin to UVR can result in an inflammatory erythematous reaction. Excess UVA and UVB causes the release of vasodilatory mediators (e.g., histamine, prostaglandins, cytokines), resulting in increased blood flow, erythema, tissue exudates, swelling, increased sensation of warmth, and a characteristic sunburn.^{3,7} Severe UVR exposure, primarily UVB, can cause blister formation, desquamation, fever, chills, weakness, and shock. Erythema caused by UVB begins within 3 to 5 hours after exposure, is maximal after 12 to 24 hours, and usually resolves over the ensuing 3 days.⁷ In contrast, erythema caused by UVA begins immediately, plateaus between 6 and 12 hours, and remains for 24 hours. UVA-induced changes in the dermis are characterized by greater damage to the vasculature and dense cellular infiltrates that penetrate to deeper levels of the skin.⁷ The dermis also may be damaged when endogenous components of the skin absorb UVR energy and subsequently interact with oxygen to form tissue-damaging oxygen-free radicals.⁹

HISTOLOGY OF SUNBURN

The skin undergoes adaptive changes in response to UVR exposure. When keratinocytes in the epidermis are damaged and lose their typical organization, both the epidermis and the stratum corneum thicken⁶ and attempt to serve as a barrier to UVR, particularly to UVB. The skin's normal protective immune response, however, is altered with exposure to UVR. Metalloproteinase proteins, proteolytic enzymes that are induced with low-dose UVR exposure, cause degradation of col-

lagen and elastin in the dermal matrix.¹⁵ Langerhans' cells (i.e., antigen-presenting cells in the skin) are decreased in number and function even after small doses of UVB.¹⁵ These cells abnormally activate suppressor T-lymphocytes and lose their ability to activate normal effector pathways of the immune system.¹⁶

IMMEDIATE PIGMENT DARKENING AND DELAYED TANNING

Tanning is an adaptive mechanism of the skin to UVR. Tanning occurs by two different mechanisms: immediate pigment darkening (Meirowsky phenomenon) and delayed tanning. The primary cell involved in tanning is the melanocyte, which produces the radiation-absorbing protein, melanin.^{3,6} Immediate pigment darkening begins during the actual exposure to UVA and certain bands of visible light,^{3,6} and the oxidation of existing melanin in the epidermis transiently turns the skin grayish brown. The degree of immediate pigment darkening depends on the duration and intensity of exposure, the extent of previous tanning (or amount of pre-existing melanin), and the skin type of the individual.³ Immediate pigment darkening is not protective against UVB erythema.⁶

Delayed tanning occurs 48 to 72 hours after exposure to either UVA or UVB. It is most intense 7 to 10 days after UV exposure and can last for weeks to months.³ Delayed tanning is the result of increased production of melanin, an increase in the size and dendricity of the melanocyte, and the rate of transfer of melanosomes (particulate bodies of melanin) to keratinocytes.^{3,6} The keratinocyte, now pigmented with melanosomes, migrates to the epidermis, producing the characteristic suntan. Delayed tanning caused by UVA is less protective against sunburn than delayed tanning caused by UVB, as epidermal thickening is not induced by UVA.³

SKIN TYPES

1. L.M., a 26-year-old woman, and G.M., her 28-year-old husband, have planned a 2-week cruise to the Caribbean and are inquiring about sunscreens for the trip. L.M. has fair complexion with blonde hair and blue eyes, and G.M. has a light brown complexion with brown hair and brown eyes. On first exposure to the sun with about an hour of intense midday sunlight, L.M. almost always develops a deep red, painful sunburn, with only minimal subsequent tanning. She freckles easily when exposed to sunlight and remembers being severely sunburned on several occasions as a child. When G.M. is first exposed to the sun in the summer, he usually develops mild erythema, followed by moderate tanning. He cannot recall being severely sunburned as a child, but does recall becoming moderately tanned each summer as a child and adolescent. L.M. is employed as a receptionist for an accounting firm, and G.M. works outdoors for a construction company. Both spend considerable amounts of time participating in outdoor activities. What data in this history would influence your recommendation of a sunscreen product for G.M. and L.M.?

One of the most important pieces of information to include in the patient history is the patient's skin type.¹⁷ Patients can be classified into six sun-reactive skin types based on their response to initial sun exposure, skin color, tendency to sunburn, ability to tan, and personal history of sunburn (Table 41-1). This skin typing system has been used by the U.S. Food and Drug Administration (FDA) since 1978 in its guidelines for sunscreen agents. L.M.'s fair complexion, propensity to

Table 41-1 Suggested SPF for Various Skin Types

| Complexion | Skin Type | Skin Characteristics | Suggested Product SPF |
|------------|-----------|-------------------------------------|-----------------------|
| Very fair | I | Always burns easily; never tans | 20–30 |
| Fair | II | Always burns easily; tans minimally | 15–20 |
| Light | III | Burns moderately; tans gradually | 10–15 |
| Medium | IV | Burns minimally; always tans well | 8–10 |
| Dark | V | Rarely burns; tans profusely | 8 |
| Very dark | VI | Never burns; deeply pigmented | 8 |

SPF, sun protection factor.

sunburn, and minimal tanning classify her as skin type II. G.M.'s light brown complexion, minimal sunburn reaction, and moderate tanning classify him as skin type IV. Hair and eye colors also provide an indication to skin reactivity to sunlight. People who have blonde, red, or light brown hair or blue or green eyes tend to have greater skin reactivity to sunlight than people with darker-colored hair or eyes. A history of severe sunburn also can be associated with skin reactivity to sunlight, although self-reported patient histories of sunburn or tanning may not be consistently reliable, and personal interviews may be a more reliable indicator. L.M.'s propensity to freckle and her history of severe sunburns as a child may give an indication as to her skin's sun reactivity. Other important information to consider in the patient history includes a medication history, history of sun-reactive dermatoses, history of allergies (particularly contact hypersensitivities to cosmetics or other topical agents), and the intended activities during sunscreen use.

Photocarcinogenesis RISK FACTORS

2. What subjective and objective evidence do L.M. and G.M. exhibit that places them at risk for the long-term adverse effects of UVR? What are the risk factors for these long-term adverse effects of UVR?

The long-term effects of UVR include photocarcinogenesis and premature aging of the skin (photoaging). The associated risks for development of these long-term effects are directly related to the congenital pigmentation of an individual (which includes skin type and hair and eye color) and intensity, duration, and frequency of exposure to UVR. With a type II skin type, L.M. is at high risk for carcinogenesis and photoaging, whereas G.M., with skin type IV, may be at a lower risk. Excessive sun exposure, especially during childhood, increases the risk of nonmelanoma and melanoma skin cancers. During the first 18 years of life, the average child receives three times the dose of UVB of the average adult; consequently, most sun exposure occurs during childhood.^{18,19} A history of frequent sunburn or intermittent high-intensity exposures to UVR may be associated with the occurrence of malignant melanoma, whereas large cumulative doses of UVR over a lifetime may contribute to the incidence of nonmelanoma skin cancers. L.M.'s history of several severe sunburns as a child may more than double her risk of cutaneous malignant melanoma (CMM).^{18,19} Cumulative doses of UVR received unintentionally from working outdoors (as in G.M.) or from participating in outdoor recreational activities also can contribute significantly to the risk of photocarcinogenesis and photoaging.⁴ A large number of

moles, congenital moles >1.5 cm wide, and abnormal moles also appear to be a risk factor for malignant melanoma.²⁰ Risk for skin cancer is increased among first-degree relatives of patients with skin cancer,²¹ because frequent sunburns, suboptimal sunscreen use, and high rates of tanning bed use are common among the children with a personal or family history of skin cancer.²²

SQUAMOUS CELL AND BASAL CELL CARCINOMA

The association of skin cancer in humans to UVR exposure is based primarily on clinical and epidemiologic evidence. Nonmelanoma skin cancers, such as SCC and BCC, occur most commonly on areas that are maximally exposed to sunlight (e.g., the face, neck, arms, back of the forearms, and hands).³ The prevalence of nonmelanoma skin cancers is inversely related to geographic distance from the equator and to the melanin content of the skin, with SCC more strongly linked than BCC to UVR.^{3,20} Persons of skin types most sensitive to sunlight, as well as persons working outdoors, have higher incidences of nonmelanoma skin cancers.³ A family history of SCC and BCC increases the risk at least twofold, depending on the histology, number of lesions, and degree of invasiveness.²³ Albinism, a genetic disease characterized by partial or total absence of pigment in the skin, hair, and eyes, is associated with increased and premature development of skin cancers.³

CUTANEOUS MALIGNANT MELANOMA

The development of CMM also may be linked to UVR exposure, specifically exposures that induce sunburn. A history of five or more severe sunburns during adolescence more than doubles the risk of CMM.²⁰ CMM, as does nonmelanoma skin cancers, demonstrates an inverse relationship to geographic distance from the equator and melanin content of the skin.³ Unlike nonmelanoma skin cancers, however, CMM does not demonstrate a clear relationship to the cumulative dose of UVR, and it occurs on areas of the body exposed to the sun intermittently (e.g., on the back in men and the lower legs in women). In addition, it occurs most commonly in the middle-aged and individuals who work indoors, as well as those whose sun exposure is limited to weekends and vacations.²⁰ A family history of melanoma increases the risk of melanoma two- to eightfold.²⁴

MECHANISMS OF CARCINOGENESIS

Mechanisms of carcinogenesis may include damage to DNA and alterations in immunologic status. Epidermal and dermal DNA can absorb UVR, which can contribute to abnormal formation of pyrimidine dimers. Normally, these pyrimidine

dimers are excised and repaired; however, if left uncorrected, these DNA lesions can lead to interruption of transcription, with possible mutagenesis and malignancy.²⁵

TANNING BOOTHS

3. B.P., a 32-year-old woman, is preparing for a business trip to Cancun. She is seeking advice about the use of a tanning bed to stimulate melanin for the prevention of sunburn while on her trip. B.P. has skin type III and light brown hair and green eyes. She recently heard, however, that a tan produced by artificial sunlight may not protect against sunburn and may even cause skin cancer. What advice will you offer her? What precautions would you recommend if she decides to visit a tanning salon?

Most tanning beds, booths, or salons use an artificial light source that emits about 95% UVA with minimal (i.e., 1% to 5%) UVB.^{26,27} Although UVA is much less likely to produce photoaging and photocarcinogenic changes of the skin than UVB, high doses of UVA received during a tanning session, as well as increasing cumulative UVA doses over time, and increased exposure to sunlight in general, raise great concern over the long-term effects of UVA.²⁸ UVA causes many of the same effects on the skin as UVB, including immunologic, degenerative, and neoplastic changes, as well as damage to DNA and the formation of reactive oxygen species.²⁹ UVA also contributes to cataract formation and the activation of herpetic lesions.³⁰ In addition, UVA may augment the photocarcinogenic effect of UVB,² and growing evidence indicates the relationship between indoor tanning and melanoma.³¹ This issue is compounded by a recent study that suggests that excessive UV exposure may have a behavioral component.³²

With a skin type III, B.P. may be able gradually to achieve a moderate tan with minimal burning, thus providing some protection from UVR because of increased melanization of the skin. This UVA-induced tan, however, may not be as protective as a tan achieved under normal sunlight conditions because UVA does not thicken the stratum corneum.³³ An artificially produced tan plus subsequent sun exposure has not been found to provide any net reduction in long-term damage to the skin when compared with the same amount of tan obtained by sunbathing alone.³³ For these reasons, B.P. should not use the tanning booth to obtain a protective tan, and she should use appropriate photoprotective measures during her trip.

If B.P. decides to artificially tan despite your recommendation, she should undertake some precautions. Because she has skin type III, her UVR exposure should be limited to 30 to 50 half-hour sessions a year and she should keep a record of total joules of exposure that she has received over time.³ To minimize cataract development, B.P. always should wear protective eye wear that absorbs all UVA, UVB, and visible light up to 500 nm; simply closing her eyes or wearing regular sunglasses provides no protective effect against eye damage.

Photoaging

NORMAL AGING AND HISTOLOGY OF PHOTODAMAGED SKIN

Photoaging, or premature aging of the skin, involves skin changes that differ from those associated with normal chronological aging.^{34,35} Normal aging of the skin involves fine wrinkling of the skin, atrophy of the dermis, and a decrease in the amount of subcutaneous adipose tissue, all of which lead to a state of hypocellularity of the skin.³⁴ Photoaging involves

a chronic inflammatory state induced by long-term exposure to sunlight, leading to a hypermetabolic state of the skin.³³ Photodamaged skin is characterized histologically by an accumulation of excessive quantities of thickened, degenerated elastic connective tissue fibers (elastosis).³⁴ Type I collagen predominates in normal skin, but in photodamaged skin, type III collagen increases about fourfold and the mature matrix of type I collagen slightly decreases.²⁹ These degenerative changes in connective tissue may be caused by hyperactive fibroblasts or by enzymatic degradation via cellular infiltrates in inflamed skin.³ The elastic connective tissue then replaces the collagen in upper parts of the dermis.³³ The ground substance, composed of proteoglycans and glycosaminoglycans, also is increased considerably in photoaged skin.³ Capillaries in the dermis become dilated and tortuous, resulting in telangiectasias, ecchymosis, and purpura.³⁵ The epidermis thickens, and epidermal cells become hyperplastic and possibly neoplastic. Actinic keratosis, a premalignant lesion found mostly in the older population, is a risk factor for the development of BCC, because a low percentage of these lesions transform into SCC.^{35,36} Large cumulative doses of UVA, UVB, and possibly infrared radiation over the course of a lifetime are strongly implicated as the cause of these changes in photoaged skin.³

Photodamaged skin is characterized as being wrinkled, yellowed, and sagging. Mildly affected skin becomes irregularly pigmented, rough, and dry, with mild wrinkles. Moderately affected skin becomes deeply wrinkled, sagging, thickened, and leathery, with vascular lesions.³⁵ Largely irreversible, severely affected skin can become deeply furrowed, permanently (and irregularly) pigmented, and may manifest premalignant and malignant lesions.³⁵ Areas of the body most commonly affected are the face, back of the neck, back of the arms and hands, the V-line of the neck of women, and balding areas of the head of men.

TOPICAL RETINOIDS

4. P.B. is a 38-year-old woman who has enjoyed many outdoor activities over the years. She lives in a moderate climate, with hot, sunny summers and cold winters. She feels that she appears older than other women her age because of wrinkling and color changes of her skin. Her facial color is somewhat yellowish in appearance and the fine wrinkles at the corners of her eyes and mouth have become more obvious. She has noticed the formation of small brown spots mottling parts of her face, hands, and forearms. P.B. has skin type III; a clear complexion; and skin that is sensitive to soaps, heavy cosmetics, and perfumes. Would P.B. be an appropriate candidate for therapy with a topical retinoid product (e.g., tretinoin)?

Tretinoin (transretinoic acid) is available as a cream (0.025%, 0.05%, and 0.1%), gel (0.01%, 0.025%, 0.04% [in microspheres], 0.1% [in microspheres]), or liquid (0.05%). Tazarotene, another retinoic acid, is available as a 0.05% or 0.1% cream. Adapalene is available as a 0.1% cream, and a 0.1% or 0.3% gel. These agents are effective in partially reversing some of the clinical and histologic changes of photoaging by lessening fine wrinkles, mottled pigmentation, and the tactile roughness associated with photoaged skin.³⁷⁻⁴⁰ Adverse drug events include erythema, peeling, burning, and stinging. These adverse effects, as well as the clinical and histologic improvements, are thought to be dose dependent. Mild to

moderate reactions decrease gradually after the second week of therapy. Additional benefits of retinoid therapy include the formation of new dermal collagen and vessels, reduction in the number and melanization of freckles, resorption of degenerated connective tissue fibers, and treatment of premalignant and malignant skin lesions.⁴¹ In one of the initial trials, all subjects treated (100%) demonstrated global improvement in the signs of photoaging, with 53% showing moderate changes and the remainder having at least slight improvement. Of the clinical parameters assessed, the most impressive improvements were found with facial skin sallowness, with respondents developing a healthy, rosy glow.³⁸

Patient Selection

Topical retinoid therapy is most effective for patients 50 to 70 years of age with moderate to severe photoaging and for prophylactic use in patients undergoing the initial changes of photoaging.³⁷ Recently, P.B. has noticed some of the skin changes consistent with early photoaging and would be a good candidate for prophylactic therapy with topical tretinoin. Treatment may improve her sallowness, lessen the mottling on her face, forearms, and fine wrinkles at the corners of her eyes and mouth; as well as prevent worsening of the photoaging process that she is experiencing.

Patient Counseling

5. P.B.'s physician asks if tretinoin 0.05% cream would be a good starting dose. What do you recommend? What patient counseling should P.B. be given?

Because both the beneficial and adverse effects of topical retinoid therapy are dose dependent, the underlying goal is to provide the maximal benefit by using the highest concentration that causes minimal skin irritation. Considering P.B.'s skin sensitivity to soaps, cosmetics, and perfumes, her skin is likely to be irritated easily by tretinoin; therefore, it would be best to initiate therapy with the lowest strength (e.g., tretinoin 0.025% cream). An alternative retinoid is tazarotene 0.1% cream. These agents are usually applied every night at bedtime, but in some instances, they are applied initially on an every-other-night basis until the skin accommodates to the irritant effects. The likelihood of irritation depends on the type of vehicle, more than on the concentration of the agent.⁴¹ The cream formulation causes the least skin irritation and would be preferred for initiating therapy for P.B. Tretinoin is also available as a gel with an alcohol base, with a tendency to be drying and irritating. It is preferred for patients with persistent acne or for those with focal actinic lesions. The vehicle in the gel formulation of tretinoin can evaporate, resulting in the potentiation of its effects. Younger patients often prefer the gel because it leaves no residue and is compatible with most cosmetics. The solution and gel may be better tolerated in older patients with oily, thick, pigmented skin.

Before applying the cream to her face at bedtime, P.B. should wash her face gently, using her fingertips and mild soap, then patting her skin dry with a towel. If gentle washing with her fingers does not remove the dry, peeling skin, a washcloth can be used gently on the face. The treated stratum corneum is fragile, and erosions could occur if P.B. is not careful when washing. After waiting about 15 minutes, she should apply a pea-sized amount of cream to her forehead and spread the cream evenly over her entire face. Care should be exercised

while applying the cream to the areas adjacent to the eyes and mouth because tretinoin can cause irritation and burning of mucous membranes.

Skin irritation can be expected to start in the first 3 to 5 days of therapy and, hopefully, will subside in 1 to 3 months. If P.B. experiences excessive irritation, she can reinstate the regimen on a slower timeline by applying the cream on an every-other-night or every-third-night basis for the first 2 weeks to reduce skin irritation, or she can also apply a topical corticosteroid product such as hydrocortisone 1% cream. As she begins to tolerate the therapy, her frequency of applications and strength of cream should be titrated to cause mild scaling with only occasional mild erythema. A thicker film of cream can be applied to photodamaged areas. After 9 to 12 months of therapy, she can begin maintenance therapy, which consists of application two or three nights a week indefinitely.

Because these agents can dry the skin, P.B. should be counseled to use moisturizers during the day to help decrease the dryness and irritation of the skin. Nighttime application of moisturizers should be discouraged when topical tretinoin is being used because the moisturizers can cause a pH incompatibility with the cream and possibly dilute the concentration of tretinoin. With a thinning of the stratum corneum, P.B.'s skin may be more susceptible to the effects of UVR. For this reason, as well as to prevent further actinic damage, P.B. should begin prophylactic daytime application of a sunscreen. Considering her skin type (III) and early photoaging changes, a sunscreen with a sun protective factor (SPF) of at least 30 would be appropriate. P.B. should be counseled not to become discouraged by any apparent lack of response; her skin damage is mild, her response to therapy will be gradual, and part of the goal of therapy is to prevent further damage. Her wrinkles may actually appear to worsen early in therapy owing to an initial buildup of the stratum corneum. P.B. should avoid facial saunas and irritating soaps and cosmetics.

Phototoxicity and Photoallergy

PATIENT HISTORY

6. D.L., a 16-year-old, blond-haired, blue-eyed teenager with skin type II, presents with a severe sunburn. He states that he started a new summer job 2 days ago with typical sun exposure. He is surprised at the severity of this sunburn, which is worse than normal for the same amount of sun exposure. What nonprescription remedies might you recommend for D.L. at this time?

Treatment recommendations for D.L.'s sunburn are inappropriate without first obtaining additional data (e.g., a history and brief visual examination of the condition). Information that may be important in the history of the condition include the temporal relationship between sun exposure and onset of symptoms; the nature and duration of symptoms; recent ingestion or topical application of medications; possible exposure to photosensitizers, chemical irritants, or plants that can cause allergic contact dermatitis (e.g., poison ivy); and the potential for arthropod bites. Information that may be important from the physical examination includes the distribution and morphology of the reaction, as well as areas of the body spared of the reaction.

A drug-induced photosensitivity reaction most commonly appears as a sunburn of greater severity than would normally be expected or as a rash in areas exposed to the sun or tanning apparatus. With an increased emphasis on health that includes

exercise and physical activity outdoors, the incidence of these reactions is common, with a greater frequency during both the summer and winter. Further, with an increase in the use of complementary or alternative medications, many people are unaware that some of these products (e.g., St. John's Wort) can also cause photosensitivity reactions. Chemicals with photosensitization potential are found in medications, cosmetics, shampoos, moisturizing lotions, hair dyes or tints, soaps, and other topically applied medications and agents.

Drug-induced photosensitivity reactions can be subdivided into phototoxic and photoallergic reactions. The same medication or agent may produce both phototoxic and photoallergic reactions, and it may at times be difficult to differentiate clinically between the two types of reactions.

PHOTOSENSITIZERS AND SYMPTOMS OF PHOTOTOXICITY

7. On further questioning, you discover that D.L. first experienced painful erythema of the extensor surface of his hands and forearms, the anterior aspect of his neck, and parts of his face within hours of starting his new job at an outdoor garden and greenhouse. Besides painful erythema, the symptoms also included an immediate prickling and burning sensation. The symptoms continued to worsen until the following morning, about 24 hours after initial exposure to the sun. D.L. does not recall orally ingesting or topically applying any medication or other preparation to his skin, nor does he recall exposure to any chemical irritants, or poison ivy or oak. The morphology of the skin lesions is that of an exaggerated sunburn. The skin lesions are patchy in distribution with greater density on his forearms and hands than on his neck and face. The posterior aspect of his neck and covered areas of his body were spared completely. What are some possible causes of his exaggerated sunburn reaction?

The most likely explanation for D.L.'s exaggerated sunburn reaction is *phototoxicity*, secondary to contact with psoralen-like chemicals from the plants at his job at the outdoor garden and greenhouse. Phototoxicity is an immediate or delayed inflammatory reaction that occurs when a compound with photosensitizing ability absorbs a sufficient concentration of UVR in or on the skin, and when the skin is exposed simultaneously to a specific wavelength of light.⁴² This spectrum of offending UVR occurs from the UVB to the UVA range. These compounds include many drugs (see Table 38-8 in Chapter 38, Dermatotherapy and Drug Induced Skin Disorders) and naturally occurring psoralen-like (furocoumarin) compounds that are found in many plants (e.g., limes, parsley, celery, figs).⁴³ When the photosensitizing compound is deposited on the skin surface, the photosensitizer absorbs the radiologic energy and transfers the energy to surrounding molecules, which then become destructive to the surrounding tissue.^{3,42}

The most common type of drug-induced photosensitivity reaction is phototoxicity, in which the offending agent is thought to act as a chromophore, absorbing UVR. When the chromophore reaches a sufficient concentration in or on the skin and when the skin is exposed to the appropriate wavelength of UVR, energy is emitted, which damages the adjacent tissue to cause a phototoxic reaction. The wavelength of radiation necessary to produce such a reaction depends on the absorption spectrum of the offending agent.

Phototoxic photosensitivity reactions are dose dependent and occur in almost any person who takes or applies an adequate amount of the offending agent. The dose necessary to

produce such a reaction varies from person to person and depends on such factors as complexion, hair and eye color, usual ability to tan, and type and amount of UVR exposure. Phototoxic photosensitivity reactions are not immunologically mediated or true allergic reactions; they can occur on first exposure to the agent, and generally show no cross-sensitivity to chemically related agents.

A phototoxic reaction usually has a rapid onset, often within several hours after UVR exposure and presents as an exaggerated or intensified sunburn with erythema, pain, and prickling or burning. Blistering, desquamation, and hyperpigmentation can occur in severe cases.⁴² Symptoms generally peak 24 to 48 hours after the initial exposure and are usually limited to the areas of UVR-exposed skin. Because phototoxicity reactions do not involve the immune system, prior exposure to the photosensitizer is unnecessary for this reaction to occur.

Presumably, D.L. came into contact with psoralen-containing plants and simultaneous exposure to sunlight. With an unusual distribution of lesions on his hands, forearms, neck, and face, the lack of lesions on areas not contacted by the plants or sunlight, the temporal relationship between the exposure and onset of symptoms place phototoxicity higher in the differential diagnosis.

PHOTOSENSITIZERS AND SYMPTOMS OF PHOTOALLERGY

Photoallergy is another possible cause of D.L.'s symptoms. Although much less common than phototoxicity, photoallergy requires prior or prolonged exposure to the photosensitizing compound. Photoallergy results from a similar mechanism to phototoxicity, except that the immune system is involved. Most commonly, it is caused by polycyclic photosensitizers that react with UVA to form antigenic macromolecules, evoking a delayed hypersensitivity response. Clinically, photoallergy differs from phototoxicity in that it produces an intensely pruritic, eczematous form of dermatitis.⁴² The rash is preceded by pruritus and may subside within an hour. In 5% to 10% of cases, persistent hypersensitivity to light occurs, even after the offending chemical has been eliminated.⁴²

In photoallergic photosensitivity reactions, the suspected medication or chemical agent is altered in the presence of UVR to become antigenic or to become a hapten (i.e., an incomplete antigen), which can combine with a tissue antigen. These antigen-antibody or immune-mediated processes differentiate photoallergic from phototoxic reactions. Photoallergic reactions do not occur on first exposure to the medication, but as with other allergic reactions, they require prior or prolonged exposure (sensitization period) to the offending agent.⁴² Once sensitization has occurred, subsequent exposure to even small amounts of the offending product will produce a photoallergic reaction.

Photoallergic reactions are not dose related, and eruptions can also be caused by chemically related agents owing to a cross-sensitivity or cross-allergenicity. As a type of delayed hypersensitivity reaction, time is required to develop an immune response and the onset of a photoallergic reaction is often delayed for 1 to 3 days. These reactions can present as macular, bullous, or purpuric lesions. Acute urticaria can occur within minutes after UVR exposure. Recovery is slower than from a phototoxic reaction, and it can persist after the offending product has been removed. These reactions may present with erythema and possible edema secondary to the inflammation, but are most commonly found to be eczematous, characterized

by erythema; pruritus (possible severe); and papules, vesicles, or both, with weeping, oozing, and crusting. Scaling, lichenification, and pigmentation may occur later.

In a small percentage of cases, hypersensitivity to UVR can persist after the suspected agent is discontinued. Photoallergic reactions primarily occur on the skin at sites that are exposed to UVR, but may extend to nonexposed areas. These reactions are more common in adults, usually caused by topical medications or chemicals, but also can be seen with the use of systemic medications.

D.L. is unlikely to have a photoallergic reaction because of the lack of a delayed temporal relationship between the onset of symptoms and combined exposure to plant furocoumarins and sunlight. Unlike phototoxicity reactions, photoallergic reactions can spread to areas that have not been exposed to sunlight; however, D.L.'s lesions were limited to areas of skin exposed to sunlight.

MANAGEMENT

8. What recommendations should you give D.L. for management of his photosensitivity?

General recommendations for the management of phototoxicity and photoallergy reactions are focused on the removal of exposure to the potential photosensitizer and reduced exposure to the sun. Patients should be counseled not to take any medications, orally or topically, without first consulting with their health care provider to minimize exposure to other photosensitizers. D.L. should try wearing long-sleeved shirts, pants, and gloves when working to limit exposure to plant photosensitizers. He also may try applying a broad-spectrum sunscreen to protect his skin from UVB and UVA radiation. If these measures do not prevent further photosensitivity reactions, D.L. should consider a different type of employment. His presenting symptoms should be managed in a manner similar to that for an exaggerated sunburn.

Photoprotection

Broad-Spectrum Products

Sunscreens are used to prevent sunburn and reduce the incidence of premature aging and carcinogenesis.^{36,44,45} The original formulations were developed to protect against the effects of UVB radiation because the potential adverse effects of UVA were not yet recognized. Because UVA plays a significant role in many of the adverse effects associated with UVR exposure, broad-spectrum sunscreen products with absorption spectra in the UVA range have become commercially available, in combination with UVB absorbers. These broad-spectrum products provide additional benefit for patients with photosensitivity reactions caused by wavelengths not covered by single-ingredient sunscreens.

Numerous public health information programs have targeted sun protection for younger children. These programs are used to counter the fact that starting in the years of early adolescence, use of sun protective measures continually decrease, with the nadir by the high school to college-level years of early adulthood.⁴⁶ Sunscreens should be considered as only one component of an overall program to reduce UV exposure and protect against long-term photodamage.⁴⁷⁻⁴⁹ The American Cancer Society has adopted the “*Slip, Slop, Slap*” slogan

from an Australian public health skin cancer prevention campaign, and recommends that anyone going out into the sun should slip on a shirt, slop on sunscreen, and slap on a hat. Since the Australian campaign was introduced in 1981, the overall incidence of skin cancer in Australia has decreased. This program was extended in later years to encourage the use of sunglasses (i.e., slip on a shirt, slop on the sunscreen, slap on a hat, and wrap on some sun glasses: “*Slip, Slop, Slap, Wrap*”).

For health care providers and their patients, the tenets of this program can be recalled with the acronym C-H-E-S-S:

- C* Clothing that is sun protective (i.e., tightly woven and in dark colors)
- H* Hats with wide brims all around
- E* Eyeglasses that block both UVA and UVB light
- S* Sunscreen with an SPF of at least 15 that is applied appropriately
- S* Shade, especially between 10 AM and 4 PM

Table 41-2 lists the available sunscreen chemicals that have been judged to be both safe and effective.

Table 41-2 Sunscreens and UVR Absorbance

| Sunscreen | Absorbance |
|---|------------|
| Anthranilates | |
| Meradimate (menthyl anthranilate) | 260–380 |
| Benzophenones | |
| Dioxybenzone | 250–390 |
| Oxybenzone (benzophenone-3) | 270–350 |
| Sulisobenzone (Eusolex 4360) | 260–375 |
| Cinnamates | |
| Cinoxate (diethanolamine p-methoxycinnamate) | 280–310 |
| Octocrylene | 250–360 |
| Octinoxate (octyl methoxycinnamate, Parsol MCX) | 290–320 |
| Dibenzoylmethanes | |
| Avobenzene (butyl methoxydibenzoylmethane, Parsol 1789) | 320–400 |
| Aminobenzoic Acid and Ester Derivatives | |
| Lisadimate (Glyceryl PABA) | 264–315 |
| Para-aminobenzoic acid (PABA) | 260–313 |
| Padimate O (octyl dimethyl PABA) | 290–315 |
| Roxadimate | 280–330 |
| Salicylates | |
| Homosalate | 295–315 |
| Octisalate (octyl salicylate) | 280–320 |
| Triethanolamine salicylate | 260–320 |
| Trolamine salicylate | 260–320 |
| Camphor Derivatives | |
| Benzoate-4 methylbenzylidene camphor | 290–300 |
| Ecamsule (terephthalylidene dicamphor sulfonic acid; Mexoryl) | 290–400 |
| Others | |
| Ensulizole (phenylbenzimidazole sulfonic acid) | 290–340 |
| Physical Sunscreens | |
| Red petrolatum | 290–365 |
| Titanium dioxide | 290–700 |
| Zinc oxide | 290–700 |

UVR, ultraviolet radiation.

Evaluation of Sunscreens

SUN PROTECTION FACTOR

The effectiveness of a sunscreen formulation is based on its SPF and its substantivity.⁵⁰ SPF is a measure of how much solar energy (UV radiation) is required to produce sunburn on protected skin (i.e., in the presence of sunscreen) relative to the amount of solar energy required to produce sunburn on unprotected skin. As the SPF value increases, sunburn protection increases. It is defined as the ratio of the minimal dose of UVR required to produce an erythral response in sunscreen-protected skin compared with unprotected skin.³⁶ SPF are based on tests of volunteers with skin types I through III, using either natural sunlight or a solar simulator that generates both UVB and UVA.^{36,50} Because the SPF can be influenced by the composition, chemical properties, emollient properties, and pH of the vehicle, sunscreen formulations must be evaluated on an individual basis.⁵⁰ SPF also is influenced by the amount applied to the skin, the time of initial application before UVR exposure, the frequency of application, and environmental factors, such as photodegradation during UVR exposure; therefore, the SPF achieved during actual use can be significantly less than indicated on the label.^{51–55} Consumers have been shown to routinely apply only one fourth to one-half thickness of the layer of sunscreen used to determine the SPF prior to marketing.⁵⁶

A popular misconception is that SPF relates to time of solar exposure. For example, many people believe that if they normally get sunburn in 1 hour, then an SPF 15 sunscreen allows them to stay in the sun for 15 hours (i.e., 15 times longer) without getting sunburn. This is untrue because SPF is not directly related to time of solar exposure, but to the amount of solar exposure. Although solar energy amount is related to solar exposure time, other factors have an impact on the amount of solar energy. For example, the intensity of the solar energy has an impact on the amount. Generally, it takes less time to be exposed to the same amount of solar energy at midday compared with early morning or late evening because the sun is more intense at midday relative to the other times. The following exposures may result in the same amount of solar energy: 1 hour at 9:00 AM versus 15 minutes at 1:00 PM. Solar intensity is also related to geographic location, with greater solar intensity occurring at lower latitudes. Also, as clouds absorb solar energy, solar intensity is generally greater on clear days than on cloudy days.

In 1978, the FDA Over-the-Counter (OTC) Review Panel on sunscreens reclassified sunscreens from cosmetics to drugs intended to protect the structure and function of the human integument against actinic damage. In 1999, the FDA finalized its regulations for OTC sunscreens. Manufacturers of cosmetic tanning preparations that do not contain a sunscreen were required to include a warning statement (see the following discussion) on their products. These regulations list the active ingredients that can be used in sunscreens, labeling and testing requirements, and also provide for uniform, streamlined labeling for all OTC products intended for use as sunscreens to assist consumers in making decisions on sun protection. These regulations include the following:

- Similar labeling requirements for all OTC products intended for use as sunscreens (including sunscreen–cosmetic combinations, such as makeup products carrying sun protec-

tion claims) to provide good, useful information to consumers.

- Uniform, streamlined labeling for all sunscreens. Accommodations in labeling must be made for sunscreens that are labeled for use only on specific small areas of the face (e.g., lips, nose, ears, or around eyes).
- A list of 16 allowed sunscreen active ingredients, with zinc oxide and avobenzone being the two most recent additions.
- Both required and optional label claims, warnings, and directions.
- Required SPF testing for all agents.
- A new SPF category of “30” plus (or “30%”) for SPF values above 30.
- Simplification of the previously proposed five product sun protection categories down to three:
 - *Minimum* (corresponding to the current SPF of 2 to 12)
 - *Moderate* (corresponding to an SPF of 12 to 30)
 - *High* (corresponding to an SPF of 30 or greater)
- A “Sun Alert” statement that reflects the important role that sunscreens play in a total program to reduce the harmful effects of the sun (i.e., “Sun alert: Limiting sun exposure, wearing protective clothing, and using sunscreens may reduce the risks of skin aging, skin cancer, and other harmful effects of the sun”).
- Cessation of unsupported, absolute, or misleading and confusing terms such as *sun block*, *waterproof*, *all-day protection*, *deep tanning*, and *visible and/or infrared light protection*.

In addition to the aforementioned changes, cosmetic regulations require tanning preparations that do not contain a sunscreen ingredient to display the following warning: “Warning—this product does not contain a sunscreen and does not protect against sunburn. Repeated exposure of unprotected skin while tanning may increase the risk of skin aging, skin cancer, and other harmful effects to the skin even if you do not burn.”

In 2006, the FDA introduced final regulations on sunscreen labeling. The term *sunscreen* was redefined¹²: “A product with active ingredients to affect the structure or function of the body by absorbing, reflecting, or scattering the harmful, burning rays of the sun, thereby altering the normal physiological response to solar radiation”. These ingredients also help to prevent diseases such as sunburn and may reduce the chance of premature skin aging, skin cancer, and other harmful effects due to the sun when used in conjunction with limiting sun exposure and wearing protective clothing. Sunscreen ingredients may also be used in some products for nontherapeutic, nonphysiologic uses (e.g., as a color additive or to protect the color of the product). Further, for sunscreen products that retain SPF after 40 minutes of activity in the water, sweating, or perspiring, the term *water resistant* is used. For products that retain SPF activity after 80 minutes, the term *very water resistant* is allowed. Further, the following phases may be used for sunscreen products: *reapply as needed or after towel drying, swimming, or sweating* (or *perspiring*).

SUBSTANTIVITY

Substantivity is a measure of the sunscreen formulation’s effectiveness. The substantivity of a sunscreen formulation is its ability to be adsorbed by, or adhere to, the skin while swimming

Table 41-3 Examples of Commercially Available Sunscreen Products

| Name (Active Ingredients) | Formulation | SPF |
|---|------------------------|------------------|
| Anthelios SX (avobenzone, ecamsule, octocrylene) | Cream | 15 |
| Banana Boat Baby Sunblock (octinoxate, octisalate, homosalate, titanium dioxide) | Lotion | 50 |
| Banana Boat Sport Sun Gear Sunblock (avobenzone, homosalate, octocrylene, oxybenzone, octisalate) | Lotion | 50 |
| Banana Boat Quik Blok Kids (octinoxate, homosalate, octisalate, oxybenzone, avobenzone) | Lotion | 25 ⁺ |
| Banana Boat Sport Sunblock (octinoxate, octisalate, oxybenzone, octocrylene) | Lotion | 50 |
| Blistex Ultra Protection (homosalate, meradimate, octinoxate, octisalate, oxybenzone) | Lip balm | 30 |
| Blue Lizard Australian Suncream (octinoxate, octocrylene, oxybenzone, zinc oxide) | Lotion | 30 ⁺ |
| Bullfrog Superblock (octocrylene, octinoxate, oxybenzone) | Lotion | 45 |
| Bullfrog For Kids (octocrylene, octinoxate, oxybenzone, octisalate, titanium dioxide, meradimate) | Gel | 36 |
| Bullfrog Extreme Sport (octocrylene, octinoxate, octisalate, oxybenzone) | Lotion | 30 |
| Bullfrog Sunblock (octinoxate, oxybenzone, octisalate, octocrylene) | Gel | 36 |
| ChapStick (padimate O) | Lip balm | 15 |
| ChapStick Ultra (octocrylene, octinoxate, oxybenzone, octisalate) | Lip balm | 30 |
| ChapStick Sunblock (oxybenzone, padimate O) | Lip balm, or ointment | 15 |
| Coppertone BUG & SUN for Adults (with DEET; octocrylene, octinoxate, oxybenzone) | Lotion | 30 |
| Coppertone KIDS Quick Cover Sunblock (avobenzone, octocrylene, octisalate, oxybenzone, homosalate) | Lotion/Spray | 50 |
| Coppertone Sport (octinoxate, oxybenzone, octisalate) | Lotion | 15/30/50 |
| Coppertone Ultra Sheer Faces (avobenzone, homosalate, octisalate, octocrylene, oxybenzone) | Lotion | 30 |
| DuraScreen (octinoxate, octisalate, oxybenzone, ensulizole, titanium dioxide) | Lotion/Stick | 15, 30 |
| Eau Thermale Avène (titanium dioxide, zinc oxide) | Cream | 25, 50 |
| Hawaiian Tropic Ozone (octocrylene, oxybenzone, avobenzone) | Lotion | 70 |
| Hawaiian Tropic Kids (avobenzone, octocrylene, oxybenzone) | Lotion | 60 ⁺ |
| Hawaiian Tropic 45 Plus Sunblock (octinoxate, octisalate, titanium dioxide) | Lotion | 45 |
| Neutrogena MoistureShine Lip Soother (octinoxate, oxybenzone) | Lip balm | 20 |
| Neutrogena Healthy Defense Oil-Free Sunblock (avobenzone, homosalate, octinoxate, octisalate) | Lotion/Spray/ Stick | 30, 45 |
| Neutrogena Age Shield Sunblock (avobenzone, homosalate, octocrylene, octisalate, oxybenzone) | Lotion | 30, 45 |
| Neutrogena Ultra Sheer Dry-Touch Sunblock (octinoxate, octocrylene, homosalate, octisalate, oxybenzone, avobenzone) | Lotion | 30, 45 55, 70 |
| Off! Skintastic with Sunscreen (with DEET; octinoxate, octocrylene, oxybenzone) | Lotion | 30 |

SPF, sun protective factor.

or perspiring. In the past, labeling of a product as “waterproof” or “water-resistant” indicated that the SPF of the product was maintained after 80 minutes of moderate activity or 40 minutes while swimming, respectively. Because testing is performed indoors under close to ideal conditions (e.g., lower humidity), the effects of the actual environment where it is used and the evaporation of the vehicle may reduce considerably the overall effectiveness of the sunscreen. The substantivity of a product largely depends on the vehicle, as well as the active ingredient (Table 41-3).⁵⁷ The affinity of a sunscreen to the keratinaceous layer of the stratum corneum is directly related to the keratin or vehicle partition coefficient. The saturation of the active agent in keratin depends on the drug’s lipophilicity, whereas its substantivity is independent of its lipophilicity. Sunscreen compounds with a high solubility in the product’s vehicle penetrate the skin most easily. Classically, vehicles such as water-in-oil emulsions or ointments tend to have a higher degree of substantivity. Some of the newer products have improved substantivity with the addition of a polymer, such as polyacrylamide, to the formulation.

SUNBURN PREVENTIVE AND SUNTANNING AGENTS

Sunburn preventive agents are those active ingredients that absorb >95% of UVB radiation, and have the potential to prevent sunburn. Suntanning agents are those with active in-

redients that absorb 85% to 95% of UVB radiation, thereby allowing suntanning without significant sunburn in the average individual. Chemical sunscreens include both of the aforementioned designations. Opaque sunblocks, or physical sunscreens, are those active ingredients that reflect or scatter all UVA, UVB, and visible light, thereby preventing or minimizing sunburn and suntanning.⁵⁸ Limiting UV exposure by starting sunscreen use during childhood can reduce the lifetime risk of nonmelanoma skin cancers by up to 78%⁵⁹; however, some investigators have suggested that sunscreen use, through increased UV exposure, may actually cause melanoma, perhaps because its use allows for a longer exposure to the sun.^{60,61} Also, sunscreen use appears to be associated with the occurrence of nevi (pigmented “moles”), which is a strong predictor of melanoma development^{25,62}; however, epidemiologic analyses have refuted this proposed association.^{63,64}

Of note, *sunless tanner*, a commercial term, denotes a product that provides a tanned appearance without exposure to the sun or other sources of UVR. One commonly used ingredient in these products is dihydroxyacetone (DHA), a color additive that darkens the skin to orange-brown by reacting with amino acids in the stratum corneum. The term *bronzer* is used to describe a variety of products intended to achieve a temporary tanned appearance. For example, among the products that are marketed as bronzers are tinted moisturizers and brush-on

powders. These produce a temporary effect, similar to other types of makeup, and wash off over time. Some products are marketed with other ingredients in addition to DHA to provide a tanned appearance. Neither sunless tanners nor bronzers provide any protective activity to UV exposure by themselves.⁶⁵ Effective May 22, 2000, the FDA required that all suntanning preparations that do not contain sunscreen ingredients are required to carry the following warning statement on the label: “Warning—This product does not contain a sunscreen and does not protect against sunburn. Repeated exposure of unprotected skin while tanning may increase the risk of skin aging, skin cancer, and other harmful effects to the skin even if you do not burn.”

Tanning pills are promoted for tinting the skin by ingesting massive doses of color additives, usually canthaxanthin. At large doses, canthaxanthin is deposited in various organs, including skin, imparting an orange-bronze color. This color varies from individual to individual. This colorization is not the result of an increase in the skin’s supply of melanin. Although canthaxanthin is approved by FDA for use as a color additive in foods, where it is used in small amounts, its use in these so-called tanning pills is not approved. Reported adverse events include drug-induced retinopathy, nausea, gastrointestinal cramping, diarrhea, pruritus, and urticaria. None of the above noted unapproved agents should be recommended for use.

Chemical Sunscreens

Chemical sunscreens are compounds capable of absorbing UVR, thereby protecting the skin structures from the adverse effects of the selective wavelengths absorbed.³⁶ After application to the skin, these aromatic compounds convert the high UVR energy into harmless longer-wave radiation, which may or may not be perceived as warmth.³⁶ Chemical sunscreens usually are nonopaque because they do not absorb the wavelengths of visible light.

MOLAR ABSORPTIVITY, ABSORBANCE SPECTRUM, AND PHOTOSTABILITY

The molar absorptivity and absorption spectrum determines the effectiveness of an individual chemical sunscreen agent, mostly by its chemical structure. *Molar absorptivity* is a measure of the amount of UVR absorbed by a particular sunscreen, and it depends on the concentration of the sunscreen in the product and the amount applied to the skin. Sunscreens with an absorbance spectrum in the UVB range with a maximal absorption between 310 and 320 nm, are the most effective at preventing a sunburn.⁵⁰ Chemical sunscreens with absorption spectra in the UVB range are para-aminobenzoic acid (PABA) and its esters, cinnamates, and the salicylates. Sunscreens with absorption spectra that extend into the UVA range are the anthranilates (e.g., meradimate), dibenzoylmethanes (e.g., azobenzene), and benzophenones (e.g., oxybenzone). *Photostability* means the ability to stabilize under sunlight. The process of photostability is a key factor in sunscreen protection efficacy. High photostability means the sunscreen will maintain a higher UVA protective barrier longer, and not degrade as quickly as other UVA filters when exposed to the sun.

Seventeen chemical ingredients that act as sunscreens are currently approved in the United States (with their FDA-allowable maximal concentration in sunscreen products listed in parentheses):

- P-aminobenzoic acid (PABA; up to 15%)
- Avobenzone (3%)
- Cinoxate (3%)
- Dioxybenzone (3%)
- Ecamsule (3%)
- Ensulizole (4%)
- Homosalate (15%)
- Meradimate (5%)
- Octocrylene (10%)
- Octinoxate (7.5%)
- Octisalate (5%)
- Oxybenzone (6%)
- Padimate O (8%)
- Sulisobenzene (10%)
- Titanium dioxide (25%)
- Trolamine salicylate (12%)
- Zinc oxide (25%)

PARA-AMINOBENZOIC ACID (PABA) AND ESTERS

Commonly used in the past, PABA absorbs UVR in the UVB range from 260 to 313 nm, with maximal absorbance around 290 nm; its molar absorptivity is considered to be high.⁵⁰ PABA readily penetrates and binds to the stratum corneum and, after several days of application, may remain in the skin and provide protection even after swimming, perspiration, and bathing.⁵⁰ It is commonly formulated as an alcoholic mixture, which can cause stinging, dryness, or tightness, particularly when applied to the face. Its major disadvantage is the potential to cause contact or photocontact dermatitis. Responsible for more sensitivity reactions than any other sunscreen,⁵³ PABA can also cause cross-sensitivity reactions with benzocaine, thiazides, sulfonamides, paraphenylenediamine (a common ingredient in hair dyes), and other PABA derivatives. It can cause discoloration of clothes as well. The use of PABA in commercial sunscreens has decreased to the point where many of the newer sunscreens are promoted as being PABA-free.

The PABA esters include octyldimethyl PABA (Padimate O) and glyceryl PABA. These esters are incorporated easily into formulations, demonstrate good substantivity, and do not discolor clothing. Their absorption spectra are similar to that of PABA (Table 41-2). With a maximal absorbance of 311 nm, Padimate O has the lowest likelihood of any PABA ester to cause cross-sensitivity reactions or contact and photocontact dermatitis.⁶⁶ Glyceryl PABA can cause contact dermatitis and cross-sensitivities, both of which may be caused by benzocaine impurities in the commercial products.⁶⁷

CINNAMATES

Cinnamates have UVB-absorbing qualities. Octinoxate (octyl methoxycinnamate, Parsol MCX), which has high molar absorptivity and a maximal absorbance of 305 nm, is the most commonly used cinnamate.⁶⁸ Cinnamates are related chemically to balsam of Peru, balsam of Tolu, coca leaves, cinnamic acid, cinnamic aldehyde, cinnamic oil, ingredients that are used in perfumes, topical medications, cosmetics, and flavorings.⁶⁷ These agents do not bind well to the stratum corneum, leading to poor substantivity. Cinnamate-based sunscreens tend to be comedogenic because the vehicle may contain other occlusive ingredients that are added to improve the substantivity. Cinnamates, which absorb only UVB radiation, are often used in

combination with benzophenones, appear to be nonstaining, and rarely cause contact dermatitis.⁶⁸

BENZOPHENONES

Benzophenones, such as oxybenzone and dioxybenzone, are UVB-absorbing sunscreens that have absorbance spectra extending into the UVA range.⁶⁹ Benzophenones are also found in shampoos, soaps, hair sprays and dyes, paints, varnishes, and lacquers. The maximal absorbance for each is about 290 nm, but both are limited because of poor substantivity and sensitization.⁶⁹ Photocontact dermatitis with oxybenzone and contact dermatitis with dioxybenzone occur commonly, with the latter usually occurring as a contact urticaria.

SALICYLATES

Salicylates are weak UVB absorbers often found in PABA-free products. Topical salicylates are considered among the safest sunscreens, even though they are used in high concentrations.⁷⁰ Salicylates have low molar absorptivities, are incorporated easily into formulations, and are used to boost the SPF of combination products. Sensitization to the salicylates is rare⁷⁰; however, it has been reported with the use of octyl salicylate.⁷¹

ANTHRANILATES

Anthranilates, such as meradimate (menthylantranilate), are weak UVB-absorbing sunscreens with an absorbance spectrum extending into the UVA range. As with the salicylates, they have low molar absorptivity, with a maximal absorbance of approximately 336 nm.⁵⁰ Meradimate has a low risk of sensitization and a desirable absorbance spectrum, especially when it is used in combination with other sunscreens to give broad-spectrum protection.⁷⁰

DIBENZOYLMETHANES

As a prototype of the dibenzoylmethanes class, avobenzone (butyl methoxydibenzoylmethane, Parsol 1789) has high molar absorptivity and absorption spectra exclusively in the UVA range, with maximal absorbance at approximately 360 nm.⁷² It is commonly formulated with UVB sunscreens to broaden UVR coverage. Even though protection is provided throughout the UVA and UVB ranges in these combination products, it is unknown whether sufficient protection is available for patients who are highly UVA sensitive. Avobenzone loses approximately 35% of its absorbance capacity about 15 minutes after UVR exposure, because of the photoinstability of the compound.² When UVA and UVB inorganic protective filters were first introduced using cosmetically acceptable concentrations, they provided minimal protection against UVA rays. Avobenzone was approved for use in 1992; however, it was discovered that when used by itself, avobenzone degrades when exposed to the sun, thereby reducing its UVA protection efficacy. One molecule of avobenzone can absorb UVA radiation only once, making it inactive from that time forward as opposed to zinc oxide or titanium dioxide that can reflect UVA radiation over and over again with minimal decay. All of the avobenzone applied to the skin is virtually rendered inactive after 5 hours of UVA exposure.

In 2006, the FDA approved the combination of 2% ecamsule/2% avobenzone/10% octocrylene cream (*Anthelios SX*, L'Oreal USA) for the prevention of sunburn and protection

from UVA and UVB rays. This OTC product is only available in the United States as a moisturizing cream with a SPF rating of 15, although it is available in Europe up to SPF 50. The actions of the individual components of this combination are as follows: (a) octocrylene, to protect against UVB rays, (b) avobenzone protects against long UVA rays and is stabilized by octocrylene, and (c) ecamsule (Mexoryl), a camphor derivative, protects against short UVA rays. This combination provides continuous protection across most of the UV spectrum (290–400 nm range), with ecamsule providing protection within the short UVA range (320–340 nm), filling the gap between octocrylene and avobenzone capabilities (210–290 nm, and 340–400 nm, respectively). The photostability of the ecamsule and octocrylene–avobenzone combination provides residual protection at 1 and 5 hours (1 hour, 100% UVB protection and 97% UVA protection; 5 hours, 90% UVB protection and 80% UVA protection, respectively). Adverse events associated with its use are infrequent and include acne, dermatitis, dry skin, eczema, erythema, pruritus, skin discomfort, and sunburn.

There are two additional formulations of ecamsule. Mexoryl SX is a water-soluble form suitable for daytime sunscreens, including sunscreen-containing moisturizers and facial foundations. Mexoryl XL, an oil-soluble formulation, is suitable for water-resistant sunscreen formulations, including those worn on the beach and during vigorous physical exercise.

The other extended spectrum agent on the market in the United States at present is Helioplex, a combination of avobenzone, oxybenzone, and a photostabilizing solvent, Hallbrite TQ. Neutrogena uses it in products such as UltraSheer Dry-Touch Sunblock SPF 30/45/55/70, Age Shield Sunblock SPF 30/45, Fresh Cooling Body Mist Sunblock SPF 30/45, and Moisture Rich Sunless Tanner SPF 20.

ANTIOXIDANTS

Antioxidants have received increased attention for use as photoprotective agents, particularly because of the observation that vitamin C levels in the skin can be severely depleted after UVR exposure.⁷³ Vitamins C and E, either taken orally or applied topically (incorporated into a commercially available sunscreen product), may provide additive protection against both UVA- and UVB-induced photodamage.^{73,74} Topically applied antioxidants do not have adequate diffusion into the epidermal layer, however, and are susceptible to chemical instability.⁷⁵

PHYSICAL SUNSCREENS

Physical sunscreens are opaque formulations made of particulate insoluble compounds, incorporated into a vehicle. The skin is shielded from sunlight by reflection and scattering of both UV and visible radiation; both size of the particles and thickness of the film determine the degree of protection.⁷⁶ The most effective and commonly used physical sunscreens are titanium dioxide and zinc oxide, which reflect and scatter UVR as well as reflect and scatter.^{76,77} Other physical sunscreens include magnesium oxide, red veterinarian petrolatum, iron oxides, kaolin, ichthammol, and talc.

These compounds are used in conjunction with chemical sunscreens to formulate products of higher SPF and as single-ingredient sunblocks. When used alone, they are usually placed in an ointment base designed specifically for vulnerable parts of the body, such as the nose, cheeks, lips, ears, and shoulders.⁵⁸

Physical sunscreens are important in individuals who are unusually sensitive to UVA and visible light, such as those with vitiligo, a skin condition with amelanotic lesions (white patches) surrounded by areas of normally pigmented skin. Appropriately colored formulations can be used to camouflage and protect these vulnerable amelanotic lesions.⁵⁸ Physical sunscreen agents are preferred for persons who need absolute UVR and visible light protection (e.g., young children; persons with skin types I through IV who receive constant exposure; and persons with drug photosensitivity reactions, xeroderma pigmentosa, lupus erythematosus, and other photosensitive skin reactions).⁵⁸

Physical sunscreens are not widely accepted because they are visible to others, messy, and occlusive when applied to the skin. They have a higher substantivity, but may melt in the heat of the sun, limiting their protection to a few hours. Physical sunscreen products tend to be so occlusive that they may cause or worsen acne or obstruct sweat glands.⁵⁸ Neutrogena Sensitive Skin Sunblock Lotion SPF 30 (titanium dioxide 9.1%) is an example of a physical sunscreen with cosmetically appealing properties (e.g., ease of application).

Product Selection

9. R.J. and her husband J.J. are parents of two children: P.J., a 6-month-old girl, and L.J., an 18-month-old boy. They are spending a week in August vacationing on the Outer Banks of North Carolina, with plans for time at the beach, bicycling, and sailing. R.J. is 25 years of age, has type V skin, brown hair and brown eyes, and has no history of photosensitivity reactions or medication allergies. She has a history of contact dermatitis on her scalp and around her hairline on several occasions after dyeing her hair and using certain shampoos. J.J. is 27 years of age and has skin type II with blonde hair and blue eyes. As a teenager, he suffered from frequent sinus infections and often was treated with trimethoprim-sulfamethoxazole (TMP-SMX [Septra/Bactrim]) because of an allergy to penicillin. He remembers developing a severe sunburn after minimal exposure to the sun while taking the sulfa-containing antibiotic. He recently has been started on hydrochlorothiazide (HCTZ), 12.5 mg PO QD, for hypertension. What considerations are important in recommending sunscreens for R.J. and J.J.? Recommend an appropriate sunscreen for each member of the family with appropriate directions for application while on vacation.

CROSS-SENSITIVITY

The first consideration for recommending an appropriate sunscreen for R.J. and J.J. is their skin type. R.J. has skin type V, suggesting that a sunscreen with an SPF of at least 8 would provide adequate protection for her (Table 41-1). J.J. has skin type II, suggesting that a sunscreen with an SPF of 30 would be required to provide adequate protection for him. Furthermore, the history of contact dermatitis and photosensitivity reaction exhibited by R.J. and J.J., respectively, is important when recommending use of a sunscreen.⁷⁸ The contact dermatitis that R.J. experienced from hair dyes and shampoos may have been caused by para-phenylenediamine, an ingredient of hair dyes,⁶⁵ or a benzophenone, which sometimes is included in products such as hair dyes and shampoos.⁶⁹ Because a cross-reactivity between para-phenylenediamine and PABA or its derivatives is possible, a sunscreen for R.J. that does not contain PABA or

a benzophenone should be recommended. A wide-spectrum PABA-free sunscreen that does not contain a benzophenone may be ideal for R.J. because cinnamates and anthranilates rarely cause contact dermatoses.

Because both contain sulfa moieties, the photosensitivity reaction that J.J. experienced while taking TMP-SMX may indicate that he might be susceptible to a cross-sensitivity reaction with PABA or its derivatives. This reaction to TMP-SMX also indicates that J.J. may be susceptible to a photosensitivity reaction with HCTZ. If a photosensitivity reaction is likely, it is advisable to recommend an SPF of 30. Because drug-induced photosensitivity reactions are caused by UVA, a PABA-free, broad-spectrum sunscreen that absorbs UVA as well as UVB would be necessary to provide J.J. with adequate protection. Broad-spectrum chemical sunscreens commonly contain a benzophenone and a cinnamate. A broad-spectrum sunscreen containing both of these chemical classes (e.g., Shade Sunblock Lotion, with octyl methoxycinnamate, oxybenzone, homosalate, and octyl salicylate; [Table 41-3]) would be an acceptable broad-spectrum product. Alternatively, because Padimate O is the least likely of the PABA ester derivatives to cause photocontact dermatitis,⁶⁵ a broad-spectrum combination product that contains Padimate O could be recommended for J.J. If the photosensitivity reaction is caused by visible light, it would also be necessary to recommend a physical sunscreen to block all sunlight or complete avoidance of the sun.⁵⁴ With all of these issues considered, it may be preferable to recommend an alternative antihypertensive medication for J.J. that would not place him at risk for a photosensitivity reaction.

APPLICATION

Because R.J. and J.J. are planning to be active on the beach, sunscreens that are water-resistant or waterproof are recommended (Table 41-3). Before complete application of the sunscreen to the body, because of the risk of cross-sensitivity reactions, patients can perform a patch test by applying small quantity of the sunscreen to the inner aspect of the forearm and covering with a small bandage overnight. Most persons apply 20% to 60% of the required amount of sunscreen needed to achieve the SPF of their product.^{52,56} Because of this, a method has been developed to determine an approximate volume of sunscreen product needed for adequate protection.⁷⁹ One study of sunscreen application techniques at the beach demonstrated inadequate application at all body sites.⁸⁰ The worst protected areas were the ears and top of the feet, and the back was poorly protected if sunscreen was self-applied.

Dosing for sunscreen can be calculated using the formula for body surface area and subsequently subtracting the area covered by clothing that provides effective UV protection. The dose used in FDA sunscreen testing is 2 mg/cm². Considering only the face, this translates to about one fourth to one-third of a teaspoon for the average adult face. For protection in the beach environment, for example, an average-size adult should apply and rub in 2 to 2.5 ounces evenly to all exposed skin surfaces at least 30 to 45 minutes before exposure.⁷⁹ Patients should be reminded to apply sunscreen on those often forgotten areas, such as the hands, cheeks, neck, ears, and dorsum of the feet. It is best to reapply the sunscreen every 1 to 2 hours or after sweating, swimming, or towel drying off.

10. How long might J.J. expect to be protected with the sunscreen properly applied? Do products with an SPF >15 provide any additional benefit?

If J.J. (skin type II) normally burns after 30 minutes of exposure to the sun, a sunscreen with an SPF of 15 to 30 may provide up to 7.5 hours (0.5 hours 15 [SPF 15]) of photoprotection from UVB. However, a high SPF product may provide only partial protection against UVA, with little or no protection from infrared radiation.⁵⁰ Because of this, sun exposure should be limited to 90 to 120 minutes for each outing after appropriate sunscreen application. Further, environmental factors, such as elevated atmospheric humidity, and inadequate application techniques may reduce photoprotection by as much as half.

Sunscreen formulations with SPF as high as 50 can be made using combinations of chemical and physical sunscreen agents (e.g., Hawaiian Tropic Baby Faces Sunblock Lotion, with octinoxate, octocrylene, oxybenzone, octisalate, and titanium dioxide; [Table 41-3]).³ Individuals who are extremely sensitive to the sun may benefit from formulations with higher SPF, but the average fair-skinned person gains adequate protection for sunbathing or for average daily exposure from a product with an SPF of 30.⁵²

Photoprotection for Children

11. What photoprotective measures should be provided for P.J. and L.J.? What nonsunscreen protection is appropriate for use with children?

AGE-RELATED RECOMMENDATIONS AND OTHER PROTECTIVE BEHAVIOR

Sun protection during childhood is very important, considering that most of a person's lifetime of sun exposure occurs in childhood and that the harmful effects of UVR are cumulative.⁶² The FDA has recommended that sunscreen agents not be used for children younger than 6 months of age because of the possible chemical absorption through the skin and lowered ability of children of this age to metabolize the absorbed drug.⁸¹ P.J. needs to be kept out of direct sunlight and, when outside, must be protected with proper clothing and shading.⁸²⁻⁸⁵ The FDA has recommended that children <2 years of age be treated with an SPF >4 because of inadequate UVR protection with lower SPF products for most individuals.⁸¹

L.J. should be protected with a PABA-free sunscreen with an SPF of at least 15. Regular use of a sunscreen with an SPF of at least 15 for the first 18 years of life can reduce the lifetime incidence of nonmelanoma skin cancers by about three-fourths.⁸⁵ If L.J. is in the sun during 6 hours of maximal exposure (i.e., 10 AM-4 PM), or otherwise for an extended period, he should wear protective clothing, covering as much of his body as possible.⁸⁴ Tightly woven clothing, long sleeves, and pants protect the skin from almost all UVR, whereas loosely woven clothing or wet T-shirts can allow up to 30% of UVR to pass through to the skin. Although not complete, water is thought to reduce UVR scattering, thus decreasing its transmission. An average-weight cotton T-shirt provides only an SPF of 7 or 8.⁸⁴ The transmission of UVR through a fabric is measured using a spectrophotometer or spectroradiometer. The ultraviolet protection factor (UPF), rather than SPF, has been recommended as a measure of the sun-protective properties of fabrics.^{86,87} It is calculated using a formula based on UV transmission through

Table 41-4 Relative Ultraviolet Protection Factor (UPF) by Ultraviolet Ray (UVR) Transmission and Absorption

| UVR Transmitted (%) | UVR Absorbed(%) | UPF | Protection Category |
|---------------------|-----------------|-----|---------------------------|
| 10 | 90.0 | 10 | Moderate protection |
| 5 | 95.0 | 20 | High protection |
| 3.3 | 96.7 | 30 | Very high protection |
| 2.5 | 97.5 | 40 | Extremely high protection |
| <2.0 | >98.0 | 50 | Maximal protection |

the fabric and the erythema response for human skin. For example, if a fabric has a UPF of 20, then only one-twentieth of the UVR at the surface of the fabric actually passes through it. Table 41-4 compares the UPF with the amount of effective UVR transmitted and absorbed.

No woven fabric provides complete coverage because the holes between the threads permit UVR transmission. A baseball cap shields little more than the upper central forehead. Broad-rimmed hats can protect the ears, neck, nose, and cheeks, but may provide inadequate protection against SCC of the head or neck.⁸⁸ The use of an ultraviolet-absorbing ingredient for fabric softeners (e.g., Tinosorb-FD, Ciba) are promoted to reduce transmission of excessive UVA and UVB radiation through fabrics to the skin, through absorption of UV radiation without impairing whiteness. This chemical absorbance process has a high affinity for cotton fibers at various washing temperatures. Available as a laundry additive (e.g., detergent or fabric softener), it works by binding to laundered fibers, and through accumulation, it increases the UV protection through repeated wash and rinse cycles.^{89,90}

PRODUCT SELECTION

Two types of sunscreens are appropriate for use in children. A lotion is preferred for total body application versus an alcoholic lotion or gel because alcoholic preparations can cause stinging, burning, and irritation of the skin and eyes. Physical sunscreens (e.g., zinc oxide) are available in bright colors and are recommended for selected body areas, such as the nose, cheeks, and shoulders. PABA and its derivatives are considered potentially harmful to a child's tender skin. For adolescents with acne vulgaris, the use of an oil-free, noncomedogenic sunscreen formulation (e.g., Neutrogena Healthy Defense Oil-Free Sunblock) and a lip balm that contains a sunscreen of at least SPF 15 (e.g., ChapStick or Blistex Regular (SPF 15), Blistex Ultra (SPF 30) or ChapStick Ultra (SPF 30) would be appropriate.

Photoeffects on the Eye

12. Why should R.J. and J.J. be concerned about the effect of prolonged sunlight on their eyes? Recommend appropriate protective eyewear for them while they are on vacation.

CATARACT FORMATION

Age-related opacification of the ocular lens, or senescent cataracts, has been attributed to a lifetime of exposure to sunlight. The incidence of cataracts increases steadily after age 50, reaching nearly 50% in individuals over the age of 75.³⁰ UVB is absorbed by the cornea and lens, which slowly results in protein oxidation and precipitation within the lens. UVA

penetrates the ocular lens and can cause cumulative damage to deeper structures of the eye. Decreased transmittance and increased scattering of light by the opacified lens eventually result in blurred vision, rings or halos around lights, changes in color perception, and blindness.⁹¹ In advanced cases, the only treatment is surgical removal of the cataract.

High exposure of the eye to UVR (which can range from a few seconds of exposure to arc welding, a few minutes of exposure to a UVC-emitting germicidal lamp, commercial tanning, or UVR reflection by snow or sand) can cause conjunctivitis or photokeratitis, a painful inflammation of the cornea. Photokeratitis usually begins 30 minutes to 24 hours after the exposure and time to onset depends on the intensity of the exposure.⁹² Conjunctivitis commonly accompanies photokeratitis and is characterized by the sensation of a foreign body or grit in the eyes. Varying degrees of photophobia, lacrimation, and blepharospasm also may accompany photokeratitis.⁹² Because the corneal epithelium has a great regenerative capacity, photokeratitis tends to be transient, with regression in 24 to 48 hours. Treatment consists of cool, wet compresses and mild anti-inflammatory analgesics, such as ibuprofen, aspirin, or naproxen sodium.

PROTECTIVE EYEWEAR

R.J. and J.J. should wear sunglasses when outdoors to decrease their lifelong exposure to solar radiation and while at the beach to prevent high exposure of UVR and possible photokeratitis or conjunctivitis. Many manufacturers of sunglasses label their products according to three categories: cosmetic, general purpose, and special purpose. Cosmetic sunglasses block at least 70% of UVB, at least 20% of UVA, and <60% of visible light and are appropriate for casual wear when high exposure to UVR is unlikely. General-purpose sunglasses block at least 95% of UVB, at least 60% of UVA, 60% to 92% of visible light, and are appropriate for most activities in sunny environments.⁹³ Special-purpose sunglasses block at least 99% of UVB, at least 60% of UVA, and at least 97% of visible light and are appropriate for very bright environments, such as ski slopes or tropical beaches.⁹³ Special- or general-purpose sunglasses are appropriate recommendations for R.J. and J.J. to wear while on vacation.

TREATMENT OF SUNBURN

13. G.B., a 31-year-old man with skin type IV, returned a few hours ago from an afternoon of activity in the sun. His shoulders, back, neck, and arms are bright red and are beginning to feel hot, stretched, and painful. G.B. has been otherwise healthy, has no significant medical history, and has no known allergies to medications. What treatment recommendations would you give G.B. for his sunburn?

Sunburn is a self-limiting condition, and treatment is usually symptomatic. Suggested treatments that G.B. can try for his first-degree burn are oral (e.g., ibuprofen, aspirin) or topical (e.g., camphor, menthol) analgesics, topical anti-inflammatory agents (e.g., hydrocortisone cream or aloe vera gel), cooling compresses (tap water, saline, or aluminum acetate solution [Burow's solution]) applied to the skin, or cool protectant baths (e.g., colloidal oatmeal). Nonsteroidal anti-inflammatory drugs (NSAID), such as aspirin or ibuprofen, may be preferred over acetaminophen because of blockade of the inflammatory

prostaglandin-mediated sunburn process.⁹⁴ Topical NSAID use, commonly seen as a cream formulation of indomethacin, possesses anti-inflammatory activity, especially if applied before UVR exposure, which may prove impractical for many individuals.

Treatment beyond self-management is unnecessary unless the sunburn is extensive with constitutional symptoms (i.e., severe first- or second-degree burns), involves second-degree burns on the eyes or genitalia, or becomes infected. In such cases, referral of the patient to his/her continuity provider is indicated as a short course (i.e., up to 3 days) of an oral corticosteroid may need to be given (e.g., 1 mg/kg of prednisone or equivalent, given once daily).

Topical anesthetics, such as benzocaine or lidocaine, provide only transient analgesia for up to 15 to 45 minutes. These agents should not be used in large quantities or applied more than three or four times a day. In addition, they should not be used on raw, blistered, or abraded skin. Benzocaine has minimal systemic toxicities, but is associated with contact sensitization.⁹⁵ In contrast, lidocaine is associated with a low incidence of contact sensitization, but has the potential to cause significant systemic toxicity (e.g., cardiovascular) if adequate serum drug concentrations are reached as a result of cutaneous absorption.⁹⁶

If G.B. desires to try one of these agents, application or administration is recommended when the pain is particularly bothersome, such as at bedtime. Topical 1% hydrocortisone, when applied to mild to moderate sunburn, may provide some additional benefit. If G.B. experiences fever, chills, nausea, vomiting, and prostration, he should be referred to his health care provider. These symptoms generally respond to oral prednisone 20 mg/day for 3 days. Antihistamines may help control pruritus associated with sunburn, as well as aid with sleep, if taken at bedtime.

MINOR BURNS

Burn injuries rank second only to motor vehicle accidents as the leading cause of death in children between 1 and 4 years of age and rank third after motor vehicle accidents and drowning as the leading cause of injury and death in persons between 0 and 19 years of age.⁹⁷ Of the 2 million Americans treated for burns yearly, >80,000 require hospitalization; burns cause an overall yearly mortality of approximately 6,500.^{98,99} Complications such as fluid and electrolyte imbalances, metabolic derangements, respiratory failure, sepsis, scarring, and functional impairment are the primary causes of hospitalization for these cases. Most burns, however, are minor and can be managed in an ambulatory environment, provided the burned patient is evaluated carefully, the severity of the burn is assessed accurately, and proper and continuous follow-up care is ensured. Most partial thickness burns in this country are managed by practitioners in hospital and community settings who do not treat burns on a regular basis.¹⁰⁰

Epidemiology

Burn injuries range from relatively minor, superficial injuries to severe, extensive skin loss resulting from contact with hot solids and liquids, steam, chemical agents, electricity, or other physical agents, such as UVR or infrared radiation. House

fires, commonly caused by cigarettes or malfunctioning heating or electrical equipment, are responsible for 84% of fire- and burn-related deaths.⁹⁷ The peak incidence of burn injuries occurs in up to 10% of preschool-aged children, who are often scalded by or immersed into hot liquids, frequently as a result of child abuse and neglect that crosses all socioeconomic classes.^{98,101–103} School-aged children and adolescents often are injured when experimenting with matches or gasoline or in association with cars, motorcycles, fireworks, or flammables.⁹⁷ Teenagers and adults between 17 and 30 years of age most commonly are involved in accidents with flammable liquids, but the mortality associated with clothing ignition continues to decrease as a result of the use of flame-retardant forms of fabric in clothing. Categories of individuals who have a higher reported incidence of burn injuries are the very young, elderly, males, blacks, economically disadvantaged, individuals who have ingested alcohol, handicapped children, and children with previous history of burn.⁹⁹

With the development of multidisciplinary burn centers and a better understanding of the pathophysiology of the burn wound, survival of patients with second- and third-degree burns has improved by five to six times over the last three decades.¹⁰⁴ An increased national focus on burn treatment and prevention, societal changes such as an overall decrease in tobacco use, decreased alcohol abuse, changes in home cooking practices, and reduced industrial employment have contributed to the lower national burn incidence.⁹⁹ The techniques of improved burn wound management that have contributed to this decline include topical antimicrobial therapy, early excision or enzymatic débridement of devitalized tissue, and skin grafting or substitutes.^{105–107}

Zones of Injury

The skin functions as a protective barrier of the underlying organ systems from trauma, temperature variations, harmful penetrations, moisture, humidity, radiation, and invasion by microorganisms (see Fig. 38-1 in Chapter 38.) It also is involved with carbohydrate, protein, fat, and vitamin D metabolism; it produces secretions that lubricate the skin, is involved with the immune response, and provides the body with the sense of touch.

Burn wounds caused by thermal injury can be described by varying zones of injury.^{106,107} The most peripheral area of injury is the *zone of hyperemia*. The tissue in this area is characterized by inflammatory changes with minimal tissue damage. The *zone of stasis* is the next area of injury, extending inward from the zone of hyperemia. This area involves ischemic, damaged tissue, with blood vessels only partially thrombosed. The damaged endothelial linings of blood vessels within this zone of injury may trigger further thrombosis, resulting in further ischemia, cell death, and deepening of the burn wound. This process of further injury can occur 24 to 48 hours after the initial injury. Drying of the burn wound or infection can cause deepening of the burn wound by preventing re-establishment of circulation to injured tissue. The central-most area, or the *zone of coagulation*, is characterized by thrombotic vessels and necrotic tissue. This area absorbs the most thermal energy, resulting in the greatest tissue damage. Minor burns may involve only the most peripheral zones of injury, whereas severe burns encompass all three zones of injury.

Extent of Injury

RULE OF NINES

Burn severity is proportional to the percent of body surface area (BSA) involvement and wound depth. The percent of BSA for adults can be estimated by using the “rule of nines,” in which each arm constitutes 9% of the BSA, the head 9%, each leg 18%, the front and back of the torso 18% each, and the genitalia 1%. For children <10 years of age, the percent BSA must be adjusted because their bodies have different proportions. The Lund and Browder chart has been used for this purpose.¹⁰⁸ At birth, the infant’s head constitutes about 19% of the BSA. For each additional year of age, the head decreases by about 1% and the BSA of the legs increases by about 1% of the patient’s total body surface area (TBSA), so a quick estimation of the percent BSA of a burn can be made.¹⁰¹

CLASSIFICATION OF WOUNDS

Burn wounds also are classified according to the depth of tissue damage. Determining the depth of the burn wound can be difficult during the first 24 to 48 hours because of the presence of edema and continued tissue ischemia and infection, both of which can cause deepening of the wound. In addition, the depth of destruction can vary within the same burn, and skin surface characteristics may not match underlying tissue damage, making assessment of the burn wound difficult.¹⁰⁶

First-Degree Burns

First-degree burns result from injury to the superficial cells of the epidermis. A common example is a mild sunburn. The burned skin does not form blisters, but it does become erythematous and mildly painful. This partial-thickness burn heals within 3 to 4 days without scarring.

Second-Degree Burns

Second-degree burns may be superficial or deep, depending on the depth of dermal involvement. Superficial second-degree burns involve the epidermis and the upper layer of the dermis. The burn surface often is erythematous, blistered, weeping, painful, and very sensitive to stimuli. The erythema blanches with pressure, and the hair follicles, sweat, and sebaceous glands are spared. Superficial second-degree burns heal spontaneously within 3 weeks with little, if any, scarring. Deep second-degree burns involve the deeper elements of the dermis and may be difficult to distinguish from third-degree burns. The burn surface is pale, feels indurated or boggy, and does not blanch with pressure. This wound is less painful than more superficial wounds; some areas may be insensitive to stimuli. Healing occurs slowly over about 35 days with eschar formation and possible severe scarring and permanent loss of hair follicles and sweat and sebaceous glands.

Third-Degree Burns

Third-degree burns entail complete destruction of the full thickness of the skin, including all skin elements. The wound may appear pearly white, gray, or brown and is dry and inelastic. Pain is sensed only when deep pressure is applied. If the wound is small, healing over several months can occur by epithelial migration from the margins of the injury, with scar and contracture formation. Third-degree burns are repaired most often by excision and grafting of the wound to prevent contractures of the skin.¹⁰⁹

Fourth-Degree Burns

Fourth-degree burns are similar to third-degree burns except that devitalized tissue extends into the subcutaneous tissue, fascia, and bone. These burns are blackened in appearance; they are dry and generally painless (because of destruction of nerve endings) and are at great risk for infection.

Complications of Burn Wounds

FLUID LOSS

In severe burns, release of vasoactive mediators and capillary injury cause sequestration of large amounts of body fluid, plasma, and electrolytes in extravascular compartments, resulting in edema both locally and throughout the entire body. This redistribution of fluid is compounded by the loss of large amounts of fluid, electrolytes, and protein into the open wound. The cumulative effect is a marked decrease in blood volume, a fall in cardiac output, and decreased tissue and organ perfusion. During the first 24 to 48 hours after a severe burn injury, adequate fluid must be given to replace fluid lost from the vascular space to prevent shock and, possibly, multiple organ failure, and death.¹⁰⁹

INFECTION

The most important threat to survival of the fully resuscitated patient is infection, with burn wound sepsis and pneumonia being the leading causes of death.¹⁰⁹ The local mechanical defenses of the skin and respiratory tract often are damaged in burn victims, making these common foci for fatal infections. Loss of circulation to the burn wound margins disallows proper functioning of cellular and humoral defense mechanisms, which increases susceptibility to infection. Devitalized tissue and tissue exudates provide an ideal environment for the proliferation of bacteria. Colonization of gram-positive bacteria occurs if topical antimicrobial therapy is not initiated promptly, and gram-negative bacteria may predominate by the fifth day after injury.¹⁰⁹ Systemic antibiotics are of limited benefit in full-thickness burns and are used only to treat infections documented by wound biopsy, which reveal $>10^5$ bacteria/g of burn tissue.¹⁰⁹ Topical antimicrobials, local wound care, and strict infection control practices are the mainstays of controlling burn wound infections. Devitalized tissue initiates and perpetuates a sepsislike state in the absence of an identifiable focus of infection.¹⁰⁹ For this reason, as well as for infection control, early excision of devitalized tissue and closure of the burn wound by skin grafting or substitutes have been adopted by many burn centers.

INHALATION INJURY

Burn injuries complicated by inhalation injury are associated with greatly increased mortality rates. Injury to the tracheobronchial mucosa is caused by inhalation of smoke or flames and may result in bronchospasm, ulceration of the mucous membranes, damage to cell membranes, edema, and impairment of bacterial ciliary clearance. Even patients with minor burns can have inhalation injury and require hospital admission. The early symptoms of pulmonary injury (hoarseness, dyspnea, tachypnea, and wheezing) may not be evident for 24 to 48 hours, so patients with suspected inhalation injury (i.e., facial burns or entrapment in a closed space) must be examined carefully. Singed nasal hair, soot-coated tongue or oropharynx, and upper airway edema are indications of in-

halation injury. The diagnosis is established by bronchoscopy, and management may include endotracheal intubation and mechanical ventilation. Maintenance of the patient's fluid status is essential. Corticosteroids do not influence survival rates and should not be routinely administered to patients with inhalation injury. They can also increase morbidity and mortality associated with burns and inhalation injury by increasing the risk of infection.¹⁰⁹ The use of exogenous surfactant in the treatment of inhalation burns in patients with adult respiratory distress syndrome (ARDS) improves the survival of these high-risk patients.¹¹⁰

Triage

14. S.T., a 17-year-old, nonobese boy, has just burned the calf of his right leg on the muffler of his motorcycle. Immediately after being burned, S.T. was able to rinse his leg with cool water from a garden hose. The burn on his leg is about twice the size of the palm of his hand and appears erythematous and weeping. He sustained no other injury, but now he is in considerable pain. S.T. has no significant medical history. Should S.T. be referred to a health care provider or can he safely self-treat his burn? What patient information is necessary to consider in making this decision?

Before recommending treatment for a patient with a minor burn, it is important to accurately assess the patient to determine whether he or she can self-treat safely or whether referral or hospitalization is necessary. The location and severity of the burn, the patient's age and state of health, and the cause of the burn injury all must be considered.

American Burn Association Treatment Categories

Three treatment categories for burn injuries are recommended by the American Burn Association: major burn injuries; moderate, uncomplicated burn injuries; and minor burn injuries.¹¹¹

- *Major burn injuries* are second-degree burns with $>25\%$ BSA involvement in adults (20% in children); all third-degree burns with 10% BSA involvement; all burns involving the hands, face, eyes, ears, feet, and perineum that may result in functional or cosmetic impairment; high-voltage electrical injury; and burns complicated by inhalation injury, major trauma, or poor-risk patients (elderly patients and those with debilitating disease).
- *Moderate, uncomplicated burns* are second-degree burns with 15% to 25% BSA involvement in adults (10%–20% in children); third-degree burns with 2% to 10% BSA involvement; and burns not involving risk to areas of specialized function, such as the eyes, ears, face, hands, feet, or perineum.
- *Minor burn injuries* include second-degree burns with $<15\%$ BSA involvement in adults (10% in children), third-degree burns with $<2\%$ BSA, and burns not involving functional or cosmetic risk to areas of specialized function.

Patients with minor burn injuries may be treated on an outpatient basis if no other trauma is present; if circumferential burns of the neck, trunk, arms, or legs are not present; and if the patient is able to comply with therapy. After initial evaluation by a health care provider, patients may self-treat a second- or third-degree burn only if $<1\%$ BSA is involved.

Major or moderate, uncomplicated burns necessitate hospital admission, and surgical referral is recommended for patients of all ages who have deep second- or third-degree burns covering 3% of the TBSA.

Both the American Burn Association and the American College of Surgeons recommend transfer to a burn center for all acutely burned patients who meet any of the following criteria¹¹¹:

- Partial-thickness burns $\geq 20\%$ TBSA in patients aged 10 to 50 years
- Partial-thickness burns $\geq 10\%$ TBSA in children aged 10 or adults aged 50 years
- Full-thickness burns $\geq 5\%$ TBSA in patients of any age
- Patients with partial- or full-thickness burns of the hands, feet, face, eyes, ears, perineum, or major joints
- Patients with high-voltage electrical injuries, including lightning injuries
- Patients with significant burns from caustic chemicals
- Patients with burns complicated by multiple trauma in which the burn injury poses the greatest risk of morbidity or mortality (in such cases, if the trauma poses the greater immediate risk, the patient may be treated initially in a trauma center until stable before being transferred to a burn center)
- Patients with burns who suffer an inhalation injury
- Patients with significant ongoing medical disorders that could complicate management, prolong recovery, or affect mortality
- Patients who were taken to hospitals without qualified personnel or equipment for the care of children
- Burn injury in patients who will require special social, emotional, or long-term rehabilitative support, including cases involving suspected child abuse or substance abuse

Age-Related Recommendations

Children <2 years of age and elderly patients with a burn injury should be referred for evaluation because these patients may not tolerate any trauma associated with the burn. In addition to medical issues, children with burns that result from suspected child abuse should be hospitalized for legal, psychosocial, and protective reasons. Burns in varying stages of healing, demarcated patterns of burns (e.g., stocking or glove distribution), or more than two burn sites may be clues in identifying an abused child.¹⁰³

Disease-Related Recommendations

Burn patients with any other medical condition, such as diabetes mellitus, cardiovascular disease, immunodeficiency disorders (e.g., human immunodeficiency virus [HIV]-associated disease, patients receiving cancer chemotherapy), renal disease, obesity, or alcoholism, may be more susceptible to complications from the burn and may have compromised wound healing.

Etiology

The etiology of a burn should always be considered because this may provide some insight into the burn presentation and its management. Electrical burns can appear to be superficial because external injury may occur at only the entrance and exit sites of the current. These burns, however, can cause extensive

damage to underlying nerve and muscle tissue that is not initially evident. Except for very minor electrical burns, these patients should be referred for further evaluation. S.T. has sustained a superficial second-degree burn over about 2% of his BSA. Even though the burn wound on his leg was caused by thermal injury and is relatively minor, S.T. should be referred for further evaluation and treatment.

Treatment

15. How should S.T.'s burn be treated? What treatment alternatives may be used for S.T.? What immunization should S.T. be questioned about?

Goals of Treatment and Immediate Care

Treatment goals for first- and second-degree burns are to relieve the pain associated with the burn; to prevent desiccation and deepening of the wound, and infection; and to provide a protective environment for healing. Immediate care of the wound should be application of cold, wet compresses or immersion in cool water. S.T. may have prevented extension of the burn to deeper layers of tissue and alleviated some of his pain from the burn by immediately irrigating the wound with cool water. Next, the area should be cleansed with a mild hypoallergenic soap (e.g., Basis, Purpose) and water. A sterile, nonadherent, fine-mesh gauze dressing that is impregnated with hydrophilic petrolatum (Xeroflo, Adaptic) should be placed over the wound. This type of dressing prevents the gauze from adhering to the wound and allows the burn exudate to flow freely through the dressing, thus preventing maceration.

A second layer of absorbent gauze should be placed over the petrolatum gauze and a supportive layer of rolled gauze can be used to keep the dressing in place. The outer layer must not be too constricting, and the dressing should be replaced every 48 hours after recleansing the area and inspecting for signs of infection. If S.T.'s wound continues to weep, it may be beneficial to soak his wound or apply a towel saturated with water, normal saline, or Burow's solution (diluted 1:20 or 1:40) for 15 to 30 minutes at least four times daily (see Chapter 38). The use of butter, grease, or similar home remedies should be avoided in the treatment of burns because these measures tend to retain the thermal energy sustained in the burn and may increase the area of thermal injury. Because burn patients are susceptible to secondary tetanus infections, S.T. should receive a tetanus toxoid booster if he has not been immunized within the previous 10 years.

Skin Substitutes/Synthetic Dressings

Advances in the development of skin substitutes are being used to achieve the elusive goal of finding a skin replacement to mimic completely the interaction and functions of dermis and epidermis. Although this goal has yet to be achieved, a growing number of synthetic and biologic products are available that can serve important roles in caring for burn patients.¹¹² Some of the current modalities are as follows:

HUMAN CADAVER SKIN

Fresh human cadaver skin (allograft) is considered the *sine qua non* for temporary closure of burn wounds. It adheres well

to a healthy wound bed, resulting in reduced contamination and reduced protein, heat, and water loss. Cost, rejection, and disease transmission (e.g., hepatitis) are the most commonly perceived disadvantages of human cadaver skin, thus, appropriate cadaveric screening is essential.

EPIDERMAL SUBSTITUTE: CULTURED EPITHELIAL ALLOGRAFTS

The technique of culturing autologous human epidermal cells grown from a single full-thickness skin biopsy into confluent keratinizing sheets suitable for grafting has been available for over two decades and is especially useful for patients with large wounds.¹¹³ A lack of mechanical stability of cultured epithelium, causing an imperfect cover, remains a major concern; therefore, the development of a dermal substitute (or a vascularized remnant of allogenic dermis) in combination with cultured epithelial allografts to increase mechanical stability and decrease wound contracture, or a laboratory-derived autologous composite continues to receive scientific investigation.¹¹⁴

ANIMAL SUBSTITUTE: PIG SKIN

Pig skin (xenograft) has gained acceptance as a temporary dressing alternative to allograft because of its lower cost and greater availability. At 0°C, frozen pig skin has a storage life of 6 to 18 months from the date of manufacture. As with an allograft, it has the desirable properties of being able to adhere initially to a clean wound; to cover nerve endings to decrease pain; to function as an autograft test graft; and to diminish heat, protein, and electrolyte loss. A premeshed, de-epithelialized, shelf-stored form is available (EZ-Derm, Brennen Medical), which is thought to be more resistant to bacterial degradation.

DERMAL SUBSTITUTES: ALLODERMAL GRAFTS

Unlike the epidermis, the dermis can be rendered acellular and still perform its basic protective and supportive functions. With removal of the dermal cells, the antigenic elements are also eliminated; therefore, an alloplastic transplantation can occur without rejection. The principle of allodermal grafting is that an ultrathin (0.01 cm) meshed autograft laid on top of the allodermis provides skin quality that is comparable to that obtained from thick partial-thickness skin grafts. AlloDerm (LifeCell) is a shelf-stored, freeze-dried, acellular human cadaveric dermal matrix. Integra (Integra Life Sciences) is used in life-threatening burns. The inner layer of this material is a 2-mm thick combination of collagen fibers isolated from bovine tissue and the glycosaminoglycan chondroitin-6-sulfate that has a 70 to 200 μm pore size to facilitate host fibrovascular ingrowth. The outer layer is a 0.009-inch polysiloxane polymer with vapor transmission characteristics that simulate normal epithelium.⁸⁷

SEMISYNTHETIC/SYNTHETIC DRESSINGS

Biobrane (Bertek) is a bilaminar, semisynthetic, temporary skin substitute made of silicone bonded to nylon mesh. Its adherence is facilitated by collagen peptides bonded to the nylon underlayer. This substitute has been shown to be as effective as frozen human allograft for the temporary coverage of freshly excised full-thickness burn wounds before autografting.¹¹³ Duoderm (ConvaTec) (Bristol-Myers Squibb) is a hydrocolloid dressing, whereas OpSite (Smith & Nephew) and Tegaderm (3M) are elastomeric polyurethane films. Com-

feel (Coloplast) is a semipermeable polyurethane film coated with a flexible, cross-linked adhesive mass containing sodium carboxy-methylcellulose (NaCMC) as the principal absorbent and gel-forming agent. This product is permeable to water vapor but impermeable to exudates and microorganisms. In the presence of an exudate, NaCMC absorbs fluids and swells to form a cohesive gel that does not disintegrate or leave residues in the wound bed.

Alternatives in treating S.T.'s second-degree burn include the use of synthetic dressings and topical antimicrobial agents. Synthetic dressings serve as skin substitutes that are applied to fresh, clean, and moist burns. They are trimmed to about the size of the burn and left in place until the burn is healed or the dressing separates from the wound spontaneously. The synthetic dressings keep the wound warm and moist, require absorbent dressings that must be changed daily, and are indicated for superficial second-degree burns. The chief advantage over gauze dressings is that synthetic dressings prevent mechanical injury from daily cleansing and dressing changes.¹¹⁵

TISSUE-ENGINEERED BIOLOGICAL DRESSINGS

Tissue-engineered biological dressings, although relatively new, have promise in the treatment of burns, chronic ulcers, surgical wounds, and other desquamating dermatologic conditions.^{116,117} Although expensive, repeated applications of skin cells, whether these be keratinocytes or fibroblasts, autologous (the patients own) or allogeneic (from human donors), can all offer some benefit to chronic nonhealing wounds in prompting them to restart healing. In this setting, cultured cells assist the body's own wound repair mechanisms. Products include Dermagraft, Apligraf, and Epicel (cultured epidermal autograft). As an example, Apligraf is a bilayer approximating the structure of normal skin. The product is applied in a polyethylene bag containing a 10% CO₂:air ratio and agarose nutrient medium and must be stored at 20°C to 23°C until use. The first intended indication for Apligraf was full-thickness burns. In a multicenter trial, the use of meshed Apligraf in conjunction with meshed autograft resulted in better scores on the Vancouver Scar Assessment Scale than the use of meshed autograft alone. In most patients, Apligraf-treated burns were judged to have healed better than those treated with meshed autograft alone. Investigators rated Apligraf-treated sites superior to control in 58% of patients, equivalent in 16%, and worse in 16%.¹¹⁸ The principle of using an appropriate biologically active matrix is now well established for accelerating wound healing and achieving skin reconstruction. Cellular components migrate to the wound from preexisting cell populations in adjacent tissue. Increasing evidence suggests that both circulating marrow-derived stem cells and preexisting organ-specific stem cells can contribute to tissue regeneration.¹¹⁶ Although important issues concerning wound pretreatment, choice of matrix support for cell growth, and the use of allogeneic cells remain to be fully resolved, tissue-engineered approaches to wound repair still offer significant therapeutic possibilities. Such benefits may include the following:

- Reduced donor site morbidity in burn wounds
- Increased potential for healing of recalcitrant lesions
- Reduced rates of lesion recurrence (as a result of improved dermal quality)
- Reduced wound contracture and scarring

- More rapid closure (epithelialization) of large acute excisional wounds
- Delivery of exogenous growth factors (autologous, allogenic, or genetically engineered)
- Reduced overall treatment costs and hospital stay.

Topical Antimicrobial Agents

SILVER SULFADIAZINE

Silver sulfadiazine (Silvadene) is the usual agent of choice because it has broad-spectrum gram-positive and gram-negative antibacterial activity, provides reasonable eschar penetration, and is easy and painless to apply and wash off. The cream is a 1% suspension of silver sulfadiazine in a water-miscible base. As a consequence of poor water solubility, the active agent shows only limited diffusion into the eschar. Silver sulfadiazine cream is most effective when applied to burn wounds immediately after thermal injury to prevent bacterial colonization of the burn wound surface as a prelude to intraeschar proliferation. This agent has the advantages of being painless when applied to the wound and being free from acid-base and electrolyte disturbances. The limitations of silver sulfadiazine cream include neutropenia,¹¹⁹ which usually reverses when application is discontinued; hypersensitivity, which is rare; and ineffectiveness against certain strains of *Pseudomonas* organisms and virtually all strains of *Enterobacter cloacae*. A evidence-based review of use of silver sulfadiazine in burns suggested that whereas there is evidence of antibacterial activity, no direct evidence is seen of improved healing or reduced infection over normal dressings.¹²⁰ This agent should not be applied around the eyes or mouth in patients with hypersensitivity to sulfonamides or in pregnant or breastfeeding women.

MAFENIDE ACETATE

Mafenide acetate (Sulfamylon) is an 11.1% cream formulation of mafenide acetate in a water-dispersible base, or a 5% powder for topical solution. As a water-soluble agent, mafenide diffuses freely to establish an effective antibacterial concentration throughout the eschar and at the interface of viable–nonviable tissue, where bacteria characteristically proliferate before invasion. Because of this characteristic, mafenide is the best agent for use if the patient to be treated has heavily contaminated burn wounds, if treatment is delayed for several days after the burn occurred, or if a dense bacterial population already exists on and within the eschar. Adverse effects include hypersensitivity reactions in 7% of patients (usually responsive to antihistamines), pain or discomfort of 20 to 30 minutes duration when applied to partial-thickness burns (seldom a cause for discontinuation), and inhibition of carbonic anhydrase. The inhibition of carbonic anhydrase can produce both an early bicarbonate diuresis and an accentuation of postburn hyperventilation. The resulting overall reduction of serum bicarbonate levels renders such patients liable to a rapid shift from an alkalotic to an acidotic state. If acidosis should develop during use of mafenide, the frequency of application should be reduced to once daily, or it should be omitted for 24 to 48 hours, with buffering used as necessary, and with efforts made to improve pulmonary function.

Either topical silver sulfadiazine or mafenide should be applied in a one-eighth inch thick layer to the entire burn wound

with a sterile gloved hand immediately after initial débridement and wound care. Twelve hours later, to ensure continuous topical treatment, a one-eighth inch coat of cream should be reapplied to those areas of the burn wound from which it has been abraded by clothing. The topical cream should be cleansed gently once each day from all of the burn wound and the wound inspected. Daily débridement should be carried out to a point of bleeding or pain without the use of general anesthesia. After débridement, the wound should be covered again by the topical cream.

SILVER NITRATE

If topical antimicrobial creams are unavailable, multilayered occlusive gauze dressings, saturated with a 0.5% solution of silver nitrate, can be used. These soaks are changed two or three times each day and moistened every 2 hours. Evaporation should be avoided to prevent raising the silver nitrate concentration to cytotoxic levels within the soaks. Transeschar losses of sodium, potassium, chloride, and calcium should be anticipated and appropriately replaced. Similar to therapy with silver sulfadiazine cream, silver nitrate soak therapy is best for bacterial control in burn patients who are received immediately after injury before significant microbial proliferation has occurred. Silver nitrate is immediately precipitated on contact with proteinaceous material; it does not penetrate the eschar and, consequently, is ineffective in the treatment of established burn wound infection. For these reasons, it is not routinely recommended.

In S.T.'s case, *silver sulfadiazine cream* could be chosen to treat his burn on an outpatient basis if an assessment determines that he is at particular risk for infection. The cream would be applied in a thin layer over the wound and covered with absorbent gauze and wrapped with rolled gauze. The dressing must be changed twice daily to maintain an application of cream that is biologically active. Topical bacitracin and the combination of polymyxin B and bacitracin are transparent formulations that also can be used but, because of limited efficacy, may be desirable for use only on small, second-degree burns on the face.

Oral Analgesics and Topical Protectants

S.T.'s burn pain can be treated with oral OTC analgesics, aspirin, acetaminophen, or ibuprofen. If these analgesics do not provide adequate relief, oxycodone or acetaminophen (or equivalent) may be of additional benefit. Topical protectants, such as allantoin, calamine, white petrolatum, or zinc oxide, are safe and effective in treating first-degree and minor second-degree burns. These agents protect the burn from mechanical irritation caused by friction and rubbing and prevent drying of the stratum corneum.

Postwound Care

Postwound care is an essential part of total burns management to ensure adequate follow-up subsequent to wound healing, including psychological support. Good burns care that helps to alleviate physical discomfort, pain and scarring, and that promotes good wound healing will also provide psychological benefits for the patient. Healed wounds should be moisturized on a regular basis. Pruritus can be a major problem after burn injury. To reduce itching, moisturizers can be applied, and oral

antihistamines may be necessary.¹²¹ Protection from the sun will help to prevent further thermal damage or pigmentation changes to the affected area. Patients in this population should avoid the sun following a burn injury whenever possible, and

use of a sunscreen with SPF of at least 25 is recommended.¹²² If surface changes occur (e.g. skin becomes hypertrophic, or blisters or new wounds appear), the patient should be advised to return for evaluation.

Gout is a disease that most commonly manifests as recurrent episodes of acute joint pain and inflammation secondary to the deposition of monosodium urate (MSU) crystals in the synovial fluid and lining. MSU deposition in the urinary tract can cause urolithiasis and urinary obstruction.¹ Patients with gout cycle between flares of acute joint pain and inflammation and intercritical gout (i.e., periods of quiescence with no symptoms of the disease). In addition, they can also develop chronic tophaceous gout and hyperuricemia. (Tophi are hard nodules of MSU crystals that have deposited in soft tissues and are most commonly found in the toes, fingers, and elbows.) Although gout is often associated with hyperuricemia, elevated serum uric acid (SUA) is not a prerequisite for this painful condition.² Hence, *gout* should be considered as a clinical diagnosis and *hyperuricemia* as a biochemical one.

These two terms are not synonymous and are not interchangeable.

PATHOPHYSIOLOGY**Uric Acid Disposition**

Uric acid serves no biological function; it is merely the end product of purine metabolism. Unlike animals, humans lack the enzyme uricase, which degrades uric acid into more soluble products for excretion. As a consequence, uric acid is not metabolized in humans and primarily is excreted renally, although up to one third of the daily uric acid produced can be eliminated through the gastrointestinal (GI) tract.^{3,4} Increased SUA concentrations, therefore, can result from an increase in

production or a decrease in renal excretion of uric acid, or a combination of these two mechanisms.

Overproduction

Overproduction of uric acid, accounting for about 10% of gout cases,³ can result from excessive *de novo* purine synthesis, which is associated primarily with rare genetic enzyme mutation defects; neoplastic diseases (e.g., multiple myeloma, leukemias, lymphomas, Hodgkin disease); and myeloproliferative disorders (e.g., myeloid metaplasia, polycythemia vera). Aggressive cytotoxic chemotherapy can cause tumor lysis syndrome and increased uric acid production from increased nucleoprotein turnover. Overproduction of uric acid can also be the result of excessive intake of dietary purines from meat, seafood, dried peas and beans, certain vegetables (e.g., mushrooms, spinach, asparagus), beer, and other alcoholic beverages.^{5,6} Many patients attempt to avoid intake of these foods; however, dietary restrictions are seldom of much benefit (with the exception of avoiding excessive alcohol, yeast, or liver supplements), and patients should feel comfortable in eating “modest” quantities of meats, seafood, and vegetables.

Underexcretion

A defect in the renal clearance of uric acid is the main cause of hyperuricemia and gout in about 90% of patients. Uric acid is filtered in the renal glomerulus and is almost completely (98%–100%) reabsorbed in the proximal tubule. Uric acid is then secreted distal to the proximal tubular reabsorption site, and most is reabsorbed again.^{2,3} In normal patients, homeostasis between reabsorption and secretion of urate is maintained. However, many factors (e.g., renal impairment, certain drugs, alcohol excess, metabolic syndrome, hypertension [HTN], cardiovascular disease [CVD]) can cause this balance to fail, resulting in excess serum concentrations of uric acid and tissue deposition.^{4,7}

ACUTE GOUT

Epidemiology

The risk of gouty arthritis is approximately the same for both men and women at any given SUA concentration; however, many more men are hyperuricemic. For example, men are six times more likely than women to have SUA concentrations >7 mg/dL. Overall, gout occurs as often in postmenopausal elderly women as in men.⁸

Classically, gout presents during middle age; in one study, the average age at the time of the first attack was 48 years.⁹ The onset of gout is uncommon in prepubertal children, premenopausal women, and men younger than 30 years of age. The appearance of gout in these populations should alert the clinician to the possibility of a renal parenchymal disease, which decreases urate clearance, or to a genetic enzymatic defect that is associated with increased *de novo* purine production.

Clinical Features

1. E.J., a 52-year-old male school bus driver, reports to the emergency department of his local hospital with the primary complaint of extreme pain in his right elbow. He admits to playing several tennis matches yesterday followed by a few beers with friends.

He awoke in the early hours of the morning with a sore and stiff elbow, which he self-medicated with acetaminophen before trying to get back to sleep. When his pain escalated, he sought medical attention. Pertinent medical history includes the recent diagnoses of HTN, hyperlipidemia, impaired fasting glucose, and obesity. E.J. has not had regular medical care since graduating from high school, and only recently started seeing a primary care physician at the urging of his wife after his father died of an ischemic stroke. At that visit 1 month ago, E.J. was prescribed hydrochlorothiazide 12.5 mg once daily, which is his only medication. He was also encouraged to go on a diet and to increase his exercise. He states that he has no drug or food allergies and is tolerating the antihypertensive well. On physical examination, the right elbow is exquisitely tender and erythematous, and his vital signs are all within normal limits. The elbow is warm to the touch and has moderate swelling. What information in this case leads you to a consideration of gout as an explanation for E.J.'s elbow pain?

First, E.J.'s symptoms of severe, acute pain and an obviously inflamed joint are consistent with the usual presentation of gout. Next, epidemiologically, E.J.'s gender and age are consistent with the epidemiological data that are commonly associated with gout.

Pain

The pain of gout rapidly reaches its maximum within 6 to 12 hours of onset and is usually accompanied by erythema.¹⁰ It is often so severe that patients cannot even tolerate a sheet lying on top of the affected area. E.J.'s symptoms are consistent with this description.

Number and Type of Joints

Acute gout attacks affect a single joint 85% to 90% of the time, and most often affect a joint of the lower extremity.³ The first metatarsophalangeal joint (the great toe) is the most common joint affected and the term, *podagra*, specifically refers to gout in this joint. In a study of dietary intake and the occurrence of gout in North American men, 88% of those reporting gout episodes experienced podagra.⁶ An explanation for the predilection of the great toe to acute gouty arthritic attacks is based on the premise of a transient local increase in the concentration of monosodium urate in this joint, as well as lower body temperature in the extremities.¹¹ Because urate diffuses more slowly than water across a synovial membrane, resorption of synovial effusion from traumatic joints when the patient is in a recumbent position increases the urate concentration within a joint.^{12,13} Synovial effusions are also increased in the great toe during the day because of degenerative changes in that joint: the first metatarsophalangeal joint is the most common and often the only joint affected in degenerative joint disease of the foot. This tendency for degenerative changes in the big toe appears less often in non-European and non-North American populations as compared to Western societies and perhaps can be attributed to differences in traditional footwear, climate, and other variables associated with gout.¹⁴

Although initial gout attacks are primarily monoarticular, as many as 39% of the patients in one study experienced polyarticular involvement as their first manifestation of gout.¹⁵ Generally, recurrent attacks are of longer duration than first attacks, more likely to be polyarticular, and more smoldering in onset.¹⁶ Gout presenting initially in an elbow joint is much

less common than podagra, but it certainly can occur³ and does not rule out gout as a diagnosis for E.J.'s pain.

Nocturnal Occurrence

Acute gouty arthritis commonly begins at night. Thomas Sydenham's 18th-century classic description of an acute gouty attack begins, "The victim goes to bed and sleeps in good health. About two o'clock in the morning he is awakened by a severe pain in the great toe; more rarely in the heel, ankle, or instep."¹¹ According to the Simkin hypothesis,¹¹ small amounts of effusion fluid gravitationally enter into degenerative joints of the feet (or other joints) during the day, when most people are busily walking around, and are reabsorbed during the night when the lower extremities are elevated. Thus, the onset of pain in E.J. during the night is typical of gout.

Physical Stress

Gouty attacks also seem to be more common during episodes of increased physical exercise. Long walks, hikes, golf games, or tight new shoes have historically been associated with the subsequent onset of podagra.¹¹ Thus, this acute episode of elbow pain experienced by E.J. after a tennis match is compatible with the association of gout with increased physical exercise.

Risk Factors

2. What findings in the previous case put E.J. at risk for gout?

The recent diagnoses of HTN, dyslipidemia, impaired fasting glucose, and obesity in E.J. are disorders that have all been associated with gout and hyperuricemia.⁷

Metabolic Syndrome

E.J.'s recent diagnoses fulfill the criteria for *metabolic syndrome*, and it is well-known that this set of diseases increases the risk for CVD. Interestingly, hyperuricemia is often present in patients who have these diseases as well, so does that mean hyperuricemia is a risk factor for CVD? Although this relationship is strong, causality is controversial. Even though the Framingham study group found that the presence of gout was a risk for CVD in men, it is likely that this is just a marker for CVD rather than a trigger.¹⁸ In other studies, hyperuricemia was noted to be an independent risk factor for CVD and unlikely to be a cause of CVD.¹⁹ Impaired glucose utilization, often called "insulin resistance syndrome," also has a relationship with hyperuricemia. This may be mediated via reduced renal excretion of sodium and urate in hyperinsulinemia, although the complete mechanism has not been fully elucidated.²⁰ Because of these close linkages, patients who present with gout and/or hyperuricemia should be monitored closely for the development of CVD and diabetes, even if currently well.

Renal Dysfunction

Uric acid excretion is decreased in patients with renal dysfunction due to decreased glomerular filtration, and as a consequence, hyperuricemia is a common finding. The hyperuricemia does not need to be treated unless patients manifest gouty arthritis.²¹ E.J.'s workup for his sore elbow and possible gout should include a metabolic panel for blood urea nitrogen (BUN), serum creatinine (SCr), and electrolytes to clarify the status of his renal function.

Ethanol Consumption

Overindulgence of alcohol has been linked to acute gout attacks. In one case-control study, the weekly intake of alcohol was more than doubled in patients with gout compared to matched controls without gout.²² Ethanol-induced gout/hyperuricemia has been attributed to reduced renal urate excretion when acute alcohol intake causes lactic acidosis, degradation of the purines in beer and other alcoholic beverages increases uric acid production, and possible lead exposure from moonshine whiskey or port wine.²⁰ E.J.'s intake of a "few beers" after playing in a rigorous tennis tournament, when combined with possible dehydration from vigorous exercise and lactic acidemia from muscle energy expenditure, place the diagnosis of an acute gout attack near the top of the list of possible causes for his elbow pain and inflammation.

Lead Exposure

Chronic lead exposure is associated with renal dysfunction. Patients with renal dysfunction and concurrent gout have higher lead levels than gouty patients with normal renal function.²³ Unexpectedly, the serum concentrations of lead in healthy subjects with no known lead exposure were noted to be higher (albeit within normal limits) in those with gout than those without gout.²⁴ Lead exposure, however, is not a likely risk factor for gout for E.J.

Diagnosis

3. What objective data would be of value in assisting in the diagnosis of E.J.'s elbow pain and inflammation?

Laboratory Tests

Because uric acid primarily is excreted renally and renal impairment is a risk factor for gout, the serum concentrations of E.J.'s BUN and SCr should be measured along with a serum uric acid concentration, especially in light of his history of HTN, hydrochlorothiazide therapy, hyperlipidemia, and impaired glucose tolerance. A subsequent urinalysis could also be evaluated for proteinuria and glucose if his laboratory blood tests demonstrate that further workup might be warranted. Although infection, in particular, *septic arthritis*, could also present as sudden onset of joint pain and inflammation, it is not likely in this case. An elevated systemic white blood cell (WBC) count would be consistent with infection or gout. If joint infection is of genuine concern, synovial fluid aspiration could differentiate between infection and gout.

Radiography

Radiographic findings during the early phase of gout are non-specific and generally characterized by asymmetric soft tissue swelling overlying the involved joint. When gout has been long standing, bony changes can be noticed on x-ray, along with calcium deposition and increased density in the areas of soft tissue swelling.²⁵ An x-ray of E.J.'s elbow should be obtained if other *musculoskeletal disorders* (e.g., bone fracture) are likely; however, the history and physical examination of E.J. do not provide adequate support for an x-ray at this juncture.

Joint Fluid Aspiration

A definitive diagnosis of gout only can be established by finding MSU crystals in the aspirated synovial fluid of the affected

joint. The absence, however, of MSU crystals in the synovial fluid does not rule out the diagnosis of gout. In one study, when synovial fluid was aspirated from the knees of 50 patients with asymptomatic, nontophaceous gout (synovial fluid monosodium urate crystals had been previously documented in the knees or other joints of these patients), urate crystals were only found in 58% of these asymptomatic patients.²⁶ Urate crystals, however, can be found on repeated search of other involved joints,²⁷ or even of the same joint a few hours later.^{28,29} If synovial fluid is aspirated from an inflamed joint, it should also be analyzed for bacteria and a WBC count obtained. In gouty arthritis, the WBC count is likely to range from 5,000 to 50,000/L.² In septic arthritis, the WBC count of the synovial fluid is usually >50,000/L, and a Gram stain of the synovial fluid is often positive for bacteria.³⁰ In clinical practice, primary care providers generally do not aspirate an inflamed joint to diagnose gout (see Criteria for Diagnosis section).

Pseudogout

Deposition of microcrystals (i.e., calcium pyrophosphate, calcium oxalate, calcium hydroxyapatite) into joints can cause acute or chronic arthritis in a manner similar to that caused by monosodium urate deposition.³¹ The role of these microcrystals in causing acute synovitis has been greater than previously expected because improved crystallographic technology (e.g., electron microscopy, x-ray diffraction) can differentiate these diagnoses from that of acute gout. Crystal-induced diseases tend to occur in older patients because prior joint disease, especially osteoarthritis (which is generally a disease of the elderly), predisposes them to crystal deposition and acute episodes of joint inflammation. The elderly are also more prone to microcrystal-induced arthritis because these crystals generally accumulate over a long period, and must attain a sufficient concentration and size before they precipitate into the synovial fluid and cause inflammation.³²

Criteria for Diagnosis

According to the American College of Rheumatology (ACR), only 6 of the 12 criteria listed in Table 42-1 (derived from a 1977 report)³³ need to be present to confirm a diagnosis of gout when synovial fluid has not been aspirated from an inflamed

Table 42-1 Criteria for Diagnosis of Gout (at least six criteria are needed for diagnosis unless MSU crystals are present in joint fluid aspirate)

1. More than one acute attack of arthritis
2. Attack of monoarticular arthritis
3. Joint inflammation maximal within 1 day
4. Negative synovial joint fluid culture
5. Erythema over involved joint(s)
6. Podagra (first metatarsophalangeal joint)
7. Unilateral podagra
8. Unilateral attack involving tarsal joint
9. Tophi
10. Hyperuricemia
11. Asymmetric swelling within a joint on radiograph
12. Subcortical cysts without erosions on radiograph

Adapted from reference 3.

Table 42-2 EULAR Propositions for Diagnosis of Gout

| Recommendation | SOR (%) |
|---|---------|
| 1. In acute attacks, the rapid development of acute pain, swelling, and tenderness that reaches peak intensity within 6–12 hours, especially with overlying erythema, highly suggest crystal inflammation (although not specific for gout). | 88 |
| 2. For typical presentations of gout (e.g., recurrent podagra with hyperuricemia), a clinical diagnosis alone is reasonably accurate, but not definitive without crystal confirmation. | 95 |
| 3. Demonstration of MSU crystals in synovial fluid or a tophus permits a definitive diagnosis of gout. | 96 |
| 4. A routine search for MSU crystals is recommended in all synovial fluid samples obtained from undiagnosed joints. | 90 |
| 5. Identification of MSU crystals from asymptomatic joints may allow for definite diagnosis in intercritical gout. | 84 |
| 6. Gout and sepsis can coexist. When septic arthritis is suspected, synovial fluid should be Gram stained and cultured for bacteria even if MSU crystals are identified. | 93 |
| 7. Serum uric acid concentrations, although the most important risk factor for gout, do not confirm or exclude gout. Many with hyperuricemia do not develop gout, and serum uric acid concentrations during acute attacks can be normal. | 95 |
| 8. Renal uric acid excretion should be assessed in selected gout patients, especially those with a family history of young-onset gout, onset of gout at younger than 25 years, or those with renal calculi. | 72 |
| 9. Although radiographs can be useful for differential diagnosis and can show typical features of chronic gout, they are not useful in confirming the diagnosis of early or acute gout. | 86 |
| 10. Risk factors for gout and comorbidity should be assessed, including features of the metabolic syndrome (obesity, hyperglycemia, hyperlipidemia, hypertension). | 93 |

SOR, strength of recommendation.

Adapted from reference 10.

joint. Routine synovial fluid aspirates are not obtained by most practitioners due to the technical expertise required for obtaining and analyzing the specimen, as well as the pain to the patient, during the procedure. Newer evidence-based guidelines for the diagnosis (Table 42-2) and management (Table 42-3) of gout have been developed by the European League Against Rheumatism (EULAR) using the Delphi method of expert consensus to determine standard of care.^{10,34} The experts' consensus of the strength of a recommendation is listed as a percentage of concurrence in the right-hand columns of Tables 42-2 and 42-3.

4. Laboratory tests were ordered for E.J., and the results are SUA of 7.5 mg/dL, BUN of 10 mg/dL, SCr of 1 mg/dL, and a WBC count of $10.2 \times 10^3/\text{mm}^3$. An x-ray of his elbow shows soft tissue swelling with no evidence of tophi. Does E.J. have gout?

E.J.'s objective and clinical presentation fulfills five of the ACR criteria (i.e., 2, 3, 5, 10, 11) in Table 42-1; however, at least 6 of the 12 criteria must be met to achieve a diagnosis of gout. According to the EULAR propositions (Table 42-2), criteria 1 and 7 are met and consistent with, but not diagnostic

Table 42-3 EULAR Propositions for Gout Management

| Propositions | SOR (%) |
|---|---------|
| 1. Optimal treatment of gout requires nonpharmacologic and pharmacologic modalities tailored to specific risk factors (SUA levels, prior attacks); clinical phase of gout; and general risk factors (age, comorbidity, drug interactions) | 96 |
| 2. Patient education and lifestyle modifications (e.g., weight loss if obese, reduced beer and other alcohol consumption) are important. | 95 |
| 3. Associated comorbidity and risk factors (e.g., hyperlipidemia, HTN, hyperglycemia, obesity, smoking) should be addressed. | 91 |
| 4. Oral NSAIDs or colchicine are first-line agents for systemic treatment of acute gout. In the absence of contraindications, an NSAID is a convenient and well accepted treatment. | 94 |
| 5. High doses of colchicine cause side effects and low doses (e.g., 0.5 mg TID) can be sufficient. | 83 |
| 6. Intra-articular aspiration and injection of a long-acting steroid is an effective and safe treatment for an acute attack. | 80 |
| 7. Urate lowering therapy is indicated in patients with recurrent acute attacks, arthropathy, tophi, or radiographic changes of gout. | 97 |
| 8. The therapeutic goal of urate lowering (i.e., SUA less than the saturation point for MSU of 6 mg/dL) is to promote crystal dissolution and prevent crystal formation. | 91 |
| 9. Allopurinol, an appropriate long-term urate-lowering agent, should be initiated at 100 mg/day and increased by 100 mg every 2–4 weeks, if required. The dose must be adjusted in patients with renal impairment. If toxicity occurs, options include other xanthine oxidase inhibitors, a uricosuric agent, or allopurinol desensitization (in mild rash). | 91 |
| 10. Uricosuric agents (e.g., probenecid, sulfinpyrazone) can be alternatives to allopurinol in patients with normal renal function, but relatively contraindicated in patients with urolithiasis. Benzbromarone can be used in patients with moderate renal insufficiency, but carries a small risk of hepatotoxicity. | 87 |
| 11. Prophylaxis against acute attacks during the first months of urate lowering therapy can be achieved by colchicine (0.5–1 mg/day) and/or NSAID (with gastroprotection, if indicated). | 90 |
| 12. When gout is associated with diuretic therapy, discontinue the diuretic if possible. | 88 |

SOR, strength of recommendation.

Adapted from reference 34.

Treatment of Acute Gout

Goals of Therapy

5. What is the primary goal in the treatment of this acute gout attack in E.J.?

The primary goal in the treatment of an acute attack of gout is to relieve pain and inflammation. The immediate goal of therapy should not be aimed at decreasing the SUA concentration with hypouricemic agents such as allopurinol (Zyloprim) or probenecid (Benemid). Patients most likely have been hyperuricemic for several months or years, and it is not necessary to treat the hyperuricemia immediately. Furthermore, a decrease in the serum urate concentration at this time might mobilize urate stores and precipitate yet another acute gouty attack.

Drug Therapy Overview

6. What are the pharmacotherapeutic options for the treatment of E.J.'s acute pain?

Acute gouty arthritis can be effectively treated in most instances by a nonsteroidal anti-inflammatory drug (NSAID), colchicine, or corticosteroids.

NONSTEROIDAL ANTI-INFLAMMATORY DRUGS

Indomethacin (Indocin), naproxen (Naprosyn), and sulindac (Clinoril) are U.S. Food and Drug Administration (FDA)-approved for the treatment of pain associated with acute gout attacks,^{35–37} but other nonselective NSAIDs are also effective, including ibuprofen (Motrin),³⁸ fenoprofen (Nalfon),³⁹ piroxicam (Feldene),^{40,41} fluribiprofen (Ansaid),⁴² ketoprofen (Orudis),⁴³ tolmetin (Tolectin),⁴⁴ and meclufenamate (Meclomen).⁴⁵ GI bleeding and/or ulceration and inhibition of platelet aggregation are two of the most common serious adverse effects of these nonselective NSAIDs, and both adverse effects compound the risk of bleeding when given concomitantly with anticoagulants (e.g., warfarin). The NSAIDs, which are selective cyclo-oxygenase-2 (COX-2) inhibitors, do not inhibit platelets at normal doses; however, the efficacy of celecoxib (Celebrex), the only COX-2 inhibitor currently available in the United States, has not been evaluated for the treatment of gout. Etoricoxib, a COX-2 inhibitor available outside the United States, has been approved for the treatment of acute gouty arthritis in New Zealand.^{46,47} Among the nonselective NSAIDs, ibuprofen is the least likely to cause GI adverse effects and is perhaps the safest nonselective NSAID for use in patients at risk for GI bleeding. Piroxicam and indomethacin are among the worst offenders.⁴⁸

The potential adverse cardiovascular effects of NSAIDs are of concern. In 2005, the FDA issued an advisory requiring all manufacturers of over-the-counter and prescription NSAIDs to alert patients and health care professionals to increased cardiovascular risks (e.g., myocardial infarction, stroke) from selective and nonselective COX-2 inhibitors.⁴⁹ NSAIDs can also aggravate HTN, cause renal failure by inhibiting vasodilatory renal prostaglandins, inhibit diuretic-induced increases in renal sodium excretion^{50–53}, and decrease the hypotensive effect of diuretics and other antihypertensive drugs (e.g., beta-blockers).^{54,55} Although hypertensive patients are not likely to experience problems when using NSAIDs for only a few

of, gout. An important difference between the EULAR guidelines and those of the ACR is the emphasis on synovial fluid examination. Item 2 indicates that only “typical” gout presentations such as podagra can be accurately diagnosed without examination of the synovial fluid, and E.J.’s elbow involvement is an atypical presentation. An aspiration of synovial fluid from the inflamed elbow joint fluid would help diagnose gout and rule out infection, although both gout and infection could coexist. Although E.J. is reluctant to undergo this procedure, he relents, and his aspirate is positive for 25,000 WBC/L and for MSU crystals. E.J. now can be considered as having acute gout.

days, three isolated cases of hyperkalemia and renal insufficiency have occurred after indomethacin treatment of gouty arthritis.⁵⁶ Patients with CVD and renal insufficiency can be treated for a short duration with nonselective NSAIDs, albeit with much caution. The nonselective NSAIDs are safe for patients with stable, controlled HTN when given for only a few days and with closer monitoring of blood pressure.

CORTICOSTEROIDS

Corticosteroids, effective in the management of an acute gouty attack, are usually considered second-line therapy because of the potential for serious adverse effects and adrenal suppression when used long term and because of the potential for rebound pain when abruptly discontinued.^{2,57} If the acute gout episode involves only one or two joints, intra-articular corticosteroid administration could minimize adverse effects. When corticosteroid oral doses equivalent to 30 to 60 mg of prednisone/day are used, doses are tapered over 2 to 3 weeks to minimize the potential for rebound.² Corticosteroids are especially useful for elderly patients or those with renal or CVD who cannot tolerate NSAIDs.^{2,34,57} Corticosteroid adverse effects (e.g., osteoporosis, myopathy, peptic ulcer disease, central nervous system effects, HTN, predisposition to infections) are not likely with the short courses of treatment for gout attacks. Glucose intolerance, however, can occur with short-term therapy.

COLCHICINE

At one time, colchicine was the agent of choice for the treatment of an acute attack of gout. This drug not only provided symptomatic relief to more than 95% of patients when administered early in the course of an attack of gout, but it also provided diagnostic confirmation because of its relative specificity for relieving only the symptoms of acute gout. Colchicine's mechanism of action is quite unique because it is an inhibitor of microtubule polymerization, which results in inhibition of inflammatory mediators such as cytokines and chemokines.⁵⁸ It is only indicated for the treatment of gout.⁵⁹ For the fully developed acute attack, the traditional dose of colchicine has been one or two 0.5- to 0.6-mg tablets initially (only 0.6-mg tablets are available in the United States today), followed by 0.5 to 0.6 mg hourly or every other hour, until joint pain was relieved or GI effects (i.e., diarrhea, nausea, vomiting) intervened. A colchicine 0.5-mg (or 0.6-mg) TID regimen until symptoms resolve has been successful in treating patients who do not respond to, or cannot use, NSAIDs or corticosteroids.^{34,60} The dose of colchicine must not exceed 6 mg/gout episode because of significant adverse effects and a narrow therapeutic index.

INTRAVENOUS COLCHICINE

Colchicine is available for intravenous (IV) injection for patients who cannot tolerate oral colchicine, but IV colchicine for *acute gout* is no longer recommended because of a potential for bone marrow suppression, myocardial injury, muscle paralysis, acute organ failure, and fatalities.⁵⁷ The usual initial colchicine IV dose of 2 mg is instilled slowly over 2 to 5 minutes directly into a large vein that has normal saline infusing. It must not be administered subcutaneously or intramuscularly because it can cause extensive tissue necrosis, and caution must

be undertaken with IV infusions to prevent extravasation into surrounding tissue. An IV dose of 0.5 mg can be repeated every 6 hours until relief of pain, but no more than 4 mg per 24 hours or 4 mg per acute episode of gout.

OPIATE ANALGESICS

When an occasional patient requires more pain control, a dose or two of a narcotic analgesic can be a reasonable adjunct to blunt the pain of acute gouty arthritis while awaiting the apparent benefits of NSAIDs or corticosteroids. Most patients, however, generally experience benefits from NSAIDs and corticosteroids soon after a dose of either of these anti-inflammatory drugs.

Choice of Agent

7. What therapeutic intervention would be most appropriate for E.J. at this time?

An NSAID is first-line therapy for the acute treatment of gout, and although E.J. does have HTN and metabolic syndrome, his renal function is normal. Assuming his blood pressure is adequately controlled, a short course of ibuprofen 800 mg now and Q 8 hr for 3 days is appropriate. The ibuprofen should be prescribed on a scheduled basis rather than “as needed” to reduce inflammation and prevent breakthrough pain. The dose of 2,400 mg/day does not exceed the maximum recommended dose of 3,200 mg/day.

8. If E.J. were 72-years-old instead of 52 and/or his BP was 160/96 mm Hg, what therapeutic option would be appropriate?

These patient-specific parameters are relative contraindications or precautions for the use of NSAIDs for the treatment of acute gout so alternative treatments should be considered. Because E.J.'s pain is monoarticular (his elbow), an intra-articular dose of corticosteroid could be administered, but the possibility of bone necrosis from intra-articular corticosteroids would probably result in the choice of oral prednisone, which could be administered and tapered over 10 to 21 days. As an alternative, oral colchicine could be considered. IV colchicine should not be considered, and if E.J. were unable to tolerate oral therapies, then parenteral or intra-articular corticosteroids should be administered.

Management Guidelines

Gout is one of few rheumatologic diseases that can be treated successfully and even cured in many patients.⁶¹ However, despite the availability of adequate pharmacologic interventions, a survey of rheumatologists and internists in the United States found that drug therapy is often not used based on scientific evidence for both acute and chronic gout.⁶² Furthermore, in a survey of Chinese physicians, most agreed that synovial fluid aspiration from a joint in a search for crystals should be performed for a definitive diagnosis, but such joint aspiration was rarely undertaken. A comparable survey of physicians in the United States might reach similar conclusions. Also, oral colchicine was considered first-line therapy by 77% of physicians in China, which is contrary to current management guidelines.⁶³ In consideration of these issues, the EULAR gout task force developed recommendations for the management of

gout (Table 42-3) and the percentage consensus for a given recommendation.³⁴

Nonpharmacologic Interventions

ICE

The benefit of ice application to the affected joint in acute gouty arthritis should not be overlooked. In a small randomized study, the application of ice to an affected joint significantly reduced the pain of a gouty attack when used in conjunction with oral steroids or colchicine.⁶⁴

ALCOHOL CONSUMPTION

Excessive alcohol intake has been known to be a risk factor for acute gout episodes since the time of Hippocrates⁵; however, lead was also a contributory factor when it was used as a flavoring agent for wine in early Roman times. Beer was also believed to be more problematic for gout than other alcoholic beverages because of its high purine content; however, current thinking is that the quantity of alcohol consumed in the 24 hours prior to an acute attack is more important than the type of beverage consumed.⁶⁵ Moderation in alcohol consumption should be advocated.

DIET MODIFICATION

Diet has a twofold effect on the epidemiology of gout. First, obese patients are at a greater risk of developing elevated SUA levels, and gout might, in part, be related to insulin resistance of obesity.⁵ Weight reduction via a caloric- and carbohydrate-restricted diet has been associated with decreased SUA and frequency of gout attacks.⁶⁶ Furthermore, in a prospective, longitudinal study of male health professionals, weight gain was strongly associated with an increased risk of gout, and weight loss was associated with a decreased risk.⁶⁷

Second, much of the uric acid produced daily comes from metabolism of food. The excessive dietary intake of purine-rich foods, without a concomitant increase in urinary excretion, can lead to elevated serum urate concentrations.^{5,6} However, the type of protein and purine-rich foods that are detrimental, and the true impact of these foods on the incidence of increased SUA and gout episodes, are controversial issues.^{68,69} Using the NHANES-III survey (Third National Health and Nutrition Examination Survey) data, diets rich in dairy protein were noted to be helpful in preventing elevated SUA levels, while diets high in meat and seafood were detrimental.⁶⁸ Interestingly, in that survey, the type of protein was more important than the total protein intake. The more yogurt or milk servings consumed per day, the lower the SUA.

Delay of Hypouricemic Therapy

9. Why should (or should not) allopurinol be prescribed for E.J. before he leaves the emergency department?

Hypouricemic therapy should be initiated only when patients with gout have frequent acute attacks, urate tophi, or evidence of urate nephropathy (e.g., uric acid stones or renal damage). If these indications are absent, hypouricemic drug therapy should await the natural course of events because nothing is lost by waiting. The acute attack can be treated when it appears and usually resolves within days. Long-term hypouricemic medications should not be started for E.J. at this

time because criteria for therapy (see EULAR proposition 7 in Table 42-3) are not met, and initiation of urate-lowering therapy during an acute episode can mobilize urate from tissues and compound the problem. E.J. should not be treated with hypouricemic drugs at this time.

HYPERURICEMIA

Chronic Gout

10. E.J. has experienced about four to five acute gouty arthritis attacks, which were treated successfully with ibuprofen over the past year. His HTN, metabolic syndrome, and obese condition have all improved. On a routine clinic visit, his SUA is 7.5 mg/dL, and his renal function and CBC are normal. Would it be appropriate to initiate hypouricemic therapy at this time?

Drug therapy to lower SUA is warranted for patients who have recurrent gout attacks, arthropathy, tophi, or radiographic changes related to gout (Table 42-3).³⁴ Because E.J. has experienced several episodes of acute gout, hypouricemic therapy consideration is appropriate. The decision to begin hypouricemic therapy, however, should be preceded by a consideration of whether *drug-induced hyperuricemia* could be a mitigating factor.

Drug-Induced Hyperuricemia

A patient's complete medication list should be reviewed to rule out drug-induced hyperuricemia (Table 42-4) before adding a medication to decrease SUA. Perhaps the only treatment needed would be to discontinue the offending agent. Until recently, the mechanisms by which many drugs induce hyperuricemia were unknown. A urate transporter, URAT-1, is now believed to be the primary protein responsible for reabsorption of urate into the systemic circulation from the lumen of the proximal tubule of the nephron.⁷⁰ URAT-1 also appears to be the site at which some drugs (e.g., losartan, probenecid) inhibit urate reabsorption, and where other drugs (e.g., pyrazinamide, nicotinic acid) stimulate urate reabsorption and, thereby, increase SUA.² As the role of URAT-1 and other transporters are better understood, new drug therapies may be discovered.

DIURETICS

The association of hyperuricemia and diuretics is well known, and the mechanism, although not fully elucidated, is likely secondary to diuretic-induced sodium and water excretion, which in turn increases reabsorption of uric acid in the proximal tubule.⁷¹ The importance of diuretic-induced hyperuricemia, however, is now somewhat more controversial. When variables in addition to diuretic use were controlled in a study of patients with HTN, heart failure, and myocardial infarction, the risk of gout was increased in the hypertensive patients more than the risk of gout in patients on diuretics.⁷² In a case crossover survey, however, thiazides and loop diuretic use in the 48 hours before an acute gout attack had increased their risk for this attack.⁷³ Although diuretics increase SUA concentrations, the antioxidant properties of uric acid could be beneficial and perhaps sufficient to account for their favorable outcomes in the ALLHAT study.⁷⁴ Because diuretics are associated with hyperuricemia in both hypertensive and nonhypertensive patients, and because hyperuricemia has an association with acute gout

Table 42-4 Drugs Associated With Hyperuricemia

| <i>Drug</i> | <i>Mechanism</i> | <i>Comments</i> |
|--|---|---|
| Certain antiretrovirals ^{121–125} | Catabolic effect; NRTIs may increase urate through mitochondrial toxicity | NRTIs: Uric acid blood increases of 0.5–5 mg/dL have occurred in patients receiving >9.6 mg/kg/day of didanosine. Stavudine also was associated with increased uric acid. PIs: Have been associated with elevated uric acid. Ritonavir and ritonavir boosting have been associated with gout. |
| Cyclosporine ^{126,127} | Decreased urate renal clearance, either via a tubular mechanism or decrease in GFR | Cyclosporine-induced hyperuricemia may cause gout in patients with risk factors (renal dysfunction, concurrent diuretics, and male gender). |
| Cytotoxic chemotherapy ⁸⁵ | Rapid cell lysis | Occurs primarily with lymphomas and leukemias. Uric acid nephropathy, acute renal failure, and nephrolithiasis can result. |
| Diuretics ^{128–132} | Secondary to volume contraction and increased uric acid reabsorption in the proximal tubules for all diuretics; thiazides may also competitively inhibit proximal tubular secretion | Dose- and duration-dependent elevations in uric acid |
| Ethambutol ¹³³ | Decreased urate renal clearance | Hyperuricemia and gout have been demonstrated. A majority of patients were receiving 20 mg/kg/day orally. |
| Ethanol ^{65,134} | Increased uric acid production due to adenine nucleotide turnover, lead-tainted moonshine and/or high purine content in some alcoholic beverages, such as beer | Associated with increased uric acid and acute gout. Even a light-to-moderate amount triggers recurrent gout attacks within 24 hours. |
| Filgrastim ¹³⁵ | Increased WBC production | Transient effect, seen more often with higher doses (30–60 mg/kg/day). |
| Isotretinoin ¹³⁶ | Hypervitaminosis A | Hyperuricemia and rare gout cases have been reported. |
| Levodopa ¹³⁷ | Inhibition of urate excretion | Patients taking therapeutic doses have experienced hyperuricemia and gout. Secondly, interference with colorimetric assay of uric acid may contribute a false-positive increment. |
| Niacin ^{138,139} | Decreases excretion of urate | Hyperuricemia and gout have occurred. |
| Pancreatic enzymes: pancreatin and pancrelipase ¹⁴⁰ | Ingestion of pancreatic enzyme products having high purine content. | Hyperuricemia, hyperuricosuria, and uric acid crystalluria have occurred with high dosages. |
| Pyrazinamide ^{141,142} | Inhibition of renal tubular urate secretion | Hyperuricemia is more common with daily than with intermittent administration. Gouty attacks have occurred in those with a history of gout. Asymptomatic hyperuricemia was the only manifestation seen in one trial of pediatric patients. |
| Ribavirin and interferon ¹⁴³ | Mechanism unclear; commonly associated with hemolysis | Nephrolithiasis developed in a patient with diabetes and hypertension. Hyperuricemia noted in 24% of those receiving ribavirin with interferon. |
| Aspirin (low dose) ⁸⁷ | Inhibition of proximal tubular secretion of urate | Doses <1 g/day cause hyperuricemia. |
| Tacrolimus ^{144,145} | Reduced urate excretion | Associated with hyperuricemia and cases of gout; however, two prior case reports demonstrated resolution of polyarticular gout after switching cyclosporine to tacrolimus. |
| Teriparatide ¹⁴⁶ | Mechanism unknown | Elevated uric acid levels, mainly with higher doses and with moderate renal impairment, but no association with increased gout, arthralgia or nephrolithiasis. |
| Theophylline ^{147,148} | Interference with uric acid assay | False-positive elevation with automated Bittner adapted method. Interference does not appear to occur with phosphotungstate assay method. |

NRTI, nucleoside reverse transcriptase inhibitors; PI, protease inhibitors; GFR, glomerular filtration rate; WBC, white blood cell.

attacks, most clinicians would discontinue the diuretic, irrespective of possible ancillary benefits from hyperuricemia if alternatives to the diuretics are available and appropriate for a particular patient.³⁴ The hyperuricemic effect of diuretics is dose related.⁷⁵

Goal of Hypouricemic Therapy

The general goals for lowering serum concentrations of uric acid are the elimination of acute gout attacks and the mobilization of urate crystals from soft tissue. The SUA concentration in a patient who has clinical gout should be decreased to

<6 mg/dL, which is below the saturation point for monosodium urate (NB: a 1 mg/dL change in SUA is equivalent to about 60 μ mol/L SI units).³⁴

Uric Acid Urine Quantification

Urinary uric acid excretion can be determined by measuring a 24-hour collection of urine to ascertain whether the patient overproduces or underexcretes uric acid. In theory, an “over-producer” should be treated with a drug that inhibits production of uric acid (e.g., xanthine oxidase inhibitors), and an “underexcretor” should be treated with a drug that increases excretion of uric acid. Because both groups of patients usually respond to xanthine oxidase inhibitors, drugs such as allopurinol have become the first-line agents for the treatment of hyperuricemia. Alternatively, urinary uric acid overproducers can be identified by use of uric acid:creatinine (or creatinine clearance [Cl_{Cr}]) ratios based on spot-midmorning serum and urine samples.^{76,77}

Drug Therapy of Hyperuricemia

XANTHINE OXIDASE INHIBITORS

Allopurinol

Allopurinol (Xyloprim), the only available xanthine oxidase inhibitor in the United States, inhibits the production of uric acid and thereby decreases SUA concentrations. As first-line therapy of hyperuricemia, allopurinol should be initiated at a 100 mg once daily dose and the dose increased by 100 mg/day increments every 2 to 4 weeks until the SUA is at the desired goal of <6 mg/dL (Table 42-3). The ability of allopurinol to lower SUA is dose related: the higher the dose of allopurinol, the greater the decrease in uric acid serum concentration. An allopurinol dose of 200 to 300 mg/day is usually needed to normalize hyperuricemia in patients with mild disease and larger doses of 400 to 600 mg/day are needed for those with more severe disease.⁷⁸ Allopurinol doses should be adjusted for patients with renal dysfunction to minimize the potential for toxicity; however, patients with decreased doses might not achieve adequate uric acid suppression if SUA concentrations are not appropriately monitored.⁷⁹ Allopurinol doses for patients with renal insufficiency should be based on recommended guidelines for varying degrees of renal insufficiency, adjusted according to periodic evaluations of SUA concentrations, and appreciated for the increased association of adverse events, including hypersensitivity reactions, in patients with renal dysfunction.

Febuxostat

Febuxostat, a nonpurine xanthine oxidase inhibitor, is currently in Phase III trials and awaiting FDA approval for use in the management of hyperuricemia. Febuxostat is more selective than allopurinol for xanthine oxidase and does not inhibit other enzymes involved in purine and pyrimidine metabolism. In a double-blind, randomized, 52-week multicenter trial, oral febuxostat (80 or 120 mg/day) was significantly more effective than allopurinol (300 mg/day) in decreasing SUA concentrations from >8 mg/dL to an end point of <6 mg/dL.⁸⁰ It is not known if allopurinol would have been more effective if titrated further. Adverse effects were similar across all treatment groups and consisted primarily of mild to moderate diarrhea, headaches, abnormal liver function tests, and joint- or muscle-related nonspecific symptoms. During the first 8

weeks of febuxostat treatment, naproxen or colchicine was provided concurrently as prophylaxis against flares of acute gout attacks. Nevertheless, more patients in the higher-dose febuxostat treatment arm discontinued therapy because of the greater prevalence of gout flares and adverse events. The role of febuxostat for the management of hyperuricemia needs further study.⁸¹

RASBURICASE

Uricase, an enzyme endogenous in many animal species other than humans, converts uric acid to allantoin, which is much more soluble than uric acid and, therefore, more readily excreted into urine. Rasburicase (Elitek), a recombinant urate oxidase enzyme, similarly enhances the solubilized uric acid metabolic product into the urine. It is now approved for the management of hyperuricemia in children who are susceptible to hyperuricemia resulting from chemotherapy and tumor lysis. Rasburicase is especially useful in children with leukemia, lymphoma, or solid tumor malignancies about to undergo cytotoxic therapy. In a multicenter, randomized trial of 52 children with leukemia or lymphoma, IV rasburicase (0.2 mg/kg once daily), during initial chemotherapy, decreased serum urate concentrations more effectively and with a quicker onset of action than oral allopurinol (median doses of 300 mg/day).⁸² The rasburicase dose (0.15 or 0.20 mg/kg) should be infused over a 30-minute period once daily for 5 days for a single course of treatment, and about 4 to 24 hours before the initiation of chemotherapy.⁸³ Rasburicase should be reserved for patients who cannot undertake allopurinol therapy and who are at high risk for tumor lysis syndrome (see Chapter 90). Although it is not currently approved by the FDA for use in adults, rasburicase has been shown to be safe and effective for the prophylaxis or treatment of hyperuricemia in adults with leukemia or lymphoma.^{84,85} This drug is significantly more costly than allopurinol.

Rasburicase is contraindicated (a black box warning in the labeling) for patients with glucose-6-phosphate dehydrogenase deficiency, or a known history of hypersensitivity, anaphylactic, or hemolytic reactions. It also has been associated with fever, neutropenia, respiratory distress, sepsis, and mucositis. This drug can interfere with uric acid assays when a blood sample is left in room temperature and has been associated with spuriously low uric acid serum concentrations in laboratory reports.

URICOSURIC AGENTS

The uricosuric agents, probenecid (Benemid) and sulfipyrazone (Anturane), are alternatives to allopurinol for patients who are unable to tolerate allopurinol (Table 42-3).³⁴ These uricosurics should not be administered to patients with impaired renal function or urolithiasis.

Probenecid

Probenecid is well absorbed orally, and plasma concentrations peak within 2 to 4 hours. Its biological half-life is 6 to 12 hours, and its active metabolites extend the duration of action. The usual initial dose of probenecid (250 mg twice daily for the first week of therapy) can be increased to 500 mg twice a day. If necessary, the dose can be increased further to 2 g/day. Uricosuric therapy should begin with small doses because the excretion of large amounts of uric acid increases the risk of urate stone

formation in the kidney. High fluid intake to maintain urine flow of at least 2 L/day also minimizes renal stone formation. This gradual approach to the initiation of hypouricemic therapy also decreases the likelihood of precipitating an acute attack of gout.

Drug Interactions. Probenecid inhibits secretion of penicillins into the renal tubule, and thereby prolongs the serum half-life of penicillin and increases penicillin serum concentrations. Probenecid can also compete with salicylates for renal tubular transport, but its interactions with salicylates involve several mechanisms.⁸⁶ Two 300-mg tablets of aspirin every 6 hours can completely antagonize the uricosuric effects of 2 g of probenecid. Doses of salicylate that do not produce serum salicylate levels of >5 mg/dL do not significantly affect probenecid uricosuria.⁵⁵ Therefore, low-dose aspirin for cardioprotection is unlikely to interfere with probenecid therapy. Interestingly, high-dose aspirin (e.g., >1 g) has uricosuric activity of its own.⁸⁷ Acetaminophen (Tylenol) and NSAIDs do not interfere with probenecid, and are reliable alternatives for antipyresis and mild analgesia in patients taking uricosuric agents.

Sulfinpyrazone and Benzbromarone

Sulfinpyrazone (Anturane), another effective uricosuric agent, inhibits the tubular secretion of uric acid at low doses and inhibits the tubular reabsorption of uric acid at usual therapeutic doses. As with probenecid, therapy should be initiated slowly and the dose increased gradually. Benzbromarone, another uricosuric agent, is not available in the United States because of its association with hepatotoxicity.

ASCORBIC ACID

Vitamin C has a hypouricemic effect that is believed to be mediated by competition with urate for renal tubular reabsorption.⁸⁸ In a study of 184 healthy, nonsmoking adults, ascorbic acid 500 mg daily for 2 months significantly decreased SUA concentrations.⁸⁹ Overall, ascorbic acid reduced the SUA concentration a mean of 0.5 mg/dL (range, 0.3–0.7), but the decrease in subjects with baseline SUA levels of >7 mg/dL was a mean of 1.5 mg/dL. This would have brought those patients' SUA below goal, if they required treatment for their hyperuricemia. Further investigation into the potential benefits of vitamin C in the treatment of hyperuricemia either alone or as adjunct therapy is needed.

Choice of Agent

11. E.J.'s hydrochlorothiazide was discontinued about 4 weeks ago, but his SUA only has decreased from 7.5 to 7.2 mg/dL. As a result, allopurinol is to be initiated. What dose of allopurinol should be prescribed for E.J., and what parameters should be monitored for efficacy and toxicity?

Allopurinol 100 mg daily should be started, and a SUA should be obtained no earlier than 2 weeks after the initiation of therapy. If urate-lowering therapy is successful, treatment should continue for a long period of time before attempting a trial to discontinue the allopurinol. An acute attack of gout is not a catastrophic event and perhaps the future discontinuation of allopurinol is a worthwhile risk to undertake in an effort to minimize potential future difficulties when any drug is taken over a lifetime.

ONSET OF EFFECTS

SUA levels usually begin to fall within 1 to 2 days after initiation of allopurinol therapy; maximal uric acid suppression in response to a given dosage usually requires 7 to 10 days.^{78,90} Clinically observable improvement takes longer. After approximately 6 months, one should observe a gradual decrease in the size of established urate tophi, as well as the absence of new tophaceous deposits if these were present. A baseline SUA should be obtained, and then 2 to 4 weeks after onset of therapy, and after every dose change until SUA is maintained at goal (<6 mg/dL).

ONCE-DAILY DOSING

Allopurinol has a half-life of <2 hours, but its active metabolite, oxypurinol, has a serum half-life of 13 to 18 hours; therefore, once-daily dosing is effective. In renal impairment, oxypurinol accumulates and dosage adjustments should be considered.^{91,92}

ADVERSE EFFECTS

Allopurinol generally is well tolerated, with few significant adverse effects. Occasionally, GI intolerance, bone marrow suppression, renal or hepatic toxicities, and mild skin rash are reported. Hyperuricemic patients receiving allopurinol might be more susceptible to "ampicillin rash"⁹³ and to interactions with other drugs (Table 42-5). Allopurinol's interaction with azathioprine is well documented and is of major clinical significance; however, in one survey of 24 transplant patients taking both drugs, the dose of azathioprine was decreased in only 14 of 24 patients.⁹⁴ This survey exposes one weakness in our understanding of how best to adjust azathioprine dosages despite the widely acknowledged need for dosage adjustment.¹⁴

Whether allopurinol causes cataracts is controversial. In one study, allopurinol use for longer than 2 years was associated with the formation of cataracts.⁹⁵ This adverse reaction has been attributed to above-average exposure to sunlight that enhances the photobinding of allopurinol in the lens, resulting in cataracts.⁹⁵ This report disputes the finding of the Boston Collaborative Drug Surveillance Program that any association between allopurinol and cataracts was coincidental.⁹⁶ In addition, a subsequent study found no evidence to confirm a higher risk of cataract formation in allopurinol users than in nonusers.⁹⁷

HYPERSENSITIVITY REACTIONS

Of the adverse drug reactions sometimes encountered with allopurinol, hypersensitivity-type reactions have been the most notorious. These generally present as mildly erythematous, dusky red purpuric, or scaly maculopapular skin eruptions. When allopurinol is discontinued promptly, these hypersensitivity reactions should subside without sequelae. However, the continued administration of allopurinol to hypersensitive individuals has resulted in progression of these symptoms and several fatalities.^{98–107} The cutaneous reactions often progressed to include necrosis of the skin and mucous membranes, exfoliative dermatitis, Stevens-Johnson syndrome, or toxic epidermal necrolysis. Hepatomegaly, jaundice, hepatic necrosis, and renal impairment often accompanied these reactions.¹⁰⁸ The hepatic and renal changes were usually reversible when the drug was discontinued, and these organ failures were not correlated with any one cutaneous reaction pattern. Patients with renal insufficiency, those receiving thiazide diuretics, and

Table 42-5 Allopurinol Drug Interactions**Major Documentation**

Azathioprine (Imuran). Metabolized to 6-mercaptopurine (6-MP) and then to inactive metabolites by xanthine oxidase. Allopurinol inhibition of xanthine oxidase ↑ the serum concentration of 6-MP and the risk of bone marrow depression. When azathioprine (or 6-MP) is used concurrently with allopurinol, use extreme caution, and the azathioprine dose should be ↓ to one fourth of the recommended dose.

Mercaptopurine (Purinethol). See Azathioprine.

Moderate Documentation

ACE Inhibitors. Specifically, captopril and enalapril can predispose patients to severe allopurinol hypersensitivity reactions (e.g., Stevens-Johnson syndrome). Concurrent renal impairment can be an important variable.

Anticoagulants. Occasionally, patients on oral anticoagulants and allopurinol develop enhanced anticoagulant effects; however, this interaction is unpredictable and primarily based on isolated case reports.

Cyclophosphamide. Allopurinol may ↑ cyclophosphamide-induced bone marrow depression based on epidemiologic data.

Anecdotal Documentation

Ampicillin. Concomitant allopurinol might increase ampicillin rash based on epidemiologic data.

Antacids. Aluminum hydroxide inhibited the GI absorption of allopurinol in three patients on hemodialysis; however, the interaction can be avoided by the administration of allopurinol ≥3 hours before or 6 hours after aluminum hydroxide.

Chlorpropamide. Allopurinol or its metabolites might compete with chlorpropamide for renal tubular secretion and can result in an ↑ chlorpropamide effect.

Cyclosporine. Allopurinol may ↑ cyclosporine concentrations and toxicity based on case reports.

Phenytoin. Allopurinol seemed to inhibit the metabolism of phenytoin in one patient.

Probenecid. Allopurinol can inhibit the metabolism of probenecid, and probenecid can enhance the renal elimination of the active oxypurinol.

Theophylline. Allopurinol in high doses can ↑ mean theophylline AUC by approximately 27% and half-life by 25%; clearance can be ↓ approximately 21%. An active metabolite (1-methylxanthine) also can accumulate.^{149,150}

Vidarabine. An active metabolite of vidarabine is metabolized by xanthine oxidase, and accumulation of this metabolite can ↑ neurotoxicity.

ACE, angiotensin-converting enzyme; GI, gastrointestinal; AUC, area under the concentration–time curve.

tivity reaction to allopurinol.^{98,101,104,108} Although no specific mechanism or causative agent producing this toxicity has been identified, the accumulation of allopurinol or a metabolite is postulated to be a primary factor, especially because 80% of patients with this syndrome had significantly impaired renal function before the initiation of allopurinol.¹⁰⁹ In one particular incident, allopurinol serum concentrations were 50 times normal values.¹⁰⁷ Therefore, dose adjustments of allopurinol should be considered in renal impairment, but especially in patients who develop acute renal failure or have worsening renal function over time. Patients who have been titrated on allopurinol to goal SUA level, have stable but reduced renal function, and are tolerating the drug do not necessarily need a dosage decrease.

Patients who have recovered from an allopurinol hypersensitivity syndrome should avoid the future use of this drug because most will probably experience a similar reaction on re-exposure. However, a few hypersensitive individuals may tolerate low dosages (50–100 mg/day). If there is no reaction after a few days, the allopurinol dosage can be increased gradually. Nevertheless, severe toxic reactions have been produced by doses of allopurinol as low as 1 mg. Some hypersensitive patients have been desensitized with daily doses as small as 0.05 mg that were increased gradually over a period of 30 days. Although the cautious reintroduction of allopurinol through graded oral doses can be attempted in patients with cutaneous rash who have failed other options,¹¹⁰ the risk of serious hypersensitivity is significant, and an alternative agent would be appropriate.

PROPHYLAXIS AGAINST ACUTE GOUT

Symptoms of acute gout might be slightly exacerbated during the first 6 weeks of allopurinol or uricosuric therapy because of uric acid mobilization from tissues. Concurrent administration of an NSAID or low-dose daily colchicine (0.5–1 mg daily) should be prescribed for the first few months of urate-lowering therapy to prevent acute gout attacks (see proposition 11 in Table 42-3).³⁴ If a uricosuric drug is preferred, a combination product (i.e., ColBenemid) is available that contains both colchicine and probenecid. If this is used, the ColBenemid should be replaced with the single drug entity (i.e., probenecid) after a few months because the colchicine component of this fixed-combination product is only needed short term.

Comorbid Conditions**Dyslipidemia**

12. L.M. is a 57-year-old man who presents to his family physician for a regular checkup. He is currently controlled on allopurinol 300 mg/day for the management of hyperuricemia. For his dyslipidemia, L.M. takes simvastatin (Zocor) 40 mg/day. Although his low-density lipoprotein (LDL) is at goal of <130 mg/dL, he requires further lowering of his non-high-density lipoprotein (non-HDL) cholesterol (goal of <160 mg/dL). What would be the best option to consider in this patient?

In addition to therapeutic lifestyle changes, fibrates (i.e., gemfibrozil, fenofibrate) or niacin are effective in lowering total cholesterol, LDL, and triglycerides. These drugs can also increase the beneficial HDL. A fibrate or niacin can also be used in combination with this patient's current simvastatin. However, with a history of gout and hyperuricemia, a fibrate

those with chronic alcoholism or severe liver disease have been the most commonly afflicted with this syndrome.

The toxic syndrome generally appeared within the first 5 weeks of therapy; however, it has appeared as part of a delayed hypersensitivity reaction as late as 25 months after the initiation of therapy.¹⁰⁷ The mechanism by which this toxicity syndrome occurs is unknown. The cutaneous reaction and renal failure have been consistent with a diffuse systemic vasculitis, and the nonfatal cases did not improve until large steroid doses were instituted, despite the discontinuation of allopurinol. Biopsy specimens from patients provide support for the premise that vasculitis results from an immune hypersensi-

would be preferred over niacin because niacin can induce hyperuricemia (Table 42-4). Specifically, fenofibrate has been shown to decrease uric acid serum concentrations and could be beneficial in this dyslipidemic patient with a history of gout; however, the selection of a medication to manage dyslipidemia or other comorbid conditions also involves other clinical variables that might be equally applicable.^{34,111,112} Fenofibrate modestly increases renal urate excretion.⁸⁸

Hypertension

13. Because one of the first-line agents for the treatment of HTN, thiazide diuretics, is known to increase SUA, what other antihypertensives might be particularly beneficial for hyperuricemic patients?

Both amlodipine and losartan have positive effects on SUA levels. Amlodipine, a calcium channel blocker, decreased serum urate levels by increasing glomerular filtration rate in a study of renal transplant patients taking cyclosporine.¹¹³ Losartan (Cozaar), an angiotensin II receptor blocker (ARB), appears to increase renal excretion of uric acid by interacting with the URAT-1 protein in the proximal tubule of the nephron.² When used with diuretics, it appears to alleviate the hyperuricemic effect of the diuretic.⁸⁸ This does not seem to be a class effect of ARB's because, in one study, patients on losartan achieved significantly lower SUA concentrations than an irbesartan-treated group.¹¹⁴ Some advocate losartan for patients with hyperuricemia.³⁴ Because both fenofibrate and losartan have hypouricemic effects and often patients with hyperuricemia have HTN and dyslipidemia as comorbid conditions, the use of these two drugs in combination is of potential benefit under appropriate circumstances. In one study of five healthy male patients, concurrent daily losartan 100 mg and fenofibrate 300 mg decreased SUA concentrations by a mean of about 1 mg/dL (53.6 mol/L SI units) compared to the decrease during treatment alone with these drugs.¹¹¹ If further studies show promise, some patients with hyperuricemia might be managed better by selecting drugs to manage comorbid conditions rather than requiring the use of the more traditional hypouricemic agents.

Asymptomatic Hyperuricemia

14. T.M., a 50-year-old man, is seen by his physician for a routine evaluation. His physical examination is unremarkable, and

his laboratory evaluations are all within normal limits except for a SUA concentration of 9.5 mg/dL, which is noted on a basic metabolic panel. Should this hyperuricemia be treated?

Individuals with high SUA levels are more likely to develop acute gouty arthritis than normouricemic individuals, and the magnitude of the risk increases with increasing degrees of hyperuricemia. Nevertheless, it would be excessive to treat all hyperuricemic individuals with uric acid–lowering medications for a lifetime solely to prevent acute attacks of gouty arthritis. A large percentage of hyperuricemic patients may never experience an acute attack of gout.¹¹⁵ If an attack should occur, it can be treated easily within 48 to 72 hours, and after the acute episode has subsided, uric acid–lowering medications can then be considered.

The key issue in the treatment of hyperuricemia concerns the effect of uric acid on renal function. Renal disease was commonly associated with gout, and renal failure was believed to be the eventual cause of death in as many as 25% of gouty patients. Thus, treatment of asymptomatic hyperuricemia is justifiable if renal disease is prevented. However, this renal damage was noted to occur in a setting that included HTN, diabetes, renal vascular disease, glomerulonephritis, pyelonephritis, renal calculi, or some other cause of primary nephropathy independent of gout.¹¹⁶ In fact, the coexistence of gout and renal insufficiency without HTN is so rare that its presence should raise the suspicion of chronic lead toxicity.^{23,117} Therefore, the consensus now seems to be that hyperuricemia by itself has no deleterious effect on renal function.^{118,119} Considering the financial costs, risks of adverse drug reactions, and practical considerations such as patient compliance, drug treatment of asymptomatic hyperuricemia is difficult to justify.¹¹⁵

The relationship of hyperuricemia to HTN in individuals who have not experienced gout was studied prospectively in 124 hyperuricemic subjects. None of these patients had evidence of gout, HTN, or cardiovascular, renal, or other diseases. After 10 years, 22.5% of these individuals with “asymptomatic hyperuricemia” had developed HTN, and 5.4% had developed atherosclerotic heart disease. The incidences of HTN and atherosclerotic heart disease in the control group were 2.1% and 0.5%, respectively.¹²⁰ Atherosclerosis and HTN apparently were more serious problems in this population than renal disease. Although hyperuricemia may represent an important risk factor for the development of CVD,¹⁸ the evidence is not sufficiently compelling to justify the treatment of asymptomatic hyperuricemia at this time.

Epidemiology

The term *arthritis* refers to more than 100 diseases causing pain, swelling, and damage to joints and connective tissue.¹ The prevalence of arthritis is on the rise: 46.4 million Americans, or 21.6% of U.S. adults have been diagnosed with arthritis, an increase from the 2002 estimate of 42.7 million.² Arthritis is the most common chronic condition in persons older than 15 years of age, individuals who are overweight or inactive, and those without a high school education. The prevalence rate is higher

in women (25.4%) than men (17.6%), and in the elderly (50.0% of those ≥ 65 years of age versus 29.3% of those between 45 and 64 years of age). A major objective from *Healthy People 2010* is to reduce the proportion of arthritis sufferers who have a limited ability to work due to their disease (about 33% of American adults fall into this category, with prevalence rates exceeding 50% in some states).³ As more Americans work beyond 65 years of age, along with increasing arthritis prevalence with increasing age, this disease will become a growing source of economic and quality of life burden in the United States.

Table 43-1 Criteria for Diagnosis of RA

Morning stiffness in and around joints lasting ≥ 1 hr before maximal involvement^a
 Soft tissue swelling (arthritis) of ≥ 3 joint areas observed by a physician^a
 Swelling (arthritis) of the proximal interphalangeal, metacarpophalangeal, or wrist joints^a
 Symmetric arthritis^a
 Subcutaneous nodules
 Positive test for RF
 Radiographic erosions or periarticular osteopenia in hand or wrist joints

^aCriteria 1 to 4 must be present for ≥ 6 weeks; ≥ 4 criteria must be present.
 RA, rheumatoid arthritis; RF, rheumatoid factor.
 Adapted from reference 4.

Rheumatoid arthritis (RA) is a chronic systemic inflammatory disorder characterized by potentially deforming polyarthritis and a wide spectrum of extra-articular manifestations. The diagnosis of RA primarily is based on clinical criteria (Table 43-1) because no single chemical or laboratory finding is specific for this disease.⁴ The prevalence of RA is estimated to be 1% worldwide.⁵ In the United States, RA afflicts approximately 1.3 million individuals, occurring nearly twice as often in women as men.⁶ The onset of RA typically occurs between the third and fourth decades of life, and prevalence increases with advancing age up to the seventh decade.^{1,5} The average age of RA prevalence has increased from 63.3 years in 1965 to 66.8 years in 1995. RA-related morbidity, mortality, and disability are expected to increase substantially in future years as large numbers of the boomer population age.⁶

The cause of RA seems to be an interplay among multiple factors (e.g., genetic susceptibility, environmental influences, the effects of advancing age on somatic changes in the musculoskeletal and immune systems).⁵ Support for the concept of genetically controlled susceptibility comes from studies demonstrating an association between RA and class II gene products of the major histocompatibility complex (MHC). Although epidemiologic associations have not been clearly established, cigarette smoking might increase the production of rheumatoid factor (RF), which often precedes the clinical presentation of RA.⁷ In a case-control study of 2,625 men and women (1,095 with RA and 1,530 healthy adults), a history of smoking increased risk for RA in men, but not in women.⁸ A possible explanation for this gender-dependent difference is that female hormones might interfere with smoking-induced RF production and subsequent RA development.

The course of RA is variable and can be categorized as *polycyclic*, *monocyclic*, or *progressive*.⁹ The *polycyclic* course occurs in approximately 70% of patients, who initially experience mild intermittent symptoms that resolve over the course of several weeks to months. The patient can be symptom free for several weeks to months and then experience symptoms that can be more severe than those experienced initially. *Monocyclic* patients (~20% of patients) experience a rather sudden onset of symptoms followed by a prolonged clinical remission of disease activity. *Progressive* patients (~10% of patients) ex-

Table 43-2 Criteria for Complete Clinical Remission in RA

A minimum of five of the following requirements must be fulfilled for at least 2 consecutive months in a patient with RA^a:

1. Morning stiffness not >15 minutes
2. No fatigue
3. No joint pain
4. No joint tenderness or pain on motion
5. No soft tissue swelling in joints or tendon sheaths
6. ESR (Westergren's) <30 mm/hour (females) or 20 mm/hr (males)

^a Exclusions: Manifestations of active vasculitis, pericarditis, pleuritis, myositis, or unexplained recent weight loss or fever secondary to RA prohibit designation of complete clinical remission.

ESR, erythrocyte sedimentation rate; RA, rheumatoid arthritis.

perience progressive uninterrupted disease that usually evolves over the course of a few months, but the rate of disease progression in this group can be rapid or slow. Patients within this group can be divided further into a subgroup that responds to “aggressive” therapy and a subgroup that does not. Patients with more aggressive disease (multiple joint involvement, positive RF) have a >70% probability of developing damage or erosions to joints within 2 years of disease onset.¹⁰

The rate of RA disease remission was low before the increased use of medications capable of halting or slowing disease progression. The application of standardized criteria for remission (Table 43-2)¹¹ to rheumatology clinic patients reported a remission rate of about 1%.¹² In another clinic, 18% of patients were in remission at some time over 2.5 years (including >10% of patients not receiving disease-modifying drugs).¹³ Remissions, however, were temporary with fewer than 4% experiencing a remission lasting up to 2 years and only 1.2% experiencing a remission lasting up to 3 years. Some clinical trials using disease-modifying drugs early in the course of RA reported remission rates of 16% to 31% at 2 years with monotherapy and up to 37% at more than 6 years with combination drug therapy.^{14–17} In a more recent evaluation of a large dataset of RA patients, however, the use of anti-tumor necrosis factor (TNF) medications was associated with a remission rate (i.e., no disease activity) of only 7% and a minimum disease activity rate of just over 20%.¹⁸ This significant difference in treatment response rates could be due to less standardization of patients in a general RA population versus clinical trials.

In several studies, survival rates of RA patients were not different compared with the general population during the first 10 years of the disease.^{19,20} However, in analyses of more recent data, patients with RA had a lower life expectancy (median age at death was 4 years less than non-RA populations), and life expectancy was less with more severe disease.²¹ The excess mortality has been attributed primarily to accelerated cardiovascular disease, which in turn might be due to RA-induced vascular inflammation, hyperhomocysteinemia, dyslipidemia, or elevations in TNF- α .²² RA is associated with a two- to three-fold increased rate of myocardial infarction (MI), as well as lower MI survival. About one-third to one-half of RA patient deaths is due to cardiovascular disease. In comparison, only about one-fourth to one-fifth of deaths among adults without

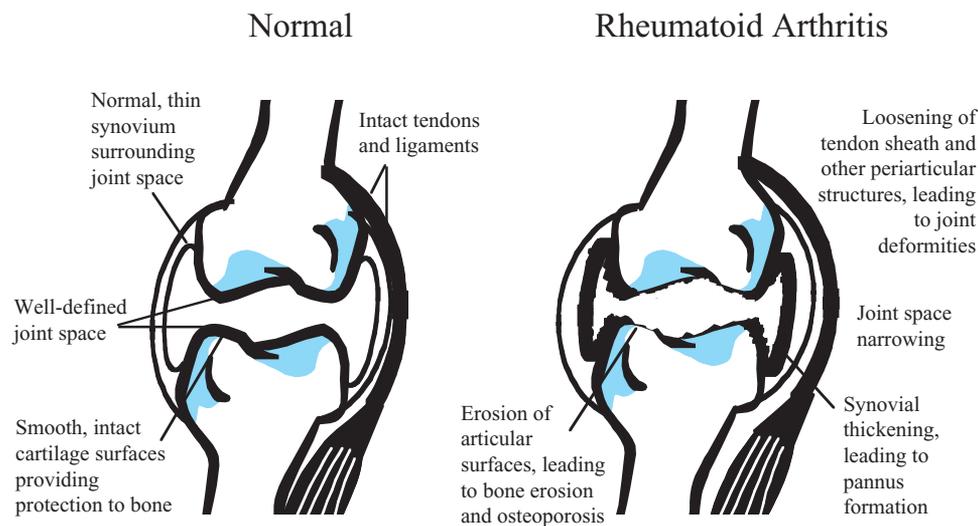

FIGURE 43-1 Overview of joint changes in RA.

RA have been attributed to cardiovascular disease. Guidelines for reducing cardiovascular disease risk in RA patients recommend the following: (a) consideration of RA as a potential independent risk factor for cardiovascular disease; (b) correction of modifiable cardiovascular risk factors (e.g., hypertension, dyslipidemia, diabetes mellitus); (c) treatment with the lowest possible dose of glucocorticoid to reduce the risk of glucocorticoid-associated cardiovascular events; (d) consideration of the use of methotrexate (MTX) therapy owing to its association with reduced cardiovascular mortality in RA patients; (e) inclusion of active RA into the consideration of cardiovascular risk factors when determining low-density lipoprotein cholesterol targeting; and (f) consideration of daily low-dose aspirin therapy for prevention of cardiovascular events with appropriate caution when other nonsteroidal anti-inflammatory drugs (NSAIDs) are being used because of possible increased risk of serious gastrointestinal (GI) toxicity.^{23,24}

Pathophysiology

RA-induced joint destruction begins with inflammation of the synovial lining.²⁵ This normally thin membrane, which surrounds the joint space, proliferates and becomes transformed into the synovial pannus. The pannus, a highly erosive enzyme-laden inflammatory exudate, invades articular cartilage (leading to narrowing of joint spaces), erodes bone (resulting in osteoporosis), and destroys periarticular structures (ligaments, tendons) resulting in joint deformities (Fig. 43-1).

Familiarity with the basic cellular processes involved in tissue destruction and sustained inflammation in rheumatoid synovium is essential to understanding pharmacologic therapies for RA.^{25–27} Under normal circumstances, the body can distinguish between self (i.e., proteins found within the body) and non-self (i.e., foreign substances such as bacteria and viruses). On occasion, immune cells (T or B lymphocytes) can react

to a self-protein while developing in the thymus or bone marrow. These developing cells are usually killed or inactivated; however, a self-targeted immune cell can escape destruction and become activated years later to initiate an autoimmune response. Some believe the activation is initiated by bacteria (possibly streptococcus) or a virus containing a protein with an amino acid sequence similar to tissue protein. When this activation source (i.e., the self-targeted immune cell) reaches the joint, complex cell-to-cell interactions take place leading to the pathology associated with RA.

The initiating interaction for an autoimmune response takes place between antigen-presenting cells (APC), which display complexes of class II MHC molecules, and CD4-lineage T-cell lymphocytes (Fig. 43-2). In addition, B cells (previously thought to have little to do with the inflammatory response) can become activated, which leads to antibody formation (including RF and anticyclic citrullinated peptide), proinflammatory cytokine production, and accumulation of polymorphonuclear leukocytes that release cytotoxins and other substances destructive to the synovium and joint structures. B cells also act as APCs, leading to T-cell activation and acceleration of the inflammatory process.²⁷ T-cell activation requires two signals: (a) an antigen-specific signal occurring when an MHC class II antigen molecule on an APC binds to a T-cell receptor; and (b) binding of CD39 on the T-cell to either CD80 or CD86 on the APC. T-cell activation leads to activation of macrophages and secretion of cytotoxins and cytokines. Cytotoxins can directly destroy cells and tissues. Cytokines are polypeptides that serve as important mediators of inflammation. Proinflammatory cytokines such as interleukin (IL)-1 and TNF- α stimulate both synovial fibroblasts and chondrocytes in neighboring articular cartilage to secrete enzymes that lead to tissue destruction by degrading proteoglycans and collagen. In healthy individuals, the inflammatory process is regulated by balancing the ratios of proinflammatory cytokines (e.g., IL-1, IL-6, TNF- α) with anti-inflammatory cytokines—for example, IL-1 receptor antagonist (IL-1Ra), IL-4, IL-10, and IL-11. In the synovium of RA patients, however, this balance is heavily weighted toward

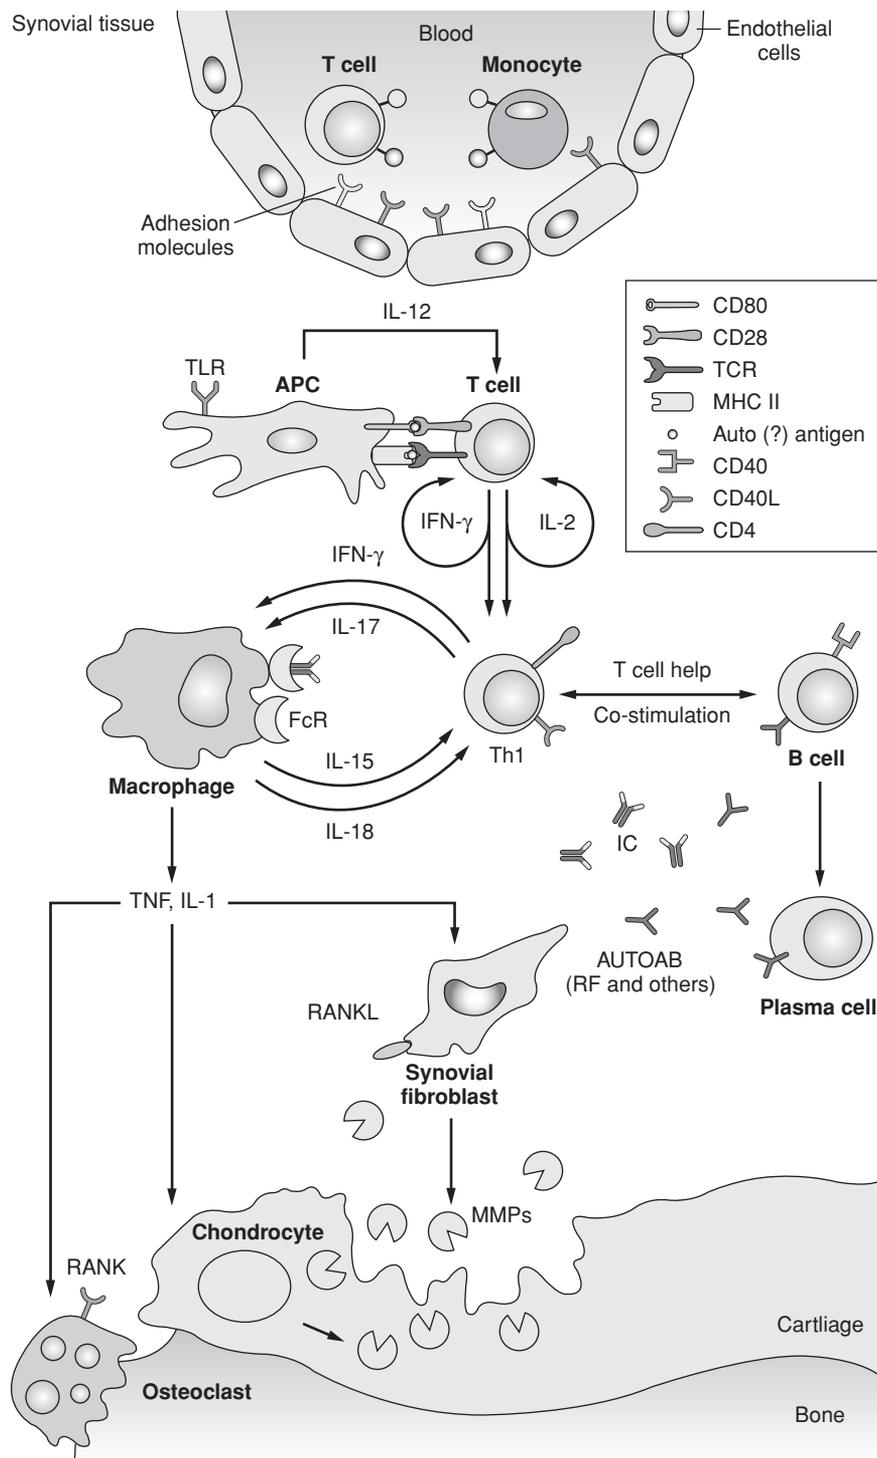

FIGURE 43-2 Schematic representation of events occurring in RA T cells invading the synovial membrane are primarily CD4⁺ memory cells, which produce interleukin-2 (IL-2) and interferon- γ (IFN- γ) to a similar extent as antigen-triggered T cells, and which are either already preactivated or become (further) activated by APCs in conjunction with arthritogenic (auto)antigen(s) and appropriate MHC class II molecules, costimulation (mainly through CD80/81 and CD28) and certain cytokines (IL-1, IL-15, IL-18). Through cell-cell contact (e.g., through CD11- and CD69-mediation) and through different cytokines, such as IFN- γ , tumor necrosis factor- α (TNF- α) and IL-17, these T cells activate monocytes, macrophages, and synovial fibroblasts. The latter then overproduce proinflammatory cytokines, mainly TNF- α , IL-1, and IL-6, which seem to constitute the pivotal event leading to chronic inflammation. Through complex signal transduction cascades, these cytokines activate a variety of genes characteristic of inflammatory responses, including genes coding for various cytokines and matrix metalloproteinases (MMPs) involved in tissue degradation. TNF- α and IL-1 also induce RANK expression on macrophages which, when interfering with RANKL on stromal cells or T cells, differentiate into osteoclasts that resorb and destroy bone. In addition, chondrocytes also become activated, leading to the release of MMPs. Initial events might also involve activation of APCs through Toll-like receptors (TLRs) before T-cell engagement. RANK, receptor activator of nuclear factor- κ B; RANKL, RANK ligand; RF, rheumatoid factor; TCR, T-cell receptor. (Reprinted with permission from reference 314.)

the proinflammatory cytokines, which results in sustained inflammation and tissue destruction.²⁸

Treatment

The treatment of RA involves a combination of interventions, which include rest, exercise (physical therapy), emotional support, occupational therapy, and drugs.¹⁰ Specific treatment should be individualized based on joint function, degree of disease activity, patient age, gender, occupation, family responsibilities, drug costs, and results of previous therapy. The ultimate goal of RA treatment is disease remission; however, in light of the fact that complete and sustained remission is uncommon, minimizing disease activity (i.e., providing pain relief, maintaining activities of daily living, maximizing quality of life, slowing of joint damage) is also a goal.

An old standard for treatment of RA, known as the “pyramid approach,” was based on the assumption that RA is a slowly progressing, benign disease that is not life threatening (Fig. 43-3).²⁹ Based on the pyramid approach, the initial treatment for any RA patient was a basic program of rest, exercise, and education along with NSAID therapy. If trials of several NSAIDs proved to be ineffective, treatment with disease-modifying antirheumatic drugs (DMARDs) was initiated with the relatively least toxic agent. As disease progressed, the patient “ascended” up the pyramid to receive more toxic DMARDs, with the “peak” of the pyramid consisting of experimental drugs and procedures. The problems with the pyramid approach are as follows: RA is not a benign condition for most patients; NSAIDs are associated with significant toxicities; DMARDs are not as toxic as once believed; and, perhaps most important, the pyramid approach has not made an impact on functional, clinical, or radiographic evidence of disease progression.¹⁰ Although symptoms of RA can be controlled in most patients by conservative management, the disease progresses in most patients, and more aggressive therapy often

is needed. Unfortunately, primary care clinicians who adopt the pyramid approach to RA management might delay consultation with rheumatologists and delay the use of important DMARDs.

Current treatment guidelines still support the use of NSAIDs to provide rapid anti-inflammatory and analgesic effects.¹⁰ However, because NSAIDs do not prevent or slow joint destruction, DMARD therapy should be initiated within the first 3 months of RA diagnosis. Traditional DMARDs (e.g., hydroxychloroquine [HCQ], sulfasalazine [SSZ], MTX, leflunomide [LEF], gold, azathioprine [AZA], or D-penicillamine [DPEN]) have the potential to slow disease progression; however, DPEN is seldom utilized because of a very slow onset of action and numerous toxicities.³⁰ These agents, alone or in combination, should be considered as initial therapy for most RA patients. The newest class of DMARDs, biological agents (also referred to as anticytokines, biologicals, biological modifiers, or biological response modifiers), include etanercept (Enbrel), infliximab (Remicade), anakinra (Kineret), adalimumab (Humira), abatacept (Orencia), and rituximab (Rituxan). These agents target the physiological proinflammatory and joint-damaging effects of TNF- α , IL-1, T-cell activation, or B cells.

MTX is the initial treatment of choice for most RA patients because of its efficacy and safety profile.^{10,30,31} TNF- α biologicals are recommended for patients who fail to achieve an adequate response either with MTX alone or MTX in combination with other traditional DMARDs, or for patients intolerant to MTX. The TNF- α biologicals, however, can worsen heart failure in patients with preexisting heart failure, and possibly increase their risk of death.^{32,33} The newer biologicals, abatacept and rituximab, are effective in patients who have an inadequate response to TNF- α biologicals and seem to be free of cardiovascular adverse effects. Abatacept and rituximab, however, are expensive, are associated with serious side effects, and the long-term effects of these agents have yet to be

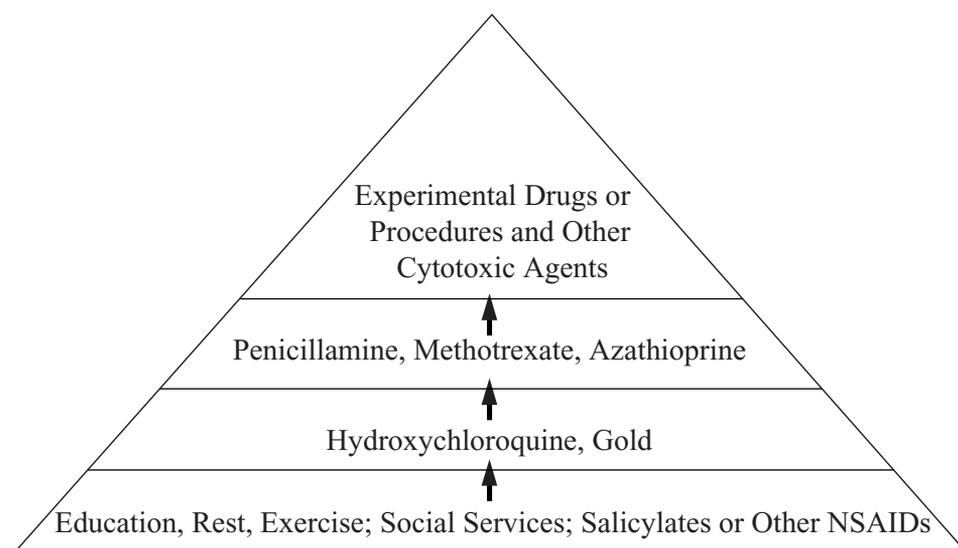

FIGURE 43-3 Traditional pyramid approach for treatment of RA. ↑ indicates worsening disease.

determined. As a result, abatacept and rituximab warrant cautious and judicious use. The glucocorticoids also are potent anti-inflammatory agents that seem to slow the progression of joint damage in RA; however, these generally are reserved for brief periods of active disease (low-dose oral therapy), or for isolated joints experiencing disease flares (local intra-articular injection), because of serious adverse effects associated with long-term systemic use. Alkylating cytotoxic drugs, although effective, are also toxic and are normally reserved for severe disease uncontrolled by other drug therapies.

Nonsteroidal Anti-Inflammatory Drugs

Aspirin, an acetylated salicylate, is inexpensive, has a long history of established efficacy, and continues to be the standard by which the effectiveness of all other NSAIDs is measured. However, aspirin (particularly nonenteric coated) is associated with a higher incidence of GI bleeding than other NSAIDs and is no longer commonly used for the treatment of RA.³⁴ Many other NSAIDs are available, including nonacetylated salicylates and nonsalicylate NSAIDs.

Although NSAIDs differ in chemical structure, they generally have similar pharmacologic properties (e.g., antipyresis, analgesia, anti-inflammatory activity, inhibition of prostaglandin synthesis), mechanisms of action (i.e., inhibition of cyclo-oxygenase [COX]; activity), harmful side effects largely attributable to COX inhibition (e.g., GI intolerance, nephrotoxicity, risk of bleeding), and pharmacokinetic properties (e.g., highly protein bound and extensively metabolized to inactive metabolites that are excreted renally).³⁴ The nonacetylated salicylates, however, have virtually no effect on COX and their mechanism of action remains unknown. The lack of COX activity and smaller early studies initially suggested that nonacetylated salicylates are less GI toxic than nonselective NSAIDs; however, in more recent comparisons both the GI and renal toxicities of nonacetylated salicylates are no different than nonselective NSAIDs.^{35,36} (Note: For simplicity and clarity, the term *NSAID* is used henceforth to describe NSAIDs other than acetylated [i.e., aspirin] and nonacetylated [e.g., diflunisal, salsalate] salicylates.)

Although NSAIDs are more similar to, than different from, aspirin, they often are better tolerated. Because it is not possible to predict patient response to a given NSAID, selection has traditionally been based on cost, duration of action, and patient preference. Courses of several different NSAIDs, even those within the same chemical class, may be necessary to determine the best choice for an individual patient. The greatest concern of NSAID therapy is the risk of serious GI bleeding, although cardiovascular (hypertension, heart failure) and renal toxicity are also of concern.

The two COX isoforms (COX-1 and COX-2) have different physiological effects. As a result, COX-2-specific NSAIDs (commonly referred to as COX-2 inhibitors) were developed to take advantage of these differences.^{37,38} Although COX-1 is expressed in most tissues of the body (e.g., GI tract, kidneys, platelets), COX-2 generally is expressed throughout the body in low concentrations.³⁹ Inflammatory mediators such as cytokines, however, upregulate COX-2 expression, resulting in high levels of COX-2 in inflamed tissues. Selective inhibition of COX-2, therefore, could be expected to produce anti-inflammatory activity with minimal adverse effects on GI mucosa (leading to less GI bleeding) and on cells (e.g., platelets).

However, after several years of blockbuster sales of COX-2 inhibitors such as celecoxib (Celebrex), rofecoxib (Vioxx), and valdecoxib (Bextra), only celecoxib remains available in the United States. Rofecoxib and valdecoxib were withdrawn from the market because of a two- to four-fold increased risk of cardiovascular events (e.g., MI, stroke) when compared with placebo-treated patients.^{39,40}

The potential risk of thrombosis and subsequent cardiovascular events associated with COX-2-specific inhibition was a recognized concern well before the first COX-2 inhibitor was marketed in the United States.^{41,42} COX-1 and COX-2 balance a multitude of physiological processes, including hemostasis and vascular tone.^{43,44} Thromboxane, a promoter of platelet activation and vasoconstriction, is produced primarily in platelets via the COX-1 enzyme. Prostacyclin, an inhibitor of platelet aggregation and a vasodilator, is produced in the vascular endothelium by COX-1 and COX-2 enzymes. Based on these facts alone, COX-2-specific inhibition has the potential to suppress prostacyclin while leaving thromboxane production unattenuated; the net clinical effect is a prothrombotic state. Celecoxib remains on the market because usual doses (up to 400 mg/day) have not been associated with an increased rate of cardiovascular events. One possible explanation for this difference in cardiovascular risk between the COX-2 inhibitors is that celecoxib is four to five times less selective for COX-2 than rofecoxib or valdecoxib.⁴⁵

Traditional Disease-Modifying Antirheumatic Drugs

DMARD therapy should be considered for all RA patients and initiation of therapy should not be delayed beyond 3 months of RA diagnosis for the majority of patients.¹⁰ Corticosteroid therapy (i.e., injections into isolated joints or low oral doses for multiple joint involvement) and NSAIDs can be used to control symptoms of pain and swelling initially and intermittently as needed. Although DMARDs have the potential to cause serious toxicity, they can substantially reduce joint inflammation, reduce or prevent joint damage, maintain joint function and integrity, and ultimately reduce health care costs and allow patients to remain productive.¹⁰

The onset of action of most traditional DMARDs is slow (about 3–6 months); however, SSZ, MTX, LEF, and cyclosporine can be beneficial within 1 to 2 months and biological agents can be beneficial within days to weeks.^{30,31} The agent of choice is determined primarily by physician and patient preferences (e.g., convenience of administration, monitoring requirements, medication and monitoring costs, time to therapeutic onset, frequency and severity of adverse reactions). Objective comparisons among these agents are limited.⁴⁶ In general, MTX is heavily favored by most rheumatologists for initial treatment for all levels of RA severity because of its relatively rapid onset, high rate of response, mild side effect profile, relatively low cost, and long sustained efficacy. The probability of continuing MTX therapy at 5 years was 62% in one study.^{47,48} Furthermore, MTX therapy is associated with a reduction in cardiovascular morbidity and mortality in patients with RA, which is important because of the strong association between RA and cardiovascular disease.^{22,24}

HCQ and SSZ are relatively safe, convenient, and inexpensive. Either can be selected as initial therapy for patients with mild RA; however, HCQ is used more often than SSZ, even though it is less potent.^{49–51} LEF is an attractive option for

treatment of severe RA because its onset of effect can occur as soon as 4 weeks and its overall efficacy (including retarding of radiographic progression) is similar to MTX.^{52–54}

Injectable gold is effective, but can be inconvenient and causes numerous intolerable adverse effects. Interestingly, a follow-up study of patients with early RA who discontinued injectable gold after about 1 year of treatment because of side effects, noted that these patients experienced sustained disease improvement (i.e., remission) for several years thereafter.⁵⁵ The rate of clinical remission among these patients was similar to that of patients who *continued* gold or MTX therapy over a 6-year period. The oral form of gold, auranofin (AUR) is rarely used because of poor GI tolerance, slow onset of action (up to 6 months), and low efficacy.

In a meta-analysis, parenteral gold, MTX, SSZ, and penicillamine were the most effective of the traditional DMARD therapies.⁵⁶ In comparison, HCQ was relatively less effective and AUR was the least effective. Parenteral gold seemed to be most toxic, whereas AUR and antimalarials were best tolerated. LEF was not evaluated in this study. Although AZA is effective, it usually is reserved for patients with severe disease who do not respond to safer alternatives because of potential myelosuppression and hepatotoxicity. DPEN is one of the slowest acting DMARDs (e.g., doses should be adjusted only once every 3 months). DPEN is seldom used because it has a relatively low response rate and is associated with rare, but serious, autoimmune diseases (e.g., systemic lupus erythematosus, myasthenia gravis, Goodpasture syndrome). Cyclosporine is reserved for severe, refractory RA because of potential toxicity (renal insufficiency and hypertension) and cost. Although cyclosporine has been associated with an increased risk of malignancy in organ transplant patients, this adverse effect does not seem to be significant in the treatment of RA patients.⁵⁷

Biological Agents

Since the late 1990s, the earliest biological agents targeted proinflammatory cytokines such as TNF- α , IL-1 (specifically IL-1 α and IL-1 β), and IL-6, which seem to be key inflammatory mediators in RA.⁵⁸ These cytokines are abundant in rheumatoid synovial tissues and fluid. Most cytokines can independently induce expression of the others, and IL-1 is capable of upregulating its own expression.⁵⁹ Excessive macrophage-produced cytokines (e.g., TNF- α , IL-1, IL-6, IL-8) correlate closely with RA disease activity and severity. Most importantly, RA improves when the physiological action of TNF- α and/or several different ILs are suppressed.

TNF- α is a proinflammatory cytokine produced by activated macrophages and T cells in RA-affected joints. TNF- α also plays a role in keeping infections localized by increasing platelet activation and adhesion, resulting in local blood vessel occlusion and containment of infection. This action of TNF- α is responsible for its tumor necrosis properties, thus leading to the name.

TNF- α exerts its physiological effects by binding to two different cell-surface receptors known as p55 (i.e., 55kD) and p75 (i.e., 75kD) on inflammatory cells.⁵⁹ These receptors, with portions extending from within the cell cytoplasm to the cell exterior, are capable of binding TNF to the domains extending above the cell surface. Soluble forms of these receptors can be

found in the serum and synovial fluid and seem to play a role in regulating TNF- α .

Two approaches have targeted the action of TNF- α : (a) the use of soluble TNF receptors with high TNF binding affinity (e.g., etanercept); and (b) antibodies against TNF- α (e.g., infliximab, adalimumab).⁵⁸ Etanercept (Enbrel) is a recombinant TNF-receptor Fc fusion protein with the extracellular portion of two p75 receptors fused to the Fc portion of human immunoglobulin (Ig)-G1.⁶⁰ Infliximab (Remicade) is a chimeric IgG antibody directed against TNF- α ; adalimumab is a genetically engineered human IgG1 monoclonal antibody. All three TNF- α inhibitors (Enbrel, Remicade, and Humira) render TNF biologically unavailable and are highly effective in reducing RA disease activity. It is not clear whether one agent is superior to the other. Anti-infliximab antibodies can develop with the long-term use of infliximab, but these can be prevented by concomitant immunosuppression with MTX.

In healthy individuals, IL-1 overexpression is prevented by naturally occurring IL-1Ra.^{59,61} Consequently, inadequate production of IL-1Ra, relative to IL-1, is hypothesized to be an important contributor to active RA. In addition to proinflammatory properties, IL-1 augments cartilage damage and inhibits bone formation. Although TNF- α seems to be key in RA inflammation regulation and symptomatology, IL-1 may be largely responsible for bony erosion and periarticular osteoporosis. In animal studies, the combination IL-1Ra with anti-TNF- α has synergistic benefits.⁶² Nevertheless, this combination is not recommended for use in humans because of a high risk of neutropenia and subsequent severe infections.⁶³

TNF- α and IL-1 serve important physiological functions (e.g., protection against infections).^{10,59} The incidence of serious infections in patients receiving biological agents was not increased during clinical trials; however, hospitalizations and deaths secondary to sepsis, tuberculosis, atypical mycobacterial infections, fungal infections, and opportunistic infections have developed in patients treated with biological agents.^{10,63} Although these infections occurred primarily among patients with significant risk factors for infection (e.g., poorly controlled diabetes, concurrent corticosteroid or DMARD therapy), biological agents should not be given to patients with active infection, history of recurring infections, or medical conditions predisposing them to infection.

Increased serum levels of TNF- α seem to be associated with worsening of heart failure through mechanisms that are not entirely clear.²² Some proposed mechanisms contributing to the onset or worsening of heart failure include accelerated left ventricular remodeling, cardiac contractile abnormalities that result in negative inotropic effects, and increased apoptosis of myocytes and endothelial cells. However, despite the association between TNF- α and worsening of heart failure, clinical trials with anti-TNF therapy (which have included etanercept and infliximab) have not reduced mortality and heart failure-related hospitalizations. Furthermore, significantly more deaths have occurred in infliximab-treated patients with moderate to severe heart failure than in placebo-treated patients.⁶⁴ As a result, anti-TNF therapy is not recommended for RA patients with moderate to severe (New York Heart Association [NYHA] class III and IV) heart failure. Anti-TNF therapy can be used with caution in patients with mild (NYHA class I and II) heart failure, but patients should be closely monitored for cardiac decompensation.³¹

The newest biological agents target T cells and B cells.³¹ Abatacept (Orencia), a fusion protein of cytotoxic T-lymphocyte-associated antigen attached to IgG1, inhibits T-cell activation by preventing the binding of CD80 and CD86 ligands on the surface of APCs to the CD28 receptor on the T-cell. Rituximab (Rituxan) has been available since 1997 for the treatment of B-cell lymphoma.⁶⁵ Rituximab, a chimeric (mouse-human) monoclonal antibody, binds to the CD20 antigen on the surface of pre-B cells and mature B cells, resulting in the depletion of B cells from peripheral blood, lymph nodes, and bone marrow. Stem cells, pro-B cells, and antibody-producing plasma cells do not express CD20 and, therefore, are not affected by rituximab. Owing to its chimeric composition, rituximab must be administered with MTX to reduce the risk of human antichimeric antibody (HACA) formation.⁶⁶ Inhibition of T-cell activation and depletion of proinflammatory B cells result in significant reductions in RA-related inflammation and joint destruction.

Safety data reflecting up to 5 years of abatacept therapy indicate that abatacept is generally safe, but associated with significant adverse effects.⁶⁷ All infections (54% vs. 48%) and serious infections (3.0% vs. 1.9%) occurred at a slightly higher rate among abatacept-treated versus placebo-treated patients, respectively.⁶⁸ When combined with anti-TNF therapy, these infection rates are significantly higher. The most common serious infections associated with abatacept included pneumonia, cellulitis, urinary tract infection, bronchitis, diverticulitis, and acute pyelonephritis. Thus far, the overall risk of malignancy seems to be no different than with placebo; however, several cases of malignancy have been reported with abatacept when combined with anti-TNF therapy. Abatacept-treated patients with chronic obstructive pulmonary disease experienced significantly more pulmonary and serious adverse effects than placebo-treated patients in one study.⁶⁸ Rituximab has a good safety profile overall, but it has several black box warnings regarding serious and potentially fatal adverse effects (e.g., fatal cardiorespiratory infusion reactions that most commonly occur within 24 hours of the first infusion, tumor lysis syndrome, severe mucocutaneous reactions, progressive multifocal leukoencephalopathy).⁶⁹ Mild infusion reactions (e.g., fever, chills, urticaria, headache, rhinitis, bronchospasm, angioedema, hypotension) occur in about 40% of RA patients treated with rituximab, especially upon administration of the first dose. These infusion reactions can be minimized by administration of methylprednisolone 100 mg IV 30 minutes before infusion of rituximab. Rituximab is also associated with a slightly increased risk of serious infection (e.g., septic arthritis, pneumonia) when compared with placebo (3% vs. 1%, respectively), including reactivation of hepatitis B and tuberculosis infections.⁶⁹

Corticosteroids

Corticosteroids administered orally at low dosages (i.e., the equivalent of 10 mg of daily prednisone or less) or through local injections are effective in relieving symptoms of active RA.¹⁰ Oral corticosteroids seem to slow the rate of disease progression, particularly when used for less than 1 year.⁷⁰ Long-term use of corticosteroids, however, is associated with many serious adverse effects (e.g., osteoporosis, weight gain, diabetes, cataract formation, adrenal suppression, hypertension,

infections, impaired wound healing).⁷¹ As a result, oral corticosteroid dosing should be limited to daily doses of 7.5 to 10 mg of prednisone (or equivalent) and should be administered for as short a time as possible. Oral corticosteroids are particularly useful when patients are waiting the onset of DMARD action or during brief flares of active RA involving multiple joints. Local corticosteroid injections are useful when flares involve only a few joints. Frequent corticosteroid injections over an extended period have the potential to accelerate bone and cartilage deterioration; therefore, the same joint should not be injected more than once every 3 months.⁷¹

Alkylating Cytotoxic Agents

Cyclophosphamide and chlorambucil are effective in the treatment of severe progressive cases of RA, but they also carry the risk of potentially serious toxicity (e.g., malignancy, infections).²⁹ Thus, use of these drugs usually is limited to patients with progressive RA unresponsive to more conservative management or, in some cases, potentially life-threatening complications of RA (e.g., rheumatoid vasculitis).³⁰

Other Therapies

Minocycline seems to be a useful adjunctive agent in the treatment of RA, and its successful use supports a speculation that RA might have an infectious etiology. A double-blind, placebo-controlled trial, involving 46 patients with recent-onset RA, evaluated the benefit of the addition of minocycline 100 mg twice daily to conventional therapy with NSAIDs, DMARDs, and corticosteroids.⁷² At 4-year follow-up, eight minocycline-treated patients without DMARD or steroid therapy were in remission compared with one patient in the placebo group ($p = 0.02$). Perhaps even more impressive are the results of a randomized trial comparing minocycline 100 mg BID to HCQ 200 mg/day in patients with early onset RA.⁷³ At 2 years, significantly more minocycline-treated patients experienced relief of RA signs and symptoms, required less prednisone, and were more likely to be completely tapered off prednisone.

Apheresis with the ProSORBA column is an effective therapeutic option for patients with severe RA refractory to several DMARDs.⁷⁴ The ProSORBA column, a medical device, contains highly purified staphylococcal protein A bound to a silica matrix that has a high affinity for IgG and complexes of IgG and IgM, including RF and circulating immune complexes. A plasmapheresis machine is used to withdraw blood from the patient, separate blood cells from plasma, pass the plasma through the ProSORBA column to remove selected immunoglobulins and immune complexes, and recombine the plasma with the blood cells for return to the patient. Removal of these immunoglobulins and immune complexes results in immunomodulation and improvement in RA symptoms. In a randomized, double-blind, sham-controlled trial, the effect of weekly apheresis with the ProSORBA column in patients with severe RA (i.e., average disease duration, 15.5 years; average number of failed DMARDs per patient, 4.2; average number of tender and swollen joints, 36.6 and 24.2, respectively) on improvement of symptoms was evaluated. According to American College of Rheumatology (ACR) criteria for response, 32% of the ProSORBA-treated and 11.4% of the sham-treated patients improved ($p < 0.019$) at

19- or 20-week follow-up. The trial was stopped early by the data safety monitoring board because of overwhelming benefit with the Prosurba column. No differences in harmful adverse effects were found; both treatment groups experienced short-term joint pain flares and swelling after treatment, which were thought to be caused by the plasmapheresis procedure. However, because of the difficulty and expense of weekly treatments, combined with a limited duration of response, this treatment should be reserved for patients with RA refractory to multiple DMARDs.¹⁰

Cyclosporine is an effective treatment option, either alone or in combination with MTX.¹⁰ Cyclosporine therapy, however, is complicated by the potential for serious side effects (particularly dose-related renal toxicity and hypertension), the inconvenience of necessary drug level monitoring, drug interactions, and high cost. As a result, consideration of cyclosporine is limited to patients with refractory RA.

Thalidomide also is a TNF- α inhibitor that is effective in treatment-resistant RA.⁷⁵ Although thalidomide is associated with serious adverse effects (e.g., teratogenesis, peripheral neuropathy), strict treatment guideline adherence and diligent monitoring make thalidomide a treatment consideration for selected cases of refractory RA.

Two new classes of NSAIDs in development may provide GI protection without COX-2 specificity.⁷⁶ *Nitric oxide NSAIDs*, also known as COX-inhibiting-nitric oxide donors, consist of standard NSAIDs linked to a nitric oxide moiety. By donating nitric oxide to the gastric mucosa, nitric oxide NSAIDs produce the same gastroprotective effect as prostaglandins.⁷⁷ The second class of new NSAIDs broadens the pharmacologic effects of currently available NSAIDs by inhibiting both enzymatic pathways of arachidonic acid metabolism (i.e., both COX and 5-lipoxygenase). Although COX inhibition is clearly associated with GI toxicity, inhibition of both enzymatic pathways of arachidonic acid metabolism has been GI-sparing in animal and initial human safety studies.⁷⁸ Interestingly, both of these new NSAID classes seem to provide extended anti-inflammatory activity and, as a result, may have disease-modifying properties.⁷⁷

Vaccine therapy has been evaluated for RA prevention. In a double-blind, placebo-controlled phase II study of a T-cell receptor peptide vaccine in 99 patients with active RA, doses of 90 or 300 mcg were administered at baseline and at 4, 8, and 20 weeks. At 20-week follow-up, significantly more patients receiving the 90-mcg vaccine dose experienced improvement in RA signs and symptoms.⁷⁹ Although both vaccine dosage groups did not improve significantly when compared with placebo, a trend toward improvement was noted and no patients withdrew because of treatment-related adverse effects.

Clinical Use of Disease-Modifying Antirheumatic Drugs

Traditional DMARDs (e.g., gold, penicillamine, antimalarials, AZA, SSZ, MTX) are effective in attenuating clinical and laboratory manifestations of RA.⁵⁶ For example, a meta-analysis of the four published placebo-controlled trials that used strict research methodologies supports parenteral gold as an effective intervention.⁸⁰ Using a strict definition of improvement, 27% of patients treated with gold achieved 50% reduction

in active joint count compared with 11% of placebo-treated patients within 6 months.⁸¹ Nevertheless, long-term, positive therapeutic outcomes have not been realized for these drugs. With the exception of MTX, sustained treatment with any of these therapies is uncommon. Fewer than 20% of individuals, who were treated initially with parenteral gold, penicillamine, or antimalarials continued with their initial therapy for up to 5 years.⁸² Many discontinue therapy because of the loss of responsiveness and still more discontinue because of toxicity. Over a 20-year period, traditional DMARDs may improve function during the first 10 years, but joint function declines considerably during the following 10 years, resulting in severe disability.

In a prospective study of 245 patients with recently diagnosed RA, long-term treatment with traditional DMARDs (i.e., HCQ, SSZ, gold, penicillamine) was evaluated by survival analysis.⁸³ When indexed for side effects, 40% of gold, 12% of HCQ, 19% of SSZ, and 13% of penicillamine regimens were discontinued at 2 years. When this study was indexed for lack of efficacy, 61% of HCQ, 46% of SSZ, 43% of gold, and 43% of penicillamine regimens were discontinued by 2 years. These studies reveal the limited effectiveness of most traditional DMARDs in RA and provide important insight on the inability of relatively short-term efficacy studies to fully characterize therapeutic outcomes achievable for chronic diseases.

In another prospective trial, DMARD therapy (injectable gold, SSZ, HCQ, DPEN, AUR, MTX, AZA) was initiated early in patients with early onset RA. In this study, one or more DMARD was used continuously for an average of 6.2 years (range, 18-111 months). Throughout the study, if efficacy seemed to be inadequate or if adverse effects occurred, another DMARD was substituted. For example, MTX use continued to rise throughout the study until 37% of patients were taking MTX by the end of the study. The use of all of the other DMARDs either fell dramatically (particularly injectable gold) or remained constant at a low level of use.⁸⁴ This approach achieved a remission rate that increased with time to 32% at final follow-up. In this trial, the beneficial effects of active and continual traditional DMARD therapy persisted for at least 6 years and yielded better long-term outcomes than those achieved in previous trials. Nevertheless, this approach is far from adequate for all patients as because RA progressed in 25% of the study patients.

MTX remains efficacious significantly longer than other traditional DMARDs.⁸⁵ In one study, about 400 patients with RA were successfully treated with continuous MTX monotherapy for an average of 42 months, and some patients continued MTX as long as 60 months. In another study, only half of 600 patients with RA were able to continue therapy with any DMARD (except MTX) beyond 9 to 24 months.⁸⁶ In contrast, 62% of patients receiving MTX were able to continue with MTX therapy after 5 years of treatment. Nevertheless, MTX monotherapy seldom results in complete disease remission; only one-third of patients are able to maintain improvement by 50% after 2 to 4 years of treatment.⁸⁷

In a comprehensive review of the literature, the Agency for Healthcare Research and Quality compared the efficacy and adverse effects of various traditional and biological DMARDs, including monotherapies and combination therapies.⁴⁶ The

efficacy of traditional DMARDs (MTX, SSZ, LEF) was deemed similar. Although MTX is the preferred first-line DMARD, SSZ or LEF seem to be reasonable options for patients who are unable to tolerate MTX. All of the anti-TNF biologicals (etanercept, infliximab, adalimumab) seem to have similar efficacy. Although the IL-1Ra, anakinra, might be less efficacious than anti-TNF therapies; this preliminary assessment was based only on adjusted indirect comparisons.

In comparative trials of monotherapies of *traditional* DMARDs and *biological* DMARDs, adalimumab and etanercept monotherapies were equal in efficacy to MTX monotherapy; however, the biological DMARDs performed significantly better than MTX based on radiographic outcomes.⁴⁶ Although this seems to be an important difference, the relationship between radiographic differences in clinical trials and long-term disease progression has not been clearly established. Both etanercept and adalimumab improved functional capacity more than MTX.

The tight control of RA, utilizing dose escalation and several different combinations of DMARDs, is key to achieving remission, or at least a satisfactory response, to DMARD therapy.⁸⁸ In addition, the combination of various biological DMARDs with MTX is more efficacious than either biological DMARD or MTX therapy alone, and not associated with greater prevalence of adverse effects. Biological DMARDs, however, are still relatively new, and insufficient time has passed to clearly establish long-term safety (especially for abatacept and rituximab). The biological DMARDs have not been compared with DMARDs other than MTX.

The combination of MTX, SSZ, and HCQ is more effective than any one or two of these therapies for up to 2 years. This triple combination has not been compared with biological DMARDs. Combinations of two biological DMARDs do not show additional benefit over biological DMARD monotherapy and serious adverse effects (e.g., cellulitis, pneumonia, herpes zoster, pneumonitis, pyelonephritis) are increased significantly by combining two biological DMARDs.⁸⁹ Corticosteroid therapy combined with traditional DMARDs significantly improves functional capacity and radiographic outcomes when compared with traditional DMARD monotherapy, thereby reemphasizing the ability of corticosteroid therapy to modify disease. Corticosteroid therapy, however, should be limited to intermittent periods of use to manage disease flares

or exacerbations because of significant adverse effects associated with long-term therapy.

Inadequate studies are available to resoundingly conclude which combination of DMARDs is most effective. The BeSt study, the only randomized controlled trial comparing different DMARD treatment strategies, found that two different treatment approaches (MTX + SSZ + high-dose tapering prednisone [60 mg tapered down to 7.5 mg/day over 7 weeks] or MTX + infliximab) resulted in less radiographic progression of RA than either sequential DMARD therapy (MTX to SSZ to LEF) or step-up combination DMARD therapy (starting with MTX, adding SSZ then HCQ then prednisone 7.5 mg/day if disease remains active) at 1- and 2-year follow-up.⁸ However, all treatment groups experienced a similar improvement in functional capacity, as measured by Health Assessment Questionnaire (HAQ) scores, and disease activity, as measured by Disease Activity Score (DAS).

Biological agents (alone or in combination with MTX) seem to more rapidly improve signs and symptoms and slow disease progression (based on radiographic evidence) of RA than traditional DMARDs. These drugs should be considered for RA patients with moderate to severe disease, as well as for patients who fail to respond to an adequate trial of MTX.^{30,46,58} Nevertheless, the long-term efficacy and safety of biological DMARDs is unknown because these drugs are relatively new and clinical studies have been of limited duration. The routes of administration, dosing frequencies, and propensity for infusion reactions of biological agents are listed in Table 43-3.

Quantifying Response to Drug Therapy

RA drug therapy, historically, has been evaluated subjectively by evaluating patient self-reported changes in disease activity. The subjectiveness of patient self-reporting of RA activity is being replaced increasingly by more objective and comprehensive measures of disease control (e.g., laboratory test results, radiographic changes). This shift has been prompted by the fact that better disease remission rates (e.g., after 6–12 months of therapy) have been reported in DMARD clinical trials than from observational studies.^{90,91} The use of validated clinical assessment tools should yield a more accurate assessment of disease activity and improve the likelihood of attaining disease remission through modifications of drug therapy.^{92,93}

Table 43-3 Dosing and Administration of Biological Disease-Modifying Antirheumatic Drugs

| Biological DMARD | Route of Administration | Dosing Interval | Any Infusion Reaction Reported? | Fatal Infusion Reactions Reported? | Can Be Self-Administered? |
|-----------------------|-------------------------|---|---------------------------------|------------------------------------|---------------------------|
| Abatacept (Orencia) | IV | Every 2 weeks × 3 doses, then every 4 weeks | Yes | No | No |
| Adalimumab (Humira) | SC | Every 1–2 weeks | No | No | No |
| Anakinra (Kineret) | SC | Daily | No | No | No |
| Etanercept (Enbrel) | SC | 1–2 times per week | No | No | No |
| Infliximab (Remicade) | IV | Every 8 weeks | Yes | Yes | No |
| Rituximab (Rituxan) | IV | Variable (usually every 24 weeks) | Yes | Yes | Yes |

IV, intravenous; SC, subcutaneous.

Successful integration of objective clinical measurements into a standard of practice requires that the measurement tools used are validated, can be quickly administered, and are simple to use. Until recently, most large RA treatment trials utilized ACR standards to quantify response to therapy such as ACR-20, which refers to a 20% reduction in tender and swollen joint counts and 20% improvement in at least three of the following: patient's assessment of pain, patient's global assessment, physician's global assessment, patient's assessment of disability, and acute phase reactant measures (i.e., erythrocyte sedimentation rate [ESR] or C-reactive protein [CRP]). ACR-50 and ACR-70 are other common thresholds used to evaluate response to therapy, and attempts are being made to improve ACR-20 standards for clinical trials.⁹⁴ ACR evaluation reflects a minimum 6-week period of evaluation and, consequently, is of limited use in clinical practice because clinicians modify therapy based on an evaluation at a particular moment in time. The DAS 28 or 44 (corresponding to a 28 or 44 joint count) is a relatively newer tool used in more recent clinical trials to evaluate response to RA drug therapy.⁹⁵ However, the DAS is also not practical for clinical use because a very complex mathematical calculation is required.⁹⁶

New tools for measurement of RA disease activity that are more suited for clinical use have been developed. The *Clinical Disease Activity Index* (CDAI) and the *Simplified Disease Activity Index* (SDAI) are very similar in that they are determined through a simple sum of swollen joint count, tender joint count, and patient global disease activity and evaluator global disease activity (both measured by a visual analog scale [VAS]).⁹⁷ The difference between the two is that the SDAI includes CRP in the summation, whereas the CDAI does not. The *Global Arthritis Scale* (GAS) utilizes a summation of tender joint count, modified Health Assessment Questionnaire, and patient self-assessment of pain and function levels. The *Routine Assessment of Patient Index Data* (RAPID) measurement tool includes assessments of pain and function levels along with patient global assessment of disease activity.^{98–100} More recently, the *Easy Rheumatoid Activity Measure* (ERAM),^{96–99} a summation of patient and clinician global disease activity using a VAS with swollen joint counts from 28 joints, demonstrated a high level of correlation with DAS28, SDAI, and CDAI.⁹⁹ An important additional finding is that the ERAM required only an average of 2.67 minutes to complete. All of these tools have distinctly defined threshold scores corresponding to high disease activity, low moderate disease activity, low disease activity, and remission. For example, remission scores for DAS, CDAI, SDAI, and GAS are ≤ 2.6 , ≤ 2.8 , ≤ 3.3 , and ≤ 3 , respectively.

Although no single tool has been adopted as a standard of practice, RA disease activity measurement tools are becoming simpler to use in clinical settings and provide a more objective and comprehensive assessment of disease status. These tools, however, should not be solely relied upon for making RA treatment decisions because radiographic changes also should be considered when making RA treatment decisions. Radiographic changes, considered the gold standard for evaluating arthritis-related joint damage, occur in more than one-half of patients categorized as in remission based on DAS score.¹⁰¹

EARLY AND PROGRESSIVE RHEUMATOID ARTHRITIS

See Questions 1 to 16 for the role of nondrug and NSAID therapy, Questions 17 to 38 for traditional DMARDs, and Questions 39 to 47 for biological agents and corticosteroid therapy.

Signs and Symptoms

1. T.W., a previously healthy 42-year-old, 60-kg woman, has been suffering from morning stiffness that persists for several hours, anorexia, fatigue, and generalized muscle and joint pain over the past 4 months. In addition, she reports that her eyes seem red most of the time and are unusually dry. Her symptoms have been much worse during the past month and a half, and she has limited her physical activities. She also can no longer wear her wedding ring because of swelling of her hand.

Physical examination reveals bilaterally symmetrical swelling, tenderness, and warmth of the metacarpophalangeal (MCP) and proximal interphalangeal (PIP) joints of the hands and the metatarsophalangeal (MTP) joints of the feet. A subcutaneous nodule is evident on the extensor surface of the left forearm. Pertinent laboratory findings include the following: ESR by the Westergren method, 52 mm/hour (normal for women, <20 mm/hour if <50 years old, <30 if >50 years old; men, <15 mm/hour if <50 years old, <20 if >50 years old); hemoglobin (Hgb), 10.6 g/dL (normal, 12–16 g/dL); hematocrit (Hct), 33% (normal, 36%–47%); platelets, 480,000/mm³ (normal, 140,000–400,000/mm³); albumin, 3.8 g/dL (normal, 4.3–5.6 g/dL); serum uric acid, 3.0 μ g/dL (normal, 2–8 mg/dL); serum iron, 40 μ g/dL (normal, 60–180 mg/dL); total iron-binding capacity, 275 mg/dL (normal, 200–400 mg/dL); positive anti-cyclic citrullinated peptide (anti-CCP) at 82 U (normal, <20 U; weak positive, 20–39 U; moderate positive, 40–59 U; strong positive, >60 U) and positive RF performed by latex fixation method in a dilution of 1:320. Tests for antinuclear antibodies (ANA) and tuberculin sensitivity are negative. Radiographic films of the hands and feet show soft tissue swelling, narrowing of joint spaces, and marginal erosions of the second and third MCP and PIP joints bilaterally with no evidence of tophi or calcification. Other routine laboratory data and physical findings are normal. What signs and symptoms of RA are manifested by T.W.?

[SI units: Hgb, 6.6 mmol/L (normal, 7.4–9.9); albumin, 38 g/L (normal, 35–50); uric acid, 178.4 mol/L (normal, 202–416); iron, 7.2 μ mol/L (normal, 9–26.9); total iron-binding capacity, 49.2 mol/L (normal, 45–73)]

The presentation of RA at onset can vary, but characteristically 50% to 70% of cases have a rather insidious onset of disease over weeks to months.⁹ Early nonspecific symptoms such as fatigue, malaise, diffuse musculoskeletal pain, and morning stiffness may precede more specific symptoms. *Fatigue* and *morning stiffness* are prominent features of RA in T.W. About half of patients with RA initially experience fatigue that later in the disease serves as a useful index of disease activity. Patients usually experience prolonged morning stiffness upon awakening. This stiffness usually lasts 30 to 60 minutes, but can be present all day with decreasing intensity after arising. Duration of morning stiffness also can be a useful index of disease activity.

Over time, nonspecific *musculoskeletal pain* localizes to the joints bilaterally. Bilaterally symmetrical joint swelling and

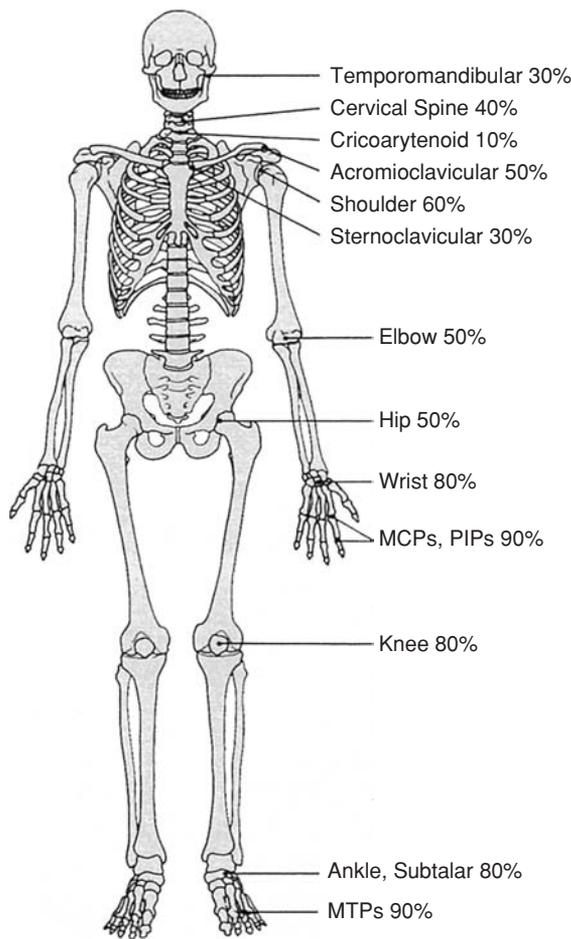

FIGURE 43-4 Frequency of involvement of different joint sites in established RA.

pain, involving the MCP and PIP joints of the hands and MTP joints of the feet, as illustrated by T.W., are characteristic of RA. The peripheral joints of the hands, wrists, and feet usually are involved first. Although MCP and PIP joints of the hands often are affected, the distal interphalangeal (DIP) joints usually are spared. Ultimately, any or all of the diarthrodial joints (elbows, knees, shoulders, ankles, hips, temporomandibular joints, sternoclavicular joints, glenohumeral joints) can be involved (Fig. 43-4). *Joint involvement* is characterized by soft tissue swelling and warmth, decreased range of motion (ROM), and sometimes muscle atrophy around affected joints. Progressive disease is characterized by irreversible joint deformities such as ulnar deviation of the fingers (Fig. 43-5), boutonniere deformities (hyperextension of the DIP joint and flexion of the PIP joint), or swan neck deformities (hyperextension of the PIP joint and flexion of the DIP joint; Fig. 43-6). Similar irreversible deformities also can involve the feet.

RA is a systemic disease, which is reflected by the extra-articular manifestations that can accompany joint involvement. *Subcutaneous nodules* are found in up to 35% of individuals with RA.⁹ As in the case of T.W., these nodules usually develop along extensor surfaces (e.g., olecranon process, proximal ulna), but occasionally are found in the hands, sacral areas, eyes, lungs, heart, soles of the feet and along the Achilles ten-

FIGURE 43-5 Ulnar deviation and MCP synovitis (left). This may progress to more marked lateral deviation with subluxation of the extensor tendons (right finger; right).

don. Patients who develop rheumatoid nodules almost always are RF positive.

Organ system involvement may be extensive. *Pleuropulmonary manifestations* (e.g., pleuritis, development of pulmonary nodules, interstitial fibrosis, pneumonitis, and rarely arteritis of the pulmonary vasculature) also can accompany the articular involvement of RA.⁹ *Cardiac involvement* can present as pericarditis or myocarditis. In addition, rheumatoid nodules can produce conduction defects or valve defects.

Some extra-articular manifestations occur as syndromes. *Sjogren syndrome* includes dry eyes (keratoconjunctivitis sicca), dry mouth (xerostomia), and connective tissue disease.¹⁰² T.W.'s eye complaints may be an extra-articular manifestation of her RA. *Felty syndrome* is characterized by chronic arthritis, splenomegaly, and neutropenia; thrombocytopenia, anemia, and lymphadenopathy also may be present.²⁵

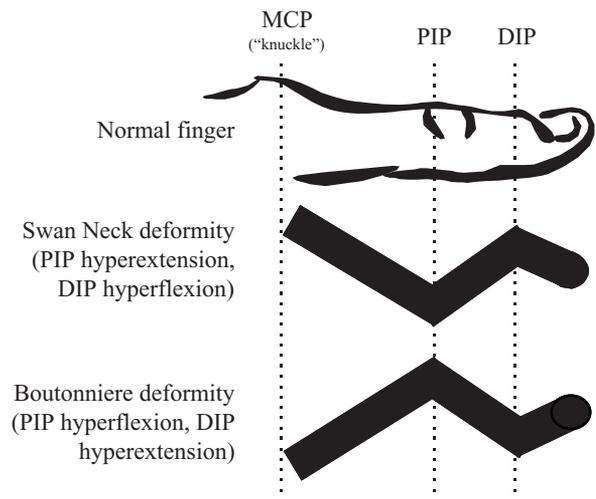

FIGURE 43-6 Characteristic finger deformities in RA. DIP, distal interphalangeal joint; MCP, metacarpophalangeal joint; PIP, proximal interphalangeal joint.

Vasculitis, another extra-articular manifestation of RA, can involve any organ system and can vary in seriousness from mild to potentially life-threatening (see Chapter 44).

2. What abnormal laboratory values in T.W. could be used to monitor the efficacy of drug therapy or disease progression?

The laboratory findings in RA are characteristic of a chronic systemic inflammatory disease. No test is specific for RA. T.W.'s elevated ESR is a nonspecific indication of inflammation. Alternatively, CRP plasma concentrations can be tested instead of ESR.¹⁰³ Levels of CRP, a plasma protein of the acute-phase response, correlate with RA disease activity better than ESR; however, CRP is also not disease specific. T.W.'s hematologic findings are consistent with a mild anemia of chronic inflammation. Although her serum iron concentration is decreased, her normal iron-binding capacity makes a diagnosis of iron-deficiency anemia unlikely. Her anemia probably results from a failure of iron release from the reticuloendothelial tissues and would not be expected to respond to iron therapy. The mild thrombocytosis is additional evidence of a systemic inflammatory response. The laboratory manifestations of inflammation should improve with effective drug therapy and, along with many of the clinical features of RA, are useful parameters for monitoring disease activity and response to therapy (Table 43-4).

T.W.'s serum albumin concentration is low (3.8 g/dL). The low serum albumin concentration in RA patients can result in higher free drug serum concentrations because of decreased protein binding of drugs (e.g., salicylates).¹⁰⁴

RF, an autoantibody (usually IgM or IgG) that reacts with the Fc portion of antigenic IgG to form an immune complex in vitro, is in the serum of approximately 75% of patients with RA.¹⁰⁵ RF is not in the serum of all patients with RA. It also can be present in 3% to 5% of healthy individuals and in patients with diseases other than RA, including almost any condition associated either with immune complex formation or

with hypergammaglobulinemia (e.g., chronic infections, lymphoproliferative and hepatic diseases, systemic forms of autoimmunity). Therefore, RF does not establish the diagnosis of RA. An RF titer of at least 1:160 is considered a positive test.¹⁰⁶ Patients with RA typically have titers of at least 1:320. Although RF titers do not parallel disease activity, high titers (>1:512) early in the disease course are associated with more severe and progressive disease. In T.W., the test for ANA ruled out systemic lupus erythematosus. The ANA, however, can be positive in 10% to 70% patients with RA.

Although RF lacks specificity for RA, the presence of RF remains one of the ACR criteria for establishing the diagnosis of RA.¹⁰ Citrullin, a nonstandard amino acid, also is established as a key component of RA antigenicity. Citrullinated proteins and anti-CCP antibodies are abundant in inflamed RA synovium. Anti-CCP antibodies can be detected in 50% to 60% of early RA patients, and the specificity of anti-CCP is very high at 95% to 98%.¹⁰⁷ In a study of 136 patients with a broad range of RA disease duration (3 months–30 years), the sensitivity of anti-CCP for the diagnosis of RA was 63% and the specificity was 89%, versus 85% and 65%, respectively, for RF. Another study found a sensitivity of 55% and a specificity of 97% for RA when both anti-CCP and RF were positive in the early cases of arthritis. Anti-CCP was detectable 1.5 to 9 years before the onset of RA (thereby suggesting a possible pathogenic role for these antibodies for RA).¹⁰⁸ A positive anti-CCP also correlates with an increase likelihood of a more erosive course of RA than either a negative anti-CCP or a positive RF.¹⁰⁸ In summary, a positive anti-CCP antibody test is highly specific for RA, predictive of the development of RA, and is a marker of an erosive disease course. Studies are currently ongoing attempting to define the optimal manner in which to incorporate anti-CCP into RA therapy management.

Treatment

Nondrug Treatment

3. What nondrug therapy should be included in the management of T.W.'s RA?

Treatment objectives in RA are reduction of joint pain and inflammation, preservation of joint function, and prevention of deformity. This is best achieved by instructing patients on proper regular exercise, joint protection and energy conservation, in combination with effective symptom-relieving and disease-modifying drug therapy.^{10,109,110} Insufficient literature evidence is available to support the use of spa therapy and thermotherapies such as ultrasound, electrotherapies (e.g., transcutaneous nerve stimulation, electrostimulation of muscles), and laser therapy. Heat treatments in general should be avoided during periods of active joint inflammation, because heat can further exacerbate pain and swelling. Overall, physical and occupational therapy can provide valuable assistance to patients with compromised activities of daily living, and thereby, maximize the potential for self-sufficiency.

EXERCISE

Passive exercise (e.g., ROM exercises) should be prescribed for T.W. until the acute inflammation subsides. Passive exercise minimizes muscle atrophy and flexion contractures and maintains joint function without increasing inflammation or

Table 43-4 Parameters Used to Assess Disease Activity and Drug Response in RA

- Duration and intensity of morning stiffness
- Number of painful or tender joints
- Number of swollen joints; severity of joint swelling
- Range of joint motion
- Time to onset of fatigue
- ESR or CRP
- Anti-CCP
- Radiographic changes: osteopenia, joint space narrowing, bony erosions
- Hgb/Hct
- Subcutaneous nodules, pleuritis, pneumonitis, myocarditis, vasculitis
- AIMS
- HAQ
- Validated clinical assessment tools: See general treatment section Quantifying Response to Drug Therapy

AIMS, arthritis impact measure scale; anti-CCP, anti-cyclic citrullinated peptide; CRP, C-reactive protein; ESR, erythrocyte sedimentation rate; HAQ, health assessment questionnaire; Hct, hematocrit; Hgb, hemoglobin; RA, rheumatoid arthritis.

radiographic progression of disease.¹⁰⁹ A properly defined exercise program should be developed with specific exercises on a scheduled basis that are not harmful to inflamed joints. Examples of ideal exercises include cycling (stationary if outdoor movement is considered unsafe), water exercises (e.g., swimming, water aerobics), and walking (assuming weight-bearing joints can tolerate the patient's bodyweight).

JOINT PROTECTION AND ENERGY CONSERVATION

Systemic and articular rest (achieved by splinting the affected joints) can reduce inflammation significantly.^{109,110} Restful and adequate sleep are important for general health and particularly important in a chronic, fatigue-inducing disease such as RA. Prolonged rest, however, can induce rapid losses in strength and endurance. Therefore, RA patients experiencing acute inflammation, such as T.W., should rest often, but daytime rest periods should be limited to 30 to 60 minutes. Splinting of joints is typically prescribed throughout the day and night during periods of active inflammation, then only at night for several weeks after cessation of inflammation.

Some orthoses, which are medical devices secured to any part of a patient's body designed to support, immobilize, align, correct or prevent deformity, or improve functioning, can reduce pain and inflammation and/or improve joint function in targeted joints for RA patients.¹⁰⁹ For example, wrist and finger/thumb splints can reduce wrist and hand pain while improving grip strength; however, these can worsen dexterity. Finger splints for patients with swan neck deformities have

been shown to improve hand function and finer stability. Special shoes and sole inserts also can reduce pain and disability.

EMOTIONAL SUPPORT

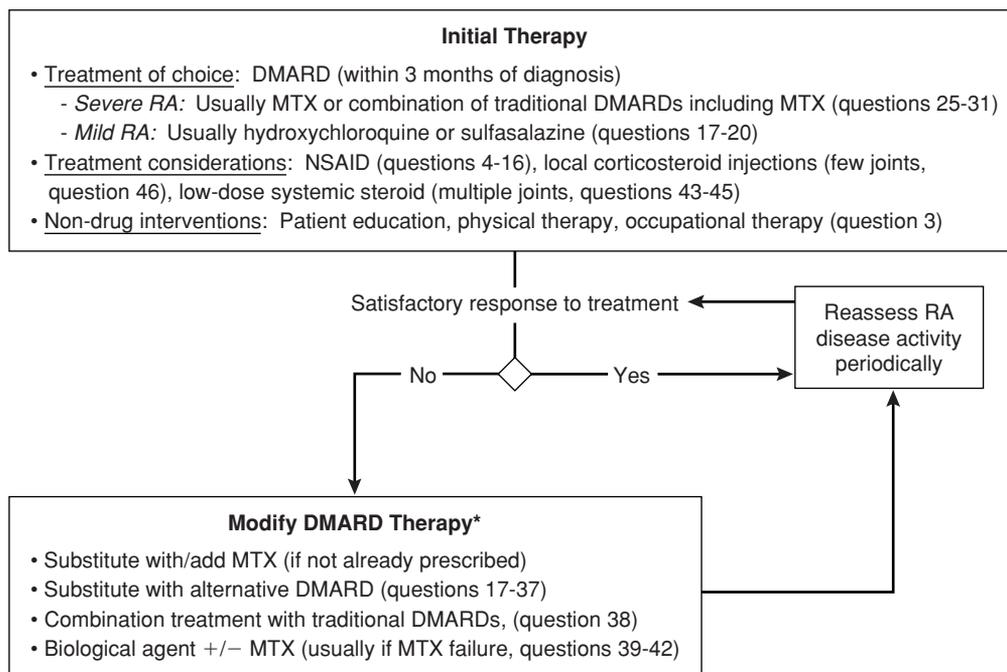

Emotional support should be provided to all patients such as T.W. A patient's reaction to RA can be affected by age, personality, and the environment at work and at home. As with all chronic debilitating diseases, the potential loss of independence, loss of self-esteem, altered interpersonal relationships with friends and family, and potential loss of employment can result in a two- to threefold increase in depression.¹¹¹ Depending on each patient's needs, the expertise of different health care disciplines (e.g., physical therapists, social workers, health educators, psychiatrists, clinical psychologists, podiatrists, vocational rehabilitation therapists, pharmacists) should be consulted. For example, pharmacists in capitated outpatient clinical practices can monitor RA drug therapy for therapeutic and adverse effects under collaborative practice agreements with other practitioners and can counsel patients on proper medication use and clarify expectations.¹¹²

Drug Treatment (Fig. 43-7)

NONSTEROIDAL ANTI-INFLAMMATORY DRUGS AND ASPIRIN

4. T.W. will be treated with a DMARD and concurrent NSAID therapy initially to rapidly control inflammation and swelling. What should be the role of NSAIDs for T.W.?

Overview: RA Drug Therapy

RA = rheumatoid arthritis; DMARD = disease-modifying antirheumatic drug; MTX = methotrexate; NSAID = nonsteroidal anti-inflammatory drug

*: Consider local corticosteroid injection(s) or low-dose systemic steroids if appropriate

FIGURE 43-7 Overview of RA drug therapy.

T.W.s clinical presentation clearly warrants DMARD therapy (see Question 17 and section on Clinical Use of Disease-Modifying Agents). The purpose of NSAID therapy, which has no disease-modifying activity, is to provide rapid pain relief and reduction of joint inflammation.

At one time, aspirin was the first line of treatment for RA patients who were able to tolerate it; however, aspirin currently seldom is the NSAID of choice because of well-documented GI toxicity and the availability of safer and more convenient NSAIDs.^{10,113}

Aspirin is low cost, and serum salicylate levels correlate well with both efficacy and toxicity.³⁴ Anti-inflammatory effects of aspirin can be achieved with dosages sufficient to provide serum salicylate concentrations of 15 to 30 mg/dL.³⁴ A reasonable initial aspirin dose is 45 mg/kg/day divided into 4- or 6-hour intervals; however, the anti-inflammatory dose of aspirin varies widely because of interindividual variations in metabolism.

After intestinal absorption, aspirin is hydrolyzed rapidly to salicylate (or salicylic acid), which subsequently is metabolized via multiple pathways. Metabolism to salicyluric acid and salicyl phenolic glucuronide is capacity limited.³⁴ The serum salicylate half-life after a single 650-mg dose of aspirin is 3.5 to 4.5 hours, but large daily doses of aspirin (e.g., 4.5 g/day) result in a serum salicylate half-life of 15 to 20 hours. The pharmacokinetics of salicylate are complex and affected by both first-order and Michaelis-Menten elimination processes. When utilizing anti-inflammatory doses of aspirin, 5 to 7 days of therapy are needed before steady-state serum concentrations of salicylate are attained.

5. A.L., a patient with RA, had her aspirin dosage increased to 975 mg QID approximately 1 week ago. She now complains of, "... ringing in my ears all the time!" What is the most probable cause of this symptom?

Aspirin-induced tinnitus (i.e., a ringing or high-pitched buzzing sensation in the head) is noticeable to most patients with normal hearing when serum levels are 10 to 30 mg/dL; however, in some patients tinnitus might not be encountered until serum levels exceed 25 mg/dL.³⁴ Serum salicylate concentrations usually are within the therapeutic range when tinnitus is apparent. Tinnitus, therefore, can be used to titrate patients to therapeutic doses of aspirin; however, patients with preexisting hearing loss might not experience tinnitus despite potentially toxic concentrations.¹¹⁴

Alternative Formulations

6. P.D., a man with an alleged aspirin allergy, avoids aspirin because it has upset his stomach in the past. However, he can take large doses of an enteric-coated aspirin (Ecotrin) without experiencing GI intolerance. What are appropriate alternatives for patients who cannot tolerate therapeutic doses of aspirin?

Patients who complain of GI side effects commonly use aspirin formulations that contain buffering agents (e.g., Alka-Seltzer, Ascriptin, Bufferin). The antacid content in Alka-Seltzer is insufficient to reduce acute GI microbleeding and symptoms, and contributes more than a gram of sodium for each 650 mg of aspirin. Ascriptin and Bufferin contain too little antacid to appreciably reduce GI microbleeding,¹¹⁵ but occasionally are better tolerated than regular aspirin.

Enteric-coated aspirin is associated with fewer GI complaints than uncoated aspirin.¹¹⁵ Although enteric coating increases the likelihood of incomplete absorption, Measurin was absorbed reliably in one study involving small numbers of patients,¹¹⁶ and other newer enteric-coated aspirin preparations can be absorbed reliably as well. Enteric-coated aspirin can be a useful alternative to regular aspirin for some patients.

Sustained-release (SR) aspirin (e.g., ZORprin, Measurin) is intended to provide more stable salicylate concentrations with less frequent administration. Twice-daily dosing of Measurin produces average serum salicylate concentrations comparable to equal doses of aspirin administered four times daily.¹¹⁷ However, the elimination half-life of regular aspirin in anti-inflammatory doses already is sufficiently long to support relatively stable serum salicylate concentrations with twice-daily dosing.^{118,119} The relative advantage of SR aspirin compared with regular or enteric-coated aspirin remains unclear. Nevertheless, some patients tolerate these SR aspirin dosage forms better than regular aspirin.

In summary, various aspirin dosage forms are available. Enteric-coated preparations, despite their expense and potential for incomplete absorption, are alternatives for patients with a history of gastroduodenal ulcers. Alternatively, some newer NSAIDs are equally effective and associated with less GI toxicity (see Question 11).

Aspirin and Nonsteroidal Anti-Inflammatory Drug Allergy

7. Aspirin was ordered for the relief of pain in C.S., who was hospitalized for evaluation and treatment of his RA. An allergy to aspirin is noted in C.S.'s medical chart. Why might another NSAID, also be contraindicated for this patient?

C.S. should be asked to describe his reaction to aspirin to determine whether his symptoms are consistent with a hypersensitivity reaction. Many patients who claim to be allergic to aspirin merely experience GI distress. In these patients, aspirin is not contraindicated and can be tolerated if administered with food or as an enteric-coated preparation.

Aspirin intolerance (hypersensitivity), especially in association with asthma, is cause for serious concern. Challenge with aspirin in these patients can precipitate an acute, life-threatening, bronchospastic reaction.¹²⁰ About 10% of asthmatics have a history of aspirin-induced bronchospasm, more often women than men and rarely in children.¹²¹ A somewhat smaller number of patients with recurrent rhinitis also experience this problem.¹²² The frequency of aspirin intolerance in patients with nasal polyps can be as high as 22%, and 70% of these patients have asthma.¹²³ All these patients also can experience a high degree of cross-reactivity to indomethacin (Indocin), naproxen (Naprosyn), ibuprofen (Motrin), fenoprofen (Nalfon), mefenamic acid (Ponstel), sodium benzoate (a widely used preservative), and tartrazine dye (FD&C Yellow No. 5), which is used in foods and some drugs. These substances are structurally dissimilar, but most are inhibitors of prostaglandin synthesis. Therefore, this reaction could be the result of an abnormal response to a common pharmacologic effect. Weak prostaglandin synthesis inhibitors (e.g., sodium and choline salicylate), have been administered to such aspirin-intolerant patients without untoward reactions.

COX-2 inhibitors also have been used safely in aspirin-sensitive asthmatics.^{124,125} In theory, these agents might

be safer because they allow COX-1 to continue producing prostaglandin E₂. Prostaglandin E₂ is an important mediator of multiple physiological processes, including reduction of leukotriene synthesis, suppression of the release of inflammatory mediators from mast cells, and prevention of aspirin-induced bronchoconstriction.

Some patients with chronic urticaria, as well as patients with rhinitis and aspirin allergy might be at increased risk to develop urticaria or angioedema on exposure to aspirin.¹²³ The pathogenic mechanism for this urticarial form of aspirin intolerance is unknown.

Prolongation of Bleeding Time

8. A.C. is scheduled to have an impacted wisdom tooth removed. She states that she is taking an aspirinlike product for arthritis. Why would the specific NSAID she is taking affect this dental procedure?

Aspirin, nonacetylated salicylates, nonaspirin NSAIDs, and COX-2 inhibitors have different effects on platelet function. Aspirin alters hemostasis most significantly and should be discontinued before surgery.³⁴ Low doses of aspirin irreversibly impair platelet aggregation throughout the life of the platelet by irreversible binding to COX and, thereby, prolong bleeding time for several days because new platelets must be released into the circulation before the bleeding time normalizes. Salicylates also can enhance blood fibrinolytic activity, and very large salicylate doses can induce a hypoprothrombinemia that is reversible by vitamin K. Salicylate-induced hypoprothrombinemia usually is not clinically significant, but it can be the cause of bleeding when associated with severe liver dysfunction or malnutrition.¹²⁶ Bleeding times normalize within 3 to 6 days after discontinuation of aspirin. Therefore, aspirin should be discontinued about 7 days before surgery.

Nonaspirin NSAIDs also can prolong bleeding times by inhibiting platelet aggregation, but these drugs bind reversibly to COX resulting in reversible platelet inhibition.³⁴ Therefore, nonaspirin NSAIDs should be discontinued about 5 half-lives before surgical procedures. Generally, the impairment of platelet aggregations is reversed within 2 days after the discontinuation of nonaspirin NSAIDs. Nonacetylated salicylates have minimal effects on COX and platelet function, and are of little concern in presurgical patients.³⁴ Likewise, COX-2 inhibitors are not expected to alter platelet function because COX-2 is not found in platelets.¹²⁷

Use in Pregnancy

9. K.H., a 28-year-old pregnant woman with RA, is concerned about the possible effects of NSAIDs on her baby. What are the risks to the fetus with uninterrupted consumption of NSAIDs? What are maternal- and lactation-related effects of these medications?

Although NSAIDs, including aspirin, are not teratogenic, they must be used cautiously in women who are pregnant and who plan to breast-feed infants.¹²⁸ Fetal effects of NSAIDs include possible premature ductus arteriosus closure, increased cutaneous and intracranial bleeding, transient renal impairment, and a reduction in urine output. High doses of aspirin (> 3 g/day) and NSAIDs can inhibit uterine contraction, resulting in prolonged labor. NSAIDs also can increase peripartum blood loss and anemia. Aspirin and nonaspirin NSAIDs should be used sparingly at lowest effective doses during in pregnancy

and discontinued at least 6 to 8 weeks before delivery to minimize adverse fetal and maternal effects.

Aspirin generally should be avoided for women who plan to nurse their baby because salicylate serum concentrations in breastfed neonates raise concerns about the potential for metabolic acidosis, bleeding, and Reye syndrome. According to the American Academy of Pediatrics, the nonaspirin NSAIDs (e.g., ibuprofen, naproxen) generally are compatible with breastfeeding.¹²⁹

NONASPIRIN NONSTEROIDAL ANTI-INFLAMMATORY DRUGS

Choice of Agent

10. NSAIDs and DMARD therapy are to be initiated for T.W. (Questions 1–4). What is the NSAID of choice for T.W.?

In general, there is no “NSAID of choice” for treatment of RA.^{10,34} There is no significant difference among the NSAIDs in efficacy, and it is difficult to predict a given patient’s response to a particular NSAID. The selection of an NSAID is based primarily on patient preference, convenience, cost, and safety.⁸ A 1- to 2-week trial of any NSAID (Table 43-5) at a moderate to high dose on a scheduled basis (i.e., not “as needed”) is the best method of determining anti-inflammatory efficacy. The analgesic and antipyretic effects are relatively prompt in onset. Although aspirin is effective, the nonaspirin NSAIDs usually are preferred.¹¹³ Nonacetylated salicylates, derivatives of salicylic acid, are weak inhibitors of COX in vitro, but have risks of GI and renal toxicity similar to nonselective NSAIDs.^{130–132}

The nonsalicylate NSAIDs (e.g., ibuprofen) have important differentiating properties.³⁴ For example, indomethacin penetrates the blood-brain barrier better than any other NSAID, achieving levels in the cerebrospinal fluid of up to 50% of serum levels. As a result, the incidence of central nervous system side effects of indomethacin often precludes the use of optimal anti-inflammatory doses, particularly in the elderly.¹³³ Loose stools or diarrhea can be dose limiting for some patients receiving meclofenamate. Piroxicam, a longer acting NSAID, has been associated with a higher frequency of peptic ulcer disease and GI bleeding¹¹³ and, therefore, should be avoided. Several NSAIDs, including celecoxib and high doses of either ibuprofen or diclofenac, seem to increase the risk of MI, whereas naproxen seems to have the best cardiovascular safety.¹³⁴

The relative GI safety of partially COX-2-selective NSAIDs (e.g., nabumetone, etodolac, meloxicam) versus nonselective NSAIDs is unclear. The only remaining COX-2-specific inhibitor that is available in the United States, celecoxib, has no effect on COX-1 and the GI protective effect of celecoxib is questionable owing to a major protocol violation in the largest GI safety study involving celecoxib¹³⁵ (see Question 11).

A low-cost NSAID with a good safety profile (e.g., ibuprofen) is a good choice for T.W. because she is relatively young and does not have any concomitant illnesses. If convenience of administration is a more important consideration, a longer acting NSAID (e.g., naproxen) would be preferable. If the first chosen NSAID is ineffective or not well tolerated, other NSAIDs can be tried to identify the optimal one for this patient.

Adverse Effects

11. Naproxen 500 mg BID with meals has been prescribed for T.W. If T.W. were to develop dyspepsia during therapy, should she

be given misoprostol (or other antiulcer therapy) for prophylaxis against GI complications of NSAID therapy or would a COX-2 selective NSAID be preferable? What is the correlation between dyspepsia and gastroduodenal mucosal injury?

About 5% and 15% of patients with RA discontinue NSAID therapy because of dyspepsia,³⁷ and about 1.3% of patients taking NSAIDs for RA experience a serious GI complication.¹³⁶ As expected, the rate is somewhat lower for patients using

NSAIDs for osteoarthritis (OA; 0.7%) because these patients generally use analgesics only on an as-needed basis. Serious NSAID-induced GI complications account for about 103,000 hospitalizations annually in the United States and for approximately 16,500 NSAID-related deaths each year.³⁷ Although these figures warrant concern, most patients who experience NSAID-induced gastropathy suffer only superficial and self-limiting injury. Nevertheless, prevention of NSAID-induced

GI bleeding should be an important focus, particularly in high-risk patients.

NSAID-induced gastroduodenal mucosal damage primarily results from inhibition of COX-1 in the mucosal lining.³⁷ This inhibition of COX-1 decreases bicarbonate secretion, mucosal blood flow, formation of protective mucus, proliferation of gastric epithelium, and the ability of the mucosa to resist injury. NSAID-induced direct topical injury to the mucosa can occur, but direct injury plays a smaller role than COX-1 inhibition. NSAID-induced gastropathy can be managed by: (a) treatment of NSAID-related dyspepsia, (b) prevention of NSAID-associated gastroduodenal ulcers, and (c) management of NSAID-related gastroduodenal ulcers.

Dyspepsia can be managed by ingesting the NSAID with meals or a large glass of water; however, these measures usually are ineffective in preventing GI ulcers. In addition, dyspepsia correlates poorly with endoscopically confirmed mucosal injury.³⁷ Histamine-2 (H₂)-receptor antagonists (e.g., ranitidine, famotidine) significantly reduce dyspepsia among NSAID users; however, NSAID users with RA who take a H₂-receptor antagonist might have a higher risk of developing serious GI complications compared with those who did not take these medications (odds ratio, 2.14; 95% confidence interval, 1.06–4.32).¹³⁷ The suppression of dyspepsia can give a false sense of security to the patient and physician, leading to higher doses of NSAIDs and increased risk of major gastropathy. Therefore, H₂-receptor antagonists are not recommended for routine use in asymptomatic patients receiving NSAIDs. Proton pump inhibitors (PPIs; e.g., lansoprazole 30 mg/day or omeprazole 20 mg/day) relieve dyspepsia better than H₂-receptor antagonists and prevent the development of NSAID-induced gastroduodenal ulcers.^{37,138,139} PPIs are safe and effective for the treatment of NSAID-induced dyspepsia and should be considered if symptoms develop in T.W.

Routine concomitant antiulcer prophylactic therapy is not warranted for all patients taking NSAIDs.^{10,34} The most effective means of preventing NSAID-related gastroduodenal ulcers is obviously to avoid their use. If NSAIDs must be used, the patient's risk for GI ulcer development must be assessed to determine the need for ulcer prevention measures.³⁷ Established risk factors for NSAID-induced GI bleeding include advancing age (>60 years of age), a history of ulcers, use of ulcer-promoting medications (corticosteroids, high-dose NSAIDs, concurrent use of more than one NSAID or aspirin at any dose, anticoagulants), and daily alcohol consumption.¹⁴⁰ *Helicobacter pylori* infection may also increase the risk of NSAID-induced GI bleeding; however, *H. pylori* eradication has a minimal impact on preventing NSAID-related gastroduode-

nal injury.¹⁴¹ Patients requiring NSAID therapy who are at high risk for GI bleeding should receive concomitant ulcer prevention therapy. Misoprostol (200 mcg three or four times daily), a prostaglandin E₁ analog, and a PPI are effective in preventing NSAID-induced gastroduodenal mucosal injury.¹⁴¹ PPI cotherapy is more commonly prescribed because of the convenience of once-daily dosing and better tolerability. Dose-related GI upset, particularly diarrhea and abdominal pain, is a frequent cause of misoprostol intolerance. No evidence is available to support the use of H₂-receptor antagonists, sucralfate, and antacids in preventing NSAID-related GI injury.

Active NSAID-induced gastroduodenal ulcers are best treated by discontinuing the NSAID and initiating either a H₂-receptor antagonist (e.g., cimetidine 800 mg, ranitidine 150 mg, nizatidine 150 mg, famotidine 40 mg) or a PPI (same dosing as for ulcer prevention). In general, a PPI is preferred because of rapid healing rates and shorter duration of treatment (4–8 weeks). If discontinuation of the NSAID is not feasible, ulcer healing can still be accomplished with a PPI but requires a longer duration of therapy (8–12 weeks).³⁷ Patients who test positive for *H. Pylori* should undergo *H. Pylori* eradication therapy. Misoprostol, and antacids are ineffective treatments for NSAID-induced ulcers.

The development of NSAIDs highly selective for COX-2 introduced the potential to reduce inflammation without the worrisome adverse effects of nonselective NSAIDs, particularly gastropathy (see general treatment section and Table 43-6). COX-2-selective inhibitors (e.g., celecoxib, rofecoxib, valdecoxib) do not interfere with COX-1 at therapeutic plasma concentrations in humans.^{142–145} Although COX-2 inhibitors are associated with significantly less endoscopically confirmed gastroduodenal ulcers when compared with nonselective NSAIDs, their effect on clinically significant gastropathy is unclear.¹⁴⁶ The incidence of clinically significant gastropathy was evaluated in two large clinical trials involving celecoxib (Celecoxib Long-Term Safety Study [CLASS]) and rofecoxib (Vioxx Gastrointestinal Outcomes Research [VIGOR]).^{135,147} The CLASS trial compared celecoxib to ibuprofen (800 mg TID) and diclofenac (75 mg BID), and the VIGOR trial compared rofecoxib to naproxen (500 mg BID). Up to 325 mg/day of aspirin use was allowed in CLASS (taken by 21% of patients). The primary endpoint for CLASS at 6 months of treatment was complicated ulcers and the secondary endpoint for CLASS included both symptomatic and complicated ulcers.

In the CLASS study, only the secondary endpoint proved to significantly favor celecoxib over ibuprofen and diclofenac. The conclusions of CLASS are controversial. The published CLASS data consisted of roughly half of the treatment

Table 43-6 Comparison of Cyclo-oxygenase (COX)-1 and COX-2 Isoforms²⁸²

| COX Isoform | COX-1 | COX-2 |
|------------------------------------|---|---|
| Expression: continuous or induced? | Primarily continuous, although some evidence of induction | Primarily induced, but present continuously in several organs |
| Common organs/tissues | Nearly all organs, including stomach, kidneys, platelets, vasculature | Induced at sites of inflammation and neoplasms Continuously active in kidneys, small intestine, pancreas, brain, ovaries, uterus |
| Primary role | Housekeeping/maintenance May be important when induced in response to inflammation | Inflammation, repair, neoplasia May be important in housekeeping/maintenance of organs which continuously express COX-2 |

duration specified in the original study design.¹⁴⁶ The study design for CLASS consisted of two separate long-term comparisons with diclofenac (12 months) and ibuprofen (16 months). The reporting of only 6 months of data seems to seriously violate the study protocol. Complete results, available through the U.S. Food and Drug Administration (FDA)'s website, indicates that the twofold reduction in combined symptomatic and complicated ulcers associated with celecoxib is only significant when compared with ibuprofen; no gastropathy advantage was identified when compared with diclofenac.¹⁴⁸ In fact, when an alternate definition of ulcer-related complications is applied to the CLASS trial (which was preplanned by the FDA), a nonsignificant trend in favor of diclofenac was found.¹⁴⁶ Consequently, the FDA has not approved of product labeling that suggest GI-sparing advantages associated with celecoxib. Although the results from VIGOR led to FDA approval of labeling to reflect reduction in serious GI complications,¹⁴⁹ rofecoxib has since been withdrawn from the market because of increased risk of cardiovascular events (see discussion in general treatment section).

Without risk factors other than NSAID use, T.W. does not need concurrent ulcer prophylaxis medication at this time.

Use in Renal Disease

12. T.Z., a 68-year-old man with heart failure previously managed with furosemide 40 mg/day, digoxin 0.125 mg/day, metoprolol 50 mg BID, and lisinopril 40 mg/day, returns for a prescription refill of ibuprofen 600 mg TID, which he takes for his RA. He has noted increased leg swelling over the past 2 weeks associated with a weight gain of several pounds, increasing shortness of breath (SOB), and easy fatigability. Why might these signs and symptoms be associated with ibuprofen?

Mild fluid retention occurs in approximately 5% of NSAID users, and NSAID-induced kidney disease occurs in <1% of patients.¹⁵⁰ NSAID therapy should be monitored carefully in patients with heart failure, liver disease with associated ascites, compromised renal function, or when diuretics are administered concomitantly. In these situations, renal function highly depends on local production of prostaglandin E₂ within the kidney to offset the vasoconstrictor effects of high concentrations of angiotensin, vasopressin, and catecholamines.¹⁵¹ Inhibition of COX by NSAIDs within the kidney reduces prostaglandin concentrations and unopposed vasoconstriction. Consequently, urine output declines, serum blood urea nitrogen and serum creatinine levels rise, and fluid is retained. This potential complication is associated with all of the currently marketed NSAIDs.¹⁵² In addition, ibuprofen is among several NSAIDs (e.g., celecoxib, high doses of diclofenac) that are associated with an increased risk of MI, which is a concern for T.Z. owing to his risk for cardiac events.¹³⁴

T.Z. should be informed that his leg swelling, weight gain, SOB, and fatigability might be caused by ibuprofen.

13. How should this drug-related problem be managed in T.Z.?

If T.Z.'s symptoms have been objectively attributed to some degree of renal dysfunction, his ibuprofen (Motrin) should be discontinued, NSAID therapy should not be restarted until renal function normalizes, and alternative approaches for management of his RA should be considered. In several studies, sulindac (Clinoril) had been associated with less adverse ef-

fects on the kidney than other NSAIDs.^{153–156} The reason(s) for this are unclear, but one explanation is that the active sulfide metabolite undergoes renal metabolism and, therefore, might not achieve tissue concentrations within the kidney sufficient to reduce prostaglandin production.¹⁵⁷ Unfortunately, patients do not seem to benefit from sulindac as much as from other NSAIDs. Nabumetone (Relafen), an NSAID with moderate COX-2 selectivity, has less of an effect on glomerular filtration than sulindac or ibuprofen.¹⁵⁸ The nonacetylated salicylates have minimal prostaglandin-inhibiting activity and could be alternatives for T.Z., although they too have been associated with renal toxicity. The COX-2 inhibitor, celecoxib, also has been associated with renal adverse effects such as edema (2.1%), new hypertension (0.8%), and exacerbation of preexisting hypertension (0.6%).¹⁵⁹ The incidence for these particular adverse events is similar to those associated with nonselective NSAIDs. Although celecoxib was associated with a slightly lower risk of death and heart failure exacerbation when compared with traditional NSAIDs,¹⁶⁰ it is not a reasonable initial option for T.Z. because celecoxib also is associated with an increased risk of MI.

NSAIDs should be used at lowest effective doses for minimal periods of time for T.Z. High-dose ibuprofen and celecoxib should be avoided owing to potential MI risk. Although acetaminophen is not an anti-inflammatory, it can provide analgesic relief. Intra-articular corticosteroid injections can be useful if inflamed joints are limited in number, or a short course of oral corticosteroids can provide rapid control of inflammation while reducing the need for longer courses of anti-inflammatory therapy. If T.Z. is not being treated with a DMARD, it should be seriously considered because all patients with RA are candidates for DMARDs, which could obviate T.Z.'s need for an NSAID. If an NSAID or short course of systemic corticosteroid is selected, close monitoring of renal function and fluid retention status is warranted.

14. What other renal syndromes are associated with NSAID therapy?

In addition to acute renal failure, NSAIDs can induce various adverse renal effects (e.g., nephrotic syndrome, interstitial nephritis, hyponatremia, abnormalities of water metabolism, hyperkalemia).¹⁶¹ The nephrotic syndrome, unlike NSAID-induced acute renal failure, can appear anytime (i.e., from days to years) after starting therapy; and can resolve as quickly as 1 month, or as long as 1 year, after discontinuation of the NSAID. Hematuria, pyuria, and proteinuria without prior renal disease differentiates nephrotic syndrome from other NSAID-induced renal problems. Histologically, NSAID-induced nephrotic syndrome is characterized by interstitial lymphocytic infiltrates, vacuolar degeneration of proximal and distal tubules, and fusion of epithelial foot processes of glomeruli.

Prostaglandin-mediated inhibition of active chloride transport, regulation of medullary blood flow within the kidney, and antagonism of antidiuretic hormone can be suppressed by NSAIDs. As a result, urine is maximally concentrated, free water clearance is limited, and water retention that is disproportionate to sodium retention can occur. The resulting hyponatremia can be severe and could be potentiated by thiazide diuretics.¹⁶²

Local prostaglandin synthesis also can stimulate renin production within the kidney. NSAID therapy can critically

attenuate this regulatory mechanism in some situations, resulting in reduced aldosterone-mediated potassium excretion and hyperkalemia.

Although the mechanism is poorly understood, some NSAIDs have been associated with sustained mean arterial pressure increases of 5 to 6 mm Hg,¹⁶³ presumably the result of COX-2 inhibition and sodium/water retention. However, in several studies, only patients taking antihypertensive medications experienced NSAID-induced mean arterial pressure elevations, whereas those who controlled their hypertension without medications were unaffected by NSAID therapy. It seems, therefore, that NSAIDs can interfere with the action of antihypertensive drug therapy by a mechanism that has yet to be identified.

Laboratory Test Monitoring for Nonsteroidal Anti-Inflammatory Drug Therapy

15. When should routine renal or liver function be tested during NSAID therapy?

Patients at high risk for NSAID-induced renal disease (see Questions 12–14) should have their serum creatinine checked weekly for several weeks after initiation of therapy because renal insufficiency more commonly occurs early in the course of therapy.¹⁶² NSAID-induced nephrotic syndrome and allergic interstitial nephritis occur, on average, about 6.6 months and 15 days after NSAID initiation, respectively.

In most cases, liver function testing (LFT) is unnecessary.¹⁶² Although NSAIDs can elevate liver enzymes, severe hepatotoxicity is rare. Abnormal LFTs without clinical symptoms have no impact on patient outcome and have not been associated with severe hepatotoxicity. However, patients who seem to be at greater risk for hepatotoxicity are those with established or suspected intrinsic liver disease and those receiving diclofenac. These patients should have liver function tested no later than 8 weeks after initiation of therapy because liver toxicity manifests early in therapy if at all.

Patient Instructions

16. What instructions should be provided to a RA patient receiving a NSAID prescription?

Patients should be informed that NSAID therapy is being prescribed to provide relief of pain and inflammation associated with RA, but does not slow or stop the progression of the disease. It should be explained that the latter only can be accomplished by DMARD therapy. Patients should also understand that moderate to high daily doses of NSAIDs are required for anti-inflammatory activity, as opposed to analgesic and antipyretic effects which can be achieved with single and low doses.

Patients should be instructed to keep the NSAID container tightly closed and to avoid storing NSAIDs, particularly aspirin, in moist environments (e.g., bathrooms). Aspirin is hydrolyzed to salicylic acid and acetic acid with moisture. Prescription NSAIDs and aspirin come in childproof safety containers, but many arthritic patients have difficulty with these safety closures because of diminished grip strength and hand deformities. If an NSAID is dispensed in a conventional closure container, it is necessary to explain the hazards of accidental ingestion by children and, as required by law in most states, obtain a signed release form.

Patients should be taught to recognize the signs and symptoms of GI bleeding (e.g., nausea, vomiting, anorexia, gastric pain), GI bleeding as manifested by melena (described to the patient as “dark, tarry stool”), or emesis of coagulated blood (described to the patient as, “coughing or vomiting up what seems to be coffee grounds”). It should be emphasized that GI bleeding can occur without gastric pain. The patient should be instructed to contact their health care provider immediately for further instructions if any of these signs or symptoms occur.

TRADITIONAL DISEASE-MODIFYING ANTIRHEUMATIC DRUGS

17. Which traditional DMARD therapies are most appropriate for T.W.?

Every newly diagnosed RA patient is a candidate for DMARD therapy, which should be started within 3 months of diagnosis.¹⁰ For most patients, MTX is the initial DMARD of choice because of high rate of clinical response for all levels of RA severity and radiographic evidence of slowing joint erosion, which is most rapid during the first several years of active disease^{164,165} (Fig. 43-8). Although most DMARDs are associated with potentially serious adverse effects, these generally are reversible and seldom lead to serious complications if the patient has been monitored appropriately.

Most patients with active RA are treated with at least one DMARD and with an NSAID.¹⁰ In addition, low-dose oral corticosteroids are often prescribed on an “as needed” basis for brief periods of severe disease activity or while awaiting the onset of DMARD action. During periods of disease remission, NSAID therapy can be discontinued; however, attempts to discontinue traditional DMARDs have resulted in disease reactivation or “rebound flare” and resumption of the discontinued traditional DMARD is not always successful in reestablishing control. Therefore, successful traditional DMARD therapy should be continued indefinitely. Safety and efficacy data, which reflect several years of DMARD therapy combined with biological agents, have been excellent, and the combination is now commonly prescribed for patients who fail MTX monotherapy (see Questions 39 and 43). The selection of DMARDs (see General Treatment section) and their use in combination seems more effective than DMARD monotherapy (see Question 38).

Antimalarials

Dosing

18. Although T.W.’s presentation could warrant a more potent DMARD, treatment was initiated with HCQ. What dosages would be appropriate, and when should clinical improvement be expected?

Although the manufacturer’s literature recommends an initial HCQ adult dose of 400 to 600 mg/day (310–465 mg of base), dosages for HCQ generally range from 2 to 6.5 mg/kg/day.²⁹ If the patient responds well, the maintenance dose can be reduced by 50% and the medication continued at a dose of 200 to 400 mg/day (155–310 mg of base). About two-thirds of patients who tolerate HCQ respond favorably. Benefits usually are apparent within 2 to 4 months of therapy, but can vary between 1 and 6 months.¹⁰ About 37% of patients discontinued HCQ within a year and 54% within 2 years primarily owing to lack of efficacy.¹⁶⁶

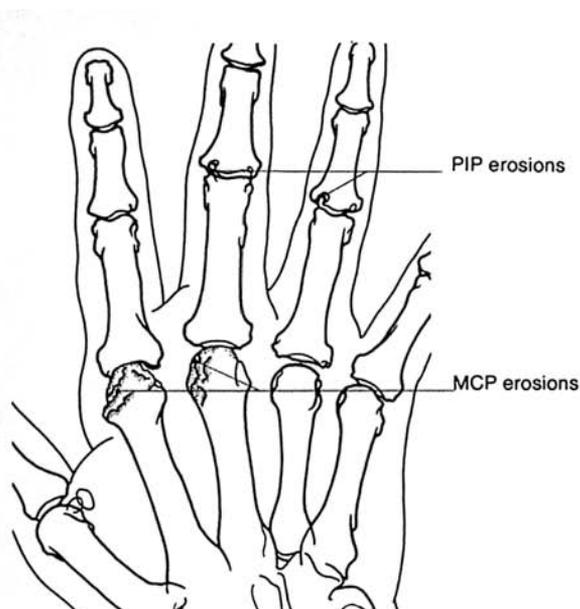

FIGURE 43-8 Radiograph of the hand in RA showing both active erosions at the metacarpophalangeal joints (MCPs) and old well-demarcated erosions at the proximal interphalangeal joints (PIPs).

Risk of Retinopathy

19. How great is the risk of retinopathy from antimalarials when used for the treatment of RA? What monitoring parameters are appropriate?

HCQ seems to be the least toxic of all DMARDs. The most serious toxicity, retinal damage and subsequent visual impairment, is rare.¹⁶² Risk of retinopathy seems to correlate with cumulative dose (>800 g) and age (>70 years). The increased risk of retinopathy in the elderly seems to be related to the increased prevalence of macular disease in this age group. HCQ doses exceeding 6.0 to 6.5 mg/kg are associated with increased risk of retinal damage, particularly in patients with renal or hepatic dysfunction.

Patients should be instructed to stop therapy immediately and undergo an ophthalmologic evaluation if experiencing symptoms of antimalarial-associated retinopathy (e.g., difficulty seeing faces or entire words, glare intolerance, poor night vision, loss of peripheral vision).¹⁶² The fully developed lesion of antimalarial retinopathy is seen on ophthalmoscopy as a pigmentary disturbance with a characteristic “bull’s eye” appearance in the macular region. The 4-amino-quinolines bind to melanin, and as a result, concentrate in the uveal tract and retinal pigment epithelium. The retinopathy can be progressive even after discontinuation of the drug.

Baseline eye examination is not required in patients younger than 40 with no family history of eye disease. The first ophthalmologic examination is recommended after 6 months of HCQ therapy, followed by an examination with central field testing

every 6 to 12 months. More frequent testing is recommended for patients with renal dysfunction or patients who have received HCQ therapy for >10 years. Benign corneal deposits of antimalarial drug may occur during therapy. Although this adverse effect may be symptomatic, it is harmless, reversible when the antimalarial drug is discontinued, and not related to the more serious and less common retinopathy.¹⁶⁷

Sulfasalazine

20. If SSZ were chosen as initial therapy for T.W., when should therapeutic effects become apparent and what adverse effects might be anticipated?

The onset of SSZ effect is generally more rapid than HCQ and can become apparent within a month¹⁰; however, a clinical response might be delayed for 4 months, and doses should be adjusted only after this period has elapsed.

Compared with other DMARDs, adverse effects associated with SSZ are relatively mild, consisting of nausea, abdominal discomfort, heartburn, dizziness, headaches, skin rashes, and, rarely, hematologic effects such as leukopenia (1%–3%) or thrombocytopenia (rare).¹⁶⁸ A complete blood count (CBC) is recommended every 2 to 4 weeks for the first 3 months of therapy, then every 3 months thereafter. Leukopenia more commonly manifests within the first 6 months of therapy. To minimize GI-related adverse effects, SSZ is initiated at 500 mg/day or 1 g/day and the dosage is increased at weekly intervals by 500 mg until 1,000 mg two or three times daily is reached.

Gold

Preparations and Adverse Reactions

21. S.S., a 41-year-old Asian woman diagnosed with RA, presents with inflammation in both hands (MCP and PIP joints), wrists, elbows, shoulders, knees, hips, ankles, and MTP joints. Objective test results include radiographic evidence of joint erosion in both hands and elbows, positive RF (dilution of 1:1,280), positive anti-CCP at 102 units, and ESR of 78 mm/hour. Her symptoms were managed over the past year with ibuprofen 800 mg TID; however, pain and inflammation have progressively worsened over several months. ROM testing reveals deficits in wrist flexion and extension (20 degrees bilaterally for both motions; normal, 90 and 70 degrees, respectively), elbow flexion (90 degrees bilaterally with flexion contracture; normal, 160 degrees), shoulder abduction (70 degrees right, 90 degrees left; normal, 180 degrees), and plantar flexion of both ankles (20 degrees bilaterally; normal, 45 degrees). Three firm, pea-sized, nontender moveable subcutaneous nodules are found on both elbows at the ulnar border, two on the right and one on the left. In your discussion about considering DMARD therapy, S.S. states that she does not want gold therapy "... because I've heard that it has terrible side effects." What gold preparations are available, and is S.S.'s concern about adverse effects warranted?

Two parenteral gold preparations are available: gold sodium thiomalate (Myochrysin), an aqueous solution, and aurothioglucose (Solganal), an oil suspension. Although an oral gold formulation, AUR (Ridaura), is also available, it is slow in onset (4–6 months) and is less efficacious.¹⁰ The parenteral formulations, containing approximately 50% gold by weight expressed as milligrams of complex, are equally effective.²⁹ Aurothioglucose must be shaken thoroughly before withdrawal from its vial and a large-bore needle is necessary to draw up this viscous suspension. Lumps at the intramuscular injection site sometimes can be troublesome to the patient.

Toxicities with both injectable gold preparations are numerous and largely responsible for their high rate of discontinuation. In a 6-year prospective trial, nearly half of patients receiving gold sodium thiomalate discontinued therapy, with 95% of those discontinuing because of toxicity.⁵⁵ The toxicity profiles of the parenteral gold preparations differ. A vasomotor reaction (also termed *nitritoid reaction*), which manifests as nausea, weakness, flushing, tachycardia, and/or syncope, can occur in up to 5% of patients receiving gold sodium thiomalate. These reactions generally are mild, are transient, and often can be alleviated by having the patient lie down.

Gold-induced myocardial ischemia or infarction is rare and possibly related to the vehicle or preservative in the thiomalate preparation because it has not been reported with aurothioglucose.¹⁶⁹ Patients with concomitant cardiovascular disease or patients who experience a nitritoid reaction after an injection of gold sodium thiomalate can be treated with aurothioglucose, although treatment with MTX, biological agents, or other alternatives should be considered.

Nonvasomotor reactions, consisting of transient stiffness, arthralgias, and myalgias, developed in 15% of patients after initiation of gold sodium thiomalate therapy,¹⁷⁰ and substituting aurothioglucose for the thiomalate formulation decreased severity of this adverse reaction in 40% of the patients.

Skin eruptions, stomatitis, and albuminuria are more common in patients who receive the aqueous gold sodium thiomalate

preparation than in patients who received the oil suspension of aurothioglucose.¹⁷¹ Aurothioglucose also is more commonly associated with renal toxicity than gold sodium thiomalate, although the overall incidence is rare.¹⁷² Membranous nephropathy (most common), nephrotic syndrome, and interstitial nephritis have been reported. Hematuria and proteinuria may be early indicators of membranous nephropathy; however, proteinuria can occur transiently in up to 50% of patients receiving aurothioglucose. Patients who develop proteinuria should undergo a renal evaluation and a urinalysis. Gold therapy should be discontinued if protein excretion is >500 mg/24 hr.

Parenteral gold preparations have been associated with sudden occurrence of idiosyncratic thrombocytopenia (1%–3%) or aplastic anemia (<1%).¹⁷² Screening for urine protein and a CBC should be performed before each weekly injection for the first 20 to 22 weeks, then before every other injection. In addition, patients should be asked about the occurrence of pruritus, skin eruptions, purpura, sore throat, and stomatitis before each dose of gold is administered.

Pruritus, erythema, or a fine morbilliform rash on the neck or extremities can develop after the first few injections of gold. These cutaneous reactions are common, usually subside within several days, and do not seem to be affected by subsequent injections. Although a highly pruritic localized eruption resembling pityriasis rosea is common, gold dermatitis may assume many different forms, including exfoliative dermatitis.²⁹ Therapy should be discontinued if a pruritic dermatitis develops. Mild dermal reactions may be managed with topical corticosteroids.¹⁷²

If discontinued, gold can be reintroduced in a reduced dosage after resolution of rashes (see Question 23). Gold treatments should be discontinued if white blood cells (WBCs) decline to <3,500 cells/mm³, if platelets fall to <100,000 cells/mm³, or if the Hgb concentration falls rapidly.¹⁶² Although eosinophilia may be associated with toxic reactions, it is not a reliable predictor of gold toxicity and is not an indication to discontinue gold therapy.¹⁷³

Thrombocytopenia can be life threatening and sometimes is difficult to treat because of the long half-life of gold.¹⁷² Most cases respond to cessation of gold therapy, but platelet or red cell transfusions might be needed for severe cases. Antibiotics should be administered to patients with fever and an absolute neutropenia count of <1,000/mm³.¹⁷²

Other unusual but potentially serious complications of gold therapy include colitis, pneumonitis, and cholestatic hepatitis.^{174–177} Corneal chrysiasis also can occur but does not lead to ocular complications.¹⁷⁸

AUR capsules, containing 3 mg of gold, are 25% bioavailable.¹⁷⁹ The recommended AUR daily dose of 6 mg can be given either as single or divided doses. AUR is better tolerated than parenteral gold formulations, but is significantly less effective.¹⁰ Like parenteral chrysotherapy, benefit can occur as early as 6 to 8 weeks after starting AUR, but objective benefits might not be apparent for several months. Overall, AUR has a slower onset of action when compared with gold sodium thiomalate.¹⁸⁰ AUR must be monitored in a manner similar to parenteral therapy. Proteinuria and bone marrow suppression occur with AUR, but the incidence is low.¹⁸¹ The incidence of rashes necessitating AUR withdrawal is lower than with parenteral gold therapy, but

loose stools and diarrhea are encountered more commonly (47%).

S.S.'s concerns have merit. Although gold is an effective DMARD and can induce complete RA remission, none of the gold formulations are ideal. Gold sodium thiomalate is easier to administer, but is associated with more frequent side effects compared with aurothioglucose. Aurothioglucose carries a low but serious risk of nephrotoxicity. Both parenteral forms of gold are commonly discontinued because of side effects. AUR is the best tolerated gold preparation, but the least effective and is associated with significant diarrhea.

Dosing

22. How is parenteral gold administered? Is serum drug monitoring of value in gold therapy?

The standard treatment schedule for parenteral gold consists of an initial intramuscular test dose of 10 mg followed by a 25 mg IM dose 1 week later. The third and subsequent weekly intramuscular injections of 25 to 50 mg should be continued until the cumulative dose reaches 1 g, toxicity occurs, or major benefit is derived.^{29,172} If a satisfactory response is achieved, maintenance doses of 25 to 50 mg every other week are recommended. If the disease remains stable, doses can be administered every third and subsequently every fourth week for an indefinite period.¹⁷²

Attempts to correlate serum gold concentrations with clinical outcomes generally have been unsuccessful.^{182,183} Furthermore, toxicity has not been correlated with serum gold concentrations.¹⁸²

23. After 10 weeks of treatment with aurothioglucose (total, 435 mg), L.T. developed pruritus and a rash on her abdomen. Gold was withheld and she was given a prescription for triamcinolone cream. Should L.T.'s gold therapy be discontinued?

Dermatologic reactions to gold occur in 15% to 30% of patients.¹⁷² Because of fears of subsequent exfoliative dermatitis and the belief that dermatologic reactions recur upon rechallenge, there is a natural reluctance to continue gold treatment after the appearance of dermatitis or stomatitis. However, in one series of patients, gold treatments were reinstated successfully in 28 of 30 patients in whom dermatologic reactions developed.¹⁸⁴ One of these patients who presented initially with severe exfoliative dermatitis was treated successfully with gold several years later. Gold therapy was reinstated in these patients as follows. After waiting at least 6 weeks after the lesions had healed completely, a 1-mg test dose of gold was administered intramuscularly. Subsequent doses were increased to 2 mg, then to 5 mg, and then to 10 mg at 2- to 4-week intervals. Thereafter, 5-mg increments were added until a dose of 50 mg/week was attained. Dermatologic reactions did not develop in any of these patients subsequently. Gold therapy, therefore, need not be abandoned in L.T.

Auranofin

24. J.M., a patient receiving gold sodium thiomalate for 1 year and responding well to a maintenance regimen of 50 mg IM Q 4 wk asks about switching to AUR. Will switching to AUR from parenteral gold maintain J.M.'s RA under good control? Can patients

who have discontinued parenteral therapy because of adverse side effects be treated with AUR?

Some patients originally treated with parenteral therapy can be switched to AUR and remain well controlled.^{185,186} This experience is not universal, however, and it is not possible to predict which patients can be switched successfully to oral therapy.

When parenteral gold is injected weekly, the relative cost of parenteral gold therapy (including office visits and monitoring) is more than the costs associated with daily AUR therapy. When gold injections are given every 2 to 3 weeks, the cost of parenteral and oral therapy is similar, depending on local laboratory and medical costs. When injections are given monthly, the cost of parenteral therapy usually is less than for oral therapy. Because this patient is well controlled, little is to be gained by switching from parenteral therapy to AUR, either from an economic or therapeutic standpoint.

Data are limited on the use of AUR in patients who experienced side effects from parenteral gold. Because rashes usually are mild and proteinuria is reversible if the patient is properly monitored, a trial of AUR in patients withdrawn from parenteral gold for these reasons may be justified.¹⁸⁷ It is inadvisable, however, to initiate AUR in patients who were withdrawn from parenteral gold because of bone marrow suppression.

Methotrexate

25. S.S. (from Question 21) will be treated with MTX. Why is MTX a good selection for her?

S.S. has many indicators of severe disease (e.g., young age of onset, multiple joint involvement, extra-articular manifestations [i.e., subcutaneous nodules], radiographic evidence of erosions, elevated ESR, and positive RF with a high titer of 1:1,280 [positive RF is generally a titer \leq 1:20 and titers correlate with disease severity]). The disease prognosis for S.S. is clearly poor, and a relatively potent DMARD should be initiated to maximize the preservation of joint function as much as possible because the patient is young and likely to have many years of life ahead of her. MTX is currently the initial DMARD of choice among most rheumatologists, particularly for patients with severe disease.¹⁰ MTX has a rapid onset (usually 1–2 months before a “plateau” of effectiveness), a high efficacy rate, and the most predictable benefit of any DMARD.¹⁰ In one study, the probability of continuing MTX therapy for at least 5 years was 62%.⁴⁸ In contrast, the use of other traditional DMARDs only results in about half of the patients being able to continue therapy beyond 9 to 24 months.⁸⁵ MTX is good choice for treating S.S.'s very active RA.

Dosing

26. How should MTX be administered when it is used in the treatment of RA?

MTX generally is administered orally at an initial dose of 7.5 mg once a week. Liquid MTX is a less expensive and equally efficacious alternative to the more-commonly administered tablet formulation.³⁰ The MTX commonly is administered as a single weekly dose, or it can be divided into 2.5 mg every 12 hours for a total of three doses (i.e., “pulse dosing”). Pulse dosing of the weekly MTX is as effective as single weekly

dosing and may be associated with less hepatotoxicity.¹⁸⁸ If the patients RA shows no objective response in 6 weeks (i.e., the time at which the plateau of therapeutic effectiveness occurs), the dose is increased to 15 mg/week (or 5 mg every 12 hours for three doses) for at least 12 additional weeks.¹⁸⁹ If no response is seen at this time, the dose can be (a) increased to the maximum of 25 mg/wk, (a) the dose can be administered as a subcutaneous or intramuscular injection to address bioavailability concerns, (c) the same dose can be continued for a longer period of time, or (d) MTX can be discontinued.^{10,30,190} When subcutaneous MTX was compared with oral MTX in a 6-month randomized controlled trial of 384 MTX-naive patients with active RA,¹⁹¹ 78% of patients treated with subcutaneous MTX achieved an ACR-20 response, and only 70% of those treated with oral MTX achieved a similar response. At week 16 of this study, patients treated with oral MTX, who failed to attain an ACR-20 response, were switched to subcutaneous MTX; patients treated with subcutaneous MTX patients, who failed to attain an ACR-20 response, were given a larger MTX dose (20 mg) subcutaneously. The patients who were converted from oral dosing to subcutaneous dosing and the patients who were given a larger subcutaneous dose had a 30% and 23% ACR response rate at week 24, respectively. As a result, subcutaneous MTX seems to be more effective than oral MTX and not associated with a higher incidence of adverse effects.

In a 6-month clinical trial, RA patients with a short disease duration (i.e., <3 years), who achieve disease remission with weekly MTX therapy, remained in remission when the same MTX dose was administered every other week (i.e., monthly dose reduced by 50%).¹⁹² It is unknown, however, whether every-other-week dosing of MTX prevents joint destruction as effectively as weekly dosing.

Adverse Effects

27. What subjective and objective data should be evaluated for evidence of MTX adverse effects in RA patients treated with MTX?

Nausea and other GI distress, malaise, dizziness, mucositis, and mild alopecia are commonly encountered adverse effects associated with low-dose MTX therapy.¹⁶² More serious, but less common, adverse effects include myelosuppression, pneumonitis, and hepatic fibrosis and cirrhosis.¹⁶² A CBC, LFTs, and a serum creatinine concentration should be evaluated at baseline, monthly for the first 6 months of therapy, and then every 4 to 8 weeks during MTX therapy. Renal dysfunction can result in accumulation of MTX and higher risk of myelosuppression. Hypersensitivity pneumonitis, occurring in 1% to 2% of patients, has no known risk factors for development, although it may be more common in patients with a history of lung disease.³⁰ In addition, hypersensitivity pneumonitis can occur at any time during therapy and at any MTX dosage. A baseline chest radiograph is recommended within the year before MTX initiation. If the patient is found to have preexisting lung disease, MTX treatment should be reconsidered because further pulmonary damage could be devastating to the patient. Patient also should be monitored carefully for cough, dyspnea on exertion, and SOB at each clinic visit.

MTX-induced liver disease is rare, but increased age, long duration of therapy, obesity, diabetes mellitus, ethanol con-

sumption, and a history of hepatitis B or C increase the risk of hepatotoxicity.¹⁶² MTX should be prescribed with great caution, if at all, in patients with preexisting liver disease. The serum concentrations of liver enzymes commonly are modestly increased after administration for 1 to 2 days. MTX, however, should be withheld if liver enzymes increase to three times the baseline value or if the liver enzyme serum concentrations remain elevated for sustained periods during therapy.¹⁹³ The ability of LFT monitoring to predict risk for serious hepatotoxicity is unclear. In one study of psoriatic patients receiving MTX, liver enzyme elevations did not predict risk of serious hepatotoxicity; however, serum concentrations of liver enzymes were evaluated only on the day of biopsy rather than at regular intervals throughout therapy.¹⁹⁴ Patients taking MTX should avoid alcohol and be instructed to report symptoms of jaundice or dark urine to their primary care provider. Routine liver biopsies to monitor for MTX-induced hepatotoxicity are unnecessary (see Question 28).

28. Should a baseline liver biopsy be performed before starting MTX?

At one time, routine liver biopsies were recommended for RA patients receiving MTX because cirrhosis developed in up to 26% of psoriatic patients.¹⁹⁵ In RA patients, however, serial liver biopsies are neither recommended nor cost effective. Nevertheless, the liver should be biopsied before treatment in patients with suspected liver disease and in patients with persistent LFT abnormalities during, or after discontinuation of, MTX therapy (Table 43-7).¹⁹⁶

29. When should folate (or folic acid) be administered to reduce the risk of MTX-related toxicity?

In early studies, folate supplementation effectively prevented, or managed, GI disturbances, mucositis (mouth or

Table 43-7 Proposed Criteria for Liver Biopsies During MTX Therapy

Baseline liver biopsy if patient has:

1. History of significant regular ethanol consumption, arbitrarily defined as 3 drinks/day
2. History of hepatitis, jaundice, or liver disease

Liver biopsy during therapy if:

1. Six of 12 monthly determinations of AST are elevated into the abnormal range
2. Baseline normal serum albumin falls to 3.3 g/dL
3. Three to 5 of 12 monthly elevations of AST are in the abnormal range for 3 consecutive years

Liver biopsy results:

Biopsy showing Roenigk class I, II, or IIIA (minimal fibrosis) would be grouped as a “benign” hepatic outcome and a repeat biopsy would be performed only if serum albumin falls to <3.3 g/dL. Roenigk Class IIIB (significant hepatic fibrosis) or IV (cirrhosis) would be cause to permanently discontinue MTX

AST, aspartate aminotransferase; MTX, methotrexate.
Adapted from reference 196.

GI ulcerations), and possibly alopecia attributable to MTX therapy.^{197–201} In larger randomized controlled trials, folic acid or folinic acid (leucovorin) was only able to decrease the incidence of alanine aminotransferase (ALT) elevation.^{202,203} When folic acid (1 mg/day), folinic acid (2.5 mg/week), or placebo was added to MTX therapy (7.5 mg/week, titrated up to 25 mg/week) to more than 400 RA patients, hepatotoxicity developed in 26% in the placebo group, but in only 4% of patients in the folic acid and folinic acid groups ($p < 0.001$ for treatment groups versus placebo). Because hepatotoxicity is one of most common reasons for MTX discontinuation, the benefit of folate supplementation is clearly important.

A slightly higher dose of MTX might be needed in folate users to produce clinical benefits similar to that achieved by patients without folate supplementation, perhaps because MTX is a folate antagonist.²⁰⁴ Clinically, however, there does not seem to be a significant attenuation of MTX efficacy associated with concomitant folate supplementation and, very importantly, folate supplementation reduces the incidence of MTX discontinuation secondary to ALT elevation.

Although either folic acid or folinic acid is effective, folic acid 1 mg/day or 7 mg once a week is preferred over folinic acid because of cost and ease of administration.¹⁶²

30. S.S. is treated with MTX 7.5 mg and with folic acid 7 mg orally once a week. Nine weeks later, she returns to the clinic with subjective and objective improvement in morning stiffness, fatigability, and joint tenderness and swelling. However, she has noted increased SOB and dyspnea over the past week. Why might these symptoms be related to MTX?

Pneumonitis, a rare complication of MTX therapy, is characterized by a nonproductive cough, malaise, and fever, progressing to severe dyspnea.²⁰⁵ Recognition of this unusual reaction is important to ensure that MTX is discontinued before the pneumonitis progresses to respiratory failure (see Question 27). After discontinuation of MTX, pulmonary function improves. Corticosteroids can accelerate improvement in pulmonary symptoms associated with pneumonitis. S.S.'s dyspnea and SOB might be related to MTX. If appropriate tests rule out other causes for her pulmonary complaints, MTX-induced pulmonary toxicity should be considered and MTX treatment discontinued.

31. What major MTX food and drug interactions need to be considered by patients and providers?

NSAIDs increase MTX serum concentrations and increase the risk of toxicity.³⁰ MTX doses should be adjusted cautiously in patients taking NSAIDs concurrently. Trimethoprim can increase the risk of MTX-induced bone marrow suppression. The concurrent use of MTX and LEF has been associated with major liver damage, including fatalities; as a result, this combination should be avoided. When 39 MTX-treated RA patients consumed low doses of caffeine (<120 mg/day), morning stiffness and joint pain were improved by more than 30% compared with high caffeine consumption (>180 mg/day).²⁰⁶ Caffeine may interfere with the anti-inflammatory effects of MTX. Because MTX is protein bound and renally excreted, other drugs (e.g., salicylates, etretinate, probenecid, penicillin, ciprofloxacin) also might interact with MTX.

Leflunomide

Place in Therapy

32. B.W., a 36-year-old woman, has severe, progressive RA and is not responding sufficiently to MTX therapy. Would LEF be a reasonable consideration for her?

LEF (Arava), an oral traditional DMARD, seems to be similar in efficacy to MTX with regards to ACR-20, radiographic response, and work productivity.⁴⁶ The onset of benefit (as early as 4 weeks) and the percentage of patients who discontinue LEF therapy because of either lack of efficacy or toxicity are similar for LEF, MTX, and SSZ.^{30,207–211} Nevertheless, postmarketing surveillance of LEF has noted more than 130 severe liver-related adverse events, including 12 liver-related fatalities.²¹² In one clinical evaluation, more than 75% of patients ($n = 369$) who received etanercept or infliximab continued with therapy after 20 months compared with only 22% of LEF-treated patients.²¹³ Although the incidence of hepatotoxicity was not specifically reported, adverse effects were the primary reason for LEF discontinuation during the first 6 months of treatment.

LEF is as safe and effective as MTX or SSZ in and can be combined with MTX therapy (see Question 38); however, postmarketing reports are a reminder that diligent patient monitoring is crucial. It is not known whether the addition of other DMARDs to MTX therapy is a better therapeutic option than substituting LEF for MTX (see Question 38).

Dosing

33. How would you initiate LEF in B.W.? How would you monitor B.W. for adverse effects?

The active metabolite of LEF, A771726 or M1, is responsible for virtually all the pharmacologic activity of LEF.²¹⁴ The serum half-life of the M1 metabolite is approximately 2 weeks. As a result, LEF should be initiated with a loading dose of 100 mg once daily for 3 days to reduce time to steady state, followed by 20 mg once daily. If this dose is not tolerated, the dose should be reduced to 10 mg once daily.

Monitoring for Adverse Effects

Diarrhea (20%–30%), rash (10%), alopecia (10%–17%), and reversible liver enzyme elevations more than three times the upper limit of normal (ULN; 2%–4%) are common adverse effects of LEF.^{211,214} Routine laboratory testing includes a baseline ALT followed by monthly ALT testing for several months. When it is evident that ALT results are stable and within normal limits, testing can be performed less often according to the clinician's judgment. Because of the risk of liver toxicity and the need for activation by the liver to the M1 active metabolite, LEF is not recommended in patients with preexisting liver disease, including hepatitis B or C.

Potential hepatotoxicity is the greatest concern with LEF. The rate of LEF-induced liver enzyme elevation is not significantly different than MTX. Guidelines for managing potential hepatotoxicity include dosage reduction from 20 to 10 mg/day if ALT increases more than twofold the ULN.²¹⁴ If ALT elevations remain steady between two to three times the ULN and treatment continuation is desired, a liver biopsy is recommended. If ALT elevations are persistently more than

three times the ULN despite dosage reduction and cholestyramine administration to enhance elimination (see Question 34), then the drug should be discontinued and another course of cholestyramine elimination therapy should be given.

Enhancement of Elimination With Cholestyramine

34. After 2 months of therapy, B.W. does not respond to LEF and the treatment discontinued, especially because she is beginning to consider starting a family. What precautions must be taken when discontinuing LEF?

LEF (pregnancy category X) has not been tested in pregnant women, but greatly increases the risk of fetal death or teratogenicity in animals receiving as little as 1% of human equivalent doses.²¹⁴ After discontinuation of therapy, however, up to 2 years may need to elapse before plasma M1 metabolite levels of LEF are undetectable. As a result, cholestyramine is recommended for all women who discontinue LEF and who are hoping to become pregnant. After stopping the medication, cholestyramine 8 g TID is administered for 11 days (which need not be consecutive). Plasma levels of the M1 metabolite are reduced by 40% to 65% in 24 to 48 hours and should become nondetectable (<0.02 mg/L) at the end of therapy. The patients blood should be tested at least 14 days apart to verify the absence of the metabolite. If plasma M1 levels remain >0.02 mg/L, more cholestyramine should be administered. Cholestyramine also can be used to enhance elimination of LEF in patients who experience hepatotoxicity or who overdose with this drug. Activated charcoal also can reduce plasma M1 levels by 50% after 48 hours, and can be an effective alternative to cholestyramine when LEF overdoses need to be managed.

Azathioprine

Indications and Adverse Effects

35. In considering options for B.W., AZA is mentioned. B.W. knows someone who is using AZA for prevention of kidney transplant rejection and thinks AZA is a highly toxic drug. How can adverse effects to AZA be minimized?

AZA is FDA approved for transplant rejection prophylaxis and for treatment of severe RA. The starting dose of AZA for RA is 1 mg/kg/day in single or divided doses.¹⁰ If the patient does not respond, the dose can be increased by 0.5 mg/kg/day after 6 to 8 weeks; and subsequently increased by the same magnitude every 4 weeks if needed until a maximum dose of 2.5 mg/kg/day is reached.

The most common adverse effect of AZA is GI intolerance and about 10% of patients discontinue therapy because of this problem.¹⁶² Myelosuppression can occur, but is reversible upon discontinuation of therapy. Patients with renal insufficiency are at increased risk for myelosuppression and doses should be adjusted accordingly for renal insufficiency. Allopurinol decreases metabolism and elimination of AZA via inhibition of xanthine oxidase, thereby increasing the risk of toxicity of AZA because of increased serum concentrations. If concomitant allopurinol therapy cannot be avoided, the dose of AZA must be reduced by 75%. Monitoring for AZA adverse effects should include a baseline CBC, renal function, and LFTs. When AZA doses are increased, a CBC should be monitored every 1 to 2 weeks; thereafter, a CBC should be

monitored every 1 to 3 months. Although serious adverse effects have limited the use of AZA for RA; diligent laboratory and clinical monitoring can minimize risk to patients.

Penicillamine

Considerations for Use

36. When would you consider penicillamine therapy for B.W.? How is penicillamine dosed and monitored?

Penicillamine is rarely used for the treatment of progressive RA because of a lengthy dose titration schedule and serious toxicities (e.g., myelosuppression, autoimmune diseases).^{10,30}

Dosing

A “go low, go slow” approach is recommended for penicillamine dosing.¹⁷² The initial dose usually is 250 mg/day, and the dose is increased to 500 mg/day after 4 to 8 weeks. If therapeutic benefits are not observed after an additional 4 to 8 weeks, the dosage is increased to 750 mg/day, then occasionally to 1,000 mg. Up to 6 months of therapy may be necessary before therapeutic benefits become apparent.

Adverse Effects

Rash, stomatitis, and dysgeusia are the most common adverse effects associated with penicillamine.¹⁶² Myelosuppression (particularly thrombocytopenia), proteinuria, renal toxicity, and autoimmune syndromes (e.g., systemic lupus erythematosus, myasthenia gravis, polymyositis, Goodpasture syndrome) have been reported but are rare. Gradual increases in DPEN doses of 125 to 250 mg every 3 months seem to reduce the risk of thrombocytopenia. Laboratory monitoring includes a baseline renal function test. A renal function test, CBC, and urine protein assay should be obtained at baseline. In addition, the latter two tests should be monitored every 2 weeks until dosing is stabilized, then every 1 to 3 months thereafter.

Although B.W. has failed to respond to MTX and LEF, DMARDs other than penicillamine have a more rapid onset of action, greater efficacy, and less toxicity, and are therefore preferable.

37. A patient with RA, M.M., is allergic to penicillin. Could he receive penicillamine for RA treatment?

Metabolites of penicillin, rather than penicillin itself, are responsible for allergic reactions. The penicilloyl group is the major haptenic determinant in penicillin allergy, but other metabolites (e.g., penicillinate, penicillate, penicillamine) also can cause allergy. Penicillamine is prescribed with caution to penicillin-allergic patients because in vitro studies note cross-sensitivity to penicillamine in 44% to 65% of penicillin-allergic patients.²¹⁵ However, none of these patients received an oral penicillamine challenge. When 40 patients with histories of penicillin allergy, confirmed by positive skin tests in 80%, were given penicillamine 250 mg orally in another study, none experienced an immediate or delayed reaction.²¹⁶ Three RA patients, who had positive penicillin skin test reactions, subsequently received penicillamine without experiencing hypersensitivity reactions during therapy. Penicillamine, therefore, need not be withheld in patients with a history of penicillin allergy. The potential for cross-reactivity, although real, seems to be small.

Traditional Disease-Modifying Antirheumatic Drug Combination Therapy

38. What evidence supports the early and safe use of DMARDs in combination?

Because most RA patients develop joint erosions within the first 2 years of disease, the initiation of disease-modifying agents early in the course of therapy, and using them in combination, have been associated with improved patient outcomes. The rationale for combination therapy is based on the premise that a combination of drugs might improve outcomes because of different pharmacological mechanisms of action or different sites of actions. A combination of drugs also may allow the use of lower doses of individual drugs, thereby reducing the risk of toxicity while maintaining or possibly increasing efficacy. The early use of combinations of potent disease-modifying agents also can expose the patient to increased risks of drug adverse effects.

A multitude of possible study designs (e.g., different DMARD combinations, variable doses, varying durations of therapy, number of patients enrolled) make it difficult to draw valid comparative conclusions from various clinical trials.³¹ Studies, most applicable to clinical practice, should compare the efficacy of MTX against a combination of drugs that incorporate MTX in the regimen because MTX is the single most effective traditional DMARD. Nevertheless, MTX alone, improves only one-third of patients by 50% after 2 to 4 years.⁸⁷

The triple combination of MTX, HCQ, and SSZ seems to be a very effective treatment approach for RA.^{217–219} In one study, this triple combination resulted in a 2-year disease remission rate of 37% versus 21% in patients treated with SSZ or MTX monotherapy with no significant differences in adverse effects.²¹⁷ Another trial compared the triple drug regimen with MTX alone and with the combination of HCQ and SSZ.²¹⁸ At 2-year follow-up, 77% of the triple-drug-treated patients responded significantly as compared with 33% of the patients treated with MTX monotherapy ($p < 0.001$) and 40% of the patients treated with SSZ plus HCQ ($p = 0.003$). Toxicity did not differ between the treatment groups. A follow-up abstract of the same study reported that triple-drug therapy remained efficacious and safe in 36 of 58 patients (62%) after 5 years.²¹⁹

In a randomized controlled trial of 263 MTX-treated patients with active persistent RA, the addition of LEF resulted in significant clinical improvement without an increase in adverse event and treatment discontinuation rates.²²⁰ However, anecdotal reports of serious liver disease, including fatalities, have prompted some to conclude that the combination of MTX with LEF is unsafe.³⁰

Aggressive DMARD therapy has been implemented through many historic approaches, including the “step-down,” “sawtooth,” and “graduated step-up” strategies.^{221–223} Although each strategy differs in specifics, they share the concepts of starting DMARD therapy earlier and a willingness to combine DMARDs to achieve improved short-term as well as long-term outcomes. After an initial response to a DMARD, disease progression accelerates (even on therapy), according to one hypothesis used to reconcile the apparent paradox of short-term improvement with failure to alter long-term outcomes in RA.²²¹ Under this premise, DMARD treatment makes disease progression to disability irregular, like the tooth of a saw. The initiation of DMARDs as soon as possible, before joints are substantially damaged by the disease, therefore, should

improve outcomes while keeping overall drug toxicity near traditional levels. In this sawtooth strategy, one or multiple DMARDs are used continually, throughout the entire disease course, while monitoring for evidence of disease progression. A ceiling is set in terms of progression, which triggers treatment changes. DMARD therapy is changed serially, alone or in combination, at each decision point. Analgesics and NSAIDs are used only as adjunctive therapy for symptomatic relief as required. The longest prospective study of the sawtooth strategy for DMARD therapy was conducted among 135 patients over 15 years.²²⁴ A total of 606 monotherapy or combination DMARD therapies were initiated. Five hundred twenty-eight (87.1%) of these therapies were discontinued after a median time of 10 months, with most discontinuing because of inefficacy (51.1%) rather than adverse effects (28.2%). Thus, the main factor limiting the sawtooth strategy was the loss of efficacy as opposed to harmful adverse effects.

The “step-down” more aggressive approach initiates treatment with prednisone 10 mg/day for 1 month.²²² If active RA is still evident, multiple DMARDs are added all at once to induce disease remission as quickly as possible. One DMARD at a time is then tapered and discontinued, eventually leaving a single agent as monotherapy.

The slightly more conservative “graduated step” approach matches disease severity and activity to “appropriate” initial and long-term therapy.²²³ This strategy increases objectivity of therapeutic decision making throughout the course of disease treatment and exposes only those patients with sufficiently active disease to the risks of combination DMARD therapy. Patients are reevaluated at 3-month intervals and disease activity is categorized as mild, moderate, or severe based on a quantified scoring system utilizing measures of pain, tender and swollen joint count, and ESR or CRP. Scores reflecting severe RA or poor disease control are indicators for treatment escalation. Subsequent treatment changes may require consideration of additional information beyond disease activity criteria (e.g., time of onset of afternoon fatigue, change in grip strength, change in Hgb concentration, onset or worsening of extra-articular disease manifestations).

As described in the Quantifying Response to Drug Therapy section, clinical assessment tools (DAS, CDAI, SDAI, GAS, RAPID, ERAM) integrate measures of RA activity (e.g., swollen joint count, tender joint count, pain, questionnaire-derived patient- and clinician-evaluated global disease activity) into a simple summary score.^{96–99} These scores can be used to categorize disease severity and modify DMARD or biological agent therapy accordingly. The BeSt Study utilized the DAS-44 (44 joints) to compare four different treatment approaches for patients with early onset RA (<2 years). Three of these treatments included exclusively traditional DMARDs.⁸⁸ Group 1 patients initially received MTX monotherapy, with dose escalation and sequential addition of SSZ and LEF if DAS-44 was >2.4. Group 2 patients also began therapy with MTX, followed by additions of SSZ, HCQ, and then prednisone if DAS-44 was >2.4. In contrast, Group 3 patients started with a prednisone taper (60 mg/day tapered down to 7.5 mg/day after 7 weeks), MTX, and SSZ. Group 4 started with infliximab and MTX. DAS-44 was evaluated every 3 months. After 1 year of treatment, all groups had similar remission rates (defined by DAS-44 <1.6), average DAS-44 scores, and adverse events. The BeSt Study demonstrated that an aggressive,

DAS-based titration regimen, utilizing a variety of traditional-based DMARDs, is a successful method of using combination DMARD therapy for early RA.

In summary, with very few exceptions every RA patient should receive DMARD therapy within the first 3 months of diagnosis, either as monotherapy or as combination therapy. Loss of efficacy and intolerable adverse effects seem to be the first and second most common reasons for DMARD discontinuation, respectively. Various combinations of traditional DMARDs, when titrated aggressively, have proven to be very effective in RA management. Nevertheless, the availability and greater efficacy of biological agents in slowing joint erosions have provided additional important therapeutic alternatives to traditional DMARDs.

BIOLOGICAL AGENTS

Etanercept

Place in Therapy

39. B.W., the patient with severe RA in Question 32, begins etanercept after both MTX and LEF therapy failed. Why is etanercept a reasonable therapeutic option?

Etanercept (Enbrel) is the first biological response modifier to be approved by the FDA for reducing the signs and symptoms of moderate to severe active RA, either alone or in combination with MTX.³² Etanercept also is approved for use in juvenile RA and psoriatic arthritis. Etanercept is a soluble TNF receptor that competitively binds two TNF molecules, rendering both inactive. Etanercept consists of two extracellular portions of the TNF receptor; and TNF primarily exists as a trimer in the human body. The dimeric structure of etanercept is believed to have a higher binding affinity for the trimeric TNF than the naturally occurring monomeric receptor.

In a randomized, placebo-controlled trial of 234 patients with active RA, significantly more patients met ACR-20 criteria after 6 months of treatment with etanercept 10 mg (51% of patients) and 25 mg (59% of patients) than placebo-treated patients (11%).²²⁵ The etanercept was administered subcutaneously twice weekly for 26 weeks. The definition of ACR-20 criteria is described in the Quantifying Response to Therapy section. All patients who were enrolled in this study had experienced an inadequate response to at least one of several DMARDs. Most patients (about 90%) had tried MTX at one time or another, followed by HCQ (about 68%), injectable gold and SSZ (about 50% each), AZA (about 30%), DPEN (about 20%) and gold (about 25%). Furthermore, 24% and 40% of the patients taking etanercept 10 mg and 25 mg, respectively, met ACR-50 response criteria compared with 5% of the placebo group ($p < 0.001$ for both doses compared with placebo, no significant difference between doses). Significant ACR-20, ACR-50, and ACR-70 responses to either etanercept dose were seen after only 2 weeks of therapy.

Another randomized, placebo-controlled trial evaluated the use of combination MTX and etanercept therapy in 89 patients with active RA refractory to at least 6 months of MTX therapy.²²⁶ A dose of 25 mg etanercept or placebo was given subcutaneously twice weekly, and a stable dose of MTX (between 15 and 25 mg/week) was provided to all patients. At 24 weeks of follow-up, an ACR-20 response was found in 71% of the MTX plus etanercept group and 27% of the MTX plus placebo group ($p < 0.001$). Similarly, 39% of the MTX plus

etanercept group met ACR-50 response criteria compared with 3% of the MTX plus placebo group ($p < 0.001$). Etanercept was also associated with significantly greater improvement in ESR or CRP test results. The addition of etanercept to MTX provided greater clinical efficacy when compared with MTX monotherapy.

In the Early Rheumatoid Arthritis trial of 632 moderate to severe early RA patients, etanercept (25 mg twice a week) was associated with significantly greater improvement in clinical and radiologic measures within the first 6 months of therapy than MTX.²²⁷ No significant therapeutic differences were found between etanercept and MTX at 12-month follow-up; however, at the conclusion of the 24-month trial, significantly less radiographic progression of disease was found among the etanercept patients. The Sharp score, which quantifies a composite of joint space narrowing and erosions, served as the basis for the radiographic evaluation. Etanercept provides rapid and significant improvement in subjective and objective measures of RA, either alone or in combination with MTX. In other studies, etanercept has demonstrated long-term safety and efficacy.^{228,229} Although cost is a significant consideration, etanercept is a reasonable choice for B.W.

Dosing and Monitoring

40. How would you initiate etanercept therapy and monitor B.W. for therapeutic and adverse effects?

The FDA-approved dose of etanercept for the treatment of active RA is 25 mg subcutaneously twice weekly.³² The medication may be self-injected by the patient after proper training. Etanercept must be reconstituted using only the diluent supplied; the contents should be swirled, not shaken, to avoid excessive foaming. Injection sites (e.g., thigh, abdomen, upper arm) should be rotated. Clinical response usually appears within 1 to 2 weeks of treatment, and nearly all patients respond within 3 months. In fact, patients who fail to respond to DMARD or biological agent therapy within 3 months should receive consideration for an alternative treatment. When pooled data from early RA trials, which evaluated MTX, anti-TNF, and the combination of MTX with anti-TNF, a significant response at 3 months correlated with response 1 year after start of therapy based on SDAI, CDAI, and DAS28 scores.²³⁰

Injection site reactions (37% vs. 10% with placebo), upper respiratory infections (29% vs. 10% with placebo), and the development of autoantibodies are encountered with etanercept treatments. Injection site reactions generally are mild to moderate in severity and usually occurred within the first month of treatment with decreased frequency over time. Upper respiratory infections (e.g., sinusitis) occur at a rate of 0.82 events per patient-year in patients treated with etanercept versus 0.68 events per patient-year in the placebo group. Autoantibodies that developed during etanercept treatment included ANA (11% vs. 5% in placebo group) and new positive anti-double-stranded DNA antibodies (15% vs. 4% in placebo group). No patients developed clinical signs of autoimmune disease, and the long-term effect of etanercept on the development of autoimmune disease is unknown. Patients with severe heart failure (e.g., NYHA class III or IV) may be at increased risk for heart failure exacerbation and mortality when taking

any anti-TNF agent.³¹ Although not a contraindication, caution is advised if etanercept is prescribed for patients with heart failure. Although an increased incidence of lymphoma has been observed among RA patients receiving any of the available anti-TNF agents, causation has not been established because both RA and MTX are associated with an increased rate of lymphoma.³² Other adverse effects, in order of decreasing frequency, include headache, rhinitis, dizziness, pharyngitis, cough, asthenia, abdominal pain, and rash.

The greatest concern with etanercept therapy is the risk of immunosuppression and subsequent serious infections, including sepsis. TNF is a key mediator of inflammation and plays a major role immune system regulation. Approximately 6 months after FDA approval of etanercept, 30 patients receiving etanercept developed serious infections.²³¹ Although the number of reports was not more than what was expected from clinical trials, six of these patients died within 2 to 16 weeks of starting therapy. Postmarketing reports of other infections such as tuberculosis (a black box warning for all anti-TNF agents), mycobacterial infections, and fungal infections further reinforces the strong recommendation against the initiation of etanercept therapy in patients with sepsis or any chronic or localized active infection.^{10,30} *Mycobacterium tuberculosis* skin testing and a baseline chest radiograph should be undertaken before initiation of anti-TNF therapy. Therapy should be postponed for patients identified as having latent tuberculosis until appropriate antituberculosis therapy has been completed. Clinicians also must be cautious when prescribing etanercept to patients with a history of recurring infection or with underlying illnesses that predispose them to infection (e.g., diabetes).

B.W. should receive a tuberculosis skin test, undergo a chest radiograph, and be warned of the potential adverse effects of etanercept, particularly the risk of immunosuppression and subsequent infection. Any sign of infection must be reported immediately to her health care provider.

Infliximab and Adalimumab

Dosing and Place in Therapy

41. After 3 weeks of etanercept therapy, B.W. seems to respond well. However, she dislikes the subcutaneous administration of etanercept twice weekly and wants another medication that can be administered on a much more convenient basis. How do the other TNF-inhibitors differ from etanercept, and is B.W. a candidate for one of these alternatives?

Two anti-TNF monoclonal antibodies are FDA approved for the treatment of RA. The first, infliximab (Remicade), is a chimeric (mouse/human) IgG antibody directed against TNF that is approved for the treatment of Crohn disease and for the treatment of RA in patients who have not responded adequately to MTX.³³ The usual dose of infliximab is 3 mg/kg intravenously at 0, 2, and 6 weeks, then every 8 weeks thereafter; thus, the convenience of infrequent dosing is tempered by the need for supervised intravenous administration. Infliximab should be given with MTX therapy to prevent the formation of antibodies to infliximab.

In a randomized, placebo-controlled trial of 101 patients with active RA who responded suboptimally to MTX therapy, 60% of patients receiving 3 or 10 mg/kg of infliximab with or without MTX (7.5 mg/week) responded to treatment after 26 weeks.²³² A control group received intravenous placebo

with MTX 7.5 mg weekly. Response to treatment was defined as a 20% Paulus response (i.e., 20% reduction in at least four of the following six criteria: [a] number of swollen joints; [b] number of tender joints; [c] duration of morning stiffness; [d] reduction in ESR; [e] a two-grade improvement in the patient's global assessment of disease severity; and [f] a two-grade improvement in the physician's global assessment of disease severity). Patients, who received a 1-mg/kg dose of infliximab, without MTX, did not respond. Although a significant number of patients receiving 1 mg/kg infliximab with MTX met the 20% Paulus response criteria after 16 weeks of treatment, this response was no longer significant at week 26.

Serious infections have occurred in patients treated with infliximab. In one case, bacterial endophthalmitis resulted in enucleation (complete removal) of the affected eye. In another case, a patient died within 24 hours of emergency admission for staphylococcal septic shock. The development of antibodies to infliximab (human antichimeric antibodies [HACA]) occurred at a rate of 53%, 21%, and 7% of patients receiving the 1-, 3-, and 10-mg/kg doses of infliximab alone, respectively. These rates were lower when MTX was given concurrently (15%, 7%, and 0%, respectively). High doses of infliximab or concurrent use of MTX apparently minimize HACA formation.

In a randomized, double-blind, multicenter, placebo-controlled trial (ATTRACT) of 428 active RA patients who failed to respond adequately to at least 12.5 mg/week of MTX, infliximab 3 or 10 mg/kg or placebo was administered every 4 or 8 weeks along with MTX therapy. This study was unblinded after 1 year because of radiographic evidence of disease modification in patients receiving infliximab. Analysis of radiographic results after 2 years demonstrated that infliximab significantly protected against joint erosion.^{233,234}

The second anti-TNF monoclonal antibody, adalimumab (Humira), is a genetically engineered, fully humanized IgG1 monoclonal antibody, as opposed to the chimeric infliximab. Adalimumab, generally is self-administered subcutaneously by the patient as a 40-mg injection every other week, whether as monotherapy or in combination with traditional DMARDs (e.g., MTX).²³⁵ When administered weekly, or every other week, monotherapy with adalimumab 40 mg significantly improved ACR-20 response rates in a randomized controlled trial of 283 RA patients refractory to traditional DMARDs.²³⁶ Patients receiving 40 mg/week had a higher response rate than patients who received the drug every other week. When adalimumab 40 mg every other week was added to the treatment regimen of RA patients receiving stable MTX doses, significantly more adalimumab-treated patients (67%) achieved an ACR-20 response than those receiving only MTX after 24 weeks.²³⁷ In radiographic data reflecting 1 or 2 years of treatment, adalimumab slowed the progression of joint damage.²³⁸ Data are available supporting the efficacy and safety of adalimumab for up to 7 years.²³⁹

Adverse Effects of Anti-Tumor Necrosis Factor Antibodies

Infliximab and adalimumab have treatment risks and side effect profiles very similar to etanercept (e.g., injection site pain, local reactions, upper respiratory tract infections, nausea, flulike symptoms, rash).²³⁸ Serious adverse effects (e.g., serious infections, increased incidence of lymphoma) are similar as well. As with all anti-TNF agents, a tuberculosis skin test result and

chest radiograph must be obtained before initiating treatment. The development of antibodies against infliximab occurs frequently with monotherapy owing to the chimeric nature of the medication, and concurrent use with MTX decreases the formation of these HACA antibodies (see Question 41). Although adalimumab is a fully humanized product, approximately 5% of RA patients develop antibodies against it at least once during therapy when used as a single agent.²³⁶ This reaction is attenuated with weekly dosing of adalimumab or concurrent use of MTX.

Patients who switch from one anti-TNF agent to another owing to loss of efficacy of the initial agent are able to attain a good response from the second.^{240–242} About 40% to 60% of patients in clinical studies were able to maintain good ACR-20 scores following the switch, and many patients respond even better to the second drug.²⁴³

B.W. seems to be a reasonable candidate for either infliximab or adalimumab therapy. Her interest in a biological agent with less frequent dosing is understandable. Although clinical trials have not compared the biological agents, key differentiating variables between these drugs need to be considered. No evidence suggests that there are any significant efficacy differences between etanercept, infliximab, and adalimumab. Although infliximab is ultimately administered every 2 months, it must be administered intravenously and in combination with MTX (or possibly at a higher dose) to minimize HACA formation. Adalimumab's ease of administration (self-injected subcutaneous injection) and infrequent dosing interval compares favorably with etanercept (twice weekly injections) and anakinra (daily injections), but it is administered more frequently than infliximab (Table 43-3). At FDA-approved doses, all biological agents (etanercept, infliximab, adalimumab, anakinra) are priced similarly (~\$1,300–\$1,500 per month retail based on 2007 prices from www.drugstore.com). Additional therapeutic benefit might be achieved from weekly dosing of adalimumab. If adalimumab is administered weekly, the cost of adalimumab therapy will be considerably more than the other biological agents.

Anakinra

42. B.W. would prefer to avoid anakinra [Kineret] because it requires daily subcutaneous injection dosing. Apart from this inconvenience, what are its therapeutic advantages over the anti-TNF agents?

Anakinra is currently the only available IL-1Ra that is almost identical in composition to human IL-1Ra (see biological agents in the general treatment section). The recommended dose of anakinra is 100 mg daily by self-administered subcutaneous injection.²⁴⁴ Anakinra significantly, but modestly, improves signs and symptoms and radiographic evidence of joint erosion in RA patients.^{30,245} In a study of 472 patients with serious active RA, three different doses of anakinra monotherapy (30, 75, and 150 mg/day) were compared with placebo.²⁴⁶ At 24-week follow-up, 34% of patients receiving anakinra 75 mg demonstrated an ACR-20 response; however, 27% of placebo patients achieved the same response. Although modest, this difference is statistically significant. Although the higher dose of 150 mg produced improvement in 43% of patients, this dose exceeds the manufacturer's recommended dose. The combination of anakinra and MTX seems to be more effective than

anakinra monotherapy. A 24-week randomized controlled trial compared five different doses of anakinra (0.04, 0.1, 0.4, 1.0, and 2.0 mg/kg/day) to placebo among 419 RA patients receiving at least 3 months of fixed MTX doses.²⁴⁷ Significantly more patients receiving the higher daily doses of anakinra (1.0 and 2.0 mg/kg) experienced the ACR-20 response (42% and 35%, respectively) versus placebo (23%) at 24-week follow-up. Local injection site reactions were frequently encountered.³⁰ Although neutropenia and severe infections are more common with anakinra than placebo, there have been no reports of patients experiencing tuberculosis reactivation. Combining anakinra with an anti-TNF agent seems to be logical based on their different mechanisms of action; however, the combination is not recommended because of a significantly increased incidence of serious infections and leukopenia.²⁴⁸ Unlike anti-TNF agents, anakinra is not associated with decompensation of heart failure.²⁴⁸

Although the anti-TNF agents have not been compared directly, anakinra seems to be relatively less effective. In addition, the advantage of being able to self-administer anakinra is offset by the need for daily injections. Anakinra is a therapeutic alternative for RA patients in whom traditional DMARD treatment fails; however, it seems to offer no advantages and some real and potential disadvantages when compared with the anti-TNF agents.

43. S.K., a 71-year-old woman, was diagnosed with RA approximately 15 years ago. Her initial drug therapy included MTX, followed by the addition of SSQ and HCQ, which seemed to keep her RA in near-remission until 2002. She began etanercept along with MTX (without SSZ and HCQ) with good results until 2005. In response to declining disease control, infliximab was substituted for MTX with excellent results. Then last month, she experienced a flare in RA activity. At that time, her CRP was 5.1 mg/dL, ESR was 90 mm/hour, and anti-CCP was positive at 112 units. She also experienced morning stiffness lasting several hours, and multiple joints with swelling ($n = 26$) and tenderness ($n = 38$). What are reasonable treatment options for S.K. at this stage of her disease?

Most patients who lose responsiveness to an initial trial of anti-TNF therapy (i.e., etanercept, infliximab, or adalimumab) can often be successfully treated with an alternative anti-TNF agent (see Question 41). However, no evidence supports switching to a third anti-TNF agent if two of the three fail. The newest biological agents, abatacept (inhibitor of T-cell activation) and rituximab (selective depletor of CD20⁺ B cells) are have great potential to fill this void; both have demonstrated excellent efficacy in patients with inadequate response to traditional DMARD (e.g., MTX) as well as anti-TNF therapy (see discussion in general treatment: Biological Agents).^{68,69}

Abatacept

The Abatacept in Inadequate Responders to Methotrexate study compared abatacept 10 mg/kg plus MTX versus placebo plus MTX.²⁴⁹ At 12-month follow-up, significantly more patients in the abatacept group than the placebo group attained an ACR-20 response (73.1% vs. 39.7%, respectively, $p < 0.001$) and better quality of life survey scores. Fewer patients experienced a change in joint erosion score (0.0 vs. 0.26, respectively, $p = 0.029$).

The Abatacept Trial in Treatment of Anti-TNF Inadequate Responders study evaluated patients on background DMARD

therapy (about 80% were using MTX) who did not achieve an adequate treatment response (despite sufficient doses given for ≥ 3 months) to etanercept, infliximab, or both.²⁵⁰ Patients were randomized to receive abatacept or placebo along with a fixed dose of background DMARD therapy. At 6-month follow-up, ACR response rates were dramatically better in the abatacept-treated patients. The ACR 20 response was 50.4% and 19.5%, ACR-50 was 20.3% and 3.8%, and ACR-70 was 10.2% and 1.5% in the abatacept and placebo treatment groups, respectively. More patients receiving abatacept were able to achieve a significant improvement in physical functioning (measured by HAQ). Efficacy and safety data reflecting 5 years of abatacept therapy indicate that abatacept maintains ACR-20, ACR-50, and ACR-70 scores over this time period, with no change in safety profile.⁶⁷

The side effects of greatest concern include infections (significantly more common when combined with anti-TNF therapy) such as pneumonia, cellulitis, urinary tract infection, bronchitis, diverticulitis, and acute pyelonephritis (see general treatment section: Biological Agents).⁶⁸ A few case reports of malignancy have been associated with abatacept, and chronic obstructive pulmonary disease patients are noted to suffer from more respiratory-related and non-respiratory-related adverse effects than chronic obstructive pulmonary disease patients treated with placebo.⁶⁸

Rituximab

In a placebo-controlled trial of 161 RA patients who responded inadequately to MTX therapy (≥ 10 mg/week), subjects were randomized to one of four treatment groups: MTX > 10 mg per week; rituximab 1,000 mg IV given on days 1 and 15; rituximab plus cyclophosphamide 750 mg IV given on days 3 and 17; or rituximab plus MTX.²⁵¹ At 24-week follow-up, ACR-50 response was significantly higher among treatment groups receiving rituximab (33%, 41%, and 43% in the rituximab only, rituximab plus cyclophosphamide, and rituximab plus MTX groups, respectively) versus the MTX only group (13%). At week 48, however, significantly more patients in the rituximab plus MTX group (35%) maintained an ACR-50 response than patients in the rituximab plus cyclophosphamide group (27%). Although cyclophosphamide is reserved for severe cases of RA (usually involving rheumatoid vasculitis), the combination of rituximab plus cyclophosphamide does not seem to be as effective as rituximab plus MTX.

The Dose-Ranging Assessment: International Clinical Evaluation of Rituximab in Rheumatoid Arthritis trial evaluated 465 patients with RA with an inadequate response to DMARD therapy.²⁵² Nearly one-third of participants previously had tried a biological agent. Patients were randomized to receive either placebo, rituximab 500 mg, or rituximab 1,000 mg on days 1 and 15. Furthermore, each of the three study groups were further randomized to receive either no premedication, IV premedication with methylprednisolone, or IV premedication plus oral premedication with prednisone for a total of 9 treatment groups. All subjects received MTX at a dose of 10 to 25 mg/week. At 24-week follow-up, significantly more subjects receiving either dose of rituximab achieved an ACR-20 response (55% and 54% for the 500 mg and 1,000 mg groups, respectively) than placebo group subjects (28%). These findings were consistent with DAS-28 scores. Premedication with IV methylprednisolone reduced the frequency and

intensity of first infusion adverse drug reactions, and the addition of prednisone was not additionally beneficial. Overall, rituximab was well tolerated, with no difference in types and severity of infections compared with placebo-treated patients.

The REFLEX (Randomized Evaluation of Long-Term Efficacy of Rituximab in RA) trial evaluated the use of rituximab (two IV infusions 2 weeks apart, 1,000 mg/infusion) plus MTX versus placebo plus MTX in 499 patients with active, long-standing RA who responded inadequately to one or more anti-TNF medications.²⁵³ At 24-week follow-up, significantly more patients in the rituximab group demonstrated an ACR-20 response than the placebo group (51% vs. 18%, respectively). Peripheral CD20⁺ B cells were depleted among rituximab-treated patients at about 4 to 5 months after treatment. Average IgG, IgM, and IgA levels remained consistent and within normal ranges. The incidence of all side effects was similar in the two treatment groups (85% of rituximab patients, 88% of placebo patients), as were side effects identified as being related to any of the study drugs, including placebo (39% and 47%, respectively). Infusion reactions were common during or soon after the first dose among rituximab-treated patients (23% vs. 18% of placebo patients). Interestingly, more placebo-treated patients experienced an infusion reaction during or soon after the second infusion (11% vs. 8% of rituximab patients). The rate of infections was slightly higher among rituximab patients (41%) than placebo patients (38%). Similarly, the rate of serious infections was higher among rituximab (5.2 per 100 patient-years) than placebo-treated patients (3.7 per 100 patient-years). No cases of tuberculosis or opportunistic infections were reported. In a 56-week follow-up report of the REFLEX trial, rituximab significantly inhibited radiographic progression of joint damage.²⁵⁴ These findings support the efficacy of rituximab for RA patients refractory to anti-TNF therapy, a very challenging population.

Dosing for Abatacept and Rituximab

Abatacept is supplied as a lyophilized powder in preservative-free, single-use vials containing 250 mg of abatacept. Abatacept must be reconstituted with 10 mL of sterile water for injection, using only the silicone-free syringe provided, along with an 18- to 21-gauge needle. Reconstitution using a siliconized syringe can result in the development of translucent particles in the medication solution; solutions prepared using siliconized syringes must be discarded. Abatacept dosing is based on body weight (500 mg for patients < 60 kg, 750 mg for patients 60–100 kg, and 1,000 mg for patients > 100 kg) and should be infused intravenously over 30 minutes. The abatacept dose should be repeated at 2 and 4 weeks after the first dose, then every 4 weeks thereafter. Abatacept can be given as monotherapy or in combination with DMARDs other than anti-TNF agents.⁶⁸

Rituximab, provided in 100- and 500-mg single-use vials at a concentration of 10 mg/mL, is administered as two 1,000-mg IV infusions separated by 2 weeks. Rituximab must be diluted to a final concentration of 1 to 4 mg/mL with either 0.9% sodium chloride or 5% dextrose in water. To reduce the incidence and severity of infusion-related adverse effects, premedication with IV methylprednisolone 100 mg, or its equivalent, 30 minutes before each infusion is strongly recommended; other premedications (e.g., acetaminophen, antihistamine) may also be beneficial. Antihypertensive medications should be

discontinued 12 hours before rituximab administration to avoid transient hypotension, which has been reported during rituximab infusions. Rituximab must be given with MTX for maximum efficacy based on clinical trials and to help reduce the risk of developing HACA, which occurs in approximately 9% of patients receiving rituximab.⁶⁹

The first IV infusion of rituximab solution should be administered at a rate of 50 mg/hour. In the absence of infusion reactions, the infusion rate can be increased in 50-mg/hour increments every 30 minutes to a maximum rate of 400 mg/hour. In the event of an infusion reaction, the infusion should be halted or slowed until symptoms improve, at which time the infusion can continue at one-half the previous rate. In patients who tolerated the first infusion well, subsequent infusions of rituximab can be administered at a higher rate (100 mg/hour) and increased by 100 mg/hour increments every 30 minutes to a maximum rate of 400 mg/hour. Patients poorly tolerant to the first infusion should receive subsequent rituximab infusions at 50 mg/hour.⁶⁹

The results of several large trials support the therapeutic value of either abatacept or rituximab for S.K. Efficacy has been demonstrated in patients with inadequate response to DMARDs, including anti-TNF agents. Both abatacept and rituximab are generally well-tolerated and have not been associated with cardiovascular events or worsening of heart failure, unlike the anti-TNF agents. However, some serious adverse effects have been associated with abatacept and rituximab that warrant consideration and diligent monitoring. Rituximab has several black box warnings (see general treatment section entitled Biological Agents) for serious and potentially fatal adverse effects (e.g., fatal cardiorespiratory infusion reactions, tumor lysis syndrome, severe mucocutaneous reactions, and progressive multifocal leukoencephalopathy).⁶⁹ Experience with both abatacept and rituximab is limited; therefore, the full range of adverse effects from these agents has not been fully manifested. In summary, abatacept and rituximab are potent treatment options with novel mechanisms of action and proven efficacy at improving RA symptoms and slowing joint erosion. However, based on a combination of current research findings, lack of long-term safety data, and cost, abatacept and rituximab should not be used before a trial with anti-TNF agents, except for patients with relative contraindications to anti-TNF agents (e.g., multiple sclerosis, moderate to severe heart failure).

Corticosteroids

Indications

44. W.M., a 57-year-old man, has progressive RA that has not been responsive to SSZ. He is having difficulty working a full day and is seeking an alternative medication. After a discussion of therapeutic options, W.M. declines MTX therapy and asks to start HCQ. Would it be appropriate to initiate corticosteroids concurrently?

Despite the potential for serious adverse effects with long-term therapy, the judicious use of low-dose corticosteroids represents an important component of treatment during the course of unremitting disease. In addition, low-dose corticosteroids may have disease-modifying properties, particularly in the first year or two of treatment.^{10,30} Considering that W.M.'s RA is sufficiently active to compromise his ability to earn an income, MTX is a much better DMARD selection. Regardless, concurrent initiation of a DMARD and an intermediate-acting

corticosteroid (e.g., prednisone in a daily or divided dose of 5–10 mg) is justified.¹⁰ In large cohort studies, prednisone doses >7.5 mg/day have been associated with a greater than twofold increase risk of cardiovascular events (MI, stroke, heart failure), as well as the risk of developing hypertension with long-term use (≥ 6 –12 months).^{255,256} Therefore, the lowest effective corticosteroid dose is preferred for the shortest duration of time possible. The onset of action of corticosteroids is relatively rapid and their immediate benefits will allow W.M. to maintain his current employment and continue taking care of home responsibilities. The corticosteroid dose can be decreased gradually and eventually discontinued as W.M. begins to respond to HCQ therapy. An important goal of low-dose corticosteroid treatment is to provide bridge therapy until the DMARD therapy becomes effective, in hopes of then being able to taper and discontinue the corticosteroid.²⁹

Dosing

45. Why are corticosteroids administered occasionally in divided daily doses rather than as single daily doses or on an every-other-day regimen when used to treat RA?

Administering intermediate- or short-acting corticosteroids as a single daily dose each morning most closely mimics the early morning physiological secretion of cortisol, and, thereby, minimizes hypothalamic-pituitary-adrenal axis suppression. Administering corticosteroids on alternate mornings further reduces the risk of hypothalamic-pituitary-adrenal axis suppression by allowing the adrenal glands to respond to hypothalamic and pituitary mediators during the “off” day.²⁵⁷ Once-a-day and alternate-day steroid therapies are most advantageous when used to prevent reactivation of some diseases (e.g., asthma, ulcerative colitis, chronic active hepatitis, sarcoidosis).²⁵⁸ In contrast, when corticosteroids are used to provide symptomatic relief in RA during periods of active, ongoing inflammation, switching patients to single daily doses or every-other-day regimens frequently results in increased symptoms during the latter part of each day and during the “off” day. The anti-inflammatory effect of prednisone or prednisolone is attenuated after 12 hours, and is either diminished or absent after 24 hours. As a result, daily prednisone doses may need to be divided in half and administered twice daily to ensure 24-hour anti-inflammatory activity. Although a larger single daily dose may provide comparable therapeutic benefits, dividing the daily dose of prednisone is preferable because larger doses are associated with more frequent and severe adverse effects.

Osteoporosis

46. What therapeutic interventions can prevent steroid-induced osteoporosis?

Chronic corticosteroid therapy induces osteoporosis by inhibiting bone formation and enhancing bone resorption. Steroids impair bone formation by inhibiting the production of bone-forming osteoblasts and enhance bone resorption by reducing GI calcium absorption and increasing the renal excretion of calcium.²⁵⁸ In addition, corticosteroids reduce the secretion of luteinizing hormone from the pituitary, resulting in a reduction in estrogen production in women and testosterone production in men.²⁵⁹ This leads to deficiencies in

circulating levels of anabolic hormones (e.g., estradiol, estrone, androstenedione, progesterone), which contribute to the development of osteoporosis. Trabecular bone of the spine and ribs seems to be affected primarily by corticosteroid therapy, with most rapid skeletal wasting occurring during the first 6 months.²⁵⁹

Before starting long-term (i.e., 6 months) corticosteroid therapy at a dose of 7.5 mg of daily prednisone or equivalent, bone mineral density should be evaluated.^{258,259} Anteroposterior measurement of the lumbar spine or hip by dual-energy x-ray absorptiometry is the preferred procedure. Follow-up measurements can be repeated up to every 6 months to monitor for corticosteroid-related bone loss, or annually for patients already receiving bone loss prevention treatment. A complete history should be obtained to identify potentially modifiable osteoporosis risk factors (e.g., smoking, alcohol consumption, other drugs that can induce osteoporosis, calcium and vitamin D intake, indicators of hormone deficiency such as menopause in women and infertility or impotence in men, lack of participation in weight-bearing exercises). Height and weight should be measured. Lifestyle changes should be encouraged to modify those risk factors that do not require drug therapy. Physical therapy referral is recommended.

All patients on corticosteroid therapy should receive calcium (1,000 mg/day) and vitamin D (800 IU/day) or an activated form of vitamin D (e.g., alfacalcidol or calcitriol) to maintain calcium balance. Supplementation with calcium and an activated form of vitamin D is needed to prevent bone loss in patients receiving medium- to high-dose corticosteroid therapy (e.g., prednisone ≥ 5 mg/day).^{258,259}

Bisphosphonates effectively prevent and treat corticosteroid-induced bone loss.²⁵⁸ In radiographic studies, bisphosphonates effectively reduced vertebral fractures in postmenopausal women with corticosteroid-induced osteoporosis. Bisphosphonate therapy is recommended for men and postmenopausal women receiving >5 mg/day of prednisone, or its equivalent, to prevent bone loss. In addition, bisphosphonates are recommended for men and postmenopausal women receiving long-term corticosteroids with a bone mineral density T-score below normal at either the lumbar spine or hip. Bisphosphonates should be considered for premenopausal women receiving corticosteroids, even though data in this population are limited. However, premenopausal women receiving bisphosphonates must be counseled about contraception because bisphosphonates are classified as FDA pregnancy risk category C. Bisphosphonates adversely affect fetal skeletal development in animals, and reduce serum calcium. Although data are limited, hypogonadal patients receiving long-term corticosteroid treatment should be offered hormone replacement therapy. Thiazide diuretics reduce urinary calcium excretion and maintain bone mineral content.²⁶⁰ A thiazide diuretic is recommended if hypercalciuria is present.

Intra-Articular Corticosteroids

47. Do intra-articular corticosteroid injections provide any benefit in RA?

Intra-articular corticosteroid injections are safe and effective for patients with RA and are often underutilized. This strategy is most sensible when flaring occurs in one or a few joints.¹⁰ Systemic side effects are minimal when compared

with oral corticosteroid therapy. Although onset of action is virtually immediate, effects are often short lived; however, a corticosteroid injection alone can be sufficient to relieve a temporary RA flare. If the decision is made to reinject a given joint, the injection site should be rotated and administration frequency should be no more than every 3 months.

JUVENILE IDIOPATHIC ARTHRITIS

In the United States, all chronic arthritis of childhood is identified as juvenile idiopathic arthritis (JIA), formerly known as juvenile rheumatoid arthritis.²⁶¹ JIA affects all races and afflicts approximately 294,000 children in the United States.²⁶²

By definition, JIA usually begins before the age of 16 and must present with objective signs of joint inflammation (e.g., swelling, pain, limited ROM, warmth, erythema) for at least 6 weeks in at least one joint or at least two of the following: tenderness, pain with movement, joint warmth, or limited motion.²⁶³ In addition, other conditions causing arthritis such as infectious arthritis and malignancy must be excluded.²⁶¹ The onset of disease is rare before 6 months of age, and the peak age of onset ranges from 1 to 3 years. However, new cases are seen throughout childhood.

Signs and Symptoms

As with adult RA, JIA begins with synovial inflammation.^{261,263} Morning stiffness and joint pain probably occur in JIA as frequently as in RA; however, children should be observed carefully for symptoms because they often cannot articulate complaints. The morning stiffness and joint pain may manifest as increased irritability, guarding of involved joints, or refusal to walk. Fatigue and low-grade fever, anorexia, weight loss, and failure to grow are other manifestations. JIA can be divided into several subsets based on characteristic signs and symptoms during the first 4 to 6 months of disease. Currently, patients are categorized according to one of six distinct subsets of symptoms: (a) polyarticular, (b) pauciarticular or oligoarthritic, (c) systemic arthritis, (d) enthesitis related, (e) psoriatic, and (f) other.²⁶³

Patterns of Onset

JIA is classified under the subgroup “polyarticular” when the disease involves five or more joints with few or no systemic manifestations of disease.^{261,263} Two types of polyarticular JIA exist: seronegative (i.e., RF negative affecting 20%–25% of all JIA patients) and seropositive (i.e., RF positive affecting 5%–10% of all JIA patients) disease. Both affect girls more often than boys, with seronegative arthritis more common in children younger than 5 years and seropositive arthritis more common in children older than 8 years. Although the onset of disease can be acute, it more commonly is insidious. Generally, the large, fast-growing joints (e.g., knees, wrists, elbows, ankles) are affected, but the small joints of the hands and feet also may be involved. Although the joints at onset usually are symmetrically involved, asymmetric patterns also can occur. Temporomandibular joint involvement is relatively common and may lead to limitation of bite and micrognathia. Systemic manifestations of disease in children with polyarticular disease are rare and include low-grade fever, slight hepatosplenomegaly,

lymphadenopathy, pericarditis, and chronic uveitis. Subcutaneous nodules are seen most typically in children with “polyarthritis onset” JIA. When present, nodules are associated with positive RF in >75% of patients. Approximately 30% to 35% of JIA presents as polyarticular.

Oligoarthritic JIA, formerly known as pauciarticular juvenile rheumatoid arthritis, accounts for approximately 40% to 60% of children with JIA, which usually involves four or fewer joints and occasionally up to as many as nine joints.²⁶¹ Joint involvement in these children most commonly involves large joints in an asymmetric distribution. The two major subgroups of pauciarticular arthritis: *early childhood onset* (more common, usually affecting girls between the ages of 1 and 5 years of age); and *late childhood onset* (less common, usually affecting boys after 8 years of age).

Approximately 20% to 30% of children with early onset oligoarthritic JIA develop iridocyclitis (inflammation of the iris and ciliary body, also known as uveitis) within the first 10 years of the disease (see Question 53). ANA testing is positive in approximately 60% of these patients. Joints commonly affected include the knees (56%), ankles (20%), hands—especially PIP joints (10%)—feet 6%, and wrists (4%).²⁶⁴ When only one joint is involved, the knee is the most common joint affected. Hip and sacroiliac joint involvements are rare. On the other hand, children with late-onset pauciarticular JIA do not test positive for ANA, have no extra-articular manifestation of the disease, and often have hip involvement in addition to other lower-limb joints (e.g., knees, ankle, feet). Arguably, this late-onset subgroup may be grouped with the spondyloarthropathies well-known in adult patients (e.g., ankylosing spondylitis).

A smaller percentage (10%–20%) of children experience severe systemic involvement associated with or preceding the onset of arthritis.²⁶¹ The hallmarks of the “systemic-onset” category of JIA, which can afflict children at any age, are a high spiking fever and a rheumatoid rash. Once or twice daily, the body temperature can increase to 103°F or higher. The temperature increase may be accompanied by a rash consisting of small, discrete erythematous morbilliform macules, which commonly appear on the trunk and proximal extremities. The lesions tend to be migratory and of short duration in any one location. Other manifestations of “systemic-onset” JIA are hepatosplenomegaly, lymphadenopathy, and pericarditis; these occur in about two-thirds of patients.

Enthesitis-related JIA is manifested as inflammation of the entheses (the site of attachment of tendon to bone) along with arthritis.²⁶¹ Children with enthesitis-related JIA commonly have two of the following: inflammatory spinal pain, sacroiliac joint tenderness, HLA B27 positivity, a family history of enthesitis-related JIA, acute anterior uveitis, and onset of polyarthritis or oligoarthritides in a boy >8 years of age. These children commonly develop a spondyloarthropathy (e.g., reactive arthritis, juvenile ankylosing spondylitis), and inflammatory bowel disease-associated arthritis. The relative proportion of JIA patients with enthesitis-related JIA is unknown.

Psoriatic JIA accounts for approximately 5% of all JIA and is diagnosed if chronic arthritis and definite psoriasis is evident.²⁶¹ Children may also be diagnosed with psoriatic JIA if any two of the following are present: dactylitis (finger or toe inflammation), onycholysis or nail pitting, or family history of psoriasis. The arthritis may develop peripherally only or both peripherally and axially; children with axial arthritis and

psoriasis are HLA B27 positive. Joint destruction in children with psoriatic JIA can be chronic and destructive, requiring DMARD or biological therapy similar to patients with polyarthritic JIA.

In contrast with adult RA, in which joint destruction is common within the first year of the disease, 70% to 90% of children with JIA experience no long-term disability. However, complete remission is uncommon, occurring in approximately one-third of all JIA patients over a 10-year period.²⁶⁵ Preservation of joint function is least favorable in children with seropositive polyarticular JIA (severe arthritis in >50%). Children with pauciarticular JIA experience the least joint disease, and those with early-onset pauciarticular JIA experience the worst uveitis. Children with systemic-onset are most prone to develop life-threatening or fatal complications with approximately 25% developing severe arthritis.

Diagnosis of Systemic Juvenile Idiopathic Arthritis

47. J.R., a 4-year-old girl, is hospitalized for high fever and arthritis. Several weeks before admission, J.R. developed a daily fever ranging from 103°F to 106°F. One week before admission, her knees became painful and swollen. J.R. is listless and irritable during her physical examination. The rectal temperature is 102.4°F. She refuses to walk. The right hip is tender and the right wrist and both knees are warm, red, and swollen. Minimal generalized lymphadenopathy and splenomegaly are present. The Westergren ESR is 82 mm/hour, the WBC count 37,000 cells/mm³ with a mild left shift, and Hct 33%. Cultures of the throat, urine, stool, and blood are negative. An intermediate-strength purified protein derivative, antistreptolysin-O titer, ANA titer, and RF titer all are normal. Radiographs of the chest and involved joints all are normal. An electrocardiogram reveals only tachycardia. After hospitalization and withholding aspirin, an evanescent rash becomes apparent in conjunction with fever spikes. What signs and symptoms of JIA does J.R. manifest?

The signs and symptoms (i.e., the spiking fever episodes, evanescent rash, arthritis, lymphadenopathy, splenomegaly) that J.R. experienced are characteristic of systemic-onset JIA. These children also may have a normocytic, hypochromic anemia, elevated ESR, thrombocytosis, and leukocytosis. Leukocytosis is common and a WBC count of 30,000 to 50,000 cells/mm³ is seen occasionally. A positive RF titer is uncommon in JIA and is present in only 5% to 10% of all cases.²⁶¹ The ANA titer more often is positive and is most prevalent in young girls and children with early-onset pauciarticular arthritis and uveitis.

Treatment

The goal of JIA treatment is to minimize the destructive effects of inflammation, control pain, preserve or restore ROM, and promote development and growth, to facilitate an acceptable quality of life.

Nonsteroidal Anti-Inflammatory Drugs SELECTION AND DOSING

48. What is the initial drug therapy for treatment of JIA?

NSAID therapy is the treatment of choice for treating the joint manifestations as well as the febrile episodes in systemic-onset JIA.^{261,263} Up to two-thirds of JIA patients

achieve good disease control with NSAID therapy.²⁶⁶ In most cases, at least two different NSAIDs should be tried before ruling out this group of medications. Failure to respond to an NSAID in a particular chemical class does not rule out the efficacy of others in the same class. As with adults, it is not possible to predict a patient's response to any one NSAID.

The most commonly prescribed NSAID for JIA is naproxen, used in over 50% of patients.²⁶¹ Naproxen is dosed at 10 to 15 mg/kg/day (maximum, 750 mg) in two daily divided doses, and is advantageous in school-age children because of the convenient dosing interval and availability in liquid or tablet formulations.³⁴ Oxaprozin can be administered once daily as a 600-mg dose if weight is between 22 and 31 kg, 900 mg if weight is between 32 and 54 kg, and 1,200 mg if weight is >55 kg. Although not FDA approved, nabumetone is also frequently used for JIA because of convenient once daily dosing. Ibuprofen doses should not exceed 40 to 50 mg/kg/day and, like naproxen, is available in liquid (suspension) form. Tolmetin usually is dosed at 20 mg/kg/day in three to four divided doses. The usual Tolmetin maintenance doses are between 15 and 30 mg/kg/day in three to four divided doses, with a maximum daily dose of 1,800 mg. Aspirin is seldom used because of its association with Reye syndrome (see Question 49). Aspirin is initiated in divided doses totaling 60 to 80 mg/kg/day.³⁴ The dosage should be increased slowly to 130 mg/kg/day to achieve anti-inflammatory serum salicylate concentrations ranging from 20 to 30 mg/dL.

REYE SYNDROME

49. Should aspirin be discontinued in a JIA patient who experiences chickenpox because of the potential for causing Reye syndrome?

Unrelated to the mild, reversible, dose-related transaminitis, Reye syndrome occurs in association with the use of aspirin as an antipyretic in children during the prodromal phase of viral illnesses such as influenza and chickenpox. Reye syndrome is characterized by fatty vacuolization of the liver producing hepatic injury, vomiting, hypoglycemia, and progressive encephalopathy. The suggestion that aspirin might be a factor in the development of Reye syndrome first was proposed in the early 1960s.²⁶⁷ Subsequently, retrospective case-controlled studies revealed a statistically significant difference in the prevalence of salicylate use in patients with Reye syndrome compared with controls.^{268–270} Virtually all cases of Reye syndrome were exposed to salicylates during an antecedent illness. In the control population, salicylate use varied from approximately 40% to 70%. Based on these findings, the Committee of Infectious Diseases of the American Academy of Pediatrics issued a statement that aspirin should not be given to febrile children who are at risk for Reye syndrome by virtue of possible infection with either influenza virus or chickenpox.²⁷¹

The risk of Reye syndrome in children receiving salicylate therapy for JIA is unknown. However, in a retrospective study, 6 of 176 patients with biopsy-confirmed Reye syndrome were treated with salicylates for connective tissue disease.²⁷² Three of these children experienced a preceding upper respiratory tract infection; the other three experienced no apparent prodromal illness. Therefore, patients with JIA also should avoid

salicylate ingestion during febrile illnesses that represent possible infection with either influenza or chickenpox.

DISEASE-MODIFYING ANTIRHEUMATIC DRUG THERAPY

50. When should DMARDs be used in JIA?

The heterogeneity of JIA is an important consideration in approaching treatment. Fortunately, most children with JIA improve significantly with NSAID treatment, particularly those with pauciarticular disease. Only a small number of these patients are considered for DMARD therapy, usually because of the evolution of their condition into the polyarticular type. Patients with polyarticular, RF-positive disease and patients with early-onset polyarthritis in association with systemic-onset disease both have poor prognosis in terms of ultimate joint function and should receive early consideration for DMARD therapy. Children with polyarticular-onset, RF-negative disease generally have a better prognosis than patients with polyarticular involvement. One may wait considerably longer before introducing a DMARD for these patients.

Most DMARDs used for adult RA are not effective for JIA,²⁶¹ and DPEN is no more effective than placebo. MTX is clearly the DMARD of choice for polyarthritic JIA.²⁷³ The recommended dose of MTX for JIA treatment is 5 to 15 mg/m² (0.15–0.5 mg/kg) orally or subcutaneously each week. Pediatric patients are often prescribed the injectable form of MTX for oral consumption via a suspension. Food reduces the bioavailability of MTX, so MTX should be administered on an empty stomach. However, in general, oral MTX doses >12 mg/m² are poorly absorbed; as a result, higher doses of MTX are usually given parenterally (subcutaneous or intramuscular). JIA patients with oligoarthritis seem to respond best to MTX, while systemic arthritis patients experience little to no benefit. Depending on the definition of response to therapy, 33% to 100% of JIA patients respond to dosages of MTX between 7.1 and 30 mg/m² (0.15 and 1 mg/kg) per week. MTX at a dose of 10 to 15 mg/m² seems to require an average of 13 months of treatment until remission is achieved in most JIA patients. Radiologic evidence of improvement or slowing of joint damage has been demonstrated in JIA patients who responded to MTX therapy over a 2-year period.²⁷⁴

The prognosis of JIA-related joint damage is much better than that associated with adult RA; therefore, discontinuation of MTX should be attempted when disease remission is apparent. The optimal length of time between achievement of disease remission and MTX discontinuation remains to be defined; however, it probably should not be discontinued sooner than 1 year after disease remission, with slower withdrawal in patients at high risk for relapse.^{275,276} In one trial involving all types of JIA subgroups, MTX discontinuation was attempted approximately 6 to 8 months after disease control was achieved.²⁷⁷ After 11 months, 50% of patients relapsed; patients younger than 4.5 years old at the time of diagnosis seemed to be at higher risk of relapse. However, all patients who relapsed responded to MTX retreatment at prediscinuation doses. In another study, patients with pauciarticular JIA who progressed to polyarticular disease were at greatest risk for relapse.²⁷⁶

Children tolerate MTX therapy well and generally experience few serious or troublesome adverse effects (e.g., transient liver enzyme elevations, nausea, vomiting, oral ulcerations).²⁷⁵ These adverse effects are reduced with daily folic acid therapy

(1 mg) or weekly folinic acid (the day after MTX dosing). Liver biopsy studies of patients with JIA receiving cumulative MTX doses up to 5,300 mg for up to 6 years have all been normal with the exception of a single case report in 1990. Liver toxicity monitoring in JIA, therefore, is the same as the guidelines recommend for MTX therapy in adult RA, including biopsy recommendations (see Questions 27 and 28). The combination of MTX and other DMARDs has not been fully evaluated.

If MTX is not tolerated or is ineffective, SSZ is often the next DMARD selected.^{261,263} SSZ (30–50 mg/kg/per day in two divided doses with a maximum of 2 g/day) is effective for pauciarticular and polyarticular JIA, but numerous adverse effects (e.g., liver enzyme elevations, leukopenia, hypoinnoglobulinemia, hematomas, diarrhea, anorexia) lead to discontinuation of therapy in about 30% of patients.²⁷⁸ HCQ may be considered if SSZ fails, but efficacy data from well-designed randomized controlled trials are not available.^{261,263}

Biological Agents

51. What biological agents are effective in JIA?

Etanercept (Enbrel), the only FDA-approved biological agent for the treatment of JIA, is indicated for patients 4 years of age and older whose conditions have failed to respond to one or more DMARDs.³² The recommended dose is 0.4 mg/kg (maximum, 25 mg) subcutaneously twice weekly. Etanercept monotherapy at this dose would be expected to yield about a 76% response rate (i.e., a minimum 30% improvement in at least three of six and $\geq 30\%$ worsening in no more than one of six JIA core set criteria, including physician and patient global assessment, active joint count, limitation of motion, functional assessment, and ESR). The safety of etanercept in children is comparable to adults with the exception of significantly more abdominal pain (17% of JIA patients vs. 5% of adult patients with RA) and vomiting (14.5% of patients with JIA vs. <3% of adult patients with RA). JIA patients should be current on immunizations before initiation of etanercept therapy because the effect of etanercept on vaccine response is unknown. Safety and efficacy data reflecting up to 8 years of treatment support the long-term use of etanercept for JIA.²⁷⁹

Other biological agents, including infliximab, adalimumab, anakinra, and abatacept, are not FDA approved for JIA but have been studied.^{273,280–282} Trials involving these agents are primarily short term and relatively small in number of participants, but available data suggest that all of these treatments may be safe and effective for JIA with no evidence of significant risk for serious adverse reactions.

In summary, NSAID therapy is normally the first medication administered for JIA. If response to NSAID therapy is inadequate, two of the three most common forms of JIA (oligoarthritis, polyarthritis) have a high response rate to MTX. Patients with systemic arthritis unresponsive to NSAID therapy or patients with oligoarthritis or polyarthritis who have a suboptimal response to MTX should receive a trial of etanercept. The use of other anti-TNF agents, anakinra, and abatacept is promising.²⁷³

Intra-Articular Corticosteroid Therapy

52. What is the evidence to support the use of intra-articular corticosteroid therapy in JIA?

Intra-articular corticosteroid therapy seems to be highly efficacious in JIA. Full disease remission of injected joints lasting longer than 6 months can be expected in 84% of patients with JIA, and 60% of patients could be expected to be able to discontinue all oral medications, with even greater success in patients with pauciarticular JIA (75%).²⁸³ In one study, after an average of 30 months of follow-up, long-term negative effects of corticosteroid therapy (e.g., joint stability, osteonecrosis, soft tissue atrophy) were not encountered. As a result, intra-articular corticosteroid therapy seems to be a safe and effective option for JIA, particularly in pauciarticular disease limited to a few troublesome joints.²⁶¹

Uveitis

53. J.R. is scheduled to be seen by an ophthalmologist every 6 months to screen for uveitis. How should her uveitis be managed?

Uveitis associated with JIA is a nongranulomatous inflammation involving the iris and ciliary body. This type of uveitis, sometimes is referred to as iridocyclitis, can occur in 2% to 4% of patients with JIA.²⁸⁴ The posterior uveal tract, or choroid, rarely is affected.²⁶¹ Chronic uveitis can progress, leading to cataracts, glaucoma, and blindness; however, careful screening and early detection are effective at preventing these conditions. Uveitis is most common in ANA-positive oligoarthritis JIA and usually occurs within 4 to 7 years of JIA diagnosis. Fewer than 1% of patients with systemic JIA develop uveitis.

Uveitis rarely presents with symptoms, and even if symptoms occur, children may have difficulty recognizing them. If symptoms of uveitis (e.g., ocular pain, decreased vision, headaches, red eye, unequal pupils) occur, urgent eye examination is warranted.

Prevention of uveitis relies on compliance with regularly scheduled slit-lamp examinations performed by an ophthalmologist.²⁸⁴ Direct ophthalmoscopy cannot detect uveitis. All JIA patients must have a baseline slit-lamp examination within 1 month of diagnosis. The highest-risk JIA patients for uveitis (e.g., ANA-positive oligoarthritis or polyarthritis, ≤ 6 years of age at JIA onset and ≤ 4 years JIA duration) require slit-lamp examination every 3 months. At the opposite extreme, low-risk oligoarthritis or polyarthritis patients (i.e., > 7 years JIA duration, > 6 years of age at JIA onset and > 4 years JIA duration, ≤ 6 years of age at JIA onset and > 4 years JIA duration who are ANA negative, > 6 years of age at JIA onset and ANA negative) and systemic JIA patients require slit-lamp examination once a year.

If detected early, the prognosis for uveitis is very good. The initial drug of choice is a topical corticosteroid (e.g., dexamethasone, prednisolone), which usually reduces ocular inflammation rapidly. More severe and chronic uveitis may require a 1- to 3-day course of intravenous methylprednisolone (30 mg/kg once daily, maximum 1 g/dose). Uveitis that responds poorly to corticosteroids should be treated with systemic NSAIDs, followed by serial trials of by MTX and anti-TNF agents if responses are inadequate.²⁶¹

OSTEOARTHRITIS

OA, also referred to as degenerative joint disease, is the most common form of arthritis in the United States. Approximately 27 million Americans have clinical OA.²⁸⁶ OA is the single

most common cause of rheumatic symptoms, and no other disease is responsible for more loss of time from work. Patients with OA are more dependent on others in climbing stairs and walking than any other disease, and OA is second only to heart disease as the most common disability leading to the receipt of Social Security benefits.

The prevalence of OA rises dramatically with age, increasing from two- to tenfold from age 30 to age 65, respectively. Although men are affected more commonly in early adulthood, men and women are generally affected equally. At age 65, OA is twice as prevalent in women, and women are more likely to have proximal and DIP joint involvement presenting with Bouchard's nodes or Heberden's nodes. Although only 30% of patients are symptomatic, >90% of all individuals older than 40 years of age have radiographic evidence of joint damage in weight-bearing joints consistent with OA.²⁸⁷

Risk factors for the development of OA include advancing age, obesity, quadriceps muscle weakness,²⁸⁸ joint overuse/injury from vocational or sports activities, genetic susceptibility,²⁸⁹ and developmental abnormalities.²⁸⁷ Obesity increases OA risk because of excess weight placed on weight-bearing joints (e.g., hips, knee). However, metabolic factors other than excess weight may also play a role in the development of OA in obese individuals. Excess adipose tissue can produce abnormal levels of hormones or growth factors that can affect cartilage or underlying bone, predisposing individuals to OA.²⁹⁰ A weight loss of 5 kg is associated with a 50% reduction in the odds of developing symptomatic knee OA.

Quadriceps muscle weakness is strongly predictive of both radiographic and symptomatic OA of the knee. The risk of knee damage associated with quadriceps weakness is more pronounced in relation to body weight. Vocational or athletic activities also can contribute to OA as the result of repetitive joint use or trauma subjected to the joints. This is consistent with the traditional "wear and tear" concept used to explain the etiology of OA. However, OA is much more complicated than simply a disease of wearing-down of joints. Under normal conditions, chondrocytes in articular cartilage, which undergo active cell division, balance matrix degradation and repair. Biomechanical stress placed on the joint is believed to stimulate cytokine-mediated release of enzymes (e.g., matrix metalloproteinase, plasmin, cathepsins) that degrade the proteoglycan and collagen components of cartilage, possibly predisposing affected joints to the development of OA.²⁸⁷

Signs and Symptoms

The clinical presentation of OA is variable and depends on the particular joints involved. Unlike RA, which is characterized by synovial proliferation within multiple joints and systemic disease, the symptoms of OA are limited to the joints in which progressive degeneration of cartilage with secondary reactive bone changes (i.e., osteophyte formation) occurs. Occasionally, secondary synovial inflammation can contribute to symptoms. The primary symptom is a deep aching pain localized to the affected joint(s). The joints most commonly involved are the DIP (known as Heberden's nodes), PIP (known as Bouchard's nodes), first carpometacarpal, knees, hips, cervical and lumbar spine, and the first MTP joints. Shoulder, elbow, and rarely the MCP joints also can become involved. In addition to joint pain, common OA symptoms include morning

stiffness and stiffness after rest during the day lasting less than 20 to 30 minutes, limited to involved joints. Joint motion may be limited secondary to loss of integrity of the joint surfaces, development of osteophytes, intra-articular loose bodies, and protective muscle spasm. Crepitus, a palpable grating or crackling due to roughened articular surfaces, may be associated with both passive and active motion of involved joints.²⁸⁷

54. G.R., a 190-lb, 60-year-old school teacher, developed painful, tender swelling in the right knee approximately 1 year ago. Since then, she has experienced intermittent pain in the right knee and hip. She now has moderate morning stiffness in the hip and knee and some joint stiffness after inactivity. Her pain is increased significantly by ambulation. Examination of her joints revealed Heberden's nodes in both hands, limitation of flexion of the right hip to 45 degrees, patellar crepitus, and mild tenderness at the joint margin of the right knee. Laboratory studies were all normal, including negative RF. What signs and symptoms of OA are present in G.R.?

Symptoms of OA usually are referable to the particular joint or joints involved. Common complaints include joint pain (particularly with motion) and stiffness after periods of rest for weight-bearing joints with aching during periods of inclement weather. Crepitation upon joint motion, limitation of motion, and changes in the shape of the joint may be detected on physical examination. The joint(s) may be tender to palpation, but signs of inflammation are relatively uncommon with the exception of effusion, which may be noted after trauma or vigorous use of the involved joint. The Heberden's nodes observed in G.R.'s hands are bony protuberances (osteophytes) at the margins on the dorsal surfaces of the DIP joints. These nodes are more common in women, have a genetic predisposition, and often are associated with a more severe disease course involving multiple joints. OA of the hip is usually rapidly progressive, possibly due to constant weight-bearing, eventually leading to limitation of ROM. Knee OA is observed frequently in older women, particularly when obesity and weak quadriceps muscles are contributing factors, and is associated with crepitus, loss of ROM, and flexion deformities. Other common manifestations of OA that are not present in G.R. include vertebral column involvement and Bouchard's nodes (i.e., osteophytes on PIP joints).

Results of laboratory studies are usually normal unless an underlying disease coexists. ESR may be elevated in patients with generalized OA characterized by involvement of three or more joint groups with evidence of local inflammation (e.g., soft tissue swelling, redness, warmth). RF is usually negative; however, as discussed previously, approximately 3 to 5% of non-RA individuals test positive for RF. Synovial fluid analysis may reveal mild inflammation-induced increase in volume, decreased viscosity, mild pleocytosis, and a slight increase in synovial fluid protein.²⁸⁷

Treatment

Nonpharmacologic and First-Line Therapy

55. How should G.R. be treated?

Because of the degenerative nature of OA, nonpharmacologic interventions aimed at preserving joint function and ROM

while maintaining muscle strength are essential. Medications are used to reduce symptoms and have no impact on the disease course. G.R. has significant pain in both the hip and knees. She should understand the pathology of OA and taught appropriate self-management techniques. Examples of effective non-pharmacologic measures include exercises that avoid stress on joints while strengthening periarticular muscles (e.g., aerobic aquatic exercises, stationary bicycle), avoidance of excessive loading of the hip or knee joints by using assistive devices (e.g., canes, walkers, orthopedic shoe), weight reduction for obese individuals, education on principles of joint protection, and thermal modalities.²⁹¹

If possible, G.R. should be referred to a physical therapist, who can help to develop an exercise program appropriate for OA patients. Occupational therapists can provide valuable techniques and assistance devices to help with activities of daily living.

OA treatment goals are to relieve pain, maintain or improve joint function, minimize disability, enhance quality of life and functional independence, minimize risks of therapy, and educate patients and their families. Because the cause and much of the pathophysiology pertaining to OA remain unexplained, drug therapy is empiric and directed toward providing symptomatic relief. Drugs have not been proven to prevent, delay the progression of, or reverse the pathologic changes of OA in humans.

In a comprehensive review of 351 OA clinical trials, acetaminophen was only effective for the treatment of mild pain, whereas NSAIDs were more effective for moderate to severe OA pain.¹³⁴ Furthermore, acetaminophen should be considered the treatment of choice for mild pain because of a lower risk of GI complications compared with NSAIDs. (See Nonsteroidal Anti-inflammatory Drugs section). In a 4-week study of patients with symptomatic OA of the knee,²⁹² acetaminophen, up to 4 g/day, was comparable to an analgesic regimen of ibuprofen (1.2 g/day) and an anti-inflammatory regimen (2.4 g/day). In a multicenter, randomized, double-blind, 2-year comparison of naproxen 750 mg/day with acetaminophen 2.6 g/day, no significant differences were noted between the treatments, knee flexion and walking time in the were improved in the naproxen group.²⁹³

NSAIDs should be prescribed for OA patients with moderate to severe pain; however, the risk of serious adverse effects, particularly GI bleeding, must be considered. Risk factors (e.g., older age, history of prior GI bleeding, concurrent use of antiplatelets or anticoagulants) may warrant the use of PPIs or misoprostol concurrently with NSAID therapy. As in the case of RA, all NSAIDs are equally efficacious for OA; patient response to a given NSAID is not predictable.¹³⁴ Therefore, a trial of several different NSAIDs, even those within the same chemical class, may be required before satisfactory analgesic effects are achieved.

Alternatives to Simple Analgesics

56. G.R. starts a regimen of acetaminophen 1 g QID PRN and returns to the clinic 4 weeks later. She states that most joint-related symptomatically and general functioning have improved; however, she claims that the pain and stiffness in her right knee is more bothersome now than 1 month ago. What is the best treatment option for G.R. at this visit?

If joint symptoms persist despite an adequate trial with acetaminophen, several options may be considered. Locally applied medications offer the advantage of minimizing the potential for systemic adverse effects associated with oral medications. Although not FDA approved, topical NSAIDs (diclofenac, ibuprofen) have been as effective as oral NSAIDs, particularly in patients with OA of the knee.¹³⁴ Evidence supporting the use of capsaicin cream is not as strong as topical NSAIDs, but is better than placebo in providing pain relief. Capsaicin cream, derived from vanillyl alkaloids found in hot peppers and related plants, induces analgesic effects by depleting local sensory nerve endings of substance P. Topical salicylates are not effective for relief of OA symptoms. Intra-articular corticosteroid injections are very effective for the treatment of pain and inflammation in isolated joints (see Corticosteroids section). A poor response to local treatment warrants consideration of NSAID use.

Nonsteroidal Anti-Inflammatory Drugs and Cyclo-Oxygenase-2 Inhibitors

57. What is the role of the NSAIDs and/or COX-2 inhibitors in managing G.R.'s OA?

Because G.R. is overweight and has experienced OA symptoms for more than 1 year, her condition is most likely more than a mild form of OA. The treatment of choice for moderate to severe OA is NSAID therapy.¹³⁴ NSAIDs or COX-2 inhibitors are also preferred for patients who have not responded adequately to maximum doses of acetaminophen and patients with joint effusions. Some patients may benefit from a combination acetaminophen plus an NSAID.^{294,295} This combination would allow for lower doses of NSAIDs when used with acetaminophen. In one study, acetaminophen 4 g/day in combination with naproxen 500 mg/day was as effective as 1,000 to 1,500 mg/day of naproxen alone in patients with OA of the hip.²⁹⁵ Patients with inflammatory OA (clinically defined as having detectable effusion in their joints) may respond better to NSAIDs.²⁹⁶

Although NSAIDs are effective for controlling pain and inflammation associated with OA, the risk of GI-related complications, including ulceration, hemorrhage, and death, must be considered.^{134,136} (See complete discussion regarding adverse effects of NSAIDs and COX-2 inhibitors in Question 11.) NSAID use is associated with a 2.5- to 5.5-fold increased risk of GI-related hospitalization and 16,500 deaths per year among arthritis patients. Risk factors for GI complications, include NSAID dose, concurrent prednisone use, history of GI bleeding, and old age, may warrant the concurrent use of gastroprotective agents such as misoprostol or PPIs. NSAIDs are also associated with other serious adverse effects including renal dysfunction, elevated blood pressure, fluid retention, and heart failure exacerbation. In one study, NSAID use was associated with approximately 19% of hospital admissions for heart failure.²⁹⁷ The burden of illness from NSAID-related heart failure may exceed the burden associated with gastro-pathy.

COX-2 inhibitors are similar to nonselective NSAIDs with regard to virtually all adverse effects, including sodium retention and reductions in glomerular filtration rate.²⁹⁸ The published results of a large trial suggesting that the only remaining COX-2 inhibitor available in the United States, celecoxib, is

associated with fewer serious GI complications when compared to nonselective NSAIDs are questionable (see Question 11). Therefore, until more reliable data are available, the safest course of action is to consider celecoxib as having the same side effect profile as nonselective NSAIDs.

The synthetic opioid tramadol is an alternative to the nonselective NSAIDs or COX-2 inhibitors for patients who have contraindications to the COX inhibitors. Tramadol relieves moderate to severe pain and is comparable to ibuprofen for the treatment of OA of the hip and knee, and may be used as adjunctive therapy to NSAIDs.²⁹² Because tramadol is a synthetic opioid, nausea, constipation, and drowsiness are common side effects. Although the abuse potential for tramadol is very low, the FDA MedWatch adverse effect surveillance program has received 766 reports of abuse and 482 cases of withdrawal associated with tramadol between 1995 and 2004.^{299,300} Therefore, tramadol seems to be safest for the short-term treatment of acute pain. If tramadol is used for chronic pain, close monitoring for abuse or addiction is warranted.

Corticosteroids

Systemic corticosteroids are not commonly prescribed for patients with OA because inflammation is not a primary component of OA pathophysiology. Intra-articular injection of a corticosteroid can be of value when isolated joints with effusions are painful and swollen. The aspiration of effusion fluid followed by an injection of a corticosteroid such as triamcinolone hexacetonide (up to 40 mg) can be effective for reducing pain and increasing muscle strength. The injections can be used as monotherapy or as adjunctive therapy along with an analgesic or NSAID. Symptomatic improvement from intra-articular corticosteroids may last only a few days, but also may persist for a month or longer. The initial relief of pain may permit more effective physical therapy and appropriate balance of rest and exercise, thus attenuating the need for repeated injections.²⁹¹ On the other hand, symptomatic improvement may lead to overuse of the joint and potentially accelerate the degenerative process. The safe frequency of repeated corticosteroid injections into the same joint is unclear. In one study, repeated weekly joint injections for up to 9 weeks in animals resulted in histologic evidence of cartilage degeneration and depressed collagen and proteoglycan synthesis.³⁰¹ In RA patients, corticosteroid injections up to 10 times per joint per year over a 10-year period were not associated with cartilage loss.³⁰² In one randomized, placebo-controlled trial, corticosteroid injections as often as every 3 months did not worsen joint space loss over a period of 2 years.³⁰³

The intra-articular injection of crystalline steroid suspension can precipitate a flare of synovitis, which usually is temporary and can be relieved with cold compresses and analgesics. Other potential, but rare, complications of intra-articular injections include osteonecrosis, tendon rupture, microcrystalline corticosteroid deposition in the synovial fluid, and joint capsule calcification.³⁰⁴ Thus, frequent injections into the same joint, particularly weight-bearing joints, should be avoided. Although the mechanism of benefit of intra-articular corticosteroids in OA is still unclear, patient response is very high, as demonstrated by the fact that a corticosteroid injection is given in one of every six patient care encounters with a rheumatologist.³⁰⁵ Although not evaluated in clinical trials, it

is common practice to mix a small amount of 1% or 2% lidocaine with corticosteroid to provide temporary analgesia upon injection.

Viscosupplements

Viscosupplements, classified by the FDA as a “medical device,” are used as substitutes for the natural hyaluronic acid in the joint fluid that breaks down in patients with OA. Two viscosupplements are currently available in the United States, hyaluronan (sodium hyaluronate) and hylan. Hyaluronan, polysaccharide molecules that occur naturally in synovial fluid, help to create a viscous environment, cushion joints, and maintain normal function. The viscosupplements (derived compound from rooster combs) act as lubricants and shock absorbers in weight-bearing joints, possibly protecting cartilage from damage.^{306,307}

The hyaluronans are usually administered when analgesics and other measures fail for knee OA. The affected knee is first aspirated and hyaluronan is administered intra-articularly into the knee as a series of three to five injections on a weekly basis. In some clinical trials, the hyaluronans provide pain relief comparable to NSAIDs for 6 months or longer after a course of treatment, longer than the duration of relief achievable by intra-articular corticosteroids. Nevertheless, in a systematic review and meta-analysis, intra-articular hyaluronic acid provided no clinical benefits for knee OA.³⁰⁸

Hyaluronan is generally well-tolerated, with the most common adverse event being mild to moderate pain, inflammation, and effusion at the injection site.^{309,310} Patients allergic to avian proteins and products, including eggs and feathers, should avoid all hyaluronans with the exception of ferring (Euflexxa), the only bioengineered formulation.

Corticosteroids or hyaluronans administered intra-articularly may provide temporary relief of pain and, if present, inflammation. Corticosteroids seem to offer a higher response rate at a much lower cost (medication cost <\$2 per injection, 2007 pricing, www.drugstore.com), although hyaluronans may provide a longer duration of effect. Both have the advantage of avoiding systemic adverse effects of oral medications, and may provide the support necessary to allow for the therapeutic success of other key interventions (e.g., weight loss, exercise and muscle strengthening, knee replacement).

Glucosamine and Chondroitin

Glucosamine, used for many years in the United States for arthritis in dogs and horses, was hypothesized to halt or reverse OA. Endogenous glucosamine, an amino-monosaccharide synthesized from glucose, is integral to the biosynthesis of proteoglycans and the glycosaminoglycans, which are building blocks of cartilage. Chondroitin sulfate reportedly provides substrate for the formation of a healthy joint matrix and blocks enzymes responsible for breaking down old cartilage. These products are often sold as combination products for the treatment of OA, but there is no evidence that the combination produces better results than glucosamine sulfate alone.³¹¹ Almost all of the clinical trials of glucosamine and chondroitin have produced weak conclusions because of small sample size or other deficiencies in study design.³¹²

As a result of the widespread promotion and use of glucosamine with or without chondroitin for OA and the lack of strong clinical trial evidence, the National Institutes of

Health sponsored a large study to end all speculation. The Glucosamine/chondroitin Arthritis Intervention Trial evaluated 1,583 patients randomized to receive either placebo, celecoxib, glucosamine, chondroitin, or glucosamine with chondroitin.³¹³ The study required investigators to manufacture their own pharmaceutical-grade glucosamine hydrochloride and chondroitin because of the inability to identify a manufacturer of a product with acceptable lot-to-lot consistency (glucosamine and chondroitin are natural products unregulated by the FDA). At 24-week follow-up, glucosamine and chondroitin, either alone or in combination, were found to be no different than placebo at achieving the primary endpoint of a 20% reduction in knee pain from baseline. On the other hand, significantly more patients treated with celecoxib achieved the primary endpoint when compared with placebo ($p = 0.008$). A preplanned subgroup analysis of 354 patients with baseline moderate to severe pain revealed a significantly higher response rate with combination glucosamine and chondroitin versus placebo (79.2% vs. 54.3%, respectively, $p = 0.002$). In general, successful treatment of more severe pain is eas-

ier to achieve than treatment of mild pain, for which there is little room for improvement. Rates of adverse events and treatment withdrawals were low and similar between all study groups. Celecoxib-treated patients had a higher incidence of blood pressure elevation, and chondroitin-treated patients had the highest incidence of nonspecific musculoskeletal and connective tissue events.

The combination of glucosamine and chondroitin is well-tolerated and may only be beneficial for moderate to severe OA. However, clinicians and patients should keep in mind that these are natural products unregulated by the FDA and, as a result, consistency in potency, safety, purity, and efficacy cannot be assured.

ACKNOWLEDGMENTS

The author acknowledges Mircea Florea, MD, for his guidance and mentoring in the evaluation and management of arthritic disorders, and William Gong, PharmD for his contributions to the earlier editions of this chapter.

Despite new knowledge in the immunology and the pathogenesis of the different connective tissue diseases (CTDs), their etiology and classification remains elusive.¹ Different textbooks approach the connective tissues disease in varied fashions. Some textbooks group systemic lupus erythematosus (SLE), progressive systemic sclerosis, inflammatory muscle disease, Sjögren's syndrome, and the systemic vasculitides together loosely. Other textbooks put them in separate sections.² The diagnosis of the different CTDs is a matter of clinical judgment as patients present with constellations of symptoms, physical findings, and laboratory features that permit their recognition. Patients may present with findings consistent with more than one CTD. There is also overlap CTD representing the presence of two defined CTDs. Examples of this include SLE/RA or what is known as lupus and myositis/scleroderma resulting in sclerodermatomyositis or scleromyositis. Complicating matters, there is also the mixed connective tissue disease (MCTD), which includes examples, such as myositis/scleroderma/RA/SLE first described in 1972.¹

Sustained inflammation is the hallmark of CTDs. The inflammatory effector mechanisms can engage mast cells, platelets, neutrophils, endothelial cells, mononuclear phagocytes, and lymphocytes as well as trigger the complement, kinin, and coagulation cascades. The diversity of the potential mechanisms activated during inflammation can lead to a broad spectrum of clinical manifestations. Environmental factors can

also serve as stimuli to the particular mechanism activated. For example, biologic agents such as group A β -hemolytic streptococci can lead to rheumatic fever or *Borrelia burgdorferi* leading to Lyme disease, drugs such as hydralazine and procainamide can lead to drug-induced lupus, and vinyl chloride can lead to progressive systemic sclerosis.²

GENERAL SIGNS AND SYMPTOMS

Many patients can have arthralgias and arthritis as part of the inflammatory disease associated with their CTD, such as those patients with SLE. Inflammatory disease is suggested by morning stiffness of >1 hour (a similar problem occurs with sitting or resting), swelling, fever, weakness, and systemic fatigue. In some patients, activities of daily living and function may be excellent despite pain and deformity; in others, because of psychologic and systemic disease, there may be poor function with minimum articular involvement. Other psychosocial aspects of their life, including sexuality, may be affected by many of the inflammatory disorders.

Dermatologic changes are often associated with a particular rheumatic disease. Examples include alopecia with SLE, onycholysis, and keratoderma blenorrhagica with Reiter's syndrome, buccal or genital ulcers with SLE or Reiter's syndrome, Raynaud's phenomenon with SLE or systemic sclerosis, calcinosis and rash over the knuckles (Gottron's papule) with dermatomyositis, and sun sensitivity malar rash with SLE. The

presence of nodules, tophi, telangiectasia, or vasculitic changes also may be detected, helping the clinician differentiate which inflammatory disease is present and what management is necessary.

The CTDs are commonly associated with musculoskeletal changes. Joints may display warmth, redness and effusion, synovial thickening, deformities, decreased range of motion, pain on motion, tenderness on palpation, and decreased function. Often, a patient's hand and arm function, as well as gait, may be altered. In addition to the signs and symptoms used to differentiate various rheumatic diseases, laboratory evaluation of patients with rheumatic complaints can often define the extent of disease or detect other organ systems that may be involved.

NONPHARMACOLOGIC AND PHARMACOLOGIC TREATMENT

The aim of present therapy is to provide pain relief, decrease joint inflammation, and more importantly, maintain or restore joint function and prevent bone and cartilage destruction. The current approach to treatment is to interrupt the complex inflammatory process. The general treatment program consists of patient education, balance between rest and exercise, physical and occupational therapy, adequate nutrition, local heat, use of supportive or rehabilitative devices, and orthopedic surgery. Depending on the disorder being treated, various drugs may be used, including the salicylate class of drugs, nonsteroidal anti-inflammatory drugs (NSAIDs), disease-modifying antirheumatic drugs (DMARDs), and corticosteroids. All drugs other than corticosteroids have been reviewed extensively in other chapters.

These agents and especially the corticosteroids used in the treatment of CTDs and systemic rheumatic disorders may have systemic toxicity as well. A good understanding of corticosteroids and their effects can help the clinician monitor the patient appropriately and order laboratory studies, such as renal or liver function tests, complete blood counts (CBCs), muscle enzyme levels, or urinalysis. More sophisticated tests may be necessary to differentiate hypothalamic-pituitary-adrenal (HPA) axis abnormalities from effects of chronic corticosteroid therapy.³ Functional evaluation and health status outcome measurements are ultimately the most important measurement tools in evaluating treatment. Psychologic function typically is assessed in terms of affective domains, such as depression and anxiety, whereas social function usually is measured in terms of social interactions and social support.

SELECTED CONNECTIVE TISSUE DISEASES

CTDs and rheumatic diseases encompass a wide range of disorders that are inflammatory in nature and related to the immune system. The following are some of the conditions that are encountered in clinical practice, which necessitates the use of corticosteroids as part of their therapy.

LUPUS ERYTHEMATOSUS: SYSTEMIC AND DISCOID

SLE is the most diverse of the autoimmune diseases as it is a multisystem CTD caused by several autoantibodies and immune complexes.⁴ Disease manifestations depend on the tissues targeted and often have musculoskeletal involvement. It

generally involves one organ system at the onset, but can affect other organ systems subsequently displaying a broad range of clinical manifestations.⁵ SLE is a dynamic disease in a sense that many patients have fluctuations or flare-ups that necessitate the use of steroids and other potent immunosuppressive agents. Discoid lupus erythematosus is a form of lupus erythematosus in which cutaneous lesions appear on the face and elsewhere. These are atrophic plaques with erythema, hyperkeratosis, follicular plugging, and telangiectasia. These are chronic cutaneous lesions and have few if any systemic manifestations. The lesions are usually sharply demarcated and can be round; therefore, the term *discoid* (or *dislike*) is used.⁶

Epidemiology

SLE generally affects women of childbearing age; this population accounts for >90% of all cases. However, SLE can affect people of all ages and gender, including children, men, and the elderly. SLE can begin at any age but occurs most frequently in women between 16 and 45 years of age. It is more common in African Americans than in whites, and the mean age for diagnosis of African American females is younger than that of white females. Its prevalence ranges from 17 to 50 per 100,000 in American European white females as compared with 60 to 280 per 100,000 in African American females.^{4,7} Asian and Hispanic patients are also susceptible with the prevalence in Chinese patients being similar to that seen in whites. There are currently no published data on the incidence in Hispanic Americans.^{7,8} Genetic epidemiology of SLE has generated strong evidence of hereditary predisposition to this disorder.⁷

Clinical Presentation

SLE is the prototype autoimmune disease as it can affect almost any organ system, and most patients have multiorgan involvement. Clinical signs of SLE are presented in Table 44-1.⁹

Table 44-1 Signs of SLE

| Organ System | Sign |
|------------------|---|
| Cutaneous | Malar rash, discoid rash, mouth/nasal sores, Raynaud phenomenon, cutaneous vasculitis, alopecia |
| Musculoskeletal | Polyarthritis, especially of the small joints of hands and wrists, myositis |
| Renal | Proteinuria, hematuria, red blood cell casts, nephrotic syndrome, elevated creatinine |
| Cardiopulmonary | Pericarditis, pleurisy, pleural effusions, pneumonitis, pulmonary emboli, pulmonary hypertension, myocardial infarction |
| Hematologic | Anemia, leucopenia, thrombocytopenia, elevated sedimentation rate, lupus anticoagulant, anticardiolipin |
| Neurologic | Seizure, psychosis, stroke, encephalopathy, transverse myelitis, mononeuritis multiplex, peripheral neuropathy |
| Gastrointestinal | Esophageal dysmotility, intestinal vasculitis, protein-losing enteropathy |
| Constitutional | Fever, weight loss, lymphadenopathy |

The most common organ systems affected include cutaneous, musculoskeletal, and renal systems. The most common sign of SLE is cutaneous involvement occurring in about 90% of the patients. Rashes are photosensitive in about 70% of the patients, and maculopapular rashes are usually indicative of disease flare-ups. The malar rash or butterfly rash is reported in 20% to 60% of the SLE patients. The rash is often precipitated by exposure to sunlight.¹⁰ Discoid lesions occur primarily in the face, but also occur in the ears and on forearms. Most patients with SLE experience fatigue and suffer from some form of arthralgias and myalgias, which mimic rheumatoid arthritis with symmetrical involvements of the joints. However, unlike rheumatoid arthritis, the affected joints of lupus arthritis are rarely erosive. Renal involvement, occurring in about 50% of the whites and 75% of the African Americans with SLE, is manifested by proteinuria, hematuria, and red blood cell casts. The more severe cases of renal involvement can lead to renal failure if not controlled early. Hematologic manifestations of lupus are frequent and can be life-threatening. Anemia generally is consistent with anemia of chronic disease and iron-deficiency anemia. Leukopenia is common, but rarely severe (i.e., $<2,000$ cells/mm³). Mild chronic thrombocytopenia is common, but can be sudden and life-threatening. Lupus patients can also present with neurologic and gastrointestinal signs as presented in Table 44-1. Vague constitutional signs of SLE (e.g., fatigue, malaise, fever, anorexia, nausea, weight loss) occur in 95% of patients during the course of their disease. Because of its multisystem organ involvement, the diagnosis of SLE may be difficult. The American College of Rheumatology has published criteria for the classification of patients having SLE. The Diagnostic and Therapeutic Criteria originally published in 1982 and updated in 1997 lists 11 characteristic signs, symptoms, and laboratory values most often associated with a positive diagnosis of SLE (Table 44-2). The presence of four or more of these criteria, either serially or simultaneously, during any period of observation, confers $>97\%$ sensitivity and 98% specificity for the diagnosis of lupus.¹¹⁻¹³

Prognosis

Although disability of varying degrees is common in patients with SLE, most will live nearly normal lives. Survival rates are

90% to 95% at 2 years, 82% to 90% at 5 years, 71% to 80% at 10 years, and 63% to 75% at 20 years.⁵ The prognosis is poor in patients with high serum creatinine levels (>1.4 mg/dL), hypertension, nephrotic syndrome, anemia, hypoalbuminemia, and hypocomplementemia at the time of diagnosis. Another 50% of the patients who go into remission remain in remission for decades. The leading causes of death are generally from complications of renal failure or infections.⁵

Treatment

Because there is no cure for SLE, therapy generally involves (a) controlling the acute symptoms of SLE and (b) providing maintenance therapy to prevent exacerbations and to keep clinical manifestations of SLE at acceptable levels. Approximately 25% of patients with SLE have mild symptoms without any life-threatening situations. These patients are normally treated for their symptoms of arthritis, arthralgias, myalgias, fever, and mild serositis with NSAIDs and salicylates. More potent agents and immunosuppressives are used for more active disease. Corticosteroids are used for the more severe life-threatening and severely disabling manifestations unresponsive to immunosuppressive agents.⁵

DRUG-INDUCED LUPUS

The first case of drug-induced lupus was reported in 1945 in a patient receiving sulfadiazine.¹⁴ Since then, approximately 75 drugs have been identified that induce a lupus-like syndrome or exacerbate pre-existing SLE. Classes of drugs that have been linked to the lupus-like syndrome include antihypertensives, antimicrobials, anti-inflammatory agents, anticonvulsants, immunosuppressive agents, recombinant cytokines, psychotropic agents, and antithyroid and hormonal drugs. Drug-induced LE occurs in at least two forms. One is characterized by serositis and the finding of a positive antihistone antibody. This form has been associated with procainamide, hydralazine, minocycline, and isoniazid. The second form involves positive anti-Ro (SS-A) antibody findings¹⁵ and is most prominently linked to hydrochlorothiazide and calcium channel blockers.¹⁶ The most common drugs causing drug-induced LE are procainamide and hydralazine followed by chlorpromazine, isoniazid,

Table 44-2 1997 Revised Criteria for Classification of SLE

| Criteria | Explanation ^a |
|----------------------|--|
| Malar rash | Fixed erythema, flat or raised |
| Discoid rash | Erythematous raised patches with adherent keratotic scaling and follicular plugging; atrophic scarring may occur in older lesions |
| Photosensitivity | Skin rash resulting from an unusual reaction to sunlight by patient history or observed by physician |
| Oral ulcers | Painless oral or nasopharyngeal ulcers observed by physician |
| Arthritis | Nonerosive arthritis involving two or more peripheral joints; characterized by tenderness, swelling, or effusion |
| Serositis | Evidence of pleuritis or pericarditis documented by ECG or rub heard by physician or evidence of pericardial effusion |
| Renal disorder | As manifested by persistent proteinuria (>0.5 g/day or $>3+$) or cellular casts |
| Neurologic disorder | Seizures or psychosis occurring without any other explanation |
| Hematologic disorder | Leukopenia ($<4,000$ /mm ³), or hemolytic anemia, or lymphopenia ($<1,500$ /mm ³), or thrombocytopenia ($<100,000$ /mm ³) |
| Immunologic disorder | Anti-double stranded DNA antibody, or anti-Sm antibody, or anti-phospholipid |
| Antinuclear antibody | An abnormal ANA titer in the absence of drugs known to be associated with drug-induced lupus |

^aThe diagnosis of SLE is made when a patient has 4 or more of the 11 criteria at any time during the course of the disease with 98% specificity and 97% sensitivity.

methyl dopa, penicillamine, quinidine, and sulfasalazine. The most commonly reported drug associated with drug-induced lupus is procainamide, which has resulted in the syndrome in approximately one third of patients who have taken it over a 1-year period. The drug-induced lupus-like syndrome onset can occur as soon as 1 month of therapy or as late as 12 years from the initiation of procainamide. Hydralazine follows procainamide, with a prevalence of drug-induced lupus-like syndrome being reported between 2% and 21%, with the wide range reflecting differences in duration of treatment, dosage, and acetylator phenotype. Drug-induced lupus from hydralazine appears to be associated with daily dosage >200 mg or a cumulative dose of 100 g. Drug-induced cutaneous lupus erythematosus occurs in 15,000 to 20,000 people yearly in the United States and is often unrecognized.¹⁷⁻¹⁹ New cases of drug-induced LE continue to occur with newer drugs such as terbinafine and celecoxib.^{15,20} In particular for celecoxib, this may be another precaution to keep mind since the COX-2 inhibitors are being widely used in the treatment of rheumatic diseases. Patients who develop drug-induced lupus have symptoms (e.g., arthralgias, myalgias, fever) similar to those of patients with idiopathic SLE; however, renal disease is rare.^{14,21} Fever, rash, anemia, and cardiac problems occur slightly less frequently than with spontaneous lupus. Although the lupus erythematosus (LE) cell and antinuclear antibody (ANA) titer can be positive, antibodies to native or double-stranded DNA are not found. Drug-induced lupus typically improves rapidly after discontinuation of the drug and usually does not require specific therapy. However, in some situations (e.g., symptoms present for a long time or patients are significantly symptomatic), a short course of low- to moderate-dose prednisone is beneficial.

SYSTEMIC SCLEROSIS (SCLERODERMA)

Systemic sclerosis, also called scleroderma (*skleros*, meaning hard; *derma*, meaning skin), is a multisystem disorder of connective tissues characterized by inflammation, fibrosis, and degenerative changes in the blood vessels, skin, synovium, skeletal muscle, and some internal organ systems (e.g., gastrointestinal tract, lung, heart, kidney). Systemic sclerosis is an acquired, noncontagious, rare disorder that affects all races worldwide. The incidence in the United States is 19 to 20 per million per year with a prevalence of 19 to 75 cases per 100,000.²² Overall, females are affected three times as often as males, and the female-to-male ratio is increased during the childbearing years when the ratios of women to men may reach 7:1 to 12:1. Onset of systemic sclerosis generally begins in people between 30 and 50 years of age. It is rare in childhood and after age 80. Environmental factors including occupational silica and organic solvent exposure have been implicated in predisposing or precipitating systemic sclerosis. It is a disease of unknown etiology, but most investigators believe the key players are endothelial cells, activated immune cells, and fibroblasts. It is hypothesized that the process is initiated by an immune attack on the endothelium resulting in endothelial cell activation and/or injury. This is followed by activation of the fibroblasts resulting in subendothelial connective tissue proliferation, narrowing of the vascular lumen, and Raynaud's phenomenon. T cells are then selectively activated and pop-

ulate the affected areas such as the dermis and lung. These cells produce cytokines that simulate resident fibroblast to produce excessive amounts of procollagen, which is then converted extracellularly to mature collagen. Later and when the inflammatory process subsides, the fibroblasts revert back to normal.

Systemic sclerosis is divided into two major classes: diffuse cutaneous and limited cutaneous disease, which are distinguished from one another based on the degree and extent of skin involvement. The term *overlap syndrome* is used when features common in one or more of the other CTDs are also present. In most cases of limited cutaneous systemic sclerosis, the initial complaint is Raynaud's phenomenon. Patients with diffuse cutaneous systemic sclerosis most often have generalized swelling of the hands, skin thickening, or arthritis as the first manifestation. The diffuse cutaneous systemic sclerosis patients will present with fatigue or lack of energy, musculoskeletal complaints, and sclerosis of the skin and certain organs. The degree and the rate of organ involvement vary among patients. The skin is taut, firm, and edematous and is firmly bound to subcutaneous tissue; it feels tough and leathery, may itch, and later becomes hyperpigmented. The dermatologic manifestations usually precede the development of signs of visceral involvement. The combination of Calcinosis with Raynaud's phenomenon, esophageal dysfunction, Sclerodactyly, and Telangiectasias normally found in limited cutaneous systemic sclerosis is called the *CREST syndrome*. Patients with limited cutaneous systemic sclerosis may have Raynaud's phenomenon for years before other signs of disease become evident. They are less likely than those with diffuse cutaneous systemic sclerosis to develop severe lung, heart, or kidney disease, although all these diseases can occur. In contrast to limited cutaneous systemic sclerosis, diffuse cutaneous systemic sclerosis develops only with a short interval between the onset of Raynaud's phenomenon and significant organ involvement.

The overall course of systemic sclerosis is highly variable and unpredictable. However, after a remission occurs, relapse is uncommon. The diffuse form of the disease generally has a worse prognosis with a 10-year survival rate of 40% to 60%, compared with a >70% 10-year survival rate in those with limited cutaneous systemic sclerosis. The prognosis is worse in white males and African American females. There is no specific therapy for systemic sclerosis. Supportive therapy is indicated for the organ systems affected. Because multisystem organs are involved, treatment is directed toward alleviating the affected organ systems. Because of potential toxicities, including precipitating acute renal failure, corticosteroids are not generally used and are typically restricted to patients with inflammatory myopathy or symptomatic serositis not adequately controlled with NSAIDs. D-Penicillamine significantly improves diffuse cutaneous systemic sclerosis symptoms in patients with skin thickening, reduces subsequent renal involvement, and increases survival. Vasodilators, such as the calcium channel blocker, nifedipine, and the angiotensin converting enzyme receptor blocking agent, losartan, have proved useful in alleviating Raynaud's phenomenon. Angiotensin-converting enzyme (ACE) inhibitors are the drugs of choice to manage renal complications and hypertension associated with systemic sclerosis. Metoclopramide, erythromycin, nifedipine, proton

pump inhibitors, and H₂ blockers can alleviate specific gastrointestinal symptoms.²³

POLYMYALGIA RHEUMATICA AND TEMPORAL ARTERITIS (GIANT CELL ARTERITIS)

Polymyalgia rheumatica (PMR) and temporal arteritis or giant cell arteritis (GCA) are clinical syndromes that usually affect the elderly population, and both can occur in the same patient. The incidence of PMR and GCA increases in patients after the age of 50 and peaks in those 70 to 80 years of age.²⁴ The occurrence of PMR is two to five times more likely than GCA. Up to 15% of patients with PMR can have GCA, and PMR is found in 40% to 60% of patients with GCA.²⁵ The incidence of PMR increases with age and has been estimated to be as high as 400 cases per 100,000 in individuals older than 65 years of age.^{26–28} Women are affected twice as much as men.²⁴ PMR generally affects whites and is uncommon in African Americans, Hispanics, Asians, and Native Americans.²⁵ A viral cause has been suspected but not confirmed in PMR and GCA, because the prevalence of antibodies against parainfluenza virus type 1 is increased in patients with PMR and GCA.²⁹

Patients with PMR generally present with malaise, weight loss, night sweats, and occasional fever. There is intense pain and stiffness in the neck, shoulder, and buttocks, and the patient may have difficulty arising from bed in the morning. The most useful supporting evidence in support of a clinical diagnosis of PMR is the ESR. It is usually in excess of 50 mm/hour and may exceed 100 mm/hour.²⁵ The C-reactive protein has been found to be a more sensitive indicator of disease activity than the ESR.^{24,30} Also, levels of interleukin-6 appear to be a sensitive indicator of active disease, but most clinical laboratories do not yet have the means to measure these levels.²⁸ As with other CTDs, the diagnosis of PMR is made based on clinical presentation despite well-recognized laboratory abnormalities. No pathognomonic laboratory test exists. Nonspecific clinical features and the frequent absence of physical signs make diagnosis difficult.

GCA is a connective tissue disorder that involves the inflammation of the medium and large arteries and almost always occurs in whites. It is more common in women and rare in African Americans. GCA rarely affects patients younger than 50 years of age, and the incidence increases with age. It is closely associated with PMR and affects many arteries throughout the body, producing symptoms and signs that mimic other medical and surgical conditions. Carotid artery involvement lends itself to the name *temporal arteritis* when the temporal arteries are distended, are tender, and pulsate early in the disease. These arteries can become occluded and lead to visual disturbances and blindness from ischemic optic neuritis. The symmetric and proximal muscle pain and stiffness of PMR are often associated with GCA.

Corticosteroids are essential for the treatment of PMR and GCA because they rapidly relieve symptoms and reduce the incidence of blindness associated with GCA. The therapeutic goal in PMR is to alleviate stiffness and constitutional features. The corticosteroids are the drugs of choice and the NSAIDs are used when PMR symptoms are mild.²⁵ For patients with PMR, the current recommendation is to start with prednisone 15 to 20 mg/day. Most patients respond significantly within

24 hours, but it may take up to 48 to 72 hours to achieve a good response in a few patients. The results are dramatic. If patients do not obtain relief of symptoms after a few days, another diagnosis should be considered.²⁴ If the patient's symptoms are not reduced by the initial dose, prednisone can be increased by an additional 10 mg/day for control. After the symptoms are controlled, the dosage of prednisone can be decreased by 2.5 mg Q 2 weeks for as long as the symptoms remain improved until 10 mg/day is reached. Afterwards, the prednisone is titrated at 1-mg decrements Q 4 weeks while following the clinical response and the ESR.²⁵ Although patients respond quickly to the corticosteroids, treatment is often required for several years. Duration of treatment may be related to the severity of the disease as measured by the ESR. High pretreatment ESRs indicate more severe disease, and these patients require longer duration of therapy.²⁸ Typically, corticosteroid treatment is required for 6 to 24 months. For patients with mild PMR disease, the NSAIDs can effectively manage their symptoms.

For patients with GCA, corticosteroid treatment must be initiated immediately as soon the diagnosis is made because GCA can lead to severe visual loss and potential blindness.²⁴ Treatment for GCA is more aggressive than PMR and usually begins with prednisone 40 to 60 mg as a single or a divided dose. Initial pulsed intravenous doses of methylprednisolone (1,000 mg/day for 3 days) may be given to patients with recent or impending visual loss. Corticosteroids may prevent, but usually do not reverse, visual loss.^{24,25} After the clinical symptoms and laboratory findings of inflammation have subsided for about 1 month, decreases in the prednisone dose should be initiated. Sometimes, it may take several months at doses of 15 to 25 mg/day before prednisone may be decreased. Prednisone dosages should be decreased gradually in 1- to 2-week intervals by a maximum of 10% of the total daily dose. Excessively rapid tapering of the prednisone dose may result in relapses and recurrence of symptoms.²⁴ The decrease in the dosage of prednisone should be based on the patient's clinical status rather than on laboratory results.²⁷ Treatment of GCA should be continued for 1 to 2 years to minimize the potential for relapse.²⁵ If the patients do not achieve clinical remission or do not respond to low doses of the corticosteroids, immunosuppressive agents, such as azathioprine, should be considered. Monitoring ESR or the C-reactive protein value is the most useful in determining disease activity.²⁴ Another study suggested that measurement of interleukin-6 levels after 4 weeks of therapy was helpful.²⁸ PMR and GCA are among the most rewarding diseases for a clinician to diagnose and treat because the unpleasant symptoms and serious consequences of these two disorders can be relieved rapidly and prevented by corticosteroids.²⁵

REITER'S SYNDROME

Reiter's syndrome is a form of reactive arthritis defined as peripheral arthritis often accompanied by one or more extra-articular manifestations that appear shortly after certain infections of the genitourinary or gastrointestinal tracts. Reactive arthritis typically begins acutely 2 to 4 weeks after venereal infections or bouts of gastroenteritis.³¹ Some evidence also suggests that respiratory infection with *Chlamydia pneumoniae* may also trigger the disease.³² Most of the cases affect

young men, with the ratio of male to female patients of 9:1. The classic triad of Reiter's syndrome is arthritis, urethritis, and conjunctivitis. Urethritis usually appears first in this syndrome, which occurs mainly in young men.³³ Mild dysuria and a mucopurulent urethral discharge are the most typical symptoms in men. Women may have dysuria, vaginal discharge, and purulent cervicitis and/or vaginitis. Reiter's syndrome has its peak onset during the third decade of life, but has been reported in children and octogenarians.³⁴

There is no specific therapy for Reiter's syndrome. Interventions should include joint protection and relief of pain, suppression of inflammation, and when appropriate, eradication of infection. The arthritis is treated symptomatically with NSAIDs. Systemic corticosteroids are relatively ineffective in the routine management of patients with seronegative spondyloarthropathies such as Reiter's syndrome.³⁴ Aggressive and unremitting Reiter's syndrome may benefit from immunosuppressive drugs.

POLYMYOSITIS AND DERMATOMYOSITIS

Polymyositis and dermatomyositis are autoimmune diseases of unknown etiology. Polymyositis is predominately a disease of adults. Dermatomyositis affects both children and adults, and more women than men. Polymyositis includes inflammation of a number of voluntary skeletal muscles simultaneously. The onset is insidious, and patients initially complain of muscle weakness of the trunk, shoulders, hip girdles, upper arms, thighs, neck, and pharynx. These patients usually report increasing difficulties in everyday tasks requiring the use of proximal muscles such as getting up from a chair, climbing stairs, stepping onto a curb, lifting objects and combing hair. Polymyositis spares the skin; however, dermatomyositis is a progressive polymyositis condition that is associated with a skin rash. The rash accompanies or more often precedes the muscle weakness of polymyositis. The rash is erythematous, scaly, and eczematous and generally affects the eyelids, bridge of the nose, cheeks, forehead, chest, elbows, knees, and knuckles and around nail beds. One-third of these cases are associated with various connective tissue disorders such as rheumatoid arthritis, SLE, and progressive sclerosis; one-tenth are associated with a malignancy. Edema, inflammation, and degeneration of muscles characterize both polymyositis and dermatomyositis.³⁵

The goal of therapy is to improve muscle weakness, thereby improving the activities of daily living. Supportive therapy such as bed rest, physiotherapy, warm baths, and moist heat applications to the affected areas can improve muscle stiffness. If mouth lesions are present, irrigation of these lesions with warm saline solution is helpful. Oral prednisone (e.g., 1–2 mg/kg/day) is the initial treatment of choice and should be initiated as soon as possible. After the symptoms are brought under control in approximately 3 to 4 weeks, the dosage of the steroid is tapered slowly over a period of 10 weeks to 1 mg/kg every other day. Afterward, the dose is further decreased to the lowest possible dose to control symptoms and to avoid adverse effects of the corticosteroids as long-term steroid usage can cause steroid myopathy. This can further confuse the issue of whether the muscle weakness is due to increased disease activity or to adverse effects of steroid therapy. Generally, there should be objective increase in muscle strength and activities

of daily living by the end of the third month of therapy. Approximately 75% of these patients may require immunosuppressive therapy if their conditions do not respond to prednisone after 3 months.³⁵

CLINICAL USE OF CORTICOSTEROIDS

Corticosteroids play an important role in the treatment of a wide variety of disease states. In physiologic doses, they are used to replace deficiencies of this endogenous hormone. In pharmacologic doses, they are used to treat and, more often, provide supportive therapy for a variety of diseases. In the past 40 years, much has been learned about the corticosteroids; however, the exact mechanism by which corticosteroids exert their anti-inflammatory and immunosuppressive effects remains unclear. Corticosteroids may be used for the treatment of many rheumatologic disorders, including ankylosing spondylitis, bursitis, tenosynovitis, acute gouty arthritis, RA, osteoarthritis, dermatomyositis, PMR, acute rheumatic carditis, SLE, mixed CTD, polymyositis, and vasculitis.

Predictable Pharmacologic Effects Relative to the Corticosteroids

1. J.L., a 62-year-old man with a 1-year history of scleroderma, is being treated with prednisone 60 mg/day and azathioprine 50 mg/day. At a recent clinic visit, his vital signs and laboratory test results were as follows: weight, 292 lb; blood pressure (BP), 180/102 mmHg; pulse, 62 beats/minute and regular; and fasting plasma glucose (FPG), 196 mg/dL. J.L. complains of occasional headaches, a “swollen face,” a modest weight gain, and increases in urinary frequency. Based on J.L.’s presentation, are any of his symptoms related to his drug therapy?

[SI unit: FPG, 10.9 mmol/L]

His “swollen face” could represent a cushingoid feature resulting from long-term corticosteroid use. Hypercortisolism alters normal body fat distribution, resulting in moon facies, buffalo hump, truncal obesity, and other localized fatty deposits. J.L.’s complaint of headaches could be related to his increased BP (180/102 mmHg) in part to fluid retention resulting from his corticosteroid use, even though hypertension usually is asymptomatic (see Chapter 14, Essential Hypertension). Although corticosteroids with the greatest mineralocorticoid activity are more likely to produce fluid retention and increase BP, even those without mineralocorticoid action (Table 44-3) can increase BP. Hypertension can also be induced by high-dose glucocorticoids due to the permissive effects of the glucocorticoids on the action of vasoactive substances (angiotensin II, catecholamines) on the vessel wall and myocardium that results in increased systemic vascular resistance and increased cardiac contractility.³⁶ A history of high BP and advanced age can predispose individuals to corticosteroid-induced increases in BP. Whether hypertension is related to the dose or duration of corticosteroid therapy is unknown; it rarely occurs in patients receiving alternate-day therapy. The hypertension usually resolves after discontinuation of the steroid. In J.L., however, the hypertension also can be attributed to other possible etiologies (e.g., scleroderma). J.L. also has urinary frequency and elevated fasting plasma glucose that could be attributed to using

Table 44-3 Comparison of Corticosteroid Preparations

| Compound | Equiv. Potency (mg) | Anti-Inflammatory Potency | Na-Retaining Potency (Mineralocorticoid Activity) | Plasma $t_{1/2}$ (min) | BIOLOGIC $t_{1/2}$ (hr) |
|---------------------------|---------------------|---------------------------|---|------------------------|-------------------------|
| Short Acting | | | | | |
| Cortisone | 25 | 0.8 | 2+ | 30 | 8–12 |
| Hydrocortisone (Cortisol) | 20 | 1 | 2+ | 80–118 | 8–12 |
| Prednisone | 5 | 4 | 1+ | 60 | 18–36 |
| Prednisolone | 5 | 4 | 1+ | 115–212 | 18–36 |
| Methylprednisolone | 4 | 5 | 0 | 78–188 | 18–36 |
| Triamcinolone | 4 | 5 | 0 | 200 | 12–36 |
| Long Acting | | | | | |
| Dexamethasone | 0.75 | 20–30 | 0 | 110–210 | 36–54 |
| Betamethasone | 0.6 | 20–30 | 0 | 300+ | 36–54 |

high doses of glucocorticoids. The increases in glucose are mainly mediated through decreased peripheral utilization of glucose and induction of gluconeogenesis in the liver. In patients whose glucose levels remain elevated and the continued use of the glucocorticosteroid is warranted, antihyperglycemic agents may be started.

The equivalent potency, sodium-retaining potency, plasma half-life, and biologic half-life of several synthetic analogs of cortisol are listed in Table 44-3. The corticosteroids are used primarily for their anti-inflammatory, immunosuppressive, or antiallergic activity. Cortisone and hydrocortisone have the highest sodium-retaining potency and, therefore, are seldom prescribed for long-term anti-inflammatory therapy. They are useful when sodium and water retention properties are desirable (e.g., adrenal insufficiency after surgery for Cushing's syndrome). All corticosteroids are 21-carbon steroid molecules. The chemical structures of the corticosteroids have been modified, resulting in large differences in duration of action, anti-inflammatory potency, and mineralocorticoid activity.³⁷ The body synthesizes cortisol by converting cholesterol to pregnenolone, which in turn is converted to progesterone and ultimately to cortisol, the major corticosteroid in humans.³⁸

Active Corticosteroid Compounds

2. M.H. is a 43-year-old woman with RA awaiting a liver transplant. Her total bilirubin is 3.1 mg/dL, aspartate aminotransferase (AST) is 93 U/L, and alanine aminotransferase (ALT) is 65 U/L. She has been well maintained on prednisone for her arthritis until recently, when her arthritis failed to respond despite escalating doses of prednisone. Why has prednisone seemed to have stopped being effective? What factors need to be considered when selecting an alternative corticosteroid for M.H.?

[SI units: bilirubin, 53.01 μ mol/L; AST, 93 U/L; ALT, 65 U/L]

Although orally administered corticosteroids are well absorbed, exogenously administered corticosteroids, which are 11-keto compounds, are devoid of corticosteroid activity until converted in vivo into active 11 β -hydroxyl compounds.³⁹ Cortisone and prednisone must be converted to the active compounds, cortisol and prednisolone, respectively, in the liver.³⁹ M.H. has very little hepatic capacity and, theoretically, might not have been converting the prednisone to its active

prednisolone metabolite. To circumvent this possibility, M.H. should be given prednisolone or perhaps a different corticosteroid (e.g., methylprednisolone). Although this explanation is logical given this patient's end stage liver disease, dosage adjustments for hepatically metabolized drugs in the setting of liver disease are difficult to predict because hepatic metabolism is complex and involves numerous oxidative and conjugative pathways that are variably affected in hepatic disease. M.H.'s ability to adhere to her medication regimen because of encephalopathic changes and other potential variables also should be considered as explanations for her decreased responsiveness to prednisone.

Approximately 95% of cortisol is bound to α -globulin transcortin or cortisol-binding globulin (CBG), and the remaining 5% is bound to albumin after this carrier is saturated.⁴⁰ However, the bond between cortisol and albumin is weak, and about 25% of the steroid disassociates from albumin and is free to circulate in the plasma. Although the dosing of corticosteroids is not a very precise science, it is important to consider adjusting dosages for patients who have decreased serum albumin concentrations. In these patients, a greater amount of free hormone will result in increased pharmacologic effects. Because albumin is synthesized by the liver, M.H. is likely to have decreased serum albumin concentrations and could be more susceptible to the pharmacologic effects of corticosteroids when given an active corticosteroid moiety.

When selecting an alternative corticosteroid to replace M.H.'s prednisone, the clinician should not base the dosing interval of the replacement corticosteroid strictly on the plasma half-lives shown in Table 44-3. Corticosteroids have biologic half-lives that are 2 to 36 times longer than their plasma half-lives. In addition, the onset of biologic effects lags behind peak plasma levels. Practitioners must always be mindful that the serum or plasma half-life of a drug might not be synonymous with the biologic half-life. For example, prednisone with a plasma half-life of only about 1 hour can be dosed on alternate days for some disorders.

Clinical Presentation of SLE

3. H.R., a 33-year-old African American woman with recently diagnosed lupus erythematosus, has experienced a recent weight loss of 15 lb (down to 130 lb), joint pain, fatigue, and a worsening of

Table 44-4 Systemic Lupus Erythematosus Disease Activity and Use of Corticosteroids

| Indication | Corticosteroid Regimen |
|--------------------------|---|
| Cutaneous manifestations | Topical or intralesional corticosteroids |
| Minor disease activity | Prednisone (or equivalent) at a dosage of <0.5 mg/kg in a single or divided daily dose (5–30 mg prednisone daily) |
| Major disease activity | Oral: Prednisone (or equivalent) at a dosage of 1–2 mg/kg in a single or divided daily dose IV bolus: Methylprednisolone (1 g or 15 mg/kg) over 30 minutes; dose often repeated for 3 consecutive days for life-threatening situations |

her facial rash. She has a temperature of 105°F, serum creatinine (SrCr) of 2.8 mg/dL, Westergren ESR of 50 mm/hour, ANA titer of 1:320, and positive anti-dsDNA and anti-Sm tests. Urinalysis (UA) reveals 3% proteinuria and a modest amount of casts. What subjective and objective data are consistent with SLE, and would therapy be likely to reflect resolution of these signs and symptoms?

[SI unit: SrCr, 247.52 μmol/L]

According to some of the objective data (fever, increased Westergren ESR, proteinuria, weight loss, high ANA titer, increased SrCr, positive anti-dsDNA and anti-Sm tests) and subjective data (fatigue, joint pain, worsening facial rash), H.R. is experiencing a flare of her SLE (major disease activity shown on Table 44-4). Three major patterns of SLE exist. The classic pattern, one of exacerbations, or “flares” of disease activities, now is called the “relapsing remitting pattern.”¹⁸ Newly diagnosed lupus continue to evolve more than 5 years after initial diagnosis and flares of lupus occur with a median time of 12 months, even in patients with longstanding disease and treatment.⁴¹ This disease tends to wax and wane, and the aggressiveness of therapy should be adjusted to accommodate these changes.

Role of Corticosteroids in SLE

4. Why might corticosteroids be indicated for H.R.?

The general management of SLE stresses patient education through which patients need to understand their disease processes. H.R. is definitely experiencing a flare of her SLE and needs aggressive therapy to control her symptoms. Normally, she would be maintained with NSAIDs (including the COX-2 inhibitors) for her joint pains and possibly an immunosuppressive agent such as hydroxychloroquine since she was recently diagnosed.⁴² H.R.’s fever, joint pain, fatigue, and worsening facial rash all reflect an inflammatory response to her SLE. These subjective symptoms along with the objective measurements of her disease activity (e.g., increased ESR, ANA, SrCr) are mediated by leukotrienes, prostaglandins, lymphocytes, and the other inflammatory responses described earlier. Therefore, corticosteroids are indicated for the treatment of H.R.

Selection of Appropriate Corticosteroid Therapy

5. What would be a reasonable corticosteroid dosage for H.R.?

Because of the great variety of clinical applications and the wide variety of corticosteroid compounds and dosages, the selection of the most appropriate dosage of a corticosteroid is as much an art as it is a science. Generally, higher dosages and shorter dosing intervals of the corticosteroid translate into an increased anti-inflammatory effect and increased side effects.³⁶ Therefore, the need to modify disease activity must be balanced against the need to minimize toxicities.

There are multiple dosage forms and uses of corticosteroids in SLE, including topical preparations for inflammatory rashes, intralesional injections for discoid lupus, low-dose oral therapy for mild active disease, and high-dose oral or bolus intravenous infusions for acute, severe manifestations. These indications and the corresponding dose of corticosteroid are listed in Table 44-4.⁴²

A review of H.R.’s subjective and objective data suggests that her disease activity probably represents a major flare-up of her SLE. Uncontrolled disease activity can be both debilitating and life-threatening and thus demands rapid an effective intervention. Therefore, a short course of a high-dose corticosteroid regimen probably would be a reasonable treatment for this episode of SLE in H.R.

A short course of steroids or even a single treatment with a high-dose corticosteroid typically can result in prompt and complete resolution of most manifestations of lupus SLE. Pulse therapy with methylprednisolone 1,000 mg intravenously daily for 1 to 3 days has proven effective for SLE, vasculitis, and RA.³⁶ High-dose steroid pulses must be considered on an individualized basis because adverse effects can be more likely with this dosing regimen. Normally, the pulse methyl prednisone therapy of 1,000 mg/day for 3 days is not given more frequently than at monthly intervals because high doses of glucocorticoids are invariably toxic.³⁶ Alternatively, the use of mini pulses of oral prednisone (100–200 mg/day) for several days also may help in disease control. In some situations, the addition of a potent immunosuppressive agent such as cyclophosphamide in combination with the corticosteroid pulse therapy may be necessary to bring the patient under control.⁴³ In any case, depending on how high the dose of glucocorticoid initiated, tapering of the glucocorticoid should be initiated within one to two weeks following initiation of therapy.³⁶ Table 44-5 provides a summary of different steroid regimens that may be used for severe and active SLE.⁴⁴ Assuming that H.R. had been taking a higher dose of oral prednisone, the rationale for IV pulse therapy seems applicable to H.R.

6. After finishing her bolus “pulse” therapy of methylprednisolone (1 g/day IV for 3 days), H.R.’s lupus has responded well. Her joint pain is decreased, and her temperature decreased to normal. The current laboratory test results are as follows: Westergren ESR, 22 mm/hour; SrCr, 2.5 mg/dL; ANA titer, 1:80; and positive anti-dsDNA. H.R. wishes to go home to finish her recovery. What dosage of oral corticosteroid would be reasonable to prescribe for H.R. at her discharge from the hospital?

Along with adjustments of the other medications that she may be taking (e.g., NSAIDs or other immunosuppressive agents), H.R. needs to have her IV doses of methylprednisolone converted to an oral formulation (Table 44-6) and consideration given to reducing the steroid dosage. Because the steroid dosage H.R. received is considered massive supraphysiologic,

Table 44-5 Usual Regimens of Systemic Corticosteroid Therapy in Severe, Active SLE

| Preparations | Dose | Rationale | Toxicities |
|---|--|--|---|
| Regimen 1: Daily oral short-acting (prednisone, prednisolone, methylprednisolone) | 1–2 mg/kg/day; begin in divided doses | Controls disease activity rapidly | High—infections, sleeplessness, mood swings, hyperglycemia, psychosis, hypertension, weight gain, hypokalemia, fragile skin, bruising, osteoporosis, osteonecrosis, irregular menses, muscle cramps, acne, hirsutism, cataracts |
| Regimen 2: Intravenous methylprednisolone | 500–1,000 mg/day for 3–5 days; then, 1–1.5 mg/kg/day of oral corticosteroids | Controls disease activity rapidly, may achieve results more rapidly than daily oral therapy; some nonresponders to oral regimen respond to the intravenous regimen | High—same as above except more rapid taper of daily maintenance steroid dose may be possible, leading to lower cumulative doses |
| Regimen 3: Combination of either regimen 1 or 2 with cytotoxic or immunosuppressive agent | | | |

the corticosteroid effects on lymphocyte function can be expected to be prolonged. Therefore, the residual benefits from the supraphysiologic doses of methylprednisolone will be additive to the effect of the oral steroid that will be prescribed for her upon departure from the hospital. Because of this fact, H.R. does not require an oral corticosteroid dose that is equivalent to the IV dose, and a lower oral daily dose can be prescribed, because she responded well to her IV doses. In some patients with presumably modest disease activity, alternate-day dosing of corticosteroids may be adequate to maintain disease suppression as there are less adverse effects associated with alternate-day dosing.^{36,41} However, more study is needed to better determine the role of alternate-day dosing of corticosteroids, because there is less efficacy in patients renal nephritis taking alternate-day therapy as compared to those taking daily glucocorticoids.^{36,41}

In the United States, prednisone is the most commonly prescribed corticosteroid for oral use in the treatment of CTDs. Prednisone is rapidly and substantially absorbed following oral administration, has an intermediate duration of action (12–36

hours), is available in many dosage forms and strengths, and is relatively inexpensive. The recommended dosage of prednisone for most CTDs is 1 mg/kg/day in three to four divided doses. Administration of corticosteroids in daily divided doses given two to four times per day provides a more rapid onset and a greater degree of anti-inflammatory effect. Considering the severity of H.R.'s lupus flare-up, this dosing appears appropriate. The dosing of oral corticosteroids is a balancing act to minimize toxicity while preventing flare-up of disease activity.³⁶ For H.R., who weighs approximately 59 kg, a maintenance regimen of prednisone 20 mg three times a day (for a total of 60 mg/day) or an equivalent dose of another corticosteroid should be prescribed. H.R. also might need an immunosuppressive agent, such as azathioprine or cyclophosphamide, because of her increased SrCr and possibility of lupus nephritis. These latter drugs would not be initiated in H.R. because she seems to be responding to her methylprednisolone without adverse sequelae thus far. The addition of immunosuppressive agents may have a “steroid-sparing” effect and could allow for steroid dosage reduction.³⁶

Once-daily Dosing

7. H.R. was discharged from the hospital taking ibuprofen 600 mg QID with food and prednisone 20 mg TID. After 3 weeks, her flare-up has subsided, and her symptoms are now back at her previous baseline. Why should a change in her medication be considered?

Once the patient's lupus flare-up is under control and has responded to steroids, the divided daily doses of a steroid can be consolidated into a single daily dose, usually administered in the morning. Endogenous cortisol levels are normally highest at about 7 to 8 AM and decline to their lowest at midnight. Thus, a once-a-day morning corticosteroid dose coincides in time with high endogenous plasma cortisol. Because this is the time that the patient's tissues would normally be exposed to the highest levels of endogenous cortisol, suppression of the HPA axis is minimized somewhat. If the divided dose regimen has been used for <2 weeks, the dose can be combined

Table 44-6 Routes of Administration of Various Corticosteroids

| Corticosteroid | Route of Administration |
|--------------------|--|
| Betamethasone | PO, IM, intra-articular, intrasynovial, intradermal, soft-tissue injection |
| Cortisone | PO, IM |
| Dexamethasone | PO, IM, IV, intra-articular, intradermal, soft-tissue injection |
| Hydrocortisone | IM, IV, PO |
| Methylprednisolone | PO, IM, IV |
| Prednisolone | PO, IM, IV, intra-articular, intradermal, soft-tissue injection |
| Prednisone | PO |
| Triamcinolone | PO, IM, intra-articular, intrasynovial, intradermal, soft-tissue injection |

IM, intramuscularly; IV, intravenously; PO, oral.

into a single daily dose immediately; however, if the divided dose regimen has been used for >2 weeks, the dose should be converted over a 2-week period to a single daily dose because patients who have taken glucocorticoids for more than 2 weeks are candidates for more HPA suppression and their dose needs to be tapered more slowly.⁴⁵ Because H.R. received her dosage for 3 weeks, the daily dose should be converted to 60 mg each morning over a 2-week period.

Hypothalamic-Pituitary-Adrenocortical Axis Suppression

8. R.S., a 48-year-old, 135-lb, 5 feet 5 inch man, has recently been diagnosed with polyarteritis. After a recent hospitalization, R.S. was discharged home taking 15 mg prednisone QID. He has been adhering to this regimen for approximately 1 month, and his symptoms are well controlled. R.S. now is scheduled for major surgery. His laboratory test evaluation revealed the following: SrCr, 1.4 mg/dL; blood urea nitrogen (BUN), 17 mg/dL; white blood cell (WBC) count, 11,200 cells/mm³; and Westergren ESR, 29 mm/hour. Why should R.S.'s corticosteroid regimen be adjusted?

[SI units: SrCr, 123.76 μmol/L; BUN, 6.07 mmol/L urea; WBC, 11.2 × 10³ ESR, 29 mm/hour]

The HPA axis regulates the amount of circulating cortisol.^{36,45} Corticotropin-releasing factor, a hormone secreted by the hypothalamus, stimulates the release of adrenocorticotropin (ACTH) from the anterior pituitary. ACTH, in turn, stimulates the adrenal cortex to secrete cortisol.⁴⁵ As serum cortisol levels rise, a negative-feedback mechanism inhibits corticotropin-releasing factor and ACTH secretion, resulting in decreased secretion of cortisol (Fig. 44-1). Under normal conditions, about 10 to 30 mg/day of cortisol is secreted by the adrenal cortex in accordance with the circadian cycle of an individual.^{39,40} Under stress and illnesses the amount of cortisol increases to up to 10-fold or 250 to 300 mg/day for patients undergoing surgery or prolonged major stress.^{39,40}

Corticosteroid doses can be classified as physiologic (i.e., replacement) or pharmacologic (i.e., supraphysiologic). A physiologic dose of a corticosteroid is equal to the amount of corticosteroid usually secreted by the adrenal cortex each day and is equal to about 5 mg/day of prednisone. A dosage of prednisone of 0.1 to 0.25 mg/kg/day is a low supraphysiologic dosage; 0.5 mg/kg/day of prednisone is a supraphysiologic dose; 1 to 3 mg/kg/day is a high-supraphysiologic dose; and 15 to 30 mg/kg/day is a massive supraphysiologic dose.

Shortly after cortisone and ACTH were accepted into clinical practice, adrenocortical insufficiency and subsequent adrenal atrophy were noted in patients who received doses of exogenous corticosteroids that exceeded the normal amount needed for hormone replacement. When corticosteroids are discontinued abruptly in the patients who had been treated with supraphysiologic doses of corticosteroids for a prolonged period, the HPA axis cannot respond to situations in which there is a need for increased cortisol (e.g., illness, stress, surgery).⁴⁵ The minimum dose, dose interval, and therapy duration required to suppress the HPA axis are difficult to assess. The best predictor of HPA axis suppression is the patient's current corticosteroid dosage and duration of the corticosteroid therapy. There is a strong correlation between prednisone mainte-

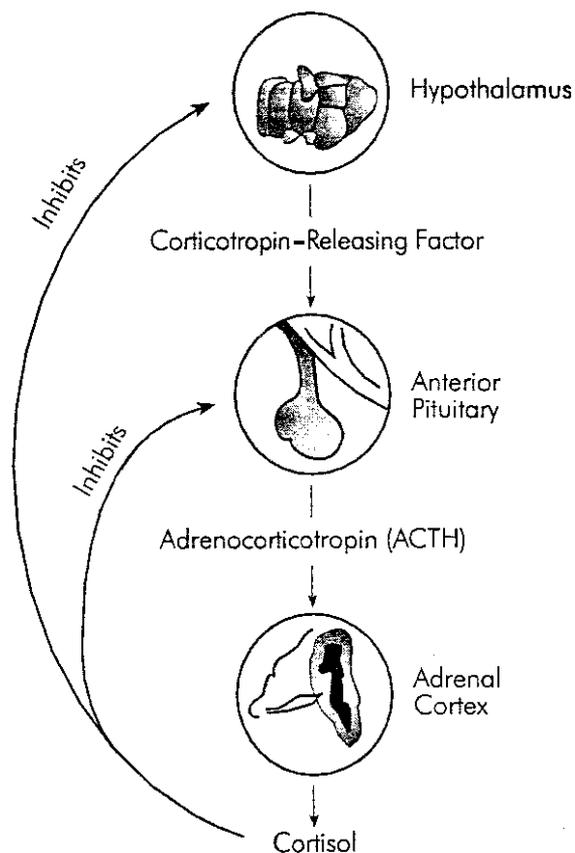

FIGURE 44-1 Hypothalamic-pituitary-adrenocortical axis regulation.

nance doses >5 mg/day and a subnormal ACTH-stimulation test result.³ Following long-term therapy, this suppression can last up to 1 year. The duration of adrenal suppression following a short course of corticosteroid therapy is unknown. Even though there is HPA axis suppression in short-term treatment of 1 week or less, clinically evident adrenal insufficiency is probably extremely rare and the suppression lasts only for a few days.³ Because R.S. is receiving prednisone 1 mg/kg/day, he is receiving a massive supraphysiologic dose that is capable of suppressing endogenous cortisol secretion. Surgery is a stressful event and supplemental doses of a corticosteroid with mineralocorticoid effects probably are warranted for R.S., because he most likely has some degree of HPA axis suppression. Although corticosteroids can decrease wound healing, this is a minor consideration relative to HPA axis suppression.

Adrenal Function Testing

9. How can the degree of adrenal suppression in R.S. be assessed?

The clinician has two options when HPA axis suppression is suspected. The first option is to treat the suspected patient as though adrenocortical insufficiency is present. The second is to try to quantify the adrenocortical reserves of the pituitary and hypothalamus. In today's environment of cost containment, the former approach usually is taken. There are currently five well-established stimulatory tests of HPA axis function. The most commonly used test to diagnose adrenal insufficiency is

the short 250- μ g ACTH (cosyntropin) stimulation test. This test directly assesses adrenal gland responsiveness to exogenous ACTH. The test measures baseline cortisol plasma concentrations both before the rapid injection of a highly supra-physiologic dose of a synthetic ACTH analog and the cortisol level 30 to 60 minutes after injection. Patients with normal adrenal gland function should be able to generate a poststimulation cortisol concentration of 20 mcg/dL. Plasma cortisol concentrations of <495 nmol/L (18 mcg/dL) suggest adrenal insufficiency.⁴⁰ The remaining four tests—insulin-induced hypoglycemia, overnight metyrapone, CRH stimulation, and low-dose (1 mcg) ACTH stimulation—are more sensitive than the 250-g ACTH stimulation test, because they depend on a completely intact HPA axis for a normal result.³ With the exception of the low-dose (1 mcg) ACTH stimulation, these tests tend to be labor intensive and expensive. The low-dose ACTH stimulation not only measures adrenal gland responsiveness, but may be able to detect subtle degrees of adrenal atrophy caused by central adrenal insufficiency.^{46,47}

Dosing During Stressful Events

10. R.S. has a cosyntropin test performed, and it demonstrates an increase of 80 mmol/L to a level of 190 mmol/L. In the consideration of this laboratory report, what dosages of corticosteroid should be ordered to prevent an Addisonian crisis during R.S.'s surgery?

A normal response includes an increase in plasma cortisol of >170 mmol/L (6 mcg/dL) from baseline to a level >495 nmol/L (18 mcg/dL).⁴⁰ R.S. apparently has adrenal insufficiency and needs cortisol supplementation during periods of stress. Depending on the amount of stress and how prolonged the stress, recommendations for corticosteroid replacement regimen for patients with suppressed HPA axis has been somewhat arbitrary (e.g., hydrocortisone 100 mg Q 6–8 hr).⁴⁵ Newer recommendations propose that the amount and duration of corticosteroid coverage should be determined by (a) the preoperative dose of corticosteroid taken by the patient, (b) the preoperative duration of the corticosteroid administration, and (c) the nature and anticipated duration of surgery.⁴⁸ Because the adrenal gland can secrete as much as 300 mg/day during acute stress, 150 mg of hydrocortisone every 6 hours is a reasonable regimen for R.S. on the day of his surgery.

Leukocytosis

11. R.S. was doing fine until 3 days after surgery when his temperature spiked to 103°F. R.S. has been back on his original prednisone dosage. Urine, blood, and sputum cultures were ordered as well as a STAT CBC, drawn at 4 PM. His CBC revealed an increase in WBCs with a differential showing an increase in segmented neutrophils (granulocytes 16,000/mm³ from 11,000 at baseline) along with decreases in both total lymphocyte and monocyte count from baseline. No “left shift” was noted. What could be causing these results?

At first, it would be reasonable to assume there may be an infectious process present. The effects of prednisone on peripheral or circulating WBC counts are well documented and predictable (e.g., granulocytosis along with lymphopenia

and monocytopenia). T-cell lymphocytes are decreased more than B-cell lymphocytes. The occurrence of a “left shift” (e.g., an increase in immature leukocytes, such as bands) is variable, and only slight if present. The increase in granulocytes (PMNs) and decrease in lymphocytes and monocytes is most significant 4 to 6 hours after a prednisone dose; these values return to normal in 24 hours. The decrease in monocyte accumulation at tissue sites of inflammation may persist for several days.

Prednisone increases granulocytes by an average of 4,000/mm³ with a range of 1,700 to 7,500/mm³. The increase in granulocytes results primarily from release of cells from bone marrow and secondarily from the shift of cells from the marginal or noncirculating cell pool to the circulating or peripheral pool.⁴⁹ The temporal relationship of WBC changes in patients taking multiple doses of corticosteroids is less predictable because of the constant flux in steroid effect.

The results from R.S.'s most recent CBC should be compared with his baseline CBC. The temporal relationship to his prednisone dose also should be determined. Because a STAT CBC, at the time of a temperature spike, was obtained only 7 hours after his prednisone dose was administered, the CBC changes (leukocytosis, monocytopenia, and lymphocytopenia) are difficult to interpret. Another CBC, 24 hours after his dose, was ordered to differentiate the cause of his CBC abnormalities. This CBC was normal, indicating that the abnormalities on the first CBC were probably steroid induced.

Alternate-day Therapy

12. One month later, R.S. states he feels much better. He has recovered from his surgery, and his polyarteritis is now asymptomatic; his WBC count, BUN, SrCr, and Westergren ESR are returning toward the normal range. Why should R.S.'s prednisone dosage be adjusted at this time?

Once a stable clinical response is attained with a single daily dose of a corticosteroid, R.S.'s corticosteroid dosage should be decreased to the lowest effective dosage and, if possible, to taper the steroid to an alternate-day regimen.^{3,45} If used appropriately, alternate-day corticosteroid therapy can help minimize HPA axis suppression and undesirable side effects, while allowing effective treatment of the disease process. A corticosteroid with a short or intermediate duration of action should be chosen for alternate-day therapy to minimize accumulation from subsequent doses that would negate the benefits of every-other-day dosing. If the dosing interval is substantially longer than the biologic half-life (e.g., giving prednisone every 48 hours), nearly normal hypophyseal-pituitary-adrenal function can be maintained. This can minimize the risks of daily therapy. Although alternate-day steroid dosing can be used to maintain disease suppression in chronic therapy, control of the active disease process usually necessitates more intensive dosage schedules.

Conversion to Alternate-day Therapy

13. How would you convert R.S.'s current 60 mg/day dosage to alternate-day therapy?

Before converting a patient to alternate-day therapy, the minimum effective daily dosage must be determined.

Generally, the optimum every-other-day dose is 2.5 to 3 times the minimal daily dose.^{45,50} The dose on the “off” day should be tapered gradually by the equivalent of 2.5 to 5 mg of prednisone or its equivalent per week until the patient is taking the steroid every other day. Tapering of the alternate-day dosage can continue until the minimum dosage sufficient to control the underlying disorder is achieved. For R.S., one approach would be to decrease the dosage of prednisone by 5 mg/week until the minimum daily dose is reached that controls his polyarteritis. For illustrative purposes, assume this dosage is 30 mg/day. The 30-mg dose is multiplied by 2.5, so R.S. would take 75 mg on one day, alternating with 30 mg of prednisone the next. The 30-mg dose would then be tapered each week by 5 mg/week until discontinued. R.S. would then be taking 75 mg of prednisone every other day. Should R.S. be asymptomatic at this dosage, a taper of the 75 mg could then be attempted. Tapering should be 2.5 mg/week until the lowest possible dosage that will control his disease is achieved.

Discontinuation of Therapy

14. R.S. has now received prednisone 60 mg QOD for 5 months, and his polyarteritis is well controlled. What would be a reasonable dosing schedule for implementing the gradual discontinuation of R.S.’s corticosteroid?

Many methods of tapering steroid dosages have been tried.³ Some suggest decreasing the corticosteroid dosage by the equivalent of 2.5 to 5 mg of prednisone every 3 to 7 days until the physiologic dose is reached. Another recommends the daily dose of prednisone (or its equivalent) can be decreased by 5% to 10% per week until a dose of 0.25 to 0.5 mg/kg/day is reached and more slowly thereafter, aiming for either a complete withdrawal or, if not possible, for a low dose of corticosteroid.³⁶ Others suggest decreasing the dosage by 2.5 mg of prednisone (or the equivalent of another corticosteroid) every 1 to 2 weeks if on daily therapy or by 5 mg of prednisone every 1 to 2 weeks if on alternate-day therapy, until it can be discontinued. Some clinicians follow this procedure until a physiologic dose is reached and, at that time, will convert the patient to hydrocortisone 20 mg/day. After 2 to 4 weeks, this dosage can be decreased by 2.5 mg every week until 10 mg/day is achieved. At this time, the patient should have a plasma cortisol concen-

tration measured. If this is normal, the hydrocortisone can be discontinued.^{45,50} During the tapering process, disease flare-up is a definite possibility; therefore, the patient must be monitored closely. Also, if the patient is stressed during this period, exogenous corticosteroid supplementation may be necessary. Abrupt withdrawal of steroids following long-term, high-dose therapy should be avoided because this may produce a steroid withdrawal syndrome manifested by the presence of nausea, vomiting, anorexia, headache, joint pain, fever, lethargy, myalgia, hypotension, and weight loss. These symptoms are thought to occur as a consequence of rapidly falling serum corticosteroid concentrations rather than the presence of low concentrations.

R.S.’s prednisone dosage of 60 mg every other day can now be decreased by 5 mg at 1- to 2-week intervals until he is receiving 5 mg on alternate days. R.S. can then be converted to hydrocortisone 20 mg/day for 2 to 4 weeks. Weekly reductions of the hydrocortisone by 2.5 mg could be undertaken until the daily dose of 10 mg is reached. At this point, R.S.’s morning dose should be held and a cortisol level taken.

If the serum cortisol concentration is normal (> 10 mcg/dL), the hydrocortisone can be discontinued. This is but one of the many possible approaches.^{45,51} All approaches to discontinuing corticosteroids must be modified based on factors such as dose, duration of therapy, disease status, patient condition, and existence of adverse effects.

Adverse Effects

In addition to suppression of the HPA axis, corticosteroid therapy produces inevitable side effects.^{36,39,45} A compilation of documented complications and adverse effects associated with various organ systems is listed in Table 44-7.⁵²

Osteoporosis

15. D.L., a 28-year-old, 5 feet 4 inch, 105-lb woman, is diagnosed with SLE. After an acute episode of lupus nephritis, D.L. has been maintained on high-dose prednisone, currently at a level of 15 mg/day. Her lupus seems well controlled, but she comes in today with complaints of back pain. A physical examination reveals no apparent joint involvement typical of a lupus flare-up. What are possible explanations for her back pain, and what additional data are needed to assist in the differential diagnosis?

Table 44-7 Adverse Effects of Corticosteroid Therapy

| Organ System | Complication |
|---------------------|---|
| Immunologic | Increased susceptibility to infections, decreased inflammatory responses, suppressed delayed hypersensitivity, neutrophilia, lymphocytopenia |
| Musculoskeletal | Osteoporosis, fractures, osteonecrosis, myopathy |
| Gastrointestinal | Peptic ulcers and gastrointestinal bleeds associated with NSAID use, pancreatitis |
| Cardiovascular | Hypertension, fluid retention accelerated atherosclerosis |
| Dermatologic | Acne, hirsutism, purple striae, skin fragility, ecchymoses |
| Neuropsychiatric | Altered mood, emotional lability, euphoria, insomnia, depression, psychosis, pseudotumor cerebri |
| Ophthalmologic | Cataracts, glaucoma |
| Endocrine-metabolic | Glucose intolerance, weight gain, fat redistribution (Cushing’s syndrome), negative nitrogen balance, growth suppression, muscle wasting, impaired wound healing, fluid retention, hypokalemia, impotence, irregular menses, HPA suppression, acute renal insufficiency |

HPA, hypothalamic-pituitary-adrenal; NSAID, nonsteroidal anti-inflammatory drug.

A good medical history combined with a physical examination and laboratory tests should be obtained to determine whether D.L. is having arthralgias due to SLE or other etiologies. It also is important to note that osteoporosis and osteonecrosis are common adverse effects of corticosteroid therapy, and that 30% to 50% of patients treated with chronic corticosteroids develop osteoporosis. During the first 3 to 6 months of corticosteroid therapy, there is a rapid bone loss of up to 12%, which slows down to 2% to 5% annually.³⁶ Prednisone dosages of >10 mg/day result in a 10% to 12% annual reduction in the bone mineral content of the lumbar spine.^{53,54} Dosages as low as prednisolone 7.5 mg/day appear to be the threshold dose for the development of osteoporosis.⁵⁴ Bone loss leading to fractures at sites such as the spine, hip, and ribs are well-recognized complications of corticosteroid therapy. Osteoporosis in postmenopausal women with RA is more evident at the hip than the spine, and the most important determinants of bone loss are disability and cumulative corticosteroid dose.⁵⁵

The mechanism of corticosteroid-induced osteoporosis is uncertain, but it appears to be different from that of postmenopausal osteoporosis. Corticosteroid-induced osteoporosis is attributable, in part, to decreased osteoblast activity, decreased matrix synthesis, and decreased active life span of osteoblasts. In general, bone formation is decreased and bone resorption may be increased as well.⁵³ The degree of bone loss correlates to the dose of the corticosteroid and the duration of treatment; however, the absolute amount and duration of corticosteroid therapy have not been determined. When large corticosteroid doses are used, vertebral bone loss can be rapid, and compression fractures can occur within weeks to months after initiation of therapy.⁵³ D.L. has multiple risk factors for osteoporosis (young, female, and small stature); therefore, her bone mineral density (BMD) should be evaluated and a vertebral radiograph should be taken to look for a compression fracture. D.L.'s bone mineral density test results will determine whether she is a candidate for either primary or secondary prevention and treatment. Primary prevention with prophylactic calcium and calcitriol, with or without calcitonin, should be initiated for any patient with multiple risk factors who possibly will be maintained on the equivalent of prednisone 7.5 mg/day or more of corticosteroids.⁵³ Primary prevention is indicated for D.L. if her bone density is not decreased. Because D.L. has been taking prednisone 15 mg/day for an extended time, she most likely would require secondary prevention and treatment. Secondary prevention and treatment are indicated when bone density is low, regardless of whether fractures are present.⁵³ Primary and secondary interventions include the bisphosphonates, calcitriol (for primary prevention only), vitamin D and calcium, calcitonin, fluoride, and selective estrogen receptor modulators (e.g., raloxifene) for postmenopausal women (also see Chapter 48, *The Transition Through Menopause*). The statins may have promise as they have been preliminarily studied to have bone anabolic activity, block osteoporosis and osteonecrosis, resulting in lower rates of fractures in human studies.^{56–58} For D.L., a bisphosphonate such as cyclical etidronate would be a good choice especially at the initiation of corticosteroid when bone loss is the worse. Although there is some concern with prolonged use of these agents in young individuals, due to their long retention in bones, this should not discourage their use when they are clearly indicated in young SLE patients. The

bisphosphonates should not be used in pregnancy or moderate-severe renal failure, and their discontinuation should be considered when the corticosteroids doses have been substantially tapered with stabilization of BMD.³⁶ If she is not able to tolerate etidronate or if safety is a concern, calcitriol may be used, although it requires regular serum calcium monitoring at 4 weeks, 3 and 6 months, and 6-month intervals afterwards.⁵³ The pathogenesis of osteonecrosis is not well-known. Symptoms of osteonecrosis usually take a few months to a few years to develop after exposure to corticosteroids.^{59,60} The risk increases with both the dose and duration of corticosteroid therapy. Corticosteroid therapies of short-term high doses, adrenal insufficiency replacement dose, and intraarticular injections have all been implicated.³⁶

Gastrointestinal

16. C.W., a 66-year-old, 5 feet 6 inch, 68-kg woman, is newly diagnosed with PMR. She is an occasional drinker and smoker (1–2 packs/week). She started prednisone 15 mg/day and naproxen 500 mg Q 12 hr PRN 1 week ago and has shown dramatic improvement in the muscle pain of her shoulder and pelvic girdle. She comes in today to begin a taper of her prednisone and comments she's been having some "stomach" problems. What may be the cause of her stomach problems, and how may it be addressed?

Whether corticosteroids lead to peptic ulcer disease is controversial despite early observations of a probable correlation.^{45,61,62} The prevalence of peptic ulcer disease is increased with the combined use of NSAIDs and corticosteroids.⁶³ Corticosteroids and NSAIDs commonly are prescribed concomitantly because many patients with connective tissue disorders have symptoms, such as arthralgias, inflammation, and pain. Corticosteroids can induce tissue atrophy and probably enhance the ulcerogenic potential of other drugs. The risk also depends on the underlying disease and the dose and duration of the steroid therapy. Several risk factors can contribute to C.W.'s stomach problems. First, she probably has been taking her prescribed naproxen, a nonspecific cyclooxygenase inhibitor (COX) for her chronic aches and pains until her diagnosis of PMR. The nonspecific COX inhibitors (see Chapter 43, *Rheumatic Disorders*) have been used significantly in the United States and are well documented to precipitate gastrointestinal complications. C.W. is also at increased risk for gastrointestinal complications because of her gender, advanced age, and her smoking and drinking history. At this time, she should have her naproxen switched to a COX-2 inhibitor (e.g., celecoxib, rofecoxib), which, theoretically, should be expected to decrease the potential for developing serious gastrointestinal complications, despite the paucity of substantive documentation. Because prednisone probably will be needed for an extended period by C.W., prophylactic therapy against ulceration may be reasonable.

Hyperglycemia

17. G.P., a 58-year-old man, has a medical history of dermatomyositis, type 2 diabetes mellitus (5 years), hypercholesterolemia, and obesity. G.P.'s current medications are prednisone 80 mg/day (started 2 months ago), lovastatin 20 mg Q HS, and glyburide 5 mg Q am. He came into clinic this morning with the following physical findings: weight, 285 lb; BP, 140/90 mmHg; pulse, 50 beats/minute and regular; and FPG, 189 mg/dL. G.P.'s diabetes

has been controlled for 3 years. What are likely explanations for his hyperglycemia?

[SI unit: FPG, 10.5 mmol/L]

Hyperglycemia in G.P. can be attributed to corticosteroid stimulation of gluconeogenesis or impairment of peripheral glucose utilization³⁶; however, other etiologies (e.g., missed glyburide dose) also should be considered. Corticosteroids can promote pancreatic glucagon secretion with resultant glycogenolysis and formation of sugar from breakdown of amino acids and lactate produced during glycogenolysis. This process is not generally ketosis producing. Corticosteroids also decrease peripheral glucose utilization by decreasing glucose cell entry and cell membrane insulin receptors. The effects of the corticosteroids on carbohydrate metabolism in susceptible patient are dose related.³⁶ Increases in blood glucose are usually mild and dosages of prednisone as low as 15 mg/day can cause this effect. Alternate-day therapy has been proposed to minimize, but does not prevent, this adverse effect and in fact produces alternate-day hyperglycemia. Hyperglycemia peaks 2 to 4 hours after administration of the corticosteroid and can last from 12 to 24 hours, depending on the size of the dose.

G.P.'s diabetes has been well controlled in the past; therefore, immediate medication changes are not warranted. He should self-monitor his blood glucose (SMBG) on a regular basis and report the results on the next clinic visit. Corticosteroid-induced hyperglycemia can occur in nondiabetic patients as well. Blood sugars in many nondiabetic patients will return to

normal as the patient adjusts to the excess glucose concentration. G.P.'s diabetes should be managed aggressively because he is overweight and at increased risk for cardiovascular complications with hypercholesterolemia. If his fasting blood glucose remains above the American Diabetes Association (ADA) guidelines on subsequent clinic visits, his glucose control may necessitate modifications in his medication management (e.g., increasing the glyburide dosage).

Ecchymosis

18. Several weeks after discharge, R.D. began noticing large purple blotches on her arms that did not blanch upon application of local pressure. Also, these "bruises" did not seem to disappear very rapidly. Why is this dermatologic effect probably prednisone induced?

Ecchymosis, easy bruisability, is a common side effect of prolonged corticosteroid use; it occurs most often in the elderly and is associated with continued use of supraphysiologic corticosteroid doses.³⁹ Steroids destroy the collagen support of small blood vessels, resulting in leakage of blood into surrounding tissue. The anti-inflammatory effects of steroids reduce the normal resorption of blood leakage into tissue, making the "bruise" last longer. A reduction in the dosage of prednisone or the use of an alternate-day prednisone dosing regimen should lessen the purpura.⁶⁴ Unfortunately, patients such as R.D. often are already receiving the lowest dosage of corticosteroid that is compatible with keeping the clinical condition under control.

MEDICAL ABORTION 45-26

The term “contraception” is defined as the intentional prevention of pregnancy. Contraceptives are therefore pharmaceuticals or devices that prevent pregnancy. The goal of contraception “therapy” is to prevent unintended pregnancy without causing adverse effects and to preserve fertility, when desired. Medically, pregnancy is defined by the U.S. Food and Drug Administration (FDA) and the National Institutes of Health (NIH) as being synonymous with implantation. An unintended pregnancy (also referred to as unplanned pregnancy) is a pregnancy

that was unplanned or unwanted at the time of conception and includes pregnancies occurring in women who were using contraceptives during the month the pregnancy occurred.

In the United States, nearly half of all the pregnancies each year (~3 million) are unintended.¹ The rate of unintended pregnancy in the United States is higher than that of other developed countries with comparable medical resources.^{2,3} Unintended pregnancy is common in the United States and affects women of all ages and socioeconomic groups. Although a

significant number (47%) of unintended pregnancies occur in the 7% of women at risk for pregnancy who do not use a method of contraception, most unintended pregnancies (53%) occur in the 94% of women at risk for pregnancy who were using a contraceptive method during the month they became pregnant.⁴ Unintended pregnancy rates are highest among women <18 years of age and decline with age until age 40. More than one-half of unintended pregnancies in the United States are terminated by elective abortion.⁵ An unintended pregnancy has significant negative consequences to both the woman and to society. The consequences to a woman from an unintended pregnancy are obvious. The consequences to society are public health issues. An unintended pregnancy results in a lost opportunity to prepare for pregnancy in ways that reduce fetal and maternal morbidity and mortality, including folic acid supplementation, management of preexisting conditions, and changes in lifestyle, such as avoidance of alcohol or tobacco.

Contraception choices have medical, personal and public health considerations. The personal aspects include issues related to sexuality, religious, or cultural beliefs. Medical conditions that affect contraceptive selection or the risks associated with pregnancy also must be considered. Public health issues include relative risk from contraceptive use, medical complications of childbearing, and abortion rates. The safety and efficacy of contraceptive options have improved significantly; however, misconceptions regarding contraception are common. A 1993 Gallup poll found that 65% of women believe oral contraceptives are at least as risky as pregnancy.⁶ The risk of death from pregnancy is more than five times the risk of death from oral contraceptive use in nonsmoking women. In the same Gallup survey, 58% of respondents could not name one noncontraceptive benefit from using oral contraceptives. The survey also found that 29% of women believed oral contraceptives cause cancer and 31% believed the failure rate to be at least 10%; both of these are incorrect. As members of the health care team, the pharmacist can play a critical role in helping women and their partners choose and use from the available methods as safely and effectively as possible.

It is estimated that nearly 20% of adolescents have had sex before the age of 15. About 15% of 14-year-old girls who have had sex report having been pregnant.⁷ Contraceptive policies in the United States and worldwide will help determine how quickly the population will grow and can help reduce the number of unwanted pregnancies.

MENSTRUAL CYCLE PHYSIOLOGY

Biological feedback mechanisms involving the hypothalamus, anterior pituitary gland, ovaries, and endometrial lining of the uterus control the average 28-day menstrual cycle.^{8,9} The hypothalamus synthesizes gonadotropin-releasing hormone (GnRH) and secretes the hormone in a pulsatile manner with varying frequencies throughout the menstrual cycle. GnRH stimulates the anterior pituitary to produce and release follicle-stimulating hormone (FSH) and luteinizing hormone (LH). FSH and LH act on the ovaries to produce estrogen and progesterone. Estrogen in turn acts on the hypothalamus and anterior pituitary, in a negative feedback manner, to stop FSH and LH secretion (Fig. 45-1).

The menstrual cycle is divided into three phases: the follicular phase, ovulation, and the luteal phase (Fig. 45-2).^{8,9} By

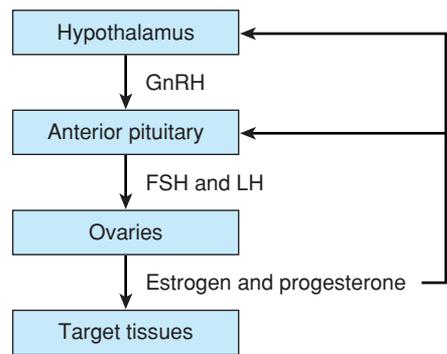

FIGURE 45-1 Menstrual cycle physiology. GnRH, gonadotropin-releasing hormone; FSH, follicle-stimulating hormone; LH, luteinizing hormone.

convention, the day bleeding begins is referred to as the first day (or day 1) of the menstrual cycle. Menstrual bleeding usually occurs between days 1 to 5 of the cycle. The follicular phase begins at the onset of menstruation (menstrual phase) and lasts approximately 10 to 14 days (Fig. 45-2). Also at the beginning of the follicular phase, several follicles begin to develop within the ovary. In the second half of the follicular phase, most of the developing follicles atrophy except for one “dominant” follicle that will develop further and produce increasing amounts of estrogen. Elevated estradiol levels cause a surge of both LH and FSH. This LH surge is responsible for final-stage growth and maturation of the follicle, ovulation, and the formation of the corpus luteum. Ovulation usually occurs 14 days before the last day of the cycle. After ovulation, the dominant follicle develops further and produces estrogen and progesterone in increasing amounts. In 90% of women, the luteal phase lasts 13 to 15 days and is the least variable part of the human reproductive cycle. During this progesterone-dominant phase, the corpus luteum produces both progesterone and estrogen. Progesterone prepares the endometrium for implantation of a fertilized ovum. If implantation does not occur, corpus luteum regression causes a decrease in the levels of estrogen and progesterone. When these hormone levels decrease, the endometrium cannot be maintained and is sloughed off (menstrual phase). Using the average 28-day cycle as an example, day 28 is the last day of the cycle and is the day before bleeding begins again for the next menstrual cycle.

COMPARISON OF CONTRACEPTIVE METHOD EFFECTIVENESS

The effectiveness of any contraceptive method depends on its mechanism of action, availability (e.g., if a prescription is required, cost), adherence, and acceptability (e.g., side effects, ease of use, religious and social beliefs). Any or all of these reasons can account for the discrepancy between the lowest observed failure rate (so called “perfect use”) and the actual failure rate in typical users observed in clinical practice. Table 45-1 compares the first-year failure rates of various contraceptive methods.⁹

HORMONAL CONTRACEPTION PHARMACOLOGY

Estrogens prevent the development of the dominant follicle by suppressing FSH secretion. Estrogens also stabilize the

Emergency Contraceptive Pills

Treatment initiated within 72 hr after unprotected intercourse reduces the risk of pregnancy by at least 75%.ⁱ

Lactational Amenorrhea Method (LAM)

LAM is a highly effective, *temporary* method of contraception.^j

^a Among *typical* couples who initiate use of a method (not necessarily for the first time), the percentage who experience an accidental pregnancy during the first year if they do not stop use for any other reason.

^b Among couples who initiate use of a method (not necessarily for the first time) and who use it *perfectly* (both consistently and correctly), the percentage who experience an accidental pregnancy during the first year if they do not stop use for any other reason. For patch and ring, the percentage comes from the package insert.

^c Among couples attempting to avoid pregnancy, the percentage who continue to use a method for 1 year.

^d The percentages becoming pregnant in columns (2) and (3) are based on data from populations where contraception is not used and from women who cease using contraception to become pregnant. Among such populations, about 89% become pregnant within 1 year. This estimate was lowered slightly (to 85%) to represent the percentages who would become pregnant within 1 year among women now relying on reversible methods of contraception if they abandoned contraception altogether.

^e Foams, creams, gels, vaginal suppositories, and vaginal film.

^f Cervical mucus (ovulation) method supplemented by calendar in the preovulatory and basal body temperature in the postovulatory phases.

^g With spermicidal cream or jelly.

^h Without spermicides.

ⁱ The treatment schedule is one dose within 72 hours after unprotected intercourse, and a second dose 12 hours after the first dose. The U.S. Food and Drug Administration has declared the following brands of oral contraceptives to be safe and effective for emergency contraception: Ovral (1 dose is 2 white pills); Alesse (1 dose is 5 pink pills); Nordette or Levlen (1 dose is 4 light-orange pills); Lo/Ovral (1 dose is 4 white pills); Triphasil or Tri-Levlen (1 dose is 4 yellow pills).

^j However, to maintain effective protection against pregnancy, another method of contraception must be used as soon as menstruation resumes, the frequency or duration of breastfeeding is reduced, bottle feeds are introduced, or the baby reaches 6 months of age. Adapted from Hatcher RA et al. *Contraceptive Technology*. 18th ed. New York: Ardent 2004.

Table 45-2 Commercially Available Brand-Name and Generic Oral Contraceptive and Progesterone-Only Pills

| Brand Name | Generic Name | Progestin Type and Dose | EE Dose (mcg) | Progestin Activity | Estrogen Activity | Androgen Activity |

| Ovrette | | Norgestrel 0.075 mg | None | | | |

^a Also available with iron tablets instead of placebo tablets during the usual placebo week.

^b as 2 days of placebo followed by 5 days of EE 10 mg during the usual placebo week.

COC, combined oral contraceptive; EE, ethinyl estradiol; H, high; I, intermediate; L, low.

endometrial lining to minimize the breakthrough bleeding seen with oral contraceptive (OC) use.^{9,10}

Progestins have multiple mechanisms of action providing contraception. Progestins may prevent ovulation by suppressing LH secretion. In addition, progestins may impede the transport of sperm through the cervical canal by thickening cervical mucus. Progestins also may inhibit implantation by causing alterations or transformation of the endometrial lining or alter the transport of sperm or ovum within the fallopian tubes.⁹

COMBINATION ORAL CONTRACEPTIVE PILLS (COC)

Manipulating the normal physiologic feedback mechanisms of the menstrual cycle using estrogen and progestin has proved

to be an effective method of contraception. COC containing estrogen and a progestin and are the most commonly used reversible method of contraception in the United States. In 1960, the U.S. Food and Drug Administration (FDA) released the first COC, Enovid 10.^{3,9} Enovid 10 (containing 150 mcg mestranol and 9.85 mg norethynodrel) contained much higher doses of estrogen and progestin than are in today's pills. The side effects caused by the early high dose COC prompted a search for lower dose, better tolerated products. Table 45-2 lists many of the available brand-name and generic COCs.

Currently available COCs are very effective in preventing pregnancy. The failure rate ranges from 0.1 to 5 pregnancies per 100 women-years (Table 45-1).⁹ Virtually all of the COCs

available in the United States contain the synthetic estrogen ethinyl estradiol (EE). Mestranol is another estrogen that has been used. Mestranol is inactive (prodrug) and is converted in the body to EE. Mestranol 50 mcg has approximately the same activity as EE 35 mcg.^{3,9} COCs contain one of the following synthetic progestins: ethynodiol diacetate, desogestrel, drospirone, levonorgestrel, norethindrone, norethindrone acetate, norgestimate, or norgestrel. Norgestrel is a mixture of dextronorgestrel and levonorgestrel. Dextronorgestrel appears to be progestationally inert compared with levonorgestrel.^{3,10} These progestins differ significantly in their progestational potency and also in the extent of their metabolism to estrogenic substances. Progestins have both estrogenic and anti-estrogenic effects. Because the progestins have a chemical structure similar to that of 19-nortestosterone, they have varying degrees of androgenic activity (Table 45-3).¹⁰ The androgenic effects are largely mitigated by the estrogen-induced increase in sex-hormone binding globulin (SHBG), which binds progestins. Minor structural changes in all of the progestins may lead to significant changes in their progestational, estrogenic, antiestrogenic, and androgenic activities in tissue culture. The clinical significance of these differences may vary widely in effect from woman to woman (Table 45-2).

Different terminology is used to describe the classes of pills that have been approved over the years. The COCs most commonly used today are also called “low-dose” COCs. They contain <35 mcg/day of EE. In the literature, COCs have been referred to by “generations,” as well.^{8,11} First-generation COCs contain >50 mcg/day of EE and are not currently in use. Second-generation COCs contain 30 to 35 mcg of EE with one of the following progestins levonorgestrel, norgestimate, norethindrone, norethindrone acetate, or ethynodiol diacetate. Third-generation COCs contain desogestrel and 20 to 30 mcg EE. There are also references to generations related to the pro-

gestin used. First-generation progestins include norethindrone and its derivatives. Second-generation progestins include levonorgestrel and norgestrel, and third-generation progestins include desogestrel, norgestimate, and gestodene (gestodene is not available in the United States).^{3,10}

Contraindications to Oral Contraceptive Use

1. M.F., a healthy 32-year-old woman, wants to know if she is a good candidate for COC. She smokes a pack of cigarettes per day. What contraindications to COC therapy must be considered? Is she a good candidate for COC?

To determine if any contraindications or precautions exist, the clinician should first obtain baseline health information from M.F.¹⁰ (Table 45-4). M.F. should be encouraged to stop smoking. She does not currently have any contraindications to COC use, but she should be informed that COCs may no longer be prescribed for her in a few years if she continues to smoke (see Question 8). Because she does not have any medical problems, she is an acceptable candidate for a COC.

Choice

2. M.F. has decided to start COC. Which COC should be selected for her?

All COCs are considered to be equally effective. For most women, the selection of any product containing 35 mcg or less of EE is preferred. Few studies have compared one product with another. For some women, formulary restrictions may also need to be considered. The information in Figure 45-3 may be used to select an initial COC or to change pill formulations

if side effects become intolerable.¹⁰ Any pill containing 20 to 35 mcg EE can be used for M.F. because she is a healthy woman without medical complications. Her blood pressure and weight should be obtained before starting the pills. A body weight >70.5 kg has been associated in some studies with increased COC failure, therefore a product with a higher dose of EE (e.g., 35 mcg) may be a better choice if she weighs more than 70.5 kg.¹²

21-Day versus 28-Day Cycle

Most 28-day COC pill packs contain 21 days of active pills (pills that contain estrogen and progestin) followed by 7 days of placebo or iron tablets. The 21-day pill packs contain only the active pills. Many clinicians prefer the use of 28-day cycle COC to minimize confusion and to promote adherence. With a 28-day pack, users take one tablet daily regardless of whether it is in the active or placebo phase of the cycle. After taking the last tablet of a 28-day pack, a new pack should start the next day. When continuous ovarian suppression is used for extended cycles or to treat estrogen-dependent disorders, such as endometriosis, the 21-day cycle packs may be preferred. Many products are only available in 28-day cycle packs. If M.F. will not be taking a COC continuously, a 28-day pack is recommended.

Multiphasic Oral Contraceptives

3. Should M.F. start a monophasic or triphasic COC? What are the advantages and disadvantages of the triphasic products relative to other regimens?

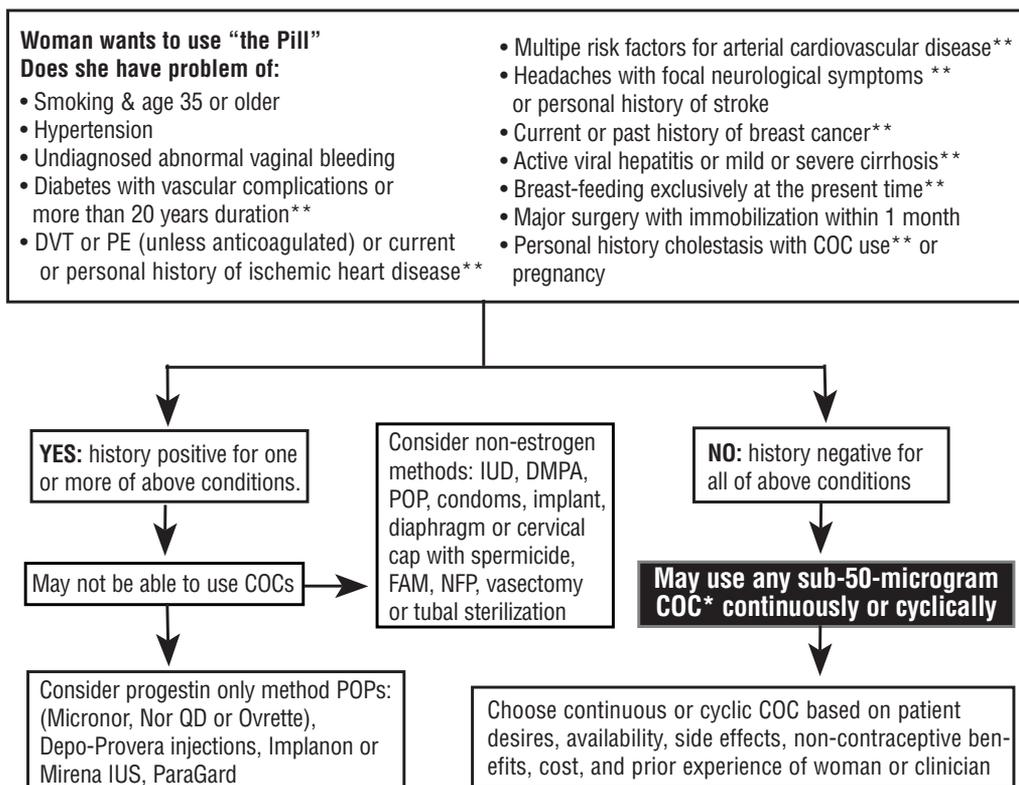

Because of metabolic and physiologic effects related to the progestin component of monophasic COCs, the biphasic and triphasic products were formulated to contain a lower total monthly dose of progestin than the monophasic products (with the exception of Mircette). These products attempt to lower

doses of progestin and provide adequate endometrial support while also providing adequate contraception.¹¹

The multiphasic products contain varying amounts of progestin and estrogen during each of the active phases. Currently, Necon 10/11, Ortho-Novum 10/11, and Jenest 28 are the only biphasic COCs marketed in the United States, and they are rarely used. Mircette can be classified as either a monophasic or biphasic OC. Mircette provides a novel regimen containing 21 days of 0.15 mg desogestrel plus 20 mcg EE (fixed doses as with a monophasic product), then only 2 days of placebo, and finally followed by 5 days of 10 mcg EE alone. The woman does not need to take missed 10 mcg EE doses or use a backup method if those tablets are missed. The 5 days of 10 mcg EE alone help minimize breakthrough bleeding with this product and may be useful for women who have estrogen deficiency symptoms, such as headaches, during the hormone-free week.

The triphasic COCs (e.g., Ortho-Novum 7/7/7, Tri-Levlen, Triphasil, Ortho Tri-Cyclen) appear to support the endometrium more consistently than the biphasic COCs.¹³ No studies, however, show superior efficacy of one triphasic over another or over monophasic COCs. The reduced progestin content may be desirable for women who experience progestin-related side effects caused by too much progestin or for women who have cardiovascular disease or metabolic abnormalities.^{9,14} Women with side effects related to progestin deficiency (e.g., late-cycle bleeding) who desire extended cycles or who have conditions necessitating progestin dominance (e.g., benign breast disease) may do better with a monophasic formulation.

One drawback associated with triphasic COC use is the confusion caused by the different-colored tablets in each of the three different phases, making the missed-dose instructions more complicated. Monophasic formulations are preferred for women who will be taking pills continuously (i.e., skipping the placebo pills). M.F. may be started on either a monophasic or triphasic product.

- The World Health Organization and the Food and Drug administration both recommend using the **lowest dose pill** that is effective. All combined pills with less than 50 μg of estrogen are considered “low-dose” and are effective and safe
- There are no studies demonstrating a decreased risk for deep vein thrombosis (DVT) in women on 20- μg pills. Data on higher dose pills have demonstrated that the less the estrogen dose, the lower the risk for DVT
- All COC's lower free testosterone. Class labeling in Canada for all combined pills states that use of pills may improve acne
- To minimize discontinuation due to spotting and breakthrough bleeding, warn women in advance, reassure that spotting and breakthrough bleeding become better over time.
- The package insert for women on Yasmin and Yaz states [Berlex-2001]: “Yasmin is different from other birth control pills because it contains the progestin drospirenone. Drospirenone may increase potassium. Therefore, you should not take Yasmin if you have kidney, liver or adrenal disease, because this could cause serious heart and health problems. Other drugs may also increase potassium. If you are currently on daily, long term treatment for a chronic condition with any of the medications below, you should consult your healthcare provider about whether Yasmin is right for you, and during the first month that you take Yasmin, you should have a blood test to check your potassium level: NSAIDs (ibuprofen [Motrin®, Advil®], naproxen [Naprosyn®, Aleve®, and others] when taken long-term and daily for treatment of arthritis or other problems); potassium-sparing diuretics (spironolactone and others); potassium supplementation; ACE inhibitors (Capoten®, Vasotec®, Zestrisk® and others); Angiotensin-II receptor antagonists (Cozaar®, Diovan®, Avapro® and others); heparin”

**These are conditions that receive a WHO:3 or a WHO:4

Patient Instructions

4. M.F. has heard that she can skip periods by skipping the placebos. What can you tell her about this? What instructions should be given to M.F. about her COC?

When to Start Oral Contraceptives

M.F. should start the first cycle of pills according to the manufacturer's package instructions or according to one of the following recommendations:^{9,10}

1. Day 1 Start: Take the first tablet in the pack on the first day of menses. This offers the advantage of more rapid contraceptive effects.
2. Sunday Start: Take the first tablet in the pack on the first Sunday after the beginning of menstruation. If menses begins on Sunday, start that day. Back-up contraception must be used for at least the first 7 days. The advantage is that bleeding usually does not occur on weekends.
3. Quick Start: This is a newer method for initiating COC.¹⁵ In Quick Start, the woman takes her first COC tablet at any

point in her cycle. She also uses back-up contraception for at least 7 days. This method can minimize confusion about when to start the first pack and can increase rates of method continuation. The quick start method provides contraceptive protection sooner and, therefore, would likely lower the risk of unintended pregnancy.

Any woman who is a candidate for COCs can use them continuously (i.e. skipping the placebo tablets and taking no break between pill packs). Any product may be used continuously, however monophasic pills usually are selected. Any duration of continuous pill use is acceptable, but many providers recommend taking the active pills from 3 to 4 pill packs and then stopping for 2-7 days. Alternatively, providers may prescribe products that are specifically packaged for continuous use (Seasonale and generics, Seasonique, Lybrel). Continuous pill use usually results in more breakthrough bleeding or spotting (see question 8) than usual pill use, so women should be informed about this. If M.F. is willing to tolerate more irregular bleeding during the first 6-12 months of continuous COC use, then she can use them continuously.

When to Use a Back-Up Method of Contraception

Some clinicians recommend that women use an alternative method of contraception (back-up) for the entire first cycle. Using a back-up method for one full cycle is recommended because many new users of COCs do not complete the first cycle of pills. Most pill package inserts state that a back-up method of contraception (e.g., condoms) is not necessary if women use the Day 1 start method.^{9,16} When using the Sunday start or Quick start methods, back-up contraception should be used for the first week (7 days) of the cycle. A back-up method is also recommended when doses are missed, as described in the following section. M.F. has decided to use the Sunday start method, so she will need to use a back-up method (e.g., condoms, diaphragm) for the first week of the cycle.

Proper Pill Taking

M.F. should take the COC tablets at exactly the same time each day. If she experiences nausea, she may find that the nausea is reduced if she takes her pill at bedtime or with food. The best time for pills to be taken depends on her schedule. The optimal time for M.F. is the time when she will have the fewest problems remembering to take her pill. Missed pills are common in COC users; estimates as high as 40% of users miss one pill in each cycle, therefore reviewing the instructions for missed pills is an important part of medication counseling.

If M.F. forgets to take one pill, she should take the missed pill as soon as she remembers and refer to the instructions in the package insert for further information.^{9,10,16} Most manufacturers recommend that if one pill is missed, the woman should take two pills when she remembers (e.g., if she forgets to take her one pill on Monday, she should take two pills on Tuesday when she remembers). Then, she should take the remaining pills in the pack as usual. A back-up method of contraception usually is not considered necessary. If she misses two tablets in a row in weeks 1 or 2 of her pack, she should take two pills on the day she remembers and two the following day (e.g., if she forgets her pill on Monday and Tuesday, she should take two pills on Wednesday and two on Thursday). Then, she

should take the remaining pills as usual. She should use an alternative method of contraception for 7 days of taking active pills.

If a woman misses two tablets in a row in the third week (for Day 1 starters), she can either discard the rest of the pack and start a new pack on that same day or continue taking one pill daily until her usual stop day (skipping the placebos) and start a new pack. For Sunday starters, she can continue taking one pill every day until Sunday and start a new pack on Sunday without taking the placebos. She must use an alternative method of contraception for 7 days after missing the pills. She may not have her menstrual period this month.

If a woman misses three or more pills in a row anytime during the period taking the active pills she will likely experience bleeding or spotting. At the time she remembers, she can discard the rest of her pack and start a new pack that same day; or Sunday starters should keep taking one pill every day until Sunday, then start a new pack on Sunday. After missing three pills, she should use an alternative method of contraception for 7 days of taking active pills. She may not have a menstrual period this month. She may also want to consider emergency contraception if she has been sexually active (see Question 44).

Drug Interactions

Antibacterials

5. G.H. is a 26-year-old woman whose last menstrual period (LMP) was 7 weeks ago. She has a history of regular menstrual cycles both before and during the use of COC. Six weeks ago, she developed an *Escherichia coli* urinary tract infection and was treated with oral (PO) sulfamethoxazole trimethoprim (TMP-SMX) BID × 3 days for 7 days. This coincided with the first seven tablets of her cycle. She has been taking Ortho-Novum 1/35 for 3 years and tetracycline 250 mg PO every day (QD) for acne. What is the clinical significance of the potential drug interactions in G.H.?

Ethinyl estradiol is conjugated in the liver, excreted in the bile, hydrolyzed by intestinal bacteria, and reabsorbed as active drug.¹⁷ Certain broad-spectrum antibiotics, by reducing the population of intestinal bacteria, may interrupt the enterohepatic circulation of the estrogen, resulting in a decreased concentration of circulating estrogen. The existence of similar antibiotic interactions with contraceptive progestins is unlikely. Although this mechanism for the drug interaction is not well established, various antibiotics have been reported to decrease COC efficacy, resulting in unintended pregnancy or abnormal bleeding patterns. The antibiotics rifampin and griseofulvin are known to cause contraceptive failure, but NOT by this mechanism. These agents reduce contraceptive efficacy by increasing the metabolism of estrogen.

Theoretically, any broad-spectrum antimicrobial with significant effects on intestinal bacterial flora could affect COC efficacy by interfering with the enterohepatic recycling of exogenous estrogen. Numerous reports of changes in bleeding patterns and contraceptive failure have been documented.¹⁷ About 30 case reports of contraceptive failure with concomitant COC and antibiotic use have been published. The antibiotics in the case reports include rifampin, ampicillin, penicillin G, tetracycline, and minocycline.^{17a} In addition, surveys of women in clinics have revealed about 20 other cases of

OC failure. A major limitation of survey data is that it relies on patients' memories, which are often unreliable. The Committee on the Safety of Medicines in the United Kingdom received 63 reports of unplanned pregnancies between 1968 and 1984 in women on antibiotics and COC. Penicillins, tetracyclines, sulfamethoxazole-trimethoprim, metronidazole, cephalosporins, and erythromycin were among the antibiotics used. Finally, more than 200 reports of COC failure have been documented in women seeking family planning services.

The probability of a clinically significant drug interaction between COC and antimicrobials depends on several factors: the hormonal content of the COC relative to the woman's requirements, the dosage and duration of use of the interacting drug, variation in the response to bacterial flora alteration, and her inherent fertility.^{17,18,19} The number and complexity of these variables make prediction of outcome in a specific woman exceedingly difficult. Even if a drug produces a several-fold increase in unwanted pregnancies in women taking COC, the likelihood of pregnancy in a given woman is still low because COC are so effective. Long-term, low-dose tetracycline use for G.H.'s acne therapy (tetracycline 250 mg daily) is unlikely to interfere with her COC efficacy, but no good data exist to support this supposition. Topical antibiotics often can control acne, do not interfere with COC, and can be recommended as alternatives to oral tetracycline.¹⁷

A practical approach to managing coadministration of COC and antibiotics is to educate women about the potential for increased risk of pregnancy and to recommend a back-up method of contraception until menses occurs. In addition, the clinician should discuss what is described in the literature about these interactions (Table 45-5). Whether TMP-SMX inhibits COC efficacy is not certain; however, clinical data are consistent with the premise that it occasionally impairs COC efficacy. In this case, G.H. should take a pregnancy test.

Liver Enzyme Induction

6. S.R., a 22-year-old woman, is taking phenytoin (Dilantin) 300 mg PO QD and phenobarbital 60 mg PO twice daily (BID). Her serum concentrations of these drugs have been consistently in the therapeutic range for at least 2 years, and she has not experienced seizures for 18 months. Is S.R. a good candidate for COC?

Ethinyl estradiol is a substrate of cytochrome P450 3A4 (CYP3A4); therefore, medications that induce CYP3A4 may decrease COCs efficacy. With the older high-dose COCs, efficacy was not decreased significantly by many drug-drug interactions because of their high hormone content. The estrogen and progestin doses in newer COC are much lower. The case reports of menstrual irregularities (e.g., spotting, breakthrough bleeding [BTB]) and unintended pregnancies attributable to drug interactions have been increasing with lower dose formulation (Table 45-5).

Carbamazepine, phenytoin, phenobarbital, and primidone are CYP3A4 inducers known to cause increased metabolism of COCs. Another inducer of CYP3A4 is St. John's wort.²⁰ The newer anticonvulsants topiramate and oxcarbazepine have also been shown to lower serum levels of estrogen.

Although drug interactions that reduce the efficacy of contraceptives are of the greatest concern, COCs also can affect

Table 45-5 Oral Contraceptive Drug Interactions

| Interacting Drug | Net Effect |
|---|---|
| Drugs that increase or may increase the metabolism of OCs | |
| | Spotting, breakthrough bleeding, or pregnancy |
| Aprepitant | |
| Bexarotene | |
| Bosentan | |
| Carbamazepine | |
| Darunavir | |
| Felbamate | |
| Fosphenytoin/Phenytoin | |
| Griseofulvin | |
| Modafanil | |
| Mycophenolate mofetil | |
| Nevirapine | |
| Oxcarbazepine | |
| Phenobarbital | |
| Pioglitazone | |
| Primidone | |
| Rifabutin | |
| Rifampin | |
| Ritonavir | |
| Secobarbital | |
| St John's Wort | |
| Topiramate | |
| Miscellaneous drug interactions with OCs | |
| Amprenavir/ fosamprenavir | Decrease concentrations of amprenavir; increase or decrease concentrations of EE or progestin |
| Atazanavir | Increase in EE concentrations |
| Atorvastatin | 30% increase in norethindrone concentration; 20% increase in EE concentration |
| Benzodiazepines | Reduced metabolism of benzodiazepines |
| Corticosteroids | Reduced metabolism of corticosteroids |
| Cyclosporine | Doubling of cyclosporine level |
| Fluconazole | Increase or decrease in EE and levonorgestrel levels |
| Fosphenytoin/ Phenytoin | Increase or decrease in phenytoin concentration |
| Ginseng | Additive estrogenic effects |
| Lamotrigine | Increase or decrease in lamotrigine concentration |
| Nelfinavir | Increase or decrease in EE and progestin concentrations |
| Paclitaxel | Reduced metabolism of paclitaxel |
| Red Clover | May increase or decrease OC effects |
| Rosuvastatin | Increase in EE and norgestrel concentrations |
| Selegiline | Increase in selegiline concentration |
| Succinylcholine | Inhibits plasma cholinesterase activity |
| Tacrine | Increase in tacrine concentrations |
| Tacrolimus | Increase in tacrolimus concentrations |
| Theophylline | 33% reduction in theophylline clearance |
| Tizanidine | 50% reduction in tizanidine clearance |
| Tricyclic antidepressants | Decreased antidepressant effects yet can cause TCA toxicity |
| Valdecoxib | Increase in EE and norethindrone concentrations |
| Voriconazole | Increase in EE, norethindrone and valdecoxib concentrations |
| Warfarin | Increase or decrease in anticoagulation |
| Zolmitriptan | Increase in adverse effects |

AUC, area under the time-concentration curve; EE, ethinyl estradiol; OC, oral contraceptives.

DRUGDEX® System (electronic version). KLASCO RK (ed) Thomson Healthcare, Greenwood Village, Colorado, USA. Available at: <http://csi.micromedex.com>. Accessed June 1, 2007.

the activity of other drugs. COCs have been reported to increase or decrease serum levels of lamotrigine and can affect seizure control. COCs may increase the activity of some benzodiazepines. One report claims that COCs might increase serum phenytoin concentrations substantially.²²

Unlike many drug classes that are carefully dosed to maintain a therapeutic range of monitored blood levels, contraceptive estrogen and progestin blood levels are obtained only in clinical drug studies. Therefore, users are managed by monitoring side effects and by changes in menstrual patterns. It is no wonder, therefore, that the drug interaction literature is less than satisfactory and management of the interactions is largely empiric. Although some prescribers suggest using a 50-mcg EE formulation in women taking enzyme-inducing drugs, most others would recommend that S.R. use a contraceptive method other than a COC. An alternative recommendation is to use a second method of contraception for 3 months of the combined therapies and monitor bleeding patterns. If no intracycle bleeding occurs, the secondary method can be discontinued.⁹

Oral Contraceptive Risks and Adverse Effects

Some women may not be candidates for a COC because of the risks and adverse effects associated with use. Other women may experience minor side effects with COC that may be managed by changing to a formulation with a different type or dose of estrogen or progestin.

Breakthrough Bleeding, Spotting, and Amenorrhea

7. V.S. comes to the family planning clinic after taking Ovcon-35 for 2 months. She had been started on Ovcon-35 to help with her acne. Her only complaint is spotting at various times during her past two menstrual cycles. What action should be taken to correct V.S.'s bleeding pattern?

Bleeding during active pills days of the cycle (intermenstrual bleeding) that requires the use of a pad or tampon is designated *breakthrough bleeding* (BTB), whereas a lesser amount of intermenstrual bleeding that does not require protection is called *spotting*. Spotting and BTB are the most frequent reasons cited by women for the discontinuation of COCs.²¹

Most clinicians will continue with the same formulation for at least 3 months if irregular bleeding is the only complaint because BTB or spotting usually resolves without intervention.^{21,22} Early-cycle intermenstrual bleeding, which usually starts before the 14th day of the menstrual cycle (or never ceases completely after menses), may be caused by insufficient estrogen. Late-cycle intermenstrual bleeding, which occurs after day 14, may be caused by insufficient progestational support of the endometrium. The most common cause of BTB or spotting, especially in long-term users of COCs, is missed pills or irregular pill taking. Before making formulation adjustments, adherence should be assessed. Other possible causes of BTB or spotting include drug interactions (see Questions 5 and 6) or infection.

The balance between estrogen and progestin components in COCs determines endometrial activity and, therefore, the likelihood of intermenstrual bleeding problems. It is helpful to

envision the estrogen component as the basic building block or “brick” of the endometrium and the progestational component providing the mortar that holds the bricks together. In addition, the estrogenic activity of the progestational component increases the number of bricks, whereas its antiestrogenic activity decreases their numbers. If bricks or mortar are insufficient or if they are present in the wrong proportions, the wall will crumble and bleeding will ensue (Table 45-2).

If V.S.'s intermenstrual bleeding continues to occur late in her cycle after 3 months of consistent use, a formulation with the same estrogen dose and more progestin should be prescribed. Desogen or Ortho-Cept would be a good choice because progestational activity would be increased and estrogenic activity would be maintained with minimal androgenic liability (Table 45-2). If V.S. develops intermenstrual bleeding early in the cycle after several months of use, she should be changed to a pill with a higher ratio of estrogen to progesterone or should try Mircette, which provides a low dose of estrogen during the placebo week.

Some women experience amenorrhea while taking COC. If this occurs, pregnancy should first be ruled out. If she is not pregnant and amenorrhea is acceptable to her, then the formulation need not be changed. If she prefers a monthly menstrual period, then a product with more estrogen or less progestin or a triphasic formulation can be tried.

Cardiovascular Disease

8. M.F. (from Questions 1–4) and her fiancé, who is with her in the health care provider's office, have been reading in the lay press about the cardiovascular risks of estrogen. What are her potential risks for cardiovascular disease from taking COC?

In women who do not smoke or use a COC, the risk of death from cardiovascular disease is 0.59 per 100,000 women <35 years of age and 3.18 per 100,000 women >35 years of age.²³ This risk is increased by 0.06 and 3.03 for COC users <35 years or >35 years, respectively. For COC users who smoke, the risk is increased by 1.73 and 19.4 for women <35 or >35, respectively.

Both the Royal College of General Practitioners and the Oxford Family Planning Association OC studies showed that women <35 years taking the new low-dose COC did not have a significantly increased mortality risk from cardiovascular disease, regardless of smoking status.^{23–25} The increase in mortality reported from COC is significant only for smokers >35 years of age.

Several studies have reported the effects of COC on serum lipoprotein concentrations because of the association between lipoproteins and atherosclerotic cardiovascular disease.^{26–28} High serum concentrations of total cholesterol (TC), triglycerides (TG), low-density lipoprotein (LDL) cholesterol, and very-low-density lipoprotein (VLDL) cholesterol are associated with the risk of developing atherosclerotic circulatory diseases, whereas high-density lipoprotein (HDL) cholesterol has an inverse relationship. Apolipoprotein levels also affect atherosclerotic risk (e.g., Lp(a) elevations increase risk).²⁹

Estrogen tends to increase serum concentrations of HDL. Progestins, depending on the dose and potency, may decrease HDL concentrations.^{27,28} Progestins can modify the composition of total HDL by changing the relative amounts of HDL₂

and HDL₃.^{30,31} HDL₂ is protective against cardiovascular disease, unlike HDL₃.³² Decreases in HDL are associated with increasing age, weight, and cigarette smoking. Increased triglyceride serum concentrations are related to the estrogen content of the COC as well as to the antiestrogenic effect of the progestin component.

Studies evaluating the effect of COC on lipids have reported similar results.^{27–29} One study found an increase in HDL from baseline with a low-androgenic progestin compared with a high-androgenic progestin.²⁷ Another study compared COC with phasic EE and levonorgestrel or desogestrel.²⁶ After six cycles, significant increases in HDL₃ and apolipoproteins (apo A-I, apo A-II, and apo B) were seen in both groups. HDL₂ also increased significantly in the desogestrel group but decreased in the levonorgestrel group. After nine cycles, levels of TG and VLDL in both groups and HDL in the desogestrel group were significantly increased from baseline. HDL did not change significantly in the levonorgestrel group after six cycles. In another study, a reduction in the COC doses of EE and levonorgestrel by one-third improved levels of LDL, TG, Lp(a), and HDL.²⁸

Lipid serum concentrations also are altered in adolescent (ages 12–17 years) users. These adolescents had significantly higher TC levels compared with nonusers, although the type of COC used was not specified.³³

Women taking COCs containing levonorgestrel may be more likely to have a myocardial infarction (MI) than users of COCs containing desogestrel or gestodene.³⁴ When confounding factors for cardiovascular disease were accounted for, women taking levonorgestrel-containing COC were 2.5 times more likely to have an MI than nonusers. Another study found the opposite effect of the two types of COC, but the results were not significant.³⁵ Heavy smoking, especially in women >35 years of age, increases the risk of MI.

M.F. and her fiancé should understand that the risk of a cardiovascular adverse effect may be increased with COC use, but the risk is still very low regardless of which COC is used. Cigarette smoking is a much more significant risk factor for MI, causing a reported 8 to 13 times increase in risk.

Cervical Dysplasia and Cervical Cancer

9. J.M., a 24 year-old woman, has an older sister who had cervical dysplasia that progressed to carcinoma in situ. Her sister never took OC. What can you tell J.M. about the risks of cervical dysplasia and cancer associated with COCs?

An estimated 11,070 new cases of, and 3,870 deaths from, cervical cancer will occur in the United States in 2008.³⁶ The human papilloma virus (HPV) infection is the most common cause of cervical cancer. Women at highest risk for cervical cancer are positive for certain subtypes of HPV, are immunosuppressed, or are smokers.⁹ Sexual behaviors that increase the risk of HPV infection and with cervical cancer include beginning sexual activity at a young age, having multiple male sexual partners, or having a male sexual partner who has had multiple partners. Women at low risk for cervical cancer have two or fewer partners, use condoms, and do not smoke.⁵

Pooled data from eight case-control studies on cervical cancer risk for COC users who are positive for HPV indicate they are more likely to develop cervical cancer.³⁷ Women who had ever used a COC and those who had used a COC for

>5 years were 1.5 and 3.4 times, respectively, more likely to develop cervical cancer. This is consistent with older studies that suggest that COC users have an increased risk of developing or dying of cervical cancer; however, COCs are not thought to cause cervical cancer. In contrast, a large cohort study conducted in England found no significant increase in deaths caused by cervical cancer in women who had ever used OC.³⁸

Epidemiologic comparisons of the prevalence of cervical cancer in COC users versus nonusers often are difficult to interpret because factors other than the hormone use need to be considered. Women using COCs are less likely to have partners using condoms and are more likely to have regular medical examinations (e.g., Pap smears), resulting in early detection and treatment of precancerous lesions.³⁹ Health care providers may wish to perform Pap smears every 6 months in women who have used a COC for >5 years who are at a higher risk because of multiple partners or a history of sexually transmitted diseases (STD).⁸ J.M. should be counseled about avoiding risk factors for cervical cancer and should be encouraged to have a Pap smear annually. Women between 9 and 26 years of age, such as J.M., are candidates for the HPV vaccine. The vaccine, given as a series of three injections, provides substantial (but not complete) protection from cervical cancer. Use of the vaccine in older women or in men is not currently approved but is being studied.

Headache

10. G.R., a 32-year-old woman, comes to the clinic complaining of headaches, which predominantly occur during the 7-day placebo phase of her 28-day cycle of Nordette. The throbbing headaches are preceded by blurred vision, nausea, and vomiting. Aspirin and acetaminophen, which normally relieve her other headaches, are ineffective. Lying down in a dark room provides some relief. Her family history is pertinent because her mother and maternal grandmother have migraine headaches. Are these headaches a relative contraindication for the continued use of a COC?

Headache is a common complaint in women, including those taking a COC. Headaches can occur while taking the active pills (estrogen related) or during the placebo week, owing to the withdrawal of estrogen.²¹ Women with migraines may find that their headaches either lessen or worsen when COCs are initiated.

Mild headaches may abate over time or if the woman is changed to a pill with less estrogen or progestin. Headaches that occur during the placebo week can be managed by trying Mircette or taking a COC continuously (i.e., skipping placebo pills). Women with severe headaches should discontinue COC use and should be evaluated by their health care provider.

Ischemic stroke is more likely to occur in COC users with a history of classic migraines (migraines with aura), especially if they are smokers.⁴⁰ Women with classic migraines should use COCs with caution or not at all, particularly if they smoke, are >35 years of age, or have other significant medical problems. Clinical experience indicates that women having increasing migraine attacks with COCs are not likely to have relief from them when the formulation is changed to one with a different hormone balance. Women with menstrual migraine (migraine

associated with menses) may have fewer headaches while taking a COC and may prefer continuous use.

G.R.'s symptoms are typical of classic migraine headache and, because she also has a family history of migraine headaches, she may need to discontinue her COC and use another method of contraception. Subsequent to a thorough medical evaluation of her headaches, she should be monitored carefully if COCs are continued.

Hypertension

11. A.M., an obese 26-year-old woman, experienced hypertension during all of her pregnancies. She restarted Lo-Ovral after her last pregnancy. She continues to smoke a half-pack of cigarettes per day. Her blood pressure (BP) before starting the COC was 126/76 mmHg. Today, her BP is 146/96 mmHg. What is the mechanism of COC-induced hypertension? Can she continue taking Lo-Ovral considering her history of hypertension during pregnancy?

The underlying mechanisms for COC-induced hypertension may be sodium and water retention and increased renin activity.^{41,42} Hypertension secondary to COC use may develop slowly over 3 to 36 months and may not decline for 3 to 6 months after discontinuing their use.⁴³

Women taking older and more potent oral contraceptives (e.g., 50 mcg EE) have been reported to have a two to three times higher incidence of hypertension (BP >140/90 mmHg) than nonusers.⁴²⁻⁴⁴ Small studies have found systolic BP to increase by 7 to 8 mmHg and diastolic BP to increase by 6 mmHg in normotensive or mildly hypertensive women.⁴³ Population-based, case-control studies have shown differing results on whether women with hypertension who use COC are more likely to have an MI than nonusers. A small study of adolescent women showed similar systolic and diastolic BP in users versus nonusers.³³

For A.M., it is reasonable to consider using a 20-mcg EE formulation such as Alesse/Apri/Levlite or one with less progestin and estrogen such as Ortho TriCyclen Lo. The effect of this change in medication on her BP should be monitored to determine whether continued use is indicated.

Liver Effect

12. T.A.'s physician is concerned about the possibility of hepatic tumors. What is the risk of hepatomas in patients using COC?

The incidence of benign liver tumors for women using low-dose COC is very low, 3.3 per 100,000 users per year compared with 0.1 per 100,000 users per year in nonusers or short-term users.⁴⁵ The incidence increases after 4 years of use. Although the tumors generally are benign, death can result from intrahepatic or extrahepatic tumor rupture and hemorrhagic shock.^{46,47} Because animal studies suggest that both estrogen and progestin can accelerate abnormal liver cell proliferation, the lowest effective tolerable COC dose should be used.^{45,48} A significant increase in death from liver disease or cancer was not seen in one large cohort study.³⁷

Cholestatic jaundice also has been associated with COC use.⁴⁹ T.A. can monitor for signs or symptoms of cholestatic jaundice, because this disorder usually presents as malaise, nausea, anorexia, and pruritus; these usually appear 4 weeks

after the initiation of COC use. Discontinuation results in complete clinical remission within a month.

Thromboembolic Events

13. B.C., a 21-year-old woman, is interested in starting COC. After taking a complete history, the provider learns that her sister and mother have both had a deep vein thrombosis (DVT). Do COC contribute to the development of a DVT or pulmonary embolism (PE)? If so, which women are at the highest risk? Should B.C. start COC?

OCs contribute to thromboembolic events by several mechanisms. Estrogens increase coagulability and thereby increase the possibility of clot formation. Although they have been shown to significantly increase some clotting factors, other studies have shown no changes or decreases in prothrombotic factors.^{27,30} Long-term OC use is associated with an increased platelet count and increased platelet aggregation similar to that seen late in pregnancy; this is generally thought to be caused by the estrogen component. More recent data showing increased thrombosis rates in users of third-generation progestins [desogestrel and gestodene (not available in the U.S.)] suggest that progestin may also have a role in thromboembolism risk.⁴

The baseline risk of venous thrombosis is low, at 4-8 for every 100,000 women per year.^{50,51} The best studies looking at thromboembolism in OC users found that most users have a three- to six-fold increased risk of developing superficial or deep venous thrombosis or PE. Therefore, the risk is still quite low, at approximately 10 to 30 per 100,000 women per year; less than the risk during pregnancy of 60 per 100,000 women per year. Patients requiring emergency major surgery while on OCs are more prone to thromboembolism than nonusers. The risk of venous thrombosis does not seem to be associated with duration of OC use, past OC use, mild obesity, or cigarette smoking. A greater risk is associated with EE doses >35 mcg.

Women with a mutation in clotting factor V (also called factor V Leiden) or a deficiency in protein C, protein S, or antithrombin are more likely to develop a venous thrombosis with OC use than women without a hereditary prothrombotic defect.⁵¹ Women with blood types other than O may also be more susceptible to clotting due to higher levels of factor VIII.

Whether third-generation progestins (desogestrel, gestodene) are associated with a higher risk of venous thromboembolism (VTE) relative to other progestins is controversial.^{50,51} It was believed that the risk of thrombosis with third-generation progestins would be lower than other progestins since they have more beneficial effects on HDL. However, most studies that compared the risk of thrombosis with third-generation progestins to second-generation progestins found that desogestrel and gestodene are associated with a greater VTE risk. Although the risk may be increased, the overall rate of thrombosis is still low. All patients using OCs should be counseled about the VTE warning signs (ACHES; Table 45-6).

The minimal risk of thrombosis associated with OCs in the general population does not justify the cost of routine screening for deficiencies in the coagulation system; however, when a patient has a family history of thrombosis, measurement of antithrombin III, protein C, activated protein C resistance ratio, protein S, anticardiolipin antibodies, prothrombin G mutation, and homocysteine levels should be considered.⁵¹

Table 45-6 Pill Early Danger Signs (ACHES)

| <i>Signals</i> | <i>Possible Problem</i> |
|--|--|
| Abdominal pain (severe) | Gallbladder disease, hepatic adenoma, blood clot, pancreatitis |
| Chest pain (severe), shortness of breath, or coughing up blood | Blood clot in lungs or myocardial infarction |
| Headaches (severe) | Stroke, hypertension, or migraine headache |
| Eye problems: blurred vision, flashing lights, or blindness | Stroke, hypertension, or temporary vascular problem |
| Severe leg pain (calf or thigh) | Blood clot in legs |

B.C. should be evaluated for hereditary prothrombotic defects. If any exist, she should avoid OC use. If none exist, she may still wish to consider a method without estrogen but should be educated on the signs and symptoms of thrombosis if she decides to start OCs.

Benefits of Oral Contraceptives

Acne

14. D.S., a 20-year-old woman, has had severe acne since menarche at age 13. She is currently taking no medications but wants to begin COC. What effect, if any, would oral contraceptives have on her acne? Which formulation would you recommend for D.S.?

Depending on the woman, COC use may cause acne to appear, disappear, or significantly improve.^{12,16} Most women will have improvement in acne with any COC used, only a few formulations are FDA approved for this indication. Progestins with higher androgenic activity may be more likely to increase acne because they stimulate sebaceous glands to produce more sebum. Higher doses of estrogen may decrease acne by suppressing the activity of sebaceous glands, decreasing the production of androgens, and increasing the synthesis of SHBG. SHBG binds androgens and thereby diminishes the effects.⁵² The triphasics are modestly estrogen-dominant contraceptives, lower in progestin potency, and may significantly reduce the overall incidence of acne. Both desogestrel- and norgestimate-containing COCs are less androgenic, thereby increasing SHBG levels and decreasing acne.⁵³

D.S.'s acne should improve with COC use. Products to consider starting with are OrthoTriCyclen, Estrostep, and Ovcon 35.

Benign Breast Disease

15. A young woman has a family history of fibrocystic breast disease. What influence do COC have on fibrocystic breast disease?

A 50% to 75% reduction in the risk of fibroadenomas, chronic cystic breast disease, and breast biopsies appears to exist in COC users.¹⁵ Protection seems directly related to length of use. Because the progestin component may be primarily responsible for this protection, progestin-dominant COCs that contain a less estrogenic progestin, such as levonorgestrel, are preferred.^{9,14,54} The progestin-only minipill could be of use here, except that progestin-only pills are less effective contraceptives than a COC. In addition, it does not provide the

same level of endometrial stability (leading to more BTB and spotting) or other benefits of a COC such as decreased dysmenorrhea, iron deficiency anemia, acne, and hirsutism (more irregular bleeding).

Dysmenorrhea and Premenstrual Syndrome

16. C.P. has a history of premenstrual syndrome (PMS) and worsened menstrual cramping with a copper intrauterine device (IUD). What effect on PMS and dysmenorrhea might she expect from a COC?

Dysmenorrhea, or painful menstruation, may be of unknown etiology; it may be caused by endometriosis or uterine fibroids. Complaints of menstrual pain may be decreased by >60% after starting COCs.¹⁰ A formulation with decreased estrogenic and increased progestational activity may be the best at relieving dysmenorrhea.

Premenstrual tension has been reported to be reduced 29% in COC users, and other premenstrual symptoms seem to be relieved as well.^{55,56} Nevertheless, the effect of COCs on PMS symptoms is inconsistent and unpredictable, probably because PMS symptoms are neither consistent nor predictable. There may be augmentation of depression and mood swings by the progestational component. Although the probability of this effect is low with a low-dose product, C.P. should be monitored for changes in her PMS symptoms. (See Chapter 47, Disorders Related to the Menstrual Cycle, for further discussion of dysmenorrhea and PMS.)

Endometrial Cancer

17. C.P. is hesitant to take a COC because her grandmother, who had been receiving estrogen replacement therapy for 5 years, died of endometrial cancer in 1970. What is the relationship between COC use and endometrial cancer?

Clinical data suggest that cyclic COCs contain sufficient progestin to prevent endometrial hyperplasia and to reduce the risk of endometrial cancer by about 50% to 70%.³⁹ The protection is directly related to duration of use and may persist for many years after discontinuation. A meta-analysis of 11 studies showed a 56%, 67%, and 72% reduction in endometrial cancer risk after 4, 8, and 12 years of COC use, respectively.⁵⁷

C.P. should be reassured that COC use will not cause endometrial cancer and will likely reduce her chances of developing this disease. She may want to find out more about her grandmother's cancer, because it may have been caused by treating her menopausal symptoms with estrogen alone rather than with estrogen plus a progestin.

Menorrhagia (Heavy Menstrual Bleeding)

18. M.V. has iron deficiency anemia attributed to heavy menses secondary to her previous use of a copper IUD. What will be the effect of COC use on her iron deficiency anemia?

The total amount of menstrual flow in established COC users is decreased by up to 40%,⁵⁸⁻⁶⁰ which may be caused by the progressive thinning of the endometrium induced by use or a lack of irregular bleeding. Bleeding may be decreased the most by COCs that have a high ratio of progestin to estrogen, because endometrial thinning is maximized.⁸ Another option would be to have her take a COC continuously so she has fewer bleeding episodes.

Ovarian Cancer and Functional Ovarian Cysts

19. C.P. (from Questions 16 and 17) is concerned also about ovarian cysts and cancer. Can COC cause ovarian problems?

The risk of developing functional ovarian cysts is decreased, pre-existing cysts are more rapidly resolved, and surgery rates for ovarian masses are reduced in women taking COCs.^{60–62} This is likely owing to reducing ovulation, suppressing androgen production, or increasing progesterone levels.

Each year of COC use decreases the relative risk of developing ovarian cancer by 7% to 9%.⁶⁰ The risk reduction continues to be seen in women using a COC for >15 years and persists after discontinuation.

C.P. should be reassured that COC use will decrease, not increase, her likelihood of developing ovarian cancer.

Pelvic Inflammatory Disease and Ectopic Pregnancy

20. M.A., a 20-year-old woman who has several sexual partners, arrives at the emergency department with a temperature of 38.2°C (normal, 37°C) and lower abdominal cramping. Examination is compatible with the diagnosis of pelvic inflammatory disease (PID), based on her cervical motion tenderness, abdominal pain, and adnexal (ovary and fallopian tube) tenderness. Can COC be used for M.A.?

Many clinicians prefer to prescribe COCs with condoms for STD protection to young women with multiple sexual partners because PID has been found to be less prevalent with this combination of contraceptive methods.^{8,63} In one study, COC users were half as likely to develop PID as nonusers.⁶⁴ Although early studies failed to distinguish between gonococcal and nongonococcal PID, the PID protective effects of COCs may depend on the organism. A Swedish study found that COCs protect against both gonococcal and chlamydial PID.⁶⁵ In contrast, one report suggested that COCs may promote chlamydial PID; and another concluded that COC users were neither more nor less likely to develop PID.^{66,67} A 1990 case-control study showed protection against symptomatic PID in women infected with chlamydia but not in those infected with gonococcus.⁶⁸

Despite the contradictory data, it is logical that the thickening of cervical mucus caused by COCs may prevent bacteria from ascending into the uterus and fallopian tubes, thereby minimizing hospitalizations as well as deaths stemming from PID. The risk of ectopic pregnancy is greater for women who already have had PID, and COC use has been shown to prevent hospitalizations and deaths stemming from ectopic pregnancies.^{69,70}

In view of these data, a COC may be initiated for M.A. if no contraindications are present. Patients and clinicians should be alert for the symptoms of cervicitis or salpingitis in women who are at high risk for STDs.

Other Issues with Oral Contraceptives

Breast Cancer

21. The medical history and physical examination of S.M. are negative for breast disease, except for a history of breast cancer in her maternal grandmother. How will COC use affect her risk of breast cancer?

Studies on the use of COCs and breast cancer have yielded conflicting results. Some studies have suggested an increased

risk of breast cancer in young, nulliparous women using COC with high progestin activity.^{71,72} In addition, the Royal College of General Practitioners' Oral Contraceptive Study in 1981 reported a significant increase in risk for breast cancer in women 30 to 34 years of age who use COCs.⁷³ Another study found an increased risk of breast cancer in women with a first-degree family history of breast cancer who had ever used a COC.⁷⁴

In contrast, other studies found no association between current or former use and breast cancer.^{37,75} In addition, both the Oxford/Family Planning Association Contraceptive Study in 1977 and the Walnut Creek Contraceptive Drug Study in 1981 found no association between breast cancer and COC use in any age group.^{76–78} The Centers for Disease Control Cancer and Steroid Hormone Study in 1983 reported a relative risk of 0.9 for COC users compared with never-users, despite other risk factors for breast cancer, such as early menarche, later age at first birth and menopause, family history of breast cancer, or benign breast disease.⁷⁹ The ongoing Nurses' Health Study identified 3,383 cases of breast cancer from 1976 to 1992 among 1.6 million person-years of COC use and found that long-term past COC use (10 years), either overall or before a first full-term pregnancy, does not appreciably increase breast cancer risk in women >40 years of age.⁸⁰

Users of COCs tend to have a greater awareness of breast cancer, examine their breasts more frequently, and are examined by clinicians more often than nonusers. Thus, early detection of breast abnormalities can preclude the progression of these abnormalities into cancerous lesions.⁸¹ A COC would not be expected to increase the risk of breast cancer in S.M. She should be instructed to perform monthly self-breast examinations and to return annually for a physical examination by her health care provider.

Depression

22. K.G. is a 24-year-old woman with persistent mild depression. Taking into account her depression, would a formulation with high or low estrogen or progestin balance be preferred for her?

Usually women notice improved mood or premenstrual symptoms when taking a COC.¹⁶ COC-related depression has been attributed to progestin or estrogen excess, however. Some COC users experience deterioration in mood during the pill-free period. Other causes of depression, such as hypothyroidism or vitamin B₆ deficiency, also should be considered. If depression worsens or is severe, the COC may be discontinued.

On further questioning, K.G. states that she noticed only a minor change in mood, denies suicidal or homicidal ideations, and desires to continue taking a COC. She can be changed from Nordette to a formulation with less estrogenic activity (e.g., Lo-Estrin 1/20), less progestational activity (e.g., Ovcon 25), or both (e.g. Alesse/Levlite/Apri) (Table 45-2). If she reports that her depression is worse during the hormone-free week, then changing her to continuous-use may be helpful.

Diabetes

23. R.D., a 33-year-old woman, experienced glucose intolerance during pregnancy that resolved after delivery. She has a father and sister with diabetes. Would a COC be appropriate for R.D.?

Generally, low-dose COCs do not alter glucose tolerance.^{26,27} Results of one controlled, randomized, prospective

study showed no adverse effect on carbohydrate or lipid metabolism in women with a history of gestational diabetes after 6 to 13 months of low-dose COC use.⁸¹ Both the users and nonusers showed a significant and similar deterioration in glucose tolerance with an overall prevalence of 14% impaired glucose tolerance and 17% diabetes mellitus. The authors concluded that low-dose COC could be prescribed safely and that serum lipids and glucose tolerance should be monitored closely, regardless of contraceptive choice.

Women with a history of gestational diabetes and those with a strong family history of diabetes in parents or siblings are at greater risk for COC-induced glucose intolerance.^{13,16,46} COCs have complex effects on carbohydrate metabolism. Progestins decrease and estrogens increase the number of insulin receptors on the cell membrane. Progestins also may alter insulin receptor affinity. The different progestins have different propensities to induce glucose intolerance. Norgestrel appears to have the greatest insulin-antagonizing activity. Ethynodiol diacetate, norethindrone, norethindrone acetate, desogestrel, and norgestimate have significantly less effect. In general, carbohydrate metabolism is not affected to an important degree in most diabetic women using low-dose COC.

For R.D., Levlen (Levora/Nordette) would be poor choices because they are known to cause glucose intolerance in women with previous history of gestational diabetes.⁸² Interestingly, the triphasic levonorgestrel product TriLevlen, Trivora, containing 39% less progestin than the monophasic product, did not alter glucose tolerance, and Alesse (Levlite/Apri), which contains 33% less EE, also should not alter glucose tolerance. Lowering the estrogen content without changing progestin content also has improved glucose tolerance and increased insulin secretion.^{83,84}

For women without diabetes, COC use may protect against developing diabetes. One large prospective, observational study found that both white and black COC users had lower fasting glucose levels and lower odds of diabetes.⁸⁵

R.D. can be started on a COC. If she smokes or has other medical problems such as hypertension, nephropathy, retinopathy, or other vascular diseases, however, a COC probably should be avoided. It seems prudent to put R.D. on a low dose of estrogen and progesterone and to monitor for any changes in glucose control.

Gallbladder Disease

24. L.S., a 26-year-old woman, arrives at the emergency department with acute epigastric pain accompanied by nausea, vomiting, and diarrhea. She has been taking a COC for 1 year. She is diagnosed as having gallstones. What is the association between gallbladder disease and COC use? What would be an appropriate contraceptive for L.S.?

The incidence of cholelithiasis has been reported to increase with COC use. Estrogens and progestins may contribute to bile stasis and cholelithiasis by reducing cholesterol clearance and altering bile acid composition.^{14,86} The incidence of gallbladder disease has been reported to increase during the first year of use but then to decline steadily to a rate lower than that of controls.⁸⁷ In another large study, long-term users experienced slightly lower rates of gallbladder disease than nonusers.⁸⁸ Finally, another study found that women who had ever used COCs were not more likely to have symptomatic gallstones, but current and long-term users were. An analysis of 482 women with

benign gallbladder disease from the Oxford Family Planning Association Contraception Study concluded that it is unlikely that COCs cause gallbladder disease.⁸⁹

The newer COCs with lower progestin and estrogen concentrations should have little effect, if any, on gallstone formation in health patients. Women who are obese, young, or long-term users may be the most likely to develop gallstones.

In L.S., it is not known whether COC use contributed to her development of gallstones. A history of or the current presence of gallstones is not a contraindication to COC use, so L.S. may continue to use a COC if desired.

Use During Pregnancy and Breastfeeding

25. P.S., a 25-year-old woman, was started on Triphasil 2 months ago because of a history of abnormal menstrual periods. Unknowingly, she was pregnant at that time and continued taking her COC for two complete cycles. What can you tell P.S. about the possible effects of COC use on her unborn child?

The fact that COCs are classified as pregnancy category X (contraindicated, fetal risks clearly outweigh maternal benefit) is very misleading.⁹⁰ Although an association between COC use during pregnancy with cardiac or limb anomalies has been reported, other contraceptive studies have not noted a teratogenic effect. Simpson⁹¹ summarized all available data on contraceptive steroid exposure during pregnancy and concluded that COC use did not substantially increase the risk of anomalies over that expected in other uneventful pregnancies.

Clearly, a COC should not be started in a woman known to be pregnant. P.S. should be reassured, however, that the risks to her fetus from the use of a low-dose COC during the first trimester should be minimal.

P.S. may resume COC use after she has her baby even if she is breastfeeding, although it may be preferable for her to use a progesterone-only method.^{9,90} For women without contraindications, the American Academy of Pediatrics considers COC use to be compatible with breastfeeding.⁹² COCs have been reported to decrease milk quantity and quality, however, especially if used early in the postpartum period before milk is well established (see Question 27).⁹⁰ Therefore, many providers suggest avoiding or delaying the use of a COC in women who are exclusively breastfeeding. If a postpartum woman would like to start COC, she should wait to begin them until at least 3 to 4 weeks postpartum or use progestin-only formulations. By waiting 3 to 4 weeks, the increased risk of thrombosis that occurs during pregnancy should be reduced to baseline and initiation of a COC is appropriate.

CONTRACEPTIVE PATCH AND RING

26. K.H. is a 16-year-old who started taking a COC 3 months ago. She is very concerned about getting pregnant because she has trouble remembering to take her pill each day. She likes all the noncontraceptive benefits but is wondering if there are dosage forms other than pills. What do you tell her?

Contraceptive Patch

Contraceptive patch users experience about 1 pregnancy per 100 women-years of use (Table 45-1). The contraceptive patch (Ortho Evra) contains 6 mg norelgestromin and 750 mcg EE and delivers transdermally, 150 mcg of norelgestromin

(a metabolite of norgestimate) and 20 mcg EE daily into the bloodstream.⁹³ The product is a thin, beige 20-cm² square patch with rounded corners. The patch uses a 4-week cycle similar to that of pills. A new patch is applied once weekly for 3 consecutive weeks, followed by 1 week with no patch. Then this cycle is repeated. Menses should begin during the patch-free week.

The contraceptive patch may be worn on the buttock, abdomen, upper torso, or upper outer arm.⁹³ K.H. should not apply the patch to the same exact spot but rather rotate within or between sites. The patch should not be applied to the breasts. When applying the patch, K.H. should select the application site and be sure it is clean and dry. She should press firmly on the patch for 10 seconds and trace her finger around the edge of the patch to be sure it sticks properly. The patch should stay attached during usual activities, including exercising, swimming, and bathing. If the patch falls off for <24 hours, she should reapply it to the same spot or apply a new patch as soon as possible, keeping her patch-change day will stay the same. No back-up contraception is needed. If the patch is off for >24 hours, she should start a new apply a new patch and begin a new 4-week cycle, she will have a new patch-change day, and she should use back-up contraception for 1 week.

The patch may be started using the Sunday start, Day 1 start, or Quick Start method, and the recommendations for back-up contraception are the same as described earlier with COC.⁹³ If K.H. forgets to start the first patch of a cycle, she should apply it as soon as she remembers. This day will become her new patch-change day, and she should use back-up contraception for 1 week. If she forgets to change the patch for 1 or 2 days during week 2 or at the end of week 1 or 2, she should apply a new patch as soon as she remembers. This becomes her new patch-change day. No back-up contraception is needed. If she leaves the patch on for >9 days at the end of week 3, she should remove the patch when she remembers and apply the new patch “on schedule” even if that is only 1 or 2 days later. No back-up contraception is needed. If she forgets to remove the patch for >2 days at the end of week 1 or 2, she should apply a new patch as soon as she remembers. This becomes her new patch change day. No back-up contraception is needed. If she forgets for >2 days, she should start a new cycle as soon as she remembers. She will need to use back-up contraception for 1 week and will have a new patch-change day.

Because the patch contains similar hormones to those in COCs, the risks and benefits are thought to be similar. The package insert lists the same contraindications and precautions with the use of the patch as for a COC (Table 45-4).⁹³ Because the delivery system and serum levels are different, future studies may find, however, that differences exist in certain risks or benefits between the products. One difference with the patch is that efficacy is reduced in users weighing >90 kg. Therefore, providers may choose to recommend another method for heavier women. The most common side effects reported with the patch are breast tenderness, headache, application site reaction, and nausea.

Contraceptive Ring

The contraceptive ring (NuvaRing) delivers 120 mcg etonogestrel (an active metabolite of desogestrel) and 15 mcg EE through the vaginal mucosa.⁹⁴ The ring is flexible, transparent,

and has a diameter of just over 2 inches. The ring is inserted vaginally and kept in place for 3 weeks in a row. After 3 weeks, the ring is removed and a new ring is inserted 1 week later. The NuvaRing must be refrigerated in the pharmacy before dispensing. On dispensing, the pharmacist should apply the label provided in the packaging indicating a 4-month expiration date when the ring is stored at room temperature. The “used” ring should be discarded in the foil package provided by the manufacturer to avoid environmental hormone exposure in trash. The failure rate for the contraceptive ring is 1 or 2 pregnancies per 100 woman-years.

The ring may be placed anywhere in the vagina, so K.H. does not need to worry about its exact position.⁹⁴ To insert the ring, she should compress it so the opposite sides of the ring are touching, and gently insert it into the vagina. If she feels discomfort with the ring, it has probably not been inserted far enough into the vagina. Most women do not feel the ring once it is in place. To remove the ring, K.H. should grasp the ring between two fingers or hook one finger inside the ring and pull it out. Menses will usually begin within 3 days following removal of the ring. If the ring slips out, it should be rinsed with cool water and reinserted. If the ring is out for <3 hours, back-up contraception is not needed. If the ring is out for >3 hours, back-up contraception should be used for 1 week. If the ring has been left in the vagina for 3 to 4 weeks (late removal of the ring), she should remove the ring when she remembers, wait 1 week, then reinsert a new ring. If the ring has been in place for >4 weeks, she should remove it, confirm that she is not pregnant, reinsert a new one right away, and use back-up contraception for 1 week.

The initial contraceptive ring should be inserted anytime during the first 5 days of the menstrual cycle.⁹⁴ Back-up contraception should be used for the first week of use. When changing from other hormonal methods to the ring, the woman should insert the ring within 7 days of the last active pill or at the end of the patch-free week. No back-up contraception is needed.

As with the patch, the ring has the same contraindications and precautions as COCs (Table 45-4).⁹⁴ The most common side effects with the ring are vaginal infections, irritation, and discharge, headache, weight gain, and nausea.

PROGESTERONE-ONLY PILL (MINIPILL)

27. P.K., a 39-year-old woman, plans to breastfeed her infant and to begin some type of contraception following her discharge from the hospital. Her previous experience with condoms and concurrent spermicidal foams or gels resulted in itching and burning, and a copper IUD caused severe cramping and bleeding. She has a strong family history of cardiac disease and smokes two packs of cigarettes a day. What are the advantages of the minipill as a contraceptive method for P.K.?

Advantages

The minipill is devoid of some of the nuisance side effects (Table 45-4) caused by estrogen (e.g., headaches, chloasma).⁹ More importantly, estrogen-mediated hypertension and clotting factor changes will be avoided in this smoker, who has a strong family history of cardiovascular disease. Confusion with pill taking is minimized because there is no placebo week and all 28 tablets in each pack are the same. Therefore, the

missed-dose directions are the same whenever any pill is missed: take two pills as soon as possible and use back-up contraception for 48 hours. The minipill is less effective for preventing pregnancy than a COC. Minipills have noncontraceptive benefits, including decreased dysmenorrhea and bleeding. They also may protect against PID and endometrial cancer.

Theoretically, progestin use in the early postpartum period may decrease milk production, because milk production is triggered by the decline in progesterone that occurs after delivery. No data, however, have consistently shown this to be a problem in postpartum women.⁹⁰ Once breastfeeding has been established, progestins have not been shown to interfere with the quantity or quality of milk produced by a nursing mother. Thus, a progestin-only contraceptive may be preferred for a woman who plans to breastfeed her infant.

Disadvantages

28. What disadvantages of the minipill should you discuss with P.K.?

The minipills, with a failure rate of 0.5% to 5%, are less effective than COC (Table 45-1).⁹ Because minipills must be taken on a more regular schedule than a COC, minipills are not often used except in women who are breastfeeding or who have contraindications to estrogen (see instructions below). Most women using progestin-only pills have fewer bleeding days because there is no withdrawal bleeding induced by pill-free days. Some women on minipills will continue to ovulate and experience regular cyclic bleeding whereas others will have little or no bleeding for extended periods. The contraceptive actions of progestins include alteration of cervical mucus, endometrial changes, and tubal transport changes and, therefore, most users do not experience contraceptive failure despite continuing to ovulate. Some women using minipills will consistently have ovulatory cycles whereas others will shift back and forth between ovulatory and anovulatory cycles. Women who consistently have regular menses on the minipill are potentially at higher risk of pregnancy and may be advised to either use a back-up method of contraception or change to a different method.

Bleeding changes, including decreased duration and amount volume of menstrual flow, spotting, or amenorrhea commonly occur while taking the minipill.⁹ Because of this, some women may be concerned that they may be pregnant. Women who are exclusively breastfeeding usually will have amenorrhea. The high incidence of irregular menses associated with the minipill may mask underlying pathology. Other side effects reported with minipills include headaches, breast tenderness, mood changes, and nausea.

Minipills should be avoided if when there is a personal history of breast cancer or undiagnosed vaginal bleeding. Caution should be exercised when using minipills in women with hepatic disease, certain cardiovascular conditions, a current DVT or PE, or complicated diabetes (Table 45-4).¹⁰

Patient Instructions

29. What instructions should P.K. receive regarding the use of a minipill?

P.K. should begin taking the minipill when she is discharged from the hospital or after her first postpartum visit (3–6 weeks postpartum). If she were not postpartum, she would begin her first pack on the first day of her menses.¹⁶ Waiting for 4 to 6 weeks postpartum often is recommended to minimize complaints of irregular bleeding and to confirm that milk flow is established. Back-up contraception is not needed with a Day 1 start or when started within 4 weeks of delivery in a woman who is breastfeeding. When back-up contraception is needed, it should be used for 48 hours. She can begin immediately postpartum or wait 3 weeks to start.

P.K. should be instructed to take the pill at the exact same time each day. If she is >3 hours late taking a pill, she should take the pill as soon as she remembers and should use back-up contraception for 48 hours. This is quite different from the directions for a COC, so this point should be stressed during consultation.

LONG-ACTING INJECTIONS: DEPO-PROVERA AND LUNELLE

Depo-Provera

30. A.K., a 35-year-old woman who is breastfeeding, returns to the gynecology clinic for her second injection of depot medroxyprogesterone acetate (Depo-Provera; DMPA). She is a smoker with a history of thromboembolism. She was given her first injection 3 months ago, immediately postpartum. She is experiencing frequent BTB and has gained 2 pounds since her injection. Is this to be expected? What are the benefits and risks of DMPA? How are the side effects to be managed?

Depo-Provera is most often given as a 150-mg deep intramuscular injection in the deltoid or gluteus maximus every 11 to 13 weeks.⁹ Since its development in the early 1960s, DMPA has been approved for use in >90 countries and has been used by >30 million women worldwide.⁹⁵ The FDA approved DMPA in 1992. DMPA inhibits ovulation, thickens the cervical mucus, and suppresses endometrial growth, making it a very effective contraceptive. A newer lower-dose 104-mg formulation for subcutaneous injection also is available. The 104-mg formulation also is given every 11 to 13 weeks and has been reported to have fewer side effects, including weight gain.

Advantages

Depo-Provera is a good contraceptive choice for A.K. because she is at risk for estrogenic side effects. She is 35 years old, smokes, and has a history of thromboembolism. Among its benefits are a low failure rate of 0.3% (Table 45-1), ease of use, lack of estrogenic side effects, decreased dysmenorrhea, reduced monthly blood loss, and a reduced risk of endometrial cancer and PID.^{9,96} Other noncontraceptive benefits may include decreasing pain and frequency of sickle cell crises, reduction in seizure frequency in epileptic patients, and a possible reduction in ovarian cancer.^{9,97} Furthermore, contraceptive efficacy is not reduced by the concurrent use of anticonvulsants as is seen with COC.

Disadvantages

The package insert states women with breast cancer should not use DMPA.⁹⁸ DMPA should be used with caution in women

with undiagnosed vaginal bleeding, certain cardiovascular diseases or multiple risk factors for cerebrovascular disease, or a current DVT or PE (Table 45-4). Some experts disagree with the Depo-Provera package insert, which lists a history of prior thromboembolism as a contraindication, because clotting factors have not been shown to be clinically affected by DMPA.⁹⁹ Some clinicians also begin DMPA immediately postpartum rather than waiting 6 weeks postpartum, as directed by the package insert. Women starting DMPA earlier are more likely to report frequent episodes of bleeding or spotting, however.^{99,100}

Estrogen production declines in women using DMPA, so A.K. should be told that DMPA may decrease bone mineral density (BMD).¹⁰¹ Numerous studies have found that women receiving DMPA injection have lower BMD compared with nonusers. Other studies have found that DMPA does not affect BMD. Although there have been reports of stress fractures in DMPA users, no studies to date have documented an increased rate of hip or vertebral fractures in DMPA users.^{102,103} Also, BMD has been shown to recover after discontinuation of the injections.¹⁰¹ Product labeling advises limiting use to 2 years unless advantages outweigh the potential risk of reduced BMD.⁹⁸

A.K. can be reassured that, although DMPA frequently causes irregular bleeding or spotting during the first few months of use or more, the irregular bleeding diminishes with continued use. Bleeding is caused by insufficient estrogen to maintain the endometrium. After 1 and 2 years of use, 55% and 68% of women experience amenorrhea, respectively. Amenorrhea leads to discontinuation of DMPA in 13% of patients women.⁹⁵ Women beginning Depo-Provera should be informed that during the first year of use, they might have menstrual changes. If unusually heavy or continuous bleeding occurs, A.K. should be evaluated. She should be counseled and reassured that her irregular bleeding probably will resolve in the next few months. If the bleeding is bothersome to her, a 4- to 21-day course of oral estrogen (e.g., conjugated estrogen 0.625–2.5 mg/day) or a COC with 20 mcg EE can be added to minimize or eliminate the bleeding.¹⁸ The bleeding may, however, recur after discontinuation of the estrogen. Low-dose estrogen may be continued if bleeding recurs. The mean weight gain after 1 year of therapy with DMPA was about 5 pounds in two-thirds of users. Users typically gain a total of about 8 pounds over 2 years, nearly 14 pounds over 4 years, and 16.5 pounds over 6 years. Other side effects include mood changes, hair loss, and headaches.

Following a 150-mg DMPA injection, return to fertility is delayed by approximately 10 months after the last injection in half of users.⁹⁸ The remaining users took longer to become pregnant, with nearly all users becoming pregnant by 18 months.

Lunelle

31. A.K. is concerned about the menstrual changes with DMPA but likes the idea of an injectable method of contraception. Are there any other options for her?

Although currently not available in the United States, another injectable contraceptive, Lunelle, contains medroxyprogesterone 25 mg and estradiol cypionate 5 mg; it is admin-

istered intramuscularly every 28 to 33 days.¹⁰⁴ With this injection, women may experience spotting initially but should have regular menses about 2 to 3 weeks after each injection. The first injection should be given within 5 days of menstrual bleeding, and no back-up contraception is needed. Unlike DMPA, ovulation resumes more rapidly, within 2 to 3 months of discontinuing Lunelle. The most common side effects of Lunelle are irregular menses, weight gain (an average of 4 pounds in the first year), fluid retention, breast symptoms, nausea, headache, and mood changes.¹⁰⁴

Lunelle was available in vials and prefilled syringes until manufacturing problems caused the product production to be discontinued. Lunelle is no longer marketed for business reasons in the United States. Lunelle has not been available since October 2002. Pfizer medical information (the product owner) does not know if it will ever become available again. At this time, A.K. will have to select an alternate method or continue DMPA.

SUBDERMAL IMPLANTS

32. A.K. returns to the gynecology clinic on the first day of her flow after missing three consecutive DMPA injections because she cannot remember to come in for her shots and does not like the weight gain and prolonged intermenstrual irregular bleeding that occurred over 6 months. A friend of hers has used Norplant in the past, and she would like to try it. What information should be given to her about this product?

The Norplant System brand of subdermal levonorgestrel implants, is not currently available in the United States. Norplant, approved by the FDA in 1990, is a device consisting of six Silastic capsules 2.4 mm wide and 34 mm long that are implanted under the skin in the upper arm.⁹ Norplant contains a total of 216 mg of levonorgestrel that is released at a constant rate of only 20 to 30 mcg/day over 5 years, after which time they are replaced.

Certain lot numbers of Norplant were recalled in 2000 however because of efficacy concerns, and users were encouraged to use back-up contraception. Further research found that the recalled lots did not have reduced efficacy, so back-up contraception is no longer required for the affected women. Wyeth does not plan to reintroduce the system.

A new implant, Implanon, a single rod containing 68 mg of etonogestrel (active metabolite of desogestrel) was approved in the United States in 2006 but has not yet been marketed (release is expected in 2008). Implanon provides highly effective, reversible contraception for 3 years. Etonogestrel side effects are similar to those seen with other progestin-only methods, including irregular bleeding, weight gain, and a potential for drug interactions with 3A4 inducers.

INTRAUTERINE DEVICES AND INTRAUTERINE SYSTEMS

Background and Mechanism of Action

33. R.P., a 23-year-old woman with hydrocephalus, is brought to the gynecology clinic by her mother, S.P., to determine the best method of contraception for her mentally impaired daughter. R.P. has never given birth or been pregnant. She is in a monogamous relationship with a mentally impaired partner. According to S.P., R.P. wishes to put off pregnancy for many years, and any method of

contraception that necessitates compliance is virtually impossible for the couple. DMPA has been considered but has not been used because of the possibility of menstrual irregularities that would upset R.P. and may not be a good long-term method owing to bone density concerns. R.P. and her mother have never heard of intrauterine devices or intrauterine systems (IUS) before. Counsel her on what is available and how they work.

The IUD and IUS available to women today are safe and effective long-term methods of contraception. The devices are not as popular in the United States (only 1%–2% of women are users) as compared with other areas of the world (15%–18% of married women of reproductive age are users).^{105,106} In the 1960s and 1970s several IUD were available to women in the United States including Lippes Loop, Safe-T-Coil, Copper-7, Tatum T, and Progestasert. The Dalkon Shield IUD introduced in the United States in 1971 and removed from the market in 1974 is responsible for much of the negative “press” related to IUD and IUS. The Dalkon Shield was removed from the market owing to increased susceptibility to PID, with subsequent tubal scarring and infertility reported in users. Although the higher incidence of PID was not seen with the other types of IUD, the negative publicity hurt the use of all IUD. By 1976, the only IUD still available in the United States was the Progestasert, which was discontinued in 2001. Currently, two devices are available in the United States, the ParaGard IUD introduced in 1988 and the Mirena IUS introduced in 2000. Although the safety issues raised by the Dalkon Shield have been reassessed and resolved, the myths and misinformation associated with IUD and IUS have continued.

The ParaGard IUD, also known as the Copper-T IUD, has a polyethylene body that is wrapped with copper wire. Once inserted, the ParaGard may be left in place for 10 years.^{9,107} The Mirena IUS also has a polyethylene body, with a levonorgestrel reservoir in the vertical stem of the T.¹⁰⁸ Mirena is effective for 5 years. The failure rate of ParaGard is 0.6 to 0.8 pregnancies per 100 woman-years compared with 0.1 for Mirena (Table 45-1). IUD and IUS are inserted by a health care provider in the office. The procedure usually takes only a few minutes and does not require sedation. Many providers will recommend that patients take a dose of an NSAID before the insertion visit. The devices are frequently inserted during or within 5 days of menses to eliminate the possibility of pregnancy at the time of insertion; however, the devices can be inserted at any time in the cycle.

The mechanisms of action for ParaGard include prevention of fertilization and implantation and by interfering with sperm transport, viability, or number. A secondary mechanism, interfering with implantation may explain the effectiveness of ParaGard for emergency contraception. Mirena contains a progestin and works by thickening the cervical mucus, preventing sperm from entering the uterus, altering the endometrial lining, preventing ovulation, and altering sperm activity.¹⁰⁸ A secondary mechanism of action for Mirena, interfering with implantation has also been proposed. The myth that IUD and IUS are abortifacient is widespread and inaccurate.

Advantages

34. R.P.’s mother thinks that an IUD or IUS is a good option for her daughter, but R.P. is not sure. What are the advantages of IUD or IUS that R.P. should be aware of?

Both the Mirena and ParaGard are both safe, highly effective, reversible, long-term methods that do not require regular action by the user. The ParaGard IUD is a good option for women who want a highly effective nonhormonal contraceptive method; however, increased menstrual bleeding and cramping are seen more often with ParaGard than with Mirena. The Mirena IUS is a good option for women who want a long-lasting method and also are good candidates for progestins. Mirena can be left in place for 5 years, is rapidly reversible and has the added advantages of reducing menstrual bleeding and cramping. Mirena is used worldwide to manage heavy bleeding and dysmenorrhea. User satisfaction with IUD or IUS is higher than for all other methods of contraception. Reasons for low use of IUD or IUS in the United States include lack of awareness of the method (only 50% of women are aware), those aware are uncertain about safety (71%) or efficacy (58%), and lack of trained health care providers to insert them.¹⁰⁵

Although the initial cost of inserting an IUD or IUS is higher than the initial cost of pills or injections (around \$500 for the device and insertion costs), there are no monthly recurring costs to R.P. as there would be with the other methods. Therefore, women who use an IUD or IUS for >1 year have an overall lower monthly overall cost than women who use COC or the contraceptive ring or patch.

Disadvantages

Insertion of an IUD or IUS requires an office visit for the minor procedure. IUD or IUS are contraindicated in women with certain anatomic abnormalities of the uterus that might interfere with insertion, unexplained vaginal bleeding, cervical cancer, and those with active untreated PID or genital infections (Table 45-4).^{18,109} The device may be safely used in women with human immunodeficiency virus (HIV) infection (World Health Organization [WHO] Category 2).^{110–112} The Mirena IUS should not be used in women with active breast cancer and should be used with caution in women with a current DVT or PE or a history of breast cancer. Breast cancer is hormonally sensitive, and the disease may be worsened by the use of levonorgestrel. Although the serum levels of levonorgestrel are low with the Mirena IUS, the manufacturer currently does not recommend that women with active or past breast cancer use the device.

It has been widely believed that IUD users are more likely to develop PID than nonusers. Users of IUD or IUD have similar rates of PID infection as nonusers. Long-term use, defined as beyond 21 days, is not associated with increased risk. The transient increase in risk of PID from IUD or IUD use occurs shortly after insertion (in the first 21 days) and is usually related to a pre-existing untreated STD at the time of insertion.^{109,111} To reduce the risk of PID associated with the device insertion, screening for gonorrhea and chlamydia before insertion is recommended. Women who are positive for either STD should consider an alternative form of contraception until treatment is completed. In addition, IUD and IUS have previously been reserved for women in monogamous relationships or who have strict use of condoms because of concerns about STD and PID; however, current product labeling no longer contains these restrictions (product labeling updated 2006). IUD and IUS have also previously not been recommended for women who have not delivered a child; this is also no longer the case. They can be safely and appropriately used in nulliparous women.

Table 45-7 Intrauterine Device or Intrauterine System (IUD/IUS) Early Danger Signs (PAINS)

| |
|---|
| Period late (pregnancy) or abnormal spotting or intermenstrual bleeding |
| Abdominal pain or pain with intercourse |
| Infection exposure (e.g., gonorrhea) or abnormal vaginal discharge |
| Not feeling well, fever, chills |
| String missing, shorter, or longer |

The IUD and IUS devices are almost as effective as sterilization for preventing pregnancy. In the unlikely event that an IUD or IUS user becomes pregnant, there is a higher risk that the pregnancy may be ectopic. This, however, is more a reflection of the effectiveness of the method and not because the devices cause ectopic pregnancy (i.e., the ratio of ectopic to uterine pregnancies is higher in IUD or IUS users than nonusers).^{107,108} If a woman using an IUD or IUS becomes pregnant, the device should be removed because her risk for spontaneous abortion, sepsis, or premature delivery are increased if the device is left in place.

Continuation rates for IUD and IUS users are high. Approximately 10% to 15% of IUD are removed because of excessive uterine bleeding, spotting, or pain.^{107,108} Another 2% to 6% of women spontaneously expel their IUD within the first year. Rarely, and IUD or IUS may become embedded in the endometrium or partially or totally perforate the uterine wall. R.P. should be instructed to look for the warning signs of a possible complication with IUD or IUS use (Table 45-7).

DIAPHRAGM

Mechanism of Action

35. R.C., a 25-year-old woman who is breastfeeding her 6-week-old infant, will consider only a barrier method of contraception. How do diaphragms prevent pregnancy?

The diaphragm is a soft, latex device with a metal spring reinforcing the rim.^{9,18} The device is inserted vaginally and placed over the cervical to mechanically block access of sperm to the cervix. It is held in place by the spring tension of the rim, vaginal muscle tone, and the pubic bone. Because the diaphragm does not fit sufficiently tightly to be a complete barrier to sperm, spermicidal gel must be placed in the dome before use.⁹

The first-year failure rate with diaphragms is 6 to 20 pregnancies per 100 woman-years (Table 45-1).⁹ R.C. should be counseled that diaphragms are less effective than other available methods and may increase her risk of UTI. Because breastfeeding offers some protection against pregnancy, breastfeeding women may be the best candidates for the diaphragm. Women allergic to latex or spermicide should not use the method.

Types

36. What types of diaphragms are available?

Diaphragms must be properly fitted to be effective. Currently available devices are made of latex, available in a range of sizes (50–95 mm in diameter) and types of circular rim

construction.^{9,18} The coil spring rim diaphragm folds flat and may be used with a diaphragm introducer. These diaphragms are indicated for women with average vaginal muscle tone and for those who can tolerate the sturdy rim and firm spring strength. The rim of the arcing spring rim diaphragm arcs when folded. Most women, even those with lax vaginal muscle tone, can tolerate the firm spring strength of the arcing spring rim diaphragm. The flat spring rim diaphragm is good for women with firm vaginal muscle tone, because the rim is less firm than the other styles. The wide-seal rim diaphragm (available as an arcing spring or coil spring) has a flexible flange designed to hold spermicide in place and to create a better seal between the diaphragm and vaginal wall.

R.C. would likely be able to tolerate any of the diaphragms. Perhaps she will find that one type is more comfortable than the others when she is fitted and the best fit can be selected during the office visit. The importance of using the diaphragm with spermicide during every act of intercourse should be stressed during counseling.

Fitting

37. How is a diaphragm size selected?

The goal of fitting a diaphragm is to select the largest rim size that is comfortable for the woman.^{9,18} A diaphragm that is too small may become dislodged during intercourse because vaginal depth increases during sexual arousal. Conversely, a diaphragm that is too large may cause vaginal pressure, abdominal pain or cramping, vaginal ulceration, or recurrent urinary tract infections.

Patient Instructions

38. What instructions should be provided to R.C. concerning the use of a diaphragm?

The diaphragm should not remain in the vagina for longer than 24 hours.⁹ Toxic shock syndrome (TSS) has been associated with diaphragm use and women should be alert to its symptoms, which include fever, diarrhea, vomiting, muscle aches, and a sunburnlike rash. Allergic reactions to the latex or spermicides also have been reported.

Before insertion, R.C. should inspect the diaphragm for holes or puckering. R.C. should be counseled that the diaphragm should always be inserted before intercourse if contraception is to be maximized. It can be inserted as much as 6 hours before intercourse if necessary. The diaphragm should not be removed for at least 6 hours after intercourse. One teaspoon of spermicidal gel should be placed into the dome (on the side adjacent to the cervix) and along the rim of the diaphragm before insertion. If intercourse is repeated, a new application of spermicide should be inserted vaginally without removal of the diaphragm.

When the diaphragm is removed, it should be washed with mild soap and water, rinsed and dried, and stored in its plastic container. Talcum or perfumed powders should not be used on the diaphragm because these may damage the diaphragm or cause irritation of the vagina or cervix. Oil-based products also may decompose the diaphragm and should not be used. Contraceptive gel, however, may be used if vaginal lubrication is needed. If R.C. gains or loses 10 to 20 pounds, has a

pregnancy, or has abdominal or pelvic surgery, the fit of her diaphragm should be checked.

CERVICAL CAP

39. R.C. is also interested in the cervical cap. What is it, how well does it work, and what information should be provided to cervical cap users?

The cervical cap is a small, flexible, cuplike device made of latex and designed to fit closely around the base of the cervix; it is available in 22-, 25-, 28-, and 31-mm internal rim diameter sizes.^{9,18} The cervical cap is less effective in women who have delivered a child, with pregnancy rates of 26 to 40 pregnancies per 100 woman-years in nulliparous women and 9 to 20 pregnancies per 100 woman-years in parous women. Women generally prefer other methods of contraception to cervical caps. In one study, 50% of women discontinued using cervical caps after 6 months, and 50% were pregnant after 2 years of use.¹¹³

To use the cervical cap, R.C. should fill the cap about one-third full with spermicidal gel, insert it vaginally, and place it over the cervix.^{9,18} Suction holds it in place. It should be left in place at least 8 hours after intercourse but no longer than 48 hours, according to the manufacturer. Most experts recommend removal after 24 hours because of problems with vaginal odor at 36 to 48 hours and the theoretic risk of TSS.

As with the diaphragm, patient users should check the cap for holes before using. Also, R.C. should avoid using oil-based lubricants or medications when using the cervical cap.

CONDOMS

40. J.D. is a 45-year-old unmarried woman who has sex infrequently. She would like a method to protect against pregnancy as well as STD. How effective are condoms in preventing pregnancy? What types of condoms are available?

Condoms are an effective method of contraception when used properly. The failure rate with condoms is 3 to 12 pregnancies per 100 woman-years of use (Table 45-1).^{9,16} The female condom is slightly less effective, with 5 to 21 pregnancies per 100 woman-years. Many different brands of condoms are available in the United States. The brands differ in size, shape, color, material, and the presence or absence of lubricants or spermicide. Most practitioners recommend lubricated condoms with reservoir ends to collect the ejaculate and to prevent breakage. Spermicides may increase the risk of HIV transmission.

The most commonly used male condom is made of latex.^{9,10} Male condoms made of polyurethane and lambskin, which are also available, are recommended for men or women when one partner is allergic to latex. Polyurethane condoms, however, are more expensive and harder to find than latex condoms and natural or lambskin condoms do not offer the same protection against STD. Female condoms are made of polyurethane.

41. What are the advantages and disadvantages of condoms? How are they used?

Because the pre-ejaculatory secretions may contain sperm, the male condom should be applied before vaginal contact.^{9,10} Female condoms should also be inserted before sexual con-

tact; they may be inserted up to 8 hours before intercourse. Condoms should be used by their expiration date and should not be reused. They should be stored in a cool, dry place, not somewhere they will be exposed to prolonged periods of heat or light.

The chief noncontraceptive benefit of condoms is the prevention of STD (including gonorrhea, chlamydia, and HIV), and they can be used for vaginal, anal, or oral sex.^{9,18} Condoms are also readily available without a prescription and do not cause systemic side effects like the hormonal methods. Latex male condoms are inexpensive. Some complain, however, that condoms reduce sensitivity and spontaneity. Female condoms are more costly (about \$3 each), can be noisy, and can be difficult to insert.¹⁸ Condoms may also break; this is less likely with the female condom. Oil-based products can degrade latex and should be avoided when using male, latex condoms. Oil-based lubricants can be used with female condoms or male polyurethane or lambskin condoms.

When using a male condom, the man or his partner holds the tip of the condom and unrolls it down to the base of the erect penis.^{9,18} The female condom consists of a smaller circular ring at one end (which secures the device around the cervix like a diaphragm) and a larger ring at the other end. The inner ring should be compressed and inserted vaginally as far as it will go, and the larger ring remains outside of the vagina, protecting the external genitalia.

VAGINAL SPERMICIDES

42. J.D. would like to use a spermicide along with condoms. What options does she have, and how effective are spermicides when used alone?

Vaginal spermicides currently are available without a prescription as gels (jellies), suppositories, foams, and films.^{8,18,114} Most of these products use a nonionic surfactant, nonoxynol-9, as the spermicide; the balance use octoxynol-9. The in vitro spermicidal potencies of the various preparations are highest with foam, followed by cream, jelly, and gel, respectively. When used in combination with a male condom, spermicides provide effective contraception.

43. What dosage form should J.D. use? How should she be instructed to use a vaginal spermicide? What side effects can be anticipated?

Table 45-8 compares the different spermicidal products.^{9,18,114} The different characteristics of the products can help guide J.D. when selecting a dosage form. Regardless of the dosage form, a new dose of spermicide should be applied before each act of intercourse.

Spermicides can cause genital irritation and, in some patients, lead to ulceration. For this reason, spermicides have been shown to increase the transmission of STD, including HIV, gonorrhea, and chlamydia.

EMERGENCY CONTRACEPTION

Emergency Contraceptive Pills

44. B.P., a 24-year-old woman, has just returned home from a vacation in Europe. Her luggage containing her COC was stolen

Table 45-8 Comparison of Vaginal Spermicides

| Formulation | Brand Name Examples | How to Use | Onset of Action | Duration of Action |
|-------------|----------------------|--|-----------------|--------------------|
| Gel | Conceptrol, Gynol II | Fill applicator, insert applicator vaginally as far as it will comfortably go, press plunger of applicator to deposit spermicide near the cervix. | Immediate | 1 hr |
| Film | VCF | Fold film in half, fold over finger, use finger to insert as far as it will comfortably go. | 15 min | 3 hr |
| Foam | Delfen, Koromex, VCF | Shake foam canister, fill applicator, insert applicator vaginally as far as it will comfortably go, press plunger of applicator to deposit spermicide near the cervix. | Immediate | 1 hr |
| Suppository | Conceptrol, Encare | Unwrap, use finger to insert as far as it will comfortably go. | 15 min | 1 hr |

2 weeks ago, and she had unprotected midcycle intercourse 24 hours ago. What can be done to prevent an unwanted pregnancy at this time?

Emergency contraception (also known EC), sometimes referred to as the morning-after pill, is a method of contraception that can be used after intercourse to prevent pregnancy.¹¹⁵ Indications for EC are failure to use a contraceptive during intercourse (e.g., forgot, were assaulted) or method failure (e.g., broken condom or missed oral contraceptives). Emergency contraceptive pills (ECP) reduce the risk of pregnancy by 75% to 89% when taken up to 120 hours after unprotected intercourse. The mechanism of action for EC has been widely debated. A 2006 article discussing the mechanism of action concluded the primary mechanism of actions is delayed or inhibited ovulation. EC may also interfere with fertilization (most likely owing to altered tubular transport of the sperm or ovum). Alternations to the endometrial lining that may affect implantation have not been reported from the use of levonorgestrel only EC; however, the possibility can not be excluded.¹¹⁶

Although ECP use is on the rise, many women are not aware that it is available. In a 1998 survey, 686 of 1,000 women aged 18 to 44 had ever heard of emergency contraception. Of those aware of EC, only 5% had learned about it from a health care professional, 44% identified the source as a television news program, and another 16% read about it in a magazine. Approximately 12% of obstetricians and gynecologists interviewed in the same survey feared women would use ECP for routine contraception.¹¹⁷ A more recent survey from 2004 found similar results. In the more recent survey, many of the women indicated awareness of EC, were not aware that it was available in the United States, confused it with Mifiprex (RU-486), or did not know that EC is taken after unprotected intercourse.¹¹⁸

Available Emergency Contraceptive Pills

PROGESTIN ONLY EMERGENCY CONTRACEPTIVE PILLS

Plan B is a progestin-only ECP approved for nonprescription sale by pharmacies and clinics to consumers (men and women) age 18 and older and by prescription to women 17 years and under. The Plan B pack consists of two white levonorgestrel 0.75-mg tablets and detailed instructions for use.^{119–121} One tablet is to be taken as soon as possible and the second is taken 12 hours later. An alternative dosing regimen that is not currently FDA approved is to take both tablets (1.5 mg levonorgestrel) at once. The single-dose regimen (1.5 mg) is available in Canada and Europe and may be more effective than the two doses 12 hours apart.¹¹⁸ Progestin-only EC is the regimen of choice because it

is more effective and has significantly fewer side effects than estrogen and progestin ECPs.¹¹⁸

The risk of pregnancy is reduced by 89% when Plan B is taken within 72 hours after a single act of intercourse. If taken within the first 24 hours after intercourse, levonorgestrel may reduce the risk of pregnancy by 95%. Although the reduction in pregnancy is greatest when used within 24 hours after unprotected intercourse, use as long as 120 hours after has been shown to be effective.¹¹⁹ The progesterone-only pill, Ovrette, may also be used for emergency contraception. This product is rarely used, however, because the woman would need to take 20 pills per dose to get the proper amount of progestin.

ESTROGEN AND PROGESTIN EMERGENCY CONTRACEPTIVE PILLS

An alternative to the progestin-only EC regimen is the Yuzpe regimen. An FDA-approved product (Preven) was released in 1999 utilizing the Yuzpe regimen but Preven is no longer being marketed in the United States. The Yuzpe regimen of emergency contraception utilizes commercially available COC to deliver 0.5 mg levonorgestrel and 100 mcg EE per dose.^{9,122} Women should take two doses 12 hours apart. Table 45-9 shows

Table 45-9 Oral Contraceptive Pills That May Be Used As Emergency Contraception

| Brand | Tablets per Dose (N) | Color |
|--------------|----------------------|--------------|
| Alesse | 5 | Pink |
| Aviane | 5 | Orange |
| Cryselle | 4 | White |
| Enpresse | 4 | Orange |
| Lessina | 5 | Pink |
| Levlen | 4 | Light-orange |
| Levlite | 5 | Pink |
| Levora | 4 | White |
| Lo-Ovral | 4 | White |
| Low-Ogestrel | 4 | White |
| Nordette | 4 | Light-orange |
| Ogestrel | 2 | White |
| Ovral | 2 | White |
| Ovrette | 20 | Yellow |
| Plan B | 1 | White |
| Portia | 4 | Pink |
| Preven | 2 | Blue |
| Tri-Levlen | 4 | Yellow |
| Triphasil | 4 | Yellow |
| Trivora | 4 | Pink |

which COC may be used and how many tablets need to be taken per dose.^{121–123} It is very important to counsel women about which pills to take, because the tablet color and number differ depending on the brand chosen. This coupled with an increase in side effects makes this method less desirable than levonorgestrel-only regimens (discussed above). As with progestin-only regimens, the reduction in pregnancy is greatest when used within 24 hours after unprotected intercourse; however, the use after as long as 120 hours has been shown to be more effective than estrogen and progestin ECP.^{119,122} The Yuzpe regimen reduces the risk of pregnancy by 89% after a single act of intercourse when taken within 72 hours.

Patient Instructions

The ECP are most effective when taken as soon as possible after intercourse; therefore, treatment should not be delayed.^{115,119,122} In the FDA-approved regimens, the first dose is to be taken within 72 hours after intercourse; however, ECP have been shown to be effective when the first dose is taken within 5 days of unprotected sex.^{118,120} The most common side effects with ECP are nausea and vomiting; however, most women do not experience side effects from the progestin-only regimen. Gastrointestinal adverse effects are more likely with the estrogen and progestin ECP than with the progestin-only ECP. B.P. should be instructed that if she vomits within 1 hour of taking either dose of medication, the dose should be repeated. When a Yuzpe regimen is used, an antiemetic (e.g., prochlorperazine or meclizine) can be given 30 to 60 minutes before each dose of ECP to prevent nausea or vomiting.¹¹⁵

B.P.'s menses may come early or late, but she should take a pregnancy test if her menses do not come within 3 weeks of taking ECP.

Women under age 18 may call the Emergency Contraception Hotline (1-888-NOT-2-Late or 1-888-668-2528) to find a provider near them who will prescribe ECP. Women may also find information about ECP at the Emergency Contraception website (<http://www.not-2-late.com>). As of January 2008, pharmacists can prescribe EC under collaborative protocol agreements in nine states.¹¹⁸

IUD for Emergency Contraception

The copper IUD is also an effective method of emergency contraception when inserted within 5 days of unprotected sex.¹²⁴

Because some women are not good candidates for IUD (see discussion above) and because IUD must be inserted by a health care provider, they are not used as regularly for emergency contraception in the United States. The biggest advantage of using of an IUD for emergency contraception is that it provides ongoing contraception and the Paragard is significantly more effective in preventing pregnancy than oral regimens (1 failure in 10,000 insertions vs. 1:100 for pills).

MEDICAL ABORTION

45. G.H. was given a pack of OCs last month, but could not remember how to start them. She has just discovered that she is 4 weeks pregnant. She is 23 yo and single and is considering terminating the pregnancy. What options are there for medical abortion?

It is estimated that about one half of pregnancies are unintended, so it is important for these women to have safe options. G.H. should be counseled extensively about her options including keeping the baby, adoption, and medical or surgical abortion. Compared with surgical abortion, medical abortion does not require a surgical procedure so it is less likely to cause infection and is less costly.⁵¹ Also some women feel more in control when choosing this option. However, some patients may not prefer medical abortion because it usually takes more medical visits and follow-up, has a slightly lower success rate (94–97%; failures will need a surgical procedure), and involves more bleeding and cramping which usually lasts for 2 weeks.

There are many variations in how medical abortions are carried out, but the general treatment remains the same.⁵¹ G.H. would first have baseline labs done including blood type and hemoglobin. She would be given mifepristone that same day to stop development of the pregnancy. In the U.S., mifepristone, and antiprogesterin, is more commonly used. Then misoprostol is given to induce uterine contractions and expel the pregnancy.

Typically, if using mifepristone, G.H. would be given 200 mg orally on day 1 then misoprostol orally or vaginally on day 2 or 3.⁵¹ Misoprostol is FDA approved for oral use. It may be given as 400 or 600 mcg orally, given sublingually or given as early as 6–8 hours after mifepristone.^{123–125} Vaginal use of misoprostol is not approved and its use is under review.

PREGNANCY

More than 4 million live births were registered in the United States in 2004, with an estimated 83.9% of women beginning prenatal care in the first trimester.¹ Although much improved, prenatal care is still not accessible to all women. The timing and quality of prenatal care can influence an infant's health and survival. Early comprehensive care can promote healthier pregnancies through early detection of risk factors, disease state management, and encouragement of healthy behaviors. Appropriate preconception counseling and treatment of women with pre-existing high-risk medical conditions, such as diabetes, hypertension and epilepsy, can greatly improve pregnancy outcomes. Essential preconception and early prenatal care, critical for normal fetal organogenesis, may not be sought because 40% of pregnancies in an American woman's lifetime are unplanned.² In 2004, the mortality rate (from birth through the first year of life) for infants of mothers beginning prenatal care after the first trimester, or not at all, was 37% higher (8.35 per 1,000 live births) than the rate for infants whose mothers' prenatal care began in the first trimester (6.11 per 1,000 births).¹

The goal of prenatal care, to promote a safe and successful pregnancy and the delivery of a healthy infant, can be achieved through education and by monitoring the health of the mother and fetus. The first prenatal visit should occur no later than the second missed menstrual period, generally 8 weeks after missed menses.²

Placental Physiology

Conception begins with the fertilization of an ovum. The time after conception is the conceptional or developmental age. The gestational age or menstrual age, is the time from the start of the last menstrual period (LMP) and generally exceeds the developmental age by 2 weeks.³ The fertilized ovum, or zygote, undergoes mitotic divisions that lead to the formation of the blastocyst, a hollow fluid-filled sphere.⁴ The outer cell mass of the blastocyst differentiates into trophoblasts, whereas the internal cell mass gives rise to the embryo. About 5 to 6 days after fertilization, the blastocyst adheres to the endometrial epithelium,

where it undergoes implantation between postconception day 7 to 12.³ The outer cell mass, or trophoblasts, invades the endometrium, and the blastocyst becomes completely buried within the endometrium. Once trophoblastic invasion of the endometrium occurs, the endometrium is transformed into the decidua, the functional layer of the pregnant endometrium, and is referred to by this term throughout pregnancy.⁵

The trophoblast secretes human chorionic gonadotropin (hCG), which maintains the corpus luteum so that menstruation is prevented and pregnancy can continue.⁶ (See Chapter 45, Contraception, for a detailed discussion of the menstrual cycle.) As more of the decidua is invaded, the walls of the decidual capillaries are eroded, thereby leaking maternal blood into spaces called lacunae.⁴ This initial contact with the maternal blood allows hCG to enter the maternal circulation by day 11 of gestation when it can be measured to aid in the diagnosis of pregnancy.⁶ The trophoblasts are the only cells of the conceptus that are in direct contact with maternal tissue or blood; embryonic cells never come in contact with maternal tissues.⁴

As the embryo within the blastocyst grows, the thickness of the decidua decreases. The part of the decidua directly below the site of implantation becomes the *decidua basalis*, and the part that lies over the growing blastocyte, which separates it from the rest of the uterine cavity, is the *decidua capsularis*; this part of the decidua contacts the chorion leave, the extraembryonic, avascular, fetal membrane. The rest of the uterus is lined by the decidua parietalis. By 14 to 16 weeks, the gestational sac is sufficient large to fill the entire uterine cavity, at which time the decidua capsularis has lost its blood supply and fuses with the decidua parietalis (which is sometimes referred to as the *decidua vera*).⁵

The vessels (spiral arteries) supplying blood to the decidua parietalis retain their endothelium and smooth muscle wall and therefore continue to respond to vasoactive agents.⁵ By contrast, the spiral arteries supplying the decidua basalis undergo trophoblastic invasion whereby they are transformed into wide-bore uteroplacental vessels that empty directly into the intervillous space in fountainlike spurts.^{3,4} This process creates a low-resistance arteriolar circuit that allows maximal placental blood flow necessary for the growing fetus.⁷ Unlike the rest of

the maternal and fetal vasculature, the resistance within these uteroplacental vessels does not change in response to vasoactive agents. The resistance is fixed and therefore directly dependent on maternal perfusion pressure.⁶ If the maternal perfusion pressure decreases, blood flow to the placenta decreases. Likewise, placental blood flow is increased when the maternal perfusion pressure is increased. Incomplete trophoblastic invasion of the spiral arteries in the myometrium results in decreased placental perfusion and ischemia. This is believed to be a factor in the pathogenesis of pre-eclampsia.⁷

The placenta has both fetal and maternal components. The placenta is made up of the amnion, chorion, chorionic villi and intervillous spaces, decidua plate, and the myometrium.³ The fetal surface of the placenta is covered by the amnion beneath which the fetal chorionic vessels cross. Figure 46-1 describes the structure of the placenta and its maternal-fetal circulation. Maternal-fetal circulation to the intervillous space is not fully established until the second trimester.³ Maternal uteroplacental arteries perfuse the intervillous spaces, and as the maternal blood flows around the villi, exchanges (oxygen and nutrients) occur with fetal blood contained within capillaries found inside these villi.³ Although the placenta serves as a strong barrier between the fetal and maternal circulations, a few cells are able to cross between the two circulations.³ Except for pathologic

conditions, fetal blood and maternal blood do not make contact. Placental blood flow reaches the fetus through a single umbilical vein. At the juncture of the placenta and umbilicus, the umbilical vein and arteries repeatedly branch and traverse the fetal surface of the placenta (between the amnion and the chorionic plate) forming capillary networks that terminate within the villi. These vessels are termed the *chorionic veins and arteries*. Fetal blood flow reaches the placenta through two umbilical arteries; carbon dioxide and waste products diffuse into the intervillous spaces and are carried away by the maternal decidual veins.³ A description of fetal circulation can be found in Chapter 94, Neonatal Therapy.

The placenta has many functions in pregnancy.³ In addition to respiratory functions, the placenta also has excretory functions, similar to those of the postnatal kidney (e.g., maintaining water and pH balance). The placenta also has resorptive functions similar to those of the gastrointestinal (GI) tract.³ The placenta and the fetus regulate the course of pregnancy. This fetoplacental unit functions as the endocrine portion of the fetal-maternal communication system, producing several hormones responsible for regulating and maintaining pregnancy (e.g., hCG, estrogens, progesterone, placental lactogen).⁶ The placenta also produces many other hormones, enzymes, proteins, and releasing factors.⁶

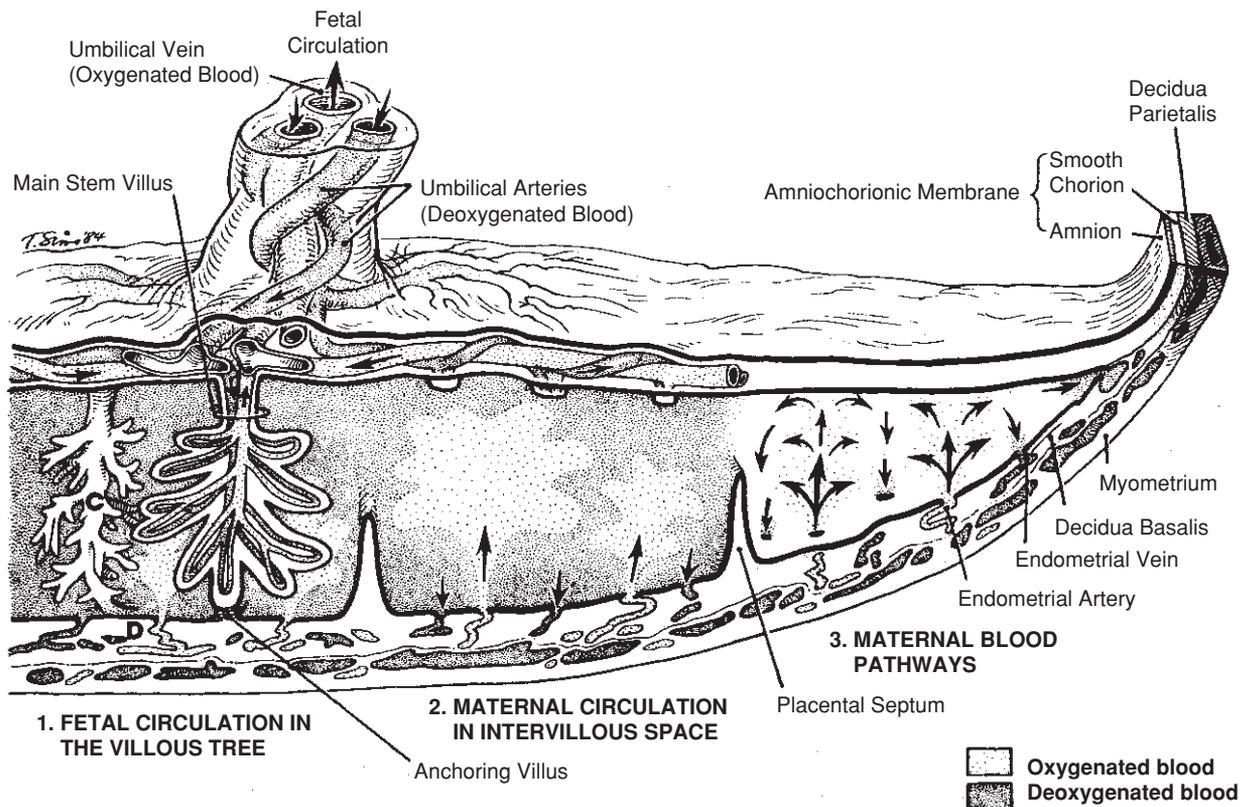

FIGURE 46-1 Term placenta. 1. The relation of the villous chorion (C) to the decidua basalis (D) and fetal placental circulation. 2. The maternal placenta circulation. Maternal blood flows into the intervillous spaces in the funnel-shaped spurts, and exchanges occur with the fetal blood as the maternal blood flows around the villi. 3. The inflowing arterial blood pushes venous blood into the endometrial veins, which are scattered over the entire surface of the decidua basalis. Note also that the umbilical arteries carry deoxygenated fetal blood to the placenta and that the umbilical vein carries oxygenated blood to the fetus. From reference 42, with permission.

Fetal Membranes

The fetal membranes are made up of an innermost membrane, the amnion, and an outer membrane, the chorion. These make up the “water bag.” The amnion at term gestation is a tough but pliable membrane whose integrity is vital for the continuation and progression of pregnancy.⁴ The fluid-filled space between the amnion and the embryo is the amniotic cavity. The membranes surround the developing fetus and function to contain the amniotic fluid and assist in its formation. This fluid provides a mechanically buffered, stable environment in which the fetus develops. The amniotic fluid has both maternal and fetal sources and is the paracrine arm of the fetal–maternal communication unit. The maternal source is plasma filtrate and, as pregnancy advances, the fetal contribution is from urine and lung fluids. The volume of amniotic fluid increases from 50 mL at 12 weeks’ gestation to a maximum of 1,000 mL at 36 weeks, and declines at term.⁸ The composition of the amniotic fluid includes water, fetal cells, hormones, lecithin, sphingomyelin, electrolytes, creatinine, and urea.⁸ Amniotic fluid can be obtained by amniocentesis and tested for the presence of some of these substances to aid in fetal assessment. For example, the lecithin-to-sphingomyelin ratio is used as a marker of fetal lung maturity when preterm delivery is being contemplated for obstetric reasons (e.g., severe pre-eclampsia).⁸

Human Chorionic Gonadotropin

Human chorionic gonadotropin, produced by the trophoblasts, is responsible for maintaining the synthesis of progesterone by the corpus luteum within the ovary until the placenta is able to synthesize the amount necessary to maintain pregnancy.⁹ The synthesis of progesterone by the corpus luteum decreases at approximately 6 weeks’ gestation (menstrual age). After 8 weeks, the syncytiotrophoblast (placenta) becomes the major source for progesterone synthesis. If the corpus luteum is removed or its function ceases before the placenta becomes the dominant source of hCG, pregnancy is terminated.⁹ In such cases, intramuscular (IM) administration of the parenteral progestin, 17-hydroxyprogesterone caproate 150 mg, may maintain the pregnancy until the placenta can produce sufficient quantities.⁹

Human chorionic gonadotropin is detected in the maternal circulation and urine approximately 11 days after conception.⁶ Concentrations in the urine closely parallel those in the maternal blood. hCG serum concentrations increase rapidly, doubling every 1.4 to 2 days.⁹ Peak concentrations are achieved at 60 to 70 days of pregnancy. Thereafter, hCG concentrations decline and reach a low at approximately 100 to 130 days.

Human chorionic gonadotropin is composed of an α - and a β -subunit. The α -subunit is identical with the α -subunit of other pituitary hormones (e.g., follicle-stimulating hormone [FSH], luteinizing hormone [LH], thyroid-stimulating hormone [TSH]); however, the β -subunit is specific to hCG. Pregnancy tests specific for this β -subunit are useful diagnostic tests for confirming pregnancy.⁹

Definitions

Parity and Gravida

Parity and *gravida* are terms used to describe a pregnant woman. Parity is the number of deliveries after 20 weeks’ ges-

tation. A delivery before the completion of 20 weeks’ gestation is considered an abortion and can be either elective or spontaneous. Parity is independent of the number of fetuses delivered (live or stillborn, single fetus, or twins) or the method of delivery. *Gravida* refers to the number of pregnancies a woman has had regardless of the outcome. For example, a woman who is currently pregnant and has previously delivered one set of twins and had two spontaneous abortions is described as a gravida 4 para 1 (G₄P₁).¹⁰

Trimesters of Pregnancy

The average pregnancy is approximately 280 days or 40 weeks when calculated from the first day of the LMP. Pregnancy is typically divided into three trimesters, approximately 13 to 14 weeks each.¹⁰ The time between the end of the 22nd week of gestation and the end of the 28th day after birth is considered the perinatal period.²

Pregnancy also can be divided into time periods, based on development, and refers to the conceptional age. The developmental or conceptional age is the time after fertilization and is about 2 weeks less than the gestational age.³

The first 2 weeks after fertilization is the pre-embryonic period. The embryonic period is from the second week of conception through the eighth week. Organogenesis occurs from the fourth through the seventh developmental week. The fetal period begins after the eighth conceptional week and continues until birth.³

Delivery

Depending on the gestational age at the time of delivery, the result can be an abortion, preterm, term, or post-term birth. An abortion (spontaneous or terminal) is a delivery before 20 weeks’ gestation. A term infant is a fetus delivered between 37 and 42 weeks gestation. A preterm birth is one occurring between 20 and 37 weeks’ gestation, and a post-term (postmaturity) birth occurs after the beginning of 43 weeks’ gestation.¹⁰ Parturition refers to labor, and the puerperium is the 6 to 8 weeks after delivery.¹⁰

Diagnosis of Pregnancy

1. S.C. is a 29-year-old, G₁P₁ woman, who has not started her menstrual period since she had unprotected intercourse about a month ago. She is worried that she may be pregnant. S.C. cannot remember the exact start date of her LMP. She asks her pharmacist for help selecting an over-the-counter commercially available home pregnancy test. How do these home pregnancy tests work and how should S.C. be counseled?

Commercially available home pregnancy tests are enzyme immunoassays with monoclonal or polyclonal antibodies, which bind to hCG in the urine.¹¹ They are highly sensitive and provide accurate results within 1 to 2 weeks after ovulation.^{9,11} Several kits are available. The tests can be performed privately and quickly, and are easily interpreted. The results are obtained rapidly—within 1 and 5 minutes—and are highly accurate when performed at the start of the first missed menstrual period. Although home pregnancy tests are reportedly 98% to 100% accurate when used correctly, consumer studies have documented accuracy rates as low as 50% to 75% if product directions are not precisely followed.¹¹ Many home pregnancy

tests include a second test, which should be repeated at a specified time after the first negative test result.

S.C. should purchase a product containing two tests and follow the instructions carefully. If the first test result is negative, S.C. should repeat the test in 1 week if she has not started menstruating. False-negative results occur when testing is done before the first day of a missed period or if the urine is not at room temperature.¹¹ False-negative results can also occur with an ectopic (outside the uterus) pregnancy or ovarian cysts and in women receiving menotropins or chorionic gonadotropin.¹¹ If the test is positive, S.C. should be counseled on the possible fetal effects of any medications or herbal products she may be taking and advised to see her physician as soon as possible.

A positive urine or blood test result for hCG is still considered a probable diagnosis of pregnancy. The diagnosis of pregnancy is positively made with the identification of fetal heart sounds, perception of active fetal movements by an examiner, or visualization of embryo or fetus by sonography.⁹

Date of Confinement (Due Date)

2. What is S.C.'s "due date?"

The assessment of gestational age is important to determine the expected date of confinement (EDC), schedule a cesarean section, or determine when it is safe to end a pregnancy prematurely. Gestational age can be determined by several methods, including the date of the LMP, pelvic examination, uterine size, and measurement of fetal parameters by ultrasound. The onset date of the LMP is most commonly used to estimate the gestational age of the fetus.

Because the day of conception rarely is known, it is more practical to measure the duration of pregnancy from the first day of the LMP. The EDC is generally determined by adding 7 days to the first day of the LMP, counting back 3 months, and adding 1 year (Nagele rule).¹² This method assumes that ovulation occurs on day 14 of a 28-day menstrual cycle. The problems with this method are that many pregnant women do not know the date of their LMP, and it is inaccurate in women with irregular or prolonged menstrual cycles. S.C.'s first day of her LMP was estimated to be 6 weeks ago on August 6. It is now September 17; therefore, her EDC or "due date" is May 13. Although this may not be an accurate date, a more exact date will be estimated using first trimester sonography.

Pregnancy-Induced Pharmacokinetic Changes

Important physiologic changes occur in almost all maternal organs during pregnancy to support the growth and development of the fetus. These physiologic changes affect the cardiovascular, respiratory, and GI systems; plasma volume, renal function, and hepatic enzymes, which can alter the absorption, distribution, metabolism, and elimination of drugs.¹³ Alterations in the pharmacokinetics of drugs are influenced by mainly by two factors: (a) maternal physiologic changes and (b) the effects of the placental-fetal compartment.¹⁴

Absorption

Pregnancy-induced changes affecting drug absorption are (a) a decrease in intestinal motility, owing to smooth muscle relax-

ation by progesterone, resulting in a 30% to 50% increase of gastric and intestinal emptying time; (b) 40% decrease in gastric acidity, which increases gastric pH; and (c) altered bioavailability or absorption attributable to increased incidence of nausea and vomiting. Bioavailability may be increased for acid-labile drugs and decreased for drugs that require acid medium for stability. A prolonged gastric and intestinal emptying time may decrease the maximum concentration (C_{max}) of a drug and the time to reach C_{max} , whereas the increased intestinal transit time may increase the area under the curve (AUC) and bioavailability of a drug. In contrast, pregnancy-induced vomiting may decrease amount of drug ingested; it is therefore better to schedule medications during the evening when the incidence of nausea and vomiting is lower or to use the rectal route for drug administration. In summary, the effect of pregnancy on drug absorption is variable and depends greatly on the physicochemical properties of the drug.¹⁴ Increased blood flow to maternal skin, which helps dissipate fetal heat production, may also increase the absorption of a topically (transdermal) administered medication.¹³

Distribution

Changes in protein binding and increased plasma volume can theoretically increase the apparent volume of distribution of drugs during pregnancy. Plasma volume increases by 6 to 8 weeks' gestation and continues to expand to 40% to 50% above pregnancy volumes by 32 to 34 weeks' gestation.^{13,14} Plasma volume expands even more with multiple gestations. The total body water (TBW) increases by 8 L; 40% of this increase can be attributable to the mother and 60% to the fetal-placental unit. This increase in TBW necessitates larger loading doses of water-soluble drugs (e.g., aminoglycosides) because of the increase in volume of distribution (V_d). A decrease in the peak serum concentration (C_{max}) would be expected.

Plasma albumin concentrations decrease during pregnancy, mostly because of dilution by the increased plasma volume.^{13,14} Albumin concentrations may be decreased because of decreased synthesis or increased catabolism.¹³ In addition, increased concentrations of steroid and placental hormones may decrease protein-binding sites for drugs.¹⁵ These changes in protein binding generally result in decreased protein binding, increased free fraction (f_u) of drugs, and increased clearance of drugs when clearance is dependent on f_u (e.g., valproic acid, carbamazepine).¹⁶ When both f_u and intrinsic clearance are increased as is the case with increased cytochrome P450 enzyme activity, both the total and free concentrations are decreased (e.g., phenytoin, phenobarbital).¹⁶ Total protein and α_1 -acid glycoprotein concentrations remain fairly unchanged.

Metabolism

Protein binding, activity of hepatic enzymes, and liver blood flow determine the hepatic clearance of drugs. Increases in estrogen and progesterone during pregnancy affect the hepatic metabolism by stimulating or decreasing different hepatic enzymes of the cytochrome P-450 system.¹⁷ CYP3A4 and CYP2D6 activities are increased during pregnancy, which results in the increased metabolism of certain drugs such as phenytoin.^{14,17} On the other hand, CYP1A2, xanthine oxidase, and *N*-acetyltransferase activity are decreased, resulting

in reduced hepatic elimination of drugs such as theophylline and caffeine.^{15,16,18} The clearance of caffeine can be decreased by 70%.¹⁸ Hepatic blood flow, as a percentage of the cardiac output, is decreased; however, the rate (L/min) remains unchanged.¹³ The activity of nonhepatic enzymes (e.g., plasma cholinesterase) is also decreased.¹⁶ The extent of effect on drug therapy of these hepatic physiologic changes during pregnancy is difficult to quantify.

Elimination

The glomerular filtration rate (GFR) begins to rise in the first half of the first trimester and increases by 50% by the beginning of the second trimester.¹⁵ Renal blood flow also increases by 25% to 50% early during gestation. As a result, renal drug excretion (e.g., β -lactams, digoxin, enoxaparin) can increase.^{14,18} This increase in GFR necessitates dosage adjustments up to 20% to 65% for renally excreted drugs throughout pregnancy to maintain therapeutic concentrations.¹⁷ The increased cardiac output and regional blood flow (e.g., renal blood flow), primarily are caused by increased stroke volume and increased heart rate, which can increase drug distribution and drug excretion.

During pregnancy, the serum creatinine concentration is lower because of the increased GFR, resulting in normal serum creatinine values of 0.3 to 0.7 mg/dL in the first and second trimesters.¹⁹ A normal value for serum creatinine in nonpregnant adults is 0.6 to 1.2 mg/dL.¹⁹ Similar changes occur with serum urea nitrogen and uric acid concentrations. These differences have important implications when assessing renal function in a pregnant patient. A serum creatinine indicative of normal renal function in a nonpregnant woman may be indica-

tive of renal insufficiency in a woman who is pregnant in her third trimester.

Placental–Fetal Compartment Effect

Maternal and fetal drug concentrations are dependent on the amount of drug that crosses the placenta, the extent of metabolism by the placenta, and fetal distribution and elimination of drug (Fig. 46-2).¹⁴ Diffusion across the placenta is the main mechanism of drug transfer giving nonionized lipophilic substances easy passage and making less lipid soluble ionized substances more difficult to cross.¹⁴ Highly protein bound or large molecular weight drugs (e.g., heparin and insulin) do not cross the placenta. Both the immature fetal liver and placenta can metabolize drugs. Fetal drug accumulation can be problematic secondary to limited metabolic enzymatic activity along with the concern that approximately half of blood flow from the umbilical vein bypasses the fetal liver and goes to the cardiac and cerebral circulations.¹⁴ Another mechanism that can also lead to prolonged effects of drugs in the fetal compartment is ion trapping. This phenomenon occurs because the fetal plasma pH is more acidic than the maternal plasma, causing weak bases (e.g., usually nonionized and lipophilic substances) to diffuse across the placental barrier and become ionized in the more acidic fetal blood. The net effect is movement of drugs from the maternal to fetal compartment.¹⁴ This equilibrium between the maternal–fetal compartment becomes important when therapeutic fetal drug concentrations are desired (e.g., digoxin therapy for intrauterine fetal arrhythmias). Drugs are eliminated by the fetus primarily through diffusion back to the maternal compartment. As the fetal kidney matures, metabolites of drugs are excreted into the amniotic fluid.¹⁴

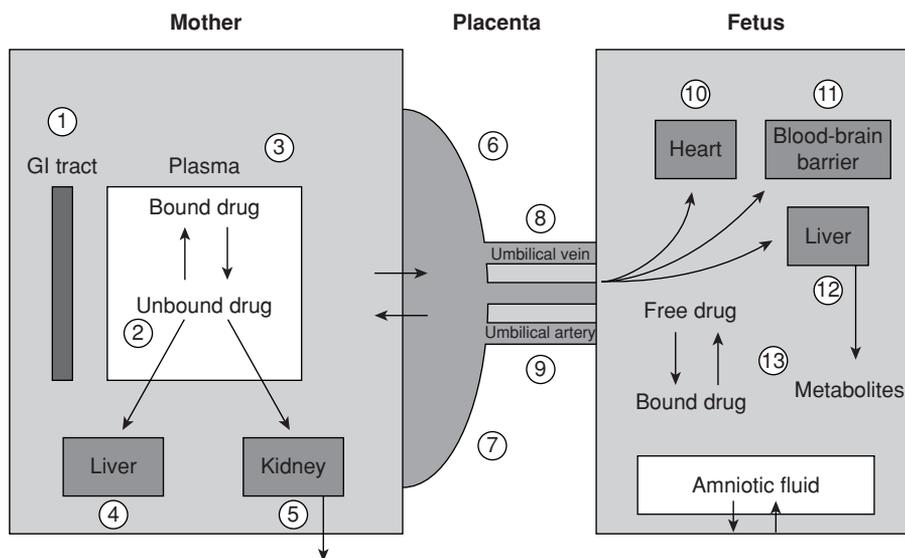

FIGURE 46-2 Drug disposition in the maternal–placental fetal system. The factors affecting the pharmacokinetics and drug effects on mother and fetus are (1) altered maternal absorption; (2) increased maternal unbound drug fraction; (3) increased maternal plasma volume; (4) altered hepatic clearance; (5) increased maternal renal blood flow and glomerular filtration rate; (6) placental transfer; (7) possible placental metabolism; (8) placental blood flow; (9) maternal–fetal blood pH; (10) preferential fetal circulation to the heart and brain; (11) undeveloped fetal blood–brain barrier; (12) immature fetal liver enzyme activity; and (13) increased fetal unbound drug fraction. GI, gastrointestinal. From reference 292, with permission.

VITAMINS AND MINERALS

3. What vitamin and mineral supplementation would you recommend for S.C. and when should she begin taking these products?

A balanced diet that provides S.C. with multiple B vitamins, oil-soluble vitamins (A, E, D, and K), folic acid, and minerals (iron, calcium, phosphorus, magnesium, iodine, zinc) should be encouraged. S.C. should be started on a prenatal multivitamin if she has not yet started taking one. Prenatal vitamins should be taken months before conception to ensure that proper nutritional requirements are met during critical periods of organogenesis and fetal growth.

Iron Requirements

Iron requirements increase during pregnancy because of maternal blood volume expansion, fetal needs, placenta and cord needs, and blood loss at time of delivery.²⁰ Maternal iron deficiency can cause anemia during infancy, spontaneous abortion, premature delivery, and delivery of a low-birth-weight infant.²⁰

A woman needs about 18 to 21 mg of iron/day during pregnancy; the body compensates by increasing iron absorption from the GI tract by about 15% to 50%.²⁰ The average diet of women in the United States does not meet these requirements because only about 6 mg of iron are absorbed from 1,000 kcal of food. In addition, some women may already have inadequate body stores of iron before pregnancy. For these reasons, the Food and Nutrition Board of the National Research Council recommends a daily elemental iron supplementation of 30 mg during the second and third trimesters of pregnancy.²¹ Prenatal vitamins usually contain 30 to 60 mg of elemental iron. Women with iron deficiency anemia should be given 60 to 120 mg of elemental iron daily. Iron deficiency anemia during pregnancy generally is associated with a hemoglobin and hematocrit <11% and <33%, respectively, during the first and third trimesters or below 10.5% and 32%, respectively, during the second trimester. Anemic women are more likely to suffer adverse effects from blood loss during delivery, hemorrhage secondary to other causes, or infections after delivery.²²

S.C.'s hemoglobin and hematocrit should be assessed now and again at 26 to 28 weeks' gestation. If her hemoglobin and hematocrit are normal, she will not need more iron than what is already available in a prenatal vitamin.

Folate Requirements

Folic acid is essential in the synthesis of DNA and RNA. Pregnant women who take 0.4 to 0.8 mg of folic acid daily during the first trimester of pregnancy are significantly less likely to have a child with neural tube defects (NTD), such as spina bifida and anencephaly.^{23,24} NTD can lead to stillbirth, neonatal death, or serious disabilities. Approximately 4,000 pregnancies in the United States are affected by NTD each year.²⁵

Neural tube defects can develop within the first month of pregnancy at a time when many women are unaware of their pregnancy. More than half of pregnancies in the United States are unplanned.^{24,25} In 1992, the US Public Health Service recommended that all women with child-bearing potential should consume 0.4 mg/day of folic acid to reduce the risk of an NTD-affected pregnancy.²⁴ If this practice were implemented in the United States, the incidence of NTD could possibly be reduced by 50%.

It may be difficult to meet the recommended daily allowance (RDA) for folic acid because foods contain only a small amount of this vitamin; overcooking and high fiber diets also can reduce the amount of available folic acid from food.²⁰ Most prenatal vitamins contain 0.8 to 1 mg of folic acid.

Folic acid supplementation is especially important in women with a history of infants born with NTD. Women who have had an NTD-affected pregnancy should receive genetic counseling because they have a 2% to 3% risk of having another such outcome. Women with previous NTD-affected pregnancies, who plan another pregnancy, should take 4 mg/day of folic acid at least 1 month before conception and through the first 3 months of pregnancy.²⁶

Women who require 4 mg/day of folic acid should be prescribed folic acid tablets as an addition to combination prenatal multivitamins (which contain folic acid), rather than just increasing the number of multivitamin tablets. When several fixed-combination multivitamin tablets are taken daily, the mother could be exposed to a potentially teratogenic dose of vitamin A. High doses of folic acid do not prevent NTD better than 0.4 mg/day in women without a previous history of NTD-affected pregnancies and may complicate the diagnosis of a B₁₂ deficiency.²⁴

S.C. should be counseled about the risks for NTD. She should receive adequate folic acid during the remainder of her pregnancy from a daily prenatal vitamin.

Calcium Requirements

Calcium is needed during pregnancy for adequate mineralization of the fetal skeleton and teeth, especially during the third trimester when teeth are formed and skeletal growth is greatest.²⁰ The RDA for calcium during pregnancy is 1,200 mg/day.²⁰ Large maternal stores can provide calcium if dietary intake is inadequate; however, depleting maternal stores may put S.C. at risk for osteoporosis later in life. Foods rich in calcium (e.g., milk, cheese, yogurt, legumes, nuts, dried fruits) or calcium supplements can be used to meet the calcium RDA.¹⁵

COMMON COMPLAINTS OF PREGNANCY

Nausea and Vomiting

4. Now S.C. is 10 weeks pregnant, and the nausea and vomiting has worsened. How long is her nausea and vomiting likely to last?

Nausea and vomiting during pregnancy (NVP) is a common condition occurring in approximately 50% to 80% of pregnancies, during weeks 5 to 12 of gestation.²⁷ For most women, NVP is a self-limiting condition that resolves after the first trimester with no long-term detrimental effect on the fetus.²⁸ The effects of NVP can have an impact on a woman's daily activities, work productivity, and quality of life. Studies estimate \$130 million per year is spent on the hospitalization for severe NVP.²⁸ The cause of NVP is unknown, but is most likely multifactorial including hormonal, psychological, and neurologic factors.^{28,29} Changes in hormonal levels of estrogen, progesterone, and hCG have been implicated as a possible cause of NVP.^{28,29} Mild to moderate NVP has been associated with lower rates of miscarriage, preterm delivery, and stillbirth.³⁰

Severe NVP can persist in less than 1% of pregnancies leading to a condition called *hyperemesis gravidarum*, which can

lead to detrimental effects on the mother and fetus.^{29,30} Weight loss of >5% of prepregnancy weight, ketonuria, and electrolyte abnormalities are associated with this condition. Treatment of hyperemesis gravidarum often requires hospitalization for parental fluid administration, electrolyte replacement, vitamin supplementation, and antiemetic therapy.²⁸ Metabolic acidosis, ketosis, hypovolemia, electrolyte disturbances, and weight loss may ensue if patients are not treated.²⁸ Reductions in lower esophageal pressure, gastric peristalsis, and gastric emptying may worsen nausea and vomiting.

S.C. may be evaluated for other causes of nausea and vomiting if her symptoms persist (e.g., gastroenteritis, cholecystitis, pancreatitis, hepatitis, peptic ulcer disease, pyelonephritis, and fatty liver of pregnancy).²⁸

Nonpharmacologic Management

5. How should S.C.'s NVP be managed?

Most mild forms of NVP can be managed with psychological support, and lifestyle and dietary changes.^{28,29} Eating smaller frequent meals consisting of a low-fat, bland, and dry diet (e.g., bananas, crackers, rice, toast), avoiding spicy and highly aromatic foods, and eliminating pills with iron may alleviate some of the symptoms.²⁸ Meals high in protein were more likely to alleviate NVP than carbohydrate or fatty meals.²⁹ Rest and avoidance of sensory stimuli that contribute to the effects of NVP can also be helpful.²⁸

Pharmacologic Management

6. S.C. does not respond to nonpharmacologic treatment of her nausea and vomiting. What antiemetic would be appropriate for her?

Antiemetics are indicated for the treatment of moderate to severe nausea and vomiting that fails to respond to nonpharmacologic interventions or when the nausea or vomiting threatens the mother's metabolic or nutritional status (e.g., hyperemesis gravidarum). Traditionally, medications for NVP have been avoided during the first trimester because of fear of the possible teratogenic effects. Most antiemetic therapies (e.g., antihistamines, multivitamins, phenothiazines) are classified in pregnancy category B or C as listed in Table 46-1. The goal of antiemetic therapy is to choose an effective medication to improve a woman's quality of life by maintaining her nutrition and hydration needs, while ensuring fetal safety.

Doxylamine with pyridoxine (vitamin B₆) can be considered first-line therapy for the treatment of NVP.²⁹ This combination, formerly known as Bendectin, was commercially available from 1958 to 1983 and withdrawn from the market owing to claims of teratogenicity.²⁹ Subsequently, a meta-analysis including 17,427 first-trimester exposures failed to find an association between the medication and an increased risk of malformations.³¹ Several randomized, controlled trials have demonstrated its effectiveness in reducing NVP.²⁸ Because of its safety and efficacy profile, doxylamine and pyridoxine are still considered a first-line therapy and are available separately as over-the-counter products.^{28,29}

Other antihistamine H₁ receptor blockers (e.g., diphenhydramine, hydroxyzine, meclizine) have been studied for NVP.²⁷⁻²⁹ The safety of antihistamines was supported in a meta-analysis including >200,000 first-trimester exposures,

Table 46-1 Medications Used for Nausea and Vomiting during Pregnancy

| Drug | Dose | Pregnancy Category |
|------------------|---|--------------------|
| Pyridoxine | 10–25 mg PO three to four times daily | A |
| Doxylamine | 12.5–25 mg PO three to four times daily | B |
| Diphenhydramine | 25–50 mg PO, IV, IM every 4–6 hrs | B |
| Droperidol | 0.5–2 mg IV or IM every 3–4 hrs | C |
| Meclizine | 25 mg PO every 4–6 hrs | B |
| Hydroxyzine | 25–50 mg PO every 6–8 hrs | C |
| Promethazine | 12.5–25 mg PO, PR every 6 hrs | C |
| Prochlorperazine | 5–10 mg PO every 6–8 hrs | C |
| Metoclopramide | 5–10 mg PO, IM, IV every 8 hrs | B |
| Ondansetron | 4–8 mg PO, IV every 8 hrs | B |

IM, intramuscular; IV, intravenous; PO, oral.

Category A: Controlled studies in women fail to demonstrate risk to the fetus.

Category B: Either animal studies have not demonstrated a risk and no controlled studies have been done in women, or animal studies have shown a risk that has not been confirmed in humans.

Category C: Either studies in animals have shown an adverse effect on the fetus and no controlled studies have been done in women, or no studies in women or animals are available.

Category D: There is evidence of fetal harm, but the benefit of the medication may outweigh the risk.

Category X: There is evidence of fetal harm, and no benefit of the medication outweighs the risk.

From reference 33, with permission

which did not find an increase in teratogenic risk.³² Phenothiazines are generally considered safe for both the mother and fetus if used occasionally in low doses.³³ Although there are some isolated reports of congenital malformations *in utero* with its use, most evidence examining the use of phenothiazines, such as prochlorperazine and promethazine, in NVP has not shown an increase in malformations.^{27,28} Trimethobenzamide has also been used in pregnancy to treat nausea and vomiting without observation of adverse effects in the fetus.³³

Metoclopramide can control vomiting and gastric reflux associated with pregnancy. Despite the limited safety data on metoclopramide, it is the antiemetic of choice in many European countries.^{27,29} Data supporting the use of ondansetron, a 5-hydroxytryptamine (5-HT₃) antagonist, during pregnancy is limited including only a small randomized trial and a few case reports with no malformations reported with first trimester use.²⁷ More studies are needed to confirm the safety and establish its efficacy in NVP. Limited experience with droperidol use in hyperemesis gravidarum has been documented in a small controlled trial.²⁷ Human and animal data suggest droperidol carries a low risk of major anomalies to the fetus.³³ Corticosteroids may improve the symptoms of NVP. Corticosteroid use during the first trimester is associated, however, with a small but significant risk of fetal oral clefts.²⁷

Alternative therapies (e.g., vitamin B₆, ginger root, acupuncture, acupressure) have improved NVP in small number of patients.²⁸ Intravenous (IV) fluids, total parenteral nutrition, and enteral nutrition may be needed in hyperemesis gravidarum.²⁹ S.C. may be started doxylamine and pyridoxine because of its safety and efficacy profile. Drug selection for S.C. mostly depends on the tolerability of adverse effects.

Reflux Esophagitis

7. S.C. is now 30 weeks pregnant and no longer complains of nausea or vomiting. However, now she has heartburn that worsens when she lies down. What causes reflux esophagitis in pregnancy and how should S.C. manage this problem?

Reflux esophagitis or heartburn is a normal occurrence in pregnancy affecting approximately two-thirds of women.³⁴ The enlarging uterus increases intra-abdominal pressure, and estrogen and progesterone relax the esophageal sphincter.³⁴ These two factors cause the reflux of stomach acid into the lower esophagus, producing symptoms of substernal burning worsened by eating, lying down, or bending over. Lifestyle and dietary modifications, such as eating smaller meals, avoiding late meals close to bedtime, and elevation of the head of the bed, should be tried first.³⁴ Avoidance of salicylates, caffeine, alcohol, and nicotine are encouraged to reduce the symptoms of reflux and fetal exposure to these harmful substances.³⁴

If these modifications are not successful, S.C. should try a calcium carbonate antacid. Animal studies have not shown antacids to cause teratogenic effects, and human data are limited.³³ Sodium bicarbonate can cause metabolic alkalosis and fluid overload and should be avoided.³⁴ Despite evidence of fetal toxicity with aluminum, available data suggest that usual doses of aluminum-containing medications are not harmful to the fetus of a pregnant woman with normal renal function.^{33,34} Sucralfate, which contains aluminum, appears to be safe in pregnancy. The American College of Gastroenterology has classified sucralfate as a medication with benefits that outweigh the risks when used in pregnant women.³³

H₂-receptor antagonists can be used when necessary because most studies in animals and humans have not found fetal harm with cimetidine, ranitidine, famotidine, or nizatidine.^{33,34} Proton pump inhibitors should be reserved for complicated reflux disease.³⁴ Animal data with lansoprazole have been reassuring, but few human data are available.³³ The proton pump inhibitors should be avoided during the first trimester, but preferably during any part of gestation because birth defects have been reported in animal pregnancies in which omeprazole was used.^{33,34}

PREVENTION OF RH D ALLOIMMUNIZATION

Maternal–Fetal Rh Incompatibility

8. G.G., a 34-year-old primigravida, had her ABO blood group and Rh status determined during her initial prenatal visit. She is was found to be type O, Rh-negative. Her husband is type O, Rh-positive. What are the risks associated with Rh incompatibility that could affect G.G.'s unborn?

Blood group incompatibility between a pregnant woman and her fetus can result in alloimmunization of the mother and hemolytic anemia in the fetus. When a woman is exposed during pregnancy, labor, or delivery to a fetal erythrocyte antigen (i.e., AB, Rh-complex) that is not found on her own erythrocytes, she forms antibodies against that antigen. This is referred to as *alloimmunization*. Antibodies of the IgG class cross the placenta and can interact with the fetal erythrocyte antigens, resulting in their destruction and leading to hemolytic disease of the fetus and newborn (HDN). Most serious cases of HDN

are caused by Rh alloimmunization involving the D antigen. The other four alleles of the Rh gene complex code for the antigens C, c, E, and e. They are also serious, but less common, causes of alloimmunization.³⁵

An Rh D-negative mother becomes immunized after exposure to fetal erythrocytes that carry the D antigen. The likelihood of having an Rh D-positive offspring is determined by whether an Rh D-positive father is homozygous or heterozygous for the D antigen. If the father is homozygous for the D antigen, all of his offspring will be D positive (Rh-positive). If he is heterozygous for the D antigen, then there is a 50% chance that his offspring will be Rh-positive.

Pregnant women can produce detectable IgG antibodies to Rh antigens within 6 weeks to 6 months.³⁶ These antibodies can cross the placenta during subsequent pregnancies and destroy fetal Rh D-positive red blood cells (RBC). Of Rh D-negative women, 175% will become alloimmunized during a term pregnancy, with most cases occurring at the time of delivery.³⁷ Approximately 1% to 2% of women will, however, become sensitized from antepartum fetomaternal hemorrhage, generally in the third trimester.³⁸ As little as 0.1 mL of blood can immunize a human. A concomitant ABO incompatibility between an Rh D-positive fetus and the Rh D-negative mother decreases the chance of alloimmunization.³⁷ This is because the ABO-incompatible RBC are rapidly hemolyzed and sequestered in the liver, wherein a lower potential for antibody production exists.

The severity of Rh-associated HDN or erythroblastosis fetalis depends on the concentration of maternal antibodies. The placental transfer of large amounts of antibody can cause substantial erythrocyte destruction. This initially results in anemia and hyperbilirubinemia with compensatory extramedullary erythropoiesis (e.g., liver, spleen). In severe hemolytic diseases, the fetus might develop hepatosplenomegaly, portal hypertension, edema, ascites, and hepatic and cardiac failure. The clinical presentation of profound anemia, anasarca, hepatosplenomegaly, cardiac failure, and circulatory collapse is termed *hydrops fetalis*.

The severity of Rh-associated HDN generally worsens with each pregnancy in the alloimmunized mother if her fetus is Rh positive. Thus, it is important to discuss the consequences of alloimmunization with any woman who is known to be alloimmunized and wishes to have more children in the future.

Rh₀(D) Immunoglobulin

9. What interventions should be undertaken to prevent G.G. from becoming alloimmunized?

Antepartum Prophylaxis

G.G. should have antibody screens at the beginning of each pregnancy, and postpartum. Although the American Association of Blood Banks recommends that an antepartum screen should also be obtained at 28 weeks, the cost-effectiveness of such screening has not been studied and it is estimated that sensitization before 28 weeks occurs at a rate of <0.18%. Therefore, the American College of Obstetrics and Gynecology (ACOG) has suggested that the decision to obtain a third-trimester antibody screen should be dictated by individual circumstances.³⁹ As pregnancy progresses, both the incidence

and the degree of fetomaternal hemorrhage increase. Administering Rh_o(D) immune globulin to G.G. before or shortly after exposure to fetal Rh D-positive erythrocytes will prevent her from becoming alloimmunized. Giving Rh_o(D) immune globulin at 28 weeks' gestation has been shown to decrease the antepartum sensitization rate from approximately 2% to 0.1%.³⁸ One mechanism by which Rh_o(D) immune globulin might prevent sensitization is by suppression of the primary immune response to the D antigen.³⁶ The anti-D immune globulin binds the D antigen, and this complex is filtered by the spleen and lymph nodes whereby it inhibits D antigen-specific B cells from proliferating.

Postpartum Prophylaxis

A second dose of Rh_o(D) immune globulin should be repeated within 72 hours of delivery. A larger dose is needed if a large transplacental bleed occurs at the time of delivery (0.4% of cases). Therefore, all Rh_o(D)-negative women who deliver an Rh_o(D)-positive newborn should be tested to detect fetal RBC in maternal blood (e.g., Kleihauer-Betke test) to calculate the correct dose of Rh_o(D) immune globulin. If a woman at risk for sensitization has not been given Rh_o(D) immune globulin within 72 hours, she should still be treated as soon as possible as it has been demonstrated that protection can be seen in some individuals up to 13 days after exposure to Rh positive red cells.⁴⁰

Adverse Effects Rh(D) Immune Globulin

The plasma from which immune globulin is obtained is tested for viral infections and the manufacturing process used to produce Rh_o(D) immune globulin inactivates viruses such as human immunodeficiency virus (HIV), hepatitis B virus (HBV), and hepatitis C virus (HCV).^{36,39} Adverse reactions associated with the use of anti-D immune globulin are rare. Pain and swelling at the injection site and rash are the most common adverse reactions.³⁶ Hypersensitivity reactions such as anaphylaxis, although rare, can occur owing to a small amount of IgA in the product.

Prophylaxis for First- and Second-Trimester Events and Procedures

10. G.G. will undergo amniocentesis at 16 weeks' gestation. Will she need a dose of Rh_o(D) at that time?

Rh_o(D) immune globulin should be given after all clinical events (e.g., spontaneous abortion) or procedures (e.g., abortion, amniocentesis, fetal blood sampling, or chorionic villus sampling) in which fetomaternal hemorrhage is a risk in an Rh-incompatible pregnancy. Although little evidence supports the need for prophylaxis in the early first trimester, adverse effects are rare and potential benefits are thought by most experts to outweigh the risks.⁴¹ Although a 50-mcg dose is available for first trimester use (e.g., chorionic villus sampling or abortion), many hospitals do not stock this dose and so a 300-mcg standard dose is often given.

Length of Protection

11. G.G. had an amniocentesis at 16 weeks for which she received Rh_o(D) IGIM 300 mcg IM. Will she need another dose at

28 weeks' gestation? How long will this dose protect G.G. against alloimmunization?

G.G. will still need a dose of 300 mcg repeated at 28 weeks' gestation and within 72 hours postpartum if her infant is Rh_o(D)-positive. The half-life of Rh_o(D) immune globulin is approximately 24 to 25 days.³⁹ Without a large fetomaternal hemorrhage, a standard dose of 300 mcg will protect against alloimmunization for up to 12 weeks. If >12 weeks have lapsed between receipt of anti-D immune globulin and delivery, many practitioners recommend administering another antepartum dose.^{36,39}

Failure of Immunoprophylaxis

12. What are the most common reasons for Rh D alloimmunization during pregnancy?

The most common reasons for Rh D alloimmunization are (a) failure to give a dose of anti-D immune globulin at 28 weeks' gestation; (b) failure to give Rh_o(D) immune globulin in a timely manner postpartum to women who have delivered an Rh_o(D)-positive or untyped fetus; and (c) failure to recognize clinical procedures and situations that increase maternal risk for alloimmunization (i.e., amniocentesis, abortions).³⁵

Thus, G.G. should be told that with proper prophylaxis with anti-D immune globulin, there is little chance for her to become alloimmunized. She need not worry about her present pregnancy or future pregnancies.

DIABETES MELLITUS

Diabetes mellitus is the most common maternal medical complication during pregnancy. Diabetes during pregnancy can be detected before or during pregnancy and can be separated in two groups: (a) *pregestational diabetes*, which includes women who have been diagnosed before pregnancy with either insulin-dependent or insulin-independent diabetes mellitus or (b) *gestational diabetes mellitus* (GDM) defined as carbohydrate intolerance first detected during pregnancy.⁴²

More prevalent than pregestational diabetes, GDM accounts for >90% of diabetes cases during pregnancy and affects approximately 4.4% of live births each year.^{43,44} More than half of women with GDM will go on to develop type 2 diabetes later in life.⁴³ Some believe that GDM is a diagnosis of type 2 diabetes that has been discovered during pregnancy.⁴²

Pregestational diabetes accounts for the remaining 10% of cases. In the United States, >8 million women have pregestational diabetes affecting about 1% of live births each year.⁴³ Most women with pregestational diabetes have type 2 diabetes characterized by peripheral insulin resistance and relative insulin deficiency. The incidence of type 2 pregestational diabetes has been rapidly rising in the past decade, most likely because of the increasing prevalence of obesity.^{42,43} In contrast to type 2 diabetes, type 1 diabetes is characterized by complete insulin deficiency resulting from autoimmune destruction of pancreatic β -cells. Less than 0.5% of all pregnancies in the United States are complicated by type 1 diabetes.⁴⁵

Fluctuating glucose levels during the first trimester may be the first signs of pregnancy for women with pregestational diabetes owing to increased insulin resistance and reduced sensitivity to insulin action. Placental hormones (e.g., human

Table 46-2 Modified White's Classification of Diabetes During Pregnancy

| <i>Class Gestational Diabetes Mellitus</i> | <i>Criteria</i> |
|--|--|
| A ₁ | Diagnosed during pregnancy Controlled by diet and exercise |
| A ₂ | Diagnosed during pregnancy Requires use of medication therapy (i.e., insulin) along with diet and exercise |
| Pregestational Diabetes Mellitus | |
| B | Age of onset ≥ 20 yrs Duration of disease < 10 yrs Absence of vascular disease |
| C | Onset of age between 10 and 19 yrs Duration of disease between 10 and 20 yrs Absence of vascular disease |
| D | Onset of age < 10 yrs Duration of disease ≥ 20 yrs Background retinopathy observed Hypertension |
| F | Nephropathy (> 500 mg/day proteinuria) |
| H | Arteriosclerotic heart disease |
| R | Proliferative retinopathy or vitreous hemorrhage |
| T | After renal transplantation |

From references 42 and 46 with permission.

placental lactogen, progesterone, prolactin, placental growth hormone, and cortisol) are thought to be responsible for the increase in insulin resistance during pregnancy.⁴³ The ACOG classifies diabetes in pregnancy according to the White Classification, modified to include gestational diabetes according to glycemic control.⁴² The White Classification relies on age at onset, duration of diabetes, and presence of vascular complications for patient classification (Table 46-2).^{42,46}

Pre-existing Diabetes Mellitus

Fetal and Infant Risks

13. K.H., a 27-year-old, 60-kg, woman known to have type 1 diabetes since age 12, has married recently and wishes to have children. She has been conscientious in her diabetes care and self-monitors her blood glucose concentrations with a glucometer. Over the past month, her fasting blood glucose (FBG) concentrations have ranged from 90 to 140 mg/dL. Today, her FBG and HbA_{1c} laboratory results are 134 mg/dL (normal, 70–110) and 7.8% (normal, 4.5–6.5), respectively. Her blood pressure (BP) is 145/94 mm Hg, renal function is normal, serum creatinine is 0.8 mg/dL (normal, 0.6–1.2), and no proteinuria. K.H. reports tingling and pain in her toes. Her current human insulin regimen consists of a combination of 16 U of isophane insulin (NPH) and 8 U of regular insulin 30 minutes before breakfast, and 8 U of NPH and 4 U of regular 30 minutes before supper. How will diabetes affect the health of a child she would like to conceive?

Perinatal mortality for infants of diabetic mothers has declined dramatically with strict maternal metabolic control, improved fetal surveillance, and neonatal intensive care.⁴⁷ Fetal and neonatal mortality rates are approximately 2% to

4%, and the risk of spontaneous abortion in well-controlled type 1 diabetics is equal to that of women without diabetes.⁴⁸ The incidence of stillbirth is greatest after 36 weeks' gestation in women with poor glycemic control, fetal macrosomia (see below), maternal vascular disease, ketoacidosis, or pre-eclampsia.⁴²

The leading cause of perinatal mortality is major congenital anomalies that occur in 6% to 12% of infants born to mothers with diabetes. The major malformations observed are usually neural tube defects and other anomalies involving the cardiac, renal, and GI systems, and rarely caudal regression syndrome.⁴³ Many of these congenital anomalies occur before the seventh week of gestation, a time when organogenesis is occurring.⁴⁹ The risk of giving birth to an infant with a major congenital anomaly correlates with the degree of glycemic control during the time just before and the 2 months after conception.^{42,47} A direct correlation exists between higher glycosylated hemoglobin levels and increased frequency of anomalies. Women with higher HbA_{1c} values during this time have a significantly higher incidence of infants with anomalies compared with women with HbA_{1c} closer to the normal range.⁴⁸ The risk of fetal anomalies increases dramatically to 20% to 25% when HbA_{1c} levels are near 10%.⁴³ HbA_{1c} levels $> 12\%$ are associated with the same risk of anomalies as infants exposed to known teratogens such as thalidomide, isotretinoin, or alcohol during organogenesis.^{33,50} HbA_{1c} values up to 1% above normal, however, are associated with rates of spontaneous abortions and congenital malformations similar to those of nondiabetic pregnancies.⁴⁷

Macrosomia, defined as birthweight > 4 kg, occurs in 20% to 25% of pregnancies complicated by diabetes. It is thought to be caused in part by fetal hyperglycemia and hyperinsulinemia.⁴² Fetal hyperglycemia occurs when glucose crosses the placenta and subsequently stimulates fetal pancreatic β -cells to release excessive insulin. Hyperinsulinemia can promote excessive fetal growth in adipose tissue causing disproportionate fat concentration around the shoulders and chest, doubling the risks of trauma (e.g., shoulder dystocia) during vaginal delivery.⁴³

Infants of diabetic mothers (IDM) also are at increased risk for prolonged hypoglycemia after delivery, respiratory distress syndrome (RDS), hypocalcemia, polycythemia, and hyperbilirubinemia during the neonatal period.⁴³

K.H. should be informed that tight glucose control, especially early in the first trimester, will maximize her chance of having a healthy baby. She should be educated before pregnancy about the healthy practices she can institute now to improve a successful pregnancy outcome.

Maternal Risks

14. K.H. wants to know what health risks she might incur from becoming pregnant and what measures could minimize these risks.

A pre-pregnancy assessment, including a history and physical examination, is necessary to determine the risks or contraindications to pregnancy for K.H. She should be evaluated for ischemic heart disease, neuropathies, or retinopathy, and her renal status must be assessed.⁴⁷ Pregnancy can exacerbate the vascular complications of diabetes. For instance, diabetic retinopathy can worsen if strict glycemic control is

implemented quickly in pregnant women with proliferative retinopathy; progression to end-stage renal disease can occur in women with mild to moderate renal insufficiency (e.g., serum creatinine >1.5 mg/dL or proteinuria >3 g/24 hours; myocardial infarction may occur with preexisting symptomatic ischemic heart disease secondary to the hemodynamic changes that occur during pregnancy).⁴³ The presence of gastroparesis should be noted, because it will make controlling her glucose more difficult.⁴⁷

Controlling K.H.'s diabetes before she becomes pregnant may benefit her hypertension and neuropathies and will minimize maternal and fetal problems. Good metabolic control of her diabetes can minimize progression of her diabetes.⁴⁷

Preconception Management

15. What pregnancy interventions relative to her general health and diabetes should K.H. undertake before she attempts to become pregnant?

K.H. should be started on prenatal vitamins containing at least 400 mcg of folic acid, and re-educated about diet and glycemic control of her diabetes. Her insulin therapy should be titrated to reduce her preprandial (capillary whole blood) glucose to 70 to 100 mg/dL and her 2-hour postprandial glucose to below 140 mg/dL.⁴⁷ Good glycemic control (HbA_{1c} levels up to >1% above normal) should be achieved months before conception to minimize risks of major congenital anomalies.⁵⁰ K.H.'s current regimen may not achieve euglycemia (see Chapter 50, Diabetes Mellitus).

Her BP of 145/94 mm Hg is high and should be decreased to a diastolic BP of about 80 mm Hg to minimize risks for preeclampsia or exacerbation of her disorder. Many women with pregestational diabetes are likely on an angiotension converting enzyme inhibitor (ACEI) or angiotension receptor blocker for hypertension treatment. K.H. should consider other antihypertensives (e.g., methyldopa or calcium channel blockers) because recent studies have observed increased rates of congenital cardiac malformation associated with the use of ACEI in the first trimester.⁵¹

Treatment

16. After lowering her BP to 125/80 mm Hg with a calcium channel blocker and HbA_{1c} to 7.3% K.H. discontinues her oral contraceptive and returns to clinic 5 months later and is noted to be about 4 weeks pregnant. How should her diabetes be managed at this time?

GOALS OF THERAPY

The overall goals of treatment of K.H.'s diabetes are to reduce the maternal and fetal morbidity and mortality associated with diabetes. Treatment of diabetes (Chapter 50, Diabetes Mellitus), should include dietary management, appropriate maternal weight gain, insulin therapy to normalize glycemic control, and exercise.

DIETARY MANAGEMENT

The goals of dietary management for diabetes during pregnancy are directed at ensuring fetal growth and development, appropriate maternal weight gain, and normalizing maternal glucose concentrations. Patients often benefit from individualized diets developed by a dietitian.^{47,49} Neonatal macrosomia has been associated with high postprandial glucose levels;

therefore, a reduction in postprandial hyperglycemia is an important goal.⁵²

INSULIN THERAPY

Insulin is the hypoglycemic of choice during pregnancy because it does not cross the placenta and has an established safety record for both mother and fetus.^{33,43} The goal with insulin therapy is to imitate the glucose levels of a healthy pregnant woman.

Insulin requirements may vary, depending on the trimester. The first trimester is characterized by unstable diabetes, followed by a stable period.⁴² During the first trimester, glucose and gluconeogenic substances in the blood are taken up by the fetus, which can lead to a decrease in maternal insulin requirements and increased episodes of hypoglycemia. On average, insulin dosages range from 0.7 to 0.8 U/kg/day in the first trimester.⁴³ If K.H. experiences nausea and vomiting during this time, glycemic control may be unstable and should be monitored closely. At about 24 weeks' gestation, insulin requirements begin to increase to 0.8 to 1 U/kg/day and insulin doses may need to be adjusted every 5 to 10 days.⁴³ These needs continue to increase during the third trimester to 0.9 to 1.2 U/kg/day, which may be twice as much as the pregnancy dose, in part, because of the placental hormones (i.e., lactogen, prolactin, estrogen, and progesterone), which antagonize the action of insulin.^{42,43} Weight-based dosing may not accurately assess the insulin requirements in all pregnant women, especially in the obese population. Insulin regimens must be individualized for each patient, taking into consideration their educational level, compliance, and schedule constraints. Dosage adjustments must take into account the level of activity, meal plan, and other factors (e.g., steroid use, stress, infections) that may affect glucose control. Some women may be admitted into the hospital in the first trimester to (a) rapidly gain glucose control, (b) accurately assess their insulin requirements, and (c) institute an individualized insulin regimen under careful monitoring of blood sugars.⁴²

An insulin regimen with three to four daily injections is most successful at maintaining adequate glucose control. Biosynthetic human insulin (e.g., regular and NPH insulin) is the usual treatment of choice in pregestational diabetes mellitus because of its chemical, biological, and immunological equivalency to pancreatic human insulin. These insulins have the most established safety profile during pregnancy, but they require more stringent timing of meals during the day.

Recent additions of rapid and long-acting insulin analogs (e.g., lispro, aspart, glargine) have sparked interest in their use during pregnancy. Insulin analogs are genetically engineered by recombinant DNA technology and usually differ by a few amino acids from human insulin.⁵² Concerns about insulin analog use during pregnancy include teratogenicity, placental drug transfer, and antibody formation.⁵² The use of insulin lispro (Humalog) during pregnancy is supported by several studies that found minimal passage to the placenta, an absence of antibody formation, and no adverse maternal or fetal effects noted.⁵³ Although the rapid onset of insulin lispro can increase adherence and patient satisfaction, it also may increase the incidence of hypoglycemia.⁴³ Insulin aspart (Novolog), another rapid-acting insulin analog, has not been studied as extensively as lispro and remains a pregnancy category C drug, meaning that the risk cannot be excluded.⁵² Insulin glargine (Lantus), the first long-acting insulin analog developed, allows for once

daily dosing and produces a peakless basal level of insulin. Only several case reports have examined the safety and efficacy of insulin glargine during pregnancy, making it a pregnancy category C drug.⁵²

ORAL HYPOGLYCEMICS

Oral hypoglycemics are used commonly to treat type 2 diabetes in nonpregnant women. With more than half of pregnancies being unplanned, many discover their pregnancy status while taking these medications. A switch to insulin therapy is recommended before conception, if possible, or at the time the pregnancy is confirmed because many patients have inadequate control with oral hypoglycemic agents.⁴³ Control of blood glucose levels during the preconception period and early first trimester is of utmost importance to decrease the risk of congenital malformations.^{43,50} If insulin is not started before conception, women should be counseled to stay on oral hypoglycemics to adequately control blood glucose until insulin therapy can be implemented. Often, patients will discontinue oral hypoglycemics from fear of taking any medication in pregnancy, resulting in hyperglycemia during the critical period of organogenesis.

The ACOG recommends that the use of oral hypoglycemics for the treatment of type 2 diabetes during pregnancy be individualized until more safety and efficacy data become available.⁴³ There is limited experience with oral hypoglycemic use in type 2 diabetes during pregnancy. Metformin, a biguanide, has been used during pregnancy for hyperinsulinemic insulin resistance or in the treatment of infertility in women with polycystic ovarian syndrome (PCOS).^{43,52,54} (See Chapter 47, Treatment of Menstrual and Menstrual-Related Disorders.) Metformin was shown to cross the human placenta; it was detected in cord serum levels and can potentially affect the fetal cellular function and development of the embryo.⁵² Studies are underway to determine the safety and efficacy of metformin in pregnancy. Until these studies can establish the role of metformin in pregnancy, women taking metformin should be switched to insulin therapy unless specific circumstances (e.g., high insulin requirements during second or third trimester) warrant its use.^{52,54}

BLOOD GLUCOSE AND HBA_{1c} MONITORING

K.H. should measure her glucose at fasting, before and after meals, at bedtime, if she feels symptomatic, and occasionally at 3:00 AM to rule out nocturnal hypoglycemia (i.e., about five to seven times daily). The goal of therapy is to maintain fasting glucose levels <95 mg/dL, premeal values of <100 mg/dL, 1-hour postprandial levels of 140 mg/dL, and 2-hour postprandial levels <120 mg/dL.⁴³ Adjusting therapy based on postprandial glucose levels (as opposed to preprandial levels) can lower HbA_{1c} levels and decrease the risk of macrosomia and neonatal hypoglycemia.⁴⁹ HbA_{1c} levels can be drawn at each trimester to reveal the glycemic control over the previous 3 months.⁴³

Gestational Diabetes Mellitus

Diagnostic Criteria

17. J.B. is a 22-year-old, Asian woman in the 26th week of her first pregnancy. She is 5 feet 2 inches, 75 kg (prepregnancy weight), and her BMI is 30. At her regular prenatal visit, her obstetrician recommends an oral glucose-screening test for GDM. Although

her mother has diabetes, J.B. has had no glucosuria during pregnancy. Why is J.B. at risk for GDM?

Gestational diabetes mellitus is defined as carbohydrate intolerance that develops or is recognized during pregnancy regardless of severity, necessity for treatment, time of onset, or persistence after pregnancy.^{55,56} GDM occurs in about 7% (range, 1%–14%), and the prevalence varies with the population and methods of detection.⁵⁵ Complications noted in the offspring of affected women include macrosomia, hypocalcemia, hypoglycemia, polycythemia, and jaundice.⁵⁵ Women with GDM are more likely to develop pregnancy-induced hypertensive disorders or require a cesarean delivery. They also are at risk for type 2 diabetes later, and their children have an increased risk for obesity and diabetes later in life.⁵⁵

Risk factors for GDM include age >25 years, obesity (BMI ≥ 25), family history of diabetes, previous delivery of an infant >4 kg, a history of a stillbirth, a history of glucose intolerance, or current glycosuria.^{55,56} Blacks, Hispanic, Asian, and Native-American women also are at increased risk for GDM.^{55,56} Some practitioners screen all pregnant women for GDM, whereas others do not screen low-risk women. Those considered at low risk must meet all of the following criteria: age <25 years, BMI ≤ 25 , member of a low-risk ethnic group, no history of abnormal glucose tolerance, no known diabetes in a first-degree relative, and no history of poor obstetric outcome.⁵⁵

The most common method of initial screening for GDM is the 50-g, 1-hour glucose challenge administered at 24 to 28 weeks gestation.⁵⁷ Women are instructed to drink a pure 50-g load of glucose and have their venous blood drawn. If the results are >140 mg/dL, a 100-g, 3-hour oral glucose tolerance test (OGTT) will be conducted.⁵⁷ If the results of the initial screen >200 mg/dL, most clinical practices may skip the 3-hour OGTT and obtain a fasting blood sugar level to diagnose GDM. Plasma glucose results from the 3-hour OGTT are used to diagnose GDM using either criterion. High-risk women should undergo OGTT early in pregnancy, and the test should be repeated in women who do not initially meet the diagnostic criteria for GDM.⁵⁵

J.B. is at risk for GDM because she is Asian, obese, and has a family history of diabetes. Because she is at risk for GDM, J.B. should undergo OGTT. The diagnosis of GDM is important to the mother and the fetus because of the increased risks related to fetal hypersulinemia and macrosomia.^{42,58} GDM does not have the same negative effect on pregnancy outcomes as pregestational diabetes.⁴²

Treatment

18. J.B. is screened with a 1-hour OGTT, resulting in 160 mg/dL. A 3-hour OGTT is then recommended. The results of a 3-hour test show a fasting plasma glucose of 115 mg/dL, a 1-hour of 185 mg/dL, a 2-hour of 175 mg/dL, and a 3-hour of 150 mg/dL. These results confirm that J.B. has GDM. How should she be managed?

Most women with gestational diabetes can control their glucose with dietary modifications and regular exercise; however, insulin therapy should be initiated if dietary management fails to maintain fasting plasma blood glucose concentrations ≤ 95 mg/dL, a 1-hour postprandial plasma concentration <140 mg/dL, or 2-hour postprandial plasma glucose concentrations <120 mg/dL.⁵⁷ Treatment of GDM with

insulin therapy is implemented similarly to the treatment for pregestational diabetes. An optimal insulin regimen for GDM has not been determined. The insulin regimen must be tailored specifically to the needs of the woman to successfully achieve target blood glucose levels. More recently, the role of oral hypoglycemics for the treatment of GDM has come into question. Traditionally, oral hypoglycemics have not been used during pregnancy because early animal studies implicated some agents as teratogens.⁵² The studies failed to show whether the primary teratogen was the drug itself or the effect of hyperglycemia and altered maternal metabolism.⁵² Glyburide, a second-generation sulfonylurea, has been used in several studies as an alternate treatment modality in women with GDM who have relatively mild hyperglycemia.⁵⁹ A gestational age of >30 weeks, fasting blood glucose levels, 110 mg/dL, and 1-hour postprandials <140 mg/dL are parameters that have been shown in one study to predict glyburide success in women with GDM who have failed diet therapy.⁶⁰ In a randomized trial, glyburide therapy was compared with an intensive insulin protocol in women between 11 and 33 weeks of gestation with GDM who failed to achieve target blood glucose goals with diet alone.⁵⁹ Equivalent glycemic control was achieved with treatment of glyburide or insulin therapy. In addition, both groups had similar pregnancy outcomes, including rates for cesarean delivery, preeclampsia, macrosomia, and neonatal hypoglycemia. Analysis of the cord serum of the infant did not detect any glyburide.⁵⁹ More randomized trials are needed to further determine and to better understand the role of oral hypoglycemics in pregnancy.

J.B. requires more extensive education than patients with type 1 diabetes who know about the disease before becoming pregnant. She needs to be educated about diabetes, the signs and symptoms of hyper- and hypoglycemia, and the use of a glucometer. If insulin is started, she will also need to learn about injection technique, and how to mix and store insulin. She is most likely not a good candidate for glyburide therapy because she is <30 weeks' gestation and has a fasting blood sugar level >110 mg/dL.⁶⁰

Risk of Developing Diabetes Mellitus

19. Why is J.B. at risk for developing diabetes mellitus after delivery?

Glucose tolerance normalizes after delivery for most women. Women with GDM, however, have a 17% to 63% chance of developing nongestational diabetes within 5 to 16 years.⁵⁶ The highest risk is in women who are obese, diagnosed before 24 weeks' gestation, or women who had marked hyperglycemia during or soon after pregnancy.⁴⁶ The risk of developing GDM in a future pregnancy is estimated to be 50% to 70%.

J.B. should try to minimize the potential for development of insulin resistance by exercising and maintaining a normal weight. She should also have her glucose checked with a 2-hour OGTT at her postpartum appointment 6 weeks after delivery and then at least every 3 years.⁵⁵ In addition, J.B. should be instructed about the importance of using an effective birth control method to prevent unplanned pregnancies. She also needs to schedule regular appointments with her primary care physician.

HYPERTENSION AND PRE-ECLAMPSIA

Classification and Definitions

Hypertensive disease occurs in 5% to 10% of all pregnancies and is a major cause of maternal and perinatal morbidity and mortality.⁶¹ From 15% to 24% of maternal deaths in developed countries are attributed to hypertensive disorders in pregnancy.^{62,63} *Hypertension in pregnancy* is defined as a systolic BP ≥ 140 mm Hg or a diastolic BP ≥ 90 mm Hg on two separate occasions at least 6 hours apart.

Women with pregnancy-associated hypertension can be grouped into the following categories: chronic hypertension, pre-eclampsia–eclampsia, pre-eclampsia superimposed on chronic hypertension, and gestational hypertension.⁶¹ After delivery, *gestational hypertension* is ultimately delineated as either (a) transient hypertension of pregnancy if pre-eclampsia is absent during delivery and BP normalizes by 12 weeks postpartum or (b) chronic hypertension if BP remains elevated.⁶¹

Chronic hypertension is defined as hypertension diagnosed before conception or before the 20th week of gestation, or hypertension persisting beyond 12 weeks postpartum.⁶¹ Hypertension noted after the 20th week of gestation might be difficult to classify, particularly if a woman has had inadequate prenatal care without appropriate BP monitoring.

Pre-eclampsia is a pregnancy-specific condition usually occurring after 20 weeks' gestation and consisting of hypertension with proteinuria.⁶¹ The signs and symptoms of pre-eclampsia can affect multiple organ systems (e.g., kidney, liver, hematologic, CNS); they are often unpredictable and can be mistaken for other disorders. Because edema is so common in normal pregnancy and is not specific, it is no longer used as a criterion for the diagnosis of pre-eclampsia. Pre-eclampsia is a consequence of progressive placental and maternal endothelial cell dysfunction, increased platelet aggregation, and loss of arterial vasoregulation.⁷ A variant of pre-eclampsia is HELLP syndrome, which consists of hemolysis (H), elevated liver enzymes (EL), and low platelet count (LP). HELLP can be also be life-threatening despite sometimes minimal proteinuria and increase in BP.⁶⁴

When women with pre-eclampsia develop seizures, the term “*eclampsia*” is applied. Women with pre-eclampsia may unpredictably progress rapidly from mild to severe pre-eclampsia and to eclampsia within days or even hours. Eclampsia is a potentially preventable complication of pre-eclampsia (see Questions 30 to 34). About 20% of women who develop eclampsia have a diastolic BP <90 mm Hg or no proteinuria.⁶⁵

The term “*gestational hypertension*” is used when BP is increased during pregnancy or is increased in the first 24 hours postpartum in a woman without signs or symptoms of pre-eclampsia and without pre-existing hypertension.⁶¹ Women with gestational hypertension are at high risk of recurrence during subsequent pregnancies.

Chronic Hypertension

Clinical Presentation

20. T.D., a 37-year-old G₁P₀, obese black woman was diagnosed with stage 1 hypertension several months before her pregnancy (BP 135 to 145 mm Hg systolic and 90 to 95 mm Hg diastolic pressure). She had no cardiovascular risk factors (i.e., smoking,

diabetes mellitus, dyslipidemias) and was prescribed a trial of lifestyle modification (i.e., weight loss and exercise). When she initiated prenatal care at 16 weeks' gestation, her BP ranged from 130 to 135 mm Hg systolic pressure and 82 to 85 mm Hg diastolic pressure. Her BP today at 28 weeks is 142/90 mm Hg. Her serum chemistry values are creatinine (Cr) 0.6 mg/dL (normal, 0.5–0.6); and uric acid (UA) 4 mg/dL (normal, 2.5–5.9). A random urinalysis did not demonstrate proteinuria. Ultrasound confirms an adequately growing fetus at 28 weeks' gestation. What is the likelihood T.D. has pre-eclampsia?

Women with chronic hypertension commonly have a normal BP during the first half of pregnancy because of the normal physiologic decline of BP during the second trimester.⁶⁶ Blood pressure usually returns to the prepregnancy level by the third trimester. T.D.'s diastolic pressure decreased from the prepregnancy levels of 90 to 95 mm Hg to 86 to 90 mm Hg during the second trimester. It is normal for T.D.'s BP to increase during the third trimester. These changes in BP make it difficult to differentiate chronic hypertension from pre-eclampsia during the second half of pregnancy in women with late prenatal care or inadequate BP monitoring. It is also difficult to diagnose pre-eclampsia superimposed on existing hypertension using BP measurements alone. A sharp increase in T.D.'s pressure of >30 mm Hg systolic or >15 mm Hg diastolic could be consistent with pre-eclampsia. Without co-existing proteinuria (≥ 0.3 g/24-hour or $\geq 1+$ in a random urine) or evidence of renal dysfunction, a diagnosis of pre-eclampsia would be a reach.⁶¹ T.D. has no proteinuria, and a normal serum creatinine and serum uric acid. It is unlikely that T.D. has pre-eclampsia at this time.

Risk Factors for Pre-eclampsia

21. What risk factors does T.D. have for developing pre-eclampsia?

Pre-eclampsia occurs most commonly during the first pregnancy (two-thirds of cases). Obesity and increasing maternal age are risk factors.⁶⁷ Chronic diseases that increase the risk for pre-eclampsia include diabetes mellitus or insulin resistance, and renal disease. Pregnancy-associated risk factors include multifetal gestations, urinary tract infection, certain fetal chromosomal anomalies, and hydatiform moles. A family history of a sister or mother with pre-eclampsia significantly increases the risk of developing pre-eclampsia. Women with previous pre-eclampsia are at high risk for recurrence in subsequent pregnancies, particularly if it developed before 30 weeks' gestation.^{67,68} In addition to her age and obesity, chronic hypertension is the most significant aspect of T.D.'s medical history, which confers a 25% risk of developing superimposed pre-eclampsia.⁶⁹

MONITORING

22. What subjective and objective data should be monitored in T.D. for the development of pre-eclampsia?

T.D. should have her BP monitored frequently. If protein is detected in a random urinalysis, then a 24-hour urine collection for protein and creatinine can be repeated to determine accurately the degree of proteinuria and severity of disease.⁶¹ Periodic ultrasounds should be obtained to assess fetal growth because intrauterine growth retardation (IUGR) is common in pregnant women with chronic hypertension.

T.D. should be taught to recognize and immediately report all signs and symptoms of pre-eclampsia, such as nondependent edema, headaches, and visual disturbances. The latter two are signs of severe pre-eclampsia and may indicate impending eclampsia. Upper abdominal pain also can be a sign of severe pre-eclampsia, indicating hepatic subcapsular hemorrhage.⁶⁷ Because T.D. has chronic hypertension, worsening of hypertension alone may not be a reliable sign of superimposed pre-eclampsia. Proteinuria is the best indicator of superimposed pre-eclampsia in a pregnant woman with chronic hypertension and no renal disease.⁶⁵

ANTIHYPERTENSIVE DRUG THERAPY

23. Why should (or should not) T.D.'s chronic hypertension be treated with antihypertensive drugs to prevent pre-eclampsia?

The goal of antihypertensive therapy for women with chronic hypertension during pregnancy is to minimize the risks to the mother of an elevated BP without compromising placental perfusion.⁶¹ The value of treating pregnant women with chronic antihypertensive drugs remains an area of ongoing debate. A sustained diastolic BP of >100 mm Hg may cause maternal vascular damage, especially if the diastolic pressure is >105 to 110 mm Hg.⁶⁷ Morbidity is unlikely with a diastolic BP of <100 mm Hg. Therefore, many clinicians recommend treatment with antihypertensive drugs to lower diastolic pressures of >100 to 110 mm Hg.⁶¹ Treatment of a diastolic BP of <100 mm Hg should be reserved for women with chronic hypertension and target organ damage (e.g., left ventricular hypertrophy) or underlying renal disease because antihypertensive drugs can decrease placental blood flow, which might increase fetal growth restriction.^{70,71} Treatment of mild to moderate hypertension is associated with a decrease in the risk of developing severe hypertension by approximately 50%, but the overall risk of developing pre-eclampsia is unchanged.⁷² Moreover, women treated with antihypertensives were more likely to develop adverse drug effects compared with those who received placebo or were untreated. Antihypertensive therapy, however, is required to reduce the risk of cardiovascular morbidity such as heart or renal failure, and acute risk of stroke in pregnant women with severe hypertension (diastolic >110 mm Hg).

T.D. has normal renal function and her BP is <100 mm Hg; she does not need antihypertensive drug treatment at this time. If T.D. had been on drug therapy before conception, some experts would have her continue during the pregnancy.^{61,65,70} In such cases, however, the doses of the antihypertensive agents often need to be lowered or discontinued altogether to prevent hypotension because the maternal BP naturally decreases during the second trimester. The only antihypertensive drugs absolutely contraindicated during pregnancy are ACEI and angiotensin II-receptor blockers because of the association with fetal and newborn morbidity and mortality.⁷⁰ Atenolol use also should be avoided because of the reported association with a high incidence of IUGR.⁷⁰

Perinatal outcomes in women with untreated chronic hypertension who do not progress to pre-eclampsia are similar to those of the general obstetric population.⁶⁵ Although chronic hypertension is a major risk factor for pre-eclampsia, treating T.D.'s uncomplicated mild chronic hypertension is unlikely to prevent the development of pre-eclampsia.

METHYLDOPA

Methyldopa (Aldomet) is a centrally-acting α -agonist that decreases sympathetic outflow to decrease BP. It is the antihypertensive most commonly used for chronic treatment of hypertension in pregnancy in the United States. The usual starting dose of 750 to 1,000 mg/day, to be administered in three to four daily divided doses, can be increased to 2 or 3 g/day if needed. Higher doses may be needed to control BP in pregnancy.⁷³

Methyldopa, classified as category B for fetal risk, has the longest and best safety record of all antihypertensive agents during pregnancy. Despite its common use, few adverse effects have been reported in neonates exposed to methyldopa *in utero*. In addition, no congenital anomalies are associated with methyldopa.³³

Dizziness and sedation, accompanied by a loss of energy, are among the most common adverse effects reported by pregnant women.⁷³ Generally, these adverse effects occur early in therapy and tend to subside, but may recur with an increased dosage. Problems with postural hypotension usually do not occur in pregnant females.⁷³ Patients should be monitored for methyldopa-induced liver damage.⁶⁵ Other drugs used to treat hypertension in pregnancy include labetalol and calcium channel blockers. A review of drug therapies for the treatment of chronic hypertension in pregnancy is listed in Table 46-3.

Mild Pre-eclampsia**Etiology and Pathogenesis**

The causes of pre-eclampsia currently remain unknown. Although the pathogenesis begins early in pregnancy, the disease

is not clinically evident until the latter half of the pregnancy and persists until the fetus is delivered.^{7,74} Incomplete physiologic placental vascular bed changes and endothelial cell dysfunction are integral to the pathogenesis of pre-eclampsia (see Placental Physiology).

PLACENTAL ISCHEMIA

Early in a normal pregnancy, the trophoblastic migration and invasion of the uterine spiral arteries result in physiologic changes within the placental vascular bed that facilitate maximal intervillous blood flow. The physiologic changes within these spiral arteries are responsible for creating a fixed low-resistance arteriolar circuit, which increases blood supply to the growing fetus. In pre-eclampsia, these physiologic changes do not occur completely, resulting in decreased perfusion and consequently, placental ischemia.^{7,74,75}

ENDOTHELIAL DAMAGE

An intact vascular endothelium assists in preserving the integrity of vasculature, mediating immune and inflammatory responses, preventing intravascular coagulation, and modulating the contractility of the underlying smooth muscle cell.⁷⁵

In normal pregnancy, prostacyclin is increased 8 to 10 times, creating an increased ratio of prostacyclin to thromboxane A₂.⁷⁴ The biologic dominance of prostacyclin along with nitric oxide plays an important role in maintaining vasodilation throughout pregnancy. Prostacyclin may be responsible for vascular refractoriness to angiotensin II in normal pregnancy. In pre-eclampsia, the ratio of prostacyclin to thromboxane A₂ is reversed. Thromboxane A₂ is biologically

Table 46-3 Drugs For Treatment of Chronic Hypertension In Pregnancy

| Drug | Dose | Comments |
|-------------------------|---|---|
| Methyldopa | 750–1000 mg/day start, increase up to 2–3 g/day, divided in three to four doses | Longest safety record in pregnancy. Considered a first-line drug. ⁶⁶ Dizziness, sedation, and lack of energy are common symptoms, which tend to resolve. Can cause liver toxicity. Low breast milk concentrations so considered safe in breast-feeding. |
| Labetolol | 200–400 mg/day start, increase to up to 2,400 mg/day, divided in two or sometimes three doses | Combined α - and β -receptor antagonist properties. Considered a first-line drug. ⁶⁶ Increasingly preferred to methyldopa owing to fewer side effects. Neonatal effects could include bradycardia and hypotension. Low concentration in breast milk and generally considered safe in breast-feeding. ²³⁵ |
| Other β -Blockers | Various | Atenolol in particular associated with decreased placental weight and IUGR. ^{287,288} IUGR thought to be related to β -blocker–induced increased vascular resistance in mother and fetus. Atenolol, acebutolol, metoprolol, nadolol, and sotalol can have high milk-to-plasma ratios and accumulate in breast milk, creating potential risk for neonatal-blockade. ^{289,290} Propranolol found in only small amounts in breast milk and generally considered safe, but infants should be monitored for hypotension, bradycardia, and blood glucose changes. |
| Nifedipine, long acting | 30 mg/day start, increase to up to 120 mg/day, single dose | Limited pregnancy data on nifedipine or other calcium channel blockers such as verapamil, iltiazem, and amlodipine. Concentrations of nifedipine in breast milk are low and considered compatible with breast-feeding. ^{235,291} |
| Diuretics | Various | Not first-line agents, although probably safe. ⁶¹ Concern regarding potential interference with normal blood volume expansion in pregnancy. Avoid if pre-eclampsia or IUGR already present. Concentration low in breast milk, but may decrease milk production. |
| ACEI or ARB | Contraindicated | Contraindicated in pregnancy in all trimesters. Fetal renal failure when used after first trimester, resulting in oligohydramnios, limb contractures, pulmonary hypoplasia, skull hypoplasia, and irreversible neonatal renal failure. ³³ Increased risk major birth defects with first trimester ACEI exposure. ⁵¹ Minimal amounts of captopril and enalapril in breast milk and both considered compatible with breast feeding. ²³⁵ Minimal amounts of benazepril in breast milk. Limited or no data on other ACEI or ARB. |

* ACEI, angiotensin-converting enzyme inhibitor. ARB, angiotensin II receptor blocker. IUGR, intrauterine growth restriction.

dominant during pre-eclampsia, leading to increased vascular sensitivity to angiotensin II and norepinephrine.⁷⁴ The increased release of thromboxane A₂ is believed to be caused by endothelial cell dysfunction. The end result is vasospasm, which further increases endothelial cell dysfunction, and increases BP.^{7,74} Reduced activity of nitric oxide synthase and decreased nitric oxide-dependent or nitric oxide-independent endothelium-derived relaxing factor are believed to increase the vasoconstrictive potential of pressors such as angiotensin II.⁶¹

Endothelial cell dysfunction in pregnancy is thought to be caused by oxidative stress. Intermittent hypoxic and reperfusion injury that occurs as a consequence of decreased placental perfusion may increase oxidative stress.^{74,75} Endothelial damage eventually leads to the disruption of the vascular lining, which causes leaking capillary membranes, allowing fluid to leak into the interstitium.⁷⁵ In severe pre-eclampsia, this results in hypovolemia, hemoconcentration, and consequently an increase in hematocrit. The loss of plasma volume, vasospasm, and microthrombi decrease perfusion of the kidney, CNS, liver, and other organs. The loss of intravascular proteins in the urine secondary to renal damage, and through damaged epithelia, decreases plasma oncotic pressure and leads to a rapid onset of nondependent edema. The imbalance of endogenous procoagulants and anticoagulants produces platelet consumption and results in thrombocytopenia and coagulation defects.⁷⁵

Clinical Presentation

24. T.D. returns to her obstetrician 3 weeks later at 31 weeks' gestation complaining of mild hand and leg edema. She has 1+ proteinuria by dipstick and her BP is 155/102 mm Hg. An ultrasound demonstrates fetal growth restriction. Laboratory results are serum Cr 0.9 mg/dL (normal, 0.5–0.7); UA 6.0 mg/dL (normal, 2.5–5.9); aspartate aminotransferase (AST) 25 U/L (normal, 0–35); alanine aminotransferase (ALT) 16 U/L (normal, 0–35); platelets 230,000/mm³ (normal, 203,000–353,000). What signs and laboratory evidence are consistent with pre-eclampsia in T.D.? Does she have mild or severe pre-eclampsia?

T.D.'s diastolic BP is now higher than it was before her pregnancy and has increased by 12 mm Hg in the last 3 weeks. Although an increase in BP by itself is not diagnostic of pre-eclampsia, the new finding of proteinuria confirms the diagnosis. Other evidence for pre-eclampsia includes the elevated serum uric acid concentration, which is a sensitive marker for pre-eclampsia, and elevated creatinine.⁶⁷ T.D. denies headaches, visual disturbances, and abdominal pain, which are symptoms of severe pre-eclampsia. The transaminases and platelet count are normal; therefore she does not have HELLP syndrome at this time. T.D.'s clinical presentation is consistent with mild pre-eclampsia; however, a 24-hour urine collection should be obtained to measure protein excretion, quantify the urine output, and further rule out severe pre-eclampsia.

Treatment

GENERAL PRINCIPLES

25. T.D. is admitted to the hospital. The 24-hour urine protein is 500 mg/24 hours. Although fetal growth is restricted, all other fetal testing is reassuring. After 24 hours, her BP decreased to

140/95. Her platelet counts remained stable and >200/mm³ and transaminases were normal. No other signs and symptoms of pre-eclampsia were noted. How should T.D.'s mild pre-eclampsia be managed?

The delivery of the fetus is the only cure for pre-eclampsia and would be the best treatment option for T.D. if she were >weeks' gestation.⁷ T.D. has mild disease, however, and is not close to term. Her delivery should be postponed because premature delivery increases neonatal morbidity and mortality. T.D.'s fetus is somewhat growth restricted, which is common in women with chronic hypertension, with or without superimposed pre-eclampsia. If T.D.'s fetus is severely growth restricted or if subsequent fetal biophysical testing is abnormal, premature delivery would be indicated.⁶¹ Because neither of these is evident in the present circumstances, T.D. should carry her fetus under very close medical supervision. It has been suggested that continued hospitalization is appropriate for women with preterm onset of mild pre-eclampsia, such as T.D.⁶¹ This would allow for rapid intervention in case of rapid progression of disease or associated complications. Probably a role exists for outpatient monitoring of some select women with very frequent maternal and fetal monitoring, and rehospitalization for worsening disease.⁶¹

T.D. is also a candidate for administration of glucocorticoids for fetal lung maturation (see also Question 55). Bedrest in the lateral decubitus position is usually suggested and may help reduce BP and promote diuresis by decreasing vasoconstriction and improving renal and uteroplacental perfusion. T.D. should have her BP measured regularly each day. Her urine should be checked daily for protein. Liver transaminases, platelets, and creatinine should be measured periodically and whenever her clinical status changes. She also should be assessed for symptoms of severe pre-eclampsia (e.g., headaches, visual disturbances, epigastric or right upper quadrant pain). Fetal surveillance is indicated.⁶¹ One approach is to perform a modified biophysical profile twice a week and whenever maternal clinical status changes, and an ultrasound for fetal growth every 3 to 4 weeks.

Severe Pre-eclampsia

Clinical Presentation

26. T.D.'s BP for about 2 weeks ranged from 140 to 150 mm Hg systolic and 90 to 100 mm Hg diastolic with bedrest. Her proteinuria remained stable at 1+ to 2+ by dipstick. During the past 2 days T.D.'s BP started to increase again, and today her BP is 160/112 mm Hg and her urine dipstick is 3+. She complains of headaches, dizziness, and visual disturbances and has significant edema in her face, hands, legs, and ankles. T.D. is transferred to the Labor and Delivery Unit for delivery. Pertinent laboratory results are Cr 1.3 mg/dL (normal, 0.5–0.6); UA 6.7 mg/dL (normal, 2.5–5.9); AST 30 U/L (normal, 0–35); ALT 16 U/L (normal, 0–35); total bilirubin 1 mg/dL (normal, 0.1–1); platelets, 95,000/mm³ (normal, 203,000–353,000); hematocrit 38% (normal, 32.7%–36%), hemoglobin 13 g/dL (normal, 10.9–13.5); random urine protein 4+. Estimated fetal weight by ultrasound is 1,700 g, which is between the 10th and 25th percentile for a gestational age of 34 weeks. What signs, symptoms, and laboratory evidence of severe pre-eclampsia supports this diagnosis in T.D.?

T.D. has developed severe pre-eclampsia.⁶⁴ Her systolic and diastolic BP are above 160 and 112 mm Hg, respectively. She has >3+ protein in a random urine sample and her serum creatinine is >1.2 mg/dL. She complains of headaches and visual disturbances. T.D. is also thrombocytopenic as her platelet count is 95,000/mm³. Although her liver transaminases are currently normal, she may be developing HELLP syndrome, a variant of severe pre-eclampsia associated with a high incidence of maternal and perinatal morbidity and mortality. Therefore, her laboratory values should continue to be monitored even as delivery is being planned.

Complications

27. To what complications of severe pre-eclampsia would T.D. be exposed?

T.D. is at risk for cerebral hemorrhage, cerebral edema, encephalopathy, coagulopathies, pulmonary edema, liver failure, renal failure, and eclamptic seizures.^{7,65} Severe pre-eclampsia is not only dangerous to T.D., but also to her fetus because uteroplacental perfusion is compromised. T.D. requires drug treatments to both lower her BP and prevent eclampsia.

Acute Treatment of Severe Hypertension

HYDRALAZINE

28. How should T.D.'s severe hypertension be treated?

The goal of antihypertensive therapy in T.D. is to prevent cerebral complications (e.g., encephalopathy, hemorrhage).⁶⁵ Although it is important to reduce the maternal BP, it must be accomplished gradually while the fetus is *in utero* because a sudden large drop in maternal BP could result in the reduction of uteroplacental perfusion.⁶⁷ Because of the potential for fetal bradycardia during or after acute treatment of maternal hypertension, continuous fetal heart rate monitoring should be considered.

Hydralazine, a direct arterial smooth muscle dilator, has been the drug of choice for the acute treatment of severe hypertension in pregnancy.^{65,73} This drug induces a baroreceptor-mediated tachycardia and increases cardiac output, which increases uterine blood flow as the BP is lowered.⁶⁷ Hydralazine 5 mg IV over 1 to 2 minutes should be administered to T.D. and repeated in doses of 5 to 10 mg every 20 to 30 minutes to a cumulative dose of 20 mg.^{7,65}

T.D. should have repeated measurements of her BP at 15-minute intervals. Because intervillous blood flow depends on maternal perfusion pressure, the goal is to decrease the diastolic pressure to not less than 90 mm Hg.^{7,65} Lowering the maternal BP excessively may decrease uteroplacental perfusion and compromise the fetus. The onset of antihypertensive effect for hydralazine ranges from 10 to 20 minutes and duration of action ranges from 3 to 6 hours after an IV dose.⁶⁷ Therefore, doses of hydralazine should not be repeated more frequently than every 20 to 30 minutes to prevent drug accumulation.⁷³ T.D. should also be monitored for nausea, vomiting, tachycardia, flushing, headache, and tremors. Some of these hydralazine-induced adverse effects mimic symptoms associated with severe pre-eclampsia and imminent eclampsia, making it difficult for a clinician to differentiate between drug-associated and disease-related problems.⁷³ Fetal hydralazine serum concentrations are reportedly the same as or higher than maternal serum concen-

trations, but drug-associated fetal abnormalities have not been reported.³³

ALTERNATIVE ANTIHYPERTENSIVE DRUGS

29. After receiving two doses of IV hydralazine (total dose 15 mg), T.D.'s BP decreased to 150/100 mm Hg. What other antihypertensive drugs could have been used to treat her severe hypertension?

Labetalol

Labetalol (Trandate) is the second most commonly used drug to treat severe hypertension during pregnancy. It should be administered IV in increasing doses of 20, 40, and 80 mg every 10 minutes to a cumulative dose of 300 mg or until the diastolic pressure is <100 mm Hg.⁷⁶ The onset of action is within 5 minutes, and its effect peaks in 10 to 20 minutes with a duration of action ranging from 45 minutes to 6 hours.

Intravenous labetalol is as effective as intravenous hydralazine in lowering BP in patients with hypertension during pregnancy, but has fewer reported adverse effects.^{73,77} In a meta-analysis of β -blocker trials for the treatment of hypertension in pregnancy, labetalol was associated with less maternal hypotension, fewer cesarean deliveries, and no increase in perinatal mortality.⁷⁷ Labetalol also does not appear to decrease uteroplacental blood flow even with a decrease in maternal BP.⁷³ Labetalol reduces cerebral perfusion pressure, which occurs in up to 43% of women with severe pre-eclampsia, without negatively affecting cerebral blood flow.⁷⁸ Decreased cerebral perfusion pressure may prevent progression to eclampsia. It, however, should be avoided in women with asthma and heart failure.⁶¹ Labetalol has also been associated with higher rates of neonatal bradycardia and hypotension than hydralazine, but not higher rates of neonatal intensive care admission.^{79,80}

Nifedipine

Nifedipine (Procardia, Adalat) has been used in doses of 10 mg for acute treatment of severe hypertension during pregnancy because it can be given orally.⁷³ Nifedipine is effective in decreasing BP without reducing uteroplacental blood flow or decreasing fetal heart rate. Short-acting nifedipine capsules are no longer recommended for the treatment of acute hypertensive urgency, however, because of the risk of stroke or myocardial infarction, and it was never US Food and Drug Administration (FDA) approved for this indication. Immediate-release nifedipine continues to be used to treat hypertension in pregnancy, however, because this unique patient population may not be at high risk for ischemic events secondary to atherosclerotic disease.⁷⁰ Calcium gluconate or calcium chloride should be available for IV administration in the event of sudden hypotension. Caution should be used when giving nifedipine to women concomitantly treated with magnesium sulfate because these drugs have synergistic effects, causing hypotension and neuromuscular blockade.⁸¹

Several studies comparing oral nifedipine with IV labetalol in hypertensive emergencies of pregnancy have found them to be equally effective in lowering BP.^{82,83} Nifedipine lowers BP to <160 mm Hg systolic and <100 mm Hg diastolic earlier than labetalol,⁸² but it increases cardiac index⁸³ (see Chapter 20, Hypertensive Emergencies).

Eclampsia

Magnesium Sulfate Prophylaxis

30. T.D. was given magnesium sulfate 4 g IV for 30 minutes and then started on a continuous IV infusion of 2 g/hour. Labor was induced, and T.D. subsequently delivered vaginally. Why was T.D.'s drug therapy appropriate?

Magnesium sulfate was given to T.D. to prevent eclamptic seizures during labor.⁶¹ Although termination of the pregnancy is the definitive treatment for severe pre-eclampsia, the intrapartum and immediate postpartum periods are also the periods of greatest risk for eclampsia.⁶⁷ Although the incidence of eclampsia is extremely low, maternal morbidity and mortality are high.⁸⁴ In the United States, it has been usual practice to treat all pre-eclamptic women with magnesium sulfate during labor and for 12 to 24 hours postpartum.^{61,65} In the United Kingdom, it is common to reserve magnesium sulfate therapy for severe pre-eclampsia.⁸⁵ The evidence for magnesium sulfate prevention of the progression of disease in mildly pre-eclamptic women has been largely anecdotal. In a large international study of more than 10,000 women, magnesium sulfate clearly decreased the risk of eclampsia in pre-eclamptic women by 58% compared with placebo.⁸⁵ An observational study of nearly 2,500 women with mild pre-eclampsia (BP of 140/90 and 1+ protein) found an incidence of eclampsia of about 1%, without the use of seizure prophylaxis.⁸⁶

In a prospective, randomized study, magnesium sulfate was superior to phenytoin for the prevention of eclampsia in hypertensive pregnant women.⁸⁴ In addition, magnesium sulfate was more effective than nimodipine for seizure prophylaxis in severely pre-eclamptic women.⁸⁷

A regimen of magnesium sulfate 4 to 6 g IV as a loading dose followed by a continuous infusion of 2 g/hour is the most commonly used regimen in the United States.⁸⁸ Continuous infusion of 1 g/hour has been associated with treatment failures.⁸⁹ Intravenous loading doses of 6 g followed by continuous infusions of 2 g/hour maintain therapeutically effective magnesium serum concentrations between 4 to 8 mg/dL.⁸⁹ Using a loading dose of 4 g consistently resulted in subtherapeutic serum levels (<4 mg/dL), prompting a protocol change to a 6-g load in one study.⁸⁶ A magnesium sulfate 50% solution can be used to administer 10 g IM in two divided doses into the upper outer quadrant of each buttock followed by 5 g IM every 4 hours, although this protocol is not commonly used.⁸⁸ Because magnesium is excreted by the kidneys and will accumulate in cases of renal dysfunction, the continuous infusion rate must be lowered with oliguria or an elevated serum creatinine.

Because of the potential for infusion errors and significant patient morbidity and even mortality with accidental overdoses of magnesium sulfate, the Institute of Medicine has identified magnesium sulfate as a high-risk medication.⁹⁰ All infusions of magnesium sulfate must be given through a controlled pump designed to protect against free flow. If such an infusion pump is not available, the IM route of administration should be used. Dispensing premixed IV bags from central pharmacy with a standardized concentration of magnesium sulfate and limiting the total grams of magnesium sulfate in each dispensed IV bag also can help guard against inadvertent overdose. Dispensing the loading dose in a separate small bag (e.g., 4 g in 100 mL)

from the maintenance bag (e.g., 20 g in 200 mL) also may be helpful.⁹¹

31. What is the proposed mechanism of action of magnesium sulfate in the prevention and treatment of eclamptic seizures?

The precise mechanism of anticonvulsant action of magnesium for the prevention and treatment of eclamptic seizures is unknown. The anticonvulsant activity may be partly mediated through blockade of an excitatory amino acid receptor, *N*-methyl-d-aspartate (NMDA).⁸¹ Seizures are thought to be caused by decreased cerebral blood flow because of vasospasm. Magnesium sulfate is a potent cerebral vasodilator and increases the synthesis of prostacyclin, an endothelial vasodilator. It also causes a dose-dependent decrease in systemic vascular resistance, which may explain its transient hypotensive effect. Magnesium may also protect against oxidative injury to endothelial cells.⁸¹

Monitoring Magnesium Sulfate Therapy

32. What subjective and objective data should be monitored during treatment of T.D. with magnesium?

Deep tendon reflexes (patellar reflex), respiratory rate, and urine output should be monitored periodically during treatment with magnesium sulfate.⁸⁴ The loss of patellar reflexes, the first sign of magnesium toxicity, generally occurs at serum concentrations of 8 to 12 mg/dL. The respiratory rate should be monitored hourly and should be >12 breaths/minute. Respiratory arrest can occur with serum concentrations of >13 mg/dL. Urine output should be carefully monitored and should be at least 100 mL every 4 hours (or 25 mL/hour).⁸⁴ Magnesium serum concentrations are not routinely measured unless renal dysfunction is evident with oliguria or elevated serum creatinine, because magnesium is almost entirely excreted by the kidney.^{81,84} Hypocalcemia and hypocalcemic tetany also can occur secondary to hypermagnesemia and can be reversed by calcium gluconate 1 g (10 mL of a 10% solution) slow IV push over 3 minutes.⁷ Neuromuscular depression can occur in infants whose mothers received magnesium sulfate.³³ Parenteral magnesium sulfate is safe and rarely causes maternal or neonatal toxicity when administered properly but requires built-in system safeguards to avoid unintended dosing errors.⁹¹

Treatment

33. What is appropriate drug therapy for eclampsia?

Diazepam, phenytoin, and magnesium sulfate have all been used to treat eclampsia. The use of magnesium sulfate to treat these seizures results in less maternal morbidity and mortality and less neonatal morbidity.^{84,92} Generally, higher serum concentrations of magnesium sulfate are needed to treat than to prevent eclamptic seizures. The same therapeutic range guides both prophylaxis and treatment, however.⁸⁸ Seizures unresponsive to magnesium sulfate treatment should prompt an evaluation for other cerebrovascular events (e.g., cerebral hemorrhage or infarction).⁸⁸

34. How long should magnesium sulfate be continued in T.D.?

Depending on the severity of pre-eclampsia, magnesium sulfate therapy usually is continued for 24 hours after delivery.⁹³ Attempts are being made to identify patient-specific

criteria that can be used to determine the optimal duration of therapy. Women with severe pre-eclampsia or pre-eclampsia superimposed on chronic hypertension are at greater risk for disease exacerbation when magnesium sulfate is discontinued too soon.

INDUCTION OF LABOR

Mechanisms of Term Labor

In pregnancy, many hormones and peptides, including progesterone, prostacyclin, relaxin, nitric oxide, and parathyroid hormone-related peptide inhibit uterine smooth muscle contractility. Labor at term occurs because the myometrium is released from its quiescent state.⁹⁴ For example, as progesterone concentrations decrease near term gestation, estrogen may stimulate uterine contractility.

Uterine activity is divided into four phases: quiescence (phase 0), activation (phase 1), stimulation (phase 2), and involution (phase 3). Each of these phases is stimulated or inhibited by several factors.⁹⁴ During activation, uterotropins, such as estrogen, and possibly others stimulate a complex series of uterine changes (e.g., increased myometrial prostaglandin and oxytocin receptors and myometrial gap junctions), which are important for the coordination of contractions. These changes help prime the myometrium and cervix for stimulation by the uterotropins oxytocin and prostaglandins E_2 and $F_{2\alpha}$. The cervix softens, shortens, and dilates, a process referred to as *cervical ripening*. Uterine stimulation is responsible for the change in myometrial activity from irregular to regular contractions. During phase 3, involution of the uterus occurs after delivery and is mediated mostly by oxytocin.⁹⁴

The exact stimulus of the biochemical scheme leading to labor in humans is unknown. The fetus may help facilitate this process by affecting placental steroid production through mechanical distention of the uterus and by activating the fetal hypothalamic-pituitary-adrenal axis. Ultimately, these lead to increased production of oxytocin and prostaglandins by the fetoplacental unit.

Labor is divided into three stages.⁹⁵ Weak, irregular, rhythmic contractions (Braxton-Hicks contractions or “false labor”) may happen for weeks before the onset of true labor. The first stage begins with the start of regular uterine contractions and ends with complete cervical dilation. Stage 1 is divided further into the latent phase, active phase, and deceleration phase. During the latent phase, the cervix effaces (thins) but dilates minimally. The contractions become progressively stronger and longer, better coordinated, and more frequent. The duration of the latent phase is the most varied and unpredictable of all aspects of labor and can continue intermittently for days. During the active phase, contractions are strong and regular, occurring every 2 to 3 minutes. The cervix dilates from 3 to 4 cm to full dilation, usually 10 cm. The second stage starts with complete cervical dilation and ends with the delivery of the fetus. The third stage of labor is the time between the delivery of the fetus and the delivery of the placenta.⁹⁵

Indications, Contraindications, and Requirements

35. J.T., a 28-year-old primigravida, is admitted to the labor and delivery suite for labor induction. She is at 42 weeks' gesta-

tion by dates and ultrasound and has a normal obstetric examination. Cervical examination reveals an unfavorable cervix for labor induction; Bishop score is 4. What are the indications and contraindications for labor induction in J.T.?

The induction of labor involves the artificial stimulation of uterine contractions that lead to labor and delivery.⁹⁶ Induction of labor is indicated when the continuation of pregnancy jeopardizes maternal or fetal health (e.g., pre-eclampsia, chorioamnionitis [infection of the fetal membranes], fetal demise, IUGR, Rh₀(D) alloimmunization, maternal medical problems, post-term pregnancy).⁹⁶ Post-term pregnancy (≥ 42 weeks' gestation), as in J.T.'s case, is the most common indication and most commonly encountered problem leading to induction of labor.^{96,97} Contraindications to labor induction are similar to those for spontaneous labor and vaginal delivery and include, but are not limited to, active genital herpes infection, placenta previa (abnormally implanted placenta), prior classic uterine incision, transverse fetal lie, and prolapsed umbilical cord. If uterine activity is appropriately monitored, induced labor yields similar maternal and perinatal outcomes as those with spontaneous labor.⁹⁶

A complete assessment of both mother and fetus should be performed before inducing labor.^{96–98} Previous labor complications or cesarean deliveries in the mother should be considered. Fetal maturity must be assessed accurately before the induction of labor to avoid the inadvertent delivery of a preterm fetus.^{96,98} Every attempt should be made to ensure fetal lung maturation before inducing labor when termination of pregnancy is necessary before 34 weeks' gestation, and antenatal corticosteroids should be administered.⁹⁹

The degree of cervical ripeness and readiness for induction of labor should be assessed because the success of labor induction depends on the degree of cervical ripeness.^{96,100} The state of the cervix is assessed using a pelvic scoring method. The Bishop method assigns a score based on the station of the fetal head relative to the maternal spine and the extent of cervical dilation, effacement, consistency, and position.^{98,100} Bishop scores of >8 are associated with a 100% induction rate and short labor.^{96,100} Bishop scores ≤ 4 , as is documented in J.T., are associated with a high likelihood of failed inductions and cesarean deliveries. Women with Bishop scores ≤ 2 who undergo cervical ripening before induction of labor still, however, have high incidence of failure and cesarean deliveries.¹⁰⁰

Cervical ripening can be accomplished by the administration of prostaglandins (E_2 and E_1) or low-dose oxytocin. Alternatively, cervical dilators or separation of the chorioamniotic membranes from the internal surface of the uterus can ripen the cervix.^{96,98,100} Osmotic or hygroscopic dilators (e.g., Dilapan, Lamichel) work by absorbing cervical mucus and gradually swelling, thereby dilating the cervical canal.^{98,100} The hygroscopic dilators require less monitoring of the mother when compared with the administration of prostaglandins; however, they do not appear to decrease the incidence of cesarean deliveries.^{98,100} Labor induction is accomplished most commonly by amniotomy (artificial rupture of the fetal membranes) and oxytocin administration.^{96,98}

Although labor induction is medically indicated in J.T. to decrease the risk of an adverse fetal outcome with continuing

a post-term pregnancy, her cervix is unfavorable for induction.

Cervical Ripening

Prostaglandin E₂ (Dinoprostone)

36. When should dinoprostone be used to induce labor?

Prostaglandins (e.g., dinoprostone) induce cervical ripening and enhance myometrial sensitivity to oxytocin by promoting the breakdown of collagen and increasing the sub-mucosal hyaluronic acid and water content.^{96,98,100} A Bishop score of ≤ 4 is a definite indication for cervical ripening. Although not universally accepted, intermediate Bishop scores of 5 to 7 indicate a need for cervical ripening.¹⁰¹ Patients with intermediate Bishop scores undergoing cervical ripening with prostaglandins are more likely to achieve labor without oxytocin.⁹⁶ Dinoprostone is the drug used most commonly for cervical ripening.⁹⁸ Up to half of the women treated with dinoprostone experience labor and deliver within 24 hours, some without oxytocin.^{102–104} Dinoprostone cervical gel (Prepidil Gel) contains dinoprostone 0.5 mg/3 g (2.5 mL gel) and is administered endocervically. Dinoprostone vaginal insert (Cervidil) contains dinoprostone 10 mg and is inserted vaginally.¹⁰⁵ Prepidil Gel must be refrigerated and Cervidil vaginal inserts must remain frozen until administration. Women with unfavorable cervixes, such as J.T., should undergo a trial of cervical ripening with dinoprostone before labor induction. Post-term women with unfavorable cervixes who receive dinoprostone have shorter durations of labor, require lower doses of oxytocin, and may have a decreased incidence of cesarean deliveries.^{100,102–104}

37. Which dinoprostone dosage form should be used in J.T.?

Both dinoprostone products are effective for cervical ripening, leading to successful induction of labor.^{100,102–104} The two dinoprostone formulations differ in dosing and application.^{105,106}

DINOPROSTONE GEL (PREPIDIL)

Prepidil 0.5 mg should be administered endocervically at room temperature in or near the labor and delivery suite.^{96,106} After administration, the patient should remain in a recumbent position for at least 30 minutes to minimize leakage from the cervix.^{96,106} Fetal heart rate and uterine activity should be monitored before administration and continuously for at least 2 hours after administration. The cervix should be reassessed and the dose repeated every 6 hours if needed or until a maximal cumulative dose of 1.5 mg (three doses) has been administered in 24 hours.¹⁰⁶ Most women need more than one application, and at least 50% need three doses.¹⁰⁷ The average wholesale price for one dose of Prepidil Gel has been about \$172/0.5-mg dose.¹⁰⁸

Once the cervix has ripened but the patient is not in active labor, oxytocin may be started if at least 6 hours have elapsed from the time the last dinoprostone dose was administered.^{105,109} Waiting at least 6 to 12 hours may decrease the incidence of uterine hyperstimulation, which is defined as uterine contractions occurring more frequently than every 2 minutes or lasting longer than 90 seconds, with or without fetal heart rate changes.¹¹⁰

DINOPROSTONE VAGINAL INSERT (CERVIDIL)

The dinoprostone 10-mg vaginal insert, Cervidil, slowly releases dinoprostone 0.3 mg/hour over a 12-hour period.¹⁰⁵ The insert is contained within a knitted pouch attached to a long tape. This is a major advantage because it can be removed quickly at the beginning of active labor or in the event of uterine hyperstimulation.^{105,109} The use of this vaginal insert requires continuous monitoring of fetal heart rate and uterine activity for as long as the insert is in place and for at least 15 minutes after its removal because of possible uterine hyperstimulation anytime during its administration.^{103,109} The dinoprostone vaginal insert allows for a shorter dosing interval for oxytocin, which can be infused as soon as 30 minutes after the removal of the dinoprostone vaginal insert.¹⁰⁵ The total cost of using Cervidil may be considerably less than Prepidil.

EFFICACY OF DINOPROSTONE GEL VERSUS VAGINAL INSERT

The number of prospective, randomized trials comparing the efficacy of dinoprostone endocervical gel and the controlled-release vaginal insert for preinduction cervical ripening are limited.^{107,111} In one study, women treated with the vaginal insert experienced shorter cervical ripening and delivery times, decreased need for oxytocin, and decreased lengths of hospital stay.¹⁰⁷ A second prospective, randomized comparison of the two products showed no difference in the number of women delivering within 24 hours, time to delivery, or cesarean deliveries.¹¹¹ Women treated with the vaginal insert achieved a greater change in Bishop score and active labor, negating the need for oxytocin.

ADVERSE EFFECTS

The most serious side effect associated with dinoprostone administration is uterine hyperstimulation with or without abnormal fetal heart rate tracings. The incidence of uterine hyperstimulation associated with the use of dinoprostone intravaginal insert is about 5%; the rate of occurrence for dinoprostone endocervical gel is about 1%.^{96,109} Uterine hyperstimulation occurs more frequently if the Bishop score is >4 before administration of dinoprostone and can occur up to 9.5 hours after placement of the intravaginal insert.^{96,97} Most episodes of uterine hyperstimulation with the use of the vaginal insert occur during active labor and resolve within a few minutes after removal of the insert.¹⁰³ Uterine contraction abnormalities may be avoided if the insert is promptly removed at the onset of labor.¹¹²

Both dinoprostone formulations are associated with fever, nausea, vomiting, and diarrhea; and neither are associated with adverse neonatal outcomes.^{96,105,106} Therefore, either formulation of dinoprostone is appropriate for cervical ripening in J.T. Cervidil may be more cost effective.

Misoprostol (Cytotec)

38. What advantages does misoprostol have over dinoprostone when used for cervical ripening?

Misoprostol (Cytotec) is a prostaglandin E₁ analog approved for use in the prevention of nonsteroidal anti-inflammatory drug (NSAID)-induced peptic ulcer disease. It also has been used for cervical ripening and the induction of labor in women despite the lack of approval by the FDA for these latter indications.^{112,113} In two large meta-analyses,

misoprostol was more effective for cervical ripening and labor induction than either placebo or treatment with dinoprostone.^{112,113} Failure to deliver within 24 hours and the need for supplemental oxytocin were both higher in women treated with dinoprostone compared with women treated with misoprostol. Women treated with misoprostol experienced labor more often during cervical ripening and had a reduced rate of cesarean deliveries, a shorter delivery time, and a greater incidence of vaginal delivery within 24 hours, but a higher incidence of uterine contraction abnormalities.^{112–114} In other comparisons, intravaginal misoprostol resulted in shorter times to delivery than either dinoprostone vaginal insert or dinoprostone endocervical gel.^{115,116} Again, uterine hyperstimulation without fetal heart rate abnormalities was most common with misoprostol use. Maternal and neonatal outcomes were similar in both groups. The need for oxytocin is decreased significantly in women treated with misoprostol compared with women treated with dinoprostone.¹¹⁷

Misoprostol has been given both orally and intravaginally, but intravaginal doses of 25 mcg every 4 hours are more effective than oral doses of 50 mcg every 4 hours for cervical ripening and labor induction.¹¹⁸ Misoprostol 25 mcg (one-fourth of a 100-mcg tablet) is inserted into the posterior vaginal fornix and repeated as needed every 3 to 6 hours.^{114,117} Higher doses of 50 mcg are associated with increased uterine contractile abnormalities.^{112,117} Continuous fetal heart rate and uterine monitoring is recommended throughout the administration of misoprostol.¹¹⁶

Misoprostol should not be used in women with previous uterine scars because of the risk for uterine rupture.^{114,115} Misoprostol appears to be an effective, and much less costly method of cervical ripening, but the incidence of uterine hyperstimulation appears to be increased relative to dinoprostone, especially with higher doses. Although misoprostol is a known teratogen in the first trimester of pregnancy, there are no reports of teratogenic effects with exposure beyond the first trimester.¹¹⁴ Misoprostol's low cost and ease of administration are advantages over dinoprostone; however, its lack of FDA approval for cervical ripening and induction of labor is a disadvantage.

Oxytocin (Pitocin)

Mechanism of Action

39. Twelve hours after administration of dinoprostone vaginal insert, J.T.'s cervix has responded and her Bishop score is now 9, but she has not developed a consistent pattern of uterine contractions. What drug therapy should be initiated at this point?

Synthetic oxytocin should be administered to J.T. to stimulate uterine contractions for accomplishing delivery. Oxy-

tocin increases the frequency, force, and duration of uterine contractions.¹¹⁹ The uterine response to oxytocin increases throughout pregnancy beginning at approximately 20 weeks' gestation and increases considerably at 30 weeks' gestation.¹¹⁹ Oxytocin is indicated for both the induction and augmentation of labor. A prolonged latent phase or dystocia (difficult labor) caused by uterine hypocontractility in the active phase of labor is indication for augmentation with oxytocin.¹²⁰

Dosing and Administration

40. How should oxytocin be administered to J.T.?

Oxytocin should be administered by continuous IV infusion using a controlled infusion device. The goal of oxytocin administration is to induce uterine contractions that dilate the cervix and aid in the descent of the fetus while avoiding uterine hyperstimulation and fetal distress.¹²¹ There are two opposing views about oxytocin administration for the induction or augmentation of labor. One view is that oxytocin infusions should mimic physiologic doses in the range of 2 to 6 mU/minute with the goal being vaginal delivery with as little as possible uterine hyperstimulation and fetal distress.¹¹⁵ The other view is that oxytocin should be used in pharmacologic doses to cause strong uterine contractions with the goals being shortened labor, timely correction of dysfunctional labor, decreased cesarean deliveries, and reduced maternal morbidity.^{111,120}

Oxytocin plasma concentrations increase linearly with increasing doses and steady-state is reached within 20 to 40 minutes. Oxytocin serum concentrations correlate poorly with uterine activity, however.¹²² Factors that may affect response to oxytocin include parity, gestational age, and cervical dilation.^{120,122}

Despite many randomized, controlled trials and much experience with oxytocin, the optimal starting doses, dosage increments, dosing intervals, and maximal doses are different in the various protocols (Table 46-4).^{110,119,121} Starting doses range from 0.5 to 0.6 mU/minute and dose increment intervals range from 15 to 60 minutes.^{96,110,121} Waiting for 30 to 40 minutes between each dosage rate increase allows time to assess the response at steady-state. Most low-dose protocols usually start oxytocin at 1 to 2 mU/minute and increase the rate of infusion by 1 to 2 mU/minute every 30 to 40 minutes.^{121,123} High-dose protocols start oxytocin at 3 to 6 mU/minute with incremental increases of 3 to 6 mU/minute every 20 to 40 minutes. The maximal dose of oxytocin for augmentation of delivery and for induction of labor are 20 mU/minute and 40 mU/minute, respectively.¹²¹ The American College of Obstetricians and Gynecologists recommends a low-dose oxytocin protocol starting at 0.5 to 2 mU/minute and increasing by 1 to 2 mU/minute every 30 to 60 minutes, using a cervical dilation rate of 1 cm/hour as a gauge of adequate progression of active labor.⁹⁶

Table 46-4 Oxytocin Regimens for Induction and Augmentation of Labor

| Regimen | Starting Dose | Incremental Increase | Dosage Interval | Maximum Dose | Reference |
|-----------|---------------|--------------------------------------|-----------------|--------------------------------------|-----------|
| Low-dose | 1 mU/min | 1 mU/min up to 8 U/min then 2 mU/min | 20 min | 20 mU/min | 131 |
| High-dose | 6 mU/min | 6 mU/min ^a | 20 or 40 min | 42 mU/min | 130 |
| | 4 mU/min | 4 mU/min | 15 min | Until adequate contractility reached | 132 |

^aUterine hyperstimulation: reduce incremental increase to 3 mU/min; recurrent hyperstimulation: reduce to 1 mU/min.

Oxytocin protocols using higher doses or shorter dose adjustment intervals (15–20 minutes) for augmentation of labor generally result in fewer cesarean deliveries for labor dystocia.^{123–125} The incidence of uterine hyperstimulation during labor induction is higher with high-dose protocols (initial dose of 6 mU/minute with incremental increases of 6 mU/minute), however, when compared with shorter dosing adjustment intervals of 20 minutes or with longer dose adjustment intervals of 40 minutes.¹²³ Women undergoing labor induction with high-dose oxytocin have a higher incidence of uterine stimulation and cesarean deliveries for fetal distress, but a reduced incidence of failed inductions and neonatal sepsis compared with women treated with low-dose oxytocin.¹²⁴ In general, lower maximal doses are needed for augmentation of labor than for induction of labor.^{121,124}

J.T. should be started on an infusion of oxytocin 10 or 20 U diluted in 1,000 mL of an isotonic solution (concentration = 10 and 20 mU/mL, respectively) at 1 mU/minute. She should have continuous uterine and fetal heart rate monitoring throughout the infusion to detect abnormal uterine contraction patterns or fetal heart rate patterns. The goal is to establish a pattern of three to five uterine contractions of 60 to 90 seconds duration per 10-minute period.¹¹⁰ The oxytocin infusion should be increased by 1 to 2 mU/minute every 30 to 40 minutes as needed for inadequate progression of labor (cervical dilation rate of <1 cm/hour).⁹⁶ Fluid intake and urine output should be assessed hourly.

Adverse Effects

41. What are the adverse effects and complications of oxytocin for which J.T. should be monitored?

Uterine hyperstimulation with fetal heart rate deceleration is the most common adverse effect of oxytocin.^{119,120} Uterine hyperstimulation, usually associated with excessive maternal dosing or increased myometrial sensitivity to oxytocin, may result in uterine rupture, vaginal and cervical lacerations, precipitous delivery, abruptio placentae, emergency cesarean delivery for fetal distress, and postpartum hemorrhage secondary to uterine atony. In general, neonatal outcomes associated with oxytocin use do not differ from those achieved by spontaneous labor.¹¹⁰ Although oxytocin has only weak antidiuretic properties, water intoxication resulting in seizures, coma, and death have been reported.⁹⁶ Intravenous bolus administration may cause paradoxical relaxation of vascular smooth muscle leading to hypotension and tachycardia.¹¹⁹

POSTPARTUM HEMORRHAGE

Prevention

42. What are other uses for oxytocin during delivery other than induction or augmentation of labor?

Oxytocin is administered routinely following the delivery of the placenta to promote uterine contraction and vasoconstriction.^{119,126} Uterine contraction leading to vasoconstriction is important for hemostasis.¹²⁶ Uterine atony, the condition in which the uterus fails to contract after delivery of the placenta, is the most common cause of postpartum hemorrhage.^{119,126,127} Risks for uterine atony include induction with oxytocin, prolonged labor, overdistended uterus, and previous postpartum hemorrhage.^{126–128} Oxytocin 10 to 20 U

IM or diluted in 0.5 to 1 L of parenteral fluid and given as an IV infusion of 200 mU/minute until the uterus is firmly contracted reduces the risk for postpartum hemorrhage secondary to uterine atony.^{119,129} Oxytocin should never be administered undiluted as a bolus dose because it can cause severe hypotension and cardiac dysrhythmias.¹²⁹

Misoprostol

Misoprostol 400 to 600 mcg can be administered orally in the third stage of labor to prevent postpartum hemorrhage.^{130,131} In a comparison of 600 mcg oral misoprostol with parenteral Oxytocin for prevention of postpartum hemorrhage, Oxytocin was, however, marginally but statistically more effective and had fewer side effects.¹³² Misoprostol also can be administered rectally. The vaginal route is not preferred in the setting of bleeding. Rectal administration is associated with a lower incidence of fever and shivering, which is common with orally administered misoprostol during the third stage of labor.¹³⁰ The rectal route of administration also is associated with lower maximal serum concentrations and lower time to maximal concentrations than when the drug is administered orally.

Treatment

43. Within a few hours of delivering her fetus, J.T. has visible vaginal bleeding. She has a distended uterus and the hemorrhage is attributed to uterine atony. Uterine massage and infusion of oxytocin do not control the bleeding. What other pharmacologic options are available to treat her?

Ergot Alkaloids

If the postpartum hemorrhaging does not respond to oxytocin administration, ergonovine maleate (Ergotrate) and its semisynthetic derivative, methylergonovine maleate (Methergine) can be used because of their potent uterotonic effects. Intramuscular administration is associated with less frequent adverse effects (nausea, vomiting, hypertension, headache, chest pain, dizziness, tinnitus, diaphoresis) than the intravenous route.^{127,133} Ergot alkaloids should be avoided in hypertensive and eclamptic patients because of the potential for arrhythmias, seizures, cerebrovascular accidents, and rarely myocardial infarction. The dose of both drugs is 0.2 mg administered IM every 2 hours as needed. This may be followed by 0.2 to 0.4 mg administered orally two to four times daily for 2 to 7 days to promote involution of the uterus.¹³³

15-Methyl Prostaglandin F₂ (Carboprost Tromethamine)

Bleeding caused by uterine atony that is unresponsive to oxytocin can be treated with 15-methyl prostaglandin F_{2α}-tromethamine, also known as carboprost tromethamine (Hemabate).^{126,128} Carboprost tromethamine, as with naturally occurring prostaglandins, stimulates uterine contraction and decreases postpartum hemorrhage; it is more potent and has a longer duration of effect than its parent compound, prostaglandin F_{2α}.

Carboprost tromethamine is approved for IM use, but also has been also administered through direct myometrial injection^{126,127} and intrauterine irrigation.¹²⁶ Intramyometrial administration has been associated with severe hypotension and pulmonary edema.¹³⁴ An initial dose of 0.25 mg IM is given followed by 0.25 mg every 15 to 90 minutes.^{127,135} The dose may be increased to 0.5 mg if a patient does not respond

adequately to several 0.25-mg IM doses. The total cumulative dose should not exceed 2 mg.¹³⁵ Carboprost tromethamine is effective in treating 60% to 85% of women with uterine atony who have failed standard treatment.¹²⁷ Improvement in bleeding typically occurs after one to two injections.

The most common adverse effects of carboprost tromethamine are gastrointestinal, including nausea, vomiting, and diarrhea. Flushing and fever also occur frequently. Many of the adverse effects are related to the contractile effect of this drug on smooth muscle.¹³⁵ Hypertension, although rare, typically occurs in women with pre-existing hypertension or preeclampsia. The potent vasoconstricting and bronchoconstricting properties of carboprost can cause uterine rupture, as well as pulmonary and cardiac problems. Carboprost is contraindicated in women with active pulmonary, cardiac, renal, or hepatic disease as well as in women with acute pelvic inflammatory disease.^{127,128,135}

Misoprostol

Several case series and small randomized trials have reported that misoprostol might be useful in the treatment of postpartum hemorrhage caused by uterine atony. The available data are very limited, however, and large randomized trials are needed to clarify the efficacy of misoprostol compared with standard therapies, as well as the optimal dose and route of administration.¹³⁶

PRETERM LABOR

Preterm delivery occurred in 12.7% of births in the United States in 2004, representing a 20% increase since 1990.¹³⁷ Approximately 55% of singleton preterm births follow spontaneous preterm labor and approximately 8% follow preterm premature rupture of the chorioamniotic membranes.¹³⁸ Premature birth is the leading cause of neonatal mortality (infant death <1 month of age), resulting in approximately 70% of deaths. Furthermore, prematurity is the second leading cause of infant mortality under the age of 1 year, and has resulted in 36% of such deaths in 2004.¹

Etiology

Spontaneous preterm labor is a heterogeneous syndrome and several known pathways can lead to preterm birth. These pathways include excessive uterine distension, decidual hemorrhage, activation of the maternal and fetal hypothalamic pituitary system, and intrauterine infection leading to inflammation. These pathways ultimately lead to a final common response with production of uterine and cervical proteases and uterotonins, which result in progressive cervical ripening and dilation; weakening of the chorioamniotic membranes, which leads to rupture; and uterine contractions. Ultimately, delivery of the infant occurs. Infection triggers an inflammatory response that results in the release of cytokines, prostaglandins, and proteases, which stimulate uterine activity, induce cervix softening and dilation, and weaken the chorioamniotic membranes.¹³⁹ Variations in maternal and fetal genes coding for cytokines have been implicated in the apparent genetic predisposition to preterm birth found in some families and racial groups.¹⁴⁰ Thrombin is another uterotonic that has been implicated in causing preterm labor associ-

ated with vaginal bleeding caused by placental abruption.¹⁴¹ Studies have shown a relationship between increasing maternal corticotropin-releasing hormone (CRH) and delivery timing.¹⁴² Maternal and fetal stress can activate the hypothalamic pituitary system and result in the rapid increase of maternal CRH before premature birth. Infection can also activate the fetal hypothalamic pituitary system, increasing CRH, cortisol, and ultimately, prostaglandins.^{139,141} Despite some progress in recent years, much remains unknown about the etiology of preterm birth, and little is known about how preterm birth can be prevented.

Clinical Presentation and Evaluation

44. B.B., a 17-year-old white girl, G₂P₁, 29 weeks' gestation, is admitted to the obstetrical unit with complaints of backache, cramps, and uterine contractions. She has no symptoms of preterm premature rupture of the membranes (PPROM). She had a previous preterm birth at 32 weeks' gestation. Cervicovaginal secretions are positive for fetal fibronectin. A pelvic examination reveals that her cervix is 2 cm dilated and 80% effaced, which is increased from 1 cm at her prenatal visit last week. Cervical cultures for *Chlamydia trachomatis* and *Neisseria gonorrhoeae* from her previous visit are negative. Vaginal wet preparations are also negative for bacterial vaginosis and *Trichomonas vaginalis*. Vital signs, urinalysis, and CBC with differential are normal. Uterine contractions and fetal heart tones are being monitored. Ultrasound reveals a fetus of 30 weeks' size with an estimated weight of 1,200 g. What signs, symptoms and laboratory evidence support a diagnosis of preterm labor?

B.B. has backache and uterine contractions, which are symptoms of preterm labor. Most women with preterm contractions are not in labor, however, which results in frequent overdiagnosis.¹⁴¹ In addition, contractions during preterm labor are frequently not painful, are not detected by the woman and, thus, are not a sensitive marker for preterm labor. Fibronectin, a protein that serves as an adhesive between the fetal membranes and decidua, normally disappears from the cervical secretions after the first half of pregnancy, reappearing only at term as labor approaches.¹⁴¹ A negative fibronectin test can exclude imminent preterm delivery in a woman at risk for preterm delivery, between 24 to 34 weeks' gestation with intact amniotic membranes, and with cervical dilatation of <3 cm.¹⁴³ Because of fibronectin's high negative predictive value of >95% for delivery in the next 1 to 2 weeks, it can be used to avoid overdiagnosis of preterm labor. Although fibronectin testing will yield false-positive results in the presence of blood, vaginal bleeding itself is independently associated with preterm birth. B.B. has the criteria necessary to establish a firm diagnosis of preterm labor. Not only is her fibronectin test positive, but she has persistent contractions with a documented change in cervix dilatation.

Risk Factors

45. What risk factors does B.B. have for spontaneous preterm labor?

B.B. has several risk factors for preterm delivery. The strongest predictor of preterm birth is prior preterm birth. She

has a fourfold increased risk of preterm delivery because of one previous preterm delivery.¹⁴¹ If this pregnancy also ends prematurely, her risk for a third preterm birth in her next pregnancy will be sixfold higher than that in the normal population. Her young age may also be a risk factor. A maternal age <18 or >35 years is associated with spontaneous preterm birth, although it is difficult to separate age from the confounding factors associated with age.¹⁴¹ Black race is an independent risk factor for both preterm labor and lower neonatal birthweight. Other risk factors include low maternal weight before pregnancy, smoking, second or third trimester bleeding, multiple gestation, and uterine anomalies.^{94,141} Studies of cervix length by transvaginal ultrasound imaging have demonstrated that shorter lengths are associated with greater risk for preterm delivery; however, the positive predictive value varies widely.^{141,143} Maternal infections, such as untreated urinary tract infections and pneumonia, are associated with preterm delivery. In addition, genital organisms such as *Gardnerella vaginalis*, *Chlamydia trachomatis*, *Neisseria gonorrhoeae*, *Ureaplasma urealyticum*, and *Trichomonas vaginalis*, are also associated with preterm births.¹³⁹ Although it is important to identify women at risk for spontaneous preterm delivery, only half of all preterm deliveries occur in women with known risk factors.¹⁴¹

Tocolysis

Goals of Therapy

46. What are the goals of tocolysis?

Treatment of spontaneous preterm labor primarily has been directed at slowing or stopping contractions which are the obvious, although likely late, sign of impending preterm birth. It has been presumed that if successful, this should prevent or delay preterm birth. Few placebo controlled trials have been conducted of agents used to diminish contractions (tocolytics), and most data suggest delay of delivery by at most 1 to 2 days. This might be because of the heterogeneous causes of spontaneous preterm birth, and because tocolytic agents may not arrest the underlying process that led to contractions. Most studies have been unable to demonstrate a clear benefit of tocolysis on neonatal morbidity and mortality. Instead they have evaluated surrogate endpoints, such as pregnancy prolongation or number of preterm births prior to various cutoff points.¹⁴⁴ The value of prolonging pregnancy will vary by gestational age, and might be substantial if time is gained to administer glucocorticoids to improve fetal lung maturation and decrease the risk of intraventricular hemorrhage (see section on Antenatal Glucocorticoid Administration). All women at risk for preterm birth within 7 days and between 24 to 34 weeks should be considered for glucocorticoid therapy.^{145,146} Delay of delivery can also allow transport to a facility best equipped to care for both mother and premature newborn.

Numerous factors affect the decision to treat preterm labor with a tocolytic agent. Fetal factors precluding tocolysis include non-reassuring fetal monitoring, significant IUGR, and lethal congenital anomalies. Maternal factors include evidence of chorioamnionitis, other significant maternal infections or illness, pre-eclampsia, and advanced labor.¹⁴¹ Tocolysis is less likely to be effective in women with cervical dilation of >3 cm and is usually unsuccessful if the patient is in advanced labor (cervical dilation >5 cm).¹⁴¹ Because the etiology of

preterm labor is multifactorial, B.B. should be evaluated thoroughly and periodically for potential causes of preterm labor and treated appropriately when diagnosed. For example, urinary tract infections are associated with preterm labor and they should be diagnosed and treated if present.¹⁴¹ Additionally, some would also perform amniocentesis to exclude subclinical chorioamnionitis as a cause of preterm labor before initiating or continuing tocolysis, and to evaluate lung maturity at later gestational ages.¹⁴⁵ B.B. has no evidence of overt infection or other complications and has no contraindications to tocolysis. Prolonging gestation, even for a few days, would be beneficial because B.B. is only 29 weeks' gestation.

Magnesium Sulfate

47. Magnesium sulfate 6 g IV loading dose for 30 minutes followed by 2 g/hour continuous IV infusion through a controlled infusion pump has been ordered. How effective is magnesium sulfate for tocolysis?

Magnesium sulfate is the most frequently used parenteral tocolytic agent in the United States and is also prescribed for the prevention and treatment of eclampsia. Magnesium sulfate relaxes uterine smooth muscle at maternal serum levels of 5 to 8 mg/dL.¹⁴¹ The mechanism by which it exerts this effect is not understood completely, but involves inhibition of myosin light-chain kinase activity by competition with intracellular calcium, reducing myometrial contractility.¹⁴⁴

Despite its widespread use, the evidence for magnesium's efficacy in prolonging gestation is inadequate. In two published randomized, placebo-controlled trials, no benefit in mean prolongation of pregnancy or mean neonatal birthweight was demonstrated. In meta-analyses of both placebo-controlled trials of magnesium for tocolysis compared with other active drugs, no prolongation of pregnancy was seen with magnesium.^{147,148} Several small randomized, controlled studies have directly compared magnesium with parenteral β -adrenergic agonists, mostly ritodrine.¹⁴⁸ Three of the four showed no differences in birth outcomes. One of the four suggested prolonged pregnancy with magnesium added to ritodrine compared with ritodrine alone. Studies on the efficacy of β -adrenergic agonists (mostly ritodrine) versus placebo have been mixed but on balance suggest delay of delivery for 48 hours, but not for 7 days. Therefore, because most trials comparing magnesium with β -adrenergic agonists did not show differences, it has been presumed that magnesium is equally effective. Magnesium is better tolerated than the β -adrenergic agonists, with fewer maternal side effects.¹⁴⁸ Magnesium is contraindicated in patients with myasthenia gravis, and renal failure.

MONITORING FOR EFFICACY AND TOXICITY

49. How should magnesium sulfate therapy in B.B. be monitored for efficacy and safety?

The hourly rate of magnesium administration for B.B. may be increased until she has one or fewer contractions per 10 minutes or a maximum of 4 g/hour is attained. B.B.'s deep tendon reflexes, respiratory rate, and urine output should be monitored regularly. Close monitoring of fluid balance is important because fluid overload has been associated with pulmonary edema and the drug is renally excreted.¹⁴⁹

Magnesium serum concentrations are commonly evaluated every 6 to 12 hours in an effort to minimize adverse effects.¹⁵⁰ The patellar reflex disappears with magnesium serum concentrations between 9 and 10 mg/dL, and as long as deep tendon reflexes are present, many practitioners will not measure concentrations. To prevent inadvertent overdoses, a controlled infusion device should always be used to deliver magnesium as a continuous infusion. Hypocalcemia and tetany can occur with hypermagnesemia. Neuromuscular blockade and respiratory arrest develop with magnesium serum concentrations of 15 to 17 mg/dL, and cardiac arrest develops with greater concentrations. The toxic effects of magnesium can be rapidly reversed with 1 g of parenteral calcium gluconate, which should be readily available where patients are receiving magnesium infusion.¹⁵¹

The most common side effects of magnesium loading doses are transient hypotension, flushing, a sense of warmth, headache, dizziness, lethargy, nystagmus, and dry mouth.^{141,149} Other adverse effects reported with magnesium are hypothermia, paralytic ileus, and pulmonary edema, which may occur in 1% to 2% of patients treated with magnesium sulfate.¹⁴⁹ Pulmonary edema occurs less frequently with magnesium sulfate than with parenteral β -sympathomimetics and is more commonly encountered with prolonged infusions, multifetal pregnancy, and the use of multiple tocolytics.^{149,151} Treatment consists of discontinuing magnesium sulfate and administration of the diuretic furosemide.

Fetal magnesium serum concentrations are similar to maternal concentrations.¹⁴⁹ The most common neonatal adverse effects are hypotonia and sleepiness. Hypotonia may continue for 3 or 4 days in the neonate because of decreased renal elimination of magnesium. Rarely, assisted mechanical ventilation for neuromuscular depression may be needed.¹⁴⁹ A possible role for magnesium sulfate in the prevention of cerebral palsy is an area of ongoing investigation.¹⁵²

β -Adrenergic Agonists EFFICACY

50. Could B.B. have been treated with a β -adrenergic agonist?

β -Adrenergic agonists are not the first-line choice for preterm labor because of high costs and the significant potential for maternal adverse effects described below.^{141,148} Both ritodrine, the only medication approved by the FDA for the treatment of preterm labor, and terbutaline, bind to β_2 -adrenergic receptors in uterine smooth muscle and ultimately inhibit smooth muscle cell contractility. Results of randomized, controlled trials of ritodrine have been mixed; however, a meta-analysis which included 1,320 women treated with β -agonists demonstrated fewer births at 48 hours but no change in number of births at 7 days. No benefit on neonatal morbidity or mortality was seen; however, the studies are limited by sample size.^{153,154} The continued use of β -agonists can result in the development of tachyphylaxis to its effects on the myometrium and may in part explain treatment failures with these drugs.^{141,153}

Terbutaline is available for IV, subcutaneously (SC), and oral administration. One SC dose of terbutaline is often administered to women with mild contractions and cervical dilation <2 cm. Intravenous β -sympathomimetics are used in cases

with more severe and frequent contractions and cervical dilation >2 cm.

MATERNAL AND FETAL ADVERSE EFFECTS

51. What adverse effects are associated with terbutaline?

β -Adrenergic agonists are not selective for myometrial β_2 -adrenergic receptors at pharmacologic doses, and this accounts for their high incidence of adverse effects.¹⁵¹ Maternal adverse effects such as pulmonary edema, palpitations, tachycardia, myocardial ischemia, hyperglycemia, hypokalemia, and hepatotoxicity result in discontinuation of therapy in up to 10% of patients.¹⁴¹ Pulmonary edema can occur and, if not recognized promptly, can lead to adult RDS and death.^{141,151} β -Sympathomimetics should not be used in women with underlying cardiac disease or arrhythmias, hypertension, diabetes mellitus, severe anemia, or thyrotoxicosis.¹⁴¹

The most commonly reported fetal or neonatal adverse effects associated with β -agonist therapy include tachycardia, hypotension, hypoglycemia, and hypocalcemia.¹⁵¹ Maternal hyperglycemia causing fetal hyperglycemia and hyperinsulinemia can lead to neonatal hypoglycemia if not properly monitored postnatally. Fetal tachycardia rarely leads to fetal myocardial ischemia or hypertrophy.¹⁵¹ The use of β -sympathomimetic drugs was reported to be associated with an increased risk of neonatal intraventricular hemorrhage in some early studies but not in others.^{141,148}

Other Tocolytic Drugs

52. What other drugs are commonly used for tocolysis?

INDOMETHACIN

Prostaglandins $F_{2\alpha}$ and especially E_2 are important regulators of myometrial contractility and cervical ripening.⁹⁴ Prostaglandin synthetase inhibitors, such as indomethacin, decrease prostaglandin production and thereby decrease contractions and inhibit cervical change. As with other tocolytics, these drugs have not been adequately studied in multiple randomized controlled trials. A review of available randomized trials of indomethacin (Indocin) compared with placebo found significant reductions in women delivering at <37 weeks, an increase in gestational age at delivery, and a trend toward fewer deliveries at 48 hours and 7 days.¹⁵⁵ In three of eight trials comparing cyclo-oxygenase (COX) inhibitors with other tocolytics, a reduction in both delivery before 37 weeks and in maternal drug reactions, was noted. Also, seen in these studies was a trend toward a reduction in delivery within 48 hours.¹⁵⁵ Indomethacin is well tolerated, and GI upset can be mitigated by antacids when it occurs. The available studies are inadequately powered to evaluate neonatal outcomes.¹⁵⁶

Although well tolerated by the mother, concerns exist about the fetal and neonatal effects of prostaglandin synthetase inhibition. Indomethacin crosses the placenta rapidly, and fetal levels rapidly approach maternal levels.^{151,156} Because indomethacin can decrease fetal urine output leading to oligohydramnios, the amniotic fluid index (AFI) should be followed and indomethacin discontinued if it falls below 5 cm. Oligohydramnios generally resolves within 48 to 72 hours of the discontinuation of indomethacin. The ductus arteriosus—a fetal vessel important in maintaining fetal circulation—constricts

in 25% to 50% of fetuses exposed to indomethacin *in utero* and generally is reversible.¹⁴¹ Permanent closure of the ductus arteriosus, however, has led to intrauterine demise. The risk for neonatal adverse effects is increased with drug exposure of >48 hours, as well as use after 32 weeks when premature closure of the ductus occurs more frequently.¹⁴¹ An increased risk for maternal postpartum hemorrhage has also been reported with indomethacin use but did not reach significance in a meta-analysis.¹⁵⁵ Indomethacin should not be used in the presence of oligohydramnios or suspected fetal renal or cardiac anomaly (see Chapter 94, Neonatal Therapy).

More serious fetal and neonatal effects have been reported in some retrospective and observational studies, including neonatal necrotizing enterocolitis, intraventricular hemorrhage, and renal failure.^{156–158} It is difficult, however, to discern whether these complications are causally related to indomethacin or to the use of the drug in cases of refractory preterm labor caused by subclinical intra-amniotic infection.^{156,159} The randomized trials have limited power to assess these serious neonatal complications. An analysis of the risks and benefits of indomethacin suggested its continued use as second-line treatment for preterm labor between 24 to 32 weeks in women with contraindications to other tocolytics.¹⁵⁶ Typical dosing regimens include a loading dose of 50 to 100 mg either rectally or orally followed by maintenance doses of 25 to 50 mg orally every 4 to 8 (most commonly given every 6 hours) hours for 24 to 48 hours.¹⁵⁷

COX-2 INHIBITORS

Only amniotic cyclooxygenase-2 (COX-2), and not COX-1, activity is increased during labor, and tocolysis with COX-2 specific inhibitors might result in fewer adverse effects than with indomethacin or other nonspecific COX inhibitors.¹⁶⁰ In a randomized, double-blind, placebo-controlled trial, celecoxib was comparable to indomethacin in efficacy and did not negatively affect ductal patency when used to treat preterm labor.¹⁶⁰ Both drugs decreased AFI; however, fluid reaccumulation was prolonged when indomethacin was discontinued, an effect not observed with the discontinuation of celecoxib. Another small double-blinded trial demonstrated a similar reversible decrease in AFI and ductus arteriosus flow from COX-2 inhibition with sulindac or nimesulide, compared with COX-1 inhibition with indomethacin.¹⁶¹ More studies with larger number of subjects are needed to determine the safety and efficacy of COX-2 enzyme inhibitors relative to indomethacin.

CALCIUM CHANNEL BLOCKERS

The calcium channel blockers nifedipine and nicardipine inhibit preterm contractions by decreasing calcium influx into uterine smooth muscle and inhibiting myometrial contractions. No placebo-controlled trials have been performed with nifedipine, the most commonly used calcium channel blocker. Meta-analysis of 12 randomized trials including a total of 1,029 women evaluated the effectiveness of calcium channel blockers compared with other tocolytics, mostly betamimetics.¹⁶² Calcium channel blockers were found to be superior in reducing preterm births within 7 days and before 34 weeks. In addition, fewer maternal side effects were seen. A more recent study of 192 women comparing nifedipine with magnesium sulfate for preterm labor found no differences in delivery in

48 hours, gestational age at delivery, or deliveries before 32 or 37 weeks.¹⁶³ Maternal side effects were significantly fewer in patients receiving calcium channel blockers compared with other tocolytics.^{162,163} Maternal side effects can include tachycardia, headache, flushing, dizziness, nausea, and hypotension in the hypovolemic patient.¹⁵¹ Nifedipine does not adversely affect uteroplacental blood flow or fetal circulation. Concurrent use with magnesium should be avoided because the combination may potentiate neuromuscular blockade.^{81,151} Nifedipine appears to be an attractive alternative for short-term tocolysis. The starting dose is usually 10 mg orally with repeated doses of 10 mg every 15 to 20 minutes for persistent contractions up to a maximum of 40 mg in the first hour.^{164,165} Depending on the tocolytic effect, nifedipine is then maintained at 10 to 20 mg orally every 4 to 6 hours.¹⁶⁴ The appropriate duration of treatment has not been established, but typically it is continued through the 34th week of gestation.^{164,162}

DURATION OF TOCOLYSIS ACUTE THERAPY

53. B.B. has been maintained on magnesium sulfate continuous IV infusion for approximately 48 hours. The dose was increased to 3 g/hour shortly after the start of the infusion. B.B. has had no contractions for the past 24 hours. How long does she need to be treated? Should she be “weaned” off magnesium sulfate?

B.B.’s contractions have completely stopped for 24 hours. Some protocols maintain magnesium sulfate for 12 to 24 hours after successful tocolysis, or for the time it takes to complete the course of corticosteroids. After successful acute tocolysis is achieved, the magnesium infusion sometimes is discontinued gradually.¹⁶⁴ The weaning of magnesium sulfate is likely unnecessary, however, and simple discontinuation of the magnesium infusion is an easier and less costly option.¹⁵⁰

CHRONIC MAINTENANCE THERAPY

54. Should B.B. be started on chronic maintenance tocolytic therapy?

Maintenance tocolysis has been used to prevent recurrence of preterm labor and prolong gestation in women in whom preterm labor was terminated successfully with parenteral tocolytics.¹⁶⁶ The use of continuous SC low-dose terbutaline infusion through a portable pump has been used widely in outpatient tocolysis and in conjunction with home uterine activity programs.^{166,167} Although continuous SC low-dose terbutaline is associated with fewer cardiopulmonary adverse effects compared with IV β -adrenergic therapy, the FDA issued a “Dear Colleague” letter in 1997 alerting practitioners about the lack of effectiveness and potential danger of continuous SC terbutaline for the treatment and prevention of preterm labor.¹⁶⁶ After additional review, the FDA reaffirmed this position in 2000. A subsequent review reached similar conclusions.¹⁶⁸ Other tocolytics, including β -adrenergic agents and oral calcium channel blockers have been evaluated for maintenance therapy. Results of meta-analysis of trials comparing placebo or no treatment with betamimetics for maintenance therapy after acute preterm labor, which included more than 900 women, showed no benefit in delay of delivery, births at <34 or 37 weeks, or neonatal complications.¹⁶⁹ Moreover, increases in maternal

adverse effects occurred, primarily tachycardia, hypotension, and palpitations. Inadequate data exist to support the use of calcium channel blockers as maintenance therapy and the single randomized, controlled trial was relatively small.^{145,170–172} B.B. should not be started on chronic maintenance tocolysis.

Antenatal Glucocorticoid Administration

55. While receiving the loading dose of magnesium sulfate, B.B. was given betamethasone 12 mg IM with a second dose in 24 hours. Why was betamethasone given?

B.B. was given betamethasone to facilitate fetal lung maturation by increasing production of fetal lung surfactant, thereby reducing the incidence and severity of RDS.⁹⁹ Antenatal corticosteroid administration (betamethasone and dexamethasone) also decreases the incidence of intraventricular hemorrhage, necrotizing enterocolitis, and neonatal death.⁹⁹ The greatest reduction in RDS occurs when delivery can be delayed 24 hours up to 7 days after starting treatment. Repeat weekly corticosteroid courses are discouraged because of the association with decreased birthweight and head circumference, hypothalamic-pituitary-adrenal axis suppression, deleterious effects on cerebral myelination and lung growth, and neonatal death (particularly in neonates born to mothers who received three or more courses).^{146,173}

The National Institutes of Health (NIH) Consensus Panel and the ACOG recommend antenatal betamethasone or dexamethasone for all women in preterm labor between 24 to 34 weeks' gestation.⁹⁹ Betamethasone, however, might be the preferred agent because fewer IM injections are needed and because in meta-analysis it was associated with a greater reduction in RDS compared with dexamethasone.¹⁷³ That conclusion, however, is not based on direct comparison of betamethasone with dexamethasone and should be interpreted with caution. One study, although limited by its retrospective nature, also suggested an advantage of betamethasone over dexamethasone in the reduction of periventricular leukomalacia, a finding associated with later risks for cerebral palsy.¹⁷⁴ In cases of PPROM, the NIH Consensus recommends that corticosteroids may be given up to 32 weeks' gestation in the absence of chorioamnionitis.⁹⁹ Recent meta-analysis supports the efficacy of corticosteroids in the reduction of neonatal death, RDS, duration of ventilator use, and intraventricular hemorrhage in infants born after ruptured membranes.¹⁷³ Women >32 weeks' gestation can be considered for amniotic fluid testing for the presence of phosphatidylglycerol or lecithin-to-sphingomyelin (L:S) ratio (>2) because these are indicators of fetal lung maturation.¹⁷⁵ Corticosteroids are not recommended for use in pregnant women who are >34 weeks' gestation unless there is an indication of fetal lung immaturity (see Chapter 94, Neonatal Therapy).

Antibiotic Therapy

56. What is the role of antibiotic therapy in the prevention or management of preterm labor? Is B.B. a candidate for a trial of antibiotics?

Antibiotics are given during preterm labor to treat bacterial vaginosis, occult or documented intra-amniotic infections in

PPROM, and prophylactically against neonatal group B *Streptococcus* (GBS) infection.

Bacterial Vaginosis

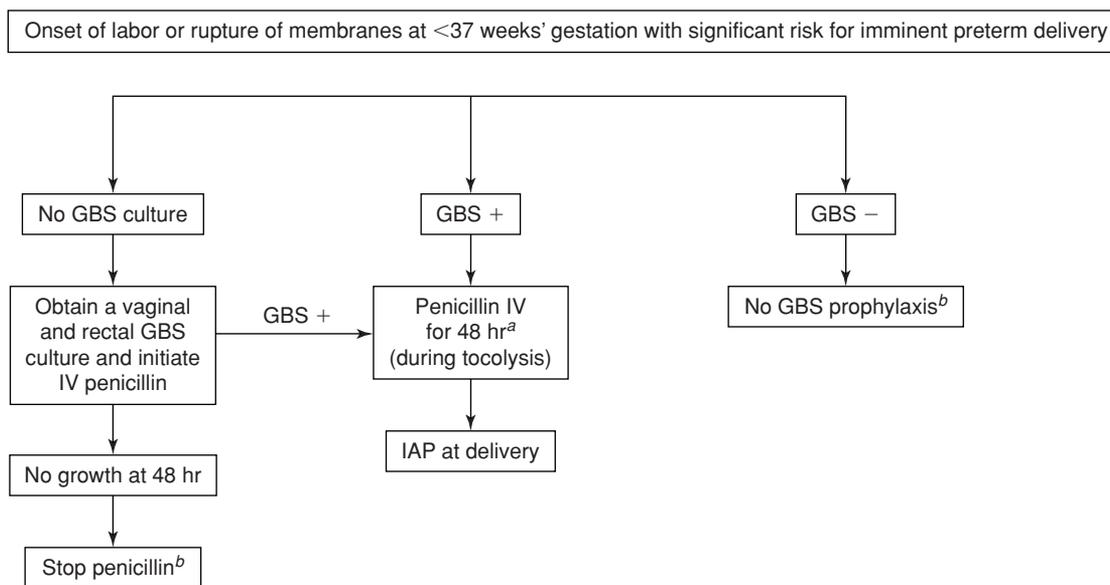

All pregnant women should be screened and treated for sexually transmitted diseases and bacteriuria. In addition, some, but not all studies have demonstrated that screening and treating asymptomatic women for bacterial vaginosis (BV) who are at high risk for preterm delivery may reduce the risk of preterm birth.^{144,176} A polymicrobial overgrowth of mostly anaerobic bacteria, BV is one of the most common genital infections in pregnancy and it is associated with an increased risk of preterm delivery.¹⁷⁷ Treatment of women with BV who had a prior preterm delivery with oral metronidazole (Flagyl) in combination with erythromycin decreased the risk of recurrent preterm delivery in one randomized clinical trial.¹⁷⁸ The use of vaginal antibiotics, antibiotic regimens not including metronidazole, or the treatment of BV in women without a history of preterm birth does not appear, however, to decrease the risk of preterm birth.^{139,179} In addition, a meta-analysis including 622 women with prior preterm birth, found no reduction in the risk of preterm birth before 37 weeks after treatment of BV with antibiotics.¹⁷⁹ B.B. does not have BV; therefore, treatment with metronidazole is unnecessary (also see GBS resistance to erythromycin in Chapter 96, Pediatric Infections Diseases).

Preterm Premature Rupture of Membranes

Increasing evidence associates preterm labor with intra-amniotic infections.^{139,180} Of preterm births, 20% to 40% may be caused by an infectious-inflammatory process.¹⁸¹ Intrauterine infection is associated with approximately 80% of early preterm deliveries.¹³⁹ Most of the bacteria found in amniotic fluid and the placenta are believed to have ascended from the vagina.¹⁸⁰ It has been suggested that the microbes responsible for preterm birth are already present in the endometrium before conception, causing a chronic, subclinical infection weeks to months before eventually causing PPROM or labor.^{139,141}

Antibiotic therapy during preterm labor is indicated in select cases. When PPROM has occurred, spontaneous labor and delivery occurs on average within 7 days, although longer intervals from PROM to delivery occur with earlier gestational ages.¹⁷⁷ Additionally, the use of antibiotics has been shown to prolong the period between PPROM and delivery (the latency period), and decrease neonatal morbidity.¹⁷⁷ In the largest and best designed trial of antibiotic treatment of PPROM, women between 24 to 32 weeks' gestation treated with ampicillin and erythromycin had both prolonged pregnancies and lower rates of chorioamnionitis.¹⁸² Their newborns experienced decreased mortality, as well as decreased morbidity including RDS, and necrotizing enterocolitis. These effects were not owing to tocolytics or corticosteroids because these were exclusionary factors. These results were confirmed by the results of a large meta-analysis including >6,000 women, although information on the best choice of antibiotics was less clear.¹⁸³ Therefore, women with PPROM benefit from antibiotic therapy with a broad-spectrum regimen and IV ampicillin plus erythromycin for 48 hours followed by 5 days of oral amoxicillin plus erythromycin for a total of 7 days treatment is a reasonable choice.¹⁸²

Antibiotics should also be given to women if delivery is anticipated resulting either from preterm labor with intact

^a Penicillin should be continued for a total of at least 48 hours, unless delivery occurs sooner. At the physician's discretion, antibiotic prophylaxis may be continued beyond 48 hours in a GBS culture positive woman if delivery has not yet occurred. For women who are GBS culture positive, antibiotic prophylaxis should be reinitiated when labor likely to proceed to delivery occurs or recurs.

^b If delivery has not occurred within 4 weeks, a vaginal and rectal GBS screening culture should be repeated and the patient should be managed as described, based on the result of the repeat culture.

GBS, group B streptococcus; IAP, intrapartum antibiotic prophylaxis.

FIGURE 46-3 Sample algorithm for group B streptococcus (GBS) prophylaxis for women with threatened preterm delivery. This algorithm is not an exclusive course of management. Variations that incorporate individual circumstances or institutional preferences may be appropriate.

membranes or after preterm PPRM, to prevent group B streptococcal infection in the newborn. Other broad-spectrum antibiotic therapy to prevent preterm delivery should not be given routinely to women in preterm labor with intact membranes. Antibiotics have not been proved to prevent premature births in the setting of acute preterm labor.^{145,181}

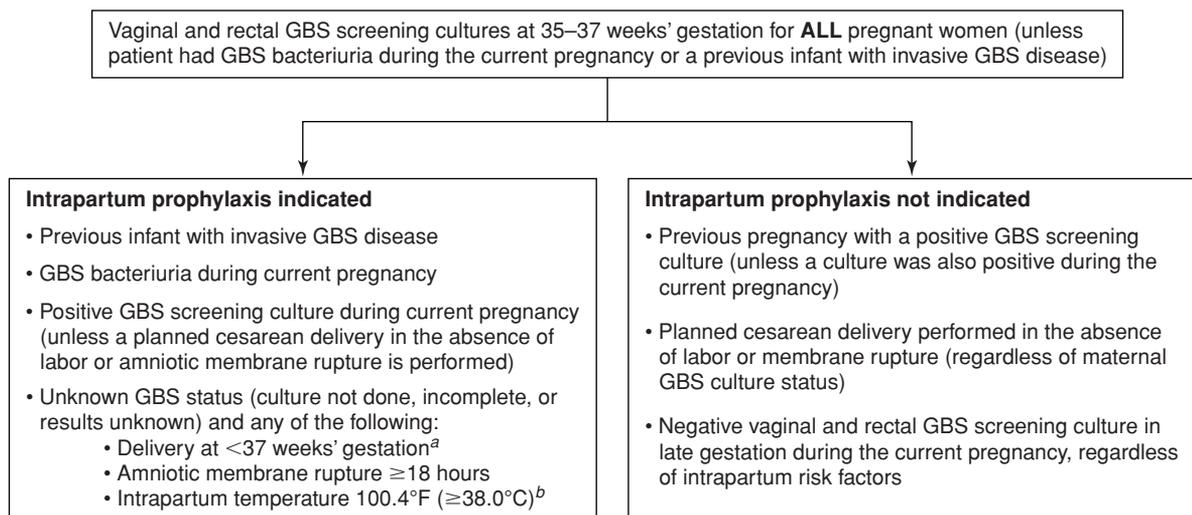

Because B.B. does not have PPRM or signs of chorioamnionitis (temperature $\geq 100.4^{\circ}\text{F}$ or 38°C), she should not be treated with broad-spectrum antibiotics. She should receive penicillin G, however, to prevent perinatal group B streptococcus infection (Fig. 46-3).

Group B Streptococcus Intrapartum Prophylaxis

Ten to 30% are colonized with GBS in the vagina or rectum, and 1% to 2% of neonates born to colonized women develop early-onset invasive GBS disease. One-fourth of all cases of neonatal GBS infections occur in preterm newborns. B.B.'s fetus, therefore, is at risk for invasive GBS or *Streptococcus agalactiae* infection from vertical transmission (mother to infant) of bacteria during labor or delivery.¹⁸⁴ The mortality rate for GBS is reported to be between 5% and 20%. During pregnancy, GBS infection causes maternal urinary tract infection, amnionitis, endometriosis, and wound infection.¹⁸⁴ Antibiotics given to the mother during preterm labor and delivery prevent neonatal GBS disease. In the past decade, the routine administration of intrapartum antibiotic prophylaxis to certain subsets

of pregnant women has led to a 70% reduction in the overall incidence of GBS disease (see Chapter 94, Neonatal Therapy). The decision to treat women with intrapartum antibiotics has been based on either a positive vaginal GBS culture or one or more of the following risk factors without culture screening: (a) previous infant with invasive GBS disease; (b) GBS bacteriuria during current pregnancy; (c) preterm labor of <37 weeks' gestation; (d) PROM ≥ 18 hours; and (e) intrapartum temperature $\geq 38^{\circ}\text{C}$ (100.4°F).¹⁸⁴ This treatment algorithm prevents an estimated 85% of all early-onset GBS disease (Fig. 46-4). A multistate, retrospective cohort study identified the culture-screening process as being 50% more effective than the risk-based process.¹⁸⁵ Consequently, the Centers for Disease Control and Prevention (CDC) and ACOG no longer recommend the risk-based approach, except in situations for which no culture results are available before delivery.¹⁸⁶

Vaginal and rectal GBS cultures should be obtained from B.B., and she should be given a loading dose of penicillin G injection 5 MU, followed by 2.5 MU IV every 4 hours until delivery, while awaiting success of tocolysis and culture results. CDC guidelines recommend that the benchmark for optimal prophylaxis should be antibiotics given at least 4 or more hours before delivery. Penicillin G is preferred over ampicillin because it has a narrower spectrum of antimicrobial activity. If B.B. had a history of anaphylaxis to penicillin, sensitivities to clindamycin and erythromycin should be requested at the time

^a If onset of labor or rupture of amniotic membranes occurs at <37 weeks' gestation and there is a significant risk for preterm delivery (as assessed by the clinician), a suggested algorithm for GBS prophylaxis management is provided (Figure 46-2).

^b If amnionitis is suspected, broad-spectrum antibiotic therapy that includes an agent known to be active against GBS should replace GBS prophylaxis.

FIGURE 46-4 Indications for intrapartum antibiotic prophylaxis to prevent perinatal group B streptococcus (GBS) disease under a universal prenatal screening strategy based on combined vaginal and rectal cultures collected at 35–37 weeks' gestation from all pregnant women.

of culture in the event GBS is found, because of increasing resistance to these drugs. Antibiotic regimens for intrapartum antimicrobial prophylaxis are listed in Table 46-5.

57. B.B.'s culture results are negative for GBS growth. She is still at high risk for imminent delivery. Should penicillin G administration be discontinued?

Penicillin should be discontinued at this time. Vaginal and rectal cultures need not be repeated if B.B. delivers within the next 4 weeks. If tocolysis is successful and delivery is delayed for more than 4 weeks, obtaining cultures and starting penicillin G pre-emptively should be repeated at that time. Intrapartum prophylaxis is effective only if antibiotics can be given immediately before and during delivery.

Table 46-5 Recommended Regimens for Intrapartum Antimicrobial Prophylaxis for Perinatal GBS Disease Prevention^a

| | |
|---|---|
| <i>Recommended:</i> Penicillin G, 5 million units IV initial dose, then 2.5 million units IV every 4 hours until delivery | |
| <i>Alternative:</i> Ampicillin, 2 g IV initial dose, then 1 g IV every 4 hours until delivery If penicillin allergic ^b | |
| <i>Patients not at high risk for anaphylaxis:</i> | Cefazolin, 2 g IV initial dose, then 1 g IV every 8 hours until delivery |
| <i>Patients at high risk for anaphylaxis^c:</i> | |
| GBS-susceptible to clindamycin and erythromycin ^d : | Clindamycin, 900 mg IV every 8 hours until delivery or Erythromycin, 500 mg IV every 6 hours until delivery |
| GBS-resistant to clindamycin or erythromycin or susceptibility unknown: | Vancomycin, ^e 1 g IV every 12 hours until delivery |

^a Broader-spectrum agents, including an agent active against GBS, may be necessary for treatment of chorioamnionitis.

^b History of penicillin allergy should be assessed to determine whether a high risk for anaphylaxis is present. Penicillin-allergic patients at high risk for anaphylaxis are those who have experienced immediate hypersensitivity to penicillin including a history of penicillin-related anaphylaxis; other high-risk patients are those with asthma or other diseases that would make anaphylaxis more dangerous or difficult to treat, such as persons being treated with beta-adrenergic-blocking agents.

^c If laboratory facilities are adequate, clindamycin and erythromycin susceptibility testing should be performed on prenatal GBS isolates from penicillin-allergic women at high risk for anaphylaxis.

^d Resistance to erythromycin is often but not always associated with clindamycin resistance. If a strain is resistant to erythromycin but appears susceptible to clindamycin, it may still have inducible resistance to clindamycin.

^e Cefazolin is preferred over vancomycin for women with a history of penicillin allergy other than immediate hypersensitivity reactions, and pharmacologic data suggest it achieves effective intra-amniotic concentrations. Vancomycin should be reserved for penicillin-allergic women at high risk for anaphylaxis.

GBS, group B streptococcus.

TERATOGENICITY

Medication Use During Pregnancy

Drug use during pregnancy presents a great challenge to clinicians because of the potential adverse effect on the embryo, fetus, and newborn. The limited availability of scientific data from randomized trials complicates the decision to prescribe and recommend medications for pregnant women, even when they are medically necessary. Most drugs are not labeled by the manufacturer for use during pregnancy because of the medical and legal implications. The potential benefits of medication therapy must be weighed against the possible risks to the fetus. Currently, only a few therapeutic agents of the thousands of drug therapies are adequately studied and considered relatively low risk on the development of the embryo and fetus. Knowledge of the teratogenic potential of these agents can be used to prevent or limit fetal exposure during the course of a pregnancy.

Many women have the general perception that use of any medication during a pregnancy can harm the developing fetus. This thought may lead to consideration of terminating wanted pregnancies or withholding necessary drug therapy during the course of the pregnancy. A thorough assessment, including knowledge of the teratogenic potential of the drug, the critical period of exposure, and magnitude of risk must be compared with the background risk. The basic principles of teratogenicity can help to assess the risk of exposure and interpretation of limited studies during pregnancy.

Rates of Drug Consumption During Pregnancy

Pregnancy is a symptom-producing condition. As a result, many drugs regularly are consumed during gestation, including some that are potential teratogens. The critical period to avoid or limit drug therapy exposure is during organogenesis (5–10 weeks after the last menstrual period or 20–55 days after conception) when most vital organs in the embryo are developing.¹⁸⁷ During these early weeks of pregnancy, the embryo is the most susceptible to medication exposure when many women are not yet aware of the pregnancy.

Earlier epidemiologic studies attempting to identify patterns of drug exposure during pregnancy have estimated that women consumed on average five to nine medications. A more recent epidemiologic collaborative study, conducted under the auspices of the World Health Organization (WHO) Drug Utilization Research Group, assessed the pattern of drug use in pregnancy in 22 countries.¹⁸⁸ This survey of 14,778 women estimated that approximately 14% did not take any medications during pregnancy. In the group that did consume drugs, the average number of drugs taken was 2.9. Vitamin and iron supplements were those most commonly used, followed by anti-infectives, and analgesics, antipyretics, and anti-inflammatory agents.¹⁸⁸ The proportion of women who consumed medications and the pattern of drug use varied by geographic distribution.

Proven Human Teratogens

The term *teratogen* is used to denote an agent that has the potential under certain exposure conditions to produce abnormal development in the fetus.¹⁸⁷ The extent to which a drug

will affect the development of the fetus depends on the physical and chemical properties of the drug as well as the dose, duration, route, and timing of exposure; and genetic composition and biological susceptibility of the mother and fetus.¹⁸⁹ Numerous drugs have been associated with congenital anomalies, but only in a few cases has a consensus been reached that a specific agent is teratogenic. Table 46-6 lists those agents generally considered or suspected to be proven human teratogens. Not all these teratogens will cause development toxicity with every exposure, however. Table 46-7 lists some medications that can be used selectively during pregnancy when indicated.

The largest concern with medication use during pregnancy is the risk of congenital malformations. Congenital malformations are defined as “structural abnormalities of prenatal origin that are present at birth and that seriously interfere with viability or physical well-being.”¹⁹⁰ Congenital anomalies or birth defects are the leading cause of infant mortality in the United States, accounting for 20% of all infant deaths.¹⁹¹ The economic impact of anomalies from the 18 most clinically significant structural birth defects is approximately \$8 billion annually.¹⁹² This estimate does not include minor anomalies or the psychological and emotional impact to the child and family. Some drug-induced defects relate to changes in functions or conditions that are not structural abnormalities (e.g., mental retardation, CNS depression, deafness, tumors, or biochemical changes). The broader term *congenital anomalies* include the four major manifestations of abnormal fetal development which include growth alterations, functional deficits, structural malformations, and fetal death.¹⁸⁷

Prevalence of Congenital Malformations

The background incidence of birth defects in the general population must be taken into consideration when interpreting the risk of drug-induced teratogenicity. The prevalence of major congenital malformations discovered at or shortly after birth in the general population is approximately 3%.¹⁹³ This number has been derived from large epidemiologic studies completed over the past several decades and depends on how terms are defined (e.g., major versus minor congenital malformations), the thoroughness with which the infant is examined, and how long the exposed person is followed after birth.¹⁸⁷ Although the collection of data on the occurrence of malformations would seem to be straightforward, it is in fact a complicated task subject to numerous errors and biases. Some studies examined only “significant anomalies,” others “major malformations,” whereas still others reported only “live births” or “single births” or “birth weights >500 g.” Stillbirths and spontaneous abortions, both often associated with congenital malformations, often were excluded from epidemiologic data. Neurodevelopmental delays and growth retardation also are potential long-term effects that will not be diagnosed in the immediate postpartum period. The prevalence of congenital anomalies is likely >3% if minor anomalies and long-term adverse effects are considered.

Despite the significant impact of drug-induced birth defects, it is difficult and unethical to conduct randomized, controlled trials to assess the risk of fetal exposure to drugs in humans. Much of the data available are derived from epidemiologic

Table 46-6 Drugs With Suspected or Proven Teratogenic Effects in Humans^a

| | |
|--|--|
| Alcohol | Growth restriction, mental retardation, midfacial hypoplasia, renal and cardiac defects |
| Aminopterin, methotrexate | Central nervous system (CNS) and limb malformations |
| Angiotensin converting enzyme (ACE) inhibitors and angiotensin receptor blockers (ARB) | Renal failure in the fetus and neonates, decreased skull ossification, renal tubular dysgenesis |
| Antithyroid drugs | Fetal and neonatal goiter and hypothyroidism, aplasia cutis (with methimazole) |
| β -Blockers (without intrinsic sympathomimetic activity) | Intrauterine growth restriction |
| Carbamazepine | Neural tube defects, minor craniofacial defects, fingernail hypoplasia |
| Cigarette smoking | Oral clefts |
| Cocaine | Bowel atresias, heart, limbs, face, and genitourinary tract malformations; microcephaly, cerebral infarctions, growth restriction |
| Corticosteroids | Oral clefts |
| Cyclophosphamide | CNS malformations, secondary cancer |
| Danazol and testosterone | Masculinization of female fetus |
| Diethylstilbestrol | Vaginal carcinoma and other genitourinary defects |
| Lithium | Ebstein anomaly |
| Misoprostol | Moebius sequence and spontaneous abortions |
| Nonsteroidal anti-inflammatory drugs | Constriction of the ductus arteriosus, oral clefts, cardiac defects, and possible spontaneous abortion |
| Paramethadione and trimethadione | Facial and CNS defects |
| Phenytoin | Fetal hydantoin syndrome, growth retardation, CNS deficits |
| Streptomycin and kanamycin | Hearing loss, eighth cranial damage (no ototoxicity reported with gentamicin use) |
| Systemic retinoids (isotretinoin and etretinate) | CNS, craniofacial, cardiovascular, and other defects |
| Tetracycline | Anomalies of teeth |
| Thalidomide | Limb shortening defects, internal organ defects |
| Trimethoprim | CNS deficits, possible cardiac defects and oral clefts |
| Vaccines (live) | Live attenuated vaccines can potentially cause fetal infection |
| Valproic acid | Neural tube defects |
| Vitamin A (high dose) | Deficiency and excess can cause teratogenicity. High dose (>25,000 IU/day): craniofacial and CNS anomalies, facial palsy and clefts, cardiac defects, limb reductions, gastrointestinal (GI) atresias, and urinary tract defects |
| Warfarin | Dandy Walker syndrome, skeletal and CNS defects |

^aTeratogenic effects include the four major manifestations of abnormal fetal development which include growth alterations, functional deficits, structural malformations, and fetal death.

^bOnly drugs that are teratogenic when used at clinically recommended doses are listed. From references, 33 and 210, with permission.

studies, anecdotal experiences in humans, and animal studies. Because birth defects are species specific and influenced by many factors including genetic predisposition, the data must be carefully interpreted and the results not over generalized.

Although once thought to be rare occurrences, the tragedy with thalidomide in the early 1960s highlights the detrimental effects of fetal exposure to drugs. With >7,000 cases, observed defects included various forms of limb defects, including phocomelia, as well as other major organ abnormalities.¹⁸⁷ The embryotoxic effects were unexpected because no teratogenicity was observed in different animal species, and only mild adverse effects were reported in human adults. Other examples of iatrogenic major birth defects include diethylstilbestrol (DES), which causes vaginal adenocarcinoma in female offspring (detected only in later years of life), and valproic acid, which causes neural tube defects.³³ Classifying thalidomide as a teratogen means that it has the potential to cause developmental toxicity under specific conditions. For example, a single 50-mg dose of thalidomide increases the risk for a major structural malformation if given on the 26th day after conception, and confers minimal risk if taken in the 10th week after conception. Furthermore, a 1-mg dose of thalidomide taken at anytime during pregnancy has no observable effects on the fetus.¹⁹⁴

Causes of Malformations

Classification

Causes of congenital malformations are generally classified into one of five categories: (a) monogenic origin; (b) chromosomal abnormalities; (c) multifactorial inheritance; (d) environmental factors; and (e) unknown.^{193,195} Single gene and chromosomal-related defects account for approximately 25% of all congenital malformations in live-born infants (monogenic, 7.5%–20%; chromosomal, 5%–6%).^{190,195} *Multifactorial inheritance* refers to defects that are polygenic in origin; it has an environmental component. One surveillance program estimated that this interaction between genetic and environmental factors causes 23% of defects.¹⁹³ Congenital dislocation of the hip is an example of a defect in this category: the depth of the acetabular socket and joint laxity are genetically determined, and a frank breech malposition is one of the environmental factors.¹⁹⁶ In most cases, however, the environmental factors in multifactorial inheritance are unknown.

Environmental factors account for approximately 10% of malformations.¹⁹⁵ These include maternal conditions, mechanical effects, chemicals and drugs, and certain infectious agents. Maternal diseases associated with malformations include diabetes, phenylketonuria, virilizing tumors, and

Table 46-7 Medications Which Can Be Used Selectively During Pregnancy When Indicated, According to Condition

| Condition | Drugs of Choice | Alternative Drugs | Comments |
|---|--|--|---|
| Acne | Topical: erythromycin, clindamycin, benzoyl peroxide | Systemic: erythromycin, topical tretinoin (vitamin A acid) | Isotretinoin is contraindicated |
| Allergic rhinitis | Topical: glucocorticoids, cromolyn, decongestants, xylometazoline, oxymetazoline, naphazoline Systemic: diphenhydramine, dimenhydrinate | | |
| Constipation | Docusate sodium, glycerin, Milk of Magnesia, Metamucil, sorbitol, lactulose | Bisacodyl | Enema use should be avoided |
| Cough | Diphenhydramine, phenergan, dextromethorphan, guaifenesin | | |
| Depression | Tricyclic antidepressants, bupropion, selective serotonin reuptake inhibitors (SSRI) but avoid paroxetine, serotonin-norepinephrine reuptake inhibitors (SNRI) | | Exposure to paroxetine during the first trimester has been associated with an increased risk for cardiac malformations. Persistent pulmonary hypertension and neonatal withdrawal syndrome may occur in infants with maternal SSRI, SNRI use. |
| Diabetes | Insulin (human) | Insulin analogs (lispro, aspart, glargine), glyburide | Limited experience with metformin, studies mostly in polycystic ovarian syndrome patients. The role of other hypoglycemics not evaluated yet. |
| Headache (tension) | Acetaminophen | Aspirin and nonsteroidal anti-inflammatory drugs (NSAID), benzodiazepines | Aspirin and NSAID should be avoided in third trimester owing to concerns of oligohydramnios and premature closure of the ductus arteriosus, which can lead to pulmonary hypertension in the newborn. Small risk of malformations and spontaneous abortions with NSAID use in first trimester. |
| Migraine | Acetaminophen, codeine, dimenhydrinate | β -adrenergic receptor antagonists, tricyclic antidepressants (used for prophylaxis) | Limited experience with ergotamine has not revealed evidence of teratogenicity, but there is concern about potent vasoconstriction and uterine contraction. |
| Hyperthyroidism | Propylthiouracil | Methimazole, β -adrenergic receptor antagonists (for symptomatic relief) | Surgery may be required; radioactive iodine should be avoided (especially after 10 weeks gestation). Small risk of aplasia cutis with methimazole use. |
| Infections | Penicillins, cephalosporins, clindamycin, erythromycin, nitrofurantoin | Gentamicin, vancomycin | Theoretic risk of hyperbilirubinemia in newborn with sulfamethoxazole in third trimester. Possible risk of hemolytic anemia in newborn with nitrofurantoin if taken close to term. |
| Mania (and bipolar affective disorders) | Lithium, chlorpromazine, haloperidol | For depressive episodes, tricyclic antidepressants drugs, SSRI (avoid paroxetine), valproic acid | If lithium is used in first trimester, fetal echocardiogram is recommended because of small risk of cardiac anomalies; valproic acid may be given after the first trimester. |
| Nausea and vomiting | Doxylamine with pyridoxine (Vitamin B ₆) | Chlorpromazine, metoclopramide, diphenhydramine, dimenhydrinate, meclizine, ondansetron | |
| Peptic ulcer disease | Antacids, magnesium hydroxide, aluminum hydroxide, calcium carbonate, ranitidine | Sucralfate, bismuth subsalicylate | Proton pump inhibitors (PPI) should be reserved for severe reflux. Omeprazole is only PPI with a pregnancy category D listing. |
| Pruritis | Topical: aluminum acetate, zinc oxide, calamine, glucocorticoids Systemic: hydroxyzine, diphenhydramine | Topical: local anesthetics | Small risk of oral clefts in first trimester if oral corticosteroids are used. |
| Smoking cessation | Nicotine lozenges, gums | Nicotine patches | Avoid during first trimester if possible, wear patches 16 hours during day to reduce nicotine exposure. Off during night. |
| Thrombophlebitis, deep vein thrombosis | Heparin, low-molecular weight heparins, antifibrinolytic, streptokinase | | Streptokinase is associated with risk of bleeding; warfarin should be avoided |

Modified and updated data taken from reference 33, with permission.

maternal hyperthermia. About 9% (range, 6.6%–13.0%) of infants of diabetic mothers develop major congenital defects, primarily consisting of cardiovascular, neural tube, and skeletal malformations.¹⁹⁷ Mechanical effects, such as intrauterine compression and abnormal cord constriction, may result in fetal deformations.^{195,197}

Probably the best known of the teratogenic viruses is rubella, which can cause a fetal rubella syndrome consisting of cataracts, heart disease, and deafness.¹⁹⁸ *In utero* exposure to rubella in the first trimester can cause defects in up to 85% of fetuses. Cytomegalovirus (CMV) infection occurs in 0.5% to 1.5% of newborns in the United States, resulting in deafness and mental retardation in 5% to 10% of these infants.¹⁹⁰ Characteristics of cytomegalic inclusion disease, the syndrome produced by CMV, include IUGR, microcephaly, and at times chorioretinitis, seizures, blindness, and optic atrophy.¹⁹⁹ Herpes simplex 1 and 2 and varicella may be associated with malformations.¹⁹⁵ The data on varicella are controversial.¹⁹⁸

The protozoan generally accepted as a teratogen is *Toxoplasma gondii*.¹⁹⁰ Most infants infected with *T. gondii* show no symptoms and develop normally. When toxicity does occur, the anomalies may consist of hepatosplenomegaly, icterus, maculopapular rash, chorioretinitis, cerebral calcifications, and hydrocephalus or microcephalous.¹⁹⁹ *Treponema pallidum* (syphilis) can cross the placenta and cause congenital syphilis as well as other defects, such as hydrocephaly, chorioretinitis, and optic atrophy.^{195,198} *In utero* exposure to syphilis after the fourth month of pregnancy is associated with higher risk.

The final category, defects of unknown cause, comprises the greatest percentage of congenital malformations, accounting for about 60% to 65% of the total.¹⁹³

Basic Principles of Teratogenicity

Several critical factors are to be considered in evaluating the effects of drug exposure in human pregnancies. Because every pregnancy has the risk of an abnormal outcome regardless of drug exposure, the objective of evaluating data on drug exposure during pregnancy is to ascertain if a particular drug increases the risk of developmental toxicity in the fetus beyond the background rate. The following basic principles of teratogenicity should be applied when assessing the potential for teratogenicity of drugs.

Critical Stage of Exposure

After fertilization, the development of the embryo and fetus is divided into three main stages: pre-embryonic period, embryonic period, and fetal period.^{195,200} In the first 2 weeks after fertilization or the pre-embryonic period (0–14 days), little is known about the effects of drugs on human development. Exposure to a teratogenic agent during this period usually produces an “all or none” effect on the ovum²⁰¹: the ovum either dies from exposure to a lethal dose of a teratogenic drug, or it regenerates completely after exposure to a sublethal dose. Some animal studies have suggested, however, that exposure to some drugs during the preimplantation stage can halt growth and development before implantation.²⁰² Although the damage can be repaired, intrauterine growth may be retarded in the offspring.

During the embryonic period (14–56 days after fertilization), when organogenesis occurs, the embryo is most suscep-

tible to the effects of teratogens or other chemicals.²⁰⁰ Exposure during this sensitive period may produce major morphologic changes. These stages of development differ significantly from other species, and knowledge of these stages is essential for the interpretation of the relationship between congenital malformations and drugs. For example, if a specific drug exposure occurs after the time of organ development, then a structural defect in that organ is less likely to be caused by that specific drug.

The fetal period (57 days to term) includes most of the stages of histogenesis and functional maturation, although the latter continues for some time after birth.^{195,200} Minor structural changes are still possible during histogenesis, but anomalies are more likely to involve growth and functional aspects such as mental development and reproduction.

Dose-Response Curve

All teratogens follow a toxicologic dose-response curve.¹⁸⁷ All teratogens have a threshold dose below which adverse effects will not occur. The threshold dose is the dosage in which the incidence of structural malformations, rate of fetal death, growth restriction, and functional deficits does not exceed the background rate in the general population.¹⁸⁷ Conversely, developmental toxicity may occur when the fetus is exposed to doses above the maximum or threshold dose. There may be an increase in the severity and incidence of malformations when the fetus is exposed to increasingly higher dosages. For example, the risk for major congenital malformations, including NTD and minor anomalies, are increased statistically in patients taking valproic acid dosages >1,000 mg/day during the first trimester.²⁰³

Extrapolation From Animal Studies

In the absence of human trials, data derived from animal studies is used to assess the level of risk of developmental toxicity in humans. Most newly marketed drugs often have to rely on preclinical data to develop an estimation of teratogenic risk based on animal studies until human data becomes available. The dose used in experimental animal data is expressed as multiples of the human dose using plasma or serum AUC or dose per unit based on body surface area (BSA).³³ The drug appears to have a low risk for teratogenicity if the toxic dose in animals (based on AUC or mg/m² comparison) is greater than 10 times the anticipated human dose.²⁰⁴ Risk assessment using animal data is more complicated than just considering the dosage alone. Other major factors, including the effects of metabolism and active metabolites, species differentiation, route of administration, and type of defects, must be considered.¹⁸⁷

Genetic Variability

The most potent teratogenic agent will not produce malformations with every exposure.¹⁸⁷ The teratogenic potential of some drugs is influenced by the genotype of both the mother and fetus. Although the effects of known teratogens can be predictable in the general population, the possibility of individual assessment is difficult. The same dose of a teratogenic agent exposed at the same gestational window will produce variable outcomes in different people. Genetic variability can confer differences in cell sensitivities, placental transport, drug metabolism, enzyme composition, and receptor binding, which may affect how much active drug will reach fetal tissues.²⁰⁵

One study showed an increased susceptibility to the teratogenic effect of phenytoin most likely caused by elevated levels of oxidative metabolites (epoxides). These epoxides are normally eliminated from the systemic circulation by enzymes called microsomal epoxide hydrolase. Women who are homozygous for the recessive allele produce low levels of epoxide hydrolase, which may expose the fetus to higher levels of epoxides. These fetuses may be at a higher risk for fetal hydantoin syndrome.²⁰⁶

Specific Grouping of Defects

Most human teratogens generally produce specific defects or grouping of defects.¹⁸⁷ These congenital malformations occur after exposure during a critical period of embryonic development. One theory suggests that a teratogenic agent can possibly be identified by grouping individual malformations by understanding their embryologic tissue of origin.¹⁸⁷ For instance, isotretinoin interferes with the neural crest cell migration and leads to malformations of the ear, heart, and neural tube.³³ Thalidomide causes limb, spine, and CNS defects.³³ The rate of malformations in these teratogens must be compared with the background incidence in the general population.

Placental Transfer of Drugs

At one time, the placenta was thought to present a barrier to the passage of drugs and noxious chemicals to the fetus. It is now known, however, that most medications cross the placenta to the fetus and, in general, what the mother consumes also is consumed by the fetus. Although the placenta acts as a biologic membrane, it initially is composed of four layers effectively separating two distinct individuals.²⁰⁷ These layers are (a) the endothelial lining of fetal vessels, (b) the connective tissue in the core of the villus, (c) the cytotrophoblastic layer, and (d) the covering syncytium. During gestation, the placenta's surface area increases while its thickness decreases from approximately 25 microns during the first trimester to 2 to 6 microns at term. Both processes tend to favor the transfer of chemicals to the fetus.

Drugs, nutrients, and other substances cross the placenta by five mechanisms: (a) simple diffusion (e.g., most drugs), (b) facilitated diffusion (e.g., glucose), (c) active transport (e.g., some vitamins, amino acids), (d) pinocytosis (e.g., immune antibodies), and (e) breaks between cells (e.g., erythrocytes).^{200,207} The latter two mechanisms are of no practical importance in the transfer of drugs.

Several factors influence the rate of drug transfer across the placenta, including molecular weight (MW), lipid solubility, ionization, protein binding, uterine and umbilical blood flow, and maternal diseases.²⁰⁰ Drugs with molecular weights <600 cross easily, whereas those >1,000 (e.g., heparin) cross with difficulty or not at all. Because most drugs have molecular weights <600, it is safe to assume that most drugs reaching the mother's circulatory system also will reach the fetus. As with other biologic membranes, lipid-soluble substances are transferred rapidly, with the rate of entry primarily governed by the lipid solubility of the nonionized molecule. Conversely, those molecules that are ionized at physiologic pH (e.g., the cholinergic quaternary amines) cross slowly, whereas weak acids and bases with pKa values between 4.3 and 8.5 are transferred rapidly to the fetus. The penetration of highly protein-bound drugs also is inhibited; only the free, unbound drugs cross the placenta.

Uterine blood flow, a major factor in determining the rate of drug transfer, increases throughout gestation. Several variables can affect uterine blood flow and the rate of drug transfer, including maternal blood pressure, cord compression, and drug therapy. Maternal hypotension reduces uterine blood flow and the rate at which substances are delivered to the membrane. Cord compression reduces the blood flow on the fetal side of the membrane. The use of drugs with α -adrenergic property (e.g., epinephrine) may constrict uterine vessels and thereby reduce blood flow.²⁰⁸ Maternal diseases, such as pregnancy-induced hypertension, erythroblastosis, and diabetes, change the permeability of the placenta and may reduce or increase transfer.²⁰⁰

Food and Drug Administration Risk Factors

In 1979, the FDA introduced a system of rating pregnancy risks associated with pharmacologic agents. This system categorizes all drugs approved after 1983 into one of five pregnancy risk categories (see Table 46-1). It establishes the level of risks to the fetus based on available animal and human data and recommends the degree of caution that should be undertaken with each drug. The risk factors assigned are sometimes difficult to interpret because they may be ambiguous, outdated, and do not provide information regarding the full range of potential developmental toxicity (i.e., structural defects, growth restriction, functional deficits, and fetal death).²⁰⁴ Level of risks also have been described and categorized by teratology specialists, and they may or may not concur with manufacturers' ratings.^{208,209} The FDA is currently working on revising the pregnancy labeling and category system to include narrative text to provide more clinical management advice that includes consideration of both animal and human data.²⁰⁴ Table 46-6 lists some drugs that are considered contraindicated during pregnancy. These lists are not all-inclusive, and a review of specialty resources on drug use in pregnancy is recommended.^{199,208,209} Teratogen information programs also are available in the United States and Canada to respond to questions concerning the risks of drug exposure during pregnancy. These programs are usually affiliated with medical or university settings.^{210,211} Because the potential for fetal risks cannot be entirely disregarded for many drugs, the need to medicate during pregnancy should be evaluated carefully.

LACTATION

Lactation is controlled primarily by prolactin (PRL), but the entire process is under the intricate control of several hormones. Breast tissue maturation during pregnancy is influenced by many factors, including estrogen, progesterone, PRL, insulin, growth hormone, cortisol, thyroxine, and human placental lactogen.²¹² PRL concentrations gradually increase during pregnancy, but high estrogen and progesterone concentrations inhibit milk secretion by blocking PRL's effect on the breast epithelium.^{212,213} It is the dramatic decrease in progesterone that triggers lactogenesis or milk secretion for the first 3 days following delivery. Infant suckling at the breast is necessary to maintain an adequate milk supply beyond postpartum day 3 or 4. Nipple stimulation transmits sensory impulses to the hypothalamus to initiate PRL release from the anterior pituitary and oxytocin from the posterior pituitary. Prolactin stimulates

the production and secretion of breast milk and oxytocin stimulates the contraction of the myoepithelial cells in the breast alveoli and ducts so that milk can be ejected from the breast (milk letdown). Oxytocin also can be secreted through other sensory pathways, which is why women can release milk on hearing, smelling, or even thinking about their infants. Prolactin, however, is released only in response to nipple stimulation.

Prolactin synthesis and release depend on the inhibition of hypothalamic prolactin inhibitory factor (PIF) secretion. Prolactin secretion is regulated primarily by dopamine-releasing neurons. Activating the dopamine receptors on the prolactin-secreting cells of the anterior pituitary inhibits the release of prolactin. PIF is believed to be closely associated with dopamine.^{212,213}

Although prolactin controls the volume of milk produced, once lactation is established, milk production is regulated by infant demand. Lactation eventually ceases if milk is not removed from the breast. Absence of suckling stops milk letdown and restores the normal production of PIF. Decreased blood flow to the breast reduces oxytocin delivery to the myoepithelium. Consequently, milk secretion stops within a few days.^{212,213}

Stimulation

Nonpharmacologic Measures

58. C.C., a 22-year-old woman, vaginally delivered her first child, a healthy term infant. C.C. plans to breast-feed and was educated about breast-feeding during obstetric visits and prenatal classes. After giving birth, C.C. tried to breast-feed in the delivery room with great difficulty. Afterward, she became extremely apprehensive and continued to have trouble breast-feeding. What can be done to encourage C.C. and help her with lactation?

The most effective stimulus for lactation is suckling. Many women nurse in the delivery room after uncomplicated vaginal deliveries because nursing increases maternal–infant bonding and helps establish good milk production. If a mother does not nurse immediately after delivery, she should be encouraged to do so as soon as she is physically able. C.C. did try to nurse after delivery, but experienced problems that may have been related to her emotional or physical state, or to the physical state of her infant. The nursing staff should encourage and support C.C. emotionally to help her relax, be comfortable, and relieve her anxiety about breast-feeding. Health care personnel also should emphasize appropriate feeding techniques and proper positioning for breast-feeding. Allowing C.C.'s infant to sleep in her room, rather than the nursery, may help C.C. develop a breast-feeding routine.

Most new mothers who have difficulty breast-feeding initially respond to the emotional and educational support of a good obstetric nursing staff. Few require pharmaceutical intervention.

Enhancement of Milk Production

59. C.C. was successful in establishing breast-feeding. Despite good technique and adequate nutrition, she, however, had trouble maintaining adequate milk production after about 2 to 3 weeks and was forced to supplement her infant with formula. How can C.C.'s milk production be enhanced?

Although not an FDA-approved indication, metoclopramide is used to stimulate lactation in women with decreased or inadequate milk production.^{33,214–218} Metoclopramide, a dopamine-antagonist, increases PRL secretion. This is particularly useful in women whose infants do not breast-feed effectively (e.g., preterm infants).²¹⁴ Metoclopramide 10 mg orally three times daily for 1 to 2 weeks is effective in restoring milk production.^{33,214–217} Improvement in lactation occurs within 2 to 5 days of starting therapy and persists after discontinuing metoclopramide.

The estimated total daily dose of metoclopramide ingested by the nursing infant of a woman on 30 mg/day is 1 to 45 mcg/kg/day.³³ This is below the maximal recommended infant daily dose of 0.5 mg/kg/day. Maternal doses of 30 mg/day do not alter PRL, thyroid-stimulating hormone, or free thyroxin serum concentrations in breast-fed infants.²¹⁸ The only adverse effect reported in nursing infants has been intestinal gas.^{33,216} The short-term use of metoclopramide for re-establishing lactation appears to be both safe and effective, even in preterm infants.^{33,214,217} The American Academy of Pediatrics (AAP), however, considers metoclopramide use in breast-feeding women to be of concern because of the potential for adverse CNS effects in infants.³³

Suppression

60. After delivery, J.G., a 26-year-old G₂P₂, informs her obstetrician that she does not wish to breast-feed. What methods are available to suppress lactation?

Suppression of lactation is indicated for women who do not want to breast-feed, women who have delivered a stillborn infant, and those who have had an abortion. Both drugs and nonpharmacologic methods have been used. In 1988, the FDA, however, recommended against drug-induced suppression of lactation.²¹⁹ The only drug therapy that the FDA recommends in women who are not breast-feeding are analgesics for the relief of breast pain. Bromocriptine (Parlodel) was approved for the postpartum suppression of lactation; however, the FDA rescinded its approval for that indication because of cardiovascular complications (e.g., stroke, myocardial infarction) associated with its use.²¹³

If breast stimulation is avoided (with or without the use of a breast binder), breast milk production will continue, leading to engorgement and distention of breast alveoli. This leads to the termination of lactation after several days. Approximately 40% of women using this method experience breast discomfort and pain; 30% experience milk leakage from their nipples.^{219,220} Ice packs may be applied to the breasts for comfort and a mild analgesic used if necessary.

DRUG EXCRETION IN HUMAN MILK

Breast milk is recognized as the optimal source of nutrition for infants, with documented benefits not only to infants but also to mothers, families, and societies.²²¹ Evidence indicates that breast-feeding decreases the incidence or severity of many infectious processes (e.g., otitis media, respiratory infections, urinary tract infections) in infants. In children and adults who were breast-fed, the risk of developing certain medical illnesses also may decrease (e.g., obesity, inflammatory bowel

disease, celiac disease, childhood leukemia).²²² Breast-feeding may also positively influence cognitive and intellectual development in children and young adults.²²³ Numerous benefits to the mother also have been identified, such as decreased postpartum blood loss, more rapid uterine involution, earlier return to prepregnancy weight, and decreased risks of breast cancer, ovarian cancer, and osteoporosis.²²¹

The AAP recommends that mothers breast-feed for ≥ 12 months. Recognition of the importance of breast-feeding is highlighted in *Healthy People 2010*, a national health promotion and disease prevention program that helps the nation address public health issues by establishing objectives and goals. In the United States, breast-feeding during the early postpartum period increased from 54% in 1988 to 73.8% in 2004.²²⁴ The percentage of women who are still breast-feeding at 6 months decreases to 41.5%. Although encouraging, these figures are still below the *Healthy People 2010* targets of 75% for early postpartum and 50% at 6 months.

The perception that nursing should be discontinued while the mother is medicated persists, although only a finite number of drugs are absolutely contraindicated during lactation. This misconception is likely a result of the uncertainty surrounding the effects of exposure of many drugs in nursing infants because of the inherent difficulties in accessing risks in controlled environments (e.g., clinical trials). Unlike the use of drugs during pregnancy, when the effects of fetal exposure are difficult to predict, drug excretion in breast milk can be approximated to a certain extent. Actual measurements of drug concentrations in milk and clinical observations in breast-fed infants have been published for selected drugs. An understanding of the basic physiochemical principles of drug excretion in breast milk and the factors that affect this process allows for better prediction of the risk of drug exposure to the nursing infant.

Pharmacokinetics

Different pharmacokinetic models of drug excretion in milk have been described.^{225–227} A two-compartment open model presents the maternal fluids as one compartment and breast milk as the other. After ingestion, the drug gets absorbed into the maternal compartment, with a proportion of drug passing into breast milk and the remaining portion distributed in and eliminated from the maternal system. Drugs reaching breast milk will ultimately leave this compartment either by diffusing back into maternal fluids or through milk production and nursing.^{226,227} A more popular model describes drug excretion in milk using a three-compartment model that incorporates the pharmacokinetics of the mother, mammary tissues, and infant.^{225,226} The overall risk to the infant depends on the amount of drug bioavailable to the mother, the amount reaching breast milk, and the actual amount of drug ingested and bioavailable to the nursing infant.

Transfer of Drugs From Plasma to Milk

Transfer of drugs from maternal plasma to milk is generally through passive diffusion.²²⁸ Low-molecular-weight, water-soluble substances diffuse through small, water-filled pores, whereas lipid-soluble compounds pass through lipid membranes.²²⁹ Many factors affect the excretion of drugs in breast milk, and they should be carefully assessed before mak-

ing a recommendation. The extent of drug passage into breast milk is often expressed quantitatively as the milk-to-plasma (M:P) ratio. This ratio should not be used as the sole determinant of whether a drug is safe for use during breast-feeding (see Estimating Infant Exposure).

Several parameters affect drug excretion into breast milk (Table 46-8). The pKa of a drug partially determines how much drug can reach the milk, because only the nonionized portion of free drug is transferred. Human milk, with an average pH of 7.1, is slightly more acidic than plasma. In general, drugs that are weak acids (e.g., penicillin) tend to have a higher concentration in plasma than milk (M:P < 1). Conversely, the concentration of weak bases (e.g., erythromycin) in milk is more likely to be higher or to reach an equilibrium with that measured in plasma (M:P ≥ 1).^{225,227} Once in the milk, the proportion of ionized weak base rises in the relatively acidic solution, and thus drug “trapping” occurs. Drug reabsorption has been found for some agents, and the prevention of passage back into the plasma by “trapping” may be clinically important. Lipid solubility also is determined to a large extent by the degree of ionization because drugs with relatively high lipid solubility exist in the nonionized form. Diffusion through lipid membranes is probably the most important pathway for drug transfer. Although pH, pKa, and lipid solubility are important elements, other factors may significantly modify predictions based solely on these chemical characteristics. Two of these other factors are protein binding and molecular weight.^{228–230} Drugs with high molecular weights such as insulin (MW > 6,000) are less likely to transfer into breast milk, whereas those with molecular weights < 300 transfer more readily.²³¹ Highly protein-bound drugs such as glyburide (99% protein bound) are less likely to be transferred into breast milk, although infants should still be monitored for signs of hypoglycemia.

Drug transfer also is influenced by the yield of milk, which is related to blood flow and prolactin secretion.²²⁵ Lactation is associated with a high blood flow to the breasts, but little is known about this flow during or between feedings. The milk yield (volume) differs slightly depending on the duration of

lactation and the time of day. A diurnal pattern has been observed, with highest yields at 6 AM and lowest yields at 6 PM or 10 PM. The mean composition of mature human milk is approximately 87% aqueous solution, 3.5% lipids, 8% carbohydrate (83% of which is lactose), 0.9% protein, and 0.2% nitrogen.²³² The proportions of these components may vary widely from woman to woman and even within the same woman. For example, hind milk contains four- to fivefold the fat content of foremilk, whereas colostrum contains little fat. Fat content also has exhibited a diurnal variation.

After a drug reaches the milk, it equilibrates between the aqueous and lipid phases. The nature of this equilibration can modify how much drug actually reaches the infant. Infant feeding patterns differ significantly from one baby to another. The time spent suckling at each breast and the volume of milk taken in also determine the amount of drug ingested, especially if the drug has partitioned into one phase more so than the other. Once the infant ingests the drug via breast milk, the pharmacologic and adverse effects on the infant will be determined by the extent of oral bioavailability, distribution, metabolism, and rate of elimination. These pharmacokinetic parameters differ, depending on the infant's age and whether he or she was born prematurely or at term.

Estimating Infant Exposure

Understanding the transfer of drugs into breast milk is important because the primary objective is to minimize infant exposure to these substances. The actual amount an infant will ingest is difficult to determine owing to varying maternal, drug, and infant parameters. Available data generally are from single or small numbers of case reports or pharmacokinetic studies involving few mother–infant pairs. An M:P ratio is sometimes used alone as the basis for a recommendation, but this should be avoided because its accuracy can be affected by many factors. The time of sampling after maternal ingestion (peak versus steady-state), dose, length of therapy, route of administration, and milk composition are a few of the variables that can influence the M:P ratio.^{225,227,230} Sampling during maternal peak drug concentration attempts to approximate the highest amount of drug that can reach the infant. This assumption is inherently flawed because peak drug concentration in the mother does not necessarily equate with peak drug concentration in milk at that same point in time.^{226,230} The amount of drug an infant actually receives also depends on the volume of milk ingested. Even if a drug has a high M:P ratio, the actual amount received by the infant could be low if only a small volume of milk was consumed. Therefore, an M:P ratio describes the likelihood of drug excretion into breast milk, but it does not indicate the level of infant exposure. In general, drugs with lower M:P ratios (<1) are preferred over those with higher M:P ratios (>1) during breast-feeding, but other parameters such as maternal condition and therapeutic efficacy should be considered.

Infant exposure to a drug via ingestion of breast milk can be estimated for some drugs. The M:P ratio is used to estimate the drug concentration in milk (Equation 46-1) and the dose the infant may ingest (Equation 46-2).^{211,226,230} The variables required to calculate Equation 46-1 can be located in the published literature, but only for some drugs. The actual volume of milk ingested by the infant is difficult to estimate, but the average consumption is approximately 150 mL/kg/day.²³⁰ The

estimated infant dose can then be used to calculate a “relative infant dose” (RID) (Equation 46-3), which is expressed as a percentage of the maternal dose.²³³ A RID <10% is generally interpreted as an acceptable level. This must be interpreted with caution, however, taking into account other variables, such as the age and health of the infant and the safety profile of the drug. It is also important to note that these are estimated values, often based on data collected from one or only a few individuals. Applying these equations using measurements specific to a woman and her infant is not clinically practical, however. Compared with the M:P ratio, experts believe that the RID is a better estimate of infant exposure.

$$\text{Drug concentration in milk} = \text{Maternal plasma drug concentration} \times \text{M/P} \quad (46-1)$$

$$\text{Infant dose (mg/kg/day)} = \frac{\text{Drug concentration in milk} \times \text{Milk volume (mL/Kg/day)}}{\text{Milk volume (mL/Kg/day)}} \quad (46-2)$$

$$\text{RID (\%)} = \frac{\text{Infant dose [mg/kg/day]}}{\text{Maternal dose [mg/kg/day]}} \times 100 \quad (46-3)$$

Reducing Risk of Exposure

If pharmacologic treatment is medically necessary for a nursing mother, every attempt should be made to minimize infant exposure to the drug. Methods of reducing risks have been proposed.^{226,227,234} Table 46-9 summarizes critical factors that should be considered. Except for drugs that are contraindicated during lactation, the decision to continue or discontinue nursing while receiving medication is ultimately the mother's.

Table 46-9 Reducing Risk of Infant Exposure to Drugs in Breast Milk^{226, 227, 233, 234}

A drug should be used only if medically necessary and treatment cannot be delayed until the infant is ready to be weaned.

Drug Selection

- Consider whether the drug can be safely given directly to the infant.
- Select a drug that passes poorly into breast milk with the lowest predicted M:P ratio, and a RID <10%.
- Avoid long-acting formulations (e.g., sustained-release).
- Consider possible routes of administration that can reduce drug excretion into milk.
- Determine length of therapy and if possible avoid long-term use.

Feeding Pattern

- Avoid nursing during times of peak drug concentration.
- If possible, plan breast-feeding before administration of the next dose.

Other Considerations

- Always observe the infant for unusual signs (e.g., sedation, irritability, rash, decreased appetite, failure to thrive).
- Discontinue breast-feeding during the course of therapy if the risks to the fetus outweigh the benefits of nursing.
- Provide adequate patient education to increase understanding of risk factors.

RID, relative infant dose; M:P, milk to plasma ratio.

Table 46-10 Drugs Considered Contraindicated During Lactation^a

| Drug or Drug Class | Effects on Nursing Infants |
|--|--|
| Amphetamine ^b | Accumulate in breast milk and may cause irritability and poor sleep patterns ^{208,235} |
| Antineoplastics | Potential for immune suppression; cytotoxic effects on drugs on dividing cells in infants unknown ²³⁵ |
| Cocaine ^b | Excreted in milk; contraindicated because of central nervous system (CNS) stimulation and intoxication ^{208,235} |
| Ergotamine | Potential for suppressing lactation; vomiting, diarrhea, and convulsions have been reported. ²⁰⁸ Considered contraindicated by some clinicians. American Academy of Pediatrics (AAP) recommends using with caution ²³⁵ |
| Heroin ^b | Possible addiction if sufficient amounts ingested ^{208,235} |
| Immunosuppressants | Potential for immune suppression ²³⁵ |
| Lithium | Milk and serum concentrations average 40% of maternal serum levels. Potential for toxicity exists. ^{208,231} Considered contraindicated by some clinicians. AAP recommends using with caution. ²³⁵ |
| Lysergic acid diethylamide (LSD) ^b | Probably excreted in milk ²⁰⁸ |
| Marijuana ^b | Excreted in milk ^{208,235} |
| Misoprostol | Excretion in milk has not been studied but contraindicated because of potential for severe diarrhea in infant ²⁰⁸ |
| Phencyclidine ^b | Potent hallucinogenic properties ^{208,235} |
| Phenindione | Massive scrotal hematoma and wound oozing after herniotomy in one infant; contraindicated ^{208,235} |
| Requiring Temporary Cessation of Breast-Feeding | |
| Metronidazole (after single-dose therapy) | Diarrhea and secondary lactose intolerance in one infant; mutagenic and carcinogenic in some species; AAP recommends halting breast-feeding for 12–24 hrs to allow clearance of drug from the milk if single-dose therapy administered. ^{231,235} |
| Radiopharmaceuticals | Halt breast-feeding temporarily to allow clearance of radioactivity from milk. Suggested times for individual agents are ²³⁵ : Copper-64 (⁶⁴ Cu) 50 hrs; Gallium-67 (⁶⁷ Ga) 2 wks; Indium-111 (¹¹¹ In) 20 hrs; Iodine-123 (¹²³ I) 36 hrs; Iodine-125 (¹²⁵ I) 12 days; Iodine-131 (¹³¹ I) 2–14 days; Radioactive Sodium 96 hrs; Technetium-99m (^{99m} Tc) 15 hrs–3 days; (^{99m} TcO ₄) (^{99m} Tc macroaggregates) 15 hrs–3 days. |

^aThis list is not all-inclusive. Selected drugs are listed by drug class and not by individual names.

^bAll drugs of abuse are contraindicated during lactation.

Therefore, patient education is an integral component in this decision-making process. The mother should be informed of the potential risks, or lack thereof, associated with a drug. She also should be made aware that certain risks may be minimized by altering feeding pattern and drug administration time and by carefully monitoring the infant for early signs of adverse effects.

Resources for Drugs and Lactation

Comprehensive sources reviewing drug use in lactation are available to assist clinicians in weighing the potential risks versus benefits of mothers using medications while breast-feeding. Table 46-10 lists some medications that are contraindicated during lactation. The AAP Committee on Drugs reviews periodically the transfer of drugs and other chemicals into human milk and publishes their findings.²³⁵ The Committee identifies drugs that should be avoided during breast-feeding, drugs that should be used with caution, drugs whose effects on infants are unknown but of concern, and those considered usually compatible with breast-feeding. This rigorous review is an ongoing process, and new guidelines are published every few years; therefore, the reader should locate the latest AAP recommendations available. In addition to the AAP guidelines, several other references also offer comprehensive information and recommendations on drug use in lactation.^{208,230}

Most drugs are excreted into breast milk to some extent, the reader is referred to specialty sources for an in-depth review of the drug in question. The best sources for information regarding drugs in lactation are (a) *Drugs in Pregnancy and Lactation* by Briggs, Freeman, and Yaffe³³ and (b) TOXNET, an online lactation database (LactMed) sponsored by the NIH,

assessable at <http://toxnet.nlm.nih.gov> and click on LactMed. These two databases are peer-reviewed and referenced sources. Categories assigned to these drugs may change as new data become available for specific drugs.

THERAPEUTIC DILEMMAS IN PREGNANT AND LACTATING WOMEN

Anticoagulation

Warfarin

FETAL WARFARIN SYNDROME

61. H.P. is a 25-year-old woman with a 5-week intrauterine pregnancy. She recently was diagnosed with a distal deep vein thrombosis (DVT) in her lower left extremity. She has a significant history of having multiple DVTs in her prior pregnancies and her thrombophilia workup was negative. Currently, she is taking warfarin 5 mg/day and just found out that she is pregnant. Does warfarin present a therapeutic problem to the fetus? If so, what changes should be made?

Warfarin (Coumadin) crosses the placenta and is generally considered contraindicated in pregnancy except under specific circumstances.²³⁶ Use of warfarin in the first trimester has been associated with a characteristic pattern of defects collectively known as the fetal warfarin syndrome (FWS).²³⁷ The susceptible period seems to be between weeks 6 and 12 of gestation.^{237,238} Nasal hypoplasia and a depressed nasal bridge are common to all known cases of FWS. The nares and air passages may be constricted to such a degree that respiratory distress results. As seen roentgenographically, stippling in uncalcified epiphyseal regions occurs in most newborns with FWS

but may not be evident after the first year of life.²³⁷ The axial skeleton, proximal femurs, and calcanei are the sites primarily involved in FWS, and this pattern of distribution distinguishes it from other syndromes and genetic disorders.²³⁷ Less common features are reduced birthweight, eye and ear defects, hypoplasia of extremities, development retardation, congenital heart disease, laryngeal calcification, and death.^{209,239}

The exact incidence of warfarin-induced anomalies is unknown, but it is estimated to range from 17% to 37%.^{208,240} The rate of FWS reported is approximately 3% to 10%.^{208,209} Therefore, the use of warfarin in H.P. is controversial. Discontinuation of warfarin should be considered, especially during the critical period between weeks 6 and 12 of gestation.

Warfarin exposure after this critical period may increase the risk of CNS anomalies in the fetus. These anomalies appear to be a result of abnormal growth arising from an earlier fetal hemorrhage and subsequent scarring.²³² Two distinct patterns of CNS damage may occur: (a) dorsal midline dysplasia, characterized by agenesis of the corpus callosum, Dandy-Walker malformation, midline cerebellar atrophy, and encephaloceles in some; and (b) ventral midline dysplasia, characterized by optic atrophy.^{232,234} The effects of CNS defects include mental retardation (ranging from mild to severe), blindness, hydrocephalus, deafness, spasticity, seizures, scoliosis, growth failure, and death. Fetal complications from warfarin may be dose dependent, as demonstrated in two retrospective studies.^{240a,240b} Cotrufo et al.^{240b} observed that daily warfarin doses >5 mg were associated with more pregnancy complications, including adverse fetal outcomes.

Heparin and more recently low-molecular-weight heparin (LMWH) are the preferred anticoagulants in pregnancy for most indications, including prevention and treatment of DVT.²³⁸ The efficacy of heparin and LMWH in pregnant women with prosthetic heart valves is less clear, although they have a better safety profile for the fetus. If heparin or LMWH is used in H.P., close monitoring for thromboembolic complications is required.²⁴¹

Heparin

62. Heparin therapy (10,000 U SC every 8 hours) is initiated, and warfarin is discontinued. What are the fetal and maternal risks of using heparin in H.P.?

Heparin is a large molecule (MW 12,000) and does not cross the placenta. According to the Seventh American College of Chest Physicians (ACCP) Consensus Conference, heparin is one of the preferred anticoagulants during pregnancy for most thromboembolic conditions because of its efficacy and more favorable safety profile compared with warfarin.²³⁸ Although earlier cases reported that the rate of fetal complications associated with heparin use may be as high as those reported with warfarin (22% versus 27%, respectively),²³⁷ subsequent evaluations demonstrated that the rate of adverse fetal outcome with heparin therapy is comparable to that reported in the normal population.^{209,240} The high incidence of fetal abnormalities reported earlier can be attributed to the use of heparin in pregnancies with comorbid conditions known to increase risks.

Nevertheless, the use of heparin during pregnancy may pose several risks to the mother. The risk of bleeding from heparin during pregnancy is approximately 2%.²³⁸ Heparin-induced thrombocytopenia (HIT) is a well-recognized com-

plication and may require discontinuation of therapy if it is an immune-mediated response. The frequency of HIT during pregnancy is unknown but has been estimated at 3% in non-pregnant patients.²³⁸

Prolonged administration of heparin (>1 month) increases the risk of developing osteoporosis. Although the occurrence of symptomatic fractures is uncommon (2%–3%), the development of osteopenia may occur in up to one third of pregnant women on chronic heparin therapy.^{242–246} This reduction in bone mineral density (BMD) may be reversible after discontinuation of heparin.^{243,245} Heparin-induced osteoporosis may be associated with higher doses of heparin and longer duration of use. In a prospective, cohort study of 184 cases by Dahlman,²⁴⁴ the incidence of osteoporosis was higher in women who received a mean dose of 25,000 units/24 hours versus a mean dose of 16,500 units/24 hours. The average duration of treatment was 25 weeks (range, 7–27 weeks). A definitive dose-response relationship cannot be confirmed, however, because reductions in BMD have been reported with lower dosages and shorter duration of heparin use. The mechanism behind this effect is thought to be heparin inhibition of the renal activation of calcifediol (25-hydroxyvitamin D₃, a major transport form of vitamin D) to calcitriol, one of the active forms of vitamin D₃. Several recent studies have suggested that LMWH may pose a lower risk of osteoporosis than unfractionated heparin (UFH).

63. H.P. presents again at 20 weeks' gestation complaining of mild muscle pain and tingling in the lower left extremity. Laboratory workup confirmed an activated partial thromboplastin time (aPTT) of 1.5 times control despite an adjusted heparin dosage of 15,000 units SC every 8 hours several weeks ago. H.P. is now in her second trimester. What subjective and objective evidence does H.P. exhibit that indicates a need to change anticoagulant therapy?

H.P. is at increased risk for thromboembolic complications because her aPTT is not within the therapeutic range and her heparin dosage is not currently adequate to maintain anticoagulation. Higher doses are generally required because of increases in plasma volume, renal clearance, heparin-binding proteins, and decreased bioavailability of heparin because of degradation by the placenta.²⁴⁷ To minimize H.P.'s risk of developing thrombotic complications and osteoporosis, an adjusted-dose regimen with SC heparin every 8 hours is warranted. The lowest effective heparin dose to achieve a mid-interval aPTT at least two times control should be maintained.²³⁸

H.P.'s symptoms are consistent with thromboembolism. Her low aPTT level despite a high dosage of heparin suggests an increased requirement for heparin. Because H.P. already is on high-dose heparin, prolonged administration will significantly increase her risk of osteoporosis. Of special concern is her apparent resistance to heparin therapy. An alternative anticoagulant should be considered to minimize her risk for further thrombotic complications.

Low-Molecular-Weight Heparin

64. Is LMWH an alternative for H.P.?

As with heparin, LMWH does not cross the placenta to the fetus. LMWH offers a better bioavailability profile, more convenient dosing, and it may be associated with less thrombocytopenia, bleeding, and osteoporosis than UFH.²³⁸ It is often preferred in most patients because it requires less monitoring

of laboratory values than UFH. A starting dosage of 1 mg/kg given SC every 12 hours should be used. Regular antifactor Xa levels drawn 3 to 4 hours after a dose at steady-state to achieve a level of 0.5 to 1.2 U/mL is recommended.²³⁸ As H.P.'s pregnancy progresses and her weight increases, the volume of distribution for LMWH also will change. Adjustments to the dosage of LMWH can be made through weight-based changes or in response to antifactor Xa levels drawn. Preliminary data suggest LMWH does not increase the risk of adverse birth outcomes.^{248,249} Although it is an effective alternative to heparin in general, its role in preventing thromboembolic complications in pregnant women with prosthetic heart valves has not been determined.

Heparin and LMWH in the Third Trimester Near Delivery

65. H.P. is now at 38 weeks' gestation and has a scheduled cesarean section in 1 week. She currently is on enoxaparin 100 mg SC every 12 hours. What advice should be given to help her manage her anticoagulation just before surgery?

To minimize bleeding complications during delivery, the Seventh ACCP Conference on Antithrombotic and Thrombolytic Therapy suggests that heparin and LMWH be discontinued 24 hours before elective induction of labor or cesarean section.²³⁸ If spontaneous labor occurs before her scheduled cesarean section, neuroaxial anesthesia can become complicated if H.P. is anticoagulated. If the aPTT or antifactor Xa is markedly prolonged near delivery, protamine sulfate may be required to decrease the risk of bleeding.

Graduated compression stockings should be used during and after H.P.'s cesarean section because some data have suggested that some patients (i.e., prior venous thromboembolism, thrombophilia, age >35 years, obesity, prolonged bedrest) are at high risk for thromboembolic complications.²³⁸ Anticoagulation with heparin should be reinitiated after surgery once H.P. is hemodynamically stable and the risk of bleeding is low. H.P. is at an increased risk for venous thrombosis during both pregnancy and the postpartum period.

Breast-Feeding

66. After vaginal delivery, H.P. is restarted on low-dose heparin and then changed to warfarin on day 5. H.P. also is breast-feeding. Does either of these drugs present a risk to the nursing infant?

Heparin does not cross into breast milk (see Drug Excretion in Human Milk) because of its high molecular weight (~12,000). Therefore, the risk from this anticoagulant is minimal. Warfarin is a weakly acidic drug (pKa 5.05) that is highly ionized at physiologic pH (>99%) in maternal serum.²²⁹ It also is highly protein bound (97%).²³⁹ These pharmacokinetic parameters make warfarin unlikely to transfer into breast milk. Case reports in lactating mothers confirm that warfarin was not detected in breast milk or infant plasma, or that very low amounts were detected in breast milk.²⁰⁸ The AAP lists warfarin under the category of "usually compatible with breast-feeding."²³⁵ As a precaution, the mother should observe the infant for bruising or other signs of hemorrhage, although the apparent risk is low.

Antiepileptic Drugs

Phenytoin

67. L.F. is a 30-year-old woman with epilepsy who is planning to start a family. Her generalized tonic-clonic seizures have been well controlled with oral phenytoin 100 mg four times daily (QID), and L.F. has had no seizures for the past 3 years. She is otherwise healthy and is not taking any medication besides phenytoin. Should L.F. become pregnant, what are the risks of phenytoin to the fetus?

Approximately 90% of women with epilepsy who receive antiepileptic drugs (AED) have uneventful pregnancies. A few women have an increased risk for fetal abnormalities, with both major and minor malformations reported. Controversy exists over whether maternal epilepsy increases the rate of malformations; however, newer studies suggest this increased incidence is most likely caused by AED therapy.^{250–252} The risk of fetal abnormalities is lowest with monotherapy and is generally considered to be two- to threefold higher than in the general population.²⁵³ In a prospective study by Holmes et al.²⁵² conducted between 1986 and 1993, congenital malformations occurred more frequently in infants exposed to one AED compared with controls (20.6% versus 8.5%; odds ratio [OR] 2.8; 95% confidence interval [CI] 1.1–9.7). The rate was even higher for infants exposed to two or more AED compared with control (28% versus 8.5%; OR 4.2; 95% CI 1.1–5.1). Abnormalities most commonly observed with the use of AED are major congenital malformations (e.g., cardiac malformations, cleft lip or palate), microcephaly, hypoplasia of the midface and fingers, and growth retardation.^{252,254,255} Preliminary data also proposed that children exposed to AED *in utero* may be more likely to have developmental delay, childhood medical problems, and behavior disorders.²⁵⁶ More studies are needed to confirm these initial findings.

FETAL HYDANTOIN SYNDROME

Phenytoin (Dilantin) can cause a recognizable pattern of malformations collectively known as the *fetal hydantoin syndrome* (FHS). It is now recognized that this syndrome is not restricted to phenytoin use and can be linked to other AED. Infants of mothers who were treated with AED have a 10% to 30% chance of developing some aspects of FHS, but the full-blown syndrome is less common.^{257–259}

Common features identified with FHS are varying degrees of craniofacial malformations, including lip and palatal changes; limb anomalies, such as hypoplasia of nails and distal phalanges; congenital heart disease; and mental and physical growth retardation.^{208,257,258}

PROPOSED MECHANISMS OF TERATOGENICITY

A study published in 1990 demonstrated a relationship between levels of activity of the enzyme epoxide hydrolase and the risk of FHS.²⁵⁷ Toxic oxidative metabolites of phenytoin normally are removed by epoxide hydrolase, which appears to be regulated by a single gene with two allelic forms. The level of enzyme activity was measured using amniocytes obtained through amniocentesis. Fetuses of women with low activity of this enzyme appear to be at an increased risk from phenytoin. If further studies confirm these findings, this would be an example of an interaction between the mother's genetic

predisposition and the environment (in this case, a drug). Two other AED, phenobarbital and carbamazepine, also are metabolized via this route.

A second proposed mechanism is altered folate concentration by AED. Phenytoin, carbamazepine, and barbiturates have been shown to decrease serum folate concentration. Valproic acid also decreases this by interfering with folate metabolism. Decreased folate concentration is correlated with an increased risk of developing NTD.^{251,260,261}

CARCINOGENIC POTENTIAL

Phenytoin may be a human transplacental carcinogen: several tumors have been observed in children exposed to this drug during gestation.²⁰⁸ The reported tumors are neuroblastoma (five cases), ganglioneuroblastoma (one case), melanotic neuroectodermal tumor (one case), extrarenal Wilms tumor (one case), mesenchymoma (one case), lymphangioma (one case), and ependymoblastoma (one case). Exposed children must be evaluated closely for several years because tumors may take that long to appear.

HEMORRHAGIC DISEASE OF THE NEWBORN

The use of phenytoin and other AED during the third trimester increases the risk of HDN.²⁰⁸ Both early HDN (onset, 0–24 hours) and classic HDN (onset, 2–5 days) may occur in gestationally exposed infants. The hemorrhage is often life-threatening, with intracranial bleeding common. It is thought to result from phenytoin induction of fetal liver microsomal enzymes that further deplete the already low reserves of fetal vitamin K. Suppression of the vitamin K-dependent clotting factors, II, VII, IX, and X, results from the hypovitaminosis. Phenytoin-induced thrombocytopenia also may play a role in the bleeding. Vitamin K₁ (phytonadione) 1 mg should be given IM to the neonate at birth for prophylaxis against HDN.^{250,258}

Teratogenicity of Nonhydantoin Antiepileptic Drugs

68. Do other AED offer an advantage over phenytoin in pregnancy?

For patients with generalized tonic-clonic seizures, the drugs that offer the most effective therapy are phenytoin, carbamazepine (Tegretol), and valproic acid (Depakene). Primidone (Mysoline), phenobarbital, and clonazepam (Klonopin) may be effective as alternative or adjunctive agents, whereas ethosuximide (Zarontin) and trimethadione (Tridione) are not indicated. Whether these AED offer any advantage over phenytoin depends on many variables, including fetal risks to drug exposure and the likelihood of maintaining seizure control if phenytoin were discontinued or another AED initiated.

CARBAMAZEPINE

Carbamazepine, an AED structurally related to the tricyclic antidepressants, has been used frequently in pregnancy. It was once thought to be the AED of choice because earlier reviews failed to demonstrate a relationship with congenital malformations.^{262,263} Evidence since has linked carbamazepine to fetal abnormalities.^{208,209} Numerous case reports and epidemiologic studies have been published involving carbamazepine-induced anomalies. Earlier reports described a pattern of malformations similar to FHS.²⁶⁴ It

has been postulated that carbamazepine and phenytoin may cause a similar pattern of fetal abnormalities because both are metabolized through the arene oxide pathway to produce an oxidative intermediate that is embryotoxic.^{264,265} Matalon et al.²⁶⁶ conducted a meta-analysis of 1,255 *in utero* exposures to carbamazepine that confirmed a 2.89 times increased risk of major congenital anomalies in exposed children compared with healthy controls. No significant difference in congenital anomalies was observed in untreated epileptic women compared with controls. Anomalies reported with carbamazepine include cardiac defects, urinary tract defects, craniofacial defects, cleft palate, fingernail hypoplasia, and low birthweight.^{264,266,267} In addition, exposure to carbamazepine *in utero* carries a 0.5% to 1% risk of developing NTD, including spina bifida.^{261,268} If possible, carbamazepine should be avoided in women with family histories of NTDs.²⁵⁰

VALPROIC ACID

In utero exposure to valproic acid is associated with a broad range of major and minor congenital anomalies often referred to as *fetal valproate syndrome* (FVS).^{209,269} Abnormalities may involve craniofacial defects, organ malformations, and growth and developmental defects. In a review of 70 cases of valproic acid exposure, some of the more common features were small or broad nose (57%), small or abnormal ears (46%), long or flat philtrum (43%), and hypertelorism (27%).²⁶⁹ Use of valproic acid during pregnancy is associated with a 1% to 2% risk of NTD, ranging from spina bifida to meningocele.²⁰⁸ Other major adverse fetal effects observed with this drug include craniofacial, cardiac, digital, skeletal and limb, urogenital, skin and muscle, and miscellaneous anomalies.²⁰⁸ A small observational study of nine infants from mothers who received valproic acid during pregnancy suggests that valproic acid may cause immediate and long-term (evaluated at 6 years of age) neurologic dysfunction in some children.²⁷⁰ If valproic acid must be used during pregnancy, the total dose should be divided over three or four administrations per day to avoid high plasma concentrations, because NTD may be dose dependent.^{250,258,271} Dosages >1,000 mg/day may be associated with an increased risk of congenital anomalies.²⁶⁹ As with carbamazepine, valproic acid should be avoided in women with a family history of NTD.²⁵⁰ High serum concentration of the free fraction of valproic acid during labor and at birth may be responsible for a fetal or newborn toxicity consisting of fetal distress and low Apgar scores.²⁷² Because of the high incidence of teratogenicity, valproic acid does not offer any advantage over phenytoin in L.F.

PHENOBARBITAL

Phenobarbital often is used in combination with phenytoin, although it is used much less frequently as a single agent for the treatment of the type of seizures that L.F. has. Although a recognizable pattern of malformations, such as FHS, does not occur in epileptic women treated only with phenobarbital, some of the minor anomalies composing FHS are observed.²⁰⁸ In three cases, women treated during the first trimester with only primidone, a structural analog of phenobarbital, bore infants with malformations similar to those with FHS. Another pharmacologically related AED is mephobarbital (Mebaral), which is partially demethylated by the liver to

phenobarbital. The teratogenic potential of mephobarbital is unknown because information about its use during pregnancy is limited.²⁰⁸

All of these agents may induce maternal folic acid deficiency, a situation similar to that observed with phenytoin. Low folate concentration is linked to NTD. Hemorrhagic disease of the newborn has been reported after phenobarbital or primidone exposure and should be expected after mephobarbital use as well. The mechanism of this effect and its treatment are the same as that described for phenytoin.

In addition, barbiturate withdrawal has been observed in newborns exposed to phenobarbital during gestation. The average onset of symptoms was 6 days (range, 3–14 days) after birth, and withdrawal has been reported with daily doses as low as 64 mg.²⁰⁸ Neonates should be monitored for withdrawal symptoms for 2 to 6 weeks because phenobarbital has a long elimination half-life (100 hours).²⁵¹ Recent data also suggest that infants exposed to phenobarbital *in utero* may experience some decline in cognitive performance.²⁵⁸ Use of phenobarbital could be considered for L.F.; however, carbamazepine, valproic acid, and phenytoin are the preferred AED for tonic-clonic seizures.

ALTERNATIVE ANTIEPILEPTIC DRUGS

Experience with clonazepam as an AED is limited in human pregnancy. One infant exposed *in utero* and delivered prematurely at 36 weeks' gestation developed apnea, cyanosis, lethargy, and hypotonia at 6 hours of age.²⁷³ Although congenital malformations were not evident, the toxic symptoms persisted for several days. Clonazepam usually is given in combination with other AED; hence, an increased rate of malformations caused by the agent would be difficult to detect. Thus, too little information is available to recommend this drug.

NEWER ANTIEPILEPTIC DRUGS

69. Several AED have been approved in the past few years. Have they been associated with teratogenicity, and do they offer any advantage over phenytoin for L.F.?

Most of the newer AED are approved as adjunctive therapy for partial seizures; currently, they are not first-line therapy for generalized tonic-clonic seizures. Their safety in women with epilepsy during pregnancy is yet to be determined because little information is available to assess their teratogenic potential.

Of the newer AED, preliminary pregnancy outcomes are available for lamotrigine (Lamictal). The manufacturer of lamotrigine, GlaxoSmithKline, initiated the International Lamotrigine Pregnancy Registry in 1992 to monitor the occurrence of major structural birth defects associated with *in utero* exposure to lamotrigine. As of September 30, 2001, birth outcomes for 389 pregnancies were prospectively collected and analyzed.²⁷⁴ Of these, 168 infants were exposed to lamotrigine monotherapy. Three cases (1.8%) of major birth defects (esophageal malformation, cleft soft palate, right clubfoot) were observed. The occurrence of birth defects was higher in women on polytherapy, especially those who received lamotrigine and valproic acid (5 of 50; 10%). In comparison, the rate of major birth defects for infants exposed to lamotrigine polytherapy without valproic acid was 4.3% (5 of 116). Lamotrigine is rated preg-

nancy risk category C and has been found to cross the placenta in one case report.²⁷⁵

Other new AED available include felbamate (Felbatol), gabapentin (Neurontin), levetiracetam (Keppra), oxcarbazepine (Trileptal), tiagabine (Gabitril), topiramate (Topamax), and zonisamide (Zonegran). The teratogenic risk of these new agents has not been determined. They are rated pregnancy risk category C, and malformations have been reported in animals exposed to these agents.²⁷⁶ The use of felbamate in any epileptic patient is limited because of the risk of aplastic anemia and acute liver failure. Until more data become available, these new AED do not appear to offer any advantage for L.F.

Reducing Fetal Risks

70. If L.F. chooses to become pregnant, what steps should her physician implement to lessen the risks of AED toxicity to her fetus?

Preconception planning with patient education is an extremely important component in epileptic women desiring to bear a child. Achieving good seizure control before conception is imperative. Although no clear consensus on the AED of choice during pregnancy has been reached, discontinuation of the agent should be considered in women who have been free of seizures for at least 2 to 5 years.²⁵⁸ The dose should be tapered over 1 to 3 months. In patients for whom withdrawal is not an option, monotherapy is preferred, and the lowest effective dose of the appropriate AED should be used.^{250,253,258} Because L.F. has had no seizure activity for the past 3 years, her phenytoin should be gradually discontinued before conception. If discontinuation is not an option, a careful reduction of her dose may be possible.

Close monitoring of phenytoin plasma concentrations is required during pregnancy to ensure maintenance of therapeutic levels and to help prevent seizures, which may increase the risk of fetal malformations. Consideration also should be given to changing L.F.'s drug therapy to another AED effective for tonic-clonic seizures. Any change to her regimen should be initiated and seizure control achieved before conception is attempted.

SUPPLEMENTAL FOLIC ACID

Folic acid deficiency increases the risk of NTD, such as spina bifida and anencephaly. The Medical Research Council (MRC) vitamin study evaluated the protective effects of folic acid in 1,817 pregnant women carrying fetuses at high risk for NTD.²⁷⁷ High-dose folic acid (4 mg once daily), given from the date of randomization until 12 weeks of pregnancy, reduced the risk of NTD by 72%. Women with epilepsy were excluded from this study because of concerns that elevated folate concentrations might interfere with AED therapy. It is now recommended that all women of childbearing age take 0.4 mg folic acid as a daily supplement. Women at high risk of having a child with NTD should consult with their health care provider and consider supplementing with 4 mg folic acid daily from at least 1 month before conception through the first 3 months of pregnancy.^{258,271} Because AED can significantly decrease folate concentrations, supplementation with folic acid 4 mg daily in epileptic women may be warranted to decrease the risk of NTD.

L.F. is at risk of having a child with NTD because of phenytoin therapy. The addition of folic acid 4 mg daily to her drug regimen should be considered, especially before conception and during the first 3 months of pregnancy.

Phenytoin in Breast Milk

71. If L.F. decides to breast-feed her newborn, would the use of phenytoin be expected to cause any problems?

Phenytoin is readily bioavailable after oral administration, but its high protein binding (95%) hinders its passage into breast milk.²³⁹ The estimated M:P ratio of 0.13:0.45 is low.²³⁰ Because an infant may receive about 5% of the maternal dose,²²⁷ the AAP considers maternal use of phenytoin compatible with breast-feeding.²³⁵ L.F. should be counseled on ways to reduce the risk of exposure (Table 46-9).

Isotretinoin

72. P.J., a 19-year-old woman with severe, recalcitrant nodular acne, has been treated with isotretinoin. After several months of therapy, P.J. suspects she is pregnant. What is the risk to P.J.'s fetus from isotretinoin exposure in early pregnancy?

Isotretinoin (Accutane), an isomer of vitamin A, was introduced in 1982 as a treatment for severe, recalcitrant nodular acne. The drug is rated pregnancy risk category X and is a known human teratogen.²⁷⁶ Serious fetal abnormalities, including spontaneous abortion, can occur with any amounts, even for a short duration of use after conception. A recognized pattern of embryopathy is reported with isotretinoin,^{209,276} which includes defects of the skull, ear (e.g., microtia or anotia), eye (e.g., microphthalmia), face, CNS, thymus, and cardiovascular system. Other adverse outcomes reported include cleft palate, rare limb defects, and low IQ scores.

To prevent unintended pregnancies in women, such as P.J., on isotretinoin, the manufacturer of Accutane established a more stringent prescribing program known as the System to Manage Accutane-Related Teratogenicity (SMART).²⁷⁶ Both the physician and patient are required to follow the steps of this program before isotretinoin is prescribed and dispensed. In general, routine pregnancy avoidance counseling, regular pregnancy testing, and use of two forms of effective contraception are required. Pregnancy should be avoided for at least 1 month after stopping therapy. The health care provider should refer to the package insert and contact the manufacturer for details.

Isotretinoin must be discontinued immediately for P.J. She has a significant chance of spontaneously aborting her fetus. Should her pregnancy continue to term, the likelihood of delivering an infant with a major congenital malformation is high. Her health care provider must discuss these risks with P.J. and closely monitor her for adverse fetal outcomes. After this pregnancy, whether P.J. remains a candidate for isotretinoin must be carefully reassessed.

Tretinoin

73. If P.J. had been treated with topical retinoic acid (tretinoin), another vitamin A derivative used for acne vulgaris, would this have placed her fetus at risk?

Tretinoin, as with other retinoids, is a potent teratogen when taken systemically. Topical use, however, is associated with minimal risk because, at most, only about one-third of a topical dose is absorbed.²⁰⁸ Assuming a 1-g/day application of a 0.1% preparation, this would amount to about one-seventh of the vitamin A activity received from a typical prenatal vitamin supplement. P.J.'s fetus would not have been at risk from this degree of exposure.

Antidepressants

Selective Serotonin Receptor Inhibitors (SSRI) Use in First Trimester

74. B.C. has been diagnosed with major depressive disorder since 3 years ago when she was started on oral fluoxetine 10 mg daily. She has recently had some sleep disturbances, decreased libido, and fatigue. Her dosage was increased to 20 mg daily a few months ago. Today, B.C. learns that she is pregnant at 6 weeks' gestation. The pregnancy was unplanned. B.C. has recently heard in the news that paroxetine can affect the development of a baby's heart. Because she is on fluoxetine, she is worried that it may have the same effects. What effects do SSRI have on the developing fetus during the first trimester?

Clinical depression can affect up to 20% of pregnant women.²⁷⁸ Depression during pregnancy can have adverse effects on the fetus and the mother if untreated. Pharmacotherapy is often needed in many cases. A recent study in 2006 showed an increase in relapse of major depression up to 68% in patients who discontinued their antidepressant medications during pregnancy compared with 26% of those who maintained treatment.²⁷⁹ Possible effects of antidepressants on pregnancy outcome have not yet been established. Antidepressants used during pregnancy have been associated with preterm delivery, low birthweight, growth impairment, neonatal toxicity, and physical and behavioral teratogenicity.²⁷⁸

Selective serotonin receptor inhibitors (e.g., fluoxetine, fluvoxamine, paroxetine, sertraline, escitalopram, and citalopram) are the most common antidepressants used in pregnancy. Although all the SSRI share a similar mechanism of action, their chemical structures differ.³³ These differences may also confer differences on pregnancy outcomes but further studies are needed to define the effects.

Recent studies have suggested that paroxetine may be associated with a small but significant increase in congenital malformations. Two epidemiologic studies found that paroxetine use during the first trimester increased the risk for congenital malformations 1.8 times and increased the risk for cardiac defects 1.5 to 2.0 times.²⁸⁰ Doses of paroxetine above 25 mg/day were more likely associated with major malformations and cardiac defects.²⁸¹ In December 2005, the FDA changed the pregnancy category for paroxetine from C to D and advised that it should be avoided if possible in the first trimester of pregnancy.²⁸² Two case control studies published in 2007 found that the absolute risk of any birth defects from paroxetine and other SSRI is small.^{283,284} The absolute risk for right ventricular outflow tract obstruction defects and all congenital heart defects would probably not exceed 1% and 2% respectively.²⁸⁵

Because B.C. has a history of major depressive disorder that has been well controlled on fluoxetine, she should continue on her antidepressant because she may be at high risk for relapse

of a major depressive episode if she discontinues treatment. Fluoxetine, the most studied SSRI in pregnancy, was not associated with an increased risk of cardiac anomalies.^{278,283,284} The risk of fetal harm must be weighed against the possible risk of untreated depression. The decision to continue or start antidepressants during pregnancy must be made on a case-by-case basis that involves a thorough discussion examining the risks.

Effect of SSRI in Third Trimester and in the Neonate

75. What are some risks to the fetus associated with SSRI use in third trimester and in the neonate after delivery?

Exposure to SSRI's use after 20 weeks' gestation was associated with persistent pulmonary hypertension in the newborn (PPHN). A case control study in 2006 found the absolute risk to be about 1%.²⁸⁶ Developmental toxicities are also associated with SSRI use during pregnancy, including spontaneous abortions, low birth-weight, premature delivery, poor neonatal adaptation syndrome, and possible long-term neurocognitive effects.²⁷⁸

POLYCYSTIC OVARY SYNDROME

Polycystic ovary syndrome (PCOS) affects approximately 6% to 8%, or 1 of 15 women of reproductive age, making it the leading cause of anovulatory infertility and the most common endocrine abnormality for this age group.¹ This syndrome, or constellation of symptoms, was first described in 1935 by Stein and Leventhal when they reported infertility and amenorrhea in seven women with enlarged cystic ovaries.² Excessive male-patterned hair growth and obesity were added later to the description of this syndrome.³ PCOS also has been referred to as Stein–Leventhal syndrome, polycystic ovary, polycystic ovarian disease, hyperandrogenic chronic anovulatory syndrome, and functional ovarian hyperandrogenism. The name “polycystic ovary syndrome” has been most widely accepted because it best describes the heterogeneous nature of this disorder.

Diagnostic Criteria

The diagnosis of PCOS is complicated by variations among women of the presenting signs and symptoms and because diagnostic criteria have changed over time. Precise and uniform criteria for diagnosis have not been firmly established. Three major diagnostic criteria for PCOS have been proposed by different organizations (Table 47-1).

The initial diagnostic criteria were developed in 1990 during an expert conference sponsored by the National Institutes of Health (NIH) and National Institute of Child Health and Human Development (NICHD). The panel concluded that the major criteria for PCOS should include (in order of importance): (a) hyperandrogenism (clinical signs of hyperandrogenism such as hirsutism) or hyperandrogenemia (biochemical signs of hyperandrogenism such as elevated testosterone

Table 47-1 Criteria for Defining Polycystic Ovary Syndrome (PCOS)

| Clinical Criteria | Proposed Definitions | | |
|--|---------------------------------|---|---|
| | NIH 1990 (all marked with ×) | ESHRE/ASRM (Rotterdam) 2003 (2 of first 3 criteria and last) | AES 2006 (first criterion, 1 of criteria 2 or 3, and last) |
| 1. Hyperandrogenism or hyperandrogenemia | × | × | × |
| 2. Oligo-ovulation or anovulation | × | × | × |
| 3. Polycystic ovaries (by ultrasound) | — | × | × |
| 4. Exclusion of related disorders | × | × | × |

AES, Androgen Excess Society; ESHRE/ASRM, European Society for Human Reproduction and Embryology/ American Society for Reproductive Medicine; NIH, National Institutes of Health.
Adapted from references, 4–6.

levels), (b) oligo-ovulation (infrequent or irregular ovulation with fewer than nine menses per year), and (c) exclusion of other known disorders such as hyperprolactinemia, thyroid abnormalities, and congenital adrenal hyperplasia.⁴ The second set of criteria was proposed at an expert conference in Rotterdam sponsored by the European Society for Human Reproduction and Embryology (ESHRE) and the American Society for Reproductive Medicine (ASRM) in 2003.⁵ They concluded that the presence of two of the following three features, after exclusion of related disorders, confirmed diagnosis of PCOS: (a) oligo-ovulation or anovulation, (b) clinical or biochemical signs of hyperandrogenism, or (c) polycystic ovaries. The third set of criteria was developed by a task force of the Androgen Excess Society (AES) in 2006.⁶ They concluded hyperandrogenism, hyperandrogenemia (highest priority), or both and ovarian dysfunction, as evidenced by oligo-ovulation, polycystic ovaries, or both must be present after exclusion of other androgen excess or related disorders. Strengths and weaknesses exist in each of the criteria proposed, but it is clear that the definition of and diagnostic criteria for PCOS will continue to evolve as new information is released.

Clinical Characteristics

Common clinical signs of PCOS include hirsutism, acne, and alopecia. Hirsutism, the most common of these characteristics, occurs in 60% to 70% of women with PCOS.⁶ It is defined as an excess of thickly pigmented body hair in a male pattern distribution and commonly found on the upper lip, lower abdomen, and around the nipples. Women seeking treatment for hirsutism may be evaluated for PCOS. Acne affects 15% to 25% of women with PCOS, but this prevalence may not be different than in the general population. Alopecia occurs in approximately 5% of women with PCOS and presents as scalp hair loss in the crown and vertex areas.⁷

Ovulatory dysfunction in PCOS is typically described as oligo-ovulation or anovulation, presenting clinically as a woman with irregular menstrual cycles. Overall, 60% to 85% of women with PCOS and oligo-ovulation have menstrual dysfunction, usually oligomenorrhea or amenorrhea.¹ The menstrual disturbances usually begin in the peripubertal years. An increased luteinizing hormone (LH) to follicle-stimulating hormone (FSH) ratio >2 or 3 may provide evidence for irregular ovulation. This occurs in 20% to 60% of women with PCOS.¹

Obesity occurs in approximately 30% to 60% of women with PCOS.¹ Central or abdominal obesity is the typical pat-

tern. Central obesity is a risk factor for the development of diabetes and heart disease and, when present in a woman with PCOS, worsens the clinical features (e.g., anovulation, hyperandrogenism, insulin resistance) of the syndrome.⁸ Therefore, lifestyle modification with appropriate diet and exercise is a cornerstone of therapy for many women with PCOS.

Pathophysiology

The pathophysiology of PCOS is complex. The primary defect in PCOS is unknown, but at least three potential mechanisms, acting alone or synergistically, appear to create the characteristic clinical presentation. These mechanisms include inappropriate gonadotropin secretion, excessive androgen production, and insulin resistance with hyperinsulinemia. Figure 47-1 displays the closely integrated relationship between these mechanisms in the development of PCOS.

A genetic basis for PCOS has been postulated, but its mode of transmission is unclear.⁹ Theories include an autosomal-dominant model and a polygenic model with genetic-environmental interactions. The complex presentation and various mechanisms make it impossible to target just one gene locus; in fact, >50 candidate genes have been proposed. A familial pattern to the development of PCOS may exist, because the incidence is higher in women with relatives with the disorder.

Gonadotropin Secretion

In normal menstrual cycles, ovulation occurs when the hypothalamus produces gonadotropin-releasing hormone (GnRH), a neurohormone that regulates the release of FSH and LH from the anterior pituitary in a pulsatile fashion every 60 to 90 minutes. FSH is important to stimulate growth of ovarian follicles and LH is critical for ovulation and sex steroid production. Typically, FSH concentrations rise during the follicular phase, stimulating the growth and development of a small group of follicles until a dominant follicle emerges late in the follicular phase. Estrogen levels rise during this time, generating the LH surge and resulting in ovulation. During the luteal phase that follows, progesterone is synthesized and secreted, which is necessary for implantation of an embryo should pregnancy occur. If pregnancy does not occur, progesterone concentrations decrease and menstruation occurs.

In PCOS, there is an increased frequency of GnRH stimulation, leading to an increase in LH pulse frequency and amplitude, while FSH secretion remains normal. The development

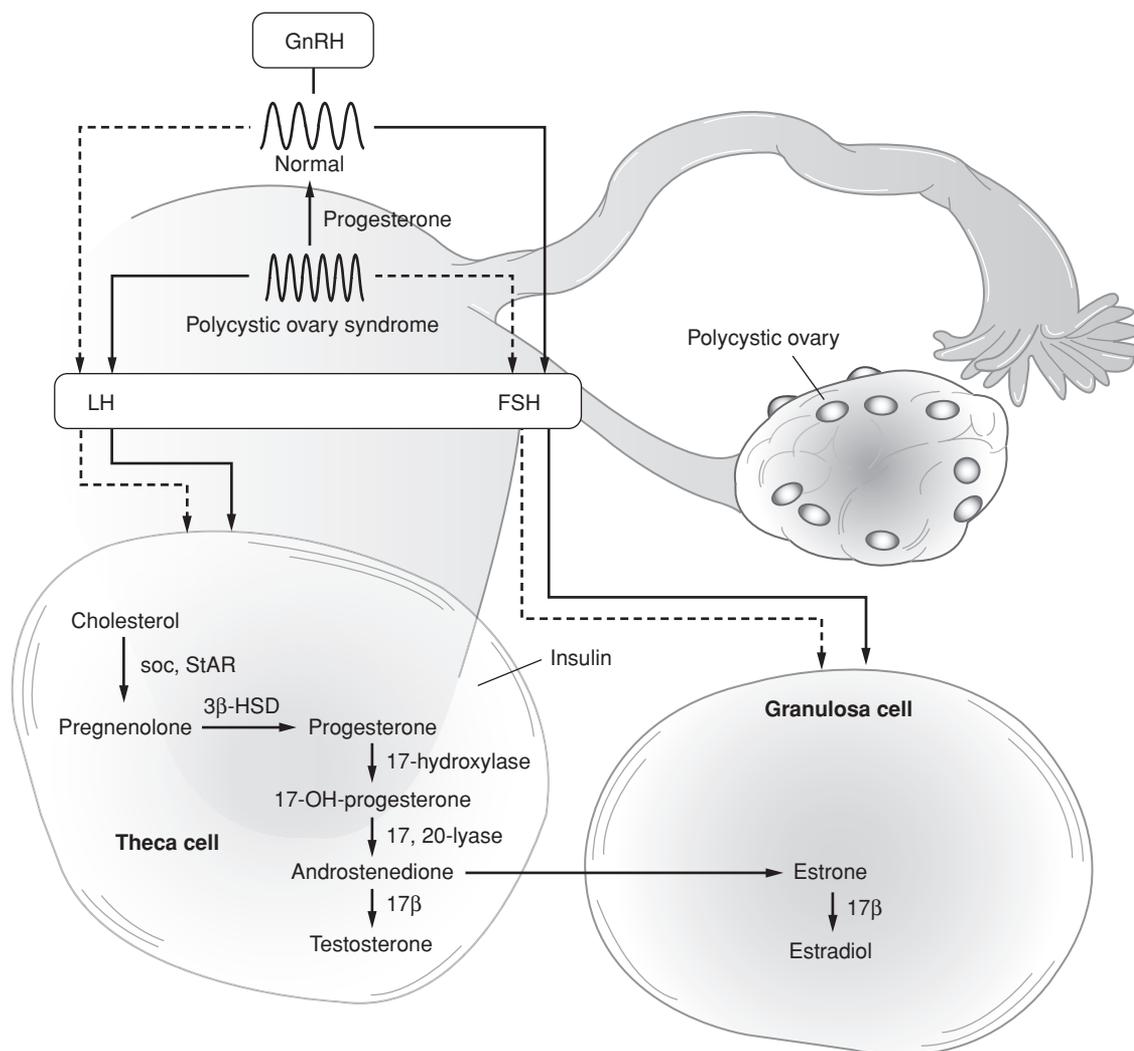

FIGURE 47-1 Relationship of gonadotropin secretion, androgen production, and insulin in polycystic ovary syndrome (PCOS). From reference 10, with permission.

of a dominant follicle does not occur because LH secretion occurs too early in the menstrual cycle. Therefore, a woman is left with several immature follicles and usually will not ovulate. It is not clear whether the abnormal pulse frequency of GnRH is an intrinsic problem in the GnRH pulse generator or a result of relatively low progesterone concentrations from infrequent ovulation.¹⁰ A woman with this abnormality does not enter the luteal phase of her menstrual cycle, leaving estrogen unopposed. Unopposed estrogen leads to endometrial hyperplasia and increases the risk for endometrial cancer. Increased LH stimulation also leads to increased steroidogenesis in the ovary, leading to excess androgen production.

Excess Androgen Production

Androgen production occurs in the theca cell of the ovary to facilitate follicular growth and estradiol synthesis in the granulosa cell. In women with PCOS, hypersecretion of LH and insulin increase the production of androgens, causing abnormal sex steroid synthesis, hyperandrogenism, and hyperandrogenemia. The dysregulation in steroid synthesis and metabolism is believed to result primarily from a dysfunction of the cy-

tochrome P450c17 enzyme in the ovaries, an enzyme with 17-hydroxylase and 17,20-lyase activities that are required to form androstenedione.^{10,11} Androstenedione is then converted to testosterone or is aromatized by the aromatase enzyme to form estrone. Theca cells in women with PCOS are more efficient at the conversion to testosterone than normal theca cells.¹² Also, a similar steroid pathway occurs in the adrenal cortex and, when hyperandrogenism or hyperinsulinemic states exist, androgen production is exacerbated.

Elevated androgen levels are seen in approximately 60% to 80% of women with PCOS, mostly as increased free testosterone concentrations.⁶ Assays for testosterone tend, however, to be highly variable and inaccurate, so measurement of androgen concentrations should be used only as an adjuvant test and never as the sole criterion for diagnosis. Clinical assessment is the primary tool for assessment of excess androgen.

Insulin

Women with PCOS experience an increased risk of insulin resistance with compensatory hyperinsulinemia.¹ Insulin resistance is associated with reproductive and metabolic

abnormalities in women with PCOS and can occur in both obese and nonobese women. There are several mechanisms by which this occurs. One major mechanism is a postbinding defect in insulin-receptor signaling.¹³ Specifically, abnormal receptor autophosphorylation increases serine phosphorylation in targeted cells, which contributes to insulin resistance.^{14,15} The insulin resistance in PCOS has been shown to be a selective, tissue-specific process where insulin sensitivity is increased in the ovarian androgenic pathway (causing hyperandrogenism), but insulin resistance is seen in other tissues involved with carbohydrate metabolism, specifically in the fat and muscle. Hyperinsulinemia results because of the compensatory increase in insulin secretion secondary to insulin resistance.

Insulin has both direct and indirect roles in PCOS. In the ovary, insulin acts alone or synergistically with LH to increase androgen production in theca cells. In the liver, insulin inhibits synthesis of sex-hormone binding globulin (SHBG), a key protein that binds to testosterone, and thus increases the free fraction of androgens available for biologic activity. Therefore, hyperinsulinemia is a major contributor to both hyperandrogenism and hyperandrogenemia in PCOS. Treatments targeted to improve insulin resistance in women with PCOS have shown improvements in ovulatory function, hirsutism, androgen levels, and metabolic profiles.^{16,17} Indirectly, insulin may enhance the amplitude of LH pulses, targeting the gonadotropin secretion defect in PCOS.¹⁸

1. E.F. is a 20-year-old college student with mild hair growth above her upper lip, mild acne, and a history of irregular menstrual periods. Since age 12, she has had six to nine periods per year at intervals that vary from 30 to 90 days. When she does have a period, she considers them to be “normal” without pain or excessive bleeding. Her irregular periods were not bothersome until recently when she became sexually active and worries about becoming pregnant. She uses condoms for birth control. She reports no other medical conditions. E.F. is 5 feet 7 inches tall and weighs 180 pounds (body mass index [BMI] 28.2). Her vital signs today are BP 118/84 mmHg, heart rate (HR) 70 beats/minute, temperature 98.6°F, respiratory rate (RR) 18. Her physical examination is normal, with the exception of noted excessive facial hair and mild acne. She takes a multivitamin daily and acetaminophen as needed for headaches. She has no known medication allergies. What signs and symptoms does E.F. have that are consistent with PCOS?

E.F. exhibits several signs and symptoms that would indicate the presence of PCOS. According to the criteria of all organizations, her history of abnormal menstrual periods (oligomenorrhea) and clinical signs of hyperandrogenism, including hirsutism and acne, would indicate PCOS. E.F. is overweight, which is common in women with PCOS but is not considered a criterion for diagnosis. Before a diagnosis of PCOS is made, laboratory testing to exclude other related causes of her symptoms would have to be performed. Studies may include prolactin, thyroid-stimulating hormone, testosterone, and 17-hydroxyprogesterone concentrations to rule out hyperprolactinemia, hypothyroidism, virilizing tumor, and congenital adrenal hyperplasia, respectively. PCOS is primarily diagnosed by clinical assessment; therefore, these tests assist only in confirming or excluding a diagnosis. To determine the presence of polycystic ovaries, defined as more than eight follicles

per ovary that are <10 mm (usually 2–8 mm) in diameter, a transvaginal ultrasound could be performed.

Long-term Complications

2. E.F. does not smoke, drinks one to two beers on weekends, and exercises by walking to class (20 minutes total) daily. Her mother has diabetes and hypertension and her father has diabetes, hypertension, and dyslipidemia. Her significant laboratory values include fasting glucose 102 mg/dL, low-density lipoprotein (LDL) 150 mg/dL, high-density lipoprotein (HDL) 52 mg/dL, triglycerides 130 mg/dL, and total cholesterol 228 mg/dL. What risk does E.F. have for developing long-term complications from PCOS?

E.F. has an increased risk for developing impaired glucose tolerance, diabetes, and metabolic syndrome, especially considering her family history. Furthermore, the diagnosis of PCOS places her at possible increased risk for sleep apnea and endometrial cancer.

Impaired Glucose Tolerance and Diabetes

Studies have shown that women with PCOS have a higher prevalence of impaired glucose tolerance, diabetes, and insulin resistance compared with women without the syndrome.¹⁹ A family history increases the risk of these conditions further. In a study of 254 women with PCOS, 38.6% were found to have either impaired glucose tolerance (IGT) or undiagnosed diabetes.²⁰ Compared with those without PCOS, the prevalence of IGT and diabetes was significantly higher in both obese and nonobese (BMI <27) women. Waist-to-hip ratio and BMI appeared to be the most clinically important predictors of glucose intolerance. Women with PCOS who have IGT appear to develop type 2 diabetes at higher rates than the general population.¹⁹ Therefore, screening and diagnosis of these conditions is important for women with PCOS. E.F.'s mildly elevated fasting glucose and obesity suggest that she may be at increased risk for impaired glucose tolerance.

Glucose tolerance should be assessed in all women with PCOS using a fasting and 2-hour oral (75 g) glucose tolerance test.¹⁹ Routine screening for diabetes with an oral glucose tolerance test should be performed for all women with PCOS by the age of 30 years.²¹ The American Diabetes Association or World Health Organization criteria should be used for the appropriate diagnosis of IGT or diabetes. Insulin concentrations are typically not obtained in clinical settings because they are inaccurate.

Metabolic Syndrome and Cardiovascular Risk

Approximately one-third to one-half of women with PCOS have a metabolic syndrome using the National Cholesterol Education Panel-Adult Treatment Panel III (NCEP-ATP III) criteria (Table 47-2).^{22–25} The incidence of a metabolic syndrome in women with PCOS is significantly higher than the rate for the general U.S. population (45% vs. 6% ages 20–29 years, 53% vs. 14% ages 30–39 years) and independent of body weight.²² It is believed that insulin resistance is the primary contributing factor to metabolic syndrome in women with PCOS.²⁶ Insulin resistance in the metabolic syndrome has been associated with a twofold increased risk of cardiovascular disease and a fivefold increased risk of type 2 diabetes.²⁷ Low

Table 47-2 NCEP ATP III Criteria for Metabolic Syndrome²²

Three or more of the following:

Central obesity: >40 inches in males, >35 inches in females (may need to adjust lower when individuals or ethnic groups are prone to insulin resistance)

Elevated triglycerides: ≥ 150 mg/dL or on drug treatment for this lipid abnormality

Reduced high-density lipoprotein cholesterol (HDL-C): <45 mg/dL in males, <50 mg/dL in females, or on drug treatment for this lipid abnormality

Hypertension: systolic blood pressure ≥ 135 mmHg or diastolic blood pressure ≥ 85 mmHg, or on drug treatment for hypertension

Elevated fasting plasma glucose: ≥ 100 mg/dL

NCEP ATP, National Cholesterol Education Program Adult Treatment Panel.

HDL cholesterol (HDL-C) is seen most frequently in women with PCOS (68%), followed by increased BMI and waist circumference (67%), high blood pressure (45%), hypertriglyceridemia (35%), and elevated fasting glucose (4%).²³ Another group found that elevated fasting insulin concentrations, obesity, and a family history of diabetes conferred higher risk of having the metabolic syndrome in women with PCOS.²⁵

Compared with women without PCOS, women with PCOS are reported to have a higher prevalence of cardiovascular risk factors, including hypertension, dyslipidemia, and surrogate markers for early atherosclerosis (e.g., increased C-reactive protein concentrations).²⁶ With increasing age, and especially as women with PCOS become postmenopausal, the risk of hypertension increases. Postmenopausal women with PCOS have a twofold increased risk of hypertension compared with age-matched controls.²⁸ Dyslipidemia in women with PCOS typically presents as decreased HDL-C (which is a strong predictor of cardiovascular disease in women), elevated triglycerides, elevated LDL cholesterol (LDL-C), and higher LDL-to-HDL ratios.²⁹ Women with PCOS are noted to have more atherogenic, small dense LDL-C compared with controls and this substantially increases cardiovascular risk.³⁰ Women with PCOS may have other surrogate markers for early atherosclerosis and cardiovascular disease, impaired endothelial dysfunction, and other markers of cardiovascular risk such as coronary artery calcifications and increased carotid intima-media thickness.²⁶ Although cardiovascular risk exists, women with PCOS do not appear to have markedly higher rates of mortality from cardiovascular disease.

Obstructive Sleep Apnea

Obstructive sleep apnea is cessation of breathing that occurs during sleep. It can disrupt sleep and cause daytime fatigue. Patients may not be aware that they are having the symptoms of sleep apnea, which include snoring and a gasping or snorting when breathing resumes. Studies indicate that the prevalence of obstructive sleep apnea in the PCOS is higher than expected and cannot be explained by obesity alone.^{31–33} Insulin resistance appears to be a strong predictor of sleep apnea—more so than age, BMI, or the circulating testosterone concentration.³¹

Endometrial Hyperplasia and Cancer

Chronic anovulation in women with PCOS results in an endometrium that is exposed to the prolonged effects of estrogen

unopposed by progesterone. Therefore, PCOS is a risk factor for endometrial hyperplasia. It is unknown if this translates into an increased risk for endometrial cancer because it is a rare occurrence in young women (4% of all cases occur in women <40 years of age).³⁴ It is considered prudent management to induce artificial withdrawal bleeding by administering a course of progestin at least every 3 months to prevent endometrial hyperplasia in women with PCOS who experience either amenorrhea or oligomenorrhea. Alternatively, ultrasound scans can also be used to measure endometrial thickness and morphology every 6 to 12 months.

Treatment Goals

3. E.F. worries about becoming pregnant when she does not have regular periods. She also has mild hair growth above her upper lip which is somewhat bothersome. Given these concerns, what are the treatment goals for E.F.?

The primary goals for E.F. are to prevent pregnancy and address her hirsutism. Additionally, treatment goals in E.F. would include maintaining a normal endometrium, blocking the actions of androgens at target tissues, reducing insulin resistance and hyperinsulinemia, reducing weight, and preventing long-term complications. Other goals of treatment in patients with PCOS may include correcting anovulation or oligo-ovulation and improve fertility.

Therapy goals should encompass both long- and short-term objectives because response to nonpharmacologic and pharmacologic therapy is slow, often requiring 3 to 9 months. Addressing long-term goals can minimize the risk for future complications and specifying short-term goals can improve motivation and adherence to therapy.

Nonpharmacologic Treatment

4. E.F. has indicated that she would like to lose weight. What nonpharmacologic method(s) would be most effective?

Weight reduction programs designed for a modest weight loss (5%–10%) with the incorporation of fitness are effective in reducing metabolic disease and improving ovulatory potential. Diet modification and exercise are the most efficient, cost-effective, and safe ways to produce weight loss and improve the endocrine and metabolic parameters of PCOS. Weight reduction should be considered first-line therapy in all overweight or obese women with PCOS.

Impact of Weight Loss in PCOS

A minimum 5% weight loss has consistently demonstrated restoration of regular menstrual cycling and ovulation in overweight and obese women with PCOS.^{8,35,36} When lifestyle modification is implemented, free testosterone concentrations decrease, but clinical outcomes of acne and hirsutism are not often reported.⁸ Obesity in PCOS is associated with a higher risk of developing endometrial cancer, but very limited evidence exists to determine the impact of weight loss on the incidence of endometrial cancer.⁸ Studies of weight loss in women without PCOS indicate a 25% to 50% reduced risk of endometrial cancer, so it is logical that addressing weight reduction may lower that risk as well.^{37,38} The Diabetes Prevention Program

trial demonstrated a 53% prevalence of metabolic syndrome; the incidence of this was reduced 41% in the lifestyle modification group.^{39,40} This was significantly better than treatment with metformin. Studies specifically evaluating cardiovascular improvements with weight loss in women with PCOS are limited, but improvements in dyslipidemia and insulin sensitivity have been noted.

Diet Composition

No single diet has been proven to be ideal for women with PCOS. A diet low in saturated fat and high in fiber from mostly low-glycemic-index-carbohydrate foods may, however, be suitable and is recommended.^{8,41} Glycemic index is a classification of carbohydrates based on the blood glucose response over 2 hours. Low-glycemic index foods include bran cereals, mixed grain breads, broccoli, peppers, lentils, and soy. High-glycemic index foods, or those that should be minimized, include white rice and bread, potatoes, chips, and foods containing simple sugars (e.g., juice). It has been shown that in women with PCOS, oral glucose intake causes larger fluctuations in plasma glucose, increased hyperinsulinemia, and stimulated adrenal steroid secretion; protein was found to be a preferred nutrient over glucose.⁴² The composition of a diet should be individualized to promote adherence and achieve specific goals.

Exercise

Exercise is a key component in the attainment and maintenance of weight loss. Exercise with muscle strengthening improves insulin sensitivity.⁸ The American Heart Association recommends 1 hour daily of physical activity for weight reduction and

30 minutes daily for all adults. The American Diabetes Association recommends at least 150 minutes per week of moderate to vigorous activity spread over at least 3 days for individuals with IGT and 1 hour daily of exercise for long-term weight loss.

Pharmacologic Treatment

5. E.F. would like to improve her menstrual irregularity, and be sure that she will not get pregnant. If possible, she would also like to minimize her hirsutism and acne. What pharmacologic treatment options would be appropriate to recommend for E.F.?

Several different pharmacologic options could be recommended to E.F. (Table 47-3). A combined oral contraceptive (COC) will address her concerns about irregular menstruation, hyperandrogenism, and pregnancy prevention. An insulin sensitizer would improve her menstrual irregularity and possibly reduce her hirsutism and acne, but it does not address her desire to prevent pregnancy. An antiandrogen, such as spironolactone, would address only hyperandrogenism and other agents would have to be used concurrently to address pregnancy prevention and the other hormonal and metabolic alterations in PCOS.

Combined Oral Contraceptives

Estrogen-progestin combination therapy with a COC is the treatment of choice for women seeking regularity in menstrual cycles and relief from hyperandrogenic symptoms. The estrogen component suppresses LH, resulting in a reduction of androgen production, and increases hepatic production of

Table 47-3 Selected Treatment Options for PCOS

| Drug Class (example) | Purpose of Therapy | Mechanism of Action | Effective Dose | Side Effects | Pregnancy Category |
|--|---|---|---|---|--------------------|
| Combined oral contraceptive (estrogen and progestin) | Menstrual cyclicity, hirsutism, acne | Suppresses LH (and FSH) and thus ovarian androgen production; increases sex hormone-binding globulin, which decreases free testosterone | One tablet orally daily for 21 (or 24) days, then 7-day (or 4-day) pill-free interval | Breast tenderness, breakthrough bleeding, mood swings, libido changes | X |
| Progestins (medroxy-progesterone) | Menstrual cyclicity | Creates withdrawal bleeding by transforming proliferative endometrium into secretory endometrium | 5–10 mg orally daily for 10–14 days every 1–2 months | Breakthrough bleeding, spotting, mood swings | X |
| Biguanide (metformin) | Menstrual cyclicity, ovulation induction, hirsutism, acne, insulin lowering | Decreases hepatic glucose production, secondarily reducing insulin levels; may have direct effects on steroidogenesis | 500 mg orally 3 times daily (up to 2,550 mg/day) | Gastrointestinal problems, diarrhea, abdominal pain | B |
| Thiazolidinediones (pioglitazone or rosiglitazone) | Menstrual cyclicity, ovulation induction, hirsutism, acne, insulin lowering | Improve insulin sensitivity at target-tissue level (muscle, adipocyte); may have direct effects on steroidogenesis | Pioglitazone: 45 mg orally daily Rosiglitazone: 4 mg orally twice daily | Edema, headache, fatigue, weight gain | C |
| Antiandrogen (spironolactone) | Hirsutism, acne | Inhibit androgens from binding to androgen receptor | 50–100 mg orally twice daily | Hyperkalemia, polymenorrhea, headache, fatigue | C |
| Antiandrogen (clomiphene citrate) | Ovulation induction | Increases GnRH secretion, which induces rise in FSH and LH | 50 mg orally daily for 5 days; may increase to 100 mg | Vasomotor symptoms, gastrointestinal problems | X |

FSH, follicle-stimulating hormone; GnRH, gonadotropin-releasing hormone; LH, luteinizing hormone.

sex-hormone-binding globulin (SHBG), thereby reducing free testosterone. The progestins in various COCs possess variable androgenic effects, so the choice of the COC is important. The potential effects of COCs on insulin resistance, glucose tolerance, and lipids have been debated and should be considered when choosing a progestin component.^{43,44} Caution should be used in those who have insulin resistance, a high propensity to develop type 2 diabetes, or abnormal lipid profiles.

6. What oral contraceptive agent should be initiated in E.F.?

Combined oral contraceptive therapy in PCOS should be initiated with a formulation that contains a low- or very-low dose of estrogen (≤ 35 mcg ethinyl estradiol) and a progestin with low androgenic or antiandrogen properties. Most COCs manufactured today have low- or very-low estrogen doses. Desogestrel and norgestimate are progestins with low androgen potential and drospirenone is an antiandrogen. A COC containing ethinyl estradiol and drospirenone would prevent pregnancy, improve menstrual cycle regularity, and reduce E.F.'s signs of hyperandrogenism (hirsutism and acne). If E.F. desired monthly cycles, she could take the typical 21/7 regimen (21 days active pill, 7 days inactive pill) or a 24/4 regimen (24 days active pill, 4 days inactive pill). Although not specifically evaluated in women with PCOS, a monophasic regimen may also be prescribed using extended cycles of 84 or even 365 days. Extended regimens reduce the number of cycles per year while providing contraception. Regardless of the COC selected, one of the long-term benefits is that her risk for endometrial cancer would be reduced by 50%, even up to two decades after discontinuation.⁴⁵⁻⁴⁷

7. What other therapy options may be beneficial for E.F. if a COC was not tolerated?

Insulin Sensitizers

A reduction in insulin levels by using insulin sensitizers can ameliorate the sequelae of hyperinsulinemia and hyperandrogenemia. Currently available insulin sensitizers include metformin, rosiglitazone, and pioglitazone. More efficacy data are available regarding the use of metformin compared with the thiazolidinediones. Metformin is statistically significantly better in women with PCOS for ovulation induction when compared with rosiglitazone.⁴⁸ For these reasons, metformin tends to be the preferred insulin sensitizer for women with PCOS.

METFORMIN

Metformin inhibits hepatic glucose output, providing lower insulin concentrations and reducing androgen production in the ovary. Metformin also appears to influence ovarian steroidogenesis directly.⁴⁹ Most studies demonstrate that metformin improves menstrual cycle regulation, ovulation, and fertility in both obese and lean patients with PCOS.⁵⁰ Metformin has been used in ovulation induction protocols and has been shown to be very effective when used alone or with clomiphene citrate for inducing ovulation.^{51,52} Data also indicate that insulin and free testosterone concentrations may be decreased 20% to 50% with metformin when used in women with PCOS.^{53,54} Although few studies have been published on other clinical outcomes in PCOS, results suggest that metformin will produce reductions in hirsutism, acne, and BMI (especially in obese patients).⁵⁰

The most commonly used and most effective dose of metformin in PCOS is 500 mg three times daily (TID). It should be titrated slowly to this effective dose; doses up to 2,000 mg daily or 2,550 mg daily may be necessary for individual circumstances. The gastrointestinal (GI) side effects of diarrhea, nausea, vomiting, and abdominal bloating are usually transient and dose related, and do not require discontinuation of the drug. Serum creatinine should be evaluated at least annually in women using metformin because it is contraindicated in women who have a serum creatinine > 1.4 mg/dL.

THIAZOLIDINEDIONES

Rosiglitazone and pioglitazone have been evaluated in women with PCOS, but studies have been small in number. These agents improve insulin action in the liver, skeletal muscle, and adipose tissue. They also are reported to directly affect ovarian steroid synthesis.⁵⁵ Rosiglitazone and pioglitazone are extremely effective at reducing insulin and androgen concentrations and have modest effects on hirsutism.¹⁰ Rosiglitazone has demonstrated significantly better ovulation rates in women with PCOS compared with placebo, but it is less effective than metformin.⁴⁸ Other abstracts have indicated rosiglitazone may be beneficial for menstrual regularity, hyperandrogenism, and insulin sensitivity. Pioglitazone has proved to be as effective as metformin in small studies of women with PCOS and may be especially beneficial when used in combination with metformin for clinical and biochemical improvements.^{56,57}

Recommended doses for rosiglitazone and pioglitazone are the same as those used for the treatment of type 2 diabetes. Adverse effects include edema, headache, fatigue, and potential liver enzyme elevations. Liver enzymes should be measured before initiation of treatment and periodically thereafter. It should be noted that rosiglitazone also appears to have a negative effect on the lipid profile, an unwanted outcome considering the potential long-term consequences of PCOS.

Agents for Hirsutism

Antiandrogenic agents are beneficial therapeutic options for hirsutism and acne. They often are used alone or combination with COC for moderate to severe hirsutism or acne. Although frequently used, antiandrogens are not approved for the treatment of female hirsutism or acne in the United States. Spironolactone is commonly prescribed to women for hirsutism, but drospirenone is an antiandrogen found in COC and it has also been evaluated in the long-term treatment of hirsutism.⁵⁸ Finasteride has been used for female hirsutism, but its lack of specificity for type I 5α -reductase in the pilosebaceous unit and toxicity may make this a suboptimal treatment choice. Flutamide is effective for hirsutism, but it is not used because of hepatotoxicity. Cyproterone acetate is used in Europe but is not available in the United States. Eflornithine hydrochloride has been approved for topical use in treating facial hirsutism, but has not been evaluated in women with PCOS.

SPIRONOLACTONE

Spironolactone acts by competitively inhibiting dihydrotestosterone (DHT) from interacting with its androgen receptor. This causes a decrease in activity of ovarian-produced testosterone. Spironolactone reduces hair growth by 40% to 88%; however, it takes 6 to 9 months for improvement.⁵⁹ Spironolactone may be associated with possible teratogenicity

(feminization of the male fetus), so it is prudent to advise women to avoid pregnancy for at least 4 months after the discontinuation of spironolactone. It is recommended that spironolactone be used with a COC to avoid teratogenicity, as well as the side effect of polymenorrhea (more frequent menses) when used as monotherapy. Spironolactone in combination with a COC would also improve hormonal and metabolic manifestations of PCOS as well. The usual effective spironolactone dose is 50 to 100 mg twice daily (BID) for 6 to 12 months. Serum potassium and renal function should be monitored because this aldosterone antagonist can cause hyperkalemia. Furthermore, spironolactone should not be used with a COC containing drospirenone because of a potential risk for hyperkalemia.

FINASTERIDE

Finasteride is a type II 5 α -reductase inhibitor, which decreases the conversion of testosterone to DHT. It provides an approximate 30% reduction from baseline for hirsutism. Compared with spironolactone, finasteride is as or less effective in women with hirsutism.⁶⁰ The dose of 5 mg to 7.5 mg daily typically takes 6 months for clinical improvement. It is critical to avoid pregnancy while taking this drug owing to the potential teratogenic effect of abnormal genitalia in the male fetus. Finasteride should not be touched or handled by women who are or may be pregnant. This danger limits the usefulness of finasteride in women with PCOS because most are of childbearing age or desire pregnancy.

8. E.F. successfully used oral contraceptives for 10 years. After getting married 3 years ago, E.F. and her husband decided to have children. She lost 30 pounds with diet and exercise when she got married and has been able to maintain that weight loss. They have been trying to get pregnant for the last 18 months. The reason for infertility has been identified as oligo-ovulation associated with PCOS. What treatments for ovulation induction should be used and why?

Anovulation or oligo-ovulation in women with PCOS is usually first treated with diet, exercise, and weight reduction. Weight loss improves pregnancy rates and reduces miscarriage rates in women with PCOS.⁶¹ E.F. has been successful at losing weight and now must consider agents for ovulation induction. Clomiphene citrate is the pharmacologic agent of choice in women with PCOS. Ovulation induction and conception occur in about 50% to 80% and 35% to 40% of women with PCOS, respectively, using clomiphene citrate. Although side effects (e.g., bloating, nausea, vomiting, and multiple gestation) can occur, the benefit of this therapy outweighs the risk for E.F.

Agents for Ovulation Induction

CLOMIPHENE CITRATE

Clomiphene citrate induces ovulation via an antiestrogenic effect on the hypothalamus. GnRH secretion is increased, which increases LH and FSH production. The increase in FSH concentrations causes appropriate follicle development and estrogen secretion, which produces a positive feedback on the hypothalamic-pituitary system to create a LH surge for ovulation.

The usual initial dose of clomiphene citrate is 50 mg orally daily for 5 days, started on day 5 after a spontaneous or progestin-induced menses. The clinician must determine if

ovulation occurs with each cycle through laboratory testing, ultrasound monitoring, or both. If ovulation does not occur, the dose can be increased by 50 mg daily up to 150 mg daily; however, doses > 100 mg daily for 5 days are not recommended by the manufacturers.⁶² A repeat cycle can be administered as early as 30 days after the previous cycle as long as pregnancy has not occurred. If conception does not occur, women can use clomiphene for three to four cycles before considering another regimen. Long-term cyclic therapy is not recommended beyond a total of six cycles because of potential ovarian cancer risk. Most women respond to clomiphene citrate within three to four ovulatory cycles, but 5% to 10% have demonstrated clomiphene resistance and need to consider other options.^{61,62} For women who are clomiphene citrate resistant, dexamethasone can be used in conjunction with clomiphene or an aromatase inhibitor can be used (e.g., letrozole, anastrozole) as an alternative for infertility in PCOS.^{63–66}

In the 1990s, it was suggested that the combination of clomiphene citrate plus metformin produced higher ovulation rates than either agent alone.⁶⁷ The most clinically relevant outcome for infertility, live birth, however, had not been fully investigated.⁵² Investigators recently performed a randomized, controlled study to determine the live-birth rates in 626 women with PCOS taking metformin, clomiphene citrate, or both.⁶⁸ The live-birth rate was 22.5% in the clomiphene citrate group, 7.2% in the metformin group, and 26.8% in the combination group ($p < 0.001$ for metformin versus clomiphene citrate and combination therapy). They concluded that clomiphene citrate was superior to metformin in achieving live-birth rates, although multiple births occurred in 6% (3/50) of live births.

OTHER AGENTS

Although clomiphene citrate is the pharmacologic agent of choice in women with PCOS for infertility, it can only be used for a limited number of cycles and resistance can occur. If clomiphene citrate alone is no longer an option, other regimens, including metformin (alone or in combination with clomiphene citrate), dexamethasone (in combination with clomiphene citrate), aromatase inhibitors, ovarian drilling or controlled ovarian stimulation with gonadotropins can be recommended.⁶⁹ Based on the evidence available, it would be reasonable to start with combination clomiphene citrate and metformin.⁶² If that is not successful, dexamethasone 0.25 mg at bedtime can be used in combination with clomiphene citrate. Aromatase inhibitors and ovarian drilling are the next alternatives, followed by administration of gonadotropins or in vitro fertilization. Gonadotropins are effective, but are generally reserved as one of the last options because of ovarian hyperstimulation syndrome. Egg retrieval and in vitro fertilization may be used in conjunction with gonadotropins to increase pregnancy rate and minimize the likelihood of multiple pregnancies by limiting the number of transferred embryos.⁶²

Treatment Decisions in PCOS

9. E.F. and her husband are overwhelmed by the number of options available to treat her PCOS. What is the best approach in evaluating E.F. and making appropriate recommendations?

Woman with PCOS exhibit unique clinical features and have individual concerns that should be addressed when making treatment recommendations. Assessment should include

gathering relevant medical information, such as menstrual history, signs and symptoms of hyperandrogenism, time course of symptoms, weight history, previous agents tried, and family history. If PCOS is suspected, laboratory assessments should be performed to rule out any other related disorders. Once a diagnosis has been made, a recommendation about treatment must consider the patient's priorities and motivation.

In any obese patient, weight loss is a first step to improve many of the clinical and biochemical endocrine and metabolic abnormalities in PCOS. If contraception is desired, COCs will improve menstrual cycles and hyperandrogenism. If contraception is not needed, metformin will address menstrual cycle regulation, hyperandrogenism, and insulin resistance. COCs also will address menstrual cycle regulation, hyperandrogenism, and insulin resistance. Other agents, such as thiazolidinediones, can be used if metformin or COCs are contraindicated or have caused serious side effects. If pregnancy is desired, clomiphene citrate is the first-line pharmacologic option for ovulation induction. Other alternatives, including metformin, dexamethasone, aromatase inhibitors, gonadotropins, ovarian drilling, and in vitro fertilization, can be used if clomiphene citrate alone is not effective.

Appropriate follow-up for women such as E.F. may include quality-of-life measures, laboratory monitoring when necessary, and medication adherence monitoring. Providers should be educators, facilitators, and empathetic listeners to help women with PCOS become informed and actively engaged in their therapy plan.

DYSMENORRHEA

Dysmenorrhea, or painful cramping that occurs with the onset and first days of menstruation, can be categorized as either primary, without underlying uterine pathology, or secondary, owing to underlying uterine pathology. Secondary dysmenorrhea can result from uterine conditions, including endometriosis, uterine polyps, or fibroids; complications of intrauterine contraceptive device (IUD) use; or pelvic inflammatory disease.

Up to 93% of adolescents report some pain with menstruation, and up to 15% experience pain that is sufficiently severe and disabling to interfere with activities of daily life.⁷⁰ Dysmenorrhea is the single largest cause of lost productivity and school absence among adolescent girls. It most commonly begins within 1 to 2 years after the onset of menses.⁷¹ The prevalence of primary dysmenorrhea decreases with age.⁷²

Clinical Characteristics

10. A.B., a 17-year-old girl, presents at the pharmacy with complaints of severe cramping pain associated with her menstrual cycles. The pain predictably begins with the onset of menses and has been occurring for the past 5 years, but is now limiting A.B.'s ability to play sports in high school. A.B. states that she experienced her first menstrual period at age 11. The pain usually is "like a fist, clenching and relaxing," and it starts in the pelvic area, and radiates to her lower back. She reports no headache, but usually has diarrhea and some nausea, without vomiting. Her symptoms are most severe during the first 12 to 24 hours of her menses, then subside over the next few days. She usually takes two acetaminophen 325-mg tablets when her pain begins and then one

tablet every 4 to 6 hours, as needed, with little relief. She has taken no other medications for her symptoms, has no known allergies to medications, and is not taking any other medications. She has no other medical problems. Her physical examination was within normal limits. What clinical manifestations in A.B. are consistent with primary dysmenorrhea?

No specific diagnostic criteria exist for primary dysmenorrhea. Typically, the diagnosis is one of exclusion, and is based on response to known effective therapy. Thus, if patients do not respond to therapy, an investigation of pelvic pathology and secondary dysmenorrhea should occur.⁷³ A.B.'s symptoms that are typical of primary dysmenorrhea include cramping pain in the suprapubic area, which may radiate into the back and thighs, nausea, and diarrhea. Some women also experience vomiting, fatigue, headache, lightheadedness, flushing, loss of appetite, irritability, nervousness, and insomnia.⁷² Symptom severity seems to correlate with women who have early menarche (onset of menses), and those with increased duration and quantity of menstrual flow.⁷⁴ Risk factors for dysmenorrhea include age <20 years, depression or anxiety, nulliparity, menorrhagia, and smoking.⁷⁵

Primary dysmenorrhea occurs only with ovulatory cycles, which typically begin after the first year following menarche. Dysmenorrhea occurring several years after menarche is most likely secondary dysmenorrhea, and should be investigated as such. Because A.B.'s pain began within 1 year of menarche and her physical examination is normal, a trial of an effective therapy can be initiated without further investigation into secondary causes of dysmenorrhea. The typical pattern of dysmenorrhea is to have pain beginning up to 12 hours before menses, increasing in severity for up to 24 hours, and continuing with reduced intensity for 24 to 72 hours.⁷² A.B.'s description of pain, as a cramping–relaxing cycle, is typical for dysmenorrhea. Likely, her symptoms will decrease with age, after the onset of sexually activity, as well as after childbirth.⁷⁴

Pathophysiology

11. What underlying pathophysiology explains A.B.'s symptoms?

In the normal menstrual cycle, prostaglandins are released by the endometrium in the late luteal phase inducing contraction of the uterine smooth muscle and subsequent sloughing of the endometrium, leading to menstrual flow and the beginning of the follicular phase of the next cycle. Women with primary dysmenorrhea appear to have increased prostaglandin secretion, inducing more intense uterine contractions, leading to decreased uterine blood flow and uterine hypoxia, which results in the cramping and pain that are the hallmarks of dysmenorrhea.⁷³ The decreasing levels of progesterone in the late luteal phase trigger the release of arachidonic acid from cell membranes, ultimately resulting in the production of prostaglandins and leukotrienes.⁷³

The importance of prostaglandin secretion in the pathology of primary dysmenorrhea is confirmed by studies of the exogenous administration of prostaglandin $F_{2\alpha}$ ($PGF_{2\alpha}$), and PGE_2 , each of which produce pain and uterine contractions similar to those observed in women with primary dysmenorrhea.⁷⁶ These prostaglandins, with potent platelet disaggregation and vasodilatory properties, also induce nausea, vomiting, and

diarrhea. Thus, A.B.'s pain, nausea, and diarrhea may be caused by elevated prostaglandin levels. This also explains the rationale for the effectiveness of the two main treatments for primary dysmenorrhea: nonsteroidal anti-inflammatory drugs (NSAID), which inhibit prostaglandin synthesis, and combined oral contraceptives, which minimize the progesterone increase typically seen in the luteal phase.

Nearly 85% to 90% of women initially thought to have primary dysmenorrhea respond to NSAID with or without oral contraceptive therapy. The remaining women deserve further investigation into potential causes of secondary dysmenorrhea.⁷⁷

Treatment

Nonpharmacologic Treatment

12. What nonpharmacologic therapies may be effective for the treatment of A.B.'s symptoms of primary dysmenorrhea?

A.B. should be educated about the causes of primary dysmenorrhea, its associated symptoms, and the rationale behind nonpharmacologic and pharmacologic treatment options. Nonpharmacologic therapies that may have benefit in the relief of A.B.'s symptoms include aerobic exercise, heat therapy, tobacco use cessation, omega-3 polyunsaturated fatty acids, and transcutaneous electrical nerve stimulation (TENS).

Exercise, particularly aerobic exercise, has been correlated with decreased menstrual symptoms in observational studies, and is, in all patients, associated with positive general health benefits.⁷⁸ The benefit may be owing to improved pelvic blood flow and decreased ischemia, or increased release of β -endorphins. Application of local heat to the lower abdomen has been studied in two clinical trials, one comparing a heated wrap patch with ibuprofen 400 mg, the other comparing it with acetaminophen 1,000 mg.^{79,80} Heat plus ibuprofen demonstrated a reduction in the time to pain relief compared with an unheated patch plus ibuprofen; and heat provided better relief than acetaminophen. With few adverse effects, heat, in the form of a heating pad or heated patch or wrap device, represents a reasonable suggestion for women with dysmenorrhea.

Women should be advised and assisted in efforts to stop tobacco use. Although no direct evidence links smoking cessation with improvement in dysmenorrhea, an association exists with increased risk and severity of dysmenorrhea in women who smoke.⁷⁴ Increased intake of omega-3 polyunsaturated fatty acids, a low-fat vegetarian diet, or both may decrease the intensity and duration of symptoms.^{81–83}

Transcutaneous electrical nerve stimulation has been evaluated in seven small trials, and when high frequency stimulation was utilized, it was more effective than placebo in achieving pain relief.⁸⁴ Acupuncture may also be effective, although few trials, utilizing heterogeneous techniques and study designs have been conducted, which makes interpretation difficult.⁸⁴ In extreme cases, surgical interruption of pelvic nerve pathways has been utilized as a last resort, with continued pain control up to 12 months in clinical trials.⁸⁵

A.B.'s therapy should be based on her specific symptoms, response to previous therapy, and any adverse effects of therapy. The regimen of acetaminophen that A.B. is currently using is not providing relief owing to its lack of effect on prostaglandin activity. Discussion of the nonpharmacologic therapies, partic-

ularly heat, exercise, and smoking cessation, provide low risk, potentially beneficial and low-cost suggestions for pain relief, in addition to drug therapy.

Pharmacologic Therapy

Pharmacologic therapy for primary dysmenorrhea is focused on reducing prostaglandin activity. Anti-inflammatory drugs act by directly inhibiting prostaglandin synthesis. Hormonal contraceptives reduce the amount of endometrial proliferation and, as a result, decrease the amount of prostaglandins secreted. By inhibiting ovulation, hormonal contraceptives eliminate the cyclic changes in progesterone that induce prostaglandin release. Both NSAID and hormonal contraceptives provide relief from the symptoms of primary dysmenorrhea for most women.

Choice of therapy depends on the need for contraception, concomitant medical conditions, and patient preference. Treatment efficacy can be monitored by evaluating pain relief, improved functionality, reduced absenteeism, and relief of other symptoms (e.g., diarrhea, nausea) associated with dysmenorrhea. Nonsteroidal agents should be tried for two to three cycles before switching to other agents. Hormonal contraceptives may require 3 or more months to provide maximal relief of symptoms. The goals of therapy, namely reduction in pain and associated symptoms, as well as improvement in functionality, should be explained to the patient, and reviewed at each contact.

ANTI-INFLAMMATORY DRUGS

Mechanism of Action

Prostaglandins, leukotrienes, thromboxanes, and prostacyclin are synthesized via the arachidonic acid pathway. Free, unesterified fatty acids, such as arachidonic acid (derived from phospholipids, cholesterol, and triglycerides), are prostaglandin precursors. Arachidonic acid may be synthesized from phospholipids found in cell membranes of the menstruating uterus through hydrolysis by the lysosomal enzyme, phospholipase A₂. It is then metabolized by one of two enzyme systems. Lipoxygenase converts arachidonic acid to 5-hydroperoxyeicosatetraenoic acid, which is converted to leukotrienes. Cyclooxygenase metabolizes arachidonic acid to unstable cyclic endoperoxides (PGG₂ and PGH₂), which are then converted to prostacyclin (PGI₂), thromboxane A₂, and the prostaglandins PGF₂ and PGE₂ by the action of prostacyclin synthetase, thromboxane synthetase, or isomerase reductase, respectively.⁸⁶ Cyclooxygenase I (COX-1) is responsible for the synthesis of prostaglandins involved in normal physiologic processes. Cyclooxygenase 2 (COX-2) is an inducible enzyme that produces prostaglandins involved in an inflammatory response. (See Chapter 43, Rheumatic Disorders, for additional information). In addition to the inhibition of prostaglandin synthesis, NSAIDs relieve pain through their analgesic effects.

Choice of Agent

13. A.B.'s family physician decides to initiate naproxen sodium 550 mg orally at the beginning of menses, followed by 275 mg every 8 hours thereafter for the 2 to 3 days she experiences dysmenorrhea. What criteria should be used to select an NSAID for primary dysmenorrhea? Explain to A.B. why she should take it according to the regimen above.

Table 47-4 NSAID and Dosing Regimens for Primary Dysmenorrhea

| Groups | Drugs | Dosages | Dosing Regimen (Maximum Daily Dose) | Approved for Primary Dysmenorrhea |
|------------------------|----------------------|-----------------------|---|-----------------------------------|
| Salicylic acids | Aspirin | 325, 500, 650, 975 mg | 500–600 mg PO Q 4–6 hr | No |
| Indole acetic acids | Diclofenac | 50 mg (as potassium) | 50 mg PO TID; some patients may need a first dose of 100 mg followed by 50 mg TID; (150 mg/day, may give 200 mg on first day) | Yes |
| Propionic acids | Ibuprofen | 300–800 mg doses | 400 mg PO Q 4–6 hr ^a (3.2 g/day) | Yes |
| | Ketoprofen | 12.5, 25, 50, 75 mg | 25–50 mg Q 6–8 hr ^b (300 mg/day) | Yes |
| | Naproxen | 250, 375, 500 mg | 500 mg PO first dose; 250 mg PO Q 6–8 hr (1,250 mg/day) | Yes |
| | Naproxen sodium | 220, 275 mg | 550 mg PO first dose; 275 mg PO Q 6–8 hr (1,375 mg/day) ^c | Yes |
| Fenamates | Meclofenamate sodium | 50, 100 mg | 100 mg TID for up to 6 days (300 mg/day) | No |
| | Mefenamic acid | 250 mg | 500 mg PO first dose; 250 mg PO Q 6 hr for 2–3 days (1 g/day; may give 1.25 g on first day) | Yes |
| COX-2 selective agents | Celecoxib | 100, 200, 400 mg | 400 mg PO first dose; 200 mg BID | Yes |

^aDosing recommended for dysmenorrhea when using the prescription product is higher than the over-the-counter (OTC) dosing of 200 mg Q 4–6 hr; may wish to start with the OTC dosing when an OTC product is used.

^bDosing recommended for dysmenorrhea when using the prescription product is higher than the OTC dosing of 12.5 Q 6–8 hr; may wish to start with the OTC dosing when an OTC product is used.

^cDosing recommended for dysmenorrhea when using the prescription product is higher than the OTC dosing of 220 mg Q 8–12 hr; may wish to start with the OTC dosing when an OTC product is used.

NSAID, nonsteroidal anti-inflammatory drug.

BID, twice daily; PO, orally; TID, three times daily.

From references 72, 73, 87, 93.

The NSAIDs are effective for treatment of dysmenorrhea (Table 47-4). Initial selection of therapy should be based on effectiveness, incidence of adverse effects, cost, patient history of previous benefit, and availability. Naproxen (as the sodium salt), ibuprofen, and ketoprofen are approved without a prescription for the treatment of primary dysmenorrhea. In a Cochrane review, 63 trials of NSAIDs for treatment of primary dysmenorrhea were reviewed to assess for any differences in efficacy or safety among the different NSAIDs.⁸⁷ When compared with placebo, NSAIDs were significantly more effective (odds ratio [OR] 7.91, 95% confidence interval [CI] 5.65–11.09). In limited head-to-head trials comparing NSAIDs, no significant differences in efficacy were seen, with the exception of aspirin being slightly less effective than other NSAIDs when directly compared. Adverse effects seen in these trials were generally mild GI (nausea, upset stomach) and neurologic (sleepiness, dizziness, headache) complaints. When directly compared with each other, no NSAID was found to be better tolerated than another. Naproxen and ketoprofen offer the advantage of less frequent dosing compared with ibuprofen.

A.B.'s physician suggested taking a loading dose of the naproxen sodium (550 mg). A randomized trial demonstrated increased relief from dysmenorrhea symptoms in adolescents treated with an NSAID regimen that started with a loading dose, versus those who utilized a flat dosing regimen.⁸⁸ Loading doses generally are twice the regular dose. Although all NSAIDs that have been studied for the treatment of dysmenorrhea appear to be equally effective at reducing pain, there may be theoretic advantages to those that achieve peak serum concentrations 30 to 60 minutes after administration (ibuprofen, naproxen, naproxen sodium, and meclufenamate). Some claim that meclufenamate is more beneficial for the treatment of dysmenorrhea because of its ability to block both the cy-

cloxygenase and the lipoxygenase pathway in the formation of prostaglandins, but this pharmacologic difference does not appear to confer a clinically significant advantage.⁷² If A.B. experienced adverse effects with the higher loading dose, an alternative strategy is to initiate dosing 24 hours before menses is expected to start, based on the calendar if the patient has predictable cycles, or based on the start of premenstrual syndrome-type symptoms. This prophylactic dosing may be helpful especially for patients who have severe dysmenorrhea with absenteeism and decreased work or school productivity.^{73,87} A.B.'s provider also has suggested she take the regimen on a scheduled basis, versus “as needed”. Although no specific evidence supports this practice for dysmenorrhea, avoiding as needed (“PRN”) dosing may provide consistent serum levels to maintain reduced prostaglandin levels. As the duration of therapy is typically limited to 2 or 3 days, risk of adverse effects tends to be outweighed by the potential benefit of loading doses, prophylactic dosing, and scheduled versus PRN therapy.

Although the COX-2 selective inhibitor, celecoxib, is approved for the treatment of primary dysmenorrhea, it has not been directly compared with conventional NSAID for effectiveness for pain control. The U.S. Food and Drug Administration (FDA) approved dosing of celecoxib at a 400-mg loading dose, followed by 200 mg that same day if needed, then 200 mg twice daily thereafter. Increased cost, lack of increased benefit, and limited data regarding differences in GI safety make celecoxib a second-line therapy for primary dysmenorrhea.

Adverse Effects

14. What adverse effects might A.B. experience from her NSAID?

All NSAIDs have a similar adverse effect profile. Nausea, vomiting, indigestion, anorexia, diarrhea, constipation, abdominal pain, melena, and bloating are common GI complaints. Central nervous system (CNS) adverse effects include headache, vertigo, dizziness, visual disturbances, depression, drowsiness, irritability, excitation, insomnia, fatigue, tremors, and confusion. In addition, adverse effects also may involve cardiovascular, hepatic, renal, or hematologic systems (see Chapter 43, Rheumatic Disorders).

Careful attention should be given to previous trials of NSAID for dysmenorrhea and other conditions, because women may respond favorably to one NSAID over another. If a 2- or 3-month trial of one NSAID is unsuccessful, another agent from a different class may be tried. Because dysmenorrhea is most prevalent in younger women, who tend to be healthy, the risk of adverse events may be lower than would be expected in an older population.

Contraindications

15. What medical history information is important to avoid serious adverse effects?

A.B. should be questioned about medication allergies, any prior history of ulceration, or GI bleeding, and history of cardiovascular and renal disease elicited before prescribing therapy. A thorough medication history, including over-the-counter (OTC) agents and dietary supplements should be conducted. Particular attention should be paid to any potential therapeutic duplications (i.e., prescription and OTC NSAIDs), drug–drug (e.g., warfarin), and drug–disease (hypertension) interactions.

Women who are allergic to aspirin or have a history of allergic reaction to any NSAID should not use NSAIDs or celecoxib. Celecoxib should also be avoided in women who are allergic to sulfa drugs. A.B. has not had a previous allergic reaction to NSAID or aspirin; she is not taking any medications that may interact and does not have any history of medical problems that would prevent her from a trial of NSAID therapy.

HORMONAL CONTRACEPTION

Oral Contraceptives

16. After 6 months of treatment, A.B. has some relief of her pain, nausea, and diarrhea with the naproxen sodium, and has not missed a soccer game in 5 months. She is asking about other treatment options for further pain relief. When would the use of an oral contraceptive be an appropriate choice for A.B.?

Oral contraceptives (OC) suppress ovulation, decrease menstrual fluid volume, and subsequently decrease prostaglandin production and uterine cramping.^{70,72} OCs alone, or in combination with an NSAID, are appropriate as first-line treatment in women without a need for contraception. OC relieve dysmenorrhea symptoms in 50% to 80% of women within 3 to 6 months after beginning hormone therapy.⁸⁹ A study of healthy adolescent women with primary dysmenorrhea evaluated the effects of a 20-mcg ethinyl estradiol/100-mcg levonorgestrel oral contraceptive pill as compared with placebo over a 3-month period.⁹⁰ With OC use, women reported decreased severity of pain, and used less pain medication. A Cochrane review of oral contraceptives and primary dysmenorrhea failed to demonstrate a significant difference between

various OC formulations.⁸⁹ Selection of an OC should be based on factors presented in Chapter 45, Contraception. Although many providers prescribe extended cycles of oral contraceptives to treat primary dysmenorrhea, no evidence suggests that this practice is more effective than the customary 21/7, and a change from traditional dosing to continuous dosing may be considered if symptoms occur during the placebo week.^{77,91}

Adverse effects and contraindication associated with OC use must be considered. Although serious complications from OC use are uncommon in young, healthy women, breakthrough bleeding and spotting, nausea, and breast tenderness may occur, especially early in treatment. A.B. may choose to add an OC to her naproxen sodium, with potentially improved pain relief compared with either agent alone. If pain does not respond to either course of therapy, investigation via laparoscopy for causes of secondary dysmenorrhea may be necessary.

Other Hormonal Contraceptive Agents

Other hormonal contraceptive agents that suppress ovulation have also been used in the treatment of primary dysmenorrhea, although none have undergone rigorous trials for this indication.⁷⁷ The levonorgestrel intrauterine system (IUS) is associated with amenorrhea and decreased dysmenorrhea over time, unlike the copper IUD, which may result in increased pain, cramping, and blood loss. Three years after insertion, fewer women with a levonorgestrel IUS reported menstrual pain (60% baseline, 29% after 3 years), with 47% of women with amenorrhea.⁹² In women with primary dysmenorrhea at low risk of sexually transmitted infections, and desiring long term contraception, the levonorgestrel IUS would be an option.

Medroxyprogesterone depot injection is another hormonal contraceptive agent that has been used to treat primary dysmenorrhea. Nearly two-thirds of adolescents reported fewer symptoms of dysmenorrhea with injections every 3 months.⁷² Negative effects of medroxyprogesterone injections on bone density should be weighed with potential benefit when considering this option.

OTHER AGENTS

18. What are other agents that can be recommended for the treatment of A.B.'s primary dysmenorrhea?

Although NSAID and hormonal contraceptives have the most evidence supporting their use for the treatment of primary dysmenorrhea, a variety of other agents have been evaluated. In adolescents, 91% reported using OTC medications to treat primary dysmenorrhea, usually without consultation from a health care professional.⁷¹ This lack of professional advice resulted, however, in nearly 70% of women using <50% of the maximal dose of medication on day 1 of pain. Only 66% of patients choose to use ibuprofen, whereas 44% selected acetaminophen, 30% selected acetaminophen–pyrilamine combinations, and 10% acetaminophen, magnesium salicylate, pamabrom combination products. Acetaminophen does not suppress prostaglandin synthesis and is of limited efficacy in the treatment of dysmenorrhea, when compared with NSAID or hormonal contraception.⁹³ Narcotic analgesics do not have a role in the treatment of primary dysmenorrhea.

Leukotriene receptor antagonists have also been studied in the treatment of primary dysmenorrhea, because the leukotriene pathway to prostaglandin formation is relatively

unaffected by NSAID. Although the pharmacology is promising, small trials in patients with primary dysmenorrhea with the leukotriene receptor antagonist montelukast have not demonstrated significant pain reduction.⁹⁴

Transdermal nitroglycerin ointment and transdermal patches provide rapid relief of dysmenorrhea in up to 90% of patients, but use is limited by adverse effects, including headache in up to 25% of patients.⁹⁵ Nitroglycerin serves to increase nitric oxide concentrations, which results in uterine relaxation. Guaifenesin 2,400 mg daily has been evaluated in a small trial, with a nonsignificant trend toward benefit, potentially owing to thinning effects on cervical secretions.⁹⁶

Vitamin B₁ 100 mg daily, magnesium, vitamin B₆, and omega-3 fatty acids have all shown some benefit in pain relief compared with placebo, with Vitamin B₁ and magnesium showing the most promise.⁸³ Other dietary supplements, including fennel, vitamin E, neptune krill oil, and tokishakuyaju-san, have been evaluated in small trials and need further study.⁷⁷

ENDOMETRIOSIS

Endometriosis is defined as the presence of functional endometrial tissue occurring outside the uterine cavity. It is the most common cause of secondary dysmenorrhea in young women, and can result in chronic pelvic pain, infertility, and dyspareunia.⁷² The ovaries are commonly the site of endometriosis, which can also be found in the pelvic peritoneum, cervix, vagina, vulva, rectosigmoid colon, and appendix. Less common sites of implantation of endometrial tissue include the umbilicus, scar tissue resulting from surgery, kidneys, lungs, and even arms and legs.⁹⁷ Endometriosis is present in up to 45% of women with infertility. Overall, it is difficult to determine the prevalence of endometriosis, because many women do not experience symptoms or seek treatment, and formal diagnostic criteria currently require visual identification of endometrial tissue during surgery. In women who have laparotomies for any reason, endometriosis is identified in 5% to 15%. This increases to 33% in women with chronic pelvic pain.⁹⁷ In contrast to primary dysmenorrhea, endometriosis usually occurs in women who have been menstruating for some time; it can provoke pain that is not limited to the time of the menses, but can occur anytime throughout the cycle. Endometriosis is rarely seen in women near the menarche, after menopause, or in amenorrheic women. Given the many women with endometriosis; the expense of diagnosis and treatment; and the infertility associated with it, endometriosis represents a significant area of cost in the health care system.⁹⁸

Diagnostic Criteria

Diagnosis of endometriosis is difficult, with a delay in diagnosis in the range of 8 to 12 years from initial symptom presentation.⁹⁹ Endometriosis, interstitial cystitis, irritable bowel syndrome, and pelvic adhesions represent the four most common causes of chronic pelvic pain (defined as pain not associated with the menses, severe in nature, resulting in functional disability, and lasting at least 6 months).¹⁰⁰ The delay in diagnosis is the unfortunate consequence of the lack of diagnostic laboratory markers, and its similarities to these other conditions. The physical examination is often normal,

although the most common physical finding is a fixed retroverted uterus, with scarring and tenderness. A definitive diagnosis is only possible with visualization of endometriosis on laparoscopy, although this is not considered as absolutely necessary today as it has been in the past.¹⁰¹ Although no diagnostic criteria currently exist, endometriosis can be staged at the time of laparoscopy according to the Revised American Fertility Society Classification of Endometriosis.¹⁰² The stages are minimal (stage I), mild (stage II), moderate (stage III), and severe (stage IV) as determined by an accumulated point total, with points based on the location of the endometrial lesions, the size of the lesions, the presence and extent of the adhesions, and the degree of obliteration of the posterior cul-de-sac. The classification system is designed to document the location and extent of endometriosis and does not predict infertility, aid in treatment selection or outcomes, or predict recurrence of disease. Making diagnosis and prognosis more difficult is that the reported severity of pelvic pain and level of functional disability do not seem to be correlated to the stage of endometriosis.⁹⁷

Clinical Characteristics

19. N.H. is a 32-year-old mechanical engineer who has been married for 6 years, and is currently using the vaginal contraceptive ring to prevent pregnancy. She and her spouse have been contemplating the timing of a pregnancy, but have not yet attempted to become pregnant. She presents to her gynecologist to discuss preconceptual planning, and reports that she has been having severe lower abdominal cramps, associated with her menses, occurring on day 1 and lasting until day 4 or 5. This has been occurring for the past 4 years after many years of pain-free cycles, and has recently been increasing in severity. The pain is slightly relieved by ibuprofen 400 mg TID, and over the past 6 months she has had to work from home at least 1 to 2 days per month owing to pain that has been increasing in frequency. On further questioning, she also reports mild to moderate pain that occurs randomly in her cycle, associated with low back pain, constipation with painful defecation, and pain with intercourse. Her menstrual history reveals menarche at age 10 with regular cycles every 26 to 27 days and heavy menses for 6 to 7 days. She reports discussing her symptoms with her mother, who described similar symptoms during her childbearing years.

Her physical examination is normal, with the exception of tenderness on palpation of the posterior fornix, and a fixed retroverted uterus. A pregnancy test, and tests for gonorrhea and chlamydia are negative, and a pap smear is within normal limits. What subjective and objective data in N.H.'s presentation is compatible with a diagnosis of endometriosis?

A woman presenting with endometriosis may have signs and symptoms that are difficult, initially, to distinguish from primary dysmenorrhea¹⁰³ (Table 47-5). N.H.'s symptoms of lower abdominal cramps accompanying her menses are often mistaken for primary dysmenorrhea when other history details are not evaluated in total. N.H.'s age and her nulliparity are consistent with the characteristics of women with endometriosis. Although endometriosis has been diagnosed in women of all ages, it most commonly occurs in women in their late 20s and early 30s who have delayed pregnancy or who have infrequent pregnancies.

Table 47-5 Primary Versus Secondary Dysmenorrhea

| Characteristic | Primary Dysmenorrhea | Secondary Dysmenorrhea |
|---------------------------|--|--|
| Onset | Around menarche | Any age (while menstruating) |
| Timing in menstrual cycle | Worse day 1, lasts 24–48 hr | Increases in severity, may last days |
| Change over time | Stable, predictable | Increasing pain with increasing age |
| Symptoms | Low back pain, premenstrual syndrome (PMS), nausea, bloating | Low back pain, dyspareunia, diarrhea or constipation, dysuria, infertility |
| Signs | Normal pelvic examination | Fixed retroverted uterus, tenderness, but may be completely normal |

Adapted from reference 103, with permission.

N.H.'s menstrual pattern of short cycle length with prolonged flow is characteristic of women with endometriosis. Risk factors for endometriosis are related to exposure to estrogen (i.e., early menarche and late menopause), and shorter menstrual cycle length (<28 days) with longer duration of menstrual flow (≥ 6 days), as well as having a mother or sister with endometriosis, as may be true with N.H.'s mother.¹⁰⁴ Potential, but not yet confirmed, risk factors that have been identified include genetic factors, higher social class, exposure to dioxins, and intake of caffeine and alcohol. Increased BMI and cigarette smoking appear to reduce the risk for endometriosis.^{105,106}

N.H.'s chief complaints center on her progressive pelvic pain occurring throughout the cycle, with worsening during menses, constipation, and pain with intercourse (dyspareunia). Women who report pain during intercourse may have a fixed, retroverted uterus (as N.H. does) or endometriosis located in the posterior fornix of the vagina or along the uterosacral ligaments.⁹⁷ This pain may persist for several hours after intercourse. Other symptoms such as the constipation and painful defecation N.H. is experiencing, are associated with endometriosis and may (but not always) depend on the organs affected by the location of the endometrial tissue^{107,108} (Table 47-6). Depression also is a common symptom in patients with endometriosis, particularly those with chronic pelvic pain, and may express as sadness, somatic complaints, inability to work, or carry on activities of normal living.¹⁰⁹

Although it is unclear yet whether infertility will be a problem in N.H., endometriosis occurs in up to 45% of women with infertility.⁹⁷ The cause of endometriosis-associated infertility is not clear, but is probably caused by a combination of factors, which may include physical distortion of the pelvic architecture, inflammatory factors (including prostanoids, cytokines, and growth factors that may interfere with normal reproductive processes), impaired folliculogenesis, or defects in fertilization or implantation.^{110,111} Treatment for endometriosis, in inducing a "pseudo-menopause," results in impaired fertility while actively being treated.

N.H.'s limited physical findings are not uncommon in women with endometriosis; physical findings, other than visualization of endometrial tissue during exploratory surgery, may not be present, and outward physical findings may have no correlation with the stage of endometriosis determined with surgery. Many symptoms and physical findings of endometriosis can be associated with other gynecologic conditions or diseases (particularly irritable bowel disease as mentioned) and, if the patient is not responsive to empiric therapy, laparoscopy

is indicated to confirm the diagnosis. N.H.'s negative pregnancy, chlamydia, and gonorrhea tests, as well as her normal pap smear are reassuring. Other laboratory tests that have been evaluated to diagnose endometriosis have not been sufficiently sensitive or specific in clinical trials to be routinely used. Tests, such as CA-125 are not sufficiently specific as a single test to diagnose endometriosis, but may have potential in combination with others as markers of disease severity and of treatment efficacy, and their utility is currently being investigated.¹¹²

Table 47-6 Location of Endometriosis and Associated Symptoms

| Sites | Symptoms |
|-----------------------|---------------------------|
| Most Common | |
| <i>Pelvic</i> | |
| Cervix | Abnormal uterine bleeding |
| Ovaries | Dysmenorrhea |
| Peritoneum | Dyspareunia |
| Rectovaginal septum | Infertility |
| Uterosacral ligaments | Pelvic pain |
| <i>Intestinal</i> | |
| Abdominal scars | Intestinal obstruction |
| Sigmoid colon | Midabdominal pain |
| Small intestines | Nausea |
| | Painful defecation |
| | Rectal bleeding |
| <i>Urinary Tract</i> | |
| Bladder | Cyclic flank pain |
| Ureter | Hematuria |
| | Hydronephrosis |
| | Hydroureter |
| Least Common | |
| <i>Miscellaneous</i> | |
| Breasts | Hemoptysis |
| Diaphragm | Sciatica |
| Extremities | Subarachnoid bleeding |
| Gallbladder | |
| Pleura | |
| Sciatic notch | |
| Spleen | |
| Stomach | |
| Subarachnoid space | |

Pathophysiology

Although the first description of endometriosis was made in the 1860s, the precise etiology of endometriosis remains a mystery. Several theories exist regarding the origins of endometriosis, and the exact etiology is probably a complex interplay between physical and individual patient-specific immunologic factors.⁹⁷

The most commonly cited theory is that of retrograde menstruation, or the flow of menstrual fluid, endometrial cells, and other debris backward through the fallopian tubes resulting in implantation in the peritoneal cavity. Once endometrial cells reach the peritoneum, stimulated angiogenesis (potentially by estrogen, among other factors) appears to be a determinant of the development and growth of lesions.^{113,114} Also at this point, the lesion stimulates an immune response, triggering the activation of macrophages, as well as cytokine and growth factor release. Peritoneal lesions may contribute to more distant disease by spread via hematogenous or lymphatic routes, or even by movement owing to iatrogenic causes, such as cesarean sections and other forms of gynecologic surgery. Outflow obstruction of the genital tract may also contribute to retrograde menstruation and endometriosis, particularly in adolescents with primary amenorrhea. Investigation and removal of obstruction(s) may impede the course of the disease in those patients.^{97,105,114} Although the retrograde menstruation theory makes scientific sense, it has been discovered that retrograde menstruation occurs in nearly all menstruating women (90%), and not all women have endometriosis. This suggests that an additional factor, such as genetic susceptibility or altered immunity, must be present for the pathogenesis of endometriosis in certain patients.

Another theory for the etiology of endometriosis is the coelomic metaplasia theory. This theory rests on the belief that the coelomic epithelium, the fetal originator tissue for the reproductive tract, retains its ability to differentiate into multiple cell types.^{97,105,115} The trigger for differentiation is thought to be, in part, estrogen or environmental factors. This theory would explain the presence of endometriosis in prepubertal girls, in women born without a uterus, and in the rare cases of endometriosis seen in men. Genetics also play a role in the development of endometriosis. There is a six times higher rate of endometriosis in first degree relatives in women with severe endometriosis when compared with those who do not have endometriosis; they also have more severe disease and disease that appears earlier in life.^{97,115} More than 15 different gene and gene product abnormalities have been documented in women with endometriosis. Environmental factors, as discussed, are intriguing in their role as potential causative factors, but are not definitive.^{106,115}

Once endometrial tissue becomes implanted, hormones are necessary for their continued growth. As with intrauterine endometrium, the implants of endometriosis possess estrogen, progesterone, and androgen receptors. The endometrial implants may, however, respond differently to hormonal stimulation than normal endometrium. In general, estrogens stimulate the implants, whereas androgens or lack of estrogen results in implant atrophy. Because of their complex hormonal effects, progestins have variable effects on the implants.^{102,116} (See Chapter 46 Obstetric Drug Therapy for the effects of estrogens and progestins on the endometrium.) In addition, le-

sions also show high levels of estrogen biosynthesis, owing to abnormally increased aromatase activity, with a concomitant decrease in the inactivation of estrogen, resulting in high intralesional estrogen concentrations.^{115,117} The responsiveness of endometrial implants to ovarian hormones plays a role in the pathology of endometriosis. Withdrawal of estrogen and progesterone causes the endometrial implants to bleed, leading to an inflammatory response in the adjacent tissues. Repetitive cycles of bleeding and inflammation lead to the development of scar tissue and adhesions between adjacent peritoneal tissues. On laparoscopy, these areas of involvement appear as multiple hemorrhagic foci composed of endometrial epithelium, stroma, and glands. Ovarian endometriosis usually involves the formation of endometriomas, blood-filled cysts (“chocolate cysts”) ranging in size from microscopic to 10 cm. Nodules may form on uterosacral ligaments. Fibrosis usually is present with the endometrial implants, and extensive adhesions may form between pelvic structures.¹¹⁸

Treatment

20. Given the potential mechanisms behind the pathophysiology of endometriosis, what therapeutic approaches are available for the treatment of endometriosis in N.H.?

Therapy for endometriosis should be individualized, and consider N.H.’s desire for future fertility, severity of symptoms, extent of disease, and potential for infertility. This should be done with the knowledge that a high likelihood exists of recurrence and a lack of good prognostic indicators for future severity. The goals of treatment are to relieve symptoms and, if desired, to preserve or improve fertility. Options currently available to treat endometriosis include definitive and conservative surgery, hormonal therapy with estrogen–progestin combinations or progestins alone, danazol, aromatase inhibitors, or the GnRH agonists, and expectant management. Pharmacologic treatment of endometriosis is based on manipulation of this hormonal response: danazol, GnRH agonists, progestins, aromatase inhibitors, and estrogen–progestin combination all cause endometrial tissue atrophy. No treatment has been shown to provide 100% protection against recurrence when discontinued; even surgical removal of the uterus and ovaries is associated with recurrence rates of up to 10%.¹¹⁴

Pain Management: Nonpharmacologic Therapy **“DEFINITIVE” SURGERY**

Definitive surgery, referring to total abdominal hysterectomy, bilateral salpingo-oophorectomy, and removal of all visible endometriosis, theoretically should eliminate the risk of recurrence of the disease. These procedures are not an option for the many women with endometriosis who desire pregnancy in the future. It is invasive surgery, reserved for those patients whose pain is unresponsive to other therapies or to conservative surgery. Furthermore, removal of all endometriosis is difficult, and recurring pain is not uncommon. Sinaii et al.¹¹⁹ surveyed patients with endometriosis regarding treatments and benefits, and found that, of the 1,160 women surveyed, 12% had had definitive surgery, with 40% reporting the surgery was successful, 33% reporting partial benefit, 5.6% reporting no benefit, and 6% of patients actually reported increased pain and symptoms after surgery.

CONSERVATIVE SURGERY

In contrast to definitive surgery, conservative surgery (involving ablation and removal of implants, and lysis of adhesions) preserves fertility, and is commonly conducted during the initial diagnostic laparoscopy. In the Sinaii et al. survey,¹¹⁹ 70% of patients had undergone laparoscopy with removal of lesions, with 30% considering the procedure a success, 50% reporting partial benefit, 15% with no difference in symptoms, and 10% who reported increased symptoms. On average, women reported having three surgical procedures.¹¹⁹ Drug treatment is used after conservative surgery, as it is not possible to remove all lesions, many of which are difficult to visualize. Clinical trials utilizing GnRH agonists for up to 6 months after conservative surgery have provided mixed results, and danazol and medroxyprogesterone trials have shown similar results.¹²⁰ Oral contraceptives and progestin intrauterine devices have not been evaluated for prevention of recurrence after surgery.

Pain Management: Pharmacologic Therapy

NSAID

Nonsteroidal anti-inflammatory agents, particularly those available as OTC products, are often the first medications that women try for relief of pain from endometriosis, often before they are officially diagnosed. Although typically not thought of as “disease modifying agents,” NSAIDs may have a role beyond pain control because of the presence of increased cyclooxygenase (both I and II) expression in endometriosis lesions.¹¹⁷ Although evidence at this point is predominantly in animal models, a potential exists for non-pain-related benefits with NSAIDs in endometriosis. NSAIDs may provide some relief of mild symptoms, particularly in women with endometriosis who have pain associated with the menses (see Dysmenorrhea section), and are an appropriate first choice for women with mild symptoms who desire conception. They should not be the only therapy offered to patients with confirmed endometriosis.¹²¹ Pharmacists should be aware of and consider the potential for endometriosis in patients with non-cyclic pain, including pain that does not respond to an appropriate trial of an NSAID. N.H. has been taking ibuprofen with some relief; a higher dose or trial of another NSAID is an appropriate strategy at this time. Additional treatment should be considered once her response to therapy with a different NSAID has been evaluated.

ORAL CONTRACEPTIVES

For women who do not receive pain relief from a trial of an NSAID, a reasonable next step for those women desiring contraception is the use of oral contraceptives because they are considerably better tolerated over the long term versus other hormonal options. They may be used alone or in combination with NSAIDs. OCs improve symptoms of endometriosis by inhibiting ovulation, decreasing hormone levels, reducing menstrual flow, potentially to the point of amenorrhea. These mechanisms contribute to atrophy of endometrial implants. When used, the most appropriate regimen is continuous OC dosing, so that there is not a “placebo week” that allows for growth of endometrial implants. In a trial of patients who did not respond to cyclic OCs, use of continuous dosing resulted in significant pain reduction.¹²² A recent Cochrane review found that the benefits of OCs (≤ 35 mcg of ethinyl estradiol) are similar those seen with the GnRH agonist implants (goserelin).¹²³

Investigators in Japan also evaluated women with dysmenorrhea and endometriosis in a placebo-controlled trial with a low-dose OC. Over the course of three cycles, patients reported that contraceptive use decreased disability caused by pain, and reduced the number of days when analgesics were required, with minimal side effects.¹²⁴ It is important to note that these benefits were seen although the drug was administered in a cyclic fashion.

PROGESTINS

Similarly to oral contraceptives, progestins reduce symptoms of endometriosis by inhibiting ovulation, reducing hormone levels, and inducing endometrial atrophy. They may be particularly useful if estrogen use is contraindicated. Regimens used include oral medroxyprogesterone in high doses (30–100 mg daily), depot medroxyprogesterone in the usual doses (150 mg intramuscularly [IM] every 3 months or 104 mg subcutaneously [SC] every 3 months). More recent studies have evaluated the use of the levonorgestrel IUS as a means of providing consistent progestin dosing. The IUS has the advantage of providing longer term contraception. When compared with leuprolide depot, the levonorgestrel IUS provided similar benefits in reducing pelvic pain, with a decreased potential for hypoestrogenic effects, and an increased potential for early breakthrough bleeding, followed by eventual amenorrhea.¹²⁵ Progestins, although as effective as GnRH agonists in the treatment of pain, have increased side effects when compared with OCs, primarily weight gain, initial breakthrough bleeding followed by amenorrhea, and decreased bone density with prolonged use, placing them after OCs in choice of therapy.¹²⁶

GONADOTROPIN-RELEASING HORMONE AGONISTS

Gonadotropin-releasing hormone agonists induce a pseudomenopausal state, resulting in relief of endometriosis symptoms. Because the GnRH agonists have a longer half-life than endogenous GnRH, their binding to GnRH receptors in the pituitary results in downregulation of the hypothalamic-pituitary-ovarian axis, decreasing release of FSH and LH, leading to low estrogen levels and amenorrhea.¹²⁷ GnRH agonists are available in a variety of dosage forms, outlined in Table 47-7. When compared in clinical trials, GnRH agonists have efficacy that is similar to oral contraceptives, progestins, and danazol, but their increased cost, and adverse effect profile (including menopausal-type symptoms and decreased bone density) make them second-line agents, after OCs, and progestins (see Questions 25–27).¹²⁸

AROMATASE INHIBITORS

The most recently studied therapy for endometriosis, aromatase inhibitors (AIs), were originally developed for use in patients with breast cancer. Aromatase, the enzyme responsible for the synthesis of estrogens, is required for the conversion of androstenedione and testosterone to estrone and estradiol.¹²⁹ Although aromatase inhibitors, OCs, progestins, and GnRH agonists all decrease serum levels of estrogen, only AIs decrease secretion and production of estrogen by endometrial tissue itself. Anastrozole and letrozole are type II aromatase inhibitors, binding reversibly to the enzyme to produce a beneficial effect on endometriosis symptoms.¹²⁹ Although the end result of GnRH agonists and AIs is similar, the adverse effects of the AIs are decreased, with fewer hot flashes, and primarily

Table 47-7 GnRH Agonists

| GnRH Agonist (Brand Name) | Strength | Dosage Form | Dosage Regimen |
|------------------------------------|--|--------------|-----------------|
| Nafarelin (Synarel) | 2 mg/mL delivers 200 mcg/spray | Intranasal | 200–400 mcg BID |
| Leuprolide (Lupron) | 3.75, 7.5, 11.25 mg | IM depot | 3.75 mg/month |
| Goserelin (Zoladex) | 3.6 mg | SC implant | 3.6 mg/month |
| Histrelin ^a (Supprelin) | 120 mcg/0.6 mL 300 mcg/0.6 mL 600 mcg/0.6 mL | SC injection | 100 mcg/day |

^aNot U.S. Food and Drug Administration (FDA) approved for treatment of endometriosis. BID, twice daily; GnRH, gonadotropin-releasing hormone; IM, intramuscular; SC, subcutaneous.

mild headache, nausea, and diarrhea. Although few long term trials have been conducted, decreased bone density is suspected with the use of AIs and add-back therapy is appropriate.

Aromatase inhibitors have been studied alone and in combination with oral contraceptives, progestins and GnRH agonists. All studies, although small, have demonstrated reduction in pain and reduced lesion size. The largest study to date utilized a combination of anastrozole with GnRH agonists compared with GnRH agonists alone in patients after surgery.¹³⁰ Although effective at controlling pain, the combination resulted in significantly more bone loss than either regimen alone at 6 months, but no difference was seen at the 2-year follow-up.¹³⁰ Further research is needed to determine the role of AIs in the treatment of endometriosis, because currently they do not have an FDA indication for the treatment of endometriosis. Their use should be reserved at this time for those patients with severe endometriosis who have failed other therapies.

DANAZOL

Danazol, an androgenic drug derived from 17-ethinyl testosterone, also induces a pseudomenopausal state by increasing androgen levels and decreasing estrogen levels. It inhibits the enzymes involved in ovarian steroidogenesis and increases the metabolic clearance of estradiol. By creating a hypoestrogenic, hypoprogesterogenic state, danazol causes anovulation, amenorrhea, and atrophy of endometrial implants. Although effective at decreasing pelvic pain, danazol is poorly tolerated because of its significant side effects, which include weight gain, voice changes, edema, acne, hot flashes, vaginal dryness, hirsutism, liver disease, and increased cholesterol; these occur in up to 85% of treated patients.¹¹⁴ Because of safety concerns, use should be limited to 6 months at a time, and should only be initiated in women after all other therapy options have failed.¹²⁸

Clinical Application

21. N.H.'s pain is uncontrolled after trials of three different NSAID and she would like relief so she would be able to function at work and home. Although she is interested in having children in the future, she is not interested in conception in the next few years. What is the treatment of choice for N.H.?

Clinical trials in endometriosis have not singled out one treatment as the treatment of choice for all women, with most investigations demonstrating equivalence of the studied therapies. An NSAID and combined hormonal contraception (e.g., N.H.'s contraceptive vaginal ring) are the drugs of choice for

initial management, owing to their safety profile, and in this case, the contraceptive agent's dual utility in preventing conception. As a next step, progestins, GnRH agonists, and AI are options. Because of adverse effects and poor tolerability, danazol should be reserved as an agent of last choice. If N.H. were uninterested in having children in the future, surgical sterilization would be an option. Conservative surgery, including removal of endometriomas and adhesions, and ablation of visible lesions is not curative, but may provide pain relief in 50% to 95% of patients at 1 year.¹²⁷ A combination of conservative surgery, followed by postoperative progestin, GnRH agonists, or danazol has been shown to prolong the duration of pain relief and decrease recurrence after surgery.¹²⁷ Oral contraceptives have not been studied as a postsurgery treatment option.

22. N.H. is 5 feet 7 inches and weighs 145 pounds. She smokes one-half pack of cigarettes per day, and does not drink alcohol. She plays recreation league basketball and softball, but does not have a regular exercise regimen. She usually eats five servings of fruits or vegetables per day, but does not like to drink milk. She has been told she has inherited her father's high cholesterol, and is concerned because he had a cardiac stent placed at age 40. She has not had a problem in the past tolerating a variety of contraceptive products, but does have some problems with daily medication adherence, and would like to avoid needles if possible. How does this information assist in the selection of therapy for her endometriosis?

N.H. is a smoker, with poor calcium intake, and some cardiovascular risk factors (family history, "high cholesterol"), who would rather avoid injectable medication and has trouble with daily medication taking. Danazol, with its ability to increase cardiovascular risk factors, and extensive side effects, is not a good option. Although some GnRH analogs are available as nasal sprays or injectable implants, the significant risk of decreased bone density, and menopausal-like adverse effects place it as a second-line option. Progestins, particularly the long-acting progestins, either in the form of the medroxyprogesterone acetate 3-month depot injection, or the levonorgestrel IUS make these appropriate first-line options for N.H., although the risk of diminished bone density remains an issue.

23. N.H. elects to start the levonorgestrel IUS, but her insurance company will not pay for it to be used in the treatment of endometriosis because of its lack of FDA indication. She decides to start depot medroxyprogesterone acetate. What information

can you provide her regarding use, and the benefits and risks of treatment?

Depot medroxyprogesterone acetate (DMPA) is available in two dosage forms: 150 mg to be given IM every 3 months, and a 104-mg formulation given SC every 3 months. Product choice may be based on insurance coverage, or preference of the patient to self-administer (in this case, the SC product may be more patient friendly). Because N.H. does not want to use needles, either choice, administered by her provider's office, or pharmacy if law allows, would be an appropriate option. Although the DMPA does provide the contraception N.H. desires, she should be informed that it may take longer than usual (up to 1 year) to become pregnant after its use. More than 80% of patients treated with progestins will experience partial or complete pain relief.¹³¹ Although devoid of the menopausal-like adverse effects of other medications used to treat endometriosis, DMPA is associated with weight gain, which may be significant in some patients; bloating, and irregular periods or bleeding for several months, with most users eventually experiencing amenorrhea. To reduce bone density loss, which is significant but less than with GnRH agonists, N.H. should be advised to increase her calcium and vitamin D intake by diet or supplementation, counseled to stopping smoking, and start a regular weight-bearing exercise regimen.¹³² She should be monitored for pain relief, weight gain, amenorrhea or bleeding changes, and adherence to the quarterly injections. When N.H. desires conception, significant planning is required, and she may require a different therapy for her endometriosis as she regains fertility.

Gonadotropin-Releasing Hormone Agonists

DOSING

24. M.F., a 24-year-old single woman with a history of moderate to severe endometriosis, has been treated with some benefit with an NSAID, oral contraceptives, and the levonorgestrel IUS. She has no desire for conception, and is looking for pain relief. She has also had two conservative laparoscopic surgical procedures, each of which was successful, with pain relief lasting 6 months to 1 year. She recently had her "last ever" surgical procedure, and is looking to extend the improvement she has seen previously after surgery. She does not mind injections, but has had trouble with adherence in the past. Her physician has prescribed leuprolide 11.25 mg IM every 3 months. Why did she select this product, and how long should M.F. continue the medication?

Leuprolide, nafarelin, and goserelin are GnRH analogs (agonists) typically used for the treatment of endometriosis (Table 47-7). Although GnRH analogs have not been shown to produce better results than the therapies M.F. has already used, they may provide her with pain relief. Choice of GnRH agonist is driven by patient choice of administration method (nasal BID with nafarelin, monthly SC implant with goserelin, or IM injection either once monthly or once every 3 months with leuprolide). In M.F.'s case, the once every 3 months dosing with leuprolide would be most desirable for her, eliminating the need for daily administration. Efficacy is similar for all the GnRH agonists. Before use of these agents, pregnancy, undiagnosed vaginal bleeding, and breastfeeding should be ruled out. Because M.F. does not desire conception, and use of the GnRH agonists is contraindicated in pregnancy, she should

be counseled regarding choices of nonhormonal contraceptive agents.

Onset of response to GnRH therapy depends on the phase in the menstrual cycle during which the agent is initiated. Administration beginning in the luteal phase causes decreased estrogen levels within 2 to 3 weeks, and amenorrhea within 4 to 5 weeks versus the 6 to 8 weeks if started in the follicular phase.⁹⁷

Usual therapy duration is 6 months, although a small recently published pilot study suggested long-term treatment (up to 10 years) with add-back therapy (see Question 25) is without major adverse effects, with continued efficacy.¹³³ Therapy beyond 3 to 6 months requires the use of add-back therapy to reduce the risk of hypoestrogenic complications. Monitoring for efficacy includes monitoring for amenorrhea, decreases in pain and dyspareunia, and quality of life. After discontinuation of GnRH agonists, menses and ovarian function return to normal in 6 to 12 weeks, whereas benefits may be maintained for another 6 to 12 months.⁹⁷

ADVERSE EFFECTS

Adverse effects should be discussed in detail with M.F. because they differ significantly from the other therapies she has tried. Adverse effects are related to the induction of the pseudomenopausal state (Table 47-8). Nearly all patients experience hot flushes; vaginal dryness and insomnia also are common. GnRH agonists do not affect SHBG or testosterone levels, so the androgenic side effects of danazol, including changes in lipid profiles, are not experienced with these agents.⁹⁷ Significant bone loss can occur, necessitating preemptive actions to decrease loss (see Question 26).

Hypoestrogenic Effects

25. M.F. has read a significant amount about the use of GnRH agonists for endometriosis. She is confused by the use of estrogen and progestin with GnRH agonists. Explain to M.F. what is meant by "add-back" therapy.

Add-back therapy is the addition of a progestin or estrogen plus progestin to GnRH agonist therapy to decrease the hypoestrogenic adverse effects related to their use, while maintaining the therapeutic benefit of the GnRH agonist. This therapy is based on the concept of an "estrogen threshold hypothesis," formulated by Barbieri,¹¹⁸ which states that there is a critical amount of estrogen that exacerbates endometriosis, and below that level, the presence of estrogen serves to decrease adverse effects, but does not have an adverse effect on the disease itself. Add-back therapy can be initiated at the beginning of GnRH agonist therapy to try to reduce the occurrence of all hypoestrogenic adverse effects (the most common regimen), or wait until 3 to 6 months into therapy, to assess patient-specific adverse effects.

Estrogen-containing OCs contain a dose of estrogen that is above the "threshold," and they should not be used for add-back therapy. Doses of estrogen equivalent to 0.625 mg of conjugated equine estrogen have been studied in combination with either medroxyprogesterone 2.5 mg daily, or norethindrone 5 mg daily. This dose of norethindrone alone, or a dose of 20 mg of medroxyprogesterone alone, has also demonstrated benefit.¹¹⁴ To prevent bone loss, a regimen of a progestin plus a bisphosphonate has been studied with positive results. No

Table 47-8 Adverse Reactions With Danazol and the GnRH Agonists¹⁷⁰

studies have demonstrated superior efficacy or safety of one regimen over another.

Bone Demineralization

26. How significant is the bone loss associated with Gn-RH agonists?

Reduction in bone density is a significant concern with Gn-RH agonists, even at 3 months after the onset of therapy, and is particularly concerning because these agents are being used in young women, many of whom have not reached their peak bone mass. Studies have demonstrated a loss of 3.2% in lumbar spine bone mineral density (BMD) after 6 months, and a 6.3% decrease after 12 months of GnRH agonist treatment.¹²⁸ It has also been reported that endometriosis itself is also a risk factor for decreased bone density, although a long-term study did not find any association between endometriosis and fracture risk over a 20-year follow-up period.¹³⁴ Interestingly, this same study did not find any association between fracture risk and Gn-RH agonist therapy, although a significant number of women in the study did take add-back therapy.

Monitoring for decreases in bone density should be accomplished via dual-energy x-ray absorptiometry (DXA) scan every 24 months if GnRH therapy is continued. Women such as M.F. should also be counseled regarding adequate calcium and vitamin D intake, smoking cessation, and a regimen of weight-bearing exercise.

Management of Endometriosis-Related Infertility

27. K.L. is a 34-year-old woman with a history of stage II endometriosis. She currently is using a levonorgestrel IUS for both contraception and control of her pain, with positive results. She also takes ibuprofen on a regular basis. She and her spouse would like to have a child. About 6 years ago, they attempted to conceive without success after 24 months. K.L. is concerned that she will now have even more difficulty becoming pregnant, given her advanced age. What are the recommendations for improving infertility associated with endometriosis?

Of women presenting to the health care system with infertility, 30% to 45% have endometriosis, and 30% to 50% of women with endometriosis are infertile.¹³⁵ Proposed mechanisms contributing to infertility include adhesions that impair oocyte transport, changes in the peritoneum not compatible with fertility, changes in hormonal function, endocrine or ovulation dysfunction, and disorders of implantation. No evidence suggests that hormonal therapy, including therapy with GnRH agonists, improves conception rates for women with stage I/II endometriosis, similar to K.L.'s. On the other hand, surgical ablation or resection of visible endometriosis implants is beneficial in improving pregnancy rates in women with stage I/II endometriosis.

For K.L., removal of her IUS, followed by laparoscopic ablation or resection of visible implants may improve her ability to conceive, barring other factors influencing fertility (e.g.,

PCOS, male factor infertility, tubal patency). For patients with more advanced disease, or in those patients >35 years of age, a more aggressive treatment regimen is appropriate. Options include the use of agents to induce superovulation (clomiphene), and the use of in vitro fertilization techniques with embryo transfer (IVF-ET). In women with endometriosis, the success of IVF-ET is decreased by as much as 20% when compared with women without endometriosis.⁹⁷ For women contemplating IVF-ET, three prospective clinical trials have demonstrated a potential benefit in women with stage II–IV endometriosis who were treated for 3 to 6 months or more with Gn-RH agonists before IVF-ET. The treated subjects had significantly higher pregnancy rates compared with women who did not use Gn-RH agonists before IVF-ET.¹³⁶

For women who have not yet demonstrated an inability to conceive, a “wait and see” approach, with use of NSAID for pain, emotional support, and reassurance for 6 to 12 months is appropriate in women <35 years of age.

PREMENSTRUAL SYNDROME AND PREMENSTRUAL DYSPHORIC DISORDER

Premenstrual symptoms occur in up to 90% of reproductive-age women.¹³⁷ Approximately 20% to 40% of these women have more bothersome symptoms of premenstrual syndrome (PMS) and it is estimated that 3% to 8% meet the criteria for premenstrual dysphoric disorder (PMDD), a more severe variant of PMS.¹³⁷ More than 200 premenstrual symptoms have been described as occurring during the days before menstruation, including positive symptoms, such as increased energy, libido, and ability to relax, as well as negative symptoms including abdominal distention, fatigue, headaches, and crying spells.¹³⁸ It is not until the symptoms have a decidedly negative influence on the physical, psychological, or social function of a woman that PMS exists. In essence, the symptoms must induce a reduction or loss of life quality to be considered PMS or PMDD.¹³⁸

Diagnosis

No specific physical findings or laboratory tests can be used to make a diagnosis of PMS. The American College of Obstetricians and Gynecologists (ACOG) published a Practice Bulletin in 2000 that defined diagnostic criteria using cyclical patterns of symptoms in women.¹³⁹ PMS can be diagnosed if at least one of the affective and one of the somatic symptoms listed in Table 47-9 is reported 5 days before the onset of menses in the three previous cycles. The symptoms must be prospectively recorded in at least two cycles and must cease within 4 days of onset of menses and not recur until after day 12 of the menstrual cycle. A key factor that separates PMS from “normal” premenstrual symptoms is that work or social activities are adversely affected in PMS. Other diagnoses that may explain premenstrual symptoms should be excluded, including psychological, thyroid, and gynecologic disorders.¹⁴⁰

The American Psychiatric Association has developed criteria for PMDD (Table 47-10).¹⁴¹ The criteria for PMDD focus on the mood and mental health symptoms, leading to a higher level of dysfunction compared with PMS. Criteria for PMS and PMDD, however, share three essential characteristics: (a) symptoms must occur in the luteal phase and resolve within a

Table 47-9 ACOG Diagnostic Criteria for PMS

| Affective Symptoms | Somatic Symptoms |
|--------------------|-------------------------|
| Depression | Breast tenderness |
| Angry outbursts | Abdominal bloating |
| Irritability | Headache |
| Anxiety | Swelling of extremities |
| Confusion | |
| Social withdrawal | |

ACOG, American College of Obstetricians and Gynecologists; PMS, premenstrual syndrome.

1. Diagnosis made if at least one affective and one somatic symptom is reported in the three prior menstrual cycles during the 5 days before the onset of menses.
 2. The symptoms must resolve within 4 days of onset of menses and do not recur until after day 12 of the cycle.
 3. The symptoms must be present in at least two cycles during prospective recording.
 4. The symptoms must adversely affect social or work related activities.
- From reference 139, with permission.

few days of menstruation; (b) symptoms are documented over at least two menstrual cycles and are not better explained by other physical or psychological conditions; and (c) symptoms are sufficiently severe to disrupt normal activities.¹⁴⁰

The symptoms of PMS and PMDD experienced by women can vary widely. Risk factors for PMS include advancing age (>30 years) and genetic factors.¹⁴⁰ Symptoms, however, can begin in adolescents around age 14, or 2 years postmenarche,

Table 47-10 Diagnostic Criteria for Premenstrual Dysphoric Disorder

- In most menstrual cycles during the past year, at least five of the symptoms below (including one core symptom) were present for most of the time 1 week before menses (luteal phase), began to remit within a few days after the onset of menses, and were absent the week after menses (follicular phase).
 - Core symptoms
 - Markedly depressed mood, feelings of hopelessness or self-deprecating thoughts
 - Persistent and marked anger or irritability or increased interpersonal conflicts
 - Marked anxiety, tension
 - Marked affective lability (i.e., feeling suddenly sad or tearful)
 - Other symptoms
 - Decreased interest in usual activities (e.g., friends, hobbies)
 - Subjective sense of difficulty in concentrating
 - Lethargy, easy fatigability, or marked lack of energy
 - Marked change in appetite, overeating, or specific food cravings
 - Hypersomnia or insomnia
 - A subjective sense of being overwhelmed or out of control
 - Other physical symptoms (e.g., breast tenderness, bloating, weight gain, headache, joint or muscle pain)
- The symptoms seriously interfere with work or school, usual activities, or relationships with others.
- Symptoms are not merely an exacerbation of another disorder, such as major depression, panic disorder, dysthymia, or a personality disorder (although it may be superimposed on any of these disorders).
- Three major criteria above are confirmed by prospective daily self-ratings for at least two consecutive symptomatic cycles.

Adapted from reference 141, with permission.

and persist until menopause.¹⁴² Some studies suggest that women with mothers reporting PMS are more likely to develop PMS than those with unaffected mothers (70% vs. 37%, respectively).^{143,144} One article found that traumatic events, such as physical threat, childhood sexual abuse, and severe accidents, increased the risk of developing PMDD.¹⁴⁵

Pathophysiology

The wide range of symptoms exhibited in patients with PMS or PMDD can be explained by multiple possible mechanisms, probably a result of interactions between sex steroids and central neurotransmitters.¹⁴⁶ Alterations in neurotransmitters, primarily reductions in serotonin, triggered by normal hormonal fluctuations of the menstrual cycle appear to be the most probable factors for the development of PMS or PMDD. Other neurotransmitters, including endorphins and γ -aminobutyric acid (GABA), have also been implicated.^{147,148} The levels of estrogen, progesterone, and testosterone are normal in women with PMS, but they may be more vulnerable to normal fluctuations.¹⁴⁸ These potential mechanisms provide a rationale basis for the symptoms that appear in PMS and PMDD, but also support the therapeutic benefits of treatments that increase serotonin or GABA levels. Many treatments have limited and variable efficacy, which reinforces the argument that PMS or PMDD is a result of multiple factors. Furthermore, placebo responses in trials can be as high as 50% to 80%, which points to an important psychosomatic component and the consideration that PMS or PMDD has relevant biological, psychological, and social factors.¹³⁸

29. C.P., a 27-year-old woman, visits her family physician complaining of significant mood changes that occur the week before her menstrual cycle. She experiences increased irritability and anxiety as well as breast tenderness and abdominal bloating. These symptoms usually subside the first or second day after her menses begin. For 2 to 3 weeks after her menstrual period, C.P. is her “normal, usual self” until the symptoms begin again just before her next menstruation. She has had these symptoms every month for the past several years. She states that she is very uncomfortable when these symptoms occur. Although she is able to work most of the time, she typically avoids going out with her friends when she has these symptoms. Her menstrual cycles are regular, occurring every 28 to 30 days with a light flow lasting 3 to 4 days.

Pelvic, cardiovascular, and neurologic examinations are normal and all laboratory assessments are within normal limits. Her serum pregnancy test was negative. She has no history of an affective disorder. Her physician makes a preliminary diagnosis of PMS. What symptoms does C.P. have that are consistent with this diagnosis?

C.P. has symptoms that meet the ACOG criteria for PMS. Her affective symptoms include irritability and anxiety and somatic symptoms include breast tenderness and abdominal bloating. These symptoms occur during the luteal phase of the menstrual cycle, resolve within 4 days of menses, and do not recur until after day 12 of her cycle. C.P.’s symptoms appear to be affecting her social activities. She states that these symptoms have been present for years and that they occur every month, although she has not prospectively recorded this information. C.P. does not meet the criteria for PMDD because her

symptoms are not severe or markedly impairing her ability to participate in daily activities.

Treatment: PMS

28. C.P. asks about nonprescription therapy. What options are available and what is the evidence for use of these products?

Nonprescription options that have been studied and have demonstrated at least minimal benefit include calcium, magnesium, pyridoxine, chaste tree or chasteberry, and some mind-body approaches. NSAIDs and acetaminophen may be beneficial for the physical symptoms of PMS, but diuretics found in various OTC products (e.g., ammonium chloride, caffeine, pamabrom) have limited data and unproved efficacy. Given the high placebo response rate in PMS, only agents with clinically proved efficacy should be used.

Calcium

Increased estrogen during the middle of a normal menstrual cycle decreases calcium. In women with PMS, intact parathyroid hormone (PTH) increases in response to this change compared with no PTH change in women without PMS.¹⁴⁹ Therefore, women with PMS have midcycle elevations of intact PTH with transient, secondary hyperparathyroidism. This explains why calcium has demonstrated some benefit in women with PMS.

Three calcium trials have shown efficacy of PMS symptoms. A randomized, double-blind cross-over trial of 33 women receiving 1,000 mg elemental calcium daily or placebo for 3 months reported a significant overall 50% reduction in PMS symptoms for women taking calcium compared with placebo.¹⁵⁰ In a double-blind study of 10 women assigned to dietary calcium intake, 1,336 mg daily was found to benefit mood, behavior, pain, and water retention symptoms significantly during the menstrual cycle.¹⁵¹ Perhaps the most convincing evidence comes from a prospective, multicenter, randomized, double-blind, placebo-controlled, parallel-group trial conducted in 466 women with PMS.¹⁵² Elemental calcium 1,200 mg daily (given as 600 mg BID) for three menstrual cycles significantly decreased negative affect, water retention, food cravings, and pain compared with placebo. Overall, the calcium-treated group had a 48% reduction in symptoms compared with a 30% reduction in the placebo group. Because calcium is well tolerated and may provide other benefits (e.g., osteoporosis prevention) calcium supplementation should be recommended to women with symptoms of PMS if inadequate through diet or other supplementation.

Magnesium

Low levels of red cell magnesium have been correlated with women experiencing PMS, therefore magnesium supplementation has been evaluated for PMS symptoms.¹⁵³ A Cochrane Library analysis of three small trials comparing magnesium and placebo in women with dysmenorrhea concluded that magnesium was more effective for pain associated with PMS and the need for additional medication was less for those taking magnesium.¹⁵⁴ Magnesium doses that have been studied for PMS vary from 200 to 360 mg daily. Trials have reported improvements in fluid retention and negative affect, but findings have not been consistent.¹⁵⁵ The conflicting results may be caused by differences in the dosing regimens of the magnesium

Table 47-11 Menstrual Cycle Daily Diary Chart

and differing levels of magnesium stores in the study subjects. Available data support the use of magnesium in PMS, but more research is needed.

Pyridoxine (Vitamin B₆)

Vitamin B₆ has been noted to have positive effects on neurotransmitters, such as serotonin.¹⁵⁶ The most comprehensive information for this nutrient comes from a systematic review of nine trials representing 940 patients with PMS.¹⁵⁷ The overall assessment of the review was that women with PMS are likely to benefit from vitamin B₆ supplementation at a dose of 50 to 100 mg daily. An analysis of four of the trials, which specifically examined depressive symptoms, showed that pyridoxine was more effective than placebo in reducing depressive symptoms (OR 1.69; 95% CI 1.39–2.06). Although the conclusions of this review were positive, the authors felt there was insufficient evidence of high quality to recommend vitamin B₆ for PMS. Because neuropathy has been reported with pyridoxine dosages as low as 100 mg/day, patients should be advised to monitor for symptoms and to discontinue therapy and seek medical attention if they occur.

Chastetree or Chasteberry

The mechanism of action of chasteberry (*Vitex agnus-castus*) relative to PMS is unclear, but several trials have reported its beneficial effects. In a study of 1,542 women with PMS taking chasteberry extract, 33% of subjects reported total relief of symptoms whereas an additional 57% reported partial re-

lief after 4 months.¹⁵⁸ Of patients, 2% complained of adverse events including nausea, allergy, diarrhea, weight gain, heartburn, hypermenorrhea, and gastric complaints. A randomized, double-blind, placebo-controlled trial of 170 women taking chasteberry extract 20 mg daily for three menstrual cycles showed a treatment response rate of 52% compared with 24% for placebo ($p < 0.001$).¹⁵⁹ Individual symptoms of irritability, mood alteration, anger, headache, and breast fullness were reduced. Bloating was not significantly altered compared with placebo. The incidence of side effects was low, but long-term safety is unknown. In general, data indicate that chasteberry may be effective for PMS.

Mind–Body Approaches

Evidence regarding mind–body approaches for PMS is somewhat limited. Because these modalities are risk free and they are generally accepted as components of a healthy lifestyle, they are favored in the treatment of PMS. Mind–body approaches that have demonstrated benefit in PMS include relaxation response, cognitive-behavioral therapy, yoga, aerobic exercise, and light therapy.¹⁶⁰

NSAIDs and Diuretics

Nonsteroidal anti-inflammatory drugs have been used to relieve the physical symptoms (e.g., headache, joint pain) of PMS, but do not improve the mood symptoms.¹⁴⁰ Regimens have included taking naproxen or mefenamic acid during the luteal phase and stopping therapy after menses begin. Diuretics

Each Day:

1. List the major symptoms (mood, physical, emotional, behavioral) that you experience during your menstrual cycle
2. Grade the severity of the symptom
3. Record daily weight
4. Record basal body temperature
5. Check the days of the cycle when menstrual flow occurs

commonly found in OTC products, such as ammonium chloride, caffeine, and pamabrom, are not effective. Spironolactone 100 mg daily given on days 15 through 28 may have some positive effects on somatic (e.g., breast tenderness, bloating) and affective symptoms, but data are not conclusive.¹⁴⁰

30. C.P. has been taking a multivitamin daily with adequate amounts of calcium, magnesium, and vitamin B₆ for PMS relief. She also has been taking naproxen sodium 220 mg BID without significant reduction of her symptoms. Her physician requests that she keep a daily diary for two consecutive cycles to document her symptoms. What information should be included in this tool?

C.P. should keep a daily diary for two consecutive menstrual cycles to demonstrate a temporal relationship between her symptoms during the luteal phase and to document the severity of these symptoms (Table 47-11). In addition, she should indicate the presence of menstrual flow, weight, and daily basal body temperature readings to help determine when ovulation occurs. The diary establishes a baseline for each patient and documents the most troublesome symptoms. Once therapy is selected for these symptoms, the diary can aid in assessing patient response.

Treatment: PMDD

31. C.P. returns to clinic with the diary presented in Table 47-11. The physician determines that C.P. actually has PMDD. What ev-

idence supports this diagnosis and what should be recommended for treatment?

C.P. meets the criteria for PMDD as evidenced by her symptoms during the 1 week before her menstrual cycle (luteal phase). Specifically, she has at least five symptoms required for the diagnosis of PMDD: sadness or depression (core symptom), fatigue, irritability, inability to concentrate, breast tenderness, and bloating. She rated several of those symptoms as severe, which indicates the symptoms are disabling and she is unable to meet her daily obligations. There is no reason to suspect any other disorder based on her history. PMDD seems to be the most likely diagnosis for C.P.

Therapy options at this time include lifestyle modifications, psychosocial interventions, and pharmacologic therapy. Psychotropic drugs targeted to her most severe symptoms may include selective serotonin reuptake inhibitors (SSRI), serotonergic tricyclic antidepressants, and anxiolytics. An oral contraceptive has also been approved for PMDD and could be considered.

Selective Serotonin Reuptake Inhibitors

Serotonin is critical in the pathogenesis of PMDD and for that reason, SSRIs have become the treatment of choice for PMDD and severe PMS (Table 47-12).¹⁶¹ SSRIs have demonstrated efficacy in reducing irritability, depressed mood, dysphoria, psychosocial function, and the physical symptoms of PMDD, including bloating, breast tenderness, and appetite changes.

Table 47-12 Psychotropic Drugs for the Management of PMDD and Severe PMS

| Drug (Brand Name) | Daily Dosing Regimen (mg) | Intermittent Dosing Regimen (mg) ^a |
|---|---------------------------|---|
| SSRI | | |
| Citalopram (Celexa) | 5–20 | 10–30 |
| Escitalopram (Lexapro) | 10–20 | 10–20 |
| Fluoxetine (Prozac) | 20–60 | 20 or 90 weekly |
| Fluvoxamine (Luvox) | 50–150 | NS |
| Paroxetine (Paxil) | 10–30 | NS |
| Paroxetine controlled release (Paxil CR) | 12.5–25 | 12.5–25 |
| Sertraline (Zoloft) | 50–150 | 100 |
| Other Serotonergic Antidepressants | | |
| Nefazodone (Serzone) | 200–600 | NS |
| Venlafaxine (Effexor) | 50 | NS |
| Anxiolytics | | |
| Alprazolam (Xanax) | NS | 1–2 ^b |
| Buspirone (BuSpar) | NS | 25–60 |

^aDay 14 until onset of menses.
^bDose to be tapered over 2 days after onset of menses to prevent withdrawal symptoms.
 NS, not studied; PMS, premenstrual syndrome; SSRI, selective serotonin reuptake inhibitors.

Fluoxetine, sertraline, and paroxetine controlled release each have an approved indication for PMDD.

The onset of effect of SSRI in women with PMDD or severe PMS is much more rapid than when these agents are used for treatment of major depression or anxiety disorders.¹⁶¹ Women may experience symptom relief or resolution within the first menstrual cycle versus the 4 to 8 weeks for other psychological disorders. Several different dosing strategies have been studied, including continuous dosing (once daily), intermittent dosing (last 2 weeks of menstrual cycle), and semi-intermittent dosing (continuous administration throughout the cycle with increased doses during luteal phase). Continuous dosing would be reasonable for women with concurrent mood or anxiety disorders or those who may have difficulty remembering the timing of the intermittent dosing. Intermittent dosing should be considered for patients with: regular menstrual cycles who are able to adhere to the regimen, an absence of symptoms during the follicular phase, concerns about long-term affects (e.g., sexual dysfunction), and few side effects at treatment initiation. Studies evaluating these dosing strategies have reported conflicting results regarding the most effective method; treatment should be individualized based on patient history, willingness to adhere to therapy, and drug response.

In a meta-analysis of 15 randomized, placebo-controlled trials including 904 women, SSRI treatment demonstrated a significant reduction in overall PMS symptoms (OR 6.91; 95% CI 3.9–12.2).¹⁶² SSRIs were effective in treating both physical and behavioral symptoms of PMS. No detectable difference was found in PMS symptoms when comparing continuous or intermittent dosing. SSRIs are generally well tolerated; how-

ever, in this analysis, the discontinuation rate in women taking SSRI was 2.5 times higher than in those taking placebo.¹⁶² Common side effects reported with SSRI use were insomnia, fatigue, decreased libido, nausea, and dry mouth.

Other Psychotropic Agents

Non-SSRI antidepressants that affect serotonin are also beneficial in treating PMS (Table 47-12). Venlafaxine, dosed daily, is significantly better than placebo at relieving psychological and physical symptoms of PMS.¹⁶³ Alprazolam is a short-acting benzodiazepine that has been assessed for the treatment of PMS in several studies with differing results.¹⁶⁴ With conflicting data and concerns about dependence, alprazolam should be reserved for women who are unresponsive to other PMS treatments. Luteal-phase dosing may limit the risk of drug dependence of this benzodiazepine, but the dose should be tapered over several days to minimize mild withdrawal symptoms. Buspirone, a partial 5 hydroxytryptamine (5HT) receptor agonist, demonstrated significant reduction in irritability when given daily, but does not seem to affect the physical symptoms of PMS.¹⁶⁵

Combination Oral Contraceptives

32. C.P. is considering a COC. What agent(s) would be appropriate and how might this affect her PMS?

A low-dose COC formulation containing 20 mcg ethinyl estradiol and 3 mg drospirenone (an antimineralocorticoid spironolactone analog) with a 4-day hormone-free interval is approved for the treatment of emotional and physical symptoms of PMDD.¹⁶⁶ Studies using this agent have shown efficacy for reduced mood, physical, and behavioral symptoms of PMDD, including a 48% improved response with this agent compared with a 36% response using placebo ($p = 0.015$).¹⁶⁷ Side effects occurring in at least 10% of women treated with this medication included intermenstrual bleeding, headache, nausea, breast pain, and upper respiratory infection. For women desiring contraception, this particular agent is approved and has data supporting its use in PMDD. The effects of other contraceptive agents for PMDD symptoms are currently under investigation.

Other Agents

33. What other therapeutic modalities are available to treat symptoms of PMS and what evidence exists to support their use?

Treatment with Gn-RH agonists has been used for the physical and psychological symptoms of PMS.¹⁶⁸ These agents are not typically used for long periods of time, however, because of vasomotor symptoms and the potential for negative long-term effects on bone. They also have to be administered by injection or nasal spray which may affect adherence. This treatment is reserved for women with very severe PMDD who do not respond to other treatments.

Danazol has been investigated for the treatment of PMS with moderate results. Danazol 200 mg BID provides greater symptom relief than placebo for symptoms of severe PMS; however, luteal phase treatment does not appear effective for PMS symptoms.¹⁶⁹ Potential side effects are also a concern with this agent and, therefore, its use in women should be limited to those who have failed other therapies.

34. The physician working with you recognizes your strong knowledge base in PMS and PMDD through your recommendations for C.P. He requests a brief “take home” summary of the treatment strategy for PMS and PMDD. How would you respond?

If mild to moderate symptoms of PMS exist, supportive therapy can be recommended with healthy nutrition, aerobic exercise, calcium supplements, and possibly magnesium, vita-

min B₆ and chasteberry. If physical symptoms are also present, NSAIDs could be initiated. When mood symptoms predominate and are markedly impairing functionality, an SSRI should be started in either a continuous or intermittent manner. An anxiolytic could be tried for symptoms not relieved by the SSRI. If no response is seen with these agents, a GnRH agonist could be initiated, but should be done in consultation with a gynecologist.

THE TRANSITION THROUGH MENOPAUSE

The perimenopause, or climacteric, is the phase in the female aging process between the reproductive and nonreproductive years and is characterized by waning ovarian function and irregular menstrual cycles. Menopause is the last spontaneous episode of physiologic uterine bleeding confirmed by 12 months of amenorrhea and typically occurs 4 to 5 years after the beginning of the perimenopause. The postmenopausal state is characterized by significantly decreased hormone levels that may contribute to an increased risk of disease.

Although female life expectancy has increased significantly over the past century, the average age of women at menopause has remained relatively constant at 51 years.¹ Thus, women today may spend one-third of their lives with reduced ovarian hormone concentrations. Age at menopause appears to be genetically determined and is not influenced by race, physical characteristics, age at menarche, age at last pregnancy, socioeconomic status, or oral contraceptive use. Cigarette smoking decreases age of menopause by 1 to 2 years.¹ As the U.S. population ages, the number of women at risk for postmenopausal related issues will increase. Recent census data estimates that there are 47 million women age 50 years and older in the United States.²

Pathophysiology

The perimenopause results from an age-related decline in the number and competence of ovarian follicles. Loss of negative feedback due to decreased inhibin production by the failing ovary triggers increased production of FSH. Despite this increase in FSH levels, the rate of follicular maturation declines and anovulatory cycles predominate during this phase. However, ovulation can still occur and contraception should be used if pregnancy is not desired. After all ovarian follicles have been

depleted, menopause ensues. This corresponds with a 10- to 20-fold increase in FSH levels and a threefold increase in LH levels which peak 1 to 3 years after menopause.¹ Postmenopausally, estrogen production decreases to approximately 10% of premenopausal production because the ovary is no longer making estrogen. Estrogen levels after menopause are derived from peripheral conversion of the androgen, androstenedione. The aromatase enzyme responsible for this conversion is predominantly found in fat, liver, and skin and increases with age and body weight, resulting in higher estrogen levels with women with greater body fat.^{1,3} The primary estrogen no longer is estradiol, but the less potent agent, estrone.^{1,3} Estrogen concentrations do not vary in a cyclic fashion as they do in women who are in their reproductive years (Table 48-1). Progesterone levels after menopause are generally undetectable in the absence of corpus luteum formation by the failed ovary.⁴ Androgen production by the postmenopausal ovary increases, but overall postmenopausal androgen levels are decreased by 25% to 50% resulting from decreased conversion of androstenedione to testosterone.^{1,4} The androgen:estrogen ratio increases markedly after menopause due to the greater drop in estrogen levels, which may result in mild symptoms of androgenism, such as hirsutism.¹

Clinical Presentation

Although menopause is a natural consequence of aging, the concurrent decrease in estrogen production can result in clinical symptoms, such as hot flashes and vaginal atrophy. Postmenopausal osteoporosis may also result from estrogen deficiency (see Chapter 102: Osteoporosis). In addition to their presence in the sex organs, the two estrogen receptors (ER α and ER β) are found in many tissues throughout the body, including the brain, bladder, lung, bone, and skin.^{5,6} The

Table 48-1 Plasma Levels of Hormones in Pre- and Postmenopausal Women¹⁰

| | Premenopausal | Postmenopausal |
|-----------------|---------------|----------------|
| Estradiol | 50–350 pg/mL | 5–25 pg/mL |
| Estrone | 30–110 pg/mL | 20–70 pg/mL |
| Progesterone: | | 0.17 ng/mL |
| follicular | 0.2–0.7 ng/mL | |
| luteal | 3–21 ng/mL | |
| Testosterone | 0.3 ng/mL | 0.25 ng/mL |
| Androstenedione | 1.5 ng/mL | 0.6 ng/mL |

impact of estrogen deficiency and replacement therapy on these organs is not yet fully elucidated.

Hot Flashes

Signs and Symptoms

1. D.R., a 51-year-old woman, has been having sudden feelings of warmth over her chest accompanied by a patchy flushing of her skin and increased sweating for the past month, especially after drinking coffee or wine or if she is upset. She now visits her physician because she has been waking up shivering from a perspiration-drenched gown nightly for the past week. D.R. does not take any medications. She has not had a menstrual period for at least 6 months; her physical examination was normal for a 51-year-old woman. What is the assessment based on the data provided for D.R.?

It appears that D.R. is experiencing hot flashes, a vasomotor symptom experienced by 50% to 85% of all women during the menopause transition.^{1,7} The onset of vasomotor symptoms may precede the last menstrual period, but the prevalence is highest during the 2 years after menopause and declines over time.¹ Symptoms persist for longer than 1 year in 80% and longer than 5 years in 25% of women.^{1,8} Women with surgically induced menopause, including bilateral oophorectomy, are more likely to experience moderate to severe hot flashes compared to women with natural menopause.⁹ Symptoms include a feeling of warmth in the chest, neck, and facial areas that may be accompanied by visible red flushing. An average hot flush is approximately 4 minutes in duration.⁸ The flushes are characteristically episodic rather than continuous, but may be as frequent as hourly in women with severe symptoms.¹⁰ An increased environmental temperature, the ingestion of hot liquids or alcohol, and mental stress also may provoke hot flashes.

Other symptoms associated with the perimenopause may include irritability, inability to concentrate, forgetfulness, headaches, dizziness, joint stiffness, and fatigue.^{10,11} Nocturnal hot flashes may lead to insomnia and sleep deprivation. Mood changes, including depression, are not uniformly associated with menopause, but are reported more frequently in women during the perimenopausal period.¹²

2. What are the underlying causes of the hot flashes associated with the perimenopause?

The exact trigger for hot flashes is unknown, but they are clearly associated with the declining estrogen concentrations

that occur during menopause. Estrogen therapy (ET) is more effective than placebo in reducing hot flashes, and withdrawal of ET results in resumption of hot flashes. It is postulated that the drop in estrogen production leads to a decrease in 5-HT levels and an increase in the levels of norepinephrine and its metabolite, MHPG. This in turn alters thermoregulatory sensitivity and lowers temperature set point, triggering an autonomic reaction directed at cooling the body.^{1,7,8}

Treatment

First-line treatment for hot flashes includes avoidance of known triggers (e.g., hot beverages, alcohol, warm environments), regular exercise, biofeedback, and relaxation techniques.⁸ If the patient continues to experience bothersome symptoms, drug therapy should be considered. It is important to note that there is a high placebo response in clinical trials evaluating interventions for hot flashes.

ESTROGEN WITH OR WITHOUT A PROGESTIN

3. D.R. has tried lifestyle modifications for management of her hot flashes without much relief. Her physician is recommending hormone therapy but she expresses concern about its risks. How should D.R. be counseled about the risks and benefits of hormone therapy?

Hormone therapy has received a great deal of attention through the widely-publicized results of the Women's Health Initiative (WHI). The WHI prospectively studied estrogen and progestin therapy (EPT) versus placebo in 16,608 postmenopausal women and estrogen therapy (ET) versus placebo in 10,739 postmenopausal women without a uterus. Other large cohort studies, including the Million Women Study and the Nurses Health Study, have also contributed important information to the understanding of postmenopausal hormone therapy. Prior to selecting a treatment option, women should be counselled about the possible risks and benefits of ET/EPT (Table 48-2). Absolute and relative contraindications to the use of postmenopausal hormones are listed in Table 48-3.

Vasomotor Symptoms

Numerous clinical trials have established the efficacy of estrogen in reducing the frequency and severity of hot flashes compared to placebo. Oral and transdermal estrogen are equally efficacious and the addition of a progestin does not appear to alter this benefit. Some studies report a dose-response

Table 48-2 Risks and Benefits of ET/EPT (change in event frequency per 10,000 women years of exposure)^{29,34,42}

| | ET | EPT |
|---------------------------|-----------------|-----------------|
| Osteoporotic Hip Fracture | −6 ^a | −5 |
| Colorectal Cancer | NS ^b | −6 |
| Breast Cancer | NS | +8 ^c |
| Myocardial infarction | NS | +7 |
| Thromboembolism (DVT/PE) | +7 | +18 |
| Stroke | +12 | +8 |

^aNegative sign indicates that hormone therapy provides protective effect.

^bNS: no significant change in risk.

^cpositive sign indicates an increased risk with hormone therapy.

Table 48-3 Contraindications to ET^{10,94}**Absolute Contraindications**

Active thromboembolic disease or history thereof (e.g., DVT, PE, stroke, MI)
 Undiagnosed abnormal genital bleeding
 Known, suspected or history of estrogen dependent neoplasia (e.g., breast cancer, endometrial cancer)
 Impaired liver function
 Known or suspected pregnancy

Relative Contraindications (diseases that may be exacerbated by estrogens/progestins)

Gallbladder Disease
 Hypertriglyceridemia
 Asthma
 Migraine headache
 Epilepsy
 Systemic lupus erythematosus
 Porphyria

relationship.¹³ In women with hot flushes, EPT has been shown to improve quality of life and depressive symptoms.¹⁴ Combination hormonal contraceptives are effective in reducing vasomotor symptoms and preventing pregnancy in women during perimenopause.

Osteoporosis

There are strong clinical data on the efficacy of estrogen, with or without a progestin, in preventing the bone loss associated with menopause. Estrogen has also been shown to decrease the risk of osteoporotic hip and vertebral fractures by approximately 25%.¹⁵ Multiple oral and transdermal estrogen products are FDA-approved for the prevention of osteoporosis (Table 48-4); however, based on its risks and the availability of effective alternate treatments, ET/EPT should not be used solely for the prevention of osteoporosis. In women using systemic estrogen for menopausal symptoms, bone density will be maintained. After estrogen is discontinued, bone loss will resume so alternate protective therapies should be considered in women at risk (see Chapter 102: Osteoporosis).¹⁵

Endometrial Cancer

Stimulation of the endometrium by exogenous estrogen causes endometrial proliferation leading to endometrial hyperplasia rates of 8 to 62% after 1 to 3 years of use.¹⁶ Continuous exposure to unopposed estrogen can lead to the development of endometrial cancer. Use of ET alone in a woman with a uterus increases the risk of endometrial cancer by twofold to 10-fold, with higher estrogen dose and duration associated with greater risk. The elevated risk persists for at least 5 years after discontinuation of ET.¹⁷ Addition of a progestin can significantly attenuate or eliminate the increased risk of endometrial cancer, with combined-continuous regimens possibly offering greater endometrial protection than intermittent regimens^{16–18} (see Question 3).

Breast Cancer

Randomized and observational studies support a 20% increased risk of breast cancer with EPT use, beginning 5 years after initiation, increasing with continued use and returning to baseline approximately 5 years after EPT is stopped.^{19,20} Risk

appears to be similar between oral and transdermal estrogen but a dose-response relationship has not been established. The effect of ET on breast cancer is less clear. Some studies, including the estrogen only arm of the WHI, found no increased risk of breast cancer after 7 years of treatment, whereas others reported an increased risk, particularly with long-term use.^{21–23}

Ovarian Cancer

Several studies have documented an increased risk of ovarian cancer with postmenopausal hormone use.^{24–28} The risk increases with increasing duration of use and occurs with both ET and EPT. Limited data suggest that the type and route of therapy do not influence risk. It is unclear if long-term past use confers an increased risk of ovarian cancer.

Thromboembolic Disease

Current ET use increases the risk for venous thromboembolic disease, including DVT and pulmonary embolism, up to twofold.^{29,30} The greatest risk, up to 3.5-fold, is within the first year of treatment. Women who are older or have a higher BMI are at elevated risk.³¹ Concurrent use of estrogen and progestin may incur a greater risk than use of unopposed estrogen but transdermal estrogen may significantly decrease the risk compared to oral estrogen.^{32,33}

Some, but not all, studies have documented an increased risk for stroke with ET/EPT use.²³ In the WHI, ET and EPT increased the risk of ischemic, but not hemorrhagic, stroke by approximately 40%.^{34,35} The Women's Estrogen for Stroke Trial (WEST) found that use of estrogen soon after a stroke or transient ischemic attack was associated with adverse outcomes compared to placebo.³⁶

Cardiovascular Disease
